We follow the procedure for creating the training data described in Section 5.1.1 and build a word-aligned list and a cross-product list from the parallel corpus. We first train and test our unsupervised mining system on the word-aligned list and compare our results with Sajjad et al. Table 7 shows the results. Our unsupervised system achieves 0.6% and 1.8% higher F-measure than Sajjad et al. respectively.

The cross-product list is huge in comparison to the word-aligned list. It is noisier than the word-

<sup>4</sup>We implemented a bigram version of our system to learn the contextual information at the end of the word pairs, but only achieved a gain of less than 1% F-measure over our unigram semi-supervised system. Details are omitted due to space.

Table 8: Transliteration mining results of our unsupervised and semi-supervised systems trained on the word-aligned list and tested on the cross-product list of English/Hindi and English/Arabic parallel corpus

aligned list but has almost 100% recall of transliteration pairs. The English-Hindi cross-product list has almost 55% more transliteration pairs (412 types) than the word-aligned list (180 types). We can not report these numbers on the English/Arabic cross-product list since the English/Arabic gold standard is built on the word-aligned list.

In order to keep the experiment computationally inexpensive, we train our mining systems on the word-aligned list and test them on the cross-product list.<sup>5</sup> We also perform the first semi-supervised evaluation on this task. For our semi-supervised system, we additionally use the English/Hindi and English/Arabic seed data provided by NEWS10.

Table 8 shows the results of our unsupervised and semi-supervised systems on the English/Hindi and English/Arabic parallel corpora. Our unsupervised system achieves higher recall than our semi-supervised system but lower precision. The semi-supervised system shows an improvement in F-measure for both language pairs. We looked into the errors made by our systems. The mined transliteration pairs of our unsupervised system contains 65 and 111 close transliterations for the English/Hindi and English/Arabic task respectively.

<sup>5</sup>There are some multigrams of the cross-product list which are unknown to the model learned on the word-aligned list. We define their probability as the inverse of the number of multigram tokens in the Viterbi alignment of the labelled and unlabelled data together.

The close transliterations only differ by one or two characters from correct transliterations. We think these pairs provide transliteration information to the systems and help them to avoid problems with data sparseness. Our semi-supervised system uses the seed data to identify close transliterations as non-transliterations and decreases the number of false positives. They are reduced to 35 and 89 for English/Hindi and English/Arabic respectively. The seed data and the training data used in the semi-supervised system are from different domains (Wikipedia and UN). Seed data extracted from the same domain is likely to work better, resulting in even higher scores than we have reported.

## 6 Conclusion and Future Work

We presented a novel model to automatically mine transliteration pairs. Our approach is efficient and language pair independent (for alphabetic languages). Both the unsupervised and semi-supervised systems achieve higher accuracy than the only unsupervised transliteration mining system we are aware of and are competitive with the state-of-the-art supervised and semi-supervised systems. Our semi-supervised system outperformed our unsupervised system, in particular in the presence of prevalent cognates in the Russian/English data.

In future work, we plan to adapt our approach to language pairs where one language is alphabetic and the other language is non-alphabetic such as English/Japanese. These language pairs require one-to-many character mappings to learn transliteration units, while our current system only learns unigram character alignments.

# Modified Distortion Matrices for Phrase-Based Statistical Machine Translation

Arianna Bisazza and Marcello Federico

Fondazione Bruno Kessler

Trento, Italy

{bisazza, federico}@fbk.eu

## Abstract

This paper presents a novel method to suggest long word reorderings to a phrase-based SMT decoder. We address language pairs where long reordering concentrates on few patterns, and use fuzzy chunk-based rules to predict likely reorderings for these phenomena. Then we use reordered  $n$ -gram LMs to rank the resulting permutations and select the  $n$ -best for translation. Finally we encode these reorderings by modifying selected entries of the distortion cost matrix, on a per-sentence basis. In this way, we expand the search space by a much finer degree than if we simply raised the distortion limit. The proposed techniques are tested on Arabic-English and German-English using well-known SMT benchmarks.

## 1 Introduction

Despite the large research effort devoted to the modeling of word reordering, this remains one of the main obstacles to the development of accurate SMT systems for many language pairs. On one hand, the phrase-based approach (PSMT) (Och, 2002; Zens et al., 2002; Koehn et al., 2003), with its shallow and loose modeling of linguistic equivalences, appears as the most competitive choice for closely related language pairs with similar clause structures, both in terms of quality and of efficiency. On the other, tree-based approaches (Wu, 1997; Yamada, 2002; Chiang, 2005) gain advantage, at the cost of higher complexity and isomorphism assumptions, on language pairs with radically different word orders.

Lying between these two extremes are language pairs where most of the reordering happens locally,

and where long reorderings can be isolated and described by a handful of linguistic rules. Notable examples are the family-unrelated Arabic-English and the related German-English language pairs. Interestingly, on these pairs, PSMT generally prevails over tree-based SMT<sup>1</sup>, producing overall high-quality outputs and isolated but critical reordering errors that undermine the global sentence meaning.

Previous works on this type of language pairs have mostly focused on source reordering prior to translation (Xia and McCord, 2004; Collins et al., 2005), or on sophisticated reordering models integrated into decoding (Koehn et al., 2005; Al-Onaizan and Papineni, 2006), achieving mixed results. To merge the best of both approaches – namely, access to rich context in the former and natural coupling of reordering and translation decisions in the latter – we introduce *modified distortion matrices*: a novel method to seamlessly provide to the decoder a set of likely long reorderings pre-computed for a given input sentence. Added to the usual space of local permutations defined by a low distortion limit (DL), this results in a linguistically informed definition of the search space that simplifies the task of the in-decoder reordering model, besides decreasing its complexity.

The paper is organized as follows. After reviewing a selection of relevant works, we analyze salient reordering patterns in Arabic-English and German-English, and describe the corresponding chunk-based reordering rule sets. In the following sections we present a reordering selection technique based on

---

<sup>1</sup>A good comparison of phrase-based and tree-based approaches across language pairs with different reordering levels can be found in (Zollmann et al., 2008).

reordered n-gram LMs and, finally, explain the notion of modified distortion matrices. In the last part of the paper, we evaluate the proposed techniques on two popular MT tasks.

## 2 Previous work

Pre-processing approaches to word reordering aim at permuting input words in a way that minimizes the reordering needed for translation: *deterministic reordering* aims at finding a single optimal reordering for each input sentence, which is then translated monotonically (Xia and McCord, 2004) or with a low DL (Collins et al., 2005; Habash, 2007); *non-deterministic reordering* encodes multiple alternative reorderings into a word lattice and lets a monotonic decoder find the best path according to its models (Zhang et al., 2007; Crego and Habash, 2008; Elming and Habash, 2009; Niehues and Kolss, 2009). The latter approaches are ideally conceived as alternative to in-decoding reordering, and therefore require an exhaustive reordering rule set. Two recent works (Bisazza and Federico, 2010; Andreas et al., 2011) opt instead for a *hybrid way*: rules are used to generate multiple likely reorderings, but only for a specific phenomenon – namely verb-initial clauses in Arabic. This yields sparse reordering lattices that can be translated with a regular decoder performing additional reordering.

Reordering rules for pre-processing are either manually written (Collins et al., 2005) or automatically learned from syntactic parses (Xia and McCord, 2004; Habash, 2007; Elming and Habash, 2009), shallow syntax chunks (Zhang et al., 2007; Crego and Habash, 2008) or part-of-speech labels (Niehues and Kolss, 2009). Similarly to hybrid approaches, in this work we use few linguistically informed rules to generate multiple reorderings for selected phenomena but, as a difference, we do not employ lattices to represent them. We also include a competitive in-decoding reordering model in all the systems used to evaluate our methods.

Another large body of work is devoted to the modeling of reordering decisions inside decoding, based on a decomposition of the problem into a sequence of basic reordering steps. Existing approaches range from basic linear distortion to more complex models that are conditioned on the words being translated.

The *linear distortion model* (Koehn et al., 2003) encourages monotonic translations by penalizing source position jumps proportionally to their length. If used alone, this model is inadequate for language pairs with different word orders. Green et al. (2010) tried to improve it with a future distortion cost estimate. Thus they were able to preserve baseline performance at a very high DL, but not to improve it. *Lexicalized phrase orientation models* (Tillmann, 2004; Koehn et al., 2005; Zens and Ney, 2006; Galley and Manning, 2008) predict the orientation of a phrase with respect to the last translated one. These models are known to well handle local reordering and are widely adopted by the PSMT community. However, they are unsuitable to model long reordering as they classify as “discontinuous” every phrase that does not immediately follow or precede the last translated one. *Lexicalized distortion models* predict the jump from the last translated word to the next one, with a class for each possible jump length (Al-Onaizan and Papineni, 2006), or bin of lengths (Green et al., 2010). These models are conceived to deal with long reordering, but can easily suffer from data sparseness, especially for longer jumps occurring less frequently.

Following a typical sequence modeling approach, Feng et al. (2010) train n-gram language models on source data previously reordered in accordance to the target language translation. This method does not directly model reordering decisions, but rather word sequences produced by them. Despite their high perplexities, reordered LMs yield some improvements when integrated to a PSMT baseline that already includes a discriminative phrase orientation model (Zens and Ney, 2006). In this work we use similar models to rank sets of chunk permutations.

Attempting to improve the reordering space definition, Yahyaei and Monz (2010) train a classifier to guess the most likely jump length at each source position, then use its predictions to dynamically set the DL. Translation improvements are obtained on a simple task with mostly short sentences (BTEC).

Modifying the distortion function, as proposed in this paper, makes it possible to expand the permutation search space by a much finer degree than varying the DL does.

### 3 Long reordering patterns

Our study focuses on Arabic-English and German-English: two language pairs characterized by uneven distributions of word-reordering phenomena, with long-range movements concentrating on few patterns. In **Arabic-English**, the internal order of most noun phrases needs to be reversed during translation, which is generally well handled by phrase-internal reordering or local distortion. At the constituent level, instead, Arabic admits both SV(O) and VS(O) orders, the latter causing problematic long reorderings. Common errors due to this issue are the absence of main verb in the English translation, or the placement of the main verb before its own subject. In both cases, adequacy is seriously compromised. In **German-English**, the noun phrase structure is similar between source and target languages. However, at the constituent level, the *verb-second* order of German main clauses conflicts with the rigid SVO structure of English, as does the clause-final verb position of German subordinate clauses. As a further complication, German compound verbs are split apart so that the non-finite element (main verb) can appear long after the inflected auxiliary or modal.

Thanks to sophisticated reordering models, state-of-the-art PSMT systems are generally good at handling *local* reordering phenomena that are not captured by phrase-internal reordering. However, they typically fail to predict long reorderings. We believe this is mainly not the fault of the reordering models, but rather of a *too coarse definition* of the search space. To have a concrete idea, consider that a small change of the DL from 5 to 6 words, in a sentence of 8, makes the number of explorable permutations increase from about 9,000 to 22,000. Existing models cannot be powerful enough to deal with such a rapidly growing search space.

As a result, decoding at very high DLs is not a good solution for these language pairs. Indeed, decent performances are obtained within a low or medium DL, but this obviously comes at the expense of long reorderings, which are often crucial to preserve the general meaning of a translated sentence. For instance, taking English as the target language, it is precisely the relative positioning of predicate arguments that determines their role, in the absence of case markers. Thus, a wrongly reordered verb with

minor impact on automatic scores, can be judged very badly by a human evaluator.

We will now describe two rule sets aimed at capturing these reordering phenomena.

### 4 Shallow syntax reordering rules

To compute the source reorderings, we use chunk-based rules following Bisazza and Federico (2010). Shallow syntax chunking is indeed a lighter and simpler task compared to full parsing, and it can be used to constrain the number of reorderings in a softer way. While rules based on full parses are generally deterministic, chunk-based rules are non-deterministic or fuzzy, as they generate several permutations for each matching sequence<sup>2</sup>. Besides defining a unique segmentation of the sentence, chunk annotation provides other useful information that can be used by the rules – namely chunk type and POS tags<sup>3</sup>.

For **Arabic-English** we apply the rules proposed by Bisazza and Federico (2010) aimed at transforming VS(O) sentences into SV(O). Reorderings are generated by moving each verb chunk (VC), alone or with its following chunk, by 1 to 6 chunks to the right. The maximum movement of each VC is limited to the position of the next VC, so that neighboring verb-reordering sequences may not overlap. This rule set was shown to cover most (99.5%) of the verb reorderings observed in a parallel news corpus, including those where the verb must be moved along with an adverbial or a complement.

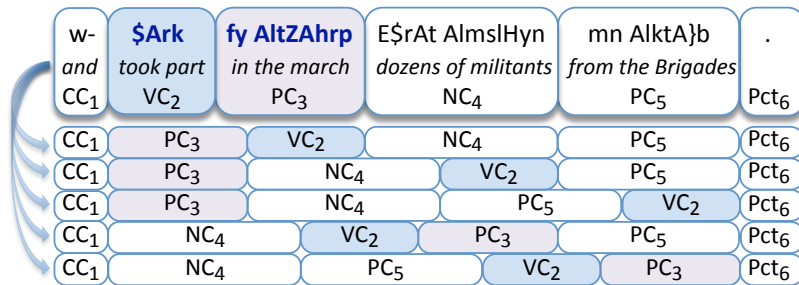

For **German-English** we propose a set of three rules<sup>4</sup> aimed at arranging the German constituents in SVO order:

- *infinitive*: move each infinitive VC right after a preceding punctuation;
- *subordinate*: if a VC is immediately followed by a punctuation, place it after a preceding subordinating conjunction (KOUS) or substitutive relative pronoun (PRELS);

<sup>2</sup>Chunk annotation does not identify subject and complement boundaries, nor the relations among constituents that are needed to deterministically rearrange a sentence in SVO order.

<sup>3</sup>We use AMIRA (Diab et al., 2004) to annotate Arabic and Tree Tagger (Schmid, 1994) to annotate German.

<sup>4</sup>A similar rule set was previously used to produce chunk reordering lattices in (Hardmeier et al., 2010).

(a) Arabic VS(O) clause: five permutations

(b) German *broken* verb chunk: three permutations

Figure 1: Examples of chunk permutations generated by shallow syntax reordering rules. Chunk types: CC conjunction, VC verb (auxiliary/past participle), PC preposition, NC noun, Pct punctuation.

- *broken verb chunk*: join each finite VC (auxiliary or modal) with the nearest following non-finite VC (infinitive or participle). Place the resulting block in any position between the original position of the finite verb and that of the non-finite verb<sup>5</sup>.

The application of chunk reordering rules is illustrated by Fig. 1: in the Arabic sentence (a), the subject ‘dozens of militants’ is preceded by the main verb ‘took part’ and its argument ‘to the march’. The rules generate 5 permutations for one matching sequence (chunks 2 to 5), out of which the 5<sup>th</sup> is the best for translation. The German sentence (b) contains a broken VC with the inflected auxiliary ‘has’ separated from the past participle ‘initiated’. Here, the rules generate 3 permutations for the chunk sequence 2 to 5, corresponding to likely locations of the merged verb phrase, the 1<sup>st</sup> being optimal.

By construction, both rule sets generate a limited number of permutations per matching sequence: in

<sup>5</sup>To bound the number of reorderings, we use the following heuristics. In ‘*infinitive*’ at most 3 punctuations preceding the VC are considered. In ‘*subordinate*’ 1 to 3 chunks are left between the conjunction (or pronoun) and the moved VC to account for the subject. In ‘*broken VC*’ if the distance between the finite and non-finite verb is more than 10 chunks, only the first 5 and last 5 positions of the verb-to-verb span are considered.

Arabic at most 12 for each VC; in German at most 3 for each infinitive VC and for each VC-punctuation sequence, at most 10 for each broken VC. Empirically, this yields on average 22 reorderings per sentence in the NIST-MT Arabic benchmark dev06-NW and 3 on the WMT German benchmark test08. Arabic rules are indeed more noisy, which is not surprising as reordering is triggered by any verb chunk.

## 5 Reordering selection

The number of chunk-based reorderings per sentence varies according to the rule set, to the size of chunks and to the context. A high degree of fuzziness can complicate the decoding process, leaving too much work to the in-decoding reordering model. A solution to this problem is using an external model to score the rule-generated reorderings and discard the less probable ones. In such a way, a further part of reordering complexity is taken out of decoding.

At this end, instead of using a Support Vector Machine classifier as was done in (Bisazza et al., 2011), we apply *reordered n-gram models* that are lighter-weight and more suitable for a ranking task.

Differently from Feng et al. (2010), we train our models on partially reordered data and at the level of chunks. Chunks can be represented simply by their

type label (such as VC or NC), but also by a combination of the type and head word, to obtain finer lexicalized distributions. LMs trained on different chunk representations can also be applied jointly, by log-linear combination.

We perform reordering selection as follows:

1. Chunk-based reordering rules are applied deterministically to the *source* side of the parallel training data, using word alignment to choose the optimal permutation (“oracle reordering”)<sup>6</sup>.
2. One or several chunk-level 5-gram LMs are trained on such reordered data, using different chunk representation modes.
3. Reordering rules are applied to the test sentences and the resulting sets of rule-matching sequence permutations are scored by the LMs. The *n*-best reorderings of each rule-matching sequence are selected for translation.

In experiments not reported here, we obtained accurate rankings by scoring source permutations with a uniformly weighted combination of two LMs trained on chunk types and on chunk-type+headword, respectively. In particular, 3-best reorderings of each rule-matching sequence yield reordering recalls of 77.2% in Arabic and 89.3% in German.

## 6 Modified distortion matrices

We present here a novel technique to encode likely long reorderings of an input sentence, which can be seamlessly integrated into the PSMT framework.

During decoding, the distance between source positions is used for two main purposes: (i) generating a distortion penalty for the current hypothesis and (ii) determining the set of source positions that can be covered at the next hypothesis expansion. We can then tackle the coarseness of both distortion penalty and reordering constraints, by replacing the distance function with a function defined *ad hoc* for each input sentence.

Distortion can be thought of as a matrix assigning a positive integer to any ordered pair of source positions  $(s_x, s_y)$ . In the linear distortion model this is

<sup>6</sup>Following Bisazza and Federico (2010), the optimal reordering for a source sentence is the one that minimizes distortion in the word alignment to a target translation, measured by number of swaps and sum of distortion costs.

defined as:

$$D_L(s_x, s_y) = |s_y - s_x - 1|$$

so that moving to the right by 1 position costs 0 and by 2 positions costs 1. Moving to the left by 1 position costs 2 and by 2 positions costs 3, and so on. At the level of phrases, distortion is computed between the last word of the last translated phrase and the first word of the next phrase. We retain this equation as the core distortion function for our model. Then, we modify entries in the matrix such that the distortion cost is minimized for the decoding paths pre-computed with the reordering rules.

Given a source sentence and its set of rule-generated permutations, the linear distortion matrix is modified as follows:

1. non-monotonic jumps (i.e. ordered pairs  $(s_i, s_{i+1})$  such that  $s_{i+1} - s_i \neq 1$ ) are extracted from the permutations;
2. then, for each extracted pair, the corresponding point in the matrix is assigned the lowest possible distortion cost, that is 0 if  $s_i < s_{i+1}$  and 2 if  $s_i > s_{i+1}$ . We call these points *shortcuts*.

Although this technique is approximate and can overgenerate minimal-distortion decoding paths<sup>7</sup>, it practically works when the number of encoded permutations per sequence is limited. This makes modified distortion matrices particularly suitable to encode just those reorderings that are typically missed by phrase-based decoders (see Sect. 3).

Since in this work we use chunk-based rules, we also have to convert chunk-to-chunk jumps into word-to-word shortcuts. We propose two ways to do this, given an ordered pair of chunks  $(c_x, c_y)$ :

**mode  $\mathbf{A} \times \mathbf{A}$**  : create a shortcut from each word of  $c_x$  to each word of  $c_y$ ;

**mode  $\mathbf{L} \times \mathbf{F}$**  : create only one shortcut from the last word of  $c_x$  to the first of  $c_y$ .

The former solution admits more chunk-internal permutations with the same minimal distortion cost, whereas the latter implies that the first word of a re-ordered chunk is covered first and the last is covered last.

<sup>7</sup>In fact, any decoding path that includes a jump marked as shortcut benefits from the same distortion discount in that point.

Figure 2: Modified distortion matrix (mode  $A \times A$ ) of the German sentence given in Fig. 1. The chunk reordering shown on top generates three *shortcuts* corresponding to the 0's and 2's highlighted in the matrix.

Fig. 2 shows the distortion matrix of the German sentence of Fig. 1, with starting positions as columns and landing positions as rows. Suppose we want to encode the reordering shown on top of Fig. 2, corresponding to the merging of the broken VC ‘hat ... eingeleitet’. This permutation contains three jumps: (2,5), (5,3) and (4,6). Converted to word-level in  $A \times A$  mode, these yield five word shortcuts<sup>8</sup>: one for the onward jump (2,5) assigned 0 distortion; two for the backward jump (5,3), assigned 2; and two for the onward jump (4,6), also assigned 0. The desired reordering is now attainable within a DL of 2 words instead of 5. The same process is then applied to other permutations of the sentence.

If compared to the word reordering lattices used by Bisazza and Federico (2010) and Andreas et al. (2011), modified distortion matrices provide a more compact, implicit way to encode likely reorderings in a sentence-specific fashion. Matrix representation does not require multiplication of nodes for the same

<sup>8</sup>In  $L \times F$  mode, instead, each chunk-to-chunk jump would yield exactly one word shortcut, for a total of three.

source word and is naturally compatible with the PSMT decoder’s standard reordering mechanisms.

## 7 Evaluation

In this section we evaluate the impact of modified distortion matrices on two news translation tasks.

Matrices were integrated into the Moses toolkit (Koehn et al., 2007) using a sentence-level XML markup. The list of word shortcuts for each sentence is provided as an XML tag that is parsed by the decoder to modify the distortion matrix just before starting the search. As usual, the distortion matrix is queried by the distortion penalty generator and by the hypothesis expander<sup>9</sup>.

### 7.1 Experimental setup

For **Arabic-English**, we use the union of all in-domain parallel corpora provided for the NIST-MT09 evaluation<sup>10</sup> for a total of 986K sentences, 31M English words. The target LM is trained on the English side of all available NIST-MT09 parallel data, UN included (147M words). For development and test, we use the newswire sections of the NIST benchmarks, hereby called dev06-NW, eval08-NW and eval09-NW: 1033, 813 and 586 sentences, respectively, each provided with four reference translations.

The **German-English** system is instead trained on WMT10 data: namely Europarl (v.5) plus News-commentary-2010 for a total of 1.6M parallel sentences, 43M English words. The target LM is trained on the monolingual news data provided for the constrained track (1133M words). For development and test, we use the WMT10 news benchmarks test08, test09 and test10: 2051, 2525 and 2489 sentences, respectively, with one reference translation.

Concerning pre-processing, we apply standard tokenization to the English data, while for Arabic we use our in-house tokenizer that removes diacritics and normalizes special characters. Arabic text is then segmented with AMIRA (Diab et al., 2004) according to the ATB scheme<sup>11</sup>. German tokenization

<sup>9</sup>Note that lexicalized reordering models use real word distances to compute the orientation class of a new hypothesis, thus they are not affected by changes in the matrix.

<sup>10</sup>That is everything except the small GALE corpus and the UN corpus. As reported by Green et al. (2010) the removal of UN data does not affect baseline performances on news test.

<sup>11</sup>The Arabic Treebank tokenization scheme isolates con-

and compound splitting is performed with Tree Tagger (Schmid, 1994) and the Gertwol morphological analyser (Koskenniemi and Haapalainen, 1994)<sup>12</sup>.

Using Moses we build competitive baselines on the training data described above. Word alignment is produced by the Berkeley Aligner (Liang et al., 2006). The decoder is based on the log-linear combination of a phrase translation model, a lexicalized reordering model, a 6-gram target language model, distortion cost, word and phrase penalties. The reordering model is a hierarchical phrase orientation model (Tillmann, 2004; Koehn et al., 2005; Galley and Manning, 2008) trained on all the available parallel data. We choose the hierarchical variant, as it was shown by its authors to outperform the default word-based on an Arabic-English task. Finally, for German, we enable the Moses option *monotone-at-punctuation* which forbids reordering across punctuation marks. The DL is initially set to 5 words for Arabic-English and to 10 for German-English. According to our experience, these are the optimal settings for the evaluated tasks. Feature weights are optimized by minimum error training (Och, 2003) on the development sets (dev06-NW and test08).

## 7.2 Translation quality and efficiency results

We evaluate translations with BLEU (Papineni et al., 2002) and METEOR (Banerjee and Lavie, 2005). As these scores are only indirectly sensitive to word order, we also compute KRS or Kendall Reordering Score (Birch et al., 2010; Bisazza et al., 2011) which is a positive score based on the Kendall’s Tau distance between the source-output and source-reference permutations. To isolate the impact of our techniques on problematic reordering, we extract from each test set the sentences that got permuted by “oracle reordering” (see Sect. 5). These constitute about a half of the Arabic sentences, and about a third of the German. We refer to the KRS computed on these test *subsets* as KRS(R). Statistically significant differences are assessed by approximate randomization as in (Riezler and Maxwell, 2005)<sup>13</sup>.

Tab. 1 reports results obtained by varying the DL

junctions *w+* and *f+*, prepositions *l+*, *k+*, *b+*, future marker *s+*, pronominal suffixes, but not the article *A/+*.

<sup>12</sup><http://www2.lingsoft.fi/cgi-bin/gertwol>

<sup>13</sup>Translation scores and significance tests are computed with the tools *multeval* (Clark et al., 2011) and *sigf* (Padó, 2006).

and modifying the distortion function. To evaluate the reordering selection technique, we also compare the encoding of all rule-generated reorderings against only the 3 best per rule-matching sequence, as ranked by our best performing reordered LM (see end of Sect. 5). We mark the DL with a ‘+’ to denote that some longer jumps are being allowed by modified distortion. Run times refer to the translation of the first 100 sentences of eval08-NW and test09 by a 4-core processor.

**Arabic-English.** As anticipated, raising the DL does not improve, but rather worsen performances. The decrease in BLEU and METEOR reported with DL=8 is not significant, but the decrease in KRS is both significant and large. Efficiency is heavily affected, with a 42% increase of the run time.

Results in the row “allReo” are obtained by encoding all the rule-generated reorderings in  $L \times F$  chunk-to-word conversion mode. Except for some gains in KRS reported on eval08-NW, most of the scores are lower or equal to the baseline. Such inconsistent behaviour is probably due to the low precision of the Arabic rule set, pointed out in Sect. 4.

Finally, we arrive to the performance of 3-best reorderings per sequence. With  $L \times F$  we obtain several improvements, but it’s with  $A \times A$  that we are able to beat the baseline according to all metrics. BLEU and METEOR improvements are rather small but significant and consistent across test sets, the best gain being reported on eval09-NW (+.9 BLEU). Most importantly, substantial word order improvements are achieved on both full test sets (+.7/+6 KRS) and selected subsets (+.7/+6 KRS(R)). According to these figures, word order is affected only in the sentences that contain problematic reordering. This is good evidence, suggesting that the decoder does not get “confused” by spurious shortcuts.

Looking at run times, we can say that modified distortion matrices are a very efficient way to address long reordering. Even when all the generated reorderings are encoded, translation time increases only by 4%. Reordering selection naturally helps to further reduce decoding overload. As for conversion modes,  $A \times A$  yields slightly higher run times than  $L \times F$  because it generates more shortcuts.

**German-English.** In this task we manage to improve translation quality with a setting that is almost

Table 1: Impact of modified distortion matrices on translation quality, measured with BLEU, METEOR and KRS (all in percentage form, higher scores mean higher quality). The settings used for weight tuning are marked with †. Statistically significant differences wrt the baseline are marked with • at the  $p \leq .05$  level and ° at the  $p \leq .10$  level.

twice as fast as the baseline. As shown by the first part of the table, the best baseline results are obtained with a rather high DL, that is 10 (only KRS improves with a lower DL). However, with modified distortion, the best results according to all metrics are obtained with a DL of 4.

Looking at the rest of the table, we see that reordering selection is not as crucial as in Arabic-English. This is in line with the properties of the more precise German reordering rule set (two rules out of three generate at most 3 reorderings per sequence). Considering all scores, the last setting (3-best reordering and A×A) appears as the best one, achieving the following gains over the baseline: +.4/+1.5 BLEU, +.2/+1.1 METEOR, +1.6/+1.7 KRS and +1.7/+1.8 KRS(R). The agreement observed among such diverse metrics makes us confident about the goodness of the approach.

## 8 Conclusions

In Arabic-English and German-English, long reordering concentrates on specific patterns describable by a small number of linguistic rules. By means of non-deterministic chunk reordering rules, we have generated likely permutations of the test

sentences and ranked them with n-gram LMs trained on pre-reordered data. We have then introduced the notion of modified distortion matrices to naturally encode a set of likely reorderings in the decoder input. Modified distortion allows for a finer and more linguistically informed definition of the search space, which is reflected in better translation outputs and more efficient decoding.

We expect that further improvements may be achieved by refining the Arabic reordering rules with specific POS tags and lexical cues. We also plan to evaluate modified distortion matrices in conjunction with a different type of in-decoding reordering model such as the one proposed by Green et al. (2010). Finally, we may try to exploit not only the ranking, but also the scores produced by the re-ordered LMs, as an additional decoding feature.

## Acknowledgments

This work was supported by the T4ME network of excellence (IST-249119) funded by the European Commission DG INFSO through the 7<sup>th</sup> Framework Programme. We thank Christian Hardmeier for helping us define the German reordering rules, and the anonymous reviewers for valuable suggestions.

## Abstract

Many semantic parsing models use tree transformations to map between natural language and meaning representation. However, while tree transformations are central to several state-of-the-art approaches, little use has been made of the rich literature on tree automata. This paper makes the connection concrete with a tree transducer based semantic parsing model and suggests that other models can be interpreted in a similar framework, increasing the generality of their contributions. In particular, this paper further introduces a variational Bayesian inference algorithm that is applicable to a wide class of tree transducers, producing state-of-the-art semantic parsing results while remaining applicable to any domain employing probabilistic tree transducers.

## 1 Introduction

Semantic parsing is the task of mapping natural language sentences to a formal representation of meaning. Typically, a system is trained on pairs of natural language sentences (NLs) and their meaning representation expressions (MRs), as in figure 1(a), and the system must generalize to novel sentences.

Most semantic parsing models rely on an assumption of structural similarity between MR and NL. Since strict isomorphism is overly restrictive, this assumption is often relaxed by applying transformations. Several approaches assume a tree structure to the NL, MR, or both (Ge and Mooney, 2005; Kate and Mooney, 2006; Wong and Mooney, 2006; Lu et al., 2008; Börschinger et al., 2011), and often in-

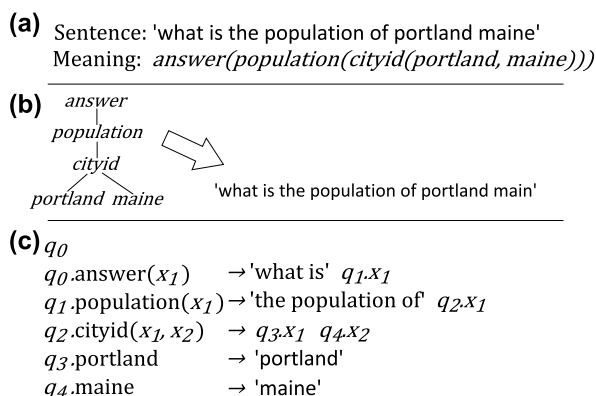

Figure 1: (a) An example sentence/meaning pair, (b) a tree transformation based mapping, and (c) a tree transducer that performs the mapping.

volve tree transformations either between two trees or a tree and a string.

The tree transducer, a formalism from automata theory which has seen interest in machine translation (Yamada and Knight, 2001; Graehl et al., 2008) and has potential applications in many other areas, is well suited to formalizing such tree transformation based models. Yet, while many semantic parsing systems resemble the formalism, each was proposed as an independent model requiring custom algorithms, leaving it unclear how developments in one line of inquiry relate to others. We argue for a unifying theory of tree transformation based semantic parsing by presenting a tree transducer model and drawing connections to other similar systems.

We make a further contribution by bringing to tree transducers the benefits of the Bayesian framework for principled handling of data sparsity and

prior knowledge. Graehl et al. (2008) present an EM training procedure for top down tree transducers, but while there are Bayesian approaches to string transducers (Chiang et al., 2010) and PCFGs (Kurihara and Sato, 2006), there has yet to be a proposal for Bayesian inference in *tree* transducers. Our variational algorithm produces better semantic parses than EM while remaining general to a broad class of transducers appropriate for other domains.

In short, our contributions are three-fold: we present a new state-of-the-art semantic parsing model, propose a broader theory for tree transformation based semantic parsing, and present a general inference algorithm for the tree transducer framework. We recommend the last of these as just one benefit of working within a general theory: contributions are more broadly applicable.

## 2 Meaning representations and regular tree grammars

In semantic parsing, an MR is typically an expression from a machine interpretable language (e.g., a database query language or a logical language like Prolog). In this paper we assume MRs can be represented as trees, either by pre-parsing or because they are already trees (often the case for functional languages like LISP).<sup>1</sup> More specifically, we assume the MR language is a regular tree language.

A regular tree grammar (RTG) closely resembles a context free grammar (CFG), and is a way of describing a language of trees. Formally, define  $T_\Sigma$  as the set of trees with symbols from alphabet  $\Sigma$ , and  $T_\Sigma(\mathcal{A})$  as the set of all trees in  $T_{\Sigma \cup \mathcal{A}}$  where symbols from  $\mathcal{A}$  only occur at the leaves. Then an RTG is a tuple  $(\mathcal{Q}, \Sigma, q_{start}, \mathcal{R})$ , where  $\mathcal{Q}$  is a set of states,  $\Sigma$  is an alphabet,  $q_{start} \in \mathcal{Q}$  is the initial state, and  $\mathcal{R}$  is a set of grammar rules of the form  $q \rightarrow t$ , where  $q$  is a state from  $\mathcal{Q}$  and  $t$  is a tree from  $T_\Sigma(\mathcal{Q})$ .

A rule typically consists of a parent state (left) and its child states and output symbol (right). We indicate states using all capital letters:

NUM  $\rightarrow$  population(PLACE).

Intuitively, an RTG is a CFG where the yield of every parse is itself a tree. In fact, for any CFG  $G$ , it

<sup>1</sup>See Liang et al. (2011) for work in representing lambda calculus expressions with trees.

is straightforward to produce a corresponding RTG that generates the set of parses of  $G$ . Consequently, while we assume we have an RTG for the MR language, there is no loss of generality if the MR language is actually context free.

## 3 Weighted root-to-frontier, linear, non-deleting tree-to-string transducers

Tree transducers (Rounds, 1970; Thatcher, 1970) are generalizations of finite state machines that operate on trees. Mirroring the branching nature of its input, the transducer may simultaneously transition to several successor states, assigning a separate state to each subtree.

There are many classes of transducer with different formal properties (Knight and Graehl, 2005; Maletti et al., 2009). Figure 1(c) is an example of a root-to-frontier, linear, non-deleting tree-to-string transducer. It is defined using rules where the left hand side identifies a state of the transducer and a fragment of the input tree, and the right hand side describes a portion of the output string. Variables  $x_i$  stand for entire sub-trees, and state-variable pairs  $q_j.x_i$  stand for strings produced by applying the transducer starting at state  $q_j$  to subtree  $x_i$ . Figure 1(b) illustrates an application of the transducer, taking the tree on the left as input and outputting the string on the right.

Formally, a weighted root-to-frontier, tree-to-string transducer is a 5-tuple  $(\mathcal{Q}, \Sigma, \Delta, q_{start}, \mathcal{R})$ .  $\mathcal{Q}$  is a finite set of states,  $\Sigma$  and  $\Delta$  are the input and output alphabets,  $q_{start}$  is the start state, and  $\mathcal{R}$  is the set of rules. Denote a pair of symbols,  $a$  and  $b$  by  $a.b$ , the cross product of two sets  $\mathcal{A}$  and  $\mathcal{B}$  by  $\mathcal{A}.\mathcal{B}$ , and let  $\mathcal{X}$  be the set of variables  $\{x_0, x_1, \dots\}$ . Then, each rule  $r \in \mathcal{R}$  is of the form  $[q.t \rightarrow u].v$ , where  $v \in \mathbb{R}^{\geq 0}$  is the rule weight,  $q \in \mathcal{Q}$ ,  $t \in T_\Sigma(\mathcal{X})$ , and  $u$  is a string in  $(\Delta \cup \mathcal{Q}.\mathcal{X})^*$  such that every  $x \in \mathcal{X}$  in  $u$  also occurs in  $t$ .

We say  $q.t$  is the left hand side of rule  $r$  and  $u$  its right hand side. The transducer is *linear* iff no variable appears more than once on the right hand side. It is *non-deleting* iff all variables on the left hand side also occur on the right hand side. In this paper we assume that every tree  $t$  on the left hand side is either a single variable  $x_0$  or of the form  $\sigma(x_0, \dots x_n)$ , where  $\sigma \in \Sigma$  (i.e., it is a tree of depth  $\leq 1$ ).

A weighted tree transducer may define a probability distribution, either a joint distribution over input and output pairs or a conditional distribution of the output given the input. Here, we will use joint distributions, which can be defined by ensuring that the weights of all rules with the same state on the left-hand side sum to one. In this case, it can be helpful to view the transducer as simultaneously generating both the input and output, rather than the usual view of mapping input trees into output strings. A joint distribution allows us to model with a single machine both the input and output languages, which is important during decoding when we want to infer the input given the output.

#### 4 A generative model of semantic parsing

Like the hybrid tree semantic parser (Lu et al., 2008) and the synchronous grammar based WASP (Wong and Mooney, 2006), our model simultaneously generates the input MR tree and the output NL string. The MR tree is built up according to the provided MR grammar, one grammar rule at a time. Coupled with the application of the MR rule, similar CFG-like productions are applied to the NL side, repeated until both the MR and NL are fully generated. In each step, we select an MR rule and then build the NL by first choosing a pattern with which to expand it and then filling out that pattern with words drawn from a unigram distribution.

This kind of coupled generative process can be naturally formalized with tree transducer rules, where the input tree fragment on the left side of each rule describes the derivation of the MR and the right describes the corresponding NL derivation.

For a simple example of a tree-to-string transducer rule consider

$$q.\text{population}(x_1) \rightarrow \text{'population of'} q.x_1 \quad (1)$$

which simultaneously generates tree fragment  $\text{population}(x_1)$  on the left and sub-string “population of  $q.x_1$ ” on the right. Variable  $x_1$  stands for an MR subtree under  $\text{population}$ , and, on the right, state-variable pair  $q.x_1$  stands for the NL substring generated while processing subtree  $x_1$  starting from  $q$ . While this rule can serve as a single step of an MR-to-NL map such as the example transducer shown in Figure 1(c), such rules do not model the

$$\text{NUM} \rightarrow \text{population}(\text{PLACE}) \quad (m)$$

$$\text{PLACE} \rightarrow \text{cityid}(\text{CITY}, \text{STATE}) \quad (r)$$

$$\text{CITY} \rightarrow \text{portland} \quad (u)$$

$$\text{STATE} \rightarrow \text{maine} \quad (v)$$

$$q_{m,1}^{\text{MR}}.x_1 \rightarrow q_r^{\text{NL}}.x_1 \quad (2)$$

$$q_{r,1}^{\text{MR}}.x_1 \rightarrow q_u^{\text{NL}}.x_1$$

$$q_{r,2}^{\text{MR}}.x_1 \rightarrow q_v^{\text{NL}}.x_1$$

$$q_m^{\text{NL}}.\text{population}(w_1, x_1, w_2) \rightarrow q_m^{\text{W}}.w_1 q_{m,1}^{\text{MR}}.x_1 q^{\text{END}}.w_2 \quad (3)$$

$$q_r^{\text{NL}}.\text{cityid}(w_1, x_1, w_2, x_2, w_3) \rightarrow q^{\text{END}}.w_1 q_{r,2}^{\text{MR}}.x_2 q_r^{\text{W}}.w_2 q_{r,1}^{\text{MR}}.x_1 q^{\text{END}}.w_3 \quad (4)$$

$$q_m^{\text{W}}.w_1 \rightarrow \text{'population'} q_m^{\text{W}}.w_1 \quad (5)$$

$$q_m^{\text{W}}.w_1 \rightarrow \text{'of'} q_m^{\text{W}}.w_1$$

$$q_m^{\text{W}}.w_1 \rightarrow \dots q_m^{\text{W}}.w_1$$

$$q_m^{\text{W}}.w_1 \rightarrow \text{'of'} q^{\text{END}}.w_1 \quad (6)$$

$$q_m^{\text{W}}.w_1 \rightarrow \dots q^{\text{END}}.w_1$$

$$q^{\text{END}}.W \rightarrow \epsilon \quad (7)$$

Figure 2: Examples of transducer rules (bottom) that generate MR and NL associated with MR rules  $m-v$  (top). Transducer rule 2 selects MR rule  $r$  from the MR grammar. Rule 3 simultaneously writes the MR associated with rule  $m$  and chooses an NL pattern (as does 4 for  $r$ ). Rules 5-7 generate the words associated with  $m$  according to a unigram distribution specific to  $m$ .

grammaticality of the MR and lack flexibility since sub-strings corresponding to a given tree fragment must be completely pre-specified. Instead, we break transductions down into a three stage process of choosing the (i) MR grammar rule, (ii) NL expansion pattern, and (iii) individual words according to a unigram distribution. Such a decomposition incorporates independence assumptions that improve generalizability. See Figure 2 for example rules from our transducer and Figure 3 for a derivation.

To ensure that only grammatical MRs are generated, each state of our transducer encodes the identity of exactly one MR grammar rule. Transitions between  $q^{\text{MR}}$  and  $q^{\text{NL}}$  states implicitly select the embedded rule. For instance, rule 2 in Figure 2 selects

MR grammar rule  $r$  to expand the  $i^{th}$  child of the parent produced by rule  $m$ . Aside from ensuring the *grammaticality* of the generated MR, rules of this type also model the *probability* of the MR, conditioning the probability of a rule both on the parent rule and the index of the child being expanded. Thus, parent state  $q_{m,1}^{MR}$  encodes not only the identity of rule  $m$ , but also the child index, 1 in this case.

Once the MR rule is selected,  $q^{NL}$  states are applied to select among rules such as 3 and 4 to generate the MR entity and choose the NL expansion pattern. These rules determine the word order of the language by deciding (i) whether or not to generate words in a given location and (ii) where to insert the result of processing each MR subtree. Decision (i) is made by either transitioning to state  $q_r^W$  to generate words or to  $q^{END}$  to generate the empty string. Decision (ii) is made with the order of  $x_i$ 's on the right hand side. Rule 4 illustrates the case where *portland* and *maine* in *cityid(portland, maine)* would be realized in reverse order as "maine ... portland".

The particular set of patterns that appear on the right of rules such as 3 embodies the binary word attachment decisions and the particular permutation of  $x_i$  in the NL. We allow words to be generated at the beginning and end of each pattern and between the  $x_i$ s. Thus, rule 4 is just one of 16 such possible patterns (3 binary decisions and 2 permutations), while rule 3 is one of 4. We instantiate all such rules and allow the system to learn weights for them according to the language of the training data.

Finally, the NL is filled out with words chosen according to a unigram distribution, implemented in a PCFG-like fashion, using a different rule for each word which recursively chooses the next word until a string termination rule is reached.<sup>2</sup> Generating word sequence "population of" entails first choosing rule 5 in Figure 2. State  $q_r^W$  is then recursively applied to choose rule 6, generating "of" at the same time as deciding to terminate the string by transitioning to a new state  $q^{END}$  which deterministically concludes by writing the empty string  $\epsilon$ .

On the MR side, rules 5-7 do very little: the tree on the left side of rules 5 and 6 consists entirely of a

<sup>2</sup>There are roughly 25,000 rules in the transducers in our experiments, and the majority of these implement the unigram word distributions since every entity in the MR may potentially produce any of the words it is paired with in training.

subtree variable  $w_1$ , indicating that nothing is generated in the MR. Rule 7 subsequently generates these subtrees as  $W$  symbols, marking corresponding locations where words might be produced in the NL, which are later removed during post processing.<sup>3</sup>

Figure 3(b) illustrates the coupled generative process. At each step of the derivation, an MR rule is chosen to expand a node of the MR tree, and then a corresponding part of the NL is expanded. Step 1.1 of the example chooses MR rule  $m$ ,  $NUM \rightarrow population(PLACE)$ . Transducer rule 3 then generates *population* in the MR (shown in the left column) at the same time as choosing an NL expansion pattern (Step 1.2) which is subsequently filled out with specific words "population" (1.3) and "of" (1.4).

This coupled derivation can be represented by a tree, shown in Figure 3(c), which explicitly represents the dependency structure of the coupled MR and NL (a simplified version is shown in (d) for clarity). In our transducer, which defines a joint distribution over both the MR and NL, the probability of a rule is conditioned on the parent state. Since each state encodes an MR rule, MR rule specific distributions are learned for both the words and their order.

## 5 Relation to existing models

The tree transducer model can be viewed either as a generative procedure for building up two separate structures or as a transformative machine that takes one as input and produces another as output. Different semantic parsing approaches have taken one or the other view, and both can be captured in this single framework.

WASP (Wong and Mooney, 2006) is an example of the former perspective, coupling the generation of the MR and NL with a synchronous grammar, a formalism closely related to tree transducers. The most significant difference from our approach is that they use machine translation techniques for automatically extracting rules from parallel corpora; similar techniques can be applied to tree transducers (Galley et al., 2004). In fact, synchronous grammars and tree transducers can be seen as instances of the same more general class of automata (Shieber,

<sup>3</sup>The addition of  $W$  symbols is a convenience; it is easier to design transducer rules where every substring on the right side corresponds to a subtree on the left.

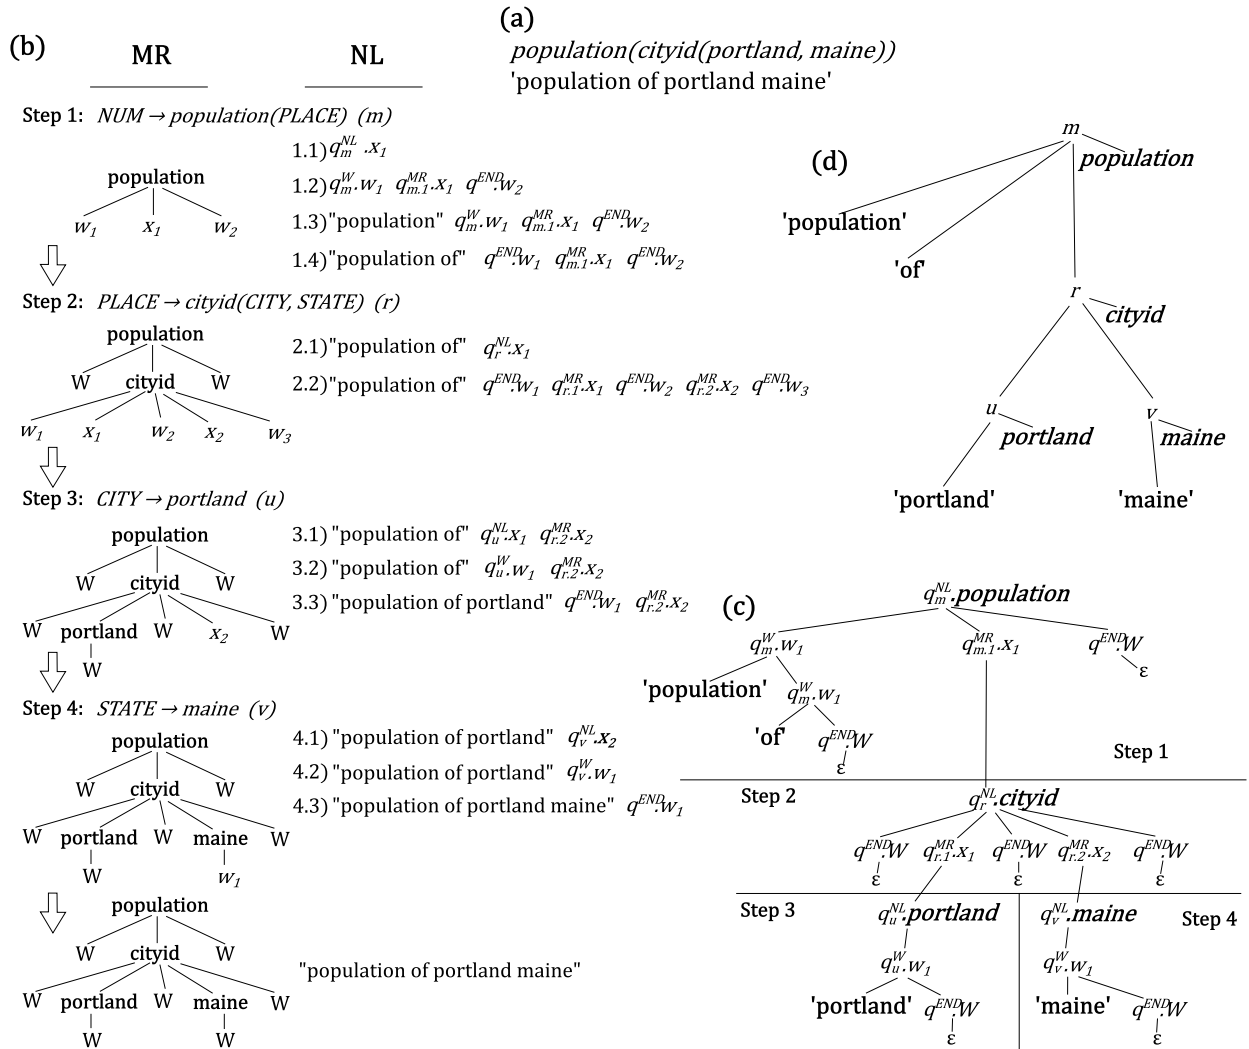

Figure 3: Coupled derivation of an (MR, NL) pair. At each step an MR grammar rule is chosen to expand the MR and the corresponding portion of the NL is then generated. Symbols  $W$  stand for locations in the tree corresponding to substrings of the output and are removed in a post-processing step. (a) The (MR, NL) pair. (b) Step by step derivation. (c) The same derivation shown in tree form. (d) The underlying dependency structure of the derivation.

2004). Rather than argue for one or the other, we suggest that other approaches could also be interpreted in terms of general model classes, grounding them in a broader base of theory.

The hybrid tree model (Lu et al., 2008) takes a transformative perspective that is in some ways more similar to our model. In fact, there is a one-to-one relationship between the multinomial parameters of the two models. However, they represent the MR and NL with a single tree and apply tree walking algorithms to extract them. Furthermore, they implement a custom training procedure for searching over the potential MR transformations. The tree

transducer, on the other hand, naturally captures the same probabilistic dependencies while maintaining the separation between MR and NL, and further allows us to build upon a larger body of theory.

KRISP (Kate and Mooney, 2006) uses string classifiers to label substrings of the NL with entities from the MR. To focus search, they impose an ordering constraint based on the structure of the MR tree, which they relax by allowing the re-ordering of sibling nodes and devise a procedure for recovering the MR from the permuted tree. This procedure corresponds to backward-application in tree transducers, identifying the most likely input tree given a

particular output string.

SCISSOR (Ge and Mooney, 2005) takes syntactic parses rather than NL strings and attempts to translate them into MR expressions. While few semantic parsers attempt to exploit syntactic information, there are techniques from machine translation for using tree transducers to map between parsed parallel corpora, and these techniques could likely be applied to semantic parsing.

Börschinger et al. (2011) argue for the PCFG as an alternative model class, permitting conventional grammar induction techniques, and tree transducers are similar enough that many techniques are applicable to both. However, the PCFG is less amenable to conceptualizing correspondences between parallel structures, and their model is more restrictive, only applicable to domains with finite MR languages, since their non-terminals encode entire MRs. The tree transducer framework, on the other hand, allows us to condition on individual MR rules.

## 6 Variational Bayes for tree transducers

As seen in the example in Figure 3(c), tree transducers not only operate on trees, their derivations are themselves trees, making them amenable to dynamic programming and an EM training procedure resembling inside-outside (Graehl et al., 2008). EM assigns zero probability to events not seen in the training data, however, limiting the ability to generalize to novel items. The Bayesian framework offers an elegant solution to this problem, introducing a prior over rule weights which simultaneously ensures that all rules receive non-zero probability and allows the incorporation of prior knowledge and intuitions. Unfortunately, the introduction of a prior makes exact inference intractable, so we use an approximate method, variational Bayesian inference (Bishop, 2006), deriving an algorithm similar to that for PCFGs (Kurihara and Sato, 2006).

The tree transducer defines a joint distribution over the input  $y$ , output  $w$ , and their derivation  $x$  as the product of the weights of the rules appearing in  $x$ . That is,

$$p(y, x, w|\theta) = \prod_{r \in \mathcal{R}} \theta(r)^{c_r(x)}$$

where  $\theta$  is the set of multinomial parameters,  $r$  is a transducer rule,  $\theta(r)$  is its weight, and  $c_r(x)$  is the

number of times  $r$  appears in  $x$ . In EM, we are interested in the point estimate for  $\theta$  that maximizes  $p(\mathcal{Y}, \mathcal{W}|\theta)$ , where  $\mathcal{Y}$  and  $\mathcal{W}$  are the  $N$  input-output pairs in the training data. In the Bayesian setting, however, we place a symmetric Dirichlet prior over  $\theta$  and estimate a posterior distribution over both  $\mathcal{X}$  and  $\theta$ .

$$\begin{aligned} p(\theta, \mathcal{X}|\mathcal{Y}, \mathcal{W}) &= \frac{p(\mathcal{Y}, \mathcal{X}, \mathcal{W}, \theta)}{p(\mathcal{Y}, \mathcal{W})} \\ &= \frac{p(\theta) \prod_{i=1}^N p(y_i, x_i, w_i|\theta)}{\int p(\theta) \prod_{i=1}^N \sum_{x \in \mathcal{X}_i} p(y_i, x, w_i|\theta) d\theta} \end{aligned}$$

Since the integral in the denominator is intractable, we look for an appropriate approximation  $q(\theta, \mathcal{X}) \approx p(\theta, \mathcal{X}|\mathcal{Y}, \mathcal{W})$ . In particular, we assume the rule weights and the derivations are independent, i.e.,  $q(\theta, \mathcal{X}) = q(\theta)q(\mathcal{X})$ . The basic idea is then to define a lower bound  $\mathcal{F} \leq \ln p(\mathcal{Y}, \mathcal{W})$  in terms of  $q$  and then apply the calculus of variations to find a  $q$  that maximizes  $\mathcal{F}$ .

$$\begin{aligned} \ln p(\mathcal{Y}, \mathcal{W}|\alpha) &= \ln E_q \left[ \frac{p(\mathcal{Y}, \mathcal{X}, \mathcal{W}|\theta)}{q(\theta, \mathcal{X})} \right] \\ &\geq E_q \left[ \ln \frac{p(\mathcal{Y}, \mathcal{X}, \mathcal{W}|\theta)}{q(\theta, \mathcal{X})} \right] = \mathcal{F}, \end{aligned}$$

Applying our independence assumption, we arrive at the following expression for  $\mathcal{F}$ , where  $\theta_t$  is the particular parameter vector corresponding to the rules with parent state  $t$ :

$$\begin{aligned} \mathcal{F} &= \sum_{t \in \mathcal{Q}} (E_{q(\theta_t)}[\ln p(\theta_t|\alpha_t)] - E_{q(\theta_t)}[\ln q(\theta_t)]) \\ &+ \sum_{i=1}^N (E_q[\ln p(w_i, x_i, y_i|\theta)] - E_{q(x_i)}[\ln q(x_i)]). \end{aligned}$$

We find the  $q(\theta_t)$  and  $q(x_i)$  that maximize  $\mathcal{F}$  by taking derivatives of the Lagrangian, setting them to zero, and solving, which yields:

$$\begin{aligned} q(\theta_t) &= \text{Dirichlet}(\theta_t|\hat{\alpha}_t) \\ q(x_i) &= \frac{\prod_{r \in \mathcal{R}} \hat{\theta}(r)^{c_r(x_i)}}{\sum_{x \in \mathcal{X}_i} \prod_{r \in \mathcal{R}} \hat{\theta}(r)^{c_r(x)}} \end{aligned}$$

where

$$\begin{aligned} \hat{\alpha}(r) &= \alpha(r) + \sum_i E_{q(x_i)}[c_r(x_i)] \\ \hat{\theta}(r) &= \exp \left( \Psi(\hat{\alpha}(r)) - \Psi \left( \sum_{r:s(r)=t} \hat{\alpha}(r) \right) \right). \end{aligned}$$

The parameters of  $q(\theta_t)$  are defined with respect to  $q(x_i)$  and the parameters of  $q(x_i)$  with respect to the parameters of  $q(\theta_t)$ .  $q(x_i)$  can be computed efficiently using inside-outside. Thus, we can perform an EM-like alternation between calculating  $\hat{\alpha}$  and  $\hat{\theta}$ .<sup>4</sup>

It is also possible to estimate the hyper-parameters  $\alpha$  from data, a practice known as *empirical Bayes*, by optimizing  $\mathcal{F}$ . We explore learning separate hyper-parameters  $\alpha_t$  for each  $\theta_t$ , using a fixed point update described by Minka (2000), where  $k_t$  is the number of rules with parent state  $t$ :

$$\alpha'_t = \left( \frac{1}{\alpha_t} + \frac{1}{k_t \alpha_t^2} \left( \frac{\partial^2 \mathcal{F}}{\partial \alpha_t^2} \right)^{-1} \left( \frac{\partial \mathcal{F}}{\partial \alpha_t} \right) \right)^{-1}$$

## 7 Training and decoding

We implement our VB training algorithm inside the tree transducer package Tiburon (May and Knight, 2006), and experiment with both manually set and automatically estimated priors. For our manually set priors, we explore different hyper-parameter settings for three different priors, one for each of the main decision types: MR rule, NL pattern, and word generation. For the automatic priors, we estimate separate hyper-parameters for each multinomial (of which there are hundreds). As is standard, we initialize the word distributions using a variant of IBM model 1, and make use of NP lists (a manually created list of the constants in the MR language paired with the words that refer to them in the corpus).

At test time, since finding the most probable *MR* for a sentence involves summing over all possible derivations, we instead find the MR associated with the most probable *derivation*.

## 8 Experimental setup and evaluation

We evaluate the system on GeoQuery (Wong and Mooney, 2006), a parallel corpus of 880 English questions and database queries about United States geography, 250 of which were translated into Spanish, Japanese, and Turkish. We present here additional translations of the full 880 sentences into

<sup>4</sup>Because of the resemblance to EM, this procedure has been called VBEM. Unlike EM, however, this procedure alternates between two estimation steps and has no maximization step.

German, Greek, and Thai. For evaluation, following from Kwiatkowski et al. (2010), we reserve 280 sentences for test and train on the remaining 600. During development, we use cross-validation on the 600 sentence training set. At test, we run once on the remaining 280 and perform 10 fold cross-validation on the 250 sentence sets.

To judge correctness, we follow standard practice and submit each parse as a GeoQuery database query, and say the parse is correct only if the answer matches the gold standard. We report raw accuracy (the percentage of sentences with correct answers), as well as F1: the harmonic mean of precision (the proportion of correct answers out of sentences with a parse) and recall (the proportion of correct answers out of all sentences).<sup>5</sup>

We run three other state-of-the-art systems for comparison. *WASP* (Wong and Mooney, 2006) and the *hybrid tree* (Lu et al., 2008) are chosen to represent tree transformation based approaches, and, while this comparison is our primary focus, we also report *UBL-S* (Kwiatkowski et al., 2010) as a non-tree based top-performing system.<sup>6</sup> The hybrid tree is notable as the only other system based on a generative model, and *uni-hybrid*, a version that uses a unigram distribution over words, is very similar to our own model. We also report the best performing version, *re-hybrid*, which incorporates a discriminative re-ranking step.

We report transducer performance under three different training conditions: *tsEM* using EM, *tsVB-auto* using VB with empirical Bayes, and *tsVB-hand* using hyper-parameters manually tuned on the German training data ( $\alpha$  of 0.3, 0.8, and 0.25 for MR rule, NL pattern, and word choices, respectively).

Table 1 shows results for 10 fold cross-validation on the training set. The results highlight the benefit of the Dirichlet prior, whether manually or automatically set. VB improves over EM considerably, most likely because (1) the handling of unknown words and MR entities allows it to return an analysis for all sentences, and (2) the sparse Dirichlet prior favors fewer rules, reasonable in this setting where only a few words are likely to share the same meaning.

<sup>5</sup>Note that accuracy and f-score reduce to the same formula if there are no parse failures.

<sup>6</sup>UBL-S is based on CCG, which can be viewed as a mapping between graphs more general than trees.

On the test set (Table 2), we only run the model variants that perform best on the training set. Test set accuracy is consistently higher for the VB trained tree transducer than the other tree transformation based models (and often highest overall), while f-score remains competitive.<sup>7</sup>

## 9 Conclusion

We have argued that tree transformation based semantic parsing can benefit from the literature on formal language theory and tree automata, and have taken a step in this direction by presenting a tree transducer based semantic parser. Drawing this connection facilitates a greater flow of ideas in the research community, allowing semantic parsing to leverage ideas from other work with tree automata, while making clearer how seemingly isolated efforts might relate to one another. We demonstrate this by both building on previous work in training tree transducers using EM (Graehl et al., 2008),

<sup>7</sup>Numbers differ slightly here from previously published results due to the fact that we have standardized the inputs to the different systems.

and describing a general purpose variational inference algorithm for adapting tree transducers to the Bayesian framework. The new VB algorithm results in an overall performance improvement for the transducer over EM training, and the general effectiveness of the approach is further demonstrated by the Bayesian transducer achieving highest accuracy among other tree transformation based approaches.

## Acknowledgments

We thank Joel Lang, Michael Auli, Stella Frank, Prachya Boonkwan, Christos Christodoulopoulos, Ioannis Konstas, and Tom Kwiatkowski for providing the new translations of GeoQuery. # Dependency Hashing for $n$ -best CCG Parsing

Dominick Ng and James R. Curran

ϱ-lab, School of Information Technologies

University of Sydney

NSW, 2006, Australia

{dominick.ng, james.r.curran}@sydney.edu.au

## Abstract

Optimising for one grammatical representation, but evaluating over a different one is a particular challenge for parsers and  $n$ -best CCG parsing. We find that this mismatch causes many  $n$ -best CCG parses to be semantically equivalent, and describe a hashing technique that eliminates this problem, improving oracle  $n$ -best F-score by 0.7% and reranking accuracy by 0.4%. We also present a comprehensive analysis of errors made by the C&C CCG parser, providing the first breakdown of the impact of implementation decisions, such as supertagging, on parsing accuracy.

## 1 Introduction

Reranking techniques are commonly used for improving the accuracy of parsing (Charniak and Johnson, 2005). Efficient decoding of a parse forest is infeasible without dynamic programming, but this restricts features to local tree contexts. Reranking operates over a list of  $n$ -best parses according to the original model, allowing poor local parse decisions to be identified using arbitrary rich parse features.

The performance of reranking depends on the quality of the underlying  $n$ -best parses. Huang and Chiang (2005)'s  $n$ -best algorithms are used in a wide variety of parsers, including an  $n$ -best version of the C&C CCG parser (Clark and Curran, 2007; Brennan, 2008). The oracle F-score of this parser (calculated by selecting the most optimal parse in the  $n$ -best list) is 92.60% with  $n = 50$  over a baseline 1-best F-score of 86.84%. In contrast, the Charniak parser records an oracle F-score of 96.80% in 50-best mode

over a baseline of 91.00% (Charniak and Johnson, 2005). The 4.2% oracle score difference suggests that further optimisations may be possible for CCG.

We describe how  $n$ -best parsing algorithms that operate over derivations do not account for absorption ambiguities in parsing, causing semantically identical parses to exist in the CCG  $n$ -best list. This is caused by the mismatch between the optimisation target (different derivations) and the evaluation target (CCG dependencies). We develop a hashing technique over dependencies that removes duplicates and improves the oracle F-score by 0.7% to 93.32% and reranking accuracy by 0.4%. Huang et al. (2006) proposed a similar idea where strings generated by a syntax-based MT rescoring system were hashed to prevent duplicate translations.

Despite this improvement, there is still a substantial gap between the C&C and Charniak oracle F-scores. We perform a comprehensive subtractive analysis of the C&C parsing pipeline, identifying the relative contribution of each error class and why the gap exists. The parser scores 99.49% F-score with gold-standard categories on section 00 of CCGbank, and 94.32% F-score when returning the best parse in the chart using the supertagger on standard settings. Thus the supertagger contributes roughly 5% of parser error, and the parser model the remaining 7.5%. Various other speed optimisations also detrimentally affect accuracy to a smaller degree.

Several subtle trade-offs are made in parsers between speed and accuracy, but their actual impact is often unclear. Our work investigates these and the general issue of how different optimisation and evaluation targets can affect parsing performance.

Figure 1: A CCG derivation with a PP adjunct, demonstrating forward and backward combinator application. Adapted from Villavicencio (2002).

## 2 Background

Combinatory Categorical Grammar (CCG, Steedman, 2000) is a lexicalised grammar formalism based on formal logic. The grammar is directly encoded in the lexicon in the form of *categories* that govern the syntactic behaviour of each word.

Atomic categories such as  $N$  (noun),  $NP$  (noun phrase), and  $PP$  (prepositional phrase) represent complete units. Complex categories encode subcategorisation information and are functors of the form  $X/Y$  or  $X \setminus Y$ . They represent structures which combine with an argument category  $Y$  to produce a result category  $X$ . In Figure 1, the complex category  $S \setminus NP$  for *swims* represents an intransitive verb requiring a subject  $NP$  to the left.

Combinatory rules are used to combine categories together to form an analysis. The simplest rules are forward and backward application, where complex categories combine with their outermost arguments. Forward and backward composition allow categories to be combined in a non-canonical order, and type-raising turns a category into a higher-order functor. A ternary coordination rule combines two identical categories separated by a *conj* into one.

As complex categories are combined with their arguments, they create a logical form representing the syntactic and semantic properties of the sentence. This logical form can be expressed in many ways; we will focus on the *dependency* representation used in CCGbank (Hockenmaier and Steedman, 2007). In Figure 1, *swims* generates one dependency:

$$\langle \text{swims}, S[\text{dcl}] \setminus NP_1, 1, \text{Jack}, - \rangle$$

where the dependency contains the head word, head category, argument slot, argument word, and whether the dependency is long-range.

Figure 2: A CCG derivation with a PP argument (note the categories of *swims* and *across*). The bracketing is identical to Figure 1, but nearly all dependencies have changed.

## 2.1 Corpora and evaluation

CCGbank (Hockenmaier, 2003) is a transformation of the Penn Treebank (PTB) data into CCG derivations, and it is the standard corpus for English CCG parsing. Other CCG corpora have been induced in a similar way for German (Hockenmaier, 2006) and Chinese (Tse and Curran, 2010). CCGbank contains 99.44% of the sentences from the PTB, and several non-standard rules were necessary to achieve this coverage. These include punctuation absorption rules and unary type-changing rules for clausal adjuncts that are otherwise difficult to represent.

The standard CCG parsing evaluation calculates labeled precision, recall, and F-score over the dependencies recovered by a parser as compared to CCGbank (Clark et al., 2002). All components of a dependency must match the gold standard for it to be scored as correct, and this makes the procedure much harsher than the PARSEVAL labeled brackets metric. In Figure 2, the PP *across the river* has been interpreted as an argument rather than an adjunct as in Figure 1. Both parses would score identically under PARSEVAL as their bracketing is unchanged. However, the adjunct to argument change results in different categories for *swims* and *across*; nearly every CCG dependency in the sentence is headed by one of these two words and thus each one changes as a result. An incorrect argument/adjunct distinction in this sentence produces a score close to 0.

All experiments in this paper use the normal-form C&C parser model over CCGbank 00 (Clark and Curran, 2007). Scores are reported for sentences which the parser could analyse; we observed similar conclusions when repeating our experiments over the subset of sentences that were parsable under all configurations described in this paper.

## 2.2 The C&C parser

The C&C parser (Clark and Curran, 2007) is a fast and accurate CCG parser trained on CCGbank 02-21, with an accuracy of 86.84% on CCGbank 00 with the normal-form model. It is a two-phase system, where a supertagger assigns possible categories to words in a sentence and the parser combines them using the CKY algorithm. An  $n$ -best version incorporating the Huang and Chiang (2005) algorithms has been developed (Brennan, 2008). Recent work on a softmax-margin loss function and integrated supertagging via belief propagation has improved this to 88.58% (Auli and Lopez, 2011).

A parameter  $\beta$  is passed to the supertagger as a multi-tagging probability beam.  $\beta$  is initially set at a very restrictive value, and if the parser cannot form an analysis the supertagger is rerun with a lower  $\beta$ , returning more categories and giving the parser more options in constructing a parse. This *adaptive* supertagging prunes the search space whilst maintaining coverage of over 99%.

The supertagger also uses a *tag dictionary*, as described by Ratnaparkhi (1996), and accepts a cutoff  $k$ . Words seen more than  $k$  times in CCGbank 02-21 may only be assigned categories seen with that word more than 5 times in CCGbank 02-21; the frequency must also be no less than 1/500th of the most frequent tag for that word. Words seen fewer than  $k$  times may only be assigned categories seen with the POS of the word in CCGbank 02-21, subject to the cutoff and ratio constraint (Clark and Curran, 2004b). The tag dictionary eliminates infrequent categories and improves the performance of the supertagger, but at the cost of removing unseen or infrequently seen categories from consideration.

The parser accepts POS-tagged text as input; unlike many PTB parsers, these tags are fixed and remain unchanged throughout during the parsing pipeline. The POS tags are important features for the supertagger; parsing accuracy using gold-standard POS tags is typically 2% higher than using automatically assigned POS tags (Clark and Curran, 2004b).

## 2.3 $n$ -best parsing and reranking

Most parsers use dynamic programming, discarding infeasible states in order to maintain tractability. However, constructing an  $n$ -best list requires keep-

ing the top  $n$  states throughout. Huang and Chiang (2005) define several  $n$ -best algorithms that allow dynamic programming to be retained whilst generating precisely the top  $n$  parses – using the observation that once the 1-best parse is generated, the 2nd best parse must differ in exactly one location from it, and so forth. These algorithms are defined on a hypergraph framework equivalent to a chart, so the parses are distinguished based on their derivations. Huang et al. (2006) develop a translation reranking model using these  $n$ -best algorithms, but faced the issue of different derivations yielding the same string. This was overcome by storing a hashtable of strings at each node in the tree, and rejecting any derivations that yielded a previously seen string.

Collins (2000)’s parser reranker uses  $n$ -best parses of PTB 02-21 as training data. Reranker features include lexical heads and the distances between them, context-free rules in the tree,  $n$ -grams and their ancestors, and parent-grandparent relationships. The system improves the accuracy of the Collins parser from 88.20% to 89.75%.

Charniak and Johnson (2005)’s reranker uses a similar setup to the Collins reranker, but utilises much higher quality  $n$ -best parses. Additional features on top of those from the Collins reranker such as subject-verb agreement,  $n$ -gram local trees, and right-branching factors are also used. In 50-best mode the parser has an oracle F-score of 96.80%, and the reranker produces a final F-score of 91.00% (compared to an 89.70% baseline).

## 3 Ambiguity in $n$ -best CCG parsing

The type-raising and composition combinators allow the same logical form to be created from different category combination orders in a derivation. This is termed *spurious ambiguity*, where different derivational structures are semantically equivalent and will evaluate identically despite having a different phrase structure. The C&C parser employs the normal-form constraints of Eisner (1996) to address spurious ambiguity in 1-best parsing.

*Absorption ambiguity* occurs when a constituent may be legally placed at more than one location in a derivation, and all of the resulting derivations are semantically equivalent. Punctuation such as commas, brackets, and periods are particularly prone to

	Avg P/sent	Distinct P/sent	% Distinct
10-best	9.8	5.1	52
50-best	47.6	16.0	34
10-best <sup>#</sup>	9.0	9.0	100
50-best <sup>#</sup>	37.9	37.9	100

Table 1: Average and distinct parses per sentence over CCGbank 00 with respect to CCG dependencies. # indicates the inclusion of dependency hashing

absorption ambiguity in CCG; Figure 3 depicts four semantically equivalent sequences of absorption and combinator application in a sentence fragment.

The Brennan (2008) CCG  $n$ -best parser differentiates CCG parses by derivation rather than logical form. To illustrate how this is insufficient, we ran the parser using Algorithm 3 of Huang and Chiang (2005) with  $n = 10$  and  $n = 50$ , and calculated how many parses were semantically distinct (i.e. yield different dependencies). The results (summarised in Table 1) are striking: just 52% of 10-best parses and 34% of 50-best parses are distinct. We can also see that fewer than  $n$  parses are found on average for each sentence; this is mostly due to shorter sentences that may only receive one or two parses.

We perform the same diversity experiment using the DepBank-style grammatical relations (GRs, King et al., 2003; Briscoe and Carroll, 2006) output of the parser. GRs are generated via a dependency to GR mapping in the parser as well as a post-processing script to clean up common errors (Clark and Curran, 2007). GRs provide a more formalism-neutral comparison and abstract away from the raw CCG dependencies; for example, in Figures 1 and 2, the dependency from *swims* to *Jack* would be abstracted into (subj swims Jack) and thus would be identical in both parses. Hence, there are even fewer distinct parses in the GR results summarised in Table 2: 45% and 27% of 10-best and 50-best parses respectively yield unique GRs.

### 3.1 Dependency hashing

To address this problem of semantically equivalent  $n$ -best parses, we define a uniqueness constraint over all the  $n$ -best candidates:

**Constraint.** *At any point in the derivation, any  $n$ -best candidate must not have the same dependencies as any candidate already in the list.*

	Avg P/sent	Distinct P/sent	% Distinct
10-best	9.8	4.4	45
50-best	47.6	13.0	27
10-best <sup>#</sup>	8.9	8.1	91
50-best <sup>#</sup>	37.1	31.5	85

Table 2: Average and distinct parses per sentence over CCGbank 00 with respect to GRs. # indicates the inclusion of dependency hashing

Enforcing this constraint is non-trivial as it is infeasible to directly compare every dependency in a partial tree with another. Due to the flexible notion of constituency in CCG, dependencies can be generated at a variety of locations in a derivation and in a variety of orders. This means that comparing all of the dependencies in a particular state may require traversing the entire sub-derivation at that point. Parsing is already a computationally expensive process, so we require as little overhead from this check as possible.

Instead, we represent all of the CCG dependencies in a sub-derivation using a hash value. This allows us to compare the dependencies in two derivations with a single numeric equality check rather than a full iteration. The underlying idea is similar to that of Huang et al. (2006), who maintain a hashtable of unique strings produced by a translation reranker, and reject new strings that have previously been generated. Our technique does not use a hashtable, and instead only stores the hash value for each set of dependencies, which is much more efficient but runs the risk of filtering unique parses due to collisions.

As we combine partial trees to build the derivation, we need to convolve the hash values in a consistent manner. The convolution operator must be *order-independent* as dependencies may be generated in an arbitrary order at different locations in each tree. We use the bitwise exclusive OR ( $\oplus$ ) operation as our convolution operator: when two partial derivations are combined, their hash values are XOR’ed together. XOR is commonly employed in hashing applications for randomly permuting numbers, and it is also order independent:  $a \oplus b \equiv b \oplus a$ . Using XOR, we enforce a unique hash value constraint in the  $n$ -best list of candidates, discarding potential candidates with an identical hash value to any already in the list.

Figure 3: All four derivations have a different syntactic structure, but generate identical dependencies.

	Collisions	Comparisons	%
10-best	300	54861	0.55
50-best	2109	225970	0.93

Table 3: Dependency hash collisions and comparisons over 00 of CCGbank.

### 3.2 Hashing performance

We evaluate our hashing technique with several experiments. A simple test is to measure the number of collisions that occur, i.e. where two partial trees with different dependencies have the same hash value. We parsed CCGbank 00 with  $n = 10$  and  $n = 50$  using a 32 bit hash, and exhaustively checked the dependencies of colliding states. We found that less than 1% of comparisons resulted in collisions in both 10-best and 50-best mode, and decided that this was acceptably low for distinguishing duplicates.

We reran the diversity experiments, and verified that every  $n$ -best parse for every sentence in CCGbank 00 was unique (see Table 1), corroborating our decision to use hashing alone. On average, there are fewer parses per sentence, showing that hashing is eliminating many equivalent parses for more ambiguous sentences. However, hashing also leads to a near doubling of unique parses in 10-best mode and a 2.3x increase in 50-best mode. Similar results are recorded for the GR diversity (see Table 2), though not every set of GRs is unique due to the many-to-many mapping from CCG dependencies. These results show that hashing prunes away equivalent parses, creating more diversity in the  $n$ -best list.

We also evaluate the oracle F-score of the parser using dependency hashing. Our results in Table 4 include a 1.1% increase in 10-best mode and 0.72% in 50-best mode using the new constraints, showing how the diversified parse list contains better candidates for reranking. Our highest oracle F-score was 93.32% in 50-best mode.

Experiment	LP	LR	LF	AF
baseline	87.27	86.41	86.84	84.91
oracle 10-best	91.50	90.49	90.99	89.01
oracle 50-best	93.17	92.04	92.60	90.68
<b>oracle 10-best<sup>#</sup></b>	<b>92.67</b>	<b>91.51</b>	<b>92.09</b>	<b>90.15</b>
<b>oracle 50-best<sup>#</sup></b>	<b>94.00</b>	<b>92.66</b>	<b>93.32</b>	<b>91.47</b>

Table 4: Oracle precision, recall, and F-score on gold and auto POS tags for the C&C  $n$ -best parser. # denotes the inclusion of dependency hashing.

	Test data	
Training data	no hashing	hashing
no hashing	86.83	86.35
hashing	<b>87.21</b>	<b>87.15</b>

Table 5: Reranked parser accuracy; labeled F-score using gold POS tags, with and without dependency hashing

### 3.3 CCG reranking performance

Finally, we implement a discriminative maximum entropy reranker for the  $n$ -best C&C parser and evaluate it when using dependency hashing. We reimplement the features described in Charniak and Johnson (2005) and add additional features based on those used in the C&C parser and on features of CCG dependencies. The training data is cross-fold  $n$ -best parsed sentences of CCGbank 02-21, and we use the MEGAM optimiser<sup>1</sup> in regression mode to predict the labeled F-score of each  $n$ -best candidate parse.

Our experiments rerank the top 10-best parses and use four configurations: with and without dependency hashing for generating the training and test data for the reranker. Table 5 shows that labeled F-score improves substantially when dependency hashing is used to create reranker training data. There is a 0.4% improvement using no hashing at test, and a 0.8% improvement using hashing

<sup>1</sup><http://hal3.name/megam>

at test, showing that more diverse training data creates a better reranker. The results of 87.21% without hashing at test and 87.15% using hashing at test are statistically indistinguishable from one other; though we would expect the latter to perform better.

Our results also show that the reranker performs extremely poorly using diversified test parses and undiversified training parses. There is a 0.5% performance loss in this configuration, from 86.83% to 86.35% F-score. This may be caused by the reranker becoming attuned to selecting between semantically indistinguishable derivations, which are pruned away in the diversified test set.

## 4 Analysing parser errors

A substantial gap exists between the oracle F-score of our improved  $n$ -best parser and other PTB  $n$ -best parsers (Charniak and Johnson, 2005). Due to the different evaluation schemes, it is difficult to directly compare these numbers, but whether there is further room for improvement in CCG  $n$ -best parsing is an open question. We analyse three main classes of errors in the C&C parser in order to answer this question: grammar error, supertagger error, and model error. Furthermore, insights from this analysis will prove useful in evaluating tradeoffs made in parsers.

*Grammar error:* the parser implements a subset of the grammar and unary type-changing rules in CCGbank for efficiency, with some rules, such as substitution, omitted for efficiency (Clark and Curran, 2007). This means that, given the correct categories for words in a sentence, the parser may be unable to combine them into a derivation yielding the correct dependencies, or it may not recognise the gold standard category at all.

There is an additional constraint in the parser that only allows two categories to combine if they have been seen to combine in the training data. This *seen rules* constraint is used to reduce the size of the chart and improve parsing speed, at the cost of only permitting category combinations seen in CCGbank 02-21 (Clark and Curran, 2007).

*Supertagger error:* The supertagger uses a restricted set of 425 categories determined by a frequency cutoff of 10 over the training data (Clark and Curran, 2004b). Words with gold categories that are not in this set cannot be tagged correctly.

The  $\beta$  parameter restricts the categories to within a probability beam, and the tag dictionary restricts the set of categories that can be considered for each word. Supertagger model error occurs when the supertagger can assign a word its correct category, but the statistical model does not assign the correct tag enough probability for it to fall within the  $\beta$ .

*Model error:* The parser model features may be rich enough to capture certain characteristics of parses, causing it to select a suboptimal parse.

### 4.1 Subtractive experiments

We develop an oracle methodology to distinguish between grammar, supertagger, and model errors. This is the most comprehensive error analysis of a parsing pipeline in the literature.

First, we supplied gold-standard categories for each word in the sentence. In this experiment the parser only needs to combine the categories correctly to form the gold parse. In our testing over CCGbank 00, the parser scores 99.49% F-score given perfect categories, with 95.61% coverage. Thus, grammar error accounts for about 0.5% of overall parser errors as well as a 4.4% drop in coverage<sup>2</sup>. All results in this section will be compared against this 99.49% result as it removes the grammar error from consideration.

### 4.2 Supertagger and model error

To determine supertagger and model error, we run the parser on standard settings over CCGbank 00 and examined the chart. If it contains the gold parse, then a model error results if the parser returns any other parse. Otherwise, it is a supertagger or grammar error, where the parser cannot construct the best parse. For each sentence, we found the best parse in the chart by decoding against the gold dependencies. Each partial tree was scored using the formula:

$$score = n_{correct} - nbad$$

where  $n_{correct}$  is the number of dependencies which appear in the gold standard, and  $nbad$  is the number of dependencies which do not appear in the gold standard. The top scoring derivation in the tree under this scheme is then returned.

<sup>2</sup>Clark and Curran (2004a) performed a similar experiment with lower accuracy and coverage; our improved numbers are due to changes in the parser.

Experiment	LP	LR	LF	AF	cover	$\Delta$ LF	$\Delta$ AF
oracle cats	99.72	99.27	99.49	99.49	95.61	0.00	0.00
best in chart -tagdict -seen rules	96.88	94.81	95.84	94.17	99.01	-3.65	-5.32
best in chart -tagdict	96.13	94.72	95.42	93.56	99.37	-4.07	-5.93
best in chart -seen rules	96.10	93.66	94.86	93.35	98.85	-4.63	-6.14
best in chart	95.15	93.50	94.32	92.60	99.16	-5.17	-6.89
baseline	87.27	86.41	86.84	84.91	99.16	-12.65	-14.58

Table 6: Oracle labeled precision, recall, F-score, F-score with auto POS, and coverage over CCGbank 00. -tagdict indicates disabling the tag dictionary, -seen rules indicates disabling the seen rules constraint

$\beta$	$k$	cats/word	sent/sec	LP	LR	LF	AF	cover	$\Delta$ LF	$\Delta$ AF
gold cats		-	-	99.72	99.27	99.49	-	95.61	0.00	0.00
0.075	20	1.27	40.5	95.46	93.90	94.68	93.07	94.30	-4.81	-6.42
0.03	20	1.43	33.0	96.23	94.87	95.54	94.01	96.03	-3.95	-5.48
0.01	20	1.72	19.1	97.02	95.82	96.42	95.02	96.86	-3.07	-4.47
0.005	20	1.98	10.7	97.26	96.09	96.68	95.32	97.23	-2.81	-4.17
0.001	150	3.57	1.18	98.33	97.37	97.85	96.76	96.13	-1.64	-2.73

Table 7: Category ambiguity, speed, labeled P, R, F-score on gold and auto POS, and coverage over CCGbank 00 for the standard supertagger parameters selecting the best scoring parse against the gold parse in the chart.

We obtain an overall maximum possible F-score for the parser using this scoring formula. The difference between this maximum F-score and the oracle result of 99.49% represents supertagger error (where the supertagger has not provided the correct categories), and the difference to the baseline performance indicates model error (where the parser model has not selected the optimal parse given the current categories). We also try disabling the seen rules constraint to determine its impact on accuracy.

The impact of tag dictionary errors must be neutralised in order to distinguish between the types of supertagger error. To do this, we added the gold category for a word to the set of possible tags considered for that word by the supertagger. This was done for categories that the supertagger could use; categories that were not in the permissible set of 425 categories were not considered. This is an optimistic experiment; removing the tag dictionary entirely would greatly increase the number of categories considered by the supertagger and may dramatically change the tagging results.

Table 6 shows the results of our experiments. The delta columns indicate the difference in labeled F-score to the oracle result, which discounts the grammar error in the parser. We ran the experiment in four configurations: disabling the tag dictionary, dis-

abling the seen rules constraint, and disabling both. There are coverage differences of less than 0.5% that will have a small impact on these results.

The “best in chart” experiment produces a result of 94.32% with gold POS tags and 92.60% with auto POS tags. These numbers are the upper bound of the parser with the supertagger on standard settings. Our result with gold POS tags is statistically identical to the oracle experiment conducted by Auli and Lopez (2011), which exchanged brackets for dependencies in the forest oracle algorithm of Huang (2008). This illustrates the validity of our technique.

A perfect tag dictionary that always contains the gold standard category if it is available results in an upper bound accuracy of 95.42%. This shows that overall supertagger error in the parser is around 5.2%, with roughly 1% attributable to the use of the tag dictionary and the remainder to the supertagger model. The baseline parser is 12.5% worse than the oracle categories result due to model error and supertagger error, so model error accounts for roughly 7.3% of the loss.

Eliminating the seen rules constraint contributes to a 0.5% accuracy improvement over both the standard parser configuration and the -tagdict configuration, at the cost of roughly 0.3% coverage to both. This is of similar magnitude to grammar error; but

Experiment	LF	cover	$\Delta$ LF
baseline	86.84	99.16	0.00
auto POS parser	86.57	99.16	-0.27
auto POS super	85.33	99.06	-1.51
auto POS both	84.91	99.06	-1.93

Table 8: Labeled F-score, coverage, and deltas over CCGbank 00 for combinations of gold and auto POS tags.

here accuracy is traded off against coverage.

The results also show that model and supertagger error largely accounts for the remaining oracle accuracy difference between the C&C  $n$ -best parser and the Charniak/Collins  $n$ -best parsers. The absolute upper bound of the C&C parser is only 1% higher than the oracle 50-best score in Table 4, placing the  $n$ -best parser close to its theoretical limit.

### 4.3 Varying supertagger parameters

We conduct a further experiment to determine the impact of the standard  $\beta$  and  $k$  values used in the parser. We reran the “best in chart” configuration, but used each standard  $\beta$  and  $k$  value individually rather than backing off to a lower  $\beta$  value to find the maximum score at each individual value.

Table 7 shows that the oracle accuracy improves from 94.68% F-score and 94.30% coverage with  $\beta = 0.075, k = 20$  to 97.85% F-score and 96.13% coverage with  $\beta = 0.001, k = 150$ . At higher  $\beta$  values, accuracy is lost because the correct category is not returned to the parser, while lower  $\beta$  values are more likely to return the correct category. The coverage peaks at the second-lowest value because at lower  $\beta$  values, the number of categories returned means all of the possible derivations cannot be stored in the chart. The back-off approach substantially increases coverage by ensuring that parses that fail at higher  $\beta$  values are retried at lower ones, at the cost of reducing the upper accuracy bound to below that of any individual  $\beta$ .

The speed of the parser varies substantially in this experiment, from 40.5 sents/sec at the first  $\beta$  level to just 1.18 sents/sec at the last. This illustrates the trade-off in using supertagging: the maximum achievable accuracy drops by nearly 5% for parsing speeds that are an order of magnitude faster.

### 4.4 Gold and automatic POS tags

There is a substantial difference in accuracy between experiments that use gold POS and auto POS tags. Table 6 shows a corresponding drop in upper bound accuracy from 94.32% with gold POS tags to 92.60% with auto POS tags. Both the supertagger and parser use POS tags independently as features, but this result suggests that the bulk of the performance difference comes from the supertagger. To fully identify the error contributions, we ran an experiment where we provide gold POS tags to one of the parser and supertagger, and auto POS tags to the other, and then run the standard evaluation (the oracle experiment will be identical to the “best in chart”).

Table 8 shows that supplying the parser with auto POS tags reduces accuracy by 0.27% compared to the baseline parser, while supplying the supertagger with auto POS tags results in a 1.51% decrease. The parser uses more features in a wider context than the supertagger, so it is less affected by POS tag errors.

## 5 Conclusion

We have described how a mismatch between the way CCG parses are modeled and evaluated caused equivalent parses to be produced in  $n$ -best parsing. We eliminate duplicates by hashing dependencies, significantly improving the oracle F-score of CCG  $n$ -best parsing by 0.7% to 93.32%, and improving the performance of CCG reranking by up to 0.4%.

We have comprehensively investigated the sources of error in the C&C parser to explain the gap in oracle performance compared with other  $n$ -best parsers. We show the impact of techniques that subtly trade off accuracy for speed and coverage. This will allow a better choice of parameters for future applications of parsing in CCG and other lexicalised formalisms.

## Abstract

Recently, it was shown (KUHLMANN, SATTÀ: *Tree-adjoining grammars are not closed under strong lexicalization*. *Comput. Linguist.*, 2012) that finitely ambiguous tree adjoining grammars cannot be transformed into a normal form (preserving the generated tree language), in which each production contains a lexical symbol. A more powerful model, the simple context-free tree grammar, admits such a normal form. It can be effectively constructed and the maximal rank of the non-terminals only increases by 1. Thus, simple context-free tree grammars strongly lexicalize tree adjoining grammars and themselves.

## 1 Introduction

Tree adjoining grammars [TAG] (Joshi et al., 1969; Joshi et al., 1975) are a mildly context-sensitive grammar formalism that can handle certain non-local dependencies (Kuhlmann and Mohl, 2006), which occur in several natural languages. A good overview on TAG, their formal properties, their linguistic motivation, and their applications is presented by Joshi and Schabes (1992) and Joshi and Schabes (1997), in which also strong lexicalization is discussed. In general, lexicalization is the process of transforming a grammar into an equivalent one (potentially expressed in another formalism) such that each production contains a lexical item (or anchor). Each production can then be viewed as lexical information on its anchor. It demonstrates a syntactical construction in which the anchor can occur. Since a lexical item is a letter of the string

alphabet, each production of a lexicalized grammar produces at least one letter of the generated string. Consequently, lexicalized grammars offer significant parsing benefits (Schabes et al., 1988) as the number of applications of productions (i.e., derivation steps) is clearly bounded by the length of the input string. In addition, the lexical items in the productions guide the production selection in a derivation, which works especially well in scenarios with large alphabets.<sup>1</sup> The GREIBACH normal form (Hopcroft et al., 2001; Blum and Koch, 1999) offers those benefits for context-free grammars [CFG], but it changes the parse trees. Thus, we distinguish between two notions of equivalence: *Weak equivalence* (Bar-Hillel et al., 1960) only requires that the generated string languages coincide, whereas *strong equivalence* (Chomsky, 1963) requires that even the generated tree languages coincide. Correspondingly, we obtain weak and strong lexicalization based on the required equivalence.

The GREIBACH normal form shows that CFG can weakly lexicalize themselves, but they cannot strongly lexicalize themselves (Schabes, 1990). It is a prominent feature of tree adjoining grammars that they can strongly lexicalize CFG (Schabes, 1990),<sup>2</sup> and it was claimed and widely believed that they can strongly lexicalize themselves. Recently, Kuhlmann and Satta (2012) proved that TAG actually cannot strongly lexicalize themselves. In fact, they prove that TAG cannot even strongly lexicalize the weaker tree insertion grammars (Schabes and Waters, 1995). However, TAG can weakly lexicalize themselves (Fujiyoshi, 2005).

<sup>1</sup>Chen (2001) presents a detailed account.

<sup>2</sup>Good algorithmic properties and the good coverage of linguistic phenomena are other prominent features.

\* Financially supported by the German Research Foundation (DFG) grant MA 4959/1-1.

Simple (i.e., linear and nondeleting) context-free tree grammars [CFTG] (Rounds, 1969; Rounds, 1970) are a more powerful grammar formalism than TAG (Mönnich, 1997). However, the monadic variant is strongly equivalent to a slightly extended version of TAG, which is called non-strict TAG (Kepser and Rogers, 2011). A GREIBACH normal form for a superclass of CFTG (viz., second-order abstract categorical grammars) was discussed by Kanazawa and Yoshinaka (2005) and Yoshinaka (2006). In particular, they also demonstrate that monadic CFTG can strongly lexicalize regular tree grammars (Gécseg and Steinby, 1984; Gécseg and Steinby, 1997).

CFTG are weakly equivalent to the simple macro grammars of Fischer (1968), which are a notational variant of the well-nested linear context-free rewriting systems (LCFRS) of Vijay-Shanker et al. (1987) and the well-nested multiple context-free grammars (MCFG) of Seki et al. (1991).<sup>3</sup> Thus, CFTG are mildly context-sensitive since their generated string languages are semi-linear and can be parsed in polynomial time (Gómez-Rodríguez et al., 2010).

In this contribution, we show that CFTG can strongly lexicalize TAG and also themselves, thus answering the second question in the conclusion of Kuhlmann and Satta (2012). This is achieved by a series of normalization steps (see Section 4) and a final lexicalization step (see Section 5), in which a lexical item is guessed for each production that does not already contain one. This item is then transported in an additional argument until it is exchanged for the same item in a terminal production. The lexicalization is effective and increases the maximal rank (number of arguments) of the non-terminals by at most 1. In contrast to a transformation into GREIBACH normal form, our lexicalization does not radically change the structure of the derivations. Overall, our result shows that if we consider only lexicalization, then CFTG are a more natural generalization of CFG than TAG.

## 2 Notation

We write  $[k]$  for the set  $\{i \in \mathbb{N} \mid 1 \leq i \leq k\}$ , where  $\mathbb{N}$  denotes the set of nonnegative integers. We use a fixed countably infinite set  $X = \{x_1, x_2, \dots\}$

<sup>3</sup>Kuhlmann (2010), Mönnich (2010), and Kanazawa (2009) discuss well-nestedness.

of (mutually distinguishable) variables, and we let  $X_k = \{x_i \mid i \in [k]\}$  be the first  $k$  variables from  $X$  for every  $k \in \mathbb{N}$ . As usual, an alphabet  $\Sigma$  is a finite set of symbols, and a ranked alphabet  $(\Sigma, \text{rk})$  adds a ranking  $\text{rk}: \Sigma \rightarrow \mathbb{N}$ . We let  $\Sigma_k = \{\sigma \mid \text{rk}(\sigma) = k\}$  be the set of  $k$ -ary symbols. Moreover, we just write  $\Sigma$  for the ranked alphabet  $(\Sigma, \text{rk})$ .<sup>4</sup> We build trees over the ranked alphabet  $\Sigma$  such that the nodes are labeled by elements of  $\Sigma$  and the rank of the node label determines the number of its children. In addition, elements of  $X$  can label leaves. Formally, the set  $T_\Sigma(X)$  of  $\Sigma$ -trees indexed by  $X$  is the smallest set  $T$  such that  $X \subseteq T$  and  $\sigma(t_1, \dots, t_k) \in T$  for all  $k \in \mathbb{N}$ ,  $\sigma \in \Sigma_k$ , and  $t_1, \dots, t_k \in T$ .<sup>5</sup>

We use positions to address the nodes of a tree. A position is a sequence of nonnegative integers indicating successively in which subtree the addressed node is. More precisely, the root is at position  $\varepsilon$  and the position  $ip$  with  $i \in \mathbb{N}$  and  $p \in \mathbb{N}^*$  refers to the position  $p$  in the  $i^{\text{th}}$  direct subtree. Formally, the set  $\text{pos}(t) \subseteq \mathbb{N}^*$  of positions of a tree  $t \in T_\Sigma(X)$  is defined by  $\text{pos}(x) = \{\varepsilon\}$  for  $x \in X$  and

$$\text{pos}(\sigma(t_1, \dots, t_k)) = \{\varepsilon\} \cup \{ip \mid i \in [k], p \in \text{pos}(t_i)\}$$

for all symbols  $\sigma \in \Sigma_k$  and  $t_1, \dots, t_k \in T_\Sigma(X)$ . The positions are indicated as superscripts of the labels in the tree of Figure 1. The subtree of  $t$  at position  $p \in \text{pos}(t)$  is denoted by  $t|_p$ , and the label of  $t$  at position  $p$  by  $t(p)$ . Moreover,  $t[u]_p$  denotes the tree obtained from  $t$  by replacing the subtree at  $p$  by the tree  $u \in T_\Sigma(X)$ . For every label set  $S \subseteq \Sigma$ , we let  $\text{pos}_S(t) = \{p \in \text{pos}(t) \mid t(p) \in S\}$  be the  $S$ -labeled positions of  $t$ . For every  $\sigma \in \Sigma$ , we let  $\text{pos}_\sigma(t) = \text{pos}_{\{\sigma\}}(t)$ . The set  $C_\Sigma(X_k)$  contains all trees  $t$  of  $T_\Sigma(X)$ , in which every  $x \in X_k$  occurs exactly once and  $\text{pos}_{X \setminus X_k}(t) = \emptyset$ . Given  $u_1, \dots, u_k \in T_\Sigma(X)$ , the first-order substitution  $t[u_1, \dots, u_k]$  is inductively defined by

$$x_i[u_1, \dots, u_k] = \begin{cases} u_i & \text{if } i \in [k] \\ x_i & \text{otherwise} \end{cases}$$

$$t[u_1, \dots, u_k] = \sigma(t_1[u_1, \dots, u_k], \dots, t_k[u_1, \dots, u_k])$$

for every  $i \in \mathbb{N}$  and  $t = \sigma(t_1, \dots, t_k)$  with  $\sigma \in \Sigma_k$  and  $t_1, \dots, t_k \in T_\Sigma(X)$ . First-order substitution is illustrated in Figure 1.

<sup>4</sup>We often decorate a symbol  $\sigma$  with its rank  $k$  [e.g.  $\sigma^{(k)}$ ].

<sup>5</sup>We will often drop quantifications like ‘for all  $k \in \mathbb{N}$ ’.

Figure 1: Tree in  $C_\Sigma(X_2) \subset T_\Sigma(X)$  with indicated positions, where  $\Sigma = \{\sigma, \gamma, \alpha\}$  with  $\text{rk}(\sigma) = 2$ ,  $\text{rk}(\gamma) = 1$ , and  $\text{rk}(\alpha) = 0$ , and an example first-order substitution.

In first-order substitution we replace leaves (elements of  $X$ ), whereas in second-order substitution we replace an internal node (labeled by a symbol of  $\Sigma$ ). Let  $p \in \text{pos}(t)$  be such that  $t(p) \in \Sigma_k$ , and let  $u \in C_\Sigma(X_k)$  be a tree in which the variables  $X_k$  occur exactly once. The second-order substitution  $t[p \leftarrow u]$  replaces the subtree at position  $p$  by the tree  $u$  into which the children of  $p$  are (first-order) substituted. In essence,  $u$  is “folded” into  $t$  at position  $p$ . Formally,  $t[p \leftarrow u] = t[u[t|_1, \dots, t|_k]]_p$ . Given  $P \subseteq \text{pos}_\sigma(t)$  with  $\sigma \in \Sigma_k$ , we let  $t[P \leftarrow u]$  be  $t[p_1 \leftarrow u] \dots [p_n \leftarrow u]$ , where  $P = \{p_1, \dots, p_n\}$  and  $p_1 > \dots > p_n$  in the lexicographic order. Second-order substitution is illustrated in Figure 2. Gécseg and Steinby (1997) present a detailed introduction to trees and tree languages.

### 3 Context-free tree grammars

In this section, we recall linear and nondeleting context-free tree grammars [CFTG] (Rounds, 1969; Rounds, 1970). The property ‘linear and nondeleting’ is often called ‘simple’. The nonterminals of regular tree grammars only occur at the leaves and are replaced using first-order substitution. In contrast, the nonterminals of a CFTG are ranked symbols, can occur anywhere in a tree, and are replaced using second-order substitution.<sup>6</sup> Consequently, the nonterminals  $N$  of a CFTG form a ranked alphabet. In the left-hand sides of productions we write  $A(x_1, \dots, x_k)$  for a nonterminal  $A \in N_k$  to indicate the variables that hold the direct subtrees of a particular occurrence of  $A$ .

**Definition 1.** A (simple) context-free tree grammar [CFTG] is a system  $(N, \Sigma, S, P)$  such that

- $N$  is a ranked alphabet of *nonterminal symbols*,
- $\Sigma$  is a ranked alphabet of *terminal symbols*,<sup>7</sup>

<sup>6</sup>see Sections 6 and 15 of (Gécseg and Steinby, 1997)

<sup>7</sup>We assume that  $\Sigma \cap N = \emptyset$ .

Figure 2: Example second-order substitution, in which the boxed symbol  $\sigma$  is replaced.

- $S \in N_0$  is the *start nonterminal* of rank 0, and
- $P$  is a finite set of *productions* of the form  $A(x_1, \dots, x_k) \rightarrow r$ , where  $r \in C_{N \cup \Sigma}(X_k)$  and  $A \in N_k$ .

The components  $\ell$  and  $r$  are called left- and right-hand side of the production  $\ell \rightarrow r$  in  $P$ . We say that it is an  $A$ -production if  $\ell = A(x_1, \dots, x_k)$ . The right-hand side is simply a tree using terminal and nonterminal symbols according to their rank. Moreover, it contains all the variables of  $X_k$  exactly once. Let us illustrate the syntax on an example CFTG. We use an abstract language for simplicity and clarity. We use lower-case Greek letters for terminal symbols and upper-case Latin letters for nonterminals.

**Example 2.** As a running example, we consider the CFTG  $G_{\text{ex}} = (\{S^{(0)}, A^{(2)}\}, \Sigma, S, P)$  where

- $\Sigma = \{\sigma^{(2)}, \alpha^{(0)}, \beta^{(0)}\}$  and
- $P$  contains the productions (see Figure 3):<sup>8</sup>

$$S \rightarrow A(\alpha, \alpha) \mid A(\beta, \beta) \mid \sigma(\alpha, \beta)$$

$$A(x_1, x_2) \rightarrow A(\sigma(x_1, S), \sigma(x_2, S)) \mid \sigma(x_1, x_2) .$$

We recall the (term) rewrite semantics (Baader and Nipkow, 1998) of the CFTG  $G = (N, \Sigma, S, P)$ . Since  $G$  is simple, the actual rewriting strategy is irrelevant. The sentential forms of  $G$  are simply  $\text{SF}(G) = T_{N \cup \Sigma}(X)$ . This is slightly more general than necessary (for the semantics of  $G$ ), but the presence of variables in sentential forms will be useful in the next section because it allows us to treat right-hand sides as sentential forms. In essence in a rewrite step we just select a nonterminal  $A \in N$  and an  $A$ -production  $\rho \in P$ . Then we replace an occurrence of  $A$  in the sentential form by the right-hand side of  $\rho$  using second-order substitution.

**Definition 3.** Let  $\xi, \zeta \in \text{SF}(G)$  be sentential forms. Given an  $A$ -production  $\rho = \ell \rightarrow r$  in  $P$  and an

<sup>8</sup>We separate several right-hand sides with ‘|’.

Figure 3: Productions of Example 2.

$A$ -labeled position  $p \in \text{pos}_A(\xi)$  in  $\xi$ , we write  $\xi \Rightarrow_G^{\rho,p} \xi[p \leftarrow r]$ . If there exist  $\rho \in P$  and  $p \in \text{pos}(\xi)$  such that  $\xi \Rightarrow_G^{\rho,p} \zeta$ , then  $\xi \Rightarrow_G \zeta$ .<sup>9</sup> The semantics  $\llbracket G \rrbracket$  of  $G$  is  $\{t \in T_\Sigma \mid S \Rightarrow_G^* t\}$ , where  $\Rightarrow_G^*$  is the reflexive, transitive closure of  $\Rightarrow_G$ .

Two CFTG  $G_1$  and  $G_2$  are (strongly) equivalent if  $\llbracket G_1 \rrbracket = \llbracket G_2 \rrbracket$ . In this contribution we are only concerned with strong equivalence (Chomsky, 1963). Although we recall the string corresponding to a tree later on (via its yield), we will not investigate weak equivalence (Bar-Hillel et al., 1960).

**Example 4.** Reconsider the CFTG  $G_{\text{ex}}$  of Example 2. A derivation to a tree of  $T_\Sigma$  is illustrated in Figure 4. It demonstrates that the final tree in that derivation is in the language  $\llbracket G_{\text{ex}} \rrbracket$  generated by  $G_{\text{ex}}$ .

Finally, let us recall the relation between CFTG and tree adjoining grammars [TAG] (Joshi et al., 1969; Joshi et al., 1975). Joshi et al. (1975) show that TAG are special footed CFTG (Kepser and Rogers, 2011), which are weakly equivalent to monadic CFTG, i.e., CFTG whose nonterminals have rank at most 1 (Mönnich, 1997; Fujiyoshi and Kasai, 2000). Kepser and Rogers (2011) show the strong equivalence of those CFTG to non-strict TAG, which are slightly more powerful than traditional TAG. In general, TAG are a natural formalism to describe the syntax of natural language.<sup>10</sup>

## 4 Normal forms

In this section, we first recall an existing normal form for CFTG. Then we introduce the property of finite ambiguity in the spirit of (Schabes, 1990; Joshi and Schabes, 1992; Kuhlmann and Satta, 2012), which allows us to normalize our CFTG even further. A major tool is a simple production elimination

<sup>9</sup>For all  $k \in \mathbb{N}$  and  $\xi \Rightarrow_G \zeta$  we note that  $\xi \in C_{N \cup \Sigma}(X_k)$  if and only if  $\zeta \in C_{N \cup \Sigma}(X_k)$ .

<sup>10</sup>XTAG Research Group (2001) wrote a TAG for English.

scheme, which we present in detail. From now on, let  $G = (N, \Sigma, S, P)$  be the considered CFTG.

The CFTG  $G$  is *start-separated* if  $\text{pos}_S(r) = \emptyset$  for every production  $\ell \rightarrow r \in P$ . In other words, the start nonterminal  $S$  is not allowed in the right-hand sides of the productions. It is clear that each CFTG can be transformed into an equivalent start-separated CFTG. In such a CFTG we call each production of the form  $S \rightarrow r$  *initial*. From now on, we assume, without loss of generality, that  $G$  is start-separated.

**Example 5.** Let  $G_{\text{ex}} = (N, \Sigma, S, P)$  be the CFTG of Example 2. An equivalent start-separated CFTG is  $G'_{\text{ex}} = (\{S'^{(0)}\} \cup N, \Sigma, S', P \cup \{S' \rightarrow S\})$ .

We start with the growing normal form of Stamer and Otto (2007) and Stamer (2009). It requires that the right-hand side of each non-initial production contains at least two terminal or nonterminal symbols. In particular, it eliminates projection productions  $A(x_1) \rightarrow x_1$  and unit productions, in which the right-hand side has the same shape as the left-hand side (potentially with a different root symbol and a different order of the variables).

**Definition 6.** A production  $\ell \rightarrow r$  is *growing* if  $|\text{pos}_{N \cup \Sigma}(r)| \geq 2$ . The CFTG  $G$  is *growing* if all of its non-initial productions are growing.

The next theorem is Proposition 2 of (Stamer and Otto, 2007). Stamer (2009) provides a full proof.

**Theorem 7.** For every start-separated CFTG there exists an equivalent start-separated, growing CFTG.

**Example 8.** Let us transform the CFTG  $G'_{\text{ex}}$  of Example 5 into growing normal form. We obtain the CFTG  $G''_{\text{ex}} = (\{S'^{(0)}, S^{(0)}, A^{(2)}\}, \Sigma, S', P'')$  where  $P''$  contains  $S' \rightarrow S$  and for each  $\delta \in \{\alpha, \beta\}$

$$S \rightarrow A(\delta, \delta) \mid \sigma(\delta, \delta) \mid \sigma(\alpha, \beta) \quad (1)$$

$$A(x_1, x_2) \rightarrow A(\sigma(x_1, S), \sigma(x_2, S)) \quad (2)$$

$$A(x_1, x_2) \rightarrow \sigma(\sigma(x_1, S), \sigma(x_2, S)) .$$

From now on, we assume that  $G$  is growing. Next, we recall the notion of finite ambiguity from (Schabes, 1990; Joshi and Schabes, 1992; Kuhlmann and Satta, 2012).<sup>11</sup> We distinguish a subset  $\Delta \subseteq \Sigma_0$  of *lexical* symbols, which are the symbols that are preserved by the yield mapping. The yield of a tree is

<sup>11</sup>It should not be confused with the notion of ‘finite ambiguity’ of (Goldstine et al., 1992; Klimann et al., 2004).

Figure 4: Derivation using the CFTG  $G_{\text{ex}}$  of Example 2. The selected positions are boxed.

a string of lexical symbols. All other symbols are simply dropped (in a pre-order traversal). Formally,  $\text{yd}_\Delta : T_\Sigma \rightarrow \Delta^*$  is such that for all  $t = \sigma(t_1, \dots, t_k)$  with  $\sigma \in \Sigma_k$  and  $t_1, \dots, t_k \in T_\Sigma$

$$\text{yd}_\Delta(t) = \begin{cases} \sigma \text{yd}_\Delta(t_1) \cdots \text{yd}_\Delta(t_k) & \text{if } \sigma \in \Delta \\ \text{yd}_\Delta(t_1) \cdots \text{yd}_\Delta(t_k) & \text{otherwise.} \end{cases}$$

**Definition 9.** The tree language  $L \subseteq T_\Sigma$  has *finite  $\Delta$ -ambiguity* if  $\{t \in L \mid \text{yd}_\Delta(t) = w\}$  is finite for every  $w \in \Delta^*$ .

Roughly speaking, we can say that the set  $L$  has finite  $\Delta$ -ambiguity if each  $w \in \Delta^*$  has finitely many parses in  $L$  (where  $t$  is a parse of  $w$  if  $\text{yd}_\Delta(t) = w$ ). Our example CFTG  $G_{\text{ex}}$  is such that  $\llbracket G_{\text{ex}} \rrbracket$  has finite  $\{\alpha, \beta\}$ -ambiguity (because  $\Sigma_1 = \emptyset$ ).

In this contribution, we want to (strongly) lexicalize CFTG, which means that for each CFTG  $G$  such that  $\llbracket G \rrbracket$  has finite  $\Delta$ -ambiguity, we want to construct an equivalent CFTG such that each non-initial production contains at least one lexical symbol. This is typically called strong lexicalization (Schabes, 1990; Joshi and Schabes, 1992; Kuhlmann and Satta, 2012) because we require strong equivalence.<sup>12</sup> Let us formalize our lexicalization property.

**Definition 10.** The production  $\ell \rightarrow r$  is  *$\Delta$ -lexicalized* if  $\text{pos}_\Delta(r) \neq \emptyset$ . The CFTG  $G$  is  *$\Delta$ -lexicalized* if all its non-initial productions are  $\Delta$ -lexicalized.

Note that the CFTG  $G_{\text{ex}}''$  of Example 8 is not yet  $\{\alpha, \beta\}$ -lexicalized. We will lexicalize it in the next section. To do this in general, we need some auxiliary normal forms. First, we define our simple production elimination scheme, which we will use in the following. Roughly speaking, a non-initial  $A$ -production such that  $A$  does not occur in its right-hand side can be eliminated from  $G$  by applying it in

<sup>12</sup>The corresponding notion for weak equivalence is called weak lexicalization (Joshi and Schabes, 1992).

all possible ways to occurrences in right-hand sides of the remaining productions.

**Definition 11.** Let  $\rho = A(x_1, \dots, x_k) \rightarrow r$  in  $P$  be a non-initial production such that  $\text{pos}_A(r) = \emptyset$ . For every other production  $\rho' = \ell' \rightarrow r'$  in  $P$  and  $J \subseteq \text{pos}_A(r')$ , let  $\rho'_J = \ell' \rightarrow r'[J \leftarrow r]$ . The CFTG  $\text{Elim}(G, \rho) = (N, \Sigma, S, P')$  is such that

$$P' = \bigcup_{\rho' = \ell' \rightarrow r' \in P \setminus \{\rho\}} \{\rho'_J \mid J \subseteq \text{pos}_A(r')\}.$$

In particular,  $\rho'_\emptyset = \rho'$  for every production  $\rho'$ , so every production besides the eliminated production  $\rho$  is preserved. We obtained the CFTG  $G_{\text{ex}}''$  of Example 8 as  $\text{Elim}(G_{\text{ex}}', A(x_1, x_2) \rightarrow \sigma(x_1, x_2))$  from  $G_{\text{ex}}'$  of Example 5.

**Lemma 12.** The CFTG  $G$  and  $G'_\rho = \text{Elim}(G, \rho)$  are equivalent for every non-initial  $A$ -production  $\rho = \ell \rightarrow r$  in  $P$  such that  $\text{pos}_A(r) = \emptyset$ .

*Proof.* Clearly, every single derivation step of  $G'_\rho$  can be simulated by a derivation of  $G$  using potentially several steps. Conversely, a derivation of  $G$  can be simulated directly by  $G'_\rho$  except for derivation steps  $\Rightarrow_G^{\rho, p}$  using the eliminated production  $\rho$ . Since  $S \neq A$ , we know that the nonterminal at position  $p$  was generated by another production  $\rho'$ . In the given derivation of  $G$  we examine which nonterminals in the right-hand side of the instance of  $\rho'$  were replaced using  $\rho$ . Let  $J$  be the set of positions corresponding to those nonterminals (thus  $p \in J$ ). Then instead of applying  $\rho'$  and potentially several times  $\rho$ , we equivalently apply  $\rho'_J$  of  $G'_\rho$ .  $\square$

In the next normalization step we use our production elimination scheme. The goal is to make sure that non-initial monic productions (i.e., productions of which the right-hand side contains at most one nonterminal) contain at least one lexical symbol. We define the relevant property and then present

the construction. A sentential form  $\xi \in \text{SF}(G)$  is *monic* if  $|\text{pos}_N(\xi)| \leq 1$ . The set of all monic sentential forms is denoted by  $\text{SF}_{\leq 1}(G)$ . A production  $\ell \rightarrow r$  is monic if  $r$  is monic. The next construction is similar to the simultaneous removal of epsilon-productions  $A \rightarrow \varepsilon$  and unit productions  $A \rightarrow B$  for context-free grammars (Hopcroft et al., 2001). Instead of computing the closure under those productions, we compute a closure under non- $\Delta$ -lexicalized productions.

**Theorem 13.** If  $\llbracket G \rrbracket$  has finite  $\Delta$ -ambiguity, then there exists an equivalent CFTG such that all its non-initial monic productions are  $\Delta$ -lexicalized.

*Proof.* Without loss of generality, we assume that  $G$  is start-separated and growing by Theorem 7. Moreover, we assume that each nonterminal is useful. For every  $A \in N$  with  $A \neq S$ , we compute all monic sentential forms without a lexical symbol that are reachable from  $A(x_1, \dots, x_k)$ , where  $k = \text{rk}(A)$ . Formally, let

$$\Xi_A = \{ \xi \in \text{SF}_{\leq 1}(G) \mid A(x_1, \dots, x_k) \Rightarrow_{G'}^+ \xi \} ,$$

where  $\Rightarrow_{G'}^+$  is the transitive closure of  $\Rightarrow_{G'}$  and the CFTG  $G' = (N, \Sigma, S, P')$  is such that  $P'$  contains exactly the non- $\Delta$ -lexicalized productions of  $P$ . The set  $\Xi_A$  is finite since only finitely many non- $\Delta$ -lexicalized productions can be used due to the finite  $\Delta$ -ambiguity of  $\llbracket G \rrbracket$ . Moreover, no sentential form in  $\Xi_A$  contains  $A$  for the same reason and the fact that  $G$  is growing. We construct the CFTG  $G_1 = (N, \Sigma, S, P \cup P_1)$  such that

$$P_1 = \{ A(x_1, \dots, x_k) \rightarrow \xi \mid A \in N_k, \xi \in \Xi_A \} .$$

Clearly,  $G$  and  $G_1$  are equivalent. Next, we eliminate all productions of  $P_1$  from  $G_1$  using Lemma 12 to obtain an equivalent CFTG  $G_2$  with the productions  $P_2$ . In the final step, we drop all non- $\Delta$ -lexicalized monic productions of  $P_2$  to obtain the CFTG  $\overline{G}$ , in which all monic productions are  $\Delta$ -lexicalized. It is easy to see that  $\overline{G}$  is growing, start-separated, and equivalent to  $G_2$ .  $\square$

The CFTG  $G''_{\text{ex}}$  only has  $\{\alpha, \beta\}$ -lexicalized non-initial monic productions, so we use a new example.

**Example 14.** Let  $(\{S^{(0)}, A^{(1)}, B^{(1)}\}, \Sigma, S, P)$  be the CFTG such that  $\Sigma = \{\sigma^{(2)}, \alpha^{(0)}, \beta^{(0)}\}$  and

Figure 5: The relevant derivations using only productions that are not  $\Delta$ -lexicalized (see Example 14).

$P$  contains the productions

$$\begin{aligned} A(x_1) &\rightarrow \sigma(\beta, B(x_1)) & B(x_1) &\rightarrow \sigma(x_1, \beta) & (3) \\ B(x_1) &\rightarrow \sigma(\alpha, A(x_1)) & S &\rightarrow A(\alpha) . \end{aligned}$$

This CFTG  $G_{\text{ex}2}$  is start-separated and growing. Moreover, all its productions are monic, and  $\llbracket G_{\text{ex}2} \rrbracket$  is finitely  $\Delta$ -ambiguous for the set  $\Delta = \{\alpha\}$  of lexical symbols. Then the productions (3) are non-initial and not  $\Delta$ -lexicalized. So we can run the construction in the proof of Theorem 13. The relevant derivations using only non- $\Delta$ -lexicalized productions are shown in Figure 5. We observe that  $|\Xi_A| = 2$  and  $|\Xi_B| = 1$ , so we obtain the CFTG  $(\{S^{(0)}, B^{(1)}\}, \Sigma, S, P')$ , where  $P'$  contains<sup>13</sup>

$$\begin{aligned} S &\rightarrow \sigma(\beta, B(\alpha)) \mid \sigma(\beta, \sigma(\alpha, \beta)) \\ B(x_1) &\rightarrow \sigma(\alpha, \sigma(\beta, B(x_1))) \\ B(x_1) &\rightarrow \sigma(\alpha, \sigma(\beta, \sigma(x_1, \beta))) . \end{aligned} \quad (4)$$

We now do one more normalization step before we present our lexicalization. We call a production  $\ell \rightarrow r$  *terminal* if  $r \in T_\Sigma(X)$ ; i.e., it does not contain nonterminal symbols. Next, we show that for each CFTG  $G$  such that  $\llbracket G \rrbracket$  has finite  $\Delta$ -ambiguity we can require that each non-initial terminal production contains at least two occurrences of  $\Delta$ -symbols.

**Theorem 15.** If  $\llbracket G \rrbracket$  has finite  $\Delta$ -ambiguity, then there exists an equivalent CFTG  $(N, \Sigma, S, P')$  such that  $|\text{pos}_\Delta(r)| \geq 2$  for all its non-initial terminal productions  $\ell \rightarrow r \in P'$ .

*Proof.* Without loss of generality, we assume that  $G$  is start-separated and growing by Theorem 7. Moreover, we assume that each nonterminal is useful and that each of its non-initial monic productions is  $\Delta$ -lexicalized by Theorem 13. We obtain the desired CFTG by simply eliminating each non-initial terminal production  $\ell \rightarrow r \in P$  such that  $|\text{pos}_\Delta(r)| = 1$ . By Lemma 12 the obtained CFTG

<sup>13</sup>The nonterminal  $A$  became useless, so we just removed it.

Figure 6: Production  $\rho = \ell \rightarrow r$  of (2) [left], a corresponding production  $\rho_\alpha$  of  $P'$  [middle] with right-hand side  $r_{\alpha,2}$ , and a corresponding production of  $P'''$  [right] with right-hand side  $(\bar{r}_{\alpha,2})_\beta$  (see Theorem 17).

is equivalent to  $G$ . The elimination process terminates because a new terminal production can only be constructed from a monic production and a terminal production or several terminal productions, but those combinations already contain two occurrences of  $\Delta$ -symbols since non-initial monic productions are already  $\Delta$ -lexicalized.  $\square$

**Example 16.** Reconsider the CFTG obtained in Example 14. Recall that  $\Delta = \{\alpha\}$ . Production (4) is the only non-initial terminal production that violates the requirement of Theorem 15. We eliminate it and obtain the CFTG with the productions

$$\begin{aligned} S &\rightarrow \sigma(\beta, B(\alpha)) \mid \sigma(\beta, \sigma(\alpha, \beta)) \\ S &\rightarrow \sigma(\beta, \sigma(\alpha, \sigma(\beta, \sigma(\alpha, \beta)))) \\ B(x_1) &\rightarrow \sigma(\alpha, \sigma(\beta, B(x_1))) \\ B(x_1) &\rightarrow \sigma(\alpha, \sigma(\beta, \sigma(\alpha, \sigma(\beta, \sigma(x_1, \beta))))). \end{aligned}$$

## 5 Lexicalization

In this section, we present the main lexicalization step, which lexicalizes non-monic productions. We assume that  $\llbracket G \rrbracket$  has finite  $\Delta$ -ambiguity and is normalized according to the results of Section 4: no useless nonterminals, start-separated, growing (see Theorem 7), non-initial monic productions are  $\Delta$ -lexicalized (see Theorem 13), and non-initial terminal productions contain at least two occurrences of  $\Delta$ -symbols (see Theorem 15).

The basic idea of the construction is that we guess a lexical symbol for each non- $\Delta$ -lexicalized production. The guessed symbol is put into a new parameter of a nonterminal. It will be kept in the parameter until we reach a terminal production, where we exchange the same lexical symbol by the parameter. This is the reason why we made sure that we have two occurrences of lexical symbols in the terminal productions. After we exchanged one for a parameter, the resulting terminal production is

still  $\Delta$ -lexicalized. Lexical items that are guessed for distinct (occurrences of) productions are transported to distinct (occurrences of) terminal productions [cf. Section 3 of (Potthoff and Thomas, 1993) and page 346 of (Hoogbeem and ten Pas, 1997)].

**Theorem 17.** For every CFTG  $G$  such that  $\llbracket G \rrbracket$  has finite  $\Delta$ -ambiguity there exists an equivalent  $\Delta$ -lexicalized CFTG.

*Proof.* We can assume that  $G = (N, \Sigma, S, P)$  has the properties mentioned before the theorem without loss of generality. We let  $N' = N \times \Delta$  be a new set of nonterminals such that  $\text{rk}(\langle A, \delta \rangle) = \text{rk}(A) + 1$  for every  $A \in N$  and  $\delta \in \Delta$ . Intuitively,  $\langle A, \delta \rangle$  represents the nonterminal  $A$ , which has the lexical symbol  $\delta$  in its last (new) parameter. This parameter is handed to the (lexicographically) first nonterminal in the right-hand side until it is resolved in a terminal production. Formally, for each right-hand side  $r \in T_{N \cup N' \cup \Sigma}(X)$  such that  $\text{pos}_N(r) \neq \emptyset$  (i.e., it contains an original nonterminal), each  $k \in \mathbb{N}$ , and each  $\delta \in \Delta$ , let  $r_{\delta,k}$  and  $\bar{r}_\delta$  be such that

$$\begin{aligned} r_{\delta,k} &= r[\langle B, \delta \rangle(r_1, \dots, r_n, x_{k+1})]_p \\ \bar{r}_\delta &= r[\langle B, \delta \rangle(r_1, \dots, r_n, \delta)]_p, \end{aligned}$$

where  $p$  is the lexicographically smallest element of  $\text{pos}_N(r)$  and  $r|_p = B(r_1, \dots, r_n)$  with  $B \in N$  and  $r_1, \dots, r_n \in T_{N \cup N' \cup \Sigma}(X)$ . For each nonterminal  $A$ -production  $\rho = \ell \rightarrow r$  in  $P$  let

$$\rho_\delta = \langle A, \delta \rangle(x_1, \dots, x_{k+1}) \rightarrow r_{\delta,k},$$

where  $k = \text{rk}(A)$ . This construction is illustrated in Figure 6. Roughly speaking, we select the lexicographically smallest occurrence of a nonterminal in the right-hand side and pass the lexical symbol  $\delta$  in the extra parameter to it. The extra parameter is used in terminal productions, so let  $\rho = \ell \rightarrow r$  in  $P$

$$S \rightarrow \begin{array}{c} \sigma \\ \alpha \quad \alpha \end{array} \quad \langle S, \alpha \rangle \begin{array}{c} | \\ x_1 \end{array} \rightarrow \begin{array}{c} \sigma \\ x_1 \quad \alpha \end{array}$$

Figure 7: Original terminal production  $\rho$  from (1) [left] and the production  $\bar{\rho}$  (see Theorem 17).

be a terminal  $A$ -production. Then we define

$$\bar{\rho} = \langle A, r(p) \rangle (x_1, \dots, x_{k+1}) \rightarrow r[x_{k+1}]_p ,$$

where  $p$  is the lexicographically smallest element of  $\text{pos}_\Delta(r)$  and  $k = \text{rk}(A)$ . This construction is illustrated in Figure 7. With these productions we obtain the CFTG  $G' = (N \cup N', \Sigma, S, \bar{P})$ , where  $\bar{P} = P \cup P' \cup P''$  and

$$P' = \bigcup_{\substack{\rho=\ell \rightarrow r \in P \\ \ell \neq S, \text{pos}_N(r) \neq \emptyset}} \{\rho_\delta \mid \delta \in \Delta\} \quad P'' = \bigcup_{\substack{\rho=\ell \rightarrow r \in P \\ \ell \neq S, \text{pos}_N(r) = \emptyset}} \{\bar{\rho}\} .$$

It is easy to prove that those new productions manage the desired transport of the extra parameter if it holds the value indicated in the nonterminal.

Finally, we replace each non-initial non- $\Delta$ -lexicalized production in  $G'$  by new productions that guess a lexical symbol and add it to the new parameter of the (lexicographically) first nonterminal of  $N$  in the right-hand side. Formally, we let

$$\begin{aligned} \bar{P}_{\text{nil}} &= \{\ell \rightarrow r \in \bar{P} \mid \ell \neq S, \text{pos}_\Delta(r) = \emptyset\} \\ P''' &= \{\ell \rightarrow \bar{r}_\delta \mid \ell \rightarrow r \in \bar{P}_{\text{nil}}, \delta \in \Delta\} , \end{aligned}$$

of which  $P'''$  is added to the productions. Note that each production  $\ell \rightarrow r \in \bar{P}_{\text{nil}}$  contains at least one occurrence of a nonterminal of  $N$  (because all monic productions of  $G$  are  $\Delta$ -lexicalized). Now all non-initial non- $\Delta$ -lexicalized productions from  $\bar{P}$  can be removed, so we obtain the CFTG  $G''$ , which is given by  $(N \cup N', \Sigma, S, R)$  with  $R = (\bar{P} \cup P''') \setminus \bar{P}_{\text{nil}}$ . It can be verified that  $G''$  is  $\Delta$ -lexicalized and equivalent to  $G$  (using the provided argumentation).  $\square$

Instead of taking the lexicographically smallest element of  $\text{pos}_N(r)$  or  $\text{pos}_\Delta(r)$  in the previous proof, we can take any fixed element of that set. In the definition of  $P'$  we can change  $\text{pos}_N(r) \neq \emptyset$  to  $|\text{pos}_\Delta(r)| \leq 1$ , and simultaneously in the definition of  $P''$  change  $\text{pos}_N(r) = \emptyset$  to  $|\text{pos}_\Delta(r)| \geq 2$ . With the latter changes the guessed lexical item is only transported until it is resolved in a production with at least two lexical items.

**Example 18.** For the last time, we consider the CFTG  $G''_{\text{ex}}$  of Example 8. We already illustrated the parts of the construction of Theorem 17 in Figures 6 and 7. The obtained  $\{\alpha, \beta\}$ -lexicalized CFTG has the following 25 productions for all  $\delta, \delta' \in \{\alpha, \beta\}$ :

$$\begin{aligned} S' &\rightarrow S \\ S &\rightarrow A(\delta, \delta) \mid \sigma(\delta, \delta) \mid \sigma(\alpha, \beta) \\ S_\delta(x_1) &\rightarrow A_\delta(\delta', \delta', x_1) \mid \sigma(x_1, \delta) \\ S_\alpha(x_1) &\rightarrow \sigma(x_1, \beta) \\ A(x_1, x_2) &\rightarrow A_\delta(\sigma(x_1, S), \sigma(x_2, S), \delta) \\ A_\delta(x_1, x_2, x_3) &\rightarrow A_\delta(\sigma(x_1, S_\delta(\delta')), \sigma(x_2, S), x_3) \\ A(x_1, x_2) &\rightarrow \sigma(\sigma(x_1, S_\delta(\delta)), \sigma(x_2, S)) \\ A_\delta(x_1, x_2, x_3) &\rightarrow \sigma(\sigma(x_1, S_\delta(x_3)), \sigma(x_2, S_\delta(\delta'))) , \end{aligned} \quad (5)$$

where  $A_\delta = \langle A, \delta \rangle$  and  $S_\delta = \langle S, \delta \rangle$ .

If we change the lexicalization construction as indicated before this example, then all the productions  $S_\delta(x_1) \rightarrow A_\delta(\delta', \delta', x_1)$  are replaced by the productions  $S_\delta(x_1) \rightarrow A(x_1, \delta)$ . Moreover, the productions (5) can be replaced by the productions  $A(x_1, x_2) \rightarrow A(\sigma(x_1, S_\delta(\delta)), \sigma(x_2, S))$ , and then the nonterminals  $A_\delta$  and their productions can be removed, which leaves only 15 productions.

## Conclusion

For  $k \in \mathbb{N}$ , let  $\text{CFTG}(k)$  be the set of those CFTG whose nonterminals have rank at most  $k$ . Since the normal form constructions preserve the nonterminal rank, the proof of Theorem 17 shows that  $\text{CFTG}(k)$  are strongly lexicalized by  $\text{CFTG}(k+1)$ . Kepser and Rogers (2011) show that non-strict TAG are strongly equivalent to  $\text{CFTG}(1)$ . Hence, non-strict TAG are strongly lexicalized by  $\text{CFTG}(2)$ .

It follows from Section 6 of Engelfriet et al. (1980) that the classes  $\text{CFTG}(k)$  with  $k \in \mathbb{N}$  induce an infinite hierarchy of string languages, but it remains an open problem whether the rank increase in our lexicalization construction is necessary.

Gómez-Rodríguez et al. (2010) show that well-nested LCFRS of maximal fan-out  $k$  can be parsed in time  $O(n^{2k+2})$ , where  $n$  is the length of the input string  $w \in \Delta^*$ . From this result we conclude that  $\text{CFTG}(k)$  can be parsed in time  $O(n^{2k+4})$ , in the sense that we can produce a parse tree  $t$  that is generated by the CFTG with  $\text{yd}_\Delta(t) = w$ . It is not clear yet whether lexicalized  $\text{CFTG}(k)$  can be parsed more efficiently in practice.

## Abstract

As one of the most popular micro-blogging services, Twitter attracts millions of users, producing millions of tweets daily. Shared information through this service spreads faster than would have been possible with traditional sources, however the proliferation of user-generated content poses challenges to browsing and finding valuable information. In this paper we propose a graph-theoretic model for tweet recommendation that presents users with items they may have an interest in. Our model ranks tweets and their authors *simultaneously* using several networks: the social network connecting the users, the network connecting the tweets, and a third network that ties the two together. Tweet and author entities are ranked following a co-ranking algorithm based on the intuition that there is a mutually reinforcing relationship between tweets and their authors that could be reflected in the rankings. We show that this framework can be parametrized to take into account user preferences, the popularity of tweets and their authors, and diversity. Experimental evaluation on a large dataset shows that our model outperforms competitive approaches by a large margin.

## 1 Introduction

Online micro-blogging services have revolutionized the way people discover, share, and distribute information. *Twitter* is perhaps the most popular such service with over 140 million active users as of

2012.<sup>1</sup> Twitter enables users to send and read text-based posts of up to 140 characters, known as *tweets*. Twitter users follow others or are followed. Being a follower on Twitter means that the user receives all the tweets from those she follows. Common practice of responding to a tweet has evolved into a well-defined markup culture (e.g., RT stands for retweet, '@' followed by an identifier indicates the user). The strict limit of 140 characters allows for quick and immediate communication in real time, whilst enforcing brevity. Moreover, the retweet mechanism empowers users to spread information of their choice beyond the reach of their original followers.

Twitter has become a prominent broadcasting medium, taking priority over traditional news sources (Teevan et al., 2011). Shared information through this channel spreads faster than would have been possible with conventional news sites or RSS feeds and can reach a far wider population base. However, the proliferation of user-generated content comes at a price. Over 340 millions of tweets are being generated daily amounting to thousands of tweets per second!<sup>2</sup> Twitter's own search engine handles more than 1.6 billion search queries per day.<sup>3</sup> This enormous amount of data renders it infeasible to browse the entire Twitter network; even if this was possible, it would be extremely difficult for users to find information they are interested in. A hypothetical tweet recommendation system could

<sup>1</sup>For details see <http://blog.twitter.com/2012/03/twitter-turns-six.html>

<sup>2</sup>In fact, the peak record is 6,939 tweets per second, reported by <http://blog.twitter.com/2011/03/numbers.html>.

<sup>3</sup>See <http://engineering.twitter.com/2011/05/engineering-behind-twitters-new-search.html>

alleviate this acute information overload, e.g., by limiting the stream of tweets to those of interest to the user, or by discovering intriguing content outside the user’s following network.

The tweet recommendation task is challenging for several reasons. Firstly, Twitter does not merely consist of a set of tweets. Rather, it contains many latent networks including the *following* relationships among users and the *retweeting* linkage (which indicates information diffusion). Secondly, the recommendations ought to be of interest to the user and likely to attract user response (e.g., to be retweeted). Thirdly, recommendations should be personalized (Cho and Schonfeld, 2007; Yan et al., 2011), avoid redundancy, and demonstrate diversity. In this paper we present a graph-theoretic approach to tweet recommendation that attempts to address these challenges.

Our recommender operates over a heterogeneous network that connects the users (or authors) and the tweets they produce. The user network represents links among authors based on their *following* behavior, whereas the tweet network connects tweets based on content similarity. A third bipartite graph ties the two together. Tweet and author entities in this network are ranked simultaneously following a co-ranking algorithm (Zhou et al., 2007). The main intuition behind co-ranking is that there is a mutually reinforcing relationship between authors and tweets that could be reflected in the rankings. Tweets are important if they are related to other important tweets and authored by important users who in turn are related to other important users. The model exploits this mutually reinforcing relationship between tweets and their authors and couples two random walks, one on the tweet graph and one on the author graph, into a combined one. Rather than creating a global ranking over all tweets in a collection, we extend this framework to individual users and produce personalized recommendations. Moreover, we incorporate diversity by allowing the random walk on the tweet graph to be time-variant (Mei et al., 2010).

Experimental results on a real-world dataset consisting of 364,287,744 tweets from 9,449,542 users show that the co-ranking approach substantially improves performance over the state of the art. We obtain a relative improvement of 18.3% (in nDCG) and 7.8% (in MAP) over the best comparison system.

## 2 Related Work

**Tweet Search** Given the large amount of tweets being posted daily, ranking strategies have become extremely important for retrieving information quickly. Many websites currently offer a real-time search service which returns ranked lists of Twitter posts or shared links according to user queries. Ranking methods used by these sites employ three criteria, namely recency, popularity and content relevance (Dong et al., 2010). State-of-art tweet retrieval methods include a linear regression model biased towards text quality with a regularization factor inspired by the hypothesis that documents similar in content may have similar quality (Huang et al., 2011). Duan et al. (2010) learn a ranking model using SVMs and features based on tweet content, the relations among users, and tweet specific characteristics (e.g., urls, number of retweets).

**Tweet Recommendation** Previous work has also focused on tweet recommendation systems, assuming no explicit query is provided by the users. Collaborative filtering is perhaps the most obvious method for recommending tweets (Hannon et al., 2010). Chen et al. (2010) investigate how to select interesting URLs linked from Twitter and recommend the top ranked ones to users. Their recommender takes three dimensions into account: the source, the content topic, and social voting. Similarly, Abel et al. (2011a; 2011b; 2011c) recommend external websites linked to Twitter. Their method incorporates user profile modeling and temporal recency, but they do not utilize the social networks among users. R. et al. (2009) propose a diffusion-based recommendation framework especially for tweets representing critical events by constructing a diffusion graph. Hong et al. (2011) recommend tweets based on popularity related features. Ramage et al. (2010) investigate which topics users are interested in following a Labeled-LDA approach, by deciding whether a user is in the followee list of a given user or not. Uysal and Croft (2011) estimate the likelihood of a tweet being reposted from a user-centric perspective.

Our work also develops a tweet recommendation system. Our model exploits the information provided by the tweets and the underlying social networks in a unified co-ranking framework. Although

these sources have been previously used to search or recommend tweets, our model considers them simultaneously and produces a ranking that is informed by both. Furthermore, we argue that the graph-theoretic framework upon which co-ranking operates is beneficial as it allows to incorporate personalization (we provide user-specific rankings) and diversity (the ranking is optimized so as to avoid redundancy). The co-ranking framework has been initially developed for measuring scientific impact and modeling the relationship between authors and their publications (Zhou et al., 2007). However, the adaptation of this framework to the tweet recommendation task is novel to our knowledge.

### 3 Tweet Recommendation Framework

Our method operates over a heterogeneous network that connects three graphs representing the tweets, their authors and the relationships between them. Let  $G$  denote the heterogeneous graph with nodes  $V$  and edges  $E$ , and  $G = (V, E) = (V_M \cup V_U, E_M \cup E_U \cup E_{MU})$ .  $G$  is divided into three subgraphs,  $G_M$ ,  $G_U$  and  $G_{MU}$ .  $G_M = (V_M, E_M)$  is a weighted undirected graph representing the tweets and their relationships. Let  $V_M = \{m_i | m_i \in V_M\}$  denote a collection of  $|V_M|$  tweets and  $E_M$  the set of links representing relationships between them. The latter are established by measuring how semantically similar any two tweets are (see Section 3.4 for details).  $G_U = (V_U, E_U)$  is an unweighted directed graph representing the social ties among Twitter users.  $V_U = \{u_i | u_i \in V_U\}$  is the set of users with size  $|V_U|$ . Links  $E_U$  among users are established by observing their *following* behavior.  $G_{MU} = (V_{MU}, E_{MU})$  is an unweighted bipartite graph that ties  $G_M$  and  $G_U$  together and represents tweet-author relationships. The graph consists of nodes  $V_{MU} = V_M \cup V_U$  and edges  $E_{MU}$  connecting each tweet with all of its authors. Typically, a tweet  $m$  is written by only one author  $u$ . However, because of *retweeting* we treat all users involved in reposting a tweet as “co-authors”. The three subnetworks are illustrated in Figure 1.

The framework includes three random walks, one on  $G_M$ , one on  $G_U$  and one on  $G_{MU}$ . A random walk on a graph is a Markov chain, its states being the vertices of the graph. It can be described by a square  $n \times n$  matrix  $\mathbf{M}$ , where  $n$  is the number of vertices in the graph.  $\mathbf{M}$  is a stochastic matrix prescribing

Figure 1: Tweet recommendation based on a co-ranking framework including three sub-networks. The undirected links between tweets indicate semantic correlation. The directed links between users denotes *following*. A bipartite graph (whose edges are shown with dashed lines) ties the tweet and author networks together.

the transition probabilities from one vertex to the next. The framework couples the two random walks on  $G_M$ , and  $G_U$  that rank tweets and their authors in isolation. and allows to obtain a more global ranking by taking into account their mutual dependence. In the following sections we first describe how we obtain the rankings on  $G_M$  and  $G_U$ , and then move on to discuss how the two are coupled.

#### 3.1 Ranking the Tweet Graph

**Popularity** We rank the tweet network following the PageRank paradigm (Brin and Page, 1998). Consider a random walk on  $G_M$  and let  $\mathbf{M}$  be the transition matrix (defined in Section 3.4). Fix some damping factor  $\mu$  and say that at each time step with probability  $(1-\mu)$  we stick to random walking and with probability  $\mu$  we do not make a usual random walk step, but instead jump to any vertex, chosen uniformly at random:

$$\mathbf{m} = (1 - \mu)\mathbf{M}^T\mathbf{m} + \frac{\mu}{|V_M|}\mathbf{1}\mathbf{1}^T \quad (1)$$

Here, vector  $\mathbf{m}$  contains the ranking scores for the vertices in  $G_M$ . The fact that there exists a unique so-

lution to (1) follows from the random walk  $\mathbf{M}$  being ergodic ( $\mu > 0$  guarantees irreducibility, because we can jump to any vertex).  $\mathbf{M}^T$  is the transpose of  $\mathbf{M}$ .  $\mathbf{1}$  is the vector of  $|V_M|$  entries, each being equal to one. Let  $\mathbf{m} \in \mathbf{R}^{V_M}$ ,  $\|\mathbf{m}\|_1 = 1$  be the only solution.

**Personalization** The standard PageRank algorithm performs a random walk, starting from any node, then randomly selects a link from that node to follow considering the weighted matrix  $\mathbf{M}$ , or jumps to a random node with equal probability. It produces a global ranking over all tweets in the collection without taking specific users into account. As there are billions of tweets available on Twitter covering many diverse topics, it is reasonable to assume that an average user will only be interested in a small subset (Qiu and Cho, 2006). We operationalize a user’s topic preference as a vector  $\mathbf{t} = [t_1, t_2, \dots, t_n]_{1 \times n}$ , where  $n$  denotes the number of topics, and  $t_i$  represents the degree of preference for topic  $i$ . The vector  $\mathbf{t}$  is normalized such that  $\sum_{i=1}^n t_i = 1$ . Intuitively, such vectors will be different for different users. Note that user preferences can be also defined at the *tweet* (rather than *topic*) level. Although tweets can illustrate user interests more directly, in most cases a user will only respond to a small fraction of tweets. This means that most tweets will not provide any information relating to a user’s interests. The topic preference vector allows to propagate such information (based on whether a tweet has been reposted or not) to other tweets within the same topic cluster.

Given  $n$  topics, we obtain a topic distribution matrix  $\mathbf{D}$  using Latent Dirichlet Allocation (Blei et al., 2003). Let  $D_{ij}$  denote the probability of tweet  $m_i$  to belong to topic  $t_j$ . Consider a user with a topic preference vector  $\mathbf{t}$  and topic distribution matrix  $\mathbf{D}$ . We calculate the response probability  $\mathbf{r}$  for all tweets for this user as:

$$\mathbf{r} = \mathbf{tD}^T \quad (2)$$

where  $\mathbf{r} = [r_1, r_2, \dots, r_{V_M}]_{1 \times |V_M|}$  represents the response probability vector and  $r_i$  the probability for a user to respond to tweet  $m_i$ . We normalize  $\mathbf{r}$  so that  $\sum_{r_i \in \mathbf{r}} r_i = 1$ . Now, given the observed response probability vector  $\mathbf{r} = [r_1, r_2, \dots, r_w]_{1 \times w}$ , where  $w < |V_M|$  for a given user and the topic distribution matrix  $\mathbf{D}$ , our task is estimate the topic preference vector  $\mathbf{t}$ . We do this using maximum-likelihood

estimation. Assuming a user has responded to  $w$  tweets, we approximate  $\mathbf{t}$  so as to maximize the observed response probability. Let  $\mathbf{r}(\mathbf{t}) = \mathbf{tD}^T$ . Assuming all responses are independent, the probability for  $w$  tweets  $r_1, r_2, \dots, r_w$  is then  $\prod_{i=1}^w r_i(\mathbf{t})$  under a given  $\mathbf{t}$ . The value of  $\mathbf{t}$  is chosen when the probability is maximized:

$$\mathbf{t} = \underset{\mathbf{t}}{\operatorname{argmax}} \left( \prod_{i=1}^w r_i(\mathbf{t}) \right) \quad (3)$$

In a simple random walk, it is assumed that all nodes in the matrix  $\mathbf{M}$  are equi-probable before the walk. In contrast, we use the topic preference vector as a prior on  $\mathbf{M}$ . Let  $\operatorname{Diag}(\mathbf{r})$  denote a diagonal matrix whose eigenvalue is vector  $\mathbf{r}$ . Then  $\mathbf{m}$  becomes:

$$\begin{aligned} \mathbf{m} &= (1 - \mu)[\operatorname{Diag}(\mathbf{r})\mathbf{M}]^T \mathbf{m} + \mu \mathbf{r} \\ &= (1 - \mu)[\operatorname{Diag}(\mathbf{tD}^T)\mathbf{M}]^T \mathbf{m} + \mu \mathbf{tD}^T \end{aligned} \quad (4)$$

**Diversity** We would also like our output to be diverse without redundant information. Unfortunately, equation (4) will have the opposite effect, as it assigns high scores to closely connected node communities. A greedy algorithm such as Maximum Marginal Relevance (Carbonell and Goldstein, 1998; Wan et al., 2007; Wan et al., 2010) may achieve diversity by iteratively selecting the most prestigious or popular vertex and then penalizing the vertices “covered” by those that have been already selected. Rather than adopting a greedy vertex selection method, we follow DivRank (Mei et al., 2010) a recently proposed algorithm that balances popularity and diversity in ranking, based on a time-variant random walk. In contrast to PageRank, DivRank assumes that the transition probabilities change over time. Moreover, it is assumed that the transition probability from one state to another is reinforced by the number of previous visits to that state. At each step, the algorithm creates a dynamic transition matrix  $\mathbf{M}^{(z)}$ . After  $z$  iterations, the matrix becomes:

$$\mathbf{M}^{(z)} = (1 - \mu)\mathbf{M}^{(z-1)} \cdot \mathbf{m}^{(z-1)} + \mu \mathbf{tD}^T \quad (5)$$

and hence,  $\mathbf{m}$  can be calculated as:

$$\mathbf{m}^{(z)} = (1 - \mu)[\operatorname{Diag}(\mathbf{tD}^T)\mathbf{M}^{(z)}]^T \mathbf{m} + \mu \mathbf{tD}^T \quad (6)$$

Equation (5) increases the probability for nodes with higher popularity. Nodes with high weights are

likely to “absorb” the weights of their neighbors directly, and the weights of their neighbors’ neighbors indirectly. The process iteratively adjusts the matrix  $\mathbf{M}$  according to  $\mathbf{m}$  and then updates  $\mathbf{m}$  according to the changed  $\mathbf{M}$ . Essentially, the algorithm favors nodes with high popularity and as time goes by there emerges a *rich-gets-richer* effect (Mei et al., 2010).

### 3.2 Ranking the Author Graph

As mentioned earlier, we build a graph of authors (and obtain the affinity  $\mathbf{U}$ ) using the *following* linkage. We rank the author network using PageRank analogously to equation (1). Besides popularity, we also take personalization into account. Intuitively, users are likely to be interested in their friends even if these are relatively unpopular. Therefore, for each author, we include a vector  $\mathbf{p} = [p_1, p_2, \dots, p_{|V_U|}]_{1 \times |V_U|}$  denoting their preference for other authors. The preference factor for author  $u$  toward other authors  $u_i$  is defined as:

$$p_i^u = \frac{\text{\#tweets from } u_i}{\text{\#tweets of } u} \quad (7)$$

which represents the proportion of tweets inherited from user  $u_i$ . A large  $p_i^u$  means that  $u$  is more likely to respond to  $u_i$ ’s tweets.

In theory, we could also apply DivRank on the author graph. However, as the authors are unique, we assume that they are sufficiently distinct and there is no need to promote diversity.

### 3.3 The Co-Ranking Algorithm

So far we have described how we rank the network of tweets  $G_M$  and their authors  $G_U$  independently following the PageRank paradigm. The co-ranking framework includes a random walk on  $G_M$ ,  $G_U$ , and  $G_{MU}$ . The latter is a bipartite graph representing which tweets are authored by which users. The random walks on  $G_M$  and  $G_U$  are *intra-class* random walks, because take place either within the tweets’ or the users’ networks. The third (combined) random walk on  $G_{MU}$  is an *inter-class* random walk. It is sufficient to describe it by a matrix  $\mathbf{MU}_{|V_M| \times |V_U|}$  and a matrix  $\mathbf{UM}_{|V_U| \times |V_M|}$ , since  $G_{MU}$  is bipartite. One intra-class step changes the probability distribution from  $(\mathbf{m}, \mathbf{0})$  to  $(M\mathbf{m}, \mathbf{0})$  or from  $(\mathbf{0}, \mathbf{u})$  to  $(\mathbf{0}, U\mathbf{u})$ , while one inter-class step changes the probability distribution from  $(\mathbf{m}, \mathbf{u})$  to  $(\mathbf{UM}^T \mathbf{u}, \mathbf{MU}^T \mathbf{m})$ . The

design of  $\mathbf{M}$ ,  $\mathbf{U}$ ,  $\mathbf{MU}$  and  $\mathbf{UM}$  is detailed in Section 3.4.

The two intra-class random walks are coupled using the inter-class random walk on the bipartite graph. The coupling is regulated by  $\lambda$ , a parameter quantifying the importance of  $G_{MU}$  versus  $G_M$  and  $G_U$ . In the extreme case, if  $\lambda$  is set to 0, there is no coupling. This amounts to separately ranking tweets and authors by PageRank. In general,  $\lambda$  represents the extent to which the ranking of tweets and their authors depend on each other.

There are two intuitions behind the co-ranking algorithm: (1) a tweet is important if it associates to other important tweets, and is authored by important users and (2) a user is important if they associate to other important users, and they write important tweets. We formulate these intuitions using the following iterative procedure:

**Step 1** Compute tweet saliency scores:

$$\begin{aligned} \mathbf{m}^{(z+1)} &= (1 - \lambda)([\text{Diag}(\mathbf{r})\mathbf{M}^{(z)}]^T)\mathbf{m}^{(z)} + \lambda\mathbf{UM}^T\mathbf{u}^{(z)} \\ \mathbf{m}^{(z+1)} &= \mathbf{m}^{(z+1)} / \|\mathbf{m}^{(z+1)}\| \end{aligned} \quad (8)$$

**Step 2** Compute author saliency scores:

$$\begin{aligned} \mathbf{u}^{(z+1)} &= (1 - \lambda)([\text{Diag}(\mathbf{p})\mathbf{U}]^T)\mathbf{u}^{(z)} + \lambda\mathbf{MU}^T\mathbf{m}^{(z)} \\ \mathbf{u}^{(z+1)} &= \mathbf{u}^{(z+1)} / \|\mathbf{u}^{(z+1)}\| \end{aligned} \quad (9)$$

Here,  $\mathbf{m}^{(z)}$  and  $\mathbf{u}^{(z)}$  are the ranking vectors for tweets and authors for the  $z$ -th iteration. To guarantee convergence,  $\mathbf{m}$  and  $\mathbf{u}$  are normalized after each iteration. Note that the tweet transition matrix  $\mathbf{M}$  is dynamic due to the computation of diversity while the author transition matrix  $\mathbf{U}$  is static. The algorithm typically converges when the difference between the scores computed at two successive iterations for any tweet/author falls below a threshold  $\epsilon$  (set to 0.001 in this study).

### 3.4 Affinity Matrices

The co-ranking framework is controlled by four affinity matrices:  $\mathbf{M}$ ,  $\mathbf{U}$ ,  $\mathbf{MU}$  and  $\mathbf{UM}$ . In this section we explain how these matrices are defined in more detail.

The tweet graph is an undirected weighted graph, where an edge between two tweets  $m_i$  and  $m_j$  represents their cosine similarity. An adjacency matrix  $\mathbf{M}$

describes the tweet graph where each entry corresponds to the weight of a link in the graph:

$$M_{ij} = \frac{\mathcal{F}(m_i, m_j)}{\sum_k \mathcal{F}(m_i, m_k)}, \mathcal{F}(m_i, m_j) = \frac{\vec{m}_i \cdot \vec{m}_j}{\|\vec{m}_i\| \|\vec{m}_j\|} \quad (10)$$

where  $\mathcal{F}(\cdot)$  is the cosine similarity and  $\vec{m}$  is a term vector corresponding to tweet  $m$ . We treat a tweet as a short document and weight each term with *tf.idf* (Salton and Buckley, 1988), where *tf* is the term frequency and *idf* is the inverse document frequency.

The author graph is a directed graph based on the *following* linkage. When  $u_i$  follows  $u_j$ , we add a link from  $u_i$  to  $u_j$ . Let the indicator function  $I(u_i, u_j)$  denote whether  $u_i$  follows  $u_j$ . The adjacency matrix  $\mathbf{U}$  is then defined as:

$$U_{ij} = \frac{I(u_i, u_j)}{\sum_k I(u_i, u_k)}, I(u_i, u_j) = \begin{cases} 1 & \text{if } e_{ij} \in E_U \\ 0 & \text{if } e_{ij} \notin E_U \end{cases} \quad (11)$$

In the bipartite tweet-author graph  $G_{MU}$ , the entry  $E_{MU}(i, j)$  is an indicator function denoting whether tweet  $m_i$  is authored by user  $u_j$ :

$$\mathcal{A}(m_i, u_j) = \begin{cases} 1 & \text{if } e_{ij} \in E_{MU} \\ 0 & \text{if } e_{ij} \notin E_{MU} \end{cases} \quad (12)$$

Through  $E_{MU}$  we define  $\mathbf{MU}$  and  $\mathbf{UM}$ , using the weight matrices  $\mathbf{MU} = [\bar{W}_{ij}]$  and  $\mathbf{UM} = [\hat{W}_{ji}]$ , containing the conditional probabilities of transitioning from  $m_i$  to  $u_j$  and vice versa:

$$\bar{W}_{ij} = \frac{\mathcal{A}(m_i, u_j)}{\sum_k \mathcal{A}(m_i, u_k)}, \hat{W}_{ji} = \frac{\mathcal{A}(m_i, u_j)}{\sum_k \mathcal{A}(m_k, u_j)} \quad (13)$$

## 4 Experimental Setup

**Data** We crawled Twitter data from 23 seed users (who were later invited to manually evaluate the output of our system). In addition, we collected the data of their *followees* and *followers* by traversing the *following* edges, and exploring all newly included users in the same way until no new users were added. This procedure resulted in a relatively large dataset consisting of 9,449,542 users, 364,287,744 tweets, 596,777,491 links, and 55,526,494 retweets. The crawler monitored the data from 3/25/2011 to 5/30/2011. We used approximately one month of this data for training and the rest for testing.

Before building the graphs (i.e., the tweet graph, the author graph, and the tweet-author graph), the dataset was preprocessed as follows. We removed tweets of low linguistic quality and subsequently discarded users without any linkage to the remaining tweets. We measured linguistic quality following the evaluation framework put forward in Pitler et al. (2010). For instance, we measured the out-of-vocabulary word ratio (as a way of gauging spelling errors), entity coherence, fluency, and so on. We further removed stopwords and performed stemming.

**Parameter Settings** We ran LDA with 500 iterations of Gibbs sampling. The number of topics  $n$  was set to 100 which upon inspection seemed generally coherent and meaningful. We set the damping factor  $\mu$  to 0.15 following the standard PageRank paradigm. We opted for more or less generic parameter values as we did not want to tune our framework to the specific dataset at hand. We examined the parameter  $\lambda$  which controls the balance of the tweet-author graph in more detail. We experimented with values ranging from 0 to 0.9, with a step size of 0.1. Small  $\lambda$  values place little emphasis on the tweet graph, whereas larger values rely more heavily on the author graph. Mid-range values take both graphs into account. Overall, we observed better performance with values larger than 0.4. This suggests that both sources of information — the content of the tweets and their authors — are important for the recommendation task. All our experiments used the same  $\lambda$  value which was set to 0.6.

**System Comparison** We compared our approach against three naive baselines and three state-of-the-art systems recently proposed in the literature. All comparison systems were subject to the same filtering and preprocessing procedures as our own algorithm. Our first baseline ranks tweets randomly (Random). Our second baseline ranks tweets according to token length: longer tweets are ranked higher (Length). The third baseline ranks tweets by the number of times they are reposted assuming that more reposting is better (RTnum). We also compared our method against Duan et al. (2010). Their model (RSVM) ranks tweets based on tweet content features and tweet authority features using the RankSVM algorithm (Joachims, 1999). Our fifth comparison system (DTC) was Uysal and Croft

(2011) who use a decision tree classifier to judge how likely it is for a tweet to be reposted by a specific user. This scenario is similar to ours when ranking tweets by retweet likelihood. Finally, we compared against Huang et al. (2011) who use weighted linear combination (WLC) to grade the relevance of a tweet given a query. We implemented their model without any query-related features as in our setting we do not discriminate tweets depending on their relevance to specific queries.

**Evaluation** We evaluated system output in two ways, i.e., automatically and in a user study. Specifically, we assume that if a tweet is retweeted it is relevant and is thus ranked higher over tweets that have not been reposted. We used our algorithm to predict a ranking for the tweets in the test data which we then compared against a goldstandard ranking based on whether a tweet has been retweeted or not. We measured ranking performance using the normalized Discounted Cumulative Gain (nDCG; Järvelin and Kekäläinen (2002)):

$$\text{nDCG}(k, V_U) = \frac{1}{|V_U|} \sum_{u \in V_U} \frac{1}{Z_u} \sum_{i=1}^k \frac{2^{r_i^u} - 1}{\log(1+i)} \quad (14)$$

where  $V_U$  denotes users,  $k$  indicates the top- $k$  positions in a ranked list, and  $Z_u$  is a normalization factor obtained from a perfect ranking for a particular user.  $r_i^u$  is the relevance score (i.e., 1: retweeted, 0: not retweeted) for the  $i$ -th tweet in the ranking list for user  $u$ .

We also evaluated system output in terms of Mean Average Precision (MAP), under the assumption that retweeted tweets are relevant and the rest irrelevant:

$$\text{MAP} = \frac{1}{|V_U|} \sum_{u \in V_U} \frac{1}{N_u} \sum_{i=1}^k P_i^u \times r_i^u \quad (15)$$

where  $N_u$  is the number of reposted tweets for user  $u$ , and  $P_i^u$  is the precision at  $i$ -th position for user  $u$  (Manning et al., 2008).

The automatic evaluation sketched above does not assess the full potential of our recommendation system. For instance, it is possible for the algorithm to recommend tweets to users with no linkage to their publishers. Such tweets may be of potential interest, however our goldstandard data can only provide information for tweets and users with *following* links.

System	nDCG@5	nDCG@10	nDCG@25	nDCG@50	MAP

Table 2: Evaluation of tweet ranking output produced by our system and comparison baselines against judgments elicited by users.

We therefore asked the 23 users whose Twitter data formed the basis of our corpus to judge the tweets ranked by our algorithm and comparison systems. The users were asked to read the systems’ recommendations and decide for every tweet presented to them whether they would retweet it or not, under the assumption that retweeting takes place when users find the tweet interesting.

In both automatic and human-based evaluations we ranked all tweets in the test data. Then for each date and user we selected the top 50 ones. Our nDCG and MAP results are averages over users and dates.

## 5 Results

Our results are summarized in Tables 1 and 2. Table 1 reports results when model performance is evaluated against the gold standard ranking obtained from the Twitter network. In Table 2 model performance is compared against rankings elicited by users.

As can be seen, the Random method performs worst. This is hardly surprising as it recommends tweets without any notion of their importance or user interest. Length performs considerably better than

Table 4: Evaluation of individual system components against human judgments.

Random. This might be due to the fact that informativeness is related to tweet length. Using merely the number of retweets does not seem to capture the tweet importance as well as Length. This suggests that highly retweeted posts are not necessarily informative. For example, in our data, the most frequently reposted tweet is a commercial advertisement calling for reposting!

The supervised systems (RSVM, DTC, and WLC) greatly improve performance over the naive baselines. These methods employ standard machine learning algorithms (such as SVMs, decision trees and linear regression) on a large feature space. Aside from the learning algorithm, their main difference lies in the selection of the feature space, e.g., the way content is represented and whether authority is taken into account. DTC performs best on most evaluation criteria. However, neither DTC nor RSVM, or WLC take personalization into account. They generate the same recommendation lists for all users. Our co-ranking algorithm models user interest with respect to the content of the tweets and their publishers. Moreover, it attempts to create diverse output and has an explicit mechanism for minimizing redundancy. In all instances, using both DCG and MAP, it outperforms the comparison systems. Interestingly, the performance of CoRank is better when measured against human judgments. This indicates that users are interested in tweets that fall outside the scope of their followers and that recommendation can improve user experience.

We further examined the contribution of the individual components of our system to the tweet recommendation task. Tables 3 and 4 show how the performance of our co-ranking algorithm varies when considering only tweet popularity using the standard PageRank algorithm, personalization (PersRank), and diversity (DivRank). Note that DivRank is only applied to the tweet graph. The PageRank algorithm on its own makes good recommendations, while incorporating personalization improves the performance substantially, which indicates that individual users show preferences to specific topics or other users. Diversity on its own does not seem to make a difference, however it improves performance when combined with personalization. Intuitively, users are more likely to repost tweets from their followees, or tweets closely related to those retweeted previously.

## 6 Conclusions

We presented a co-ranking framework for a tweet recommendation system that takes popularity, personalization and diversity into account. Central to our approach is the representation of tweets and their users in a heterogeneous network and the ability to produce a global ranking that takes both information sources into account. Our model obtains substantial performance gains over competitive approaches on a large real-world dataset (it improves by 18.3% in DCG and 7.8% in MAP over the best baseline). Our experiments suggest that improvements are due to the synergy of the two information sources (i.e., tweets and their authors). The adopted graph-theoretic framework is advantageous in that it allows to produce user-specific recommendations and incorporate diversity in a unified model. Evaluation with actual Twitter users shows that our recommender can indeed identify interesting information that lies outside the the user’s immediate following network. In the future, we plan to extend the co-ranking framework so as to incorporate information credibility and temporal recency.

## Abstract

Tweets represent a critical source of fresh information, in which named entities occur frequently with rich variations. We study the problem of named entity normalization (NEN) for tweets. Two main challenges are the errors propagated from named entity recognition (NER) and the dearth of information in a single tweet. We propose a novel graphical model to simultaneously conduct NER and NEN on multiple tweets to address these challenges. Particularly, our model introduces a binary random variable for each pair of words with the same lemma across similar tweets, whose value indicates whether the two related words are mentions of the same entity. We evaluate our method on a manually annotated data set, and show that our method outperforms the baseline that handles these two tasks separately, boosting the F1 from 80.2% to 83.6% for NER, and the Accuracy from 79.4% to 82.6% for NEN, respectively.

## 1 Introduction

Tweets, short messages of less than 140 characters shared through the Twitter service<sup>1</sup>, have become an important source of fresh information. As a result, the task of named entity recognition (NER) for tweets, which aims to identify mentions of rigid designators from tweets belonging to named-entity types such as persons, organizations and locations (2007), has attracted increasing research interest. For example, Ritter et al. (2011) develop a system that exploits a CRF model to segment named

entities and then uses a distantly supervised approach based on LabeledLDA to classify named entities. Liu et al. (2011) combine a classifier based on the k-nearest neighbors algorithm with a CRF-based model to leverage cross tweets information, and adopt the semi-supervised learning to leverage unlabeled tweets.

However, named entity normalization (NEN) for tweets, which transforms named entities mentioned in tweets to their unambiguous canonical forms, has not been well studied. Owing to the informal nature of tweets, there are rich variations of named entities in them. According to our investigation on the data set provided by Liu et al. (2011), every named entity in tweets has an average of 3.3 variations<sup>2</sup>. As an illustrative example, we show “Anneke Gronloh”, which may occur as “Mw.,Gronloh”, “Anneke Kronloh” or “Mevrouw G”. We thus propose NEN for tweets, which plays an important role in entity retrieval, trend detection, and event and entity tracking. For example, Khalid et al. (2008) show that even a simple normalization method leads to improvements of early precision, for both document and passage retrieval, and better normalization results in better retrieval performance.

Traditionally, NEN is regarded as a septated task, which takes the output of NER as its input (Li et al., 2002; Cohen, 2005; Jijkoun et al., 2008; Dai et al., 2011). One limitation of this cascaded approach is that errors propagate from NER to NEN and there is no feedback from NEN to NER. As demonstrated by Khalid et al. (2008), most NEN errors are caused

<sup>2</sup>This data set consists of 12,245 randomly sampled tweets within five days.

<sup>1</sup><http://www.twitter.com>

by recognition errors. Another challenge of NEN is the dearth of information in a single tweet, due to the short and noise-prone nature of tweets. Reportedly, the accuracy of a baseline NEN system based on Wikipedia drops considerably from 94% on edited news to 77% on news comments, a kind of user generated content (UGC) with similar style to tweets (Jijkoun et al., 2008).

We propose jointly conducting NER and NEN on multiple tweets using a graphical model, to address these challenges. Intuitively, improving the performance of NER boosts the performance of NEN. For example, consider the following two tweets: “... Alex’s jokes. Justin’s smartness. Max’s randomness...” and “... Alex Russo was like the best character on Disney Channel...”. Identifying “Alex” and “Alex Russo” as PERSON will encourage NEN systems to normalize “Alex” into “Alex Russo”. On the other hand, NEN can guide NER. For instance, consider the following two tweets: “... she knew Burger King when he was a Prince!...” and “... I’m craving all sorts of food: mcdonalds, burger king, pizza, chinese...”. Suppose the NEN system believes that “burger king” cannot be mapped to “Burger King” since these two tweets are not similar in content. This will help NER to assign them different types of labels. Our method optimizes these two tasks simultaneously by enabling them to interact with each other. This largely differentiates our method from existing work.

Furthermore, considering multiple tweets simultaneously allows us to exploit the redundancy in tweets, as suggested by Liu et al. (2011). For example, consider the following two tweets: “... Bobby Shaw you don’t invite the wind...” and “... I own yah ! Lool bobby shaw...”. Recognizing “Bobby Shaw” in the first tweet as a PERSON is easy owing to its capitalization and the following word “you”, which in turn helps to identify “bobby shaw” in the second tweet as a PERSON.

We adopt a factor graph as our graphical model, which is constructed in the following manner. We first introduce a random variable for each word in every tweet, which represents the BILOU (Beginning, the Inside and the Last tokens of multi-token entities as well as Unit-length entities) label of the corresponding word. Then we add a factor to connect two neighboring variables, forming a conven-

tional linear chain CRFs. Hereafter, we use  $t_m$  to denote the  $m^{th}$  tweet,  $t_m^i$  and  $y_m^i$  to denote the  $i^{th}$  word of  $t_m$  and its BILOU label, respectively, and  $f_m^i$  to denote the factor related to  $y_m^{i-1}$  and  $y_m^i$ . Next, for each word pair with the same lemma, denoted by  $t_m^i$  and  $t_n^j$ , we introduce a binary random variable, denoted by  $z_{mn}^{ij}$ , whose value indicates whether  $t_m^i$  and  $t_n^j$  belong to two mentions of the same entity. Finally, for any  $z_{mn}^{ij}$  we add a factor, denoted by  $f_{mn}^{ij}$ , to connect  $y_m^i$ ,  $y_n^j$  and  $z_{mn}^{ij}$ . Factors in the same group ( $\{f_{mn}^{ij}\}$  or  $\{f_m^i\}$ ) share the same set of feature templates. Figure 1 illustrates an example of our factor graph for two tweets.

Figure 1: A factor graph that jointly conducts NER and NEN on multiple tweets. Blue and green circles represent NE type ( $y$ -serials) and normalization variables ( $z$ -serials), respectively; filled circles indicate observed random variables; blue rectangles represent the factors connecting neighboring  $y$ -serial variables while red rectangles stand for the factors connecting distant  $y$ -serial and  $z$ -serial variables.

It is worth noting that our factor graph is different from the skip-chain CRFs (Galley, 2006) in the sense that any skip-chain factor of our model consists not only of two NE type variables ( $y_m^i$  and  $y_n^j$ ), which is the case for skip-chain CRFs, but also a normalization variable ( $z_{mn}^{ij}$ ). It is these normalization variables that enable us to conduct NER and NEN jointly.

We manually add normalization information to the data set shared by Liu et al. (2011), to evaluate our method. Experimental results show that our method achieves 83.6% F1 for NER and 82.6% Accuracy for NEN, outperforming the baseline with 80.2%F1 for NER and 79.4% Accuracy for NEN.

We summarize our contributions as follows.

1. We introduce the task of NEN for tweets, and propose jointly conducting NER and NEN for

multiple tweets using a factor graph, which leverages redundancy in tweets to make up for the dearth of information in a single tweet and allows these two tasks to inform each other.

2. We evaluate our method on a human annotated data set, and show that our method compares favorably with the baseline, achieving better performance in both tasks.

Our paper is organized as follows. In the next section, we introduce related work. In Section 3 and 4, we formally define the task and present our method. In Section 5, we evaluate our method. And finally we conclude our work in Section 6.

## 2 Related Work

Related work can be divided into two categories: NER and NEN.

### 2.1 NER

NER has been well studied and its solutions can be divided into three categories: 1) Rule-based (Krupka and Hausman, 1998); 2) machine learning based (Finkel and Manning, 2009; Singh et al., 2010); and 3) hybrid methods (Jansche and Abney, 2002). Owing to the availability of annotated corpora, such as ACE05, Enron (Minkov et al., 2005) and CoNLL03 (Tjong Kim Sang and De Meulder, 2003), data driven methods are now dominant.

Current studies of NER mainly focus on formal text such as news articles (Mccallum and Li, 2003; Etzioni et al., 2005). A representative work is that of Ratinov and Roth (2009), in which they systematically study the challenges of NER, compare several solutions, and show some interesting findings. For example, they show that the BILOU encoding scheme significantly outperforms the BIO schema (Beginning, the Inside and Outside of a chunk).

A handful of work on other genres of texts exists. For example, Yoshida and Tsujii build a biomedical NER system (2007) using lexical features, orthographic features, semantic features and syntactic features, such as part-of-speech (POS) and shallow parsing; Downey et al. (2007) employ capitalization cues and n-gram statistics to locate names of a variety of classes in web text; Wang (2009) introduces NER to clinical notes. A linear CRF model

is trained on a manually annotated data set, which achieves an F1 of 81.48% on the test data set; Chiticariu et al. (2010) design and implement a high-level language NERL which simplifies the process of building, understanding, and customizing complex rule-based named-entity annotators for different domains.

Recently, NER for Tweets attracts growing interest. Finin et al. (2010) use Amazons Mechanical Turk service<sup>3</sup> and CrowdFlower<sup>4</sup> to annotate named entities in tweets and train a CRF model to evaluate the effectiveness of human labeling. Ritter et al. (2011) re-build the NLP pipeline for tweets beginning with POS tagging, through chunking, to NER, which first exploits a CRF model to segment named entities and then uses a distantly supervised approach based on LabeledLDA to classify named entities. Unlike this work, our work detects the boundary and type of a named entity simultaneously using sequential labeling techniques. Liu et al. (2011) combine a classifier based on the k-nearest neighbors algorithm with a CRF-based model to leverage cross tweets information, and adopt the semi-supervised learning to leverage unlabeled tweets. Our method leverages redundancy in similar tweets, using a factor graph rather than a two-stage labeling strategy. One advantage of our method is that local and global information can interact with each other.

### 2.2 NEN

There is a large body of studies into normalizing various types of entities for formally written texts. For instance, Cohen (2005) normalizes gene/protein names using dictionaries automatically extracted from gene databases; Magdy et al. (2007) address cross-document Arabic name normalization using a machine learning approach, a dictionary of person names and frequency information for names in a collection; Cucerzan (2007) demonstrates a large-scale system for the recognition and semantic disambiguation of named entities based on information extracted from a large encyclopedic collection and Web search results; Dai et al. (2011) employ a Markov logic network to model interweaved con-

<sup>3</sup><https://www.mturk.com/mturk/>

<sup>4</sup><http://crowdfunder.com/>

straints in a setting of gene mention normalization.

Jijkoun et al. (2008) study NEN for UGC. They report that the accuracy of a baseline NEN system based on Wikipedia drops considerably from 94% on edited news to 77% on UGC. They identify three main error sources, i.e., entity recognition errors, multiple ways of referring to the same entity and ambiguous references, and exploit hand-crafted rules to improve the baseline NEN system.

We introduce the task of NEN for tweets, a new genre of texts with rich entity variations. In contrast to existing NEN systems, which take the output of NER systems as their input, our method conducts NER and NEN at the same time, allowing them to reinforce each other, as demonstrated by the experimental results.

### 3 Task Definition

A tweet is a short text message with no more than 140 characters. Here is an example of a tweet: “mycraftingworld: #Win Microsoft Office 2010 Home and Student #Contest from @office http://bit.ly/...”, where “mycraftingworld” is the name of the user who published this tweet. Words beginning with “#” like “#Win” are hash tags; words starting with “@” like “@office” represent user names; and “http://bit.ly/” is a shortened link.

Given a set of tweets, e.g., tweets within some period or related to some query, our task is: 1) To recognize each mention of entities of predefined types for each tweet; and 2) to restore each entity mention into its unambiguous canonical form. Following Liu et al. (2011), we focus on four types of entities, i.e., PERSON, ORGANIZATION, PRODUCT, and LOCATION, and constrain our scope to English tweets. Note that the NEN sub-task can be transformed as follows. Given each pair of entity mentions, decide whether they denote the same entity. Once this is achieved, we can link all the mentions of the same entity, and choose a representative mention, e.g., the longest mention, as their canonical form.

As an illustrative example, consider the following three tweets: “...Gaga’s Christmas dinner with her family. Awwwwwn...”, “...Lady Gaaaaga with her family on Christmas...” and “...Buying a magazine just because Lady Gaga’s on the cover...”. It is expected that “Gaga”, “Lady Gaaaaga” and “Lady

Gaga” are all labeled as PERSON, and can be restored as “Lady Gaga”.

## 4 Our Method

In contrast to existing work, our method jointly conducts NER and NEN for multiple tweets. We first give an overview of our method, then detail its model and features.

### 4.1 Overview

Given a set of tweets as input, our method recognizes predefined types of named entities and for each entity outputs its unambiguous canonical form.

To resolve NER, we assign a label to each word in a tweet, indicating both the boundary and entity type. Following Ratnov and Roth (2009), we use the BILOU schema. For example, consider the tweet “...without you is like an iphone without apps; Lady gaga without her telephone...”, the labeled sequence using the BILOU schema is: “...without<sub>O</sub> you<sub>O</sub> is<sub>O</sub> like<sub>O</sub> an<sub>O</sub> iphone<sub>U-PRODUCT</sub> without<sub>O</sub> apps<sub>O</sub>; Lady<sub>B-PERSON</sub> gaga<sub>L-PERSON</sub> without<sub>O</sub> her<sub>O</sub> telephone<sub>O</sub>...”, where “iphone<sub>U-PRODUCT</sub>” indicates that “iphone” is a product name of unit length; “Lady<sub>B-PERSON</sub>” means “Lady” is the beginning of a person name while “gaga<sub>L-PERSON</sub>” suggests that “gaga” is the last token of a person name.

To resolve NEN, we assign a binary value label  $z_{mn}^{ij}$  to each pair of words  $t_m^i$  and  $t_n^j$  which share the same lemma.  $z_{mn}^{ij} = 1$  or  $-1$ , indicating whether  $t_m^i$  and  $t_n^j$  belong to two mentions of the same entity<sup>5</sup>. For example, consider the three tweets presented in Section 3. “Gaga<sub>1</sub>”<sup>6</sup> and “Gaga<sub>3</sub>” will be assigned a “1” label, since they are part of two mentions of the same entity “Lady Gaga”; similarly, “Lady<sub>2</sub>” and “Lady<sub>3</sub>” are connected with a “1” label. Note that there are no NEN labels for pairs like “her<sub>1</sub>” and “her<sub>2</sub>” or “with<sub>1</sub>” and “with<sub>2</sub>”, since words like “her” and “with” are stop words.

With NE type and normalization labels obtained, we judge two mentions, denoted by  $t_m^{i_1 \dots i_k}$  and

<sup>5</sup>Stop words have no normalization labels. The stop words are mainly from <http://www.textfixer.com/resources/common-english-words.txt>.

<sup>6</sup>We use  $w_m^i$  to denote word  $w$ ’s  $i^{th}$  appearance in the  $m^{th}$  tweet. For example, “Gaga<sub>1</sub>” denotes the first occurrence of “Gaga” in the first tweet.

$t_n^{j_1 \dots j_l}$ , respectively, refer to the same entity if and only if: 1) The two mentions share the same entity type; 2)  $t_m^{i_1 \dots i_k}$  is a sub-string of  $t_n^{j_1 \dots j_l}$  or vice versa; and 3)  $z_{mn}^{ij} = 1$ ,  $i = i_1, \dots, i_k$  and  $j = j_1, \dots, j_l$ , if  $z_{mn}^{ij}$  exists. Still take the three tweets presented in Section 3 for example. Suppose ‘‘Gaga<sub>1</sub><sup>1</sup>’’ and ‘‘Lady Gaga<sub>3</sub><sup>1</sup>’’ are labeled as PERSON, and there is only one related NE normalization label, which is associated with ‘‘Gaga<sub>1</sub><sup>1</sup>’’ and ‘‘Gaga<sub>3</sub><sup>1</sup>’’ and has 1 as its value. We then consider that these two mentions can be normalized into the same entity; in a similar way, we can align ‘‘Lady<sub>2</sub><sup>1</sup> Gaaaaga’’ with ‘‘Lady<sub>3</sub><sup>1</sup> Gaga’’. Combining these pieces information together, we can infer that ‘‘Gaga<sub>1</sub><sup>1</sup>’’, ‘‘Lady<sub>2</sub><sup>1</sup> Gaaaaga’’ and ‘‘Lady<sub>3</sub><sup>1</sup> Gaga’’ are three mentions of the same entity. Finally, we can select ‘‘Lady<sub>3</sub><sup>1</sup> Gaga’’ as the representative, and output ‘‘Lady Gaga’’ as their canonical form. We choose the mention with the maximum number of words as the representative. In case of a tie, we prefer the mention with an Wikipedia entry <sup>7</sup>.

The central problem with our method is inferring all the NE type (*y*-serial) and normalization (*z*-serial) variables. To achieve this, we construct a factor graph according to the input tweets, which can evaluate the probability of every possible assignment of *y*-serials and *z*-serials, by checking the characteristics of the assignment. Each characteristic is called a feature. In this way, we can select the assignment with the highest probability. Next we will introduce our model in detail, including its training and inference procedure and features.

## 4.2 Model

We adopt a factor graph as our model. One advantage of our model is that it allows *y*-serials and *z*-serials variables to interact with each other to jointly optimize NER and NEN.

Given a set of tweets  $T = \{t_m\}_{m=1}^N$ , we can build a factor graph  $\mathcal{G} = (Y, Z, F, E)$ , where:  $Y$  and  $Z$  denote *y*-serials and *z*-serials variables, respectively;  $F$  represents factor vertices, consisting of  $\{f_m^i\}$  and  $\{f_{mn}^{ij}\}$ ,  $f_m^i = f_m^i(y_m^{i-1}, y_m^i)$  and  $f_{mn}^{ij} = f_{mn}^{ij}(y_m^i, y_n^j, z_{mn}^{ij})$ ;  $E$  stands for edges, which depends on  $F$ , and consists of edges between  $y_m^{i-1}$  and  $y_m^i$ , and those between  $y_m^i, y_n^j$  and  $f_{mn}^{ij}$ .

<sup>7</sup>If it still ends up as a draw, we will randomly choose one from the best.

$\mathcal{G} = (Y, Z, F, E)$  defines a probability distribution according to Formula 1.

$$\ln P(Y, Z | \mathcal{G}, T) \propto \sum_{m,i} \ln f_m^i(y_m^{i-1}, y_m^i) + \sum_{m,n,i,j} \delta_{mn}^{ij} \cdot \ln f_{mn}^{ij}(y_m^i, y_n^j, z_{mn}^{ij}) \quad (1)$$

where  $\delta_{mn}^{ij} = 1$  if and only if  $t_m^i$  and  $t_n^j$  have the same lemma and are not stop words, otherwise zero. A factor factorizes according to a set of features, so that:

$$\begin{aligned} \ln f_m^i(y_m^{i-1}, y_m^i) &= \sum_k \lambda_k^{(1)} \phi_k^{(1)}(y_m^{i-1}, y_m^i) \\ \ln f_{mn}^{ij}(y_m^i, y_n^j, z_{mn}^{ij}) &= \sum_k \lambda_k^{(2)} \phi_k^{(2)}(y_m^i, y_n^j, z_{mn}^{ij}) \end{aligned} \quad (2)$$

$\{\phi_k^{(1)}\}_{k=1}^{K_1}$  and  $\{\phi_k^{(2)}\}_{k=1}^{K_2}$  are two feature sets.  $\Theta = \{\lambda_k^{(1)}\}_{k=1}^{K_1} \cup \{\lambda_k^{(2)}\}_{k=1}^{K_2}$  is called the feature weight set or parameter set of  $\mathcal{G}$ . Each feature has a real value as its weight.

**Training**  $\Theta$  is learnt from annotated tweets  $T$ , by maximizing the data likelihood, i.e.,

$$\Theta^* = \arg \max_{\Theta} \ln P(Y, Z | \Theta, T) \quad (3)$$

To solve this optimization problem, we first calculate its gradient:

$$\begin{aligned} \frac{\partial \ln P(Y, Z | T; \Theta)}{\partial \lambda_k^{(1)}} &= \sum_{m,i} \phi_k^{(1)}(y_m^{i-1}, y_m^i) \\ &- \sum_{m,i} \sum_{y_m^{i-1}, y_m^i} p(y_m^{i-1}, y_m^i | T; \Theta) \phi_k^{(1)}(y_m^{i-1}, y_m^i) \end{aligned} \quad (4)$$

$$\begin{aligned} \frac{\partial \ln P(Y, Z | T; \Theta)}{\partial \lambda_k^{(2)}} &= \sum_{m,n,i,j} \delta_{mn}^{ij} \cdot \phi_k^{(2)}(y_m^i, y_n^j, z_{mn}^{ij}) \\ &- \sum_{m,n,i,j} \delta_{mn}^{ij} \sum_{y_m^i, y_n^j, z_{mn}^{ij}} p(y_m^i, y_n^j, z_{mn}^{ij} | T; \Theta) \\ &\quad \cdot \phi_k^{(2)}(y_m^i, y_n^j, z_{mn}^{ij}) \end{aligned} \quad (5)$$

Here, the two marginal probabilities  $p(y_m^{i-1}, y_m^i | T; \Theta)$  and  $p(y_m^i, y_n^j, z_{mn}^{ij} | T; \Theta)$  are computed using loopy belief propagation (Murphy et al., 1999). Once we have computed the gradient,  $\Theta^*$  can be worked out by standard techniques such as steepest descent, conjugate gradient and the

limited-memory BFGS algorithm (L-BFGS). We choose L-BFGS because it is particularly well suited for optimization problems with a large number of variables.

**Inference** Supposing the parameters  $\Theta$  have been set to  $\Theta^*$ , the inference problem is: Given a set of testing tweets  $T$ , output the most probable assignment of  $Y$  and  $Z$ , i.e.,

$$(Y, Z)^* = \arg \max_{(Y, Z)} \ln P(Y, Z | \Theta^*, T) \quad (6)$$

We adopt the max-product algorithm to solve this inference problem. The max-product algorithm is nearly identical to the loopy belief propagation algorithm, with the sums replaced by maxima in the definitions. Note that in both the training and testing stage, the factor graph is constructed in the same way as described in Section 1.

**Efficiency** We take several actions to improve our model’s efficiency. Firstly, we manually compile a comprehensive named entity dictionary from various sources including Wikipedia, Freebase<sup>8</sup>, news articles and the gazetteers shared by Ratnov and Roth (2009). In total this dictionary contains 350 million entries<sup>9</sup>. By looking up this dictionary<sup>10</sup>, we generate the possible BILOU labels, denoted by  $Y_m^i$  hereafter, for each word  $t_m^i$ . For instance, consider “... Good Morning new<sub>1</sub><sup>1</sup> york<sub>1</sub><sup>1</sup>...”. Suppose “New York City” and “New York Times” are in our dictionary, then “new<sub>1</sub><sup>1</sup> york<sub>1</sub><sup>1</sup>” is the matched string with two corresponding entities. As a result, “B-LOCATION” and “B-ORGANIZATION” will be added to  $Y_{new_1^1}$ , and “I-LOCATION” and “I-ORGANIZATION” will be added to  $Y_{york_1^1}$ . If  $Y_m^i \neq \emptyset$ , we enforce the constraint for training and testing that  $y_m^i \in Y_m^i$ , to reduce the search space.

Secondly, in the testing phase, we introduce three rules related to  $z_{mn}^{ij}$ : 1)  $z_{mm}^{ij} = 1$ , which says two words sharing the same lemma in the same tweet denote the same entity; 2) set  $z_{mn}^{ij}$  to 1, if the similarity between  $t_m$  and  $t_n$  is above a threshold (0.8 in our work), or  $t_m$  and  $t_n$  share one hash tag; and 3)  $z_{mn}^{ij} = -1$ , if the similarity between  $t_m$  and  $t_n$  is below a threshold (0.3 in work). To compute

<sup>8</sup><http://freebase.com/view/military>

<sup>9</sup>One phrase referring to  $L$  entities has  $L$  entries.

<sup>10</sup>We use case-insensitive leftmost longest match.

the similarity, each tweet is represented as a bag-of-words vector with the stop words removed, and the cosine similarity is adopted, as defined in Formula 7. These rules pre-label a significant part of  $z$ -serial variables (accounting for 22.5%), with an accuracy of 93.5%.

$$sim(t_m, t_n) = \frac{\vec{t}_m \cdot \vec{t}_n}{|\vec{t}_m| |\vec{t}_n|} \quad (7)$$

Note that in our experiments, these measures reduce the training and testing time by 36.2% and 62.8%, respectively, while no obvious performance drop is observed.

### 4.3 Features

A feature in  $\{\phi_k^{(1)}\}_{k=1}^{K_1}$  involves a pair of neighboring NE-type labels, i.e.,  $y_m^{i-1}$  and  $y_m^i$ , while a feature in  $\{\phi_k^{(2)}\}_{k=1}^{K_2}$  concerns a pair of distant NE-type labels and its associated normalization label, i.e.,  $y_m^i, y_n^j$  and  $z_{mn}^{ij}$ . Details are given below.

#### 4.3.1 Feature Set One: $\{\phi_k^{(1)}\}_{k=1}^{K_1}$

We adopts features similar to Wang (2009), and Ratnov and Roth (2009), i.e., orthographic features, lexical features and gazetteer-related features. These features are defined on the observation. Combining them with  $y_m^{i-1}$  and  $y_m^i$  constitutes  $\{\phi_k^{(1)}\}_{k=1}^{K_1}$ .

**Orthographic features:** Whether  $t_m^i$  is capitalized or upper case; whether it is alphanumeric or contains any slashes; whether it is a stop word; word prefixes and suffixes.

**Lexical features:** Lemma of  $t_m^i$ ,  $t_m^{i-1}$  and  $t_m^{i+1}$ , respectively; whether  $t_m^i$  is an out-of-vocabulary (OOV) word<sup>11</sup>; POS of  $t_m^i$ ,  $t_m^{i-1}$  and  $t_m^{i+1}$ , respectively; whether  $t_m^i$  is a hash tag, a link, or a user account.

**Gazetteer-related features:** Whether  $Y_m^i$  is empty; the dominating label/entity type in  $Y_m^i$ . Which one is dominant is decided by majority voting of the entities in our dictionary. In case of a tie, we randomly choose one from the best.

#### 4.3.2 Feature Set Two: $\{\phi_k^{(2)}\}_{k=1}^{K_2}$

Similarly, we define orthographic, lexical features and gazetteer-related features on the observation,  $y_m^i$

<sup>11</sup>We first conduct a simple dictionary-lookup based normalization with the incorrect/correct word pair list provided by Han et al. (2011) to correct common ill-formed words. Then we call an online dictionary service to judge whether a word is OOV.

and  $y_n^j$ ; and then we combine these features with  $z_{mn}^{ij}$ , forming  $\{\phi_k^{(2)}\}_{k=1}^{K_2}$ .

**Orthographic features:** Whether  $t_m^i / t_n^j$  is capitalized or upper case; whether  $t_m^i / t_n^j$  is alphanumeric or contains any slashes; prefixes and suffixes of  $t_m^i$ .

**Lexical features:** Lemma of  $t_m^i$ ; whether  $t_m^i$  is OOV; whether  $t_m^i / t_m^{i+1} / t_m^{i-1}$  and  $t_n^j / t_n^{j+1} / t_n^{j-1}$  have the same POS; whether  $y_m^i$  and  $y_n^j$  have the same label/entity type.

**Gazetteer-related features:** Whether  $Y_m^i \cap Y_n^j / Y_m^{i+1} \cap Y_n^{j+1} / Y_m^{i-1} \cap Y_n^{j-1}$  is empty; whether the dominating label/entity type in  $Y_m^i$  is the same as that in  $Y_n^j$ .

## 5 Experiments

We manually annotate a data set to evaluate our method. We show that our method outperforms the baseline, a cascaded system that conducts NER and NEN individually.

### 5.1 Data Preparation

We use the data set provided by Liu et al. (2011), which consists of 12,245 tweets with four types of entities annotated: PERSON, LOCATION, ORGANIZATION and PRODUCT. We enrich this data set by adding entity normalization information. Two annotators<sup>12</sup> are involved. For any entity mention, two annotators independently annotate its canonical form. The inter-rater agreement measured by kappa is 0.72. Any inconsistent case is discussed by the two annotators till a consensus is reached. 2,245 tweets are used for development, and the remainder are used for 5-fold cross validation.

### 5.2 Evaluation Metrics

We adopt the widely-used Precision, Recall and F1 to measure the performance of NER for a particular type of entity, and the average Precision, Recall and F1 to measure the overall performance of NER (Liu et al., 2011; Ritter et al., 2011). As for NEN, we adopt the widely-used Accuracy, i.e., to what percentage the outputted canonical forms are correct (Jijkoun et al., 2008; Cucerzan, 2007; Li et al., 2002).

<sup>12</sup>Two native English speakers.

### 5.3 Baseline

We develop a cascaded system as the baseline, which conducts NER and NEN sequentially. Its NER module, denoted by  $S_{BR}$ , is based on the state-of-the-art method introduced by Liu et al. (2011); and its NEN model, denoted by  $S_{BN}$ , follows the NEN system for user-generated news comments proposed by Jijkoun et al. (2008), which uses handcrafted rules to improve a typical NEN system that normalizes surface forms to Wikipedia page titles. We use the POS tagger developed by Ritter et al. (2011) to extract POS related features, and the OpenNLP toolkit to get lemma related features.

### 5.4 Results

Tables 1- 2 show the overall performance of the baseline and ours (denoted by  $S_{RN}$ ). It can be seen that, our method yields a significantly higher F1 (with  $p < 0.01$ ) than  $S_{BR}$ , and a moderate improvement of accuracy as compared with  $S_{BN}$  (with  $p < 0.05$ ). As a case study, we show that our system successfully identified “jaxon<sub>1</sub>” as a PERSON in the tweet “... come to see jaxon<sub>1</sub> someday...”, which is mistakenly labeled as a LOCATION by  $S_{BR}$ . This is largely owing to the fact that our system aligns “jaxon<sub>1</sub>” with “Jaxson<sub>2</sub>” in the tweet “... I love Jaxson<sub>2</sub>, Hes like my little brother...”, in which “Jaxson<sub>2</sub>” is identified as a PERSON. As a result, this encourages our system to consider “jaxon<sub>1</sub>” as a PERSON. We also find cases where our system works but  $S_{BN}$  fails. For example, “Goldman<sub>1</sub>” in the tweet “... Goldman sees massive upside risk in oil prices...” is normalized into “Albert Goldman” by  $S_{BR}$ , because it is mistakenly identified as a PERSON by  $S_{BR}$ ; in contrast, our system recognizes “Goldman<sub>2</sub> Sachs” as an ORGANIZATION, and successfully links “Goldman<sub>2</sub>” to “Goldman<sub>1</sub>”, resulting that “Goldman<sub>1</sub>” is identified as an ORGANIZATION and normalized into “Goldman Sachs”.

Table 3 reports the NER performance of our method for each entity type, from which we see that our system consistently yields better F1 on all entity types than  $S_{BR}$ . We also see that our system boosts the F1 for ORGANIZATION most significantly, reflecting the fact that a large number of organizations that are incorrectly labeled as PERSON by  $S_{BR}$ , are now correctly recognized by our method.

System	Pre	Rec	F1
$S_{RN}$	84.7	82.5	83.6
$S_{BR}$	81.6	78.8	80.2

Table 1: Overall performance (%) of NER.

System	Accuracy
$S_{RN}$	82.6
$S_{BN}$	79.4

Table 2: Overall Accuracy (%) of NEN .

System	PER	PRO	LOC	ORG
$S_{RN}$	84.2	80.5	82.1	85.2
$S_{BR}$	83.9	78.7	81.3	79.8

Table 3: F1 (%) of NER on different entity types.

Features	NER (F1)	NEN (Accuracy)
$F_o$	59.2	61.3
$F_o + F_l$	65.8	68.7
$F_o + F_g$	80.1	77.2
$F_o + F_l + F_g$	83.6	82.6

Table 4: Overall F1 (%) of NER and Accuracy (%) of NEN with different feature sets.

Table 4 shows the overall performance of our method with various feature set combinations, where  $F_o$ ,  $F_l$  and  $F_g$  denote the orthographic features, the lexical features, and the gazetteer-related features, respectively. From Table 4 we see that gazetteer-related features significantly boost the F1 for NER and Accuracy for NEN, suggesting the importance of external knowledge for this task.

## 5.5 Discussion

One main error source for NER and NEN, which accounts for more than half of all the errors, is slang expressions and informal abbreviations. For instance, our method recognizes “California<sub>1</sub>” in the tweet “... And Now, He Lives All The Way In California<sub>1</sub>...” as a LOCATION, however, it mistakenly identifies “Cali<sub>2</sub>” in the tweet “... i love Cali so much...” as a PERSON. One reason is our system does not generate any *z*-serial variable for “California<sub>1</sub>” and “Cali<sub>2</sub>” since they have different lemmas. A more complicated case is “BS<sub>1</sub>” in the tweet “... I, bobby shaw, am gonna put BS<sub>1</sub> on

everything...”, in which “BS<sub>1</sub>” is the abbreviation of “bobby shaw”. Our method fails to recognize “BS<sub>1</sub>” as an entity. There are two possible ways to fix these errors: 1) Extending the scope of *z*-serial variables to each word pairs with a common prefix; and 2) developing advanced normalization components to restore such slang expressions and informal abbreviations into their canonical forms.

Our method does not directly exploit Wikipedia for NEN. This explains the cases where our system correctly links multiple entity mentions but fails to generate canonical forms. Take the following two tweets for example: “... nitip link win7<sub>1</sub> sp1...” and “... Hit the 3TB wall on SRT installing fresh Win7<sub>2</sub>...”. Our system recognizes “win7<sub>1</sub>” and “Win7<sub>2</sub>” as two mentions of the same product, but cannot output their canonical forms “Windows 7”. One possible solution is to exploit Wikipedia to compile a dictionary consisting of entities and their variations.

## 6 Conclusions and Future work

We study the task of NEN for tweets, a new genre of texts that are short and prone to noise. Two challenges of this task are the dearth of information in a single tweet and errors propagated from the NER component. We propose jointly conducting NER and NEN for multiple tweets using a factor graph, to address these challenges. One unique characteristic of our model is that a NE normalization variable is introduced to indicate whether a word pair belongs to the mentions of the same entity. We evaluate our method on a manually annotated data set. Experimental results show our method yields better F1 for NER and Accuracy for NEN than the state-of-the-art baseline that conducts two tasks sequentially.

In the future, we plan to explore two directions to improve our method. First, we are going to develop advanced tweet normalization technologies to resolve slang expressions and informal abbreviations. Second, we are interested in incorporating knowledge mined from Wikipedia into our factor graph.

# Finding Bursty Topics from Microblogs

Qiming Diao, Jing Jiang, Feida Zhu, Ee-Peng Lim

Living Analytics Research Centre

School of Information Systems

Singapore Management University

{qiming.diao.2010, jingjiang, fdzhu, eplim}@smu.edu.sg

## Abstract

Microblogs such as Twitter reflect the general public's reactions to major events. Bursty topics from microblogs reveal what events have attracted the most online attention. Although bursty event detection from text streams has been studied before, previous work may not be suitable for microblogs because compared with other text streams such as news articles and scientific publications, microblog posts are particularly diverse and noisy. To find topics that have bursty patterns on microblogs, we propose a topic model that simultaneously captures two observations: (1) posts published around the same time are more likely to have the same topic, and (2) posts published by the same user are more likely to have the same topic. The former helps find event-driven posts while the latter helps identify and filter out "personal" posts. Our experiments on a large Twitter dataset show that there are more meaningful and unique bursty topics in the top-ranked results returned by our model than an LDA baseline and two degenerate variations of our model. We also show some case studies that demonstrate the importance of considering both the temporal information and users' personal interests for bursty topic detection from microblogs.

## 1 Introduction

With the fast growth of Web 2.0, a vast amount of user-generated content has accumulated on the social Web. In particular, microblogging sites such as Twitter allow users to easily publish short instant posts about any topic to be shared with the

general public. The textual content coupled with the temporal patterns of these microblog posts provides important insight into the general public's interest. A sudden increase of topically similar posts usually indicates a burst of interest in some event that has happened offline (such as a product launch or a natural disaster) or online (such as the spread of a viral video). Finding bursty topics from microblogs therefore can help us identify the most popular events that have drawn the public's attention. In this paper, we study the problem of finding bursty topics from a stream of microblog posts generated by different users. We focus on retrospective detection, where the text stream within a certain period is analyzed in its entirety.

Retrospective bursty event detection from text streams is not new (Kleinberg, 2002; Fung et al., 2005; Wang et al., 2007), but finding bursty topics from microblog streams has not been well studied. In his seminal work, Kleinberg (2002) proposed a state machine to model the arrival times of documents in a stream in order to identify bursts. This model has been widely used. However, this model assumes that documents in the stream are all about a given topic. In contrast, discovering interesting topics that have drawn bursts of interest from a stream of topically diverse microblog posts is itself a challenge. To discover topics, we can certainly apply standard topic models such as LDA (Blei et al., 2003), but with standard LDA temporal information is lost during topic discovery. For microblogs, where posts are short and often event-driven, temporal information can sometimes be critical in determining the topic of a post. For example, typically a post containing the

word “jobs” is likely to be about employment, but right after October 5, 2011, a post containing “jobs” is more likely to be related to Steve Jobs’ death. Essentially, we expect that on microblogs, posts published around the same time have a higher probability to belong to the same topic.

To capture this intuition, one solution is to assume that posts published within the same short time window follow the same topic distribution. Wang et al. (2007) proposed a PLSA-based topic model that exploits this idea to find correlated bursty patterns across multiple text streams. However, their model is not immediately applicable for our problem. First, their model assumes multiple text streams where word distributions for the same topic are different on different streams. More importantly, their model was applied to news articles and scientific publications, where most documents follow the global topical trends. On microblogs, besides talking about global popular events, users also often talk about their daily lives and personal interests. In order to detect global bursty events from microblog posts, it is important to filter out these “personal” posts.

In this paper, we propose a topic model designed for finding bursty topics from microblogs. Our model is based on the following two assumptions: (1) If a post is about a global event, it is likely to follow a global topic distribution that is time-dependent. (2) If a post is about a personal topic, it is likely to follow a personal topic distribution that is more or less stable over time. Separation of “global” and “personal” posts is done in an unsupervised manner through hidden variables. Finally, we apply a state machine to detect bursts from the discovered topics.

We evaluate our model on a large Twitter dataset. We find that compared with bursty topics discovered by standard LDA and by two degenerate variations of our model, bursty topics discovered by our model are more accurate and less redundant within the top-ranked results. We also use some example bursty topics to explain the advantages of our model.

## 2 Related Work

To find bursty patterns from data streams, Kleinberg (2002) proposed a state machine to model the arrival times of documents in a stream. Different states generate time gaps according to exponential density

functions with different expected values, and bursty intervals can be discovered from the underlying state sequence. A similar approach by Ihler et al. (2006) models a sequence of count data using Poisson distributions. To apply these methods to find bursty topics, the data stream used must represent a single topic.

Fung et al. (2005) proposed a method that identifies both topics and bursts from document streams. The method first finds individual words that have bursty patterns. It then finds groups of words that tend to share bursty periods and co-occur in the same documents to form topics. Weng and Lee (2011) proposed a similar method that first characterizes the temporal patterns of individual words using wavelets and then groups words into topics. A major problem with these methods is that the word clustering step can be expensive when the number of bursty words is large. We find that the method by Fung et al. (2005) cannot be applied to our dataset because their word clustering algorithm does not scale up. Weng and Lee (2011) applied word clustering to only the top bursty words within a single day, and subsequently their topics mostly consist of two or three words. In contrast, our method is scalable and each detected bursty topic is directly associated with a word distribution and a set of tweets (see Table 3), which makes it easier to interpret the topic.

Topic models provide a principled and elegant way to discover hidden topics from large document collections. Standard topic models do not consider temporal information. A number of temporal topic models have been proposed to consider topic changes over time. Some of these models focus on the change of topic composition, i.e. word distributions, which is not relevant to bursty topic detection (Blei and Lafferty, 2006; Nallapati et al., 2007; Wang et al., 2008). Some other work looks at the temporal evolution of topics, but the focus is not on bursty patterns (Wang and McCallum, 2006; Ahmed and Xing, 2008; Masada et al., 2009; Ahmed and Xing, 2010; Hong et al., 2011).

The model proposed by Wang et al. (2007) is the most relevant to ours. But as we have pointed out in Section 1, they do not need to handle the separation of “personal” documents from event-driven documents. As we will show later in our experiments, for microblogs it is critical to model users’

personal interests in addition to global topical trends.

To capture users' interests, Rosen-Zvi et al. (2004) expand topic distributions from document-level to user-level in order to capture users' specific interests. But on microblogs, posts are short and noisy, so Zhao et al. (2011) further assume that each post is assigned a single topic and some words can be background words. However, these studies do not aim to detect bursty patterns. Our work is novel in that it combines users' interests and temporal information to detect bursty topics.

### 3 Method

#### 3.1 Preliminaries

We first introduce the notation used in this paper and formally formulate our problem. We assume that we have a stream of  $D$  microblog posts, denoted as  $d_1, d_2, \dots, d_D$ . Each post  $d_i$  is generated by a user  $u_i$ , where  $u_i$  is an index between 1 and  $U$ , and  $U$  is the total number of users. Each  $d_i$  is also associated with a discrete timestamp  $t_i$ , where  $t_i$  is an index between 1 and  $T$ , and  $T$  is the total number of time points we consider. Each  $d_i$  contains a bag of words, denoted as  $\{w_{i,1}, w_{i,2}, \dots, w_{i,N_i}\}$ , where  $w_{i,j}$  is an index between 1 and  $V$ , and  $V$  is the vocabulary size.  $N_i$  is the number of words in  $d_i$ .

We define a bursty topic  $b$  as a word distribution coupled with a bursty interval, denoted as  $(\phi^b, t_s^b, t_e^b)$ , where  $\phi^b$  is a multinomial distribution over the vocabulary, and  $t_s^b$  and  $t_e^b$  ( $1 \leq t_s^b \leq t_e^b \leq T$ ) are the start and the end timestamps of the bursty interval, respectively. Our task is to find meaningful bursty topics from the input text stream.

Our method consists of a topic discovery step and a burst detection step. At the topic discovery step, we propose a topic model that considers both users' topical interests and the global topic trends. Burst detection is done through a standard state machine method.

#### 3.2 Our Topic Model

We assume that there are  $C$  (latent) topics in the text stream, where each topic  $c$  has a word distribution  $\phi^c$ . Note that not every topic has a bursty interval. On the other hand, a topic may have multiple bursty intervals and hence leads to multiple bursty topics.

We also assume a background word distribution  $\phi^B$  that captures common words. All posts are assumed to be generated from some mixture of these  $C + 1$  underlying topics.

In standard LDA, a document contains a mixture of topics, represented by a topic distribution, and each word has a hidden topic label. While this is a reasonable assumption for long documents, for short microblog posts, a single post is most likely to be about a single topic. We therefore associate a single hidden variable with each post to indicate its topic. Similar idea of assigning a single topic to a short sequence of words has been used before (Gruber et al., 2007; Zhao et al., 2011). As we will see very soon, this treatment also allows us to model topic distributions at time window level and user level.

As we have discussed in Section 1, an important observation we have is that when everything else is equal, a pair of posts published around the same time is more likely to be about the same topic than a random pair of posts. To model this observation, we assume that there is a global topic distribution  $\theta^t$  for each time point  $t$ . Presumably  $\theta^t$  has a high probability for a topic that is popular in the microblogosphere at time  $t$ .

Unlike news articles from traditional media, which are mostly about current affairs, an important property of microblog posts is that many posts are about users' personal encounters and interests rather than global events. Since our focus is to find popular global events, we need to separate out these "personal" posts. To do this, an intuitive idea is to compare a post with its publisher's general topical interests observed over a long time. If a post does not match the user's long term interests, it is more likely related to a global event. We therefore introduce a time-independent topic distribution  $\eta^u$  for each user to capture her long term topical interests.

We assume the following generation process for all the posts in the stream. When user  $u$  publishes a post at time point  $t$ , she first decides whether to write about a global trendy topic or a personal topic. If she chooses the former, she then selects a topic according to  $\theta^t$ . Otherwise, she selects a topic according to her own topic distribution  $\eta^u$ . With the chosen topic, words in the post are generated from the word distribution for that topic or from the background word distribution that captures white noise.

- 
1. Draw  $\phi^B \sim \text{Dirichlet}(\beta), \pi \sim \text{Beta}(\gamma), \rho \sim \text{Beta}(\lambda)$
  2. For each time point  $t = 1, \dots, T$ 
    - (a) draw  $\theta^t \sim \text{Dirichlet}(\alpha)$
  3. For each user  $u = 1, \dots, U$ 
    - (a) draw  $\eta^u \sim \text{Dirichlet}(\alpha)$
  4. For each topic  $c = 1, \dots, C$ ,
    - (a) draw  $\phi^c \sim \text{Dirichlet}(\beta)$
  5. For each post  $i = 1, \dots, D$ ,
    - (a) draw  $y_i \sim \text{Bernoulli}(\pi)$
    - (b) draw  $z_i \sim \text{Multinomial}(\eta^{u_i})$  if  $y_i = 0$  or  $z_i \sim \text{Multinomial}(\theta^{t_i})$  if  $y_i = 1$
    - (c) for each word  $j = 1, \dots, N_i$ 
      - i. draw  $x_{i,j} \sim \text{Bernoulli}(\rho)$
      - ii. draw  $w_{i,j} \sim \text{Multinomial}(\phi^B)$  if  $x_{i,j} = 0$  or  $w_{i,j} \sim \text{Multinomial}(\phi^{z_i})$  if  $x_{i,j} = 1$
- 

Figure 2: The generation process for all posts.

We use  $\pi$  to denote the probability of choosing to talk about a global topic rather than a personal topic.

Formally, the generation process is summarized in Figure 2. The model is also depicted in Figure 1(a).

There are two degenerate variations of our model that we also consider in our experiments. The first one is depicted in Figure 1(b). In this model, we only consider the time-dependent topic distributions that capture the global topical trends. This model can be seen as a direct application of the model by Wang et al. (2007). The second one is depicted in Figure 1(c). In this model, we only consider the users' personal interests but not the global topical trends, and therefore temporal information is not used. We refer to our complete model as *TimeUserLDA*, the model in Figure 1(b) as *TimeLDA* and the model in Figure 1(c) as *UserLDA*. We also consider a standard LDA model in our experiments, where each word is associated with a hidden topic.

## Learning

We use collapsed Gibbs sampling to obtain samples of the hidden variable assignment and to estimate the model parameters from these samples. Due to space limit, we only show the derived Gibbs sampling formulas as follows.

First, for the  $i$ -th post, we know its publisher  $u_i$  and timestamp  $t_i$ . We can jointly sample  $y_i$  and  $z_i$  based on the values of all other hidden variables. Let us use  $\mathbf{y}$  to denote the set of all hidden variables  $y$  and  $\mathbf{y}_{-i}$  to denote all  $y$  except  $y_i$ . We use similar symbols for other variables. We then have

$$p(y_i = p, z_i = c | \mathbf{z}_{-i}, \mathbf{y}_{-i}, \mathbf{x}, \mathbf{w}) \propto \frac{M_{(\cdot)}^{\pi} + \gamma}{M_{(\cdot)}^{\pi} + 2\gamma} \cdot \frac{M_{(c)}^l + \alpha}{M_{(\cdot)}^l + C\alpha} \cdot \frac{\prod_{v=1}^V \prod_{k=0}^{E_{(v)}-1} (M_{(v)}^c + k + \beta)}{\prod_{k=0}^{E_{(\cdot)}-1} (M_{(\cdot)}^c + k + V\beta)}, \quad (1)$$

where  $l = u_i$  when  $p = 0$  and  $l = t_i$  when  $p = 1$ . Here every  $M$  is a counter.  $M_{(0)}^{\pi}$  is the number of posts generated by personal interests, while  $M_{(1)}^{\pi}$  is the number of posts coming from global topical trends.  $M_{(\cdot)}^{\pi} = M_0^{\pi} + M_1^{\pi}$ .  $M_{(c)}^{u_i}$  is the number of posts by user  $u_i$  and assigned to topic  $c$ , and  $M_{(\cdot)}^{u_i}$  is the total number of posts by  $u_i$ .  $M_{(c)}^{t_i}$  is the number of posts assigned to topic  $c$  at time point  $t_i$ , and  $M_{(\cdot)}^{t_i}$  is the total number of posts at  $t_i$ .  $E_{(v)}$  is the number of times word  $v$  occurs in the  $i$ -th post and is labeled as a topic word, while  $E_{(\cdot)}$  is the total number of topic words in the  $i$ -th post. Here, topic words refer to words whose latent variable  $x$  equals 1.  $M_{(v)}^c$  is the number of times word  $v$  is assigned to topic  $c$ , and  $M_{(\cdot)}^c$  is the total number of words assigned to topic  $c$ . All the counters  $M$  mentioned above are calculated with the  $i$ -th post excluded.

We sample  $x_{i,j}$  for each word  $w_{i,j}$  in the  $i$ -th post using

$$p(x_{i,j} = q | \mathbf{y}, \mathbf{z}, \mathbf{x}_{-\{i,j\}}, \mathbf{w}) \propto \frac{M_{(q)}^{\rho} + \gamma}{M_{(\cdot)}^{\rho} + 2\gamma} \cdot \frac{M_{(w_{i,j})}^l + \beta}{M_{(\cdot)}^l + V\beta}, \quad (2)$$

where  $l = B$  when  $q = 0$  and  $l = z_i$  when  $q = 1$ .  $M_{(0)}^{\rho}$  and  $M_{(1)}^{\rho}$  are counters to record the numbers of words assigned to the background model and any topic, respectively, and  $M_{(\cdot)}^{\rho} = M_{(0)}^{\rho} + M_{(1)}^{\rho}$ .  $M_{(w_{i,j})}^B$  is the number of times word  $w_{i,j}$  occurs as a background word.  $M_{(w_{i,j})}^{z_i}$  counts the number of times word  $w_{i,j}$  is assigned to topic  $z_i$ , and  $M_{(\cdot)}^{z_i}$  is the total number of words assigned to topic  $z_i$ . Again, all counters are calculated with the current word  $w_{i,j}$  excluded.

Figure 1: (a) Our topic model for burst detection. (b) A variation of our model where we only consider global topical trends. (c) A variation of our model where we only consider users’ personal topical interests.

### 3.3 Burst Detection

Just like standard LDA, our topic model itself finds a set of topics represented by  $\phi^c$  but does not directly generate bursty topics. To identify bursty topics, we use the following mechanism, which is based on the idea by Kleinberg (2002) and Ihler et al. (2006). In our experiments, when we compare different models, we also use the same burst detection mechanism for other models.

We assume that after topic modeling, for each discovered topic  $c$ , we can obtain a series of counts  $(m_1^c, m_2^c, \dots, m_T^c)$  representing the intensity of the topic at different time points. For LDA, these are the numbers of words assigned to topic  $c$ . For TimeUserLDA, these are the numbers of posts which are in topic  $c$  and generated by the global topic distribution  $\theta^{t_i}$ , i.e whose hidden variable  $y_i$  is 1. For other models, these are the numbers of posts in topic  $c$ .

We assume that these counts are generated by two Poisson distributions corresponding to a bursty state and a normal state, respectively. Let  $\mu_0$  denote the expected count for the normal state and  $\mu_1$  for the bursty state. Let  $v_t$  denote the state for time point  $t$ , where  $v_t = 0$  indicates the normal state and  $v_t = 1$  indicates the bursty state. The probability of observing a count of  $m_t^c$  is as follows:

$$p(m_t^c | v_t = l) = \frac{e^{-\mu_l} \mu_l^{m_t^c}}{m_t^c!},$$

where  $l$  is either 0 or 1. The state sequence  $(v_0, v_1, \dots, v_T)$  is a Markov chain with the following transition probabilities:

$$p(v_t = l | v_{t-1} = l) = \sigma_l,$$

Method	P@5	P@10	P@20	P@30
LDA	0.600	0.800	0.750	N/A
TimeLDA	0.800	0.700	0.600	0.633
UserLDA	0.800	0.700	0.850	<b>0.833</b>
TimeUserLDA	<b>1.000</b>	<b>1.000</b>	<b>0.900</b>	0.800

Table 1: Precision at  $K$  for the various models.

Method	P@5	P@10	P@20	P@30
LDA	0.600	0.800	0.700	N/A
TimeLDA	0.400	0.500	0.500	0.567
UserLDA	0.800	0.500	0.500	0.600
TimeUserLDA	<b>1.000</b>	<b>0.900</b>	<b>0.850</b>	<b>0.767</b>

Table 2: Precision at  $K$  for the various models after we remove redundant bursty topics.

where  $l$  is either 0 or 1.

$\mu_0$  and  $\mu_1$  are topic specific. In our experiments, we set  $\mu_0 = \frac{1}{T} \sum_t m_t^c$ , that is,  $\mu_0$  is the average count over time. We set  $\mu_1 = 3\mu_0$ . For transition probabilities, we empirically set  $\sigma_0 = 0.9$  and  $\sigma_1 = 0.6$  for all topics.

We can use dynamic programming to uncover the underlying state sequence for a series of counts. Finally, a burst is marked by a consecutive subsequence of bursty states.

## 4 Experiments

### 4.1 Data Set

We use a Twitter data set to evaluate our models. The original data set contains 151,055 Twitter users based in Singapore and their tweets. These Twitter users were obtained by starting from a set of seed Singapore users who are active online and tracing

Bursty Period	Top Words	Example Tweets	Label
Nov 29	vote, big, awards, bang, mama, win, 2ne1, award, won	(1) why didnt 2ne1 win this time! (2) 2ne1. you deserved that urgh! (3) watching mama. whoohoo	Mnet Asian Music Awards (MAMA)
Oct 5 ~ Oct 8	steve, jobs, apple, iphone, rip, world, changed, 4s, siri	(1) breaking: apple says steve jobs has passed away! (2) google founders: steve jobs was an inspiration! (3) apple 4 life thankyousteve	Steve Jobs death
Nov 1 ~ Nov 3	reservoir, bedok, adlyn, slap, found, body, mom, singapore, steven	(1) this adelyn totally disgust me. slap her mum? queen of cine? joke please can. (2) she slapped her mum and boasted about it on fb (3) adelyn lives in woodlands , later she slap me how?	girl slapping mom
Nov 5	reservoir, bedok, adlyn, slap, found, body, mom, singapore, steven	(1) bedok = bodies either drowned or killed. (2) another body found, in bedok reservoir? (3) so many bodies found at bedok reservoir. alamak.	suicide near bedok reservoir
Oct 23	man, arsenal, united, liverpool, chelsea, city, goal, game, match	(1) damn you man city! we will get you next time! (2) wtf 90min goal! (3) 6-1 to city. unbelievable.	football game

Table 3: Top-5 bursty topics ranked by TimeUserLDA. The labels are manually given. The 3rd and the 4th bursty topics come from the same topic but have different bursty periods.

Rank	LDA	UserLDA	TimeLDA
1	Steve Jobs' death	MAMA	MAMA
2	MAMA	football game	MAMA
3	N/A	#zamanprimaryschool	MAMA
4	girl slapping mom	N/A	girl slapping mom
5	N/A	iphone 4s	N/A

Table 4: Top-5 bursty topics ranked by other models. N/A indicates a meaningless burst.

their follower/followee links by two hops. Because this data set is huge, we randomly sampled 2892 users from this data set and extracted their tweets between September 1 and November 30, 2011 (91 days in total). We use one day as our time window. Therefore our timestamps range from 1 to 91. We then removed stop words and words containing non-standard characters. Tweets containing less than 3 words were also discarded. After preprocessing, we obtained the final data set with 3,967,927 tweets and 24,280,638 tokens.

## 4.2 Ground Truth Generation

To compare our model with other alternative models, we perform both quantitative and qualitative evaluation. As we have explained in Section 3, each model gives us time series data for a number of topics, and by applying a Poisson-based state machine, we can obtain a set of bursty topics. For each method, we rank the obtained bursty topics by the number

of tweets (or words in the case of the LDA model) assigned to the topics and take the top-30 bursty topics from each model. In the case of the LDA model, only 23 bursty topics were detected. We merged these topics and asked two human judges to judge their quality by assigning a score of either 0 or 1. The judges are graduate students living in Singapore and not involved in this project. The judges were given the bursty period and 100 randomly selected tweets for the given topic within that period for each bursty topic. They can consult external resources to help make judgment. A bursty topic was scored 1 if the 100 tweets coherently describe a bursty event based on the human judge's understanding. The inter-annotator agreement score is 0.649 using Cohen's kappa, showing substantial agreement. For ground truth, we consider a bursty topic to be correct if both human judges have scored it 1. Since some models gave redundant bursty topics, we also asked one of the judges to identify unique bursty

topics from the ground truth bursty topics.

### 4.3 Evaluation

In this section, we show the quantitative evaluation of the four models we consider, namely, LDA, TimeLDA, UserLDA and TimeUserLDA. For each model, we set the number of topics  $C$  to 80,  $\alpha$  to  $\frac{50}{C}$  and  $\beta$  to 0.01 after some preliminary experiments. Each model was run for 500 iterations of Gibbs sampling. We take 40 samples with a gap of 5 iterations in the last 200 iterations to help us assign values to all the hidden variables.

Table 1 shows the comparison between these models in terms of the precision of the top- $K$  results. As we can see, our model outperforms all other models for  $K \leq 20$ . For  $K = 30$ , the UserLDA model performs the best followed by our model.

As we have pointed out, some of the bursty topics are redundant, i.e. they are about the same bursty event. We therefore also calculated precision at  $K$  for unique topics, where for redundant topics the one ranked the highest is scored 1 and the other ones are scored 0. The comparison of the performance is shown in Table 2. As we can see, in this case, our model outperforms other models with all  $K$ . We will further discuss redundant bursty topics in the next section.

### 4.4 Sample Results and Discussions

In this section, we show some sample results from our experiments and discuss some case studies that illustrate the advantages of our model.

First, we show the top-5 bursty topics discovered by the TimeUserLDA model in Table 3. As we can see, all these bursty topics are meaningful. Some of these events are global major events such as Steve Jobs' death, while some others are related to online events such as the scandal of a girl boasting about slapping her mother on Facebook. For comparison, we also show the top-5 bursty topics discovered by other models in Table 4. As we can see, some of them are not meaningful events while some of them are redundant.

Next, we show two case studies to demonstrate the effectiveness of our model.

**Effectiveness of Temporal Models:** Both TimeLDA and TimeUserLDA tend to group posts published on the same day into the same topic. We

find that this can help separate bursty topics from general ones. An example is the topic on the Circle Line. The Circle Line is one of the subway lines of Singapore's mass transit system. There were a few incidents of delays or breakdowns during the period between September and November, 2011. We show the time series data of the topic related to the Circle Line of UserLDA, TimeLDA and TimeUserLDA in Figure 3. As we can see, the UserLDA model detects a much large volume of tweets related to this topic. A close inspection tells us that the topic under UserLDA is actually related to the subway systems in Singapore in general, which include a few other subway lines, and the Circle Line topic is merged with this general topic. On the other hand, TimeLDA and TimeUserLDA are both able to separate the Circle Line topic from the general subway topic because the Circle Line has several bursts. What is shown in Figure 3 for TimeLDA and TimeUserLDA is only the topic on the Circle Line, therefore the volume is much smaller. We can see that TimeLDA and TimeUserLDA show clearer bursty patterns than UserLDA for this topic. The bursts around day 20, day 44 and day 85 are all real events based on our ground truth.

**Effectiveness of User Models:** We have stated that it is important to filter out users' "personal" posts in order to find meaningful global events. We find that our results also support this hypothesis. Let us look at the example of the topic on the Mnet Asian Music Awards, which is a major music award show that is held by Mnet Media annually. In 2011, this event took place in Singapore on November 29. Because Korean pop music is very popular in Singapore, many Twitter users often tweet about Korean pop music bands and singers in general. All our topic models give multiple topics related to Korean pop music, and many of them have a burst on November 29, 2011. Under the TimeLDA and UserLDA models, this leads to several redundant bursty topics for the MAMA event ranked within the top-30. For TimeUserLDA, however, although the MAMA event is also ranked the top, there is no redundant one within the top-30 results. We find that this is because with TimeUserLDA, we can remove tweets that are considered personal and therefore do not contribute to bursty topic ranking. We show the topic intensity of a topic about a Korean pop singer in

Figure 3: Topic intensity over time for the topic on the Circle Line.

Figure 4: Topic intensity over time for the topic about a Korean pop singer. The dotted curves show the topic on Steve Jobs' death.

Figure 4. For reference, we also show the intensity of the topic on Steve Jobs' death under each model. We can see that because this topic is related to Korean pop music, it has a burst on day 90 (November 29). But if we consider the relative intensity of this burst compared with Steve Jobs' death, under TimeLDA and UserLDA, this topic is still strong but under TimeUserLDA its intensity can almost be ignored. This is why with TimeLDA and UserLDA this topic leads to a redundant burst within the top-30 results but with TimeUserLDA the burst is not ranked high.

## 5 Conclusions

In this paper, we studied the problem of finding bursty topics from the text streams on microblogs. Because existing work on burst detection from text streams may not be suitable for microblogs, we proposed a new topic model that considers both the temporal information of microblog posts and users' personal interests. We then applied a Poisson-based state machine to identify bursty periods from the topics discovered by our model. We compared our model with standard LDA as well as two degenerate variations of our model on a real Twitter dataset. Our quantitative evaluation showed that our

model could more accurately detect unique bursty topics among the top ranked results. We also used two case studies to illustrate the effectiveness of the temporal factor and the user factor of our model.

Our method currently can only detect bursty topics in a retrospective and offline manner. A more interesting and useful task is to detect realtime bursts in an online fashion. This is one of the directions we plan to study in the future. Another limitation of the current method is that the number of topics is predetermined. We also plan to look into methods that allow appearance and disappearance of topics along the timeline, such as the model by Ahmed and Xing (2010).

## Abstract

There are a growing number of popular web sites where users submit and review instructions for completing tasks as varied as building a table and baking a pie. In addition to providing their subjective evaluation, reviewers often provide *actionable* refinements. These refinements clarify, correct, improve, or provide alternatives to the original instructions. However, identifying and reading all relevant reviews is a daunting task for a user. In this paper, we propose a generative model that jointly identifies user-proposed refinements in instruction reviews at multiple granularities, and aligns them to the appropriate steps in the original instructions. Labeled data is not readily available for these tasks, so we focus on the unsupervised setting. In experiments in the recipe domain, our model provides 90.1%  $F_1$  for predicting refinements at the review level, and 77.0%  $F_1$  for predicting refinement segments within reviews.

## 1 Introduction

People turn to the web to seek advice on a wide variety of subjects. An analysis of web search queries posed as questions revealed that “how to” questions are the most popular (Pang and Kumar, 2011). People consult online resources to answer technical questions like “how to put music on my ipod,” and to find instructions for tasks like tying a tie and cooking Thanksgiving dinner. Not surprisingly, there are many Web sites dedicated to providing instructions. For instance, on the popular DIY site *instructables.com* (“share what you

make”), users post instructions for making a wide variety of objects ranging from bed frames to “The Stirling Engine, absorb energy from candles, coffee, and more!”<sup>1</sup> There are also sites like *allrecipes.com* that are dedicated to a specific domain. On these community-based instruction sites, instructions are posted and reviewed by users. For instance, the aforementioned “Stirling engine” has received over 350 reviews on *instructables.com*.

While user-generated instructions greatly increase the variety of instructions available online, they are not necessarily foolproof, or appropriate for all users. For instance, in the case of recipes, a user missing a certain ingredient at home might wonder whether it can be safely omitted; a user who wants to get a slightly different flavor might want to find out what substitutions can be used to achieve that effect. Reviews posted by other users provide a great resource for mining such information. In recipe reviews, users often offer their customized version of the recipe by describing changes they made: e.g., “I halved the salt” or “I used honey instead of sugar.” In addition, they may clarify portions of the instructions that are too concise for a novice to follow, or describe changes to the cooking method that result in a better dish. We refer to such *actionable* information as a *refinement*.

Refinements can be quite prevalent in instruction reviews. In a random sample of recipe reviews from *allrecipes.com*, we found that 57.8% contain refinements of the original recipe. However, sifting through all reviews for refinements is a daunting

---

<sup>1</sup><http://www.instructables.com/id/The-Sterling-Engine-absorb-energy-from-candles-c>

task for a user. Instead, we would like to automatically identify refinements in reviews, summarize them, and either create an annotated version of the instructions that reflects the collective experience of the community, or, more ambitiously, revise the instructions directly.

In this paper, we take first steps toward these goals by addressing the following tasks: (1) identifying reviews that contain refinements, (2) identifying text segments within reviews that describe refinements, and (3) aligning these refinement segments to steps in the instructions being reviewed (Figure 1 provides an example). Solving these tasks provides a foundation for downstream summarization and semantic analysis, and also suggests intermediate applications. For example, we can use review classification to filter or rank reviews as they are presented to future users, since reviews that contain refinements are more informative than a review which only says “Great recipe, thanks for posting!”

To the best of our knowledge, no previous work has explored this aspect of user-generated text. While review mining has been studied extensively, we differ from previous work in that instead of focusing on *evaluative* information, we focus *actionable* information in the reviews. (See Section 2 for a more detailed discussion.)

There is no existing labeled data for the tasks of interest, and we would like the methods we develop to be easily applied in multiple domains. Motivated by this, we propose a generative model for solving these tasks jointly without labeled data. Interestingly, we find that jointly modeling refinements at both the review and segment level is beneficial. We created a new recipe data set, and manually labeled a random sample to evaluate our model and several baselines. We obtain 90.1%  $F_1$  for predicting refinements at the review level, and 77.0%  $F_1$  for predicting refinement segments within reviews.

## 2 Related Work

At first glance, the task of identifying refinements appears similar to subjectivity detection (see (Pang and Lee, 2008) for a survey). However, note that an objective sentence is not necessarily a refinement: e.g., “I took the cake to work”; and a subjective sentence can still contain a refinement: e.g., “I reduced

the sugar and it came out perfectly.”

Our end goal is similar to review summarization. However, previous work on review summarization (Hu and Liu, 2004; Popescu and Etzioni, 2005; Titov and McDonald, 2008) in product or service domains focused on summarizing evaluative information — more specifically, identifying ratable aspects (e.g., “food” and “service” for restaurants) and summarizing the overall sentiment polarity for each aspect. In contrast, we are interested in extracting a subset of the non-evaluative information. Rather than ratable aspects that are common across the entire domain (e.g., “ingredient”, “cooking method”), we are interested in actionable information that is related and *specific* to the subject of the review.

Note that while our end goal is to summarize objective information, it is still very different from standard multi-document summarization (Radev et al., 2002) of news articles. Apart from differences in the quantity and the nature of the input, we aim to summarize a distribution over what should or can be changed, rather than produce a consensus using different accounts of an event. In terms of modeling approaches, in the context of extractive summarization, Barzilay and Lee (2004) model content structure (i.e., the order in which topics appear) in documents. We also model document structure, but we do so to help identify refinement segments.

We share with previous work on predicting review quality or helpfulness an interest in identifying “informative” text. Early work tried to exploit the intuition that a helpful review is one that comments on product details. However, incorporating product-aspect-mention count (Kim et al., 2006) or similarity between the review and product specification (Zhang and Varadarajan, 2006) as features did not seem to improve the performance when the task was predicting the percentage of helpfulness votes. Instead of using the helpfulness votes, Liu et al. (2007) manually annotated reviews with quality judgements, where a *best* review was defined as one that contains complete and detailed comments. Our notion of informativeness differs from previous work. We do not seek reviews that contain detailed *evaluative* information; instead, we seek reviews that contain detailed *actionable* information. Furthermore, we are not expecting any single review to be comprehensive; rather, we seek to extract a

collection of refinements representing the collective wisdom of the community.

To the best of our knowledge, there is little previous work on mining user-generated data for actionable information. However, there has been increasing interest in language grounding. In particular, recent work has studied learning to act in an external environment by following textual instructions (Branavan et al., 2009, 2010, 2011; Vogel and Jurafsky, 2010). This line of research is complementary to our work. While we do not utilize extensive linguistic knowledge to analyze actionable information, we view this as an interesting future direction.

We propose a generative model that makes predictions at both the review and review segment level. Recent work uses a discriminative model with a similar structure to perform sentence-level sentiment analysis with review-level supervision (Täckström and McDonald, 2011). However, sentiment polarity labels at the review level are easily obtained. In contrast, refinement labels are not naturally available, motivating the use of unsupervised learning. Note that the model of Täckström and McDonald (2011) cannot be used in a fully unsupervised setting.

### 3 Refinements

In this section, we define refinements more precisely. We use recipes as our running example, but our problem formulation and models are not specific to this domain.

A *refinement* is a piece of text containing actionable information that is not entailed by the original instructions, but can be used to modify or expand the original instructions. A refinement could propose an alternative method or an improvement (e.g., “I replaced half of the shortening with butter”, “Let the shrimp sit in 1/2 marinade for 3 hours”), as well as provide clarification (“definitely use THIN cut pork chops, otherwise your panko will burn before your chops are cooked”).

Furthermore, we distinguish between a *verified* refinement (what the user actually did) and a *hypothetical* refinement (“next time I think I will try evaporated milk”). In domains similar to recipes, where instructions may be carried out repeatedly, there exist refinements in both forms. Since instructions should, in principle, contain information that

has been well tested, in this work, we consider only the former as our target class. In a small percentage of reviews we observed “failed attempts” where a user did not follow a certain step and regretted the diversion. In this work, we do not consider them to be refinements. We refer to text that does not contain refinements as *background*.

Finally, we note that the presence of a past tense verb does not imply a refinement (e.g., “Everyone *loved* this dish”, “I *got* many compliments”). In fact, not all text segments that describe an action are refinements (e.g., “I *took* the cake to work”, “I *followed* the instructions to a T”).

## 4 Models

In this section we describe our models. To identify refinements without labeled data, we propose a generative model of reviews (or more generally documents) with latent variables. We assume that each review  $x$  is divided into *segments*,  $x = (x_1, \dots, x_T)$ . Each segment is a sub-sentence-level text span. We assume that the segmentation is observed, and hence it is not modeled. The segmentation procedure we use is described in Section 5.1.

While we focus on the unsupervised setting, note that the model can also be used in a semi-supervised setting. In particular, coarse (review-level) labels can be used to guide the induction of fine-grained latent structure (segment labels, alignments).

### 4.1 Identifying Refinements

We start by directly modeling refinements at the segment level. Our first intuition is that refinement and background segments can often be identified by lexical differences. Based on this intuition, we can ignore document structure and generate the segments with a segment-level mixture of multinomials (S-Mix). In general we could use  $n$  multinomials to represent refinements and  $m$  multinomials to represent background text, but in this paper we simply use  $n = m = 1$ . Therefore, unsupervised learning in S-Mix can be viewed as clustering the segments with two latent states. As is standard practice in unsupervised learning, we subsequently map these latent states onto the labels of interest:  $r$  and  $b$ , for refinement and background, respectively. Note, however, that this model ignores potential sequential depen-

dencies among segments. A segment following a refinement segment in a review may be more likely to be a refinement than background, for example.

To incorporate this intuition, we could instead generate reviews with a HMM (Rabiner, 1989) over segments (S-HMM) with two latent states. Let  $z_i$  be the latent label variable for the  $i$ th segment. The joint probability of a review and segment labeling is

$$p(\mathbf{x}, \mathbf{z}; \theta) = \prod_{j=1}^T p(z_j | z_{j-1}; \theta) p(\mathbf{x}_j | z_j; \theta), \quad (1)$$

where  $p(z_j | z_{j-1}; \theta)$  are multinomial transition distributions, allowing the model to learn that  $p(z_j = r | z_{j-1} = r; \theta) > p(z_j = b | z_{j-1} = r; \theta)$  as motivated above, and  $p(\mathbf{x}_j | z_j; \theta)$  are multinomial emission distributions. Note that all words in a segment are generated independently conditioned on  $z_j$ .

While S-HMM models sequential dependencies, note that it imposes the same transition probabilities on each review. In a manually labeled random sample of recipe reviews, we find that refinement segments tend to be clustered together in certain reviews (“bursty”), rather than uniformly distributed across all reviews. Specifically, while we estimate that 23% of all segments are refinements, 42% of reviews do not contain any refinements. In reviews that contain a refinement, 34% of segments are refinements. S-HMM cannot model this phenomenon.

Consequently, we extend S-HMM to include a latent label variable  $y$  for each review that takes values *yes* (contains refinement) and *no* (does not contain refinement). The extended model is a mixture of HMMs (RS-MixHMM) where  $y$  is the mixture component.

$$p(\mathbf{x}, y, \mathbf{z}; \theta) = p(y; \theta) p(\mathbf{x}, \mathbf{z} | y; \theta) \quad (2)$$

The two HMMs  $p(\mathbf{x}, \mathbf{z} | y = \textit{yes}; \theta)$  and  $p(\mathbf{x}, \mathbf{z} | y = \textit{no}; \theta)$  can learn different transition multinomials and consequently different distributions over  $\mathbf{z}$  for different  $y$ . On the other hand, we do not believe the textual content of the background segments in a  $y = \textit{yes}$  review should be different from those in a  $y = \textit{no}$  review. Thus, the emission distributions are shared between the two HMMs,  $p(\mathbf{x}_j | z_j, y; \theta) = p(\mathbf{x}_j | z_j; \theta)$ .

Note that the definition of  $y$  imposes additional constraints on RS-MixHMM: 1) reviews with  $y = \textit{no}$

cannot contain refinement segments, and 2) reviews with  $y = \textit{yes}$  must contain at least one refinement segment. We enforce constraint (1) by disallowing refinement segments  $z_j = r$  when  $y = \textit{no}$ :  $p(z_j = r | z_{j-1}, y = \textit{no}; \theta) = 0$ . Therefore, with one background label, only the all background label sequence has non-zero probability when  $y = \textit{no}$ . Enforcing constraint (2) is more challenging, as the  $y = \textit{yes}$  HMM must assign zero probability when all segments are background, but permit background segments when refinement segments are present.

To enforce constraint (2), we “rewire” the HMM structure for  $y = \textit{yes}$  so that a path that does not go through the refinement state  $r$  is impossible. We first expand the state representation by replacing  $b$  with two states that encode whether or not the first  $r$  has been encountered yet:  $b_{\textit{not-yet}}$  encodes that all previous states in the path have also been background;  $b_{ok}$  encodes that at least one refinement state has been encountered<sup>2</sup>. We prohibit paths from ending with  $b_{\textit{not-yet}}$  by augmenting RS-MixHMM with a special final state  $f$ , and fixing  $p(z_{T+1} = f | z_T = b_{\textit{not-yet}}, y = \textit{yes}; \theta) = 0$ . Furthermore, to enforce the correct semantics of each state, paths cannot start with  $b_{ok}$ ,  $p(z_1 = b_{ok} | y = \textit{yes}; \theta) = 0$ , and transitions from  $b_{\textit{not-yet}}$  to  $b_{ok}$ ,  $b_{ok}$  to  $b_{\textit{not-yet}}$ , and  $r$  to  $b_{\textit{not-yet}}$  are prohibited.

Note that RS-MixHMM also generalizes to the case where there are multiple refinement ( $n > 1$ ) and background ( $m > 1$ ) labels. Let  $\mathcal{Z}_r$  be the set of refinement labels, and  $\mathcal{Z}_b$  be the set of background labels. The transition structure is analogous to the  $n = m = 1$  case, but statements involving  $r$  are applied for each  $z \in \mathcal{Z}_r$ , and statements involving  $b$  are applied for each  $z \in \mathcal{Z}_b$ . For example, the  $y = \textit{yes}$  HMM contains  $2|\mathcal{Z}_b|$  background states.

In summary, the generative process of RS-MixHMM involves first selecting whether the review will contain a refinement. If the answer is *yes*, a sequence of background segments and at least one refinement segment are generated using the  $y = \textit{yes}$  HMM. If the answer is *no*, only background segments are generated. Interestingly, by enforcing constraints (1) and (2), we break the label symmetry that necessitates mapping latent states onto labels

<sup>2</sup>In this paper, the two background states share emission multinomials,  $p(\mathbf{x}_j | z_j = b_{\textit{not-yet}}; \theta) = p(\mathbf{x}_j | z_j = b_{ok}; \theta)$ , though this is not required.

when using S-Mix and S-HMM. Indeed, in the experiments we present in Section 5.3, mapping is not necessary for RS-MixHMM.

Note that the relationship between document-level labels and segment-level labels that we model is related to the *multiple-instance* setting (Dietterich et al., 1997) in the machine learning literature. In multiple-instance learning (MIL), rather than having explicit labels at the instance (e.g., segment) level, labels are given for bags of instances (e.g., documents). In the binary case, a bag is *negative* only if all of its instances are *negative*. While we share this problem formulation, work on MIL has mostly focussed on supervised learning settings, and thus it is not directly applicable to our unsupervised setting. Foulds and Smyth (2011) propose a generative model for MIL in which the generation of the bag label  $y$  is conditioned on the instance labels  $\mathbf{z}$ . As a result of this setup, their model reduces to our S-Mix baseline in a fully unsupervised setting.

Finally, although we motivated including the review-level latent variable  $y$  as a way to improve segment-level prediction of  $\mathbf{z}$ , note that predictions of  $y$  are useful in and of themselves. They provide some notion of review *usefulness* and can be used to filter reviews for search and browsing. They additionally give us a way to measure whether a set of instructions is often modified or performed as specified. Finally, if we want to provide supervision, it is much easier to annotate whether a review contains a refinement than to annotate each segment.

## 4.2 Alignment with the Instructions

In addition to the review  $\mathbf{x}$ , we also observe the set of instructions  $\mathbf{s}$  being discussed. Often a review will reference specific parts of the instructions. We assume that each set of instructions is segmented into *steps*,  $\mathbf{s} = (s_1, \dots, s_S)$ . We augment our model with latent *alignment* variables  $\mathbf{a} = (a_1, \dots, a_T)$ , where  $a_j = \ell$  denotes that the  $j$ th review segment is referring to the  $\ell$ th step of  $\mathbf{s}$ . We also define a special NULL instruction step. An alignment to NULL signifies that the segment does not refer to a specific instruction step. Note that this encoding assumes that each review segment refers to at most one instruction step. Alignment predictions could facilitate further analysis of how refinements affect the instructions, as well as aid in summarization and visualization of

refinements.

The joint probability under the augmented model, which we refer to as RSA-MixHMM, is

$$p(\mathbf{a}, \mathbf{x}, y, \mathbf{z} | \mathbf{s}; \boldsymbol{\theta}) = p(y; \boldsymbol{\theta}) p(\mathbf{a}, \mathbf{x}, \mathbf{z} | y, \mathbf{s}; \boldsymbol{\theta}) \quad (3)$$

$$p(\mathbf{a}, \mathbf{x}, \mathbf{z} | y, \mathbf{s}; \boldsymbol{\theta}) = \prod_{j=1}^T p(a_j, z_j | a_{j-1}, z_{j-1}, y, \mathbf{s}; \boldsymbol{\theta})$$

$$\times p(\mathbf{x}_j | a_j, z_j, \mathbf{s}; \boldsymbol{\theta}).$$

Note that the instructions  $\mathbf{s}$  are assumed to be observed and hence are not generated by the model. RSA-MixHMM can be viewed as a mixture of HMMs where each state encodes both a segment label  $z_j$  and an alignment variable  $a_j$ . Encoding an alignment problem as a sequence labeling problem was first proposed by Vogel et al. (1996). Note that RSA-MixHMM uses a similar expanded state representation and transition structure as RS-MixHMM to encode the semantics of  $y$ .

In our current model, the transition probability decomposes into the product of independent label transition and alignment transition probabilities

$$p(a_j, z_j | a_{j-1}, z_{j-1}, y, \mathbf{s}; \boldsymbol{\theta}) = p(a_j | a_{j-1}, y, \mathbf{s}; \boldsymbol{\theta})$$

$$\times p(z_j | z_{j-1}, y, \mathbf{s}; \boldsymbol{\theta}),$$

and  $p(a_j | a_{j-1}, y, \mathbf{s}; \boldsymbol{\theta}) = p(a_j | y, \mathbf{s}; \boldsymbol{\theta})$  simply encodes the probability that segments align to a (non-NULL) instruction step given  $y$ . This allows the model to learn, for example, that reviews that contain refinements refer to the instructions more often.

Intuitively, a segment and the step it refers to should be lexically similar. Consequently, RSA-MixHMM generates segments using a mixture of the multinomial distribution for the segment label  $z_j$  and the (fixed) multinomial distribution<sup>3</sup> for the step  $s_{a_j}$ . In this paper, we do not model the mixture probability and simply assume that all overlapping words are generated by the instruction step. When  $a_j = \text{NULL}$ , only the segment label multinomial is used. Finally, we disallow an alignment to a non-NULL step if no words overlap:  $p(\mathbf{x}_j | a_j, z_j, \mathbf{s}; \boldsymbol{\theta}) = 0$ .

## 4.3 Inference and Parameter Estimation

Because our model is tree-structured, we can efficiently compute exact marginal distributions

<sup>3</sup>Stopwords are removed from the instruction step.

over latent variables using the *sum-product algorithm* (Koller and Friedman, 2009). Similarly, to find maximum probability assignments, we use the *max-product algorithm*.

At training time we observe a set of reviews and corresponding instructions,  $\mathcal{D} = \{(\mathbf{x}^1, \mathbf{s}^1), \dots, (\mathbf{x}^N, \mathbf{s}^N)\}$ . The other variables,  $y$ ,  $\mathbf{z}$ , and  $\mathbf{a}$ , are latent. For all models, we estimate parameters to maximize the marginal likelihood of the observed reviews. For example, for RSA-MixHMM, we estimate parameters using

$$\arg \max_{\theta} \sum_{i=1}^N \log \sum_{\mathbf{a}, \mathbf{z}, y} p(\mathbf{a}, \mathbf{x}^i, y, \mathbf{z} | \mathbf{s}^i; \theta).$$

This problem cannot be solved analytically, so we use the Expectation Maximization (EM) algorithm.

## 5 Experiments

### 5.1 Data

In this paper, we use recipes and reviews from *allrecipes.com*, an active community where we estimate that the mean number of reviews per recipe is 54.2. We randomly selected 22,437 reviews for our data set. Of these, we randomly selected a subset of 550 reviews and determined whether or not each contains a refinement, using the definition provided in Section 3. In total, 318 of the 550 (57.8%) contain a refinement. We then randomly selected 119 of the 550 and labeled the individual segments. Of the 712 segments in the selected reviews, 165 (23.2%) are refinements and 547 are background.

We now define our review segmentation scheme. Most prior work on modeling latent document substructure uses sentence-level labels (Barzilay and Lee, 2004; Täckström and McDonald, 2011). In the recipe data, we find that sentences often contain both refinement and background segments: “[I used a slow cooker with this recipe and] [it turned out great!]” Additionally, we find that sentences often contain several distinct refinements: “[I set them on top and around the pork and] [tossed in a can of undrained french cut green beans and] [cooked everything on high for about 3 hours].” To make refinements easier to identify, and to facilitate downstream processing, we allow sub-sentence segments.

Our segmentation procedure leverages a phrase structure parser. In this paper we use the Stanford

Parser<sup>4</sup>. Based on a quick manual inspection, domain shift and ungrammatical sentences do cause a significant degradation in parsing accuracy when compared to in-domain data. However, this is acceptable because we only use the parser for segmentation. We first parse the entire review, and subsequently iterate through the tokens, adding a segment break when any of the following conditions is met:

- sentence break (determined by the parser)
- token is a *coordinating conjunction* (CC) with parent other than NP, PP, ADJP
- token is a *comma* (,) with parent other than NP, PP, ADJP
- token is a *colon* (:)

The resulting segmentations are fixed during learning. In future work we could extend our model to additionally identify segment boundaries.

### 5.2 Experimental Setup

We first describe the methods we evaluate. For comparison, we provide results with a baseline that randomly guesses according to the class distribution for each task. We also evaluate a **Review-level** model:

- **R-Mix**: A review-level mixture of multinomials with two latent states.

Note that this is similar to clustering at the review level, except that class priors are estimated. R-Mix does not provide segment labels, though they can be obtained by labeling all segments with the review label.

We also evaluate the two **Segment-level** models described in Section 4.1 (with two latent states):

- **S-Mix**: A segment-level mixture model.
- **S-HMM**: A segment-level HMM (Eq. 1).

These models do not provide review labels. To obtain them, we assign  $y = \text{yes}$  if any segment is labeled as a refinement, and  $y = \text{no}$  otherwise.

Finally, we evaluate three versions of our model (**Review + Segment** and **Review + Segment +**

<sup>4</sup><http://nlp.stanford.edu/software/lex-parser.shtml>

Alignment) with one refinement segment label and one background segment label<sup>5</sup>:

- **RS-MixHMM**: A mixture of HMMs (Eq. 2) with constraints (1) and (2) (see Section 4).
- **RS-MixMix**: A variant of RS-MixHMM without sequential dependencies.
- **RSA-MixHMM**: The full model that also incorporates alignment (Eq. 3).

Segment multinomials are initialized with a small amount of random noise to break the initial symmetry. RSA-MixHMM segment multinomials are instead initialized to the RS-MixHMM solution. We apply add-0.01 smoothing to the emission multinomials and add-1 smoothing to the transition multinomials in the M-step. We estimate parameters with 21,887 unlabeled reviews by running EM until the relative percentage decrease in the marginal likelihood is  $\leq 10^{-4}$  (typically 10-20 iterations).

The models are evaluated on refinement  $F_1$  and accuracy for both review and segment predictions using the annotated data described in Section 5.1. For R-Mix and the segment (S-) models, we select the 1:1 mapping of latent states to labels that maximizes  $F_1$ . For RSA-MixHMM and the RS- models this was not necessary (see Section 4.1).

### 5.3 Results

Table 1 displays the results. R-Mix fails to accurately distinguish refinement and background reviews. The words that best discriminate the two discovered review classes are “savory ingredients” (*chicken, pepper, meat, garlic, soup*) and “baking/dessert ingredients” (*chocolate, cake, pie, these, flour*). In other words, reviews naturally cluster by topics rather than whether they contain refinements.

The segment models (S-) substantially outperform R-Mix on all metrics, demonstrating the benefit of segment-level modeling and our segmentation scheme. However, S-HMM fails to model the “burstiness” of refinement segments (see Section 4.1). It predicts that 76.2% of reviews contain refinements, and additionally that 40.9% of segments contain refinements, whereas the true values

<sup>5</sup>Attempts at modeling refinement and background subtypes by increasing the number of latent states failed to substantially improve the results.

are 57.8% and 23.2%, respectively. As a result, these models provide high recall but low precision.

In comparison, our models, which model the review labels<sup>6</sup>  $y$ , yield more accurate refinement predictions. They provide statistically significant improvements in review and segment  $F_1$ , as well as accuracy, over the baseline models. RS-MixHMM predicts that 62.9% of reviews contain refinements and 28.2% of segments contain refinements, values that are much closer to the ground truth. The refinement emission distributions for S-HMM and RS-MixHMM are fairly similar, but the probabilities of several key terms like *added, used, and instead* are higher with RS-MixHMM.

The review  $F_1$  results demonstrate that our models are able to very accurately distinguish refinement reviews from background reviews. As motivated in Section 4.1, there are several applications that can benefit from review-level predictions directly. Additionally, note that review labeling is not a trivial task. We trained a supervised logistic regression model with bag-of-words and length features (for both the number of segments and the number of words) using 10-fold cross validation on the labeled dataset. This supervised model yields mean review  $F_1$  of 78.4, 11.7  $F_1$  points below the best unsupervised result<sup>7</sup>.

Augmenting RS-MixMix with sequential dependencies, yielding RS-MixHMM, provides a moderate (though not statistically significant) improvement in segment  $F_1$ . RS-MixHMM learns that refinement reviews typically begin and end with background segments, and that refinement segments tend to appear in succession.

RSA-MixHMM additionally learns that segments in refinement reviews are more likely to align to non-NULL recipe steps. It also encourages the segment multinomials to focus modeling effort on words that appear only in the reviews. As a result, in addition to yielding alignments, RSA-MixHMM provides small improvements over RS-MixHMM (though they are not statistically significant).

<sup>6</sup>We note that enforcing the constraint that a refinement review must contain at least one refinement segment using the method in Section 4.1 provides a statistically significant improvement in review  $F_1$  of 4.0 for RS-MixHMM.

<sup>7</sup>Note that we do not consider this performance to be the upper-bound of supervised approaches; clearly, supervised approaches could benefit from additional labeled data. However, labeled data is relatively expensive to obtain for this task.

Model	review (57.8% refinement)				segment (23.2% refinement)			
	acc	prec	rec	F <sub>1</sub>	acc	prec	rec	F <sub>1</sub>
random baseline	51.2 <sup>†</sup>	57.8	57.8	57.8 <sup>†</sup>	64.4 <sup>†</sup>	23.2	23.2	23.2 <sup>†</sup>
R-Mix	61.5 <sup>†</sup>	69.1	60.4	64.4 <sup>†</sup>	55.8 <sup>†</sup>	27.9	57.6	37.6 <sup>†</sup>
S-Mix	77.5 <sup>†</sup>	72.4	<b>98.7</b>	83.5 <sup>†</sup>	80.6 <sup>†</sup>	54.7	95.2	69.5 <sup>†</sup>
S-HMM	79.8 <sup>†</sup>	74.7	98.4	84.9 <sup>†</sup>	80.3 <sup>†</sup>	54.3	<b>95.8</b>	69.3 <sup>†</sup>
RS-MixMix	87.1	85.4	93.7	89.4	86.4	65.6	86.7	74.7
RS-MixHMM	87.3	85.6	93.7	89.5	87.9	69.7	84.8	76.5
RSA-MixHMM	<b>88.2</b>	<b>87.1</b>	93.4	<b>90.1</b>	<b>88.5</b>	<b>71.7</b>	83.0	<b>77.0</b>

Table 1: Unsupervised experiments comparing models for review and segment refinement identification on the recipe data. Bold indicates the best result, and a † next to an accuracy or F<sub>1</sub> value indicates that the improvements obtained by RS-MixMix, RS-MixHMM, and RSA-MixHMM are significant ( $p = 0.05$  according to a bootstrap test).

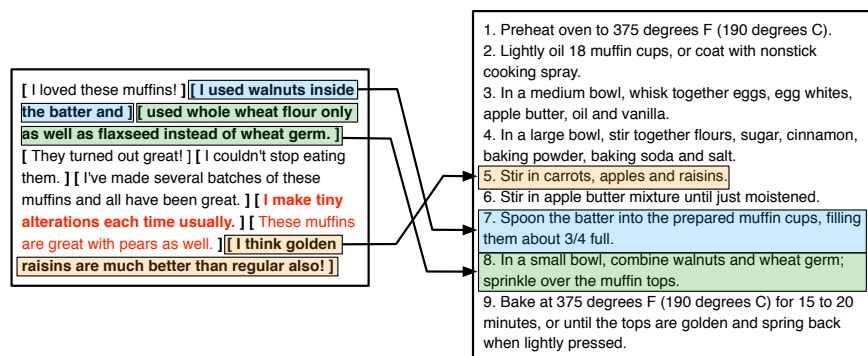

Figure 1: Example output (best viewed in color). Bold segments in the review (left) are those predicted to be refinements. Red indicates an incorrect segment label, according to our gold labels. Alignments to recipe steps (right) are indicated with colors and arrows. Segments without colors and arrows align to the NULL recipe step (see Section 4.2).

We provide an example alignment in Figure 1. Annotating ground truth alignments is challenging and time-consuming due to ambiguity, and we feel that the alignments are best evaluated via a downstream task. Therefore, we leave thorough evaluation of the quality of the alignments to future work.

## 6 Conclusion and Future Work

In this paper, we developed unsupervised methods based on generative models for mining refinements to online instructions from reviews. The proposed models leverage lexical differences in refinement and background segments. By augmenting the base models with additional structure (review labels, alignments), we obtained more accurate predictions.

However, to further improve accuracy, more linguistic knowledge and structure will need to be incorporated. The current models provide many false positives in the more subtle cases, when some words

that typically indicate a refinement are present, but the text does not describe a refinement according to the definition in Section 3. Examples include hypothetical refinements (“next time I will substitute...”) and discussion of the recipe without modification (“I found it strange to... but it worked ...”, “I love balsamic vinegar and herbs”, “they baked up nicely”).

Other future directions include improving the alignment model, for example by allowing words in the instruction step to be “translated” into words in the review segment. Though we focussed on recipes, the models we proposed are general, and could be applied to other domains. We also plan to consider this task in other settings such as online forums, and develop methods for summarizing refinements.

# Sentence Dependency Tagging in Online Question Answering Forums

Zhonghua Qu and Yang Liu  
The University of Texas at Dallas  
{qzh, yangl@hlt.utdallas.edu}

## Abstract

Online forums are becoming a popular resource in the state of the art question answering (QA) systems. Because of its nature as an online community, it contains more updated knowledge than other places. However, going through tedious and redundant posts to look for answers could be very time consuming. Most prior work focused on extracting only question answering sentences from user conversations. In this paper, we introduce the task of sentence dependency tagging. Finding dependency structure can not only help find answer quickly but also allow users to trace back how the answer is concluded through user conversations. We use linear-chain conditional random fields (CRF) for sentence type tagging, and a 2D CRF to label the dependency relation between sentences. Our experimental results show that our proposed approach performs well for sentence dependency tagging. This dependency information can benefit other tasks such as thread ranking and answer summarization in online forums.

## 1 Introduction

Automatic Question Answering (QA) systems rely heavily on good sources of data that contain questions and answers. Question answering forums, such as technical support forums, are places where users find answers through conversations. Because of their nature as online communities, question answering forums provide more updated answers to new problems. For example, when the latest release of Linux has a bug, we can expect to find solutions

in forums first. However, unlike other structured knowledge bases, often it is not straightforward to extract information such as questions and answers in online forums because such information spreads in the conversations among multiple users in a thread.

A lot of previous work has focused on extracting the question and answer sentences from forum threads. However, there is much richer information in forum conversations, and simply knowing a sentence is a question or answer is not enough. For example, in technical support forums, often it takes several iterations of asking and clarifications to describe the question. The same happens to answers. Usually several candidate answers are provided, and not all answers are useful. In this case users' feedback is needed to judge the correctness of answers.

Figure 1 shows an example thread in a technical support forum. Each sentence is labeled with its type (a detailed description of sentence types is provided Table 1). We can see from the example that questions and answers are not expressed in a single sentence or a single post. Only identifying question and answering sentences from the thread is not enough for automatic question answering. For this example, in order to get the complete question, we would need to know that sentence *S3* is a question that inquires for more details about the problem asked earlier, instead of stating its own question. Also, sentence *S5* should not be included in the correct answer since it is not a working solution, which is indicated by a negative feedback in sentence *S6*. The correct solution should be sentence *S7*, because of a user's positive confirmation *S9*. We define that there is a dependency between a pair of sentences if one sentence

**A:** [S1:M-GRET] *Hi everyone.* [S2:P-STAT] *I have recently purchased USB flash and I am having trouble renaming it, please help me.*  
**B:** [S3:A-INQU] *What is the size and brand of this flash?*  
**A:** [S4:Q-CLRF] *It is a 4GB SanDisk flash.*  
**B:** [S5:A-SOLU] *Install gparted, select flash drive and rename.*  
**A:** [S6:M-NEGA] *I got to the Right click on partition and the label option was there but grayed out.*  
**B:** [S7:A-SOLU] *Sorry again, I meant to right click the partition and select Unmount and then select Change name while in gparted.*  
**A:** [S8:C-GRAT] *Thank you so much.* [S9:M-POST] *I now have an "Epic USB" You Rock!*

Figure 1: Example of a Question Answering Thread in Ubuntu Support Forum

exists as a result of another sentence. For example, question context sentences exist because of the question itself; an answering sentence exists because of a question; or a feedback sentence exists because of an answer. The sentence dependency structure of this example dialog is shown in Figure 2.

Figure 2: Dependency Structure of the Above Example

This example shows that in order to extract information from QA forums accurately, we need to understand the sentence dependency structure of a QA thread. Towards this goal, in this paper, we define two tasks: labeling the types for sentences, and finding the dependency relations between sentences.

For the first task of sentence type labeling, we define a rich set of categories representing the purpose

of the sentences. We use linear-chain conditional random fields (CRF) to take advantage of many long-distance and non-local features. The second task is to identify relations between sentences. Most previous work only focused on finding the answer-question relationship between sentences. However, other relations can also be useful for information extraction from online threads, such as user’s feedbacks on the answers, problem detail inquiry and question clarifications. In this study, we use two approaches for labeling of dependency relation between sentences. First each sentence is considered as a source, and we run a linear-chain CRF to label whether each of the other sentences is its target. Because multiple runs of separate linear-chain CRFs ignore the dependency between source sentences, the second approach we propose is to use a 2D CRF that models all pair relationships jointly.

The data we used was collected from Ubuntu forum general help section. Our experimental results show that our proposed sentence type tagging method works very well, even for the minority categories, and that using 2D CRF further improves performance over linear-chain CRFs for identifying dependency relation between sentences.

The paper is organized as follows. In the following section, we discuss related work on finding questions and answers in online environment as well as some dialog act tagging techniques. In Section 3, we introduce the use of CRFs for sentence type and dependency tagging. Section 4 describes data collection, annotation, and some analysis. In Section 5, we show that our approach achieves promising results in thread sentence dependency tagging. Finally we conclude the paper and suggest some possible future extensions.

## 2 Related Work

There is a lot of useful knowledge in the user generated content such as forums. This knowledge source could substantially help automatic question answering systems. There has been some previous work focusing on the extraction of question and corresponding answer pairs in online forums. In (Ding et al., 2008), a two-pass approach was used to find relevant solutions for a given question, and a skip-chain CRF was adopted to model long range de-

pendency between sentences. A graph propagation method was used in (Cong et al., 2008) to rank relevant answers to questions. An approach using email structure to detect and summarize question answer pairs was introduced in (Shrestha and Mckeown, 2004). These studies focused primarily on finding questions and answers in an online environment. In this paper, in order to provide a better foundation for question answer detection in online forums, we investigate tagging sentences with a much richer set of categories, as well as identifying their dependency relationships. The sentence types we use are similar to dialog acts (DA), but defined specifically for question answering forums. Work of (Clark and Popescu-Belis, 2004) defined a reusable multi-level tagset that can be mapped from conversational speech corpora such as the ICSI meeting data. However, it is hard to reuse any available corpus or DA tagset because our task is different, and also online forum has a different style from speech data. Automatic DA tagging has been studied a lot previously. For example, in (Stolcke et al., 2000), Hidden Markov Models (HMMs) were used for DA tagging; in (Ji and Bilmes, 2005), different types of graphical models were explored.

Our study is different in several aspects: we are using forum domains, unlike most work of DA tagging on conversational speech; we use CRFs for sentence type tagging; and more importantly, we also propose to use different CRFs for sentence relation detection. Unlike the pair-wise sentence analysis proposed in (Boyer et al., 2009) in which HMM was used to model the dialog structure, our model is more flexible and does not require related sentences to be adjacent.

### 3 Thread Structure Tagging

As described earlier, we decompose the structure analysis of QA threads into two tasks, first determine the sentence type, and then identify related sentences. This section provides details for each task.

#### 3.1 Sentence Type Tagging

In human conversations, especially speech conversations, DAs have been used to represent the purpose or intention of a sentence. Different sets of

DAs have been adopted in various studies, ranging from very coarse categories to fine grained ones. In this study, we define 13 fine grained sentence types (corresponding to 4 coarse categories) tailored to our domain of QA forum threads. Table 1 shows the categories and their description. Some tags such as P-STAT and A-SOLU are more important in that users try to state a problem and provide solutions accordingly. These are the typical ones used in previous work on question answering. Our set includes other useful tags. For example, C-NEGA and C-POSI can evaluate how good an answer is. Even though C-GRAT does not provide any direct feedback on the solutions, existence of such a tag often strongly implies a positive feedback to an answer. These sentence types can be grouped into 4 coarse categories, as shown in Table 1.

Types	Category	Description
Problems	P-STAT	question of problem
	P-CONT	problem context
	P-CLRF	problem clarification
Answers	A-SOLU	solution sentence
	A-EXPL	explanation on solutions
	A-INQU	inquire problem details
Confirm.	C-GRAT	gratitude
	C-NEGA	negative feedback
	C-POSI	positive feedback
Misc.	M-QCOM	question comment
	M-ACOM	comment on the answer
	M-GRET	greeting and politeness
	M-OFF	off-topic sentences

Table 1: Sentence Types for QA Threads

To automatically label sentences in a thread with their types, we adopt a sequence labeling approach, specifically linear-chain conditional random fields (CRFs), which have shown good performance in many other tasks (Lafferty, 2001). Intuitively there is a strong dependency between adjacent sentences. For example, in our data set, 45% sentences following a greeting sentence (M-GRET) are question related sentences; 53% sentences following a question inquiry sentence (Q-INQ) are solution related sentences. The following describes our modeling approaches and features used for sentence type tagging.

### 3.1.1 Linear-chain Conditional Random Field

Linear-chain CRFs is a type of undirected graphical models. Distribution of a set of variables in undirected graphical models can be written as

$$p(x, y) = \frac{1}{Z} \prod_A \psi_A(x_A, y_A) \quad (1)$$

$Z$  is the normalization constant to guarantee valid probability distributions. CRFs is a special case of undirected graphical model in which  $\psi$  are log-linear functions:

$$\psi_A(x_A, y_A) = \exp \left\{ \sum_k \theta_{A_k} f_{A_k}(x_A, y_A) \right\} \quad (2)$$

$\theta_A$  is a real value parameter vector for feature function set  $f_A$ . In the sequence labeling task, feature functions across the sequence are often tied together. In other words, feature functions at different locations of the sequence share the same parameter vector  $\theta$ .

Figure 3: Graphical Structure of Linear-chain CRFs.

Linear-chain CRF is a special case of the general CRFs. In linear-chain CRF, cliques only involve two adjacent variables in the sequence. Figure 3 shows the graphical structure of a linear-chain CRF. In our case of sentence tagging, cliques only contain two adjacent sentences. Given the observation  $x$ , the probability of label sequence  $y$  is as follows:

$$p(y|x) = \frac{1}{Z} \prod_{i=1}^{|y|} \psi_e(x, y, i) \prod_{j=0}^{|y|} \psi_v(x, y, j) \quad (3)$$

$$\psi_e(x, y, i) = \exp \left\{ \sum_k \theta_{e_k} f_{e_k}(y_{i-1}, y_i, x, i) \right\} \quad (4)$$

$$\psi_v(x, y, j) = \exp \left\{ \sum_k \theta_{v_k} f_{v_k}(y_j, x, j) \right\} \quad (5)$$

where feature templates  $f_{e_k}$  and  $f_{v_k}$  correspond to edge features and node features respectively.

#### Feature Description

Cosine similarity with previous sentence.
Quote segment within two adjacent sentences?
Code segment within two adjacent sentences?
Does this sentence belong to author's post?
Is it the first sentence in a post?
Post author participated thread before?
Does the sentence contain any negative words?
Does the sentence contain any URL?
Does the sentence contain any positive words?
Does the sentence contain any question mark?
Length of the sentence.
Presence of verb.
Presence of adjective.
Sentence perplexity based on a background LM.
Bag of word features.

Table 2: Features Used in Sentence Type Tagging.

### 3.1.2 Sentence Type Tagging Features

We used various types of feature functions in sentence type tagging. Table 2 shows the complete list of features we used. Edge features are closely related to the transition between sentences. Here we use the cosine similarity between sentences, where each sentence is represented as a vector of words, with term weight calculated using TD-IDF (term frequency times inverse document frequency). High similarity between adjacent sentences suggests similar or related types. For node features, we explore different sources of information about the sentence. For example, the presence of a question mark indicates that a sentence may be a question or inquiry. Similarly, we include other cues, such as positive or negative words, verb and adjective words. Since technical forums tend to contain many system outputs, we include the perplexity of the sentence as a feature which is calculated based on a background language model (LM) learned from common English documents. We also use bag-of-word features as in many other text categorization tasks.

Furthermore, we add features to represent post level information to account for the structure of QA threads, for example, whether or not a sentence belongs to the author's post, or if a sentence is the beginning sentence of a post.

### 3.2 Sentence Dependency Tagging

Knowing only the sentence types without their dependency relations is not enough for question answering tasks. For example, correct labeling of an answer without knowing which question it actually refers to is problematic; not knowing which answer a positive or negative feedback refers to will not be helpful at all. In this section we describe how sentence dependency information is determined. Note that sentence dependency relations might not be a one-to-one relation. A many-to-many relation is also possible. Take question answer relation as an example. There could be potentially many answers spreading in many sentences, all depending on the same question. Also, it is very likely that a question is expressed in multiple sentences too.

Dependency relationship could happen between many different types of sentences, for example, answer(s) to question(s), problem clarification to question inquiry, feedback to solutions, etc. Instead of developing models for each dependency type, we treat them uniformly as dependency relations between sentences. Hence, for every two sentences, it becomes a binary classification problem, i.e., whether or not there exists a dependency relation between them. For a pair of sentences, we call the depending sentence the **source** sentence, and the depended sentence the **target** sentence. As described earlier, one source sentence can potentially depend on many different target sentences, and one target sentence can also correspond to multiple sources.

The sentence dependency task is formally defined as, given a set of sentences  $S_t$  of a thread, find the dependency relation  $\{(s, t) | s \in S_t, t \in S_t\}$ , where  $s$  is the source sentence and  $t$  is the target sentence that  $s$  depends on.

We propose two methods to find the dependency relationship. In the first approach, for each source sentence, we run a labeling procedure to find the dependent sentences. From the data, we found given a source sentence, there is strong dependency between adjacent target sentences. If one sentence is a target sentence of the source, often the next sentence is a target sentence too. In order to take advantage of such adjacent sentence dependency, we use the linear-chain CRFs for the sequence labeling. Features used in sentence dependency labeling are listed

in Table 3. Note that a lot of the node features used here are relative to the source sentence since the task here is to determine if the two sentences are related. For a thread of  $N$  sentences, we need to perform  $N$  runs of CRF labeling, one for each sentence (as the source sentence) in order to label the target sentence corresponding to this source sentence.

Feature Description	
*	Cosine similarity with previous sentence.
*	Is adjacent sentence of the same type?
*	Pair of types of the adjacent target sentences. Pair of types of the source and target sentence. Is target in the same post as the source? Do target and source belong to the same author? Cosine similarity between target and source sentence. Does target sentence happen before source? Post distance between source and target sentence.
* indicates an edge feature	

Table 3: Features Used in Sentence Dependency Labeling

The linear-chain CRFs can represent the dependency between adjacent target sentences quite well. However they cannot model the dependency between adjacent source sentences, because labeling is done for each source sentence individually. To model the dependency between both the source sentences and the target sentences, we propose to use 2D CRFs for sentence relation labeling. 2D CRFs are used in many applications considering two dimension dependencies such as object recognitions (Quattoni et al., 2004) and web information extraction (Zhu et al., 2005). The graphical structure of a 2D CRF is shown in Figure 4. Unlike one dimensional sequence labeling, a node in 2D environment is dependent on both x-axis neighbors and y-axis neighbors. In the sentence relation task, the source and target pair is a 2D relation in which its label depends on labels of both its adjacent source and its adjacent target sentence. As shown in Figure 4, looking from x-axis is the sequence of target sentences with a fixed source sentence, and from y-axis is the sequence of source sentences with a fixed target sentence. This model allows us to model all the sentence relationships jointly. 2D CRFs contain 3 templates of features: node template, x-axis edge template, and y-axis edge template. We use the same edge features and node features as in linear-chain CRFs for node features and y-axis edge features in

2D CRFs. For the x-axis edge features, we use the same feature functions as for y-axis, except that now they represent the relation between adjacent source sentences.

Figure 4: Graphical Structure of 2D CRF for Sentence Relation Labeling.

In a thread containing  $N$  sentences, we would have a 2D CRF containing  $N^2$  nodes in a  $N \times N$  grid. Exact inference in such a graph is intractable. In this paper we use loopy belief propagation algorithm for the inference. Loopy belief propagation is a message passing algorithm for graph inference. It calculates the marginal distribution for each node in the graph. The result is exact in some graph structures (e.g., linear-chain CRFs), and often converges to a good approximation for general graphs.

## 4 Data

We used data from ubuntu community forum general help section for the experiments and evaluation. This is a technical support section that provides answers to the latest problems in Ubuntu Linux. Among all the threads that we have crawled, we selected 200 threads for this initial study. They contain between 2 – 10 posts and at least 2 participants. Sentences inside each thread are segmented using Apache OpenNLP tools. In total, there are 706 posts and 3,483 sentences. On average, each thread contains 3.53 posts, and each post contains around 4.93 sentences. Two annotators were recruited to annotate the sentence type and the dependency relation between sentences. Annotators are both computer science department undergraduate students. They are provided with detailed explanation of the annotation standard. The distribution of sentence types in the annotated data is shown in Table 4, along with inter-annotator Kappa statistics calculated using 20

common threads annotated by both annotators. We can see that the majority of the sentences are about problem descriptions and solutions. In general, the agreement between the two annotators is quite good.

General Type	Category	Percentage	Kappa
Problems	P-STAT	12.37	0.88
	P-CONT	37.30	0.77
	P-CLRF	1.01	0.98
Answers	A-SOLU	9.94	0.89
	A-EXPL	11.60	0.89
	A-INQU	1.38	0.99
Confirmation	C-GRAT	5.06	0.98
	C-NEGA	1.98	0.96

Table 4: Distribution and Inter-annotator Agreement of Sentence Types in Data

There are in total 1,751 dependency relations identified by the annotators among those tagged sentences. Note that we are only dealing with intra-thread sentence dependency, that is, no dependency among sentences in different threads is labeled. Considering all the possible sentence pairs in each thread, the labeled dependency relations represent a small percentage. The most common dependency is problem description to problem question. This shows that users tend to provide many details of the problem. This is especially true in technical forums. Seeing questions without their context would be confusing and hard to solve. The relation of answering solutions and question dependency is also very common, as expected. The third common relation is the feedback dependency. Even though the number of feedback sentences is small in the data set, it plays a vital role to determine the quality of answers. The main reason for the small number is that, unlike problem descriptions, much fewer sentences are needed to give feedbacks.

## 5 Experiment

In the experiment, we randomly split annotated threads into three disjoint sets, and run a three-fold cross validation. Within each fold, first sentence types are labeled using linear-chain CRFs, then the

resulting sentence type tagging is used in the second pass to determine dependency relations. For part-of-speech (POS) tagging of the sentences, we used Stanford POS Tagger (Toutanova and Manning, 2000). All the graphical inference and estimations are done using MALLET package (McCallum, 2002).

In this paper, we evaluate the results using standard precision and recall. In the sentence type tagging task, we calculate precision, recall, and  $F_1$  score for each individual tag. For the dependency tagging task, a pair identified by the system is correct only if the exact pair appears in the reference annotation. Precision and recall scores are calculated accordingly.

### 5.1 Sentence Type Tagging Results

The results of sentence type tagging using linear-chain CRFs are shown in Table 5. For a comparison, we include results using a basic first-order HMM model. Because HMM is a generative model, we use only bag of word features in the generative process. The observation probability is the probability of the sentence generated by a unigram language model, trained for different sentence types. Since for some applications, fine grained categories may not be needed, for example, in the case of finding questions and answers in a thread, we also include in the table the tagging results when only the general categories are used in both training and testing.

We can see from the table that using CRFs achieves significantly better performance than HMMs for most categories, except greeting and off-topic types. This is mainly because of the advantage of CRFs, allowing the incorporation of rich discriminative features. For the two major types of problems and answers, in general, our system shows very good performance. Even for minority types like feedbacks, it also performs reasonably well. When using coarse types, the performance on average is better compared to the finer grained categories, mainly because of the fewer classes in the classification task. Using the fine grained categories, we found that the system is able to tell the difference between “problem statement” (P-STAT) and “problem context” (P-CONT). Note that in our task, a problem statement is not necessarily a question sentence. Instead it could be any sentence that expresses the need for a solu-

Table 5: Sentence Type Tagging Performance Using CRFs and HMM.

tion.

We also performed some analysis of the features using the feature weights in the trained CRF models. We find that some post level information is relatively important. For example, the feature representing whether the sentence is before a “code” segment has a high weight for problem description classification. This is because in linux support forum, people usually put some machine output after their problem description. We also notice that the weights for verb words are usually high. This is intuitive since the “verb” of a sentence can often determine its purpose.

### 5.2 Sentence Dependency Tagging Results

Table 6 shows the results using linear-chain CRFs (L-CRF) and 2D CRFs for sentence dependency tagging. We use different settings in our experiments. For the categories of sentence types, we evaluate using both the fine grained (13 types) and the coarse categories (4 types). Furthermore, we examine two ways to obtain the sentence types. First, we use the output from automatic sentence type tagging. In the second one, we use the sentence type information from the human annotated data in order to avoid the error propagation from automatic sentence type la-

belonging. This gives an oracle upper bound for the second pass performance.

Using Oracle Sentence Type				
Setup		Precision	Recall	$F_1$
13 types	L-CRF	0.973	0.453	0.618
	2D-CRF	0.985	0.532	0.691
4 general	L-CRF	0.941	0.124	0.218
	2D-CRF	0.956	0.145	0.252
Using System Sentence Type				
Setup		Precision	Recall	$F_1$
13 types	L-CRF	0.943	0.362	0.523
	2D-CRF	0.973	0.394	0.561
4 general	L-CRF	0.939	0.101	0.182
	2D-CRF	0.942	0.127	0.223

Table 6: Sentence Dependency Tagging Performance

From the results we can see that 2D CRFs outperform linear-chain CRFs for all the conditions. This shows that by modeling the 2D dependency in source and target sentences, system performance is improved. For the sentence types, when using automatic sentence type tagging systems, there is a performance drop. The performance gap between using the reference and automatic sentence types suggests that there is still room for improvement from better sentence type tagging. Regarding the categories used for the sentence types, we observe that they have an impact on dependence tagging performance. When using general categories, the performance is far behind that using the fine grained types. This is because some important information is lost when grouping categories. For example, a dependency relation can be: “A-EXPL” (explanation for solutions) depends on “A-SOLU” (solutions); however, when using coarse categories, both are mapped to “Solution”, and having one “Solution” depending on another “Solution” is not very intuitive and hard to model properly. This shows that detailed category information is very important for dependency tagging even though the tagging accuracy from the first pass is far from perfect.

Currently our system does not put constraints on the sentence types for which dependencies exist. In the system output we find that sometimes there are obvious dependency errors, such as a positive feedback depending on a negative feedback. We may improve our models by taking into account different sentence types and dependency relations.

## 6 Conclusion

In this paper, we investigated sentence dependency tagging of question and answer (QA) threads in on-line forums. We define the thread tagging task as a two-step process. In the first step, sentence types are labeled. We defined 13 sentence types in order to capture rich information of sentences to benefit question answering systems. Linear chain CRF is used for sentence type tagging. In the second step, we label actual dependency between sentences. First, we propose to use a linear-chain CRF to label possible target sentences for each source sentence. Then we improve the model to consider the dependency between sentences along two dimensions using a 2D CRF. Our experiments show promising performance in both tasks. This provides a good pre-processing step towards automatic question answering. In the future, we plan to explore using constrained CRF for more accurate dependency tagging. We will also use the result from this work in other tasks such as answer quality ranking and answer summarization.

## Abstract

We predict entity type distributions in Web search queries via probabilistic inference in graphical models that capture how entity-bearing queries are generated. We jointly model the interplay between latent user intents that govern queries and unobserved entity types, leveraging observed signals from query formulations and document clicks. We apply the models to resolve entity types in new queries and to assign prior type distributions over an existing knowledge base. Our models are efficiently trained using maximum likelihood estimation over millions of real-world Web search queries. We show that modeling user intent significantly improves entity type resolution for head queries over the state of the art, on several metrics, without degradation in tail query performance.

## 1 Introduction

Commercial search engines are providing ever-richer experiences around entities. Querying for a dish on Google yields recipe filters such as cook time, calories, and ingredients. Querying for a movie on Yahoo triggers user ratings, cast, tweets and showtimes. Bing further allows the movie to be directly added to the user's Netflix queue. Entity repositories such as Freebase, IMDB, Facebook Pages, Factual, Pricegrabber, and Wikipedia are increasingly leveraged to enable such experiences.

There are, however, inherent problems in the entity repositories: (a) coverage: although coverage of head entity types is often reliable, the tail can be sparse; (b) noise: created by spammers, extraction

errors or errors in crowdsourced content; (c) ambiguity: multiple types or entity identifiers are often associated with the same surface string; and (d) over-expression: many entities have types that are never used in the context of Web search.

There is an opportunity to automatically tailor knowledge repositories to the Web search scenario. Desirable capabilities of such a system include: (a) determining the prior type distribution in Web search for each entity in the repository; (b) assigning a type distribution to new entities; (c) inferring the correct sense of an entity in a particular query context; and (d) adapting to a search engine and time period.

In this paper, we build such a system by leveraging Web search usage logs with large numbers of user sessions seeking or transacting on entities. We cast the task as performing probabilistic inference in a graphical model that captures how queries are generated, and then apply the model to contextually recognize entity types in new queries. We motivate and design several generative models based on the theory that search users' (unobserved) intents govern the types of entities, the query formulations, and the ultimate clicks on Web documents. We show that jointly modeling user intent and entity type significantly outperforms the current state of the art on the task of entity type resolution in queries. The major contributions of our research are:

- We introduce the idea that latent user intents can be an important factor in modeling type distributions over entities in Web search.
- We propose generative models and inference procedures using signals from query context, click, entity, entity type, and user intent.

- We propose an efficient learning technique and a robust implementation of our models, using real-world query data, and a realistic large set of entity types.
- We empirically show that our models outperform the state of the art and that modeling latent intent contributes significantly to these results.

## 2 Related Work

### 2.1 Finding Semantic Classes

A closely related problem is that of finding the semantic classes of entities. Automatic techniques for finding semantic classes include unsupervised clustering (Schütze, 1998; Pantel and Lin, 2002), hyponym patterns (Hearst, 1992; Pantel et al., 2004; Kozareva et al., 2008), extraction patterns (Etzioni et al., 2005), hidden Markov models (Ritter et al., 2009), classification (Rahman and Ng, 2010) and many others. These techniques typically leverage large corpora, while projects such as WordNet (Miller et al., 1990) and Freebase (Bollacker et al., 2008) have employed editors to manually enumerate words and entities with their semantic classes.

The aforementioned methods do not use query logs or explicitly determine the relative probabilities of different entity senses. A method might learn that there is independently a high chance of *eBay* being a *website* and an *employer*, but does not specify which usage is more common. This is especially problematic, for example, if one wishes to leverage Freebase but only needs the most commonly used senses (e.g., *Al Gore* is a US Vice President), rather than all possible obscure senses (Freebase contains 30+ senses, including ones such as *Impersonated Celebrity* and *Quotation Subject*). In scenarios such as this, our proposed method can increase the usability of systems that find semantic classes. We also expand upon text corpora methods in that the type priors can adapt to Web search signals.

### 2.2 Query Log Mining

Query logs have traditionally been mined to improve search (Baeza-Yates et al., 2004; Zhang and Nasraoui, 2006), but they can also be used in place of (or in addition to) text corpora for learning semantic classes. Query logs can contain billions of en-

tries, they provide an independent signal from text corpora, their timestamps allow the learning of type priors at specific points in time, and they can contain information such as clickthroughs that are not found in text corpora. Sekine and Suzuki (2007) used frequency features on context words in query logs to learn semantic classes of entities. Paşca (2007) used extraction techniques to mine instances of semantic classes from query logs. Rüd et al. (2011) found that cross-domain generalizations learned from Web search results are applicable to NLP tasks such as NER. Alfonseca et al. (2010) mined query logs to find attributes of entity instances. However, these projects did not learn relative probabilities of different senses.

### 2.3 User Intents in Search

Learning from query logs also allows us to leverage the concept of *user intents*. When users submit search queries, they often have specific intents in mind. Broder (2002) introduced 3 top level intents: *Informational* (e.g., wanting to learn), *Navigational* (wanting to visit a site), and *Transactional* (e.g., wanting to buy/sell). Rose and Levinson (2004) further divided these into finer-grained subcategories, and Yin and Shah (2010) built hierarchical taxonomies of search intents. Jansen et al. (2007), Hu et al. (2009), and Radlinski et al. (2010) examined how to infer the intent of queries. We are not aware of any other work that has leveraged user intents to learn type distributions.

### 2.4 Topic Modeling on Query Logs

The closest work to ours is Guo et al.’s (2009) research on Named Entity Recognition in Queries. Given an entity-bearing query, they attempt to identify the entity and determine the type posteriors. Our work significantly scales up the type posteriors component of their work. While they only have four potential types (*Movie*, *Game*, *Book*, *Music*) for each entity, we employ over 70 popular types, allowing much greater coverage of real entities and their types. Because they only had four types, they were able to hand label their training data. In contrast, our system self-labels training examples by searching query logs for high-likelihood entities, and must handle any errors introduced by this process. Our models also expand upon theirs by jointly modeling

entity type with latent user intents, and by incorporating click signals.

Other projects have also demonstrated the utility of topic modeling on query logs. Carman et al. (2010) modeled users and clicked documents to personalize search results and Gao et al. (2011) applied topic models to query logs in order to improve document ranking for search.

### 3 Joint Model of Types and User Intents

We turn our attention now to the task of mining the type distributions of entities and of resolving the type of an entity in a particular query context. Our approach is to probabilistically describe how entity-bearing queries are generated in Web search. We theorize that search queries are governed by a latent user intent, which in turn influences the entity types, the choice of query words, and the clicked hosts. We develop inference procedures to infer the prior type distributions of entities in Web search as well as to resolve the type of an entity in a query, by maximizing the probability of observing a large collection of real-world queries and their clicked hosts.

We represent a query  $q$  by a triple  $\{n_1, e, n_2\}$ , where  $e$  represents the entity mentioned in the query,  $n_1$  and  $n_2$  are respectively the pre- and post-entity contexts (possibly empty), referred to as *refiners*. Details on how we obtain our corpus are presented in Section 4.2.

#### 3.1 Intent-based Model (IM)

In this section we describe our main model, **IM**, illustrated in Figure 1. We derive a learning algorithm for the model in Section 3.2 and an inference procedure in Section 3.3.

Recall our discussion of intents from Section 2.3. The unobserved semantic type of an entity  $e$  in a query is strongly correlated with the unobserved user intent. For example, if a user queries for “*song*”, then she is likely looking to ‘listen to it’, ‘download it’, ‘buy it’, or ‘find lyrics’ for it. Our model incorporates this user intent as a latent variable.

The choice of the query refiner words,  $n_1$  and  $n_2$ , is also clearly influenced by the user intent. For example, refiners such as “lyrics” and “words” are more likely to be used in queries where the intent is

<p>For each query/click pair <math>\{q, c\}</math>  type <math>t \sim \text{Multinomial}(\tau)</math>  intent <math>i \sim \text{Multinomial}(\theta_t)</math>  entity <math>e \sim \text{Multinomial}(\psi_i)</math>  switch <math>s_1 \sim \text{Bernoulli}(\sigma_i)</math>  switch <math>s_2 \sim \text{Bernoulli}(\sigma_i)</math>  if <math>(s_1)</math> l-context <math>n_1 \sim \text{Multinomial}(\phi_i)</math>  if <math>(s_2)</math> r-context <math>n_2 \sim \text{Multinomial}(\phi_i)</math>  click <math>c \sim \text{Multinomial}(\omega_i)</math></p>
---

Table 1: Model **IM**: Generative process for entity-bearing queries.

to ‘find lyrics’ than in queries where the intent is to ‘listen’. The same is true for clicked hosts: clicks on “lyrics.com” and “songlyrics.com” are more likely to occur when the intent is to ‘find lyrics’, whereas clicks on “pandora.com” and “last.fm” are more likely for a ‘listen’ intent.

Model **IM** leverages each of these signals: latent intent, query refiners, and clicked hosts. It generates entity-bearing queries by first generating an entity type, from which the user intent and entity is generated. In turn, the user intent is then used to generate the query refiners and the clicked host. In our data analysis, we observed that over 90% of entity-bearing queries did not contain any refiner words  $n_1$  and  $n_2$ . In order to distribute more probability mass to non-empty context words, we explicitly represent the empty context using a switch variable that determines whether a context will be empty.

The generative process for **IM** is described in Table 1. Consider the query “*ymca lyrics*”. Our model first generates the type `song`, then given the type it generates the entity “*ymca*” and the intent ‘find lyrics’. The intent is then used to generate the pre- and post-context words  $\emptyset$  and “*lyrics*”, respectively, and a click on a host such as “*lyrics.com*”.

For mathematical convenience, we assume that the user intent is generated independently of the entity itself. Without this assumption, we would require learning a parameter for each intent-type-entity configuration, exploding the number of parameters. Instead, we choose to include these dependencies at the time of inference, as described later.

Recall that  $q = \{n_1, e, n_2\}$  and let  $s = \{s_1, s_2\}$ , where  $s_1 = 1$  if  $n_1$  is not empty and  $s_2 = 1$  if  $n_2$  is not empty, 0 otherwise. The joint probability of the model is the product of the conditional distributions, as given by:

Figure 1: Graphical models for generating entity-bearing queries. **Guo’09** represents the current state of the art (Guo et al., 2009). Models **M0** and **M1** add an empty context switch and click information, respectively. Model **IM** further constrains the query by the latent user intent.

$$P(t, i, q, c | \tau, \Theta, \Psi, \sigma, \Phi, \Omega) = P(t | \tau)P(i | t, \Theta)P(e | t, \Psi)P(c | i, \Omega) \prod_{j=1}^2 P(n_j | i, \Phi)^{I[s_j=1]}P(s_j | i, \sigma)$$

We now define each of the terms in the joint distribution. Let  $T$  be the number of entity types. The probability of generating a type  $t$  is governed by a multinomial with probability vector  $\tau$ :

$$P(t=\hat{t}) = \prod_{j=1}^T \tau_j^{I[j=\hat{t}]}, \text{ s.t. } \sum_{j=1}^T \tau_j = 1$$

where  $I$  is an indicator function set to 1 if its condition holds, and 0 otherwise.

Let  $K$  be the number of latent user intents that govern our query log, where  $K$  is fixed in advance. Then, the probability of intents  $i$  is defined as a multinomial distribution with probability vector  $\theta_t$  such that  $\Theta = [\theta_1, \theta_2, \dots, \theta_T]$  captures the matrix of parameters across all  $T$  types:

$$P(i=\hat{i} | t=\hat{t}) = \prod_{j=1}^K \Theta_{\hat{i},j}^{I[j=\hat{i}]}, \text{ s.t. } \forall t \sum_{j=1}^K \Theta_{t,j} = 1$$

Let  $E$  be the number of known entities. The probability of generating an entity  $e$  is similarly governed by a parameter  $\Psi$  across all  $T$  types:

$$P(e=\hat{e} | t=\hat{t}) = \prod_{j=1}^E \Psi_{\hat{t},j}^{I[j=\hat{e}]}, \text{ s.t. } \forall t \sum_{j=1}^E \Psi_{t,j} = 1$$

The probability of generating an empty or non-empty context  $s$  given intent  $i$  is given by a Bernoulli with parameter  $\sigma_i$ :

$$P(s | i=\hat{i}) = \sigma_{\hat{i}}^{I[s=1]}(1 - \sigma_{\hat{i}})^{I[s=0]}$$

Let  $V$  be the shared vocabulary size of all query refiner words  $n_1$  and  $n_2$ . Given an intent,  $i$ , the probability of generating a refiner  $n$  is given by a multinomial distribution with probability vector  $\phi_i$  such that  $\Phi = [\phi_1, \phi_2, \dots, \phi_K]$  represents parameters across intents:

$$P(n=\hat{n} | i=\hat{i}) = \prod_{v=1}^V \Phi_{\hat{i},v}^{I[v=\hat{n}]}, \text{ s.t. } \forall i \sum_{v=1}^V \Phi_{i,v} = 1$$

Finally, we assume there are  $H$  possible click values, corresponding to  $H$  Web hosts. A click on a host is similarly determined by an intent  $i$  and is governed by parameter  $\Omega$  across all  $K$  intents:

$$P(c=\hat{c} | i=\hat{i}) = \prod_{h=1}^H \Omega_{\hat{i},h}^{I[h=\hat{c}]}, \text{ s.t. } \forall i \sum_{h=1}^H \Omega_{i,h} = 1$$

## 3.2 Learning

Given a query corpus  $\mathcal{Q}$  consisting of  $N$  independently and identically distributed queries  $q^j = \{n_1^j, e^j, n_2^j\}$  and their corresponding clicked hosts  $c^j$ , we estimate the parameters  $\tau, \Theta, \Psi, \sigma, \Phi$ , and  $\Omega$  by maximizing the (log) probability of observing  $\mathcal{Q}$ . The log  $P(\mathcal{Q})$  can be written as:

$$\log P(\mathcal{Q}) = \sum_{j=1}^N \sum_{t,i} P^j(t, i | q, c) \log P^j(q, c, t, i)$$

In the above equation,  $P^j(t, i | q, c)$  is the posterior distribution over types and user intents for the  $j^{\text{th}}$  query. We use the Expectation-Maximization (EM) algorithm to estimate the parameters. The parameter updates are obtained by computing the derivative of  $\log P(\mathcal{Q})$  with respect to each parameter, and setting the resultant to 0.

The update for  $\tau$  is given by the average of the posterior distributions over the types:

$$\tau_{\hat{t}} = \frac{\sum_{j=1}^N \sum_i P^j(t=\hat{t}, i | q, c)}{\sum_{j=1}^N \sum_{t,i} P^j(t, i | q, c)}$$

For a fixed type  $t$ , the update for  $\theta_t$  is given by the weighted average of the latent intents, where the weights are the posterior distributions over the types, for each query:

$$\Theta_{\hat{t}, \hat{i}} = \frac{\sum_{j=1}^N P^j(t=\hat{t}, i=\hat{i} | q, c)}{\sum_{j=1}^N \sum_i P^j(t=\hat{t}, i | q, c)}$$

Similarly, we can update  $\Psi$ , the parameters that govern the distribution over entities for each type:

$$\Psi_{\hat{t}, \hat{e}} = \frac{\sum_{j=1}^N \sum_i P^j(t=\hat{t}, i | q, c) I[e^j=\hat{e}]}{\sum_{j=1}^N \sum_i P^j(t=\hat{t}, i | q, c)}$$

Now, for a fixed user intent  $i$ , the update for  $\omega_i$  is given by the weighted average of the clicked hosts, where the weights are the posterior distributions over the intents, for each query:

$$\Omega_{\hat{i}, \hat{c}} = \frac{\sum_{j=1}^N \sum_t P^j(t, i=\hat{i} | q, c) I[c^j=\hat{c}]}{\sum_{j=1}^N \sum_t P^j(t, i=\hat{i} | q, c)}$$

Similarly, we can update  $\Phi$  and  $\sigma$ , the parameters that govern the distribution over query refiners and empty contexts for each intent, as:

$$\Phi_{\hat{i}, \hat{n}} = \frac{\sum_{j=1}^N \sum_t P^j(t, i=\hat{i} | q, c) \left[ I[n_1^j=\hat{n}] I[s_1^j=1] + I[n_2^j=\hat{n}] I[s_2^j=1] \right]}{\sum_{j=1}^N \sum_t P^j(t, i=\hat{i} | q, c) \left[ I[s_1^j=1] + I[s_2^j=1] \right]}$$

and

$$\sigma_{\hat{i}} = \frac{\sum_{j=1}^N \sum_t P^j(t, i=\hat{i} | q, c) \left[ I[s_1=1] + I[s_2=1] \right]}{2 \sum_{j=1}^N \sum_t P^j(t, i=\hat{i} | q, c)}$$

### 3.3 Decoding

Given a query/click pair  $\{q, c\}$ , and the learned IM model, we can apply Bayes' rule to find the posterior distribution,  $P(t, i | q, c)$ , over the types and intents, as it is proportional to  $P(t, i, q, c)$ . We compute this quantity exactly by evaluating the joint for each combination of  $t$  and  $i$ , and the observed values of  $q$  and  $c$ .

It is important to note that at runtime when a new query is issued, we have to resolve the entity in the absence of any observed click. However, we do have access to historical click probabilities,  $P(c | q)$ .

We use this information to compute  $P(t | q)$  by marginalizing over  $i$  as follows:

$$P(t | q) = \sum_i \sum_{j=1}^H P(t, i | q, c_j) P(c_j | q) \quad (1)$$

### 3.4 Comparative Models

Figure 1 also illustrates the current state-of-the-art model **Guo'09** (Guo et al., 2009), described in Section 2.4, which utilizes only query refinement words to infer entity type distributions. Two extensions to this model that we further study in this paper are also shown: Model **M0** adds the empty context switch parameter and Model **M1** further adds click information. In the interest of space, we omit the update equations for these models, however they are trivial to adapt from the derivations of Model **IM** presented in Sections 3.1 and 3.2.

### 3.5 Discussion

**Full Bayesian Treatment:** In the above models, we learn point estimates for the parameters  $(\tau, \Theta, \Psi, \sigma, \Phi, \Omega)$ . One can take a Bayesian approach and treat these parameters as variables (for instance, with Dirichlet and Beta prior distributions), and perform Bayesian inference. However, exact inference will become intractable and we would need to resort to methods such as variational inference or sampling. We found this extension unnecessary, as we had a sufficient amount of training data to estimate all parameters reliably. In addition, our approach enabled us to learn (and perform inference in) the model with large amounts of data with reasonable computing time.

**Fitting to an existing Knowledge Base:** Although in general our model decodes type distributions for arbitrary entities, in many practical cases it is beneficial to constrain the types to those admissible in a fixed knowledge base (such as Freebase). As an example, if the entity is "ymca", admissible types may include `song`, `place`, and `educational_institution`. When resolving types, during inference, one can restrict the search space to only these admissible types. A desirable side effect of this strategy is that only valid ambiguities are captured in the posterior distribution.

## 4 Evaluation Methodology

We refer to *QL* as a set of English Web search queries issued to a commercial search engine over a period of several months.

### 4.1 Entity Inventory

Although our models generalize to any entity repository, we experiment in this paper with entities covering a wide range of web search queries, coming from 73 types in Freebase. We arrived at these types by grepping for all entities in Freebase within *QL*, following the procedure described in Section 4.2, and then choosing the top most frequent types such that 50% of the queries are covered by an entity of one of these types<sup>1</sup>.

### 4.2 Training Data Construction

In order to learn type distributions by jointly modeling user intents and a large number of types, we require a large set of training examples containing tagged entities and their potential types. Unlike in Guo et al. (2009), we need a method to automatically label *QL* to produce these training cases since manual annotation is impossible for the range of entities and types that we consider. Reliably recognizing entities in queries is not a solved problem. However, for training we do not require high coverage of entities in *QL*, so high precision on a sizeable set of query instances can be a proper proxy.

To this end, we collect candidate entities in *QL* via simple string matching on Freebase entity strings within our preselected 73 types. To achieve high precision from this initial (high-recall, low-precision) candidate set we use a number of heuristics to only retain highly likely entities. The heuristics include retaining only matches on entities that appear capitalized more than 50% in their occurrences in Wikipedia. Also, a standalone score filter (Jain and Pennacchiotti, 2011) of 0.9 is used, which is based on the ratio of string occurrence as

---

<sup>1</sup>In this process, we omitted any non-core Freebase type (e.g., `/user/*` and `/base/*`), types used for representation (e.g., `/common/*` and `/type/*`), and too general types (e.g., `/people/person` and `/location/location`) identified by if a type contains multiple other prominent subtypes. Finally, we conflated seven of the types that overlapped with each other into four types (such as `/book/written_work` and `/book/book`).

an exact match in queries to how often it occurs as a partial match.

The resulting queries are further filtered by keeping only those where the pre- and post-entity contexts ( $n_1$  and  $n_2$ ) were empty or a single word (accounting for a very large fraction of the queries). We also eliminate entries with clicked hosts that have been clicked fewer than 100 times over the entire *QL*. Finally, for training we filter out any query with an entity that has more than two potential types<sup>2</sup>. This step is performed to reduce recognition errors by limiting the number of potential ambiguous matches. We experimented with various thresholds on allowable types and settled on the value two.

The resulting training data consists of several million queries, 73 different entity types, and approximately 135K different entities, 100K different refiner words, and 40K clicked hosts.

### 4.3 Test Set Annotation

We sampled two datasets, *HEAD* and *TAIL*, each consisting of 500 queries containing an entity belonging to one of the 73 types in our inventory, from a frequency-weighted random sample and a uniform random sample of *QL*, respectively.

We conducted a user study to establish a gold standard of the correct entity types in each query. A total of seven different independent and paid professional annotators participated in the study. For each query in our test sets, we displayed the query, associated clicked host, and entity to the annotator, along with a list of permissible types from our type inventory. The annotator is tasked with identifying all applicable types from that list, or marking the test case as faulty because of an error in entity identification, bad click host (e.g. dead link) or bad query (e.g. non-English). This resulted in 2,092 test cases (`{query, entity, type}`-tuples). Each test case was annotated by two annotators. Inter-annotator agreement as measured by Fleiss'  $\kappa$  was 0.445 (0.498 on *HEAD* and 0.386 on *TAIL*), considered moderate agreement.

From *HEAD* and *TAIL*, we eliminated three categories of queries that did not offer any interesting type disambiguation opportunities:

- queries that contained entities with only one

---

<sup>2</sup>For testing we did not omit any entity or type.

	HEAD				TAIL			
	nDCG	MAP	MAP <sub>w</sub>	Prec@1	nDCG	MAP	MAP <sub>w</sub>	Prec@1
<b>B<sub>FB</sub></b>	0.71	0.60	0.45	0.30	0.73	0.64	0.49	0.35
<b>Guo'09</b>	0.79 <sup>†</sup>	0.71 <sup>†</sup>	0.62 <sup>†</sup>	0.51 <sup>†</sup>	<b>0.80<sup>†</sup></b>	<b>0.73<sup>†</sup></b>	<b>0.66<sup>†</sup></b>	<b>0.52<sup>†</sup></b>

<b>M1</b>	0.83 <sup>‡</sup>	0.76 <sup>‡</sup>	0.72 <sup>‡</sup>	0.61 <sup>‡</sup>	<b>0.81<sup>†</sup></b>	<b>0.74<sup>†</sup></b>	<b>0.67<sup>†</sup></b>	<b>0.55<sup>†</sup></b>
<b>IM</b>	<b>0.87<sup>‡</sup></b>	<b>0.82<sup>‡</sup></b>	<b>0.77<sup>‡</sup></b>	<b>0.73<sup>‡</sup></b>	<b>0.80<sup>†</sup></b>	<b>0.72<sup>†</sup></b>	<b>0.66<sup>†</sup></b>	<b>0.52<sup>†</sup></b>

Table 2: Model analysis on HEAD and TAIL. <sup>†</sup> indicates statistical significance over **B<sub>FB</sub>**, and <sup>‡</sup> over both **B<sub>FB</sub>** and **Guo'09**. Bold indicates statistical significance over all non-bold models in the column. Significance is measured using the Student's *t*-test at 95% confidence.

potential type from our inventory;

- queries where the annotators rated all potential types as good; and
- queries where judges rated none of the potential types as good

The final test sets consist of 105 head queries with 359 judged entity types and 98 tail queries with 343 judged entity types.

#### 4.4 Metrics

Our task is a ranking task and therefore the classic IR metrics **nDCG** (normalized discounted cumulative gain) and **MAP** (mean average precision) are applicable (Manning et al., 2008).

Both **nDCG** and **MAP** are sensitive to the rank position, but not the score (probability of a type) associated with each rank,  $S(r)$ . We therefore also evaluate a weighted mean average precision score **MAP<sub>w</sub>**, which replaces the precision component of **MAP**,  $P(r)$ , for the  $r^{th}$  ranked type by:

$$P(r) = \frac{\sum_{\hat{r}=1}^r I(\hat{r})S(\hat{r})}{\sum_{\hat{r}=1}^r S(\hat{r})} \quad (2)$$

where  $I(r)$  indicates if the type at rank  $r$  is judged correct.

Our fourth metric is **Prec@1**, i.e. the precision of only the top-ranked type of each query. This is especially suitable for applications where a single sense must be determined.

#### 4.5 Model Settings

We trained all models in Figure 1 using the training data from Section 4.2 over 100 EM iterations, with two folds per model. For Model **IM**, we varied the number of user intents ( $K$ ) in intervals from 100 to 400 (see Figure 3), under the assumption that multiple intents would exist per entity type.

We compare our results against two baselines.

The first baseline is an assignment of Freebase types according to their frequency in our query set **B<sub>FB</sub>**, and the second is Model **Guo'09** (Guo et al., 2009) illustrated in Figure 1.

## 5 Experimental Results

Table 2 lists the performance of each model on the *HEAD* and *TAIL* sets over each metric defined in Section 4.4. On head queries, the addition of the empty context parameter  $\sigma$  and click signal  $\Omega$  together (Model **M1**) significantly outperforms both the baseline and the state-of-the-art model **Guo'09**. Further modeling the user intent in Model **IM** results in significantly better performance over all models and across all metrics. Model **IM** shows its biggest gains in the first position of its ranking as evidenced by the **Prec@1** metric.

We observe a different behavior on tail queries where all models significantly outperform the baseline **B<sub>FB</sub>**, but are not significantly different from each other. In short, the strength of our proposed model is in improving performance on the head at no noticeable cost in the tail.

We separately tested the effect of adding the empty context parameter  $\sigma$ . Figure 2 illustrates the result on the *HEAD* data. Across all metrics,  $\sigma$  improved performance over all models<sup>3</sup>. The more expressive models benefitted more than the less expressive ones.

Table 2 reports results for Model **IM** using  $K = 200$  user intents. This was determined by varying  $K$  and selecting the top-performing value. Figure 3 illustrates the performance of Model **IM** with different values of  $K$  on the *HEAD*.

<sup>3</sup>Note that model **M0** is just the addition of the  $\sigma$  parameter over **Guo'09**.

Figure 2: The switch parameter  $\sigma$  improves performance of every model and metric.

Figure 3: Model performance vs. the number of latent intents (K).

Our models can also assign a prior type distribution to each entity by further marginalizing Eq. 1 over query contexts  $n_1$  and  $n_2$ . We measured the quality of our learned type priors using the subset of queries in our *HEAD* test set that consisted of only an entity without any refiners. The results for Model IM were:  $nDCG = 0.86$ ,  $MAP = 0.80$ ,  $MAP_W = 0.75$ , and  $Prec@1 = 0.70$ . All metrics are statistically significantly better than  $B_{FB}$ ,  $Guo'09$  and M0, with 95% confidence. Compared to Model M1, Model IM is statistically significantly better on  $Prec@1$  and not significantly different on the other metrics.

**Discussion and Error Analysis:** Contrary to our results, we had expected improvements for both *HEAD* and *TAIL*. Inspection of the *TAIL* queries revealed that entities were greatly skewed towards people (e.g., actor, author, and politician). Analysis of the latent user intent parameter  $\Theta$  in Model IM showed that most people types had most of their probability mass assigned to the same three generic and common intents for people types: ‘see pictures of’, ‘find biographical information about’, and ‘see video of’. In other words, latent intents in Model IM are over-expressive and they do not help in differentiating people types.

The largest class of errors came from queries bearing an entity with semantically very similar types where our highest ranked type was not judged correct by the annotators. For example, for the query “*philippine daily inquirer*” our system ranked newspaper ahead of periodical but a judge rejected the former and approved the latter. For “*ikea catalogue*”, our system ranked magazine ahead of periodical, but again a judge rejected magazine in favor of periodical.

An interesting success case in the *TAIL* is highlighted by two queries involving the entity “*ymca*”, which in our data can either be a song, place, or educational institution. Our system learns the following priors: 0.63, 0.29, and 0.08, respectively. For the query “*jamestown ymca ny*”, IM correctly classified “*ymca*” as a place and for the query “*ymca palomar*” it correctly classified it as an educational institution. We further issued the query “*ymca lyrics*” and the type song was then highest ranked.

Our method is generalizable to any entity collection. Since our evaluation focused on the Freebase collection, it remains an open question how noise level, coverage, and breadth in a collection will affect our model performance. Finally, although we do not formally evaluate it, it is clear that training our model on different time spans of queries should lead to type distributions adapted to that time period.

## 6 Conclusion

Jointly modeling the interplay between the underlying user intents and entity types in web search queries shows significant improvements over the current state of the art on the task of resolving entity types in head queries. At the same time, no degradation in tail queries is observed. Our proposed models can be efficiently trained using an EM algorithm and can be further used to assign prior type distributions to entities in an existing knowledge base and to insert new entities into it.

Although this paper leverages latent intents in search queries, it stops short of understanding the nature of the intents. It remains an open problem to characterize and enumerate intents and to identify the types of queries that benefit most from intent models.

## Abstract

The amount of labeled sentiment data in English is much larger than that in other languages. Such a disproportion arouse interest in cross-lingual sentiment classification, which aims to conduct sentiment classification in the target language (e.g. Chinese) using labeled data in the source language (e.g. English). Most existing work relies on machine translation engines to directly adapt labeled data from the source language to the target language. This approach suffers from the limited coverage of vocabulary in the machine translation results. In this paper, we propose a generative cross-lingual mixture model (CLMM) to leverage unlabeled bilingual parallel data. By fitting parameters to maximize the likelihood of the bilingual parallel data, the proposed model learns previously unseen sentiment words from the large bilingual parallel data and improves vocabulary coverage significantly. Experiments on multiple data sets show that CLMM is consistently effective in two settings: (1) labeled data in the target language are unavailable; and (2) labeled data in the target language are also available.

## 1 Introduction

Sentiment Analysis (also known as opinion mining), which aims to extract the sentiment information from text, has attracted extensive attention in recent years. Sentiment classification, the task of determining the sentiment orientation (positive, negative or neutral) of text, has been the most extensively studied task in sentiment analysis. There is

already a large amount of work on sentiment classification of text in various genres and in many languages. For example, Pang et al. (2002) focus on sentiment classification of movie reviews in English, and Zagibalov and Carroll (2008) study the problem of classifying product reviews in Chinese. During the past few years, NTCIR<sup>1</sup> organized several pilot tasks for sentiment classification of news articles written in English, Chinese and Japanese (Seki et al., 2007; Seki et al., 2008).

For English sentiment classification, there are several labeled corpora available (Hu and Liu, 2004; Pang et al., 2002; Wiebe et al., 2005). However, labeled resources in other languages are often insufficient or even unavailable. Therefore, it is desirable to use the English labeled data to improve sentiment classification of documents in other languages. One direct approach to leveraging the labeled data in English is to use machine translation engines as a *black box* to translate the labeled data from English to the target language (e.g. Chinese), and then using the translated training data directly for the development of the sentiment classifier in the target language (Wan, 2009; Pan et al., 2011).

Although the machine-translation-based methods are intuitive, they have certain limitations. First, the vocabulary covered by the translated labeled data is limited, hence many sentiment indicative words can not be learned from the translated labeled data. Duh et al. (2011) report low overlapping between vocabulary of natural English documents and the vocabulary of documents translated to English from Japanese, and the experiments of Duh

\*Contribution during internship at Microsoft Research Asia.

<sup>1</sup><http://research.nii.ac.jp/ntcir/index-en.html>

et al. (2011) show that vocabulary coverage has a strong correlation with sentiment classification accuracy. Second, machine translation may change the sentiment polarity of the original text. For example, the negative English sentence “It is too good to be true” is translated to a positive sentence in Chinese “这是好得是真实的” by Google Translate (<http://translate.google.com/>), which literally means “It is good and true”.

In this paper we propose a cross-lingual mixture model (**CLMM**) for cross-lingual sentiment classification. Instead of relying on the unreliable machine translated labeled data, CLMM leverages bilingual parallel data to bridge the language gap between the source language and the target language. CLMM is a generative model that treats the source language and target language words in parallel data as generated *simultaneously* by a set of mixture components. By “synchronizing” the generation of words in the source language and the target language in a parallel corpus, the proposed model can (1) improve vocabulary coverage by learning sentiment words from the unlabeled parallel corpus; (2) transfer polarity label information between the source language and target language using a parallel corpus. Besides, CLMM can improve the accuracy of cross-lingual sentiment classification consistently regardless of whether labeled data in the target language are present or not. We evaluate the model on sentiment classification of Chinese using English labeled data. The experiment results show that CLMM yields 71% in accuracy when no Chinese labeled data are used, which significantly improves Chinese sentiment classification and is superior to the SVM and co-training based methods. When Chinese labeled data are employed, CLMM yields 83% in accuracy, which is remarkably better than the SVM and achieve state-of-the-art performance.

This paper makes two contributions: (1) we propose a model to effectively leverage large bilingual parallel data for improving vocabulary coverage; and (2) the proposed model is applicable in both settings of cross-lingual sentiment classification, irrespective of the availability of labeled data in the target language.

The paper is organized as follows. We review related work in Section 2, and present the cross-lingual mixture model in Section 3. Then we present the ex-

perimental studies in Section 4, and finally conclude the paper and outline the future plan in Section 5.

## 2 Related Work

In this section, we present a brief review of the related work on monolingual sentiment classification and cross-lingual sentiment classification.

### 2.1 Sentiment Classification

Early work of sentiment classification focuses on English product reviews or movie reviews (Pang et al., 2002; Turney, 2002; Hu and Liu, 2004). Since then, sentiment classification has been investigated in various domains and different languages (Zagiblov and Carroll, 2008; Seki et al., 2007; Seki et al., 2008; Davidov et al., 2010). There exist two main approaches to extracting sentiment orientation automatically. The Dictionary-based approach (Turney, 2002; Taboada et al., 2011) aims to aggregate the sentiment orientation of a sentence (or document) from the sentiment orientations of words or phrases found in the sentence (or document), while the corpus-based approach (Pang et al., 2002) treats the sentiment orientation detection as a conventional classification task and focuses on building classifier from a set of sentences (or documents) labeled with sentiment orientations.

Dictionary-based methods involve in creating or using sentiment lexicons. Turney (2002) derives sentiment scores for phrases by measuring the mutual information between the given phrase and the words “excellent” and “poor”, and then uses the average scores of the phrases in a document as the sentiment of the document. Corpus-based methods are often built upon machine learning models. Pang et al. (2002) compare the performance of three commonly used machine learning models (Naive Bayes, Maximum Entropy and SVM). Gamon (2004) shows that introducing deeper linguistic features into SVM can help to improve the performance. The interested readers are referred to (Pang and Lee, 2008) for a comprehensive review of sentiment classification.

### 2.2 Cross-Lingual Sentiment Classification

Cross-lingual sentiment classification, which aims to conduct sentiment classification in the target language (e.g. Chinese) with labeled data in the source

language (e.g. English), has been extensively studied in the very recent years. The basic idea is to explore the abundant labeled sentiment data in source language to alleviate the shortage of labeled data in the target language.

Most existing work relies on machine translation engines to directly adapt labeled data from the source language to target language. Wan (2009) proposes to use ensemble method to train better Chinese sentiment classification model on English labeled data and their Chinese translation. English Labeled data are first translated to Chinese, and then two SVM classifiers are trained on English and Chinese labeled data respectively. After that, co-training (Blum and Mitchell, 1998) approach is adopted to leverage Chinese unlabeled data and their English translation to improve the SVM classifier for Chinese sentiment classification. The same idea is used in (Wan, 2008), but the ensemble techniques used are various voting methods and the individual classifiers used are dictionary-based classifiers.

Instead of ensemble methods, Pan et al. (2011) use matrix factorization formulation. They extend Non-negative Matrix Tri-Factorization model (Li et al., 2009) to bilingual view setting. Their bilingual view is also constructed by using machine translation engines to translate original documents. Prettenhofer and Stein (2011) use machine translation engines in a different way. They generalize Structural Correspondence Learning (Blitzer et al., 2006) to multi-lingual setting. Instead of using machine translation engines to translate labeled text, the authors use it to construct the word translation oracle for pivot words translation.

Lu et al. (2011) focus on the task of jointly improving the performance of sentiment classification on two languages (e.g. English and Chinese). The authors use an unlabeled parallel corpus instead of machine translation engines. They assume parallel sentences in the corpus should have the same sentiment polarity. Besides, they assume labeled data in both language are available. They propose a method of training two classifiers based on maximum entropy formulation to maximize their prediction agreement on the parallel corpus. However, this method requires labeled data in *both* the source language and the target language, which are not always readily available.

### 3 Cross-Lingual Mixture Model for Sentiment Classification

In this section we present the cross-lingual mixture model (CLMM) for sentiment classification. We first formalize the task of cross-lingual sentiment classification. Then we describe the CLMM model and present the parameter estimation algorithm for CLMM.

#### 3.1 Cross-lingual Sentiment Classification

Formally, the task we are concerned about is to develop a sentiment classifier for the target language  $T$  (e.g. Chinese), given labeled sentiment data  $D_S$  in the source language  $S$  (e.g. English), unlabeled parallel corpus  $U$  of the source language and the target language, and *optional* labeled data  $D_T$  in target language  $T$ . Aligning with previous work (Wan, 2008; Wan, 2009), we only consider binary sentiment classification scheme (positive or negative) in this paper, but the proposed method can be used in other classification schemes with minor modifications.

#### 3.2 The Cross-Lingual Mixture Model

The basic idea underlying CLMM is to enlarge the vocabulary by learning sentiment words from the parallel corpus. CLMM defines an intuitive generation process as follows. Suppose we are going to generate a positive or negative Chinese sentence, we have two ways of generating words. The first way is to *directly* generate a Chinese word according to the polarity of the sentence. The other way is to first generate an English word with the same polarity and meaning, and then *translate* it to a Chinese word. More formally, CLMM defines a generative mixture model for generating a parallel corpus. The *unobserved* polarities of the unlabeled parallel corpus are modeled as hidden variables, and the *observed* words in parallel corpus are modeled as generated by a set of words generation distributions conditioned on the hidden variables. Given a parallel corpus, we fit CLMM model by maximizing the likelihood of generating this parallel corpus. By maximizing the likelihood, CLMM can estimate words generation probabilities for words unseen in the labeled data but present in the parallel corpus, hence expand the vocabulary. In addition, CLMM can utilize words in both the source language and target language for de-

terminating polarity classes of the parallel sentences.

Figure 1: The generation process of the cross-lingual mixture model

Figure 1 illustrates the detailed process of generating words in the source language and target language respectively for the parallel corpus  $U$ , from the four mixture components in CLMM. Particularly, for each pair of parallel sentences  $u_i \in U$ , we generate the words as follows.

1. **Document class generation:** Generating the polarity class.
  - (a) Generating a polarity class  $c_s$  from a Bernoulli distribution  $P_s(C)$ .
  - (b) Generating a polarity class  $c_t$  from a Bernoulli distribution  $P_t(C)$
2. **Words generation:** Generating the words
  - (a) Generating source language words  $w_s$  from a Multinomial distribution  $P(w_s|c_s)$
  - (b) Generating target language words  $w_t$  from a Multinomial distribution  $P(w_t|c_t)$
3. **Words projection:** Projecting the words onto the other language
  - (a) Projecting the source language words  $w_s$  to target language words  $w_t$  by word projection probability  $P(w_t|w_s)$
  - (b) Projecting the target language words  $w_t$  to source language words  $w_s$  by word projection probability  $P(w_s|w_t)$

CLMM finds parameters by using MLE (Maximum Likelihood Estimation). The parameters to be estimated include conditional probabilities of word to class,  $P(w_s|c)$  and  $P(w_t|c)$ , and word projection

probabilities,  $P(w_s|w_t)$  and  $P(w_t|w_s)$ . We will describe the log-likelihood function and then show how to estimate the parameters in subsection 3.3. The obtained word-class conditional probability  $P(w_t|c)$  can then be used to classify text in the target languages using Bayes Theorem and the Naive Bayes independence assumption.

Formally, we have the following log-likelihood function for a parallel corpus  $U^2$ .

$$L(\theta|U) = \sum_{i=1}^{|U_s|} \sum_{j=1}^{|C|} \sum_{s=1}^{|V_s|} [N_{si} \log (P(w_s|c_j) + P(w_s|w_t)P(w_t|c_j))] + \sum_{i=1}^{|U_t|} \sum_{j=1}^{|C|} \sum_{t=1}^{|V_t|} [N_{ti} \log (P(w_t|c_j) + P(w_t|w_s)P(w_s|c_j))] \quad (1)$$

where  $\theta$  is the model parameters;  $N_{si}$  ( $N_{ti}$ ) is the occurrences of the word  $w_s$  ( $w_t$ ) in document  $d_i$ ;  $|D_s|$  is the number of documents;  $|C|$  is the number of class labels;  $V_s$  and  $V_t$  are the vocabulary in the source language and the vocabulary in the target language.  $|U_s|$  and  $|U_t|$  are the number of unlabeled sentences in the source language and target language.

Meanwhile, we have the following log-likelihood function for labeled data in the source language  $D_s$ .

$$L(\theta|D_s) = \sum_{i=1}^{|D_s|} \sum_{j=1}^{|C|} \sum_{s=1}^{|V_s|} N_{si} \log P(w_s|c_j) \delta_{ij} \quad (2)$$

where  $\delta_{ij} = 1$  if the label of  $d_i$  is  $c_j$ , and 0 otherwise.

In addition, when labeled data in the target language is available, we have the following log-likelihood function.

$$L(\theta|D_t) = \sum_{i=1}^{|D_t|} \sum_{j=1}^{|C|} \sum_{t=1}^{|V_t|} N_{ti} \log P(w_t|c_j) \delta_{ij} \quad (3)$$

Combining the above three likelihood functions together, we have the following likelihood function.

$$L(\theta|D_t, D_s, U) = L(\theta|U) + L(\theta|D_s) + L(\theta|D_t) \quad (4)$$

Note that the third term on the right hand side ( $L(\theta|D_t)$ ) is optional.

<sup>2</sup>For simplicity, we assume the prior distribution  $P(C)$  is uniform and drop it from the formulas.

### 3.3 Parameter Estimation

Instead of estimating word projection probability ( $P(w_s|w_t)$  and  $P(w_t|w_s)$ ) and conditional probability of word to class ( $P(w_t|c)$  and  $P(w_s|c)$ ) simultaneously in the training procedure, we estimate them separately since the word projection probability stays invariant when estimating other parameters. We estimate word projection probability using word alignment probability generated by the Berkeley aligner (Liang et al., 2006). The word alignment probabilities serves two purposes. First, they connect the corresponding words between the source language and the target language. Second, they adjust the strength of influences between the corresponding words. Figure 2 gives an example of word alignment probability. As is shown, the three words “tour de force” altogether express a positive meaning, while in Chinese the same meaning is expressed with only one word “杰作” (masterpiece). CLMM use word alignment probability to decrease the influences from “杰作” (masterpiece) to “tour”, “de” and “force” individually, using the word projection probability (i.e. word alignment probability), which is 0.3 in this case.

Figure 2: Word Alignment Probability

We use Expectation-Maximization (EM) algorithm (Dempster et al., 1977) to estimate the conditional probability of word  $w_s$  and  $w_t$  given class  $c$ ,  $P(w_s|c)$  and  $P(w_t|c)$  respectively. We derive the equations for EM algorithm, using notations similar to (Nigam et al., 2000).

In the E-step, the distribution of hidden variables (i.e. class label for unlabeled parallel sentences) is computed according to the following equations.

$$P(c_j|u_{si}) = Z(c_{u_{si}} = c_j) = \frac{\prod_{w_s \in u_{si}} [P(w_s|c_j) + \sum_{P(w_s|w_t) > 0} P(w_s|w_t)P(w_t|c_j)]}{\sum_{c_j} \prod_{w_s \in u_{si}} [P(w_s|c_j) + \sum_{P(w_s|w_t) > 0} P(w_s|w_t)P(w_t|c_j)]} \quad (5)$$

$$P(c_j|u_{ti}) = Z(c_{u_{ti}} = c_j) = \frac{\prod_{w_t \in u_{ti}} [P(w_t|c_j) + \sum_{P(w_t|w_s) > 0} P(w_t|w_s)P(w_s|c_j)]}{\sum_{c_j} \prod_{w_t \in u_{ti}} [P(w_t|c_j) + \sum_{P(w_t|w_s) > 0} P(w_t|w_s)P(w_s|c_j)]} \quad (6)$$

where  $Z(c_{u_{si}} = c_j)$  ( $Z(c_{u_{ti}} = c_j)$ ) is the probability of the source (target) language sentence  $u_{si}$  ( $u_{ti}$ ) in the  $i$ -th pair of sentences  $u_i$  having class label  $c_j$ .

In the M-step, the parameters are computed by the following equations.

$$P(w_s|c_j) = \frac{1 + \sum_{i=1}^{|D_s|} \Lambda_s(i) N_{si} P(c_j|d_i)}{|V| + \sum_{s=1}^{|V_s|} \Lambda(i) N_{si} P(c_j|d_i)} \quad (7)$$

$$P(w_t|c_j) = \frac{1 + \sum_{i=1}^{|D_t|} \Lambda_t(i) N_{ti} P(c_j|d_i)}{|V| + \sum_{t=1}^{|V_t|} \Lambda(i) N_{ti} P(c_j|d_i)} \quad (8)$$

where  $\Lambda_s(i)$  and  $\Lambda_t(i)$  are weighting factor to control the influence of the unlabeled data. We set  $\lambda_s(i)$  ( $\lambda_t(i)$ ) to  $\lambda_s$  ( $\lambda_t$ ) when  $d_i$  belongs to unlabeled data, 1 otherwise. When  $d_i$  belongs to labeled data,  $P(c_j|d_i)$  is 1 when its label is  $c_j$  and 0 otherwise. When  $d_i$  belongs to unlabeled data,  $P(c_j|d_i)$  is computed according to Equation 5 or 6.

## 4 Experiment

### 4.1 Experiment Setup and Data Sets

**Experiment setup:** We conduct experiments on two common cross-lingual sentiment classification settings. In the first setting, no labeled data in the target language are available. This setting has realistic significance, since in some situations we need to quickly develop a sentiment classifier for languages that we do not have labeled data in hand. In this case, we classify text in the target language using only labeled data in the source language. In the second setting, labeled data in the target language are also available. In this case, a more reasonable strategy is to make full use of both labeled data in the source language and target language to develop the sentiment classifier for the target language. In our experiments, we consider English as the source language and Chinese as the target language.

**Data sets:** For Chinese sentiment classification, we use the same data set described in (Lu et al., 2011). The labeled data sets consist of two English data sets and one Chinese data set. The English data set is from the Multi-Perspective Question Answering (MPQA) corpus (Wiebe et al., 2005) and the NTCIR Opinion Analysis Pilot Task data set (Seki et al., 2008; Seki et al., 2007). The Chinese data set also comes from the NTCIR Opinion Analysis Pilot Task data set. The unlabeled parallel sentences

are selected from ISI Chinese-English parallel corpus (Munteanu and Marcu, 2005). Following the description in (Lu et al., 2011), we remove neutral sentences and keep only high confident positive and negative sentences as predicted by a maximum entropy classifier trained on the labeled data. Table 1 shows the statistics for the data sets used in the experiments. We conduct experiments on two data settings: (1) MPQA + NTCIR-CH and (2) NTCIR-EN + NTCIR-CH.

	MPQA	NTCIR-EN	NTCIR-CH
Positive	1,471(30%)	528 (30%)	2,378 (55%)
Negative	3,487(70%)	1,209(70%)	1,916(44%)
Total	4,958	1,737	4,294

Table 1: Statistics about the Data

CLMM includes two hyper-parameters ( $\lambda_s$  and  $\lambda_t$ ) controlling the contribution of unlabeled parallel data. Larger weights indicate larger influence from the unlabeled data. We set the hyper-parameters by conducting cross validations on the labeled data. When Chinese labeled data are unavailable, we set  $\lambda_t$  to 1 and  $\lambda_s$  to 0.1, since no Chinese labeled data are used and the contribution of target language to the source language is limited. When Chinese labeled data are available, we set  $\lambda_s$  and  $\lambda_t$  to 0.2.

To prevent long sentences from dominating the parameter estimation, we preprocess the data set by normalizing the length of all sentences to the same constant (Nigam et al., 2000), the average length of the sentences.

## 4.2 Baseline Methods

For the purpose of comparison, we implement the following baseline methods.

*MT-SVM*: We translate the English labeled data to Chinese using Google Translate and use the translation results to train the SVM classifier for Chinese.

*SVM*: We train a SVM classifier on the Chinese labeled data.

*MT-Cotrain*: This is the co-training based approach described in (Wan, 2009). We summarize the main steps as follows. First, two monolingual SVM classifiers are trained on English labeled data and Chinese data *translated* from English labeled data. Second, the two classifiers make prediction on Chinese unlabeled data and their English translation,

respectively. Third, the 100 most confidently predicted English and Chinese sentences are added to the training set and the two monolingual SVM classifiers are re-trained on the expanded training set. The second and the third steps are repeated for 100 times to obtain the final classifiers.

*Para-Cotrain*: The training process is the same as MT-Cotrain. However, we use a different set of English unlabeled sentences. Instead of using the corresponding machine translation of Chinese unlabeled sentences, we use the parallel English sentences of the Chinese unlabeled sentences.

*Joint-Train*: This is the state-of-the-art method described in (Lu et al., 2011). This model use English labeled data and Chinese labeled data to obtain initial parameters for two maximum entropy classifiers (for English documents and Chinese documents), and then conduct EM-iterations to update the parameters to gradually improve the agreement of the two monolingual classifiers on the unlabeled parallel sentences.

## 4.3 Classification Using Only English Labeled Data

The first set of experiments are conducted on using only English labeled data to create the sentiment classifier for Chinese. This is a challenging task, since we do not use any Chinese labeled data. And MPQA and NTCIR data sets are compiled by different groups using different annotation guidelines.

Method	NTCIR-EN NTCIR-CH	MPQA-EN NTCIR-CH
MT-SVM	62.34	54.33
SVM	N/A	N/A
MT-Cotrain	65.13	59.11
Para-Cotrain	67.21	60.71
Joint-Train	N/A	N/A
CLMM	<b>70.96</b>	<b>71.52</b>

Table 2: Classification Accuracy Using Only English Labeled Data

Table 2 shows the accuracy of the baseline systems as well as the proposed model (CLMM). As is shown, sentiment classification does not benefit much from the direct machine translation. For NTCIR-EN+NTCIR-CH, the accuracy of MT-SVM

is only 62.34%. For MPQA-EN+NTCIR-CH, the accuracy is 54.33%, even lower than a trivial method, which achieves 55.4% by predicting all sentences to be positive. The underlying reason is that the vocabulary coverage in machine translated data is low, therefore the classifier learned from the labeled data is unable to generalize well on the test data. Meanwhile, the accuracy of MT-SVM on NTCIR-EN+NTCIR-CH data set is much better than that on MPQA+NTCIR-CH data set. That is because NTCIR-EN and NTCIR-CH cover similar topics. The other two methods using machine translated data, MT-Cotrain and Para-Cotrain also do not perform very well. This result is reasonable, because the initial Chinese classifier trained on machine translated data (MT-SVM) is relatively weak. We also observe that using a parallel corpus instead of machine translations can improve classification accuracy. It should be noted that we do not have the result for Joint-Train model in this setting, since it requires both English labeled data and Chinese labeled data.

#### 4.4 Classification Using English and Chinese Labeled Data

The second set of experiments are conducted on using both English labeled data and Chinese labeled data to develop the Chinese sentiment classifier. We conduct 5-fold cross validations on Chinese labeled data. We use the same baseline methods as described in Section 4.2, but we use *natural* Chinese sentences instead of *translated* Chinese sentences as labeled data in MT-Cotrain and Para-Cotrain. Table 3 shows the accuracy of baseline systems as well as CLMM.

Method	NTCIR-EN NTCIR-CH	MPQA-EN NTCIR-CH
MT-SVM	62.34	54.33
SVM	80.58	80.58
MT-Cotrain	82.28	80.93
Para-Cotrain	82.35	82.18
Joint-Train	83.11	83.42
CLMM	82.73	83.02

Table 3: Classification Accuracy Using English and Chinese Labeled Data

As is seen, SVM performs significantly better than MT-SVM. One reason is that we use natural Chi-

nese labeled data instead of translated Chinese labeled data. Another reason is that we use 5-fold cross validations in this setting, while the previous setting is an *open test* setting. In this setting, SVM is a strong baseline with 80.6% accuracy. Nevertheless, all three methods which leverage an unlabeled parallel corpus, namely Para-Cotrain, Joint-Train and CLMM, still show big improvements over the SVM baseline. Their results are comparable and all achieve state-of-the-art accuracy of about 83%, but in terms of training speed, CLMM is the fastest method (Table 4). Similar to the previous setting, We also have the same observation that using a parallel corpus is better than using translations.

Method	Iterations	Total Time
Para-Cotrain	100	6 hours
Joint-Train	10	55 seconds
CLMM	10	30 seconds

Table 4: Training Speed Comparison

#### 4.5 The Influence of Unlabeled Parallel Data

We investigate how the size of the unlabeled parallel data affects the sentiment classification in this subsection. We vary the number of sentences in the unlabeled parallel from 2,000 to 20,000. We use only English labeled data in this experiment, since this more directly reflects the effectiveness of each model in utilizing unlabeled parallel data. From Figure 3 and Figure 4, we can see that when more unlabeled parallel data are added, the accuracy of CLMM consistently improves. The performance of CLMM is remarkably superior than Para-Cotrain and MT-Cotrain. When we have 10,000 parallel sentences, the accuracy of CLMM on the two data sets quickly increases to 68.77% and 68.91%, respectively. By contrast, we observe that the performance of Para-Cotrain and MT-Cotrain is able to obtain accuracy improvement only after about 10,000 sentences are added. The reason is that the two methods use machine translated labeled data to create initial Chinese classifiers. As is depicted in Table 2, these classifiers are relatively weak. As a result, in the initial iterations of co-training based methods, the predictions made by the Chinese classifiers are inaccurate, and co-training based methods need to see more parallel

Figure 3: Accuracy with different size of unlabeled data for NTICR-EN+NTCIR-CH

Figure 4: Accuracy with different size of unlabeled data for MPQA+NTCIR-CH

Figure 5: Accuracy with different size of labeled data for NTCIR-EN+NTCIR-CH

Figure 6: Accuracy with different size of labeled data for MPQA+NTCIR-CH

sentences to refine the initial classifiers.

#### 4.6 The Influence of Chinese Labeled Data

In this subsection, we investigate how the size of the Chinese labeled data affects the sentiment classification. As is shown in Figure 5 and Figure 6, when only 500 labeled sentences are used, CLMM is capable of achieving 72.52% and 74.48% in accuracy on the two data sets, obtaining 10% and 8% improvements over the SVM baseline, respectively. This indicates that our method leverages the unlabeled data effectively. When more sentences are used, CLMM consistently shows further improvement in accuracy. Para-Cotrain and Joint-Train show similar trends. When 3500 labeled sentences are used, SVM achieves 80.58%, a relatively high accuracy for sentiment classification. However, CLMM and the other two models can still gain improvements. This further demonstrates the advantages of expanding vocabulary using bilingual parallel data.

## 5 Conclusion and Future Work

In this paper, we propose a cross-lingual mixture model (CLMM) to tackle the problem of cross-lingual sentiment classification. This method has two advantages over the existing methods. First, the proposed model can learn previously unseen sentiment words from large unlabeled data, which are not covered by the limited vocabulary in machine translation of the labeled data. Second, CLMM can effectively utilize unlabeled parallel data regardless of whether labeled data in the target language are used or not. Extensive experiments suggest that CLMM consistently improve classification accuracy in both settings. In the future, we will work on leveraging parallel sentences and word alignments for other tasks in sentiment analysis, such as building multi-lingual sentiment lexicons.

## Abstract

We present a novel answer summarization method for community Question Answering services (cQAs) to address the problem of “incomplete answer”, i.e., the “best answer” of a complex multi-sentence question misses valuable information that is contained in other answers. In order to automatically generate a novel and non-redundant community answer summary, we segment the complex original multi-sentence question into several sub questions and then propose a general Conditional Random Field (CRF) based answer summary method with group  $L_1$  regularization. Various textual and non-textual QA features are explored. Specifically, we explore four different types of contextual factors, namely, the information novelty and non-redundancy modeling for local and non-local sentence interactions under question segmentation. To further unleash the potential of the abundant cQA features, we introduce the group  $L_1$  regularization for feature learning. Experimental results on a Yahoo! Answers dataset show that our proposed method significantly outperforms state-of-the-art methods on cQA summarization task.

## 1 Introduction

Community Question and Answering services (cQAs) have become valuable resources for users to pose questions of their interests and share their knowledge by providing answers to questions. They perform much better than the traditional frequently asked questions (FAQ) systems (Jijkoun and Rijke, 2005; Riezler et al., 2007) which are just based

on natural language processing and information retrieving technologies due to the need for human intelligence in user generated contents (Gyongyi et al., 2007). In cQAs such as Yahoo! Answers, a resolved question often gets more than one answers and a “best answer” will be chosen by the asker or voted by other community participants. This {question, best answer} pair is then stored and indexed for further uses such as question retrieval. It performs very well in simple factoid QA settings, where the answers to factoid questions often relate to a single named entity like a person, time or location. However, when it comes to the more sophisticated multi-sentence questions, it would suffer from the problem of “incomplete answer”. That is, such question often comprises several sub questions in specific contexts and the asker wishes to get elaborated answers for as many aspects of the question as possible. In which case, the single best answer that covers just one or few aspects may not be a good choice (Liu et al., 2008; Takechi et al., 2007). Since “everyone knows something” (Adamic et al., 2008), the use of a single best answer often misses valuable human generated information contained in other answers.

In an early literature, Liu et al. (2008) reported that no more than 48% of the 400 best answers were indeed the unique best answers in 4 most popular Yahoo! Answers categories. Table 1 shows an example of the “incomplete answer” problem from Yahoo! Answers<sup>1</sup>. The asker wishes to know why his teeth bleed and how to prevent it. However, the best answer only gives information on the reason of teeth

<sup>1</sup><http://answers.yahoo.com/question/index?qid=20100610161858AAmAGrV>

bleeding. It is clear that some valuable information about the reasons of gums bleeding and some solutions are presented in other answers.

<p><b>Question</b></p> <p>Why do teeth bleed at night and how do you prevent/stop it? This morning I woke up with blood caked between my two front teeth. This is the third morning in a row that it has happened. I brush and floss regularly, and I also eat a balanced, healthy diet. Why is this happening and how do I stop it?</p>
<p><b>Best Answer - Chosen by Asker</b></p> <p>Periodontal disease is a possibility, gingivitis, or some gum infection. Teeth don't bleed; gums bleed.</p>
<p><b>Other Answers</b></p> <p>Vitamin C deficiency!</p> <p>Ever heard of a dentist? Not all the problems in life are solved on the Internet.</p> <p>You could be brushing or flossing too hard. Try a brush with softer bristles or brushing/flossing lighter and slower. If this doesn't solve your problem, try seeing a dentist or doctor. Gums that bleed could be a sign of a more serious issue like leukemia, an infection, gum disease, a blood disorder, or a vitamin deficiency.</p> <p>wash your mouth with warm water and salt, it will help to strengthen your gum and teeth, also salt avoid infection. You probably have weak gums, so just try to follow the advice, it works in many cases of oral problems.</p>

Table 1: An example of question with incomplete answer problem from Yahoo! Answers. The “best answer” seems to miss valuable information and will not be ideal for re-use when similar question is asked again.

In general, as noted in (Jurafsky and Martin, 2009), most interesting questions are not factoid questions. User’s needs require longer, more informative answers than a single phrase. In fact, it is often the case, that a complex multi-sentence question could be answered from multiple aspects by different people focusing on different sub questions. Therefore we address the incomplete answer problem by developing a novel summarization technique taking different sub questions and contexts into consideration. Specifically we want to learn a concise summary from a set of corresponding answers as supplement or replacement to the “best answer”.

We tackle the answer summary task as a sequential labeling process under the general Conditional Random Fields (CRF) framework: every answer sentence in the question thread is labeled as a *summary* sentence or *non-summary* sentence, and we concatenate the sentences with *summary* label to form the final summarized answer. The contribution of this paper is two-fold:

First, we present a general CRF based framework

and incorporate four different contextual factors based on question segmentation to model the local and non-local semantic sentence interactions to address the problem of redundancy and information novelty. Various textual and non-textual question answering features are exploited in the work.

Second, we propose a group  $L_1$ -regularization approach in the CRF model for automatic optimal feature learning to unleash the potential of the features and enhance the performance of answer summarization.

We conduct experiments on a Yahoo! Answers dataset. The experimental results show that the proposed model improve the performance significantly (in terms of precision, recall and F1 measures) as well as the ROUGE-1, ROUGE-2 and ROUGE-L measures as compared to the state-of-the-art methods, such as Support Vector Machines (SVM), Logistic Regression (LR) and Linear CRF (LCRF) (Shen et al., 2007).

The rest of the paper is arranged as follows: Section 2 presents some definitions and a brief review of related research. In Section 3, we propose the summarization framework and then in Section 4 and 5 we detail the experimental setups and results respectively. We conclude the paper in Section 6.

## 2 Definitions and Related Work

### 2.1 Definitions

In this subsection we define some concepts that would be helpful to clarify our problems. First we define a *complex multi-sentence* question as a question with the following properties:

**Definition:** A *complex multi-sentence question* is one that contains multiple sub-questions.

In the cQAs scenario a question often consists of one or more main question sentences accompany by some context sentences described by askers. We treat the original question and context as a whole single complex multi-sentence question and obtain the sub questions by question segmentation. We then define the *incomplete answer* problem as:

**Definition:** The *incomplete answer problem* is one where the best answer of a complex multi-sentence question is voted to be below certain star ratings or the average similarity between the best answer and all the sub questions is below some thresh-

olds.

We study the issues of similarity threshold and the minimal number of stars empirically in the experimental section and show that they are useful in identifying questions with the incomplete answer problem.

## 2.2 Related Work

There exist several attempts to alleviate the answer completeness problem in cQA. One of them is to segment the multi-sentence question into a set of sub-questions along with their contexts, then sequentially retrieve the sub questions one by one, and return similar questions and their best answers (Wang et al., 2010). This strategy works well in general, however, as the automatic question segmentation is imperfect and the matched similar questions are likely to be generated in different contextual situations, this strategy often could not combine multiple independent best answers of sub questions seamlessly and may introduce redundancy in final answer.

On general problem of cQA answer summarization, Liu et al.(2008) manually classified both questions and answers into different taxonomies and applied clustering algorithms for answer summarization. They utilized textual features for open and opinion type questions. Through exploiting metadata, Tomasoni and Huang(2010) introduced four characteristics (constraints) of summarized answer and combined them in an additional model as well as a multiplicative model. In order to leverage context, Yang et al.(2011) employed a dual wing factor graph to mutually enhance the performance of social document summarization with user generated content like tweets. Wang et al. (2011) learned online discussion structures such as the replying relationship by using the general CRFs and presented a detailed description of their feature designs for sites and edges embedded in discussion thread structures. However there is no previous work that explores the complex multi-sentence question segmentation and its contextual modeling for community answer summarization.

Some other works examined the evaluation of the quality of features for answers extracted from cQA services (Jeon et al., 2006; Hong and Davison , 2009; Shah et al., 2010). In the work of Shah et al.(2010), a large number of features extracted for

predicting asker-rated quality of answers was evaluated by using a logistic regression model. However, to the best of our knowledge, there is no work in evaluating the quality of features for community answer summarization. In our work we model the feature learning and evaluation problem as a group  $L_1$  regularization problem (Schmidt , 2010) on different feature groups.

## 3 The Summarization Framework

### 3.1 Conditional Random Fields

We utilize the probabilistic graphical model to solve the answer summarization task, Figure 1 gives some illustrations, in which the sites correspond to the sentences and the edges are utilized to model the interactions between sentences. Specifically, let  $\mathbf{x}$  be the sentence sequence to all answers within a question thread, and  $\mathbf{y}$  be the corresponding label sequence. Every component  $y_i$  of  $\mathbf{y}$  has a binary value, with +1 for the summary sentence and -1 otherwise. Then under CRF (Lafferty et al., 2001), the conditional probability of  $\mathbf{y}$  given  $\mathbf{x}$  obeys the following distribution:

$$p(\mathbf{y}|\mathbf{x}) = \frac{1}{Z(\mathbf{x})} \exp\left(\sum_{v \in V, l} \mu_l g_l(v, \mathbf{y}|_v, \mathbf{x}) + \sum_{e \in E, k} \lambda_k f_k(e, \mathbf{y}|_e, \mathbf{x})\right), \quad (1)$$

where  $Z(\mathbf{x})$  is the normalization constant called partition function,  $g_l$  denotes the cQA feature function of site  $l$ ,  $f_k$  denotes the function of edge  $k$  (modeling the interactions between sentences),  $\mu$  and  $\lambda$  are respectively the weights of function of sites and edges, and  $\mathbf{y}|_t$  denotes the components of  $\mathbf{y}$  related to site (edge)  $t$ .

### 3.2 cQA Features and Contextual Modeling

In this section, we give a detailed description of the different sentence-level cQA features and the contextual modeling between sentences used in our model for answer summarization.

#### Sentence-level Features

Different from the conventional multi-document summarization in which only the textual features are utilized, we also explore a number of non-textual author related features (Shah et al., 2010) in cQAs.

**The textual features used are:**

1. **Sentence Length:** The length of the sentence in the answers with the stop words removed. It seems that a long sentence may contain more information.
2. **Position:** The sentence's position within the answer. If a sentence is at the beginning or at the end of one answer, it might be a generation or viewpoint sentence and will be given higher weight in the summarization task.
3. **Answer Length:** The length of the answer to which the sentence belonged, again with the stop words removed.
4. **Stopwords Rate:** The rate of stop words in the sentence. If a sentence contains too many stop words, it is more likely a spam or chitchat sentence rather than an informative one.
5. **Uppercase Rate:** The rate of uppercase words. Uppercase words are often people's name, address or other name entities interested by askers.
6. **Has Link** Whether the sentence contains a hyperlink or not. The link often points to a more detailed information source.
7. **Similarity to Question:** Semantic similarity to the question and question context. It imports the semantic information relevance to the question and question context.

**The non-textual features used include:**

8. **Best Answer Star:** The stars of the best answer received by the askers or voters.
9. **Thumbs Up:** The number of thumbs-ups the answer which contains the sentence receives. Users are often used to support one answer by giving a thumbs up after reading some relevant or interesting information for their intentions.
10. **Author Level:** The level of stars the author who gives the answer sentence acquires. The higher the star level, the more authoritative the asker is.
11. **Best Answer Rate:** Rate of answers annotated as the best answer the author who gives the answer sentence receives.
12. **Total Answer Number:** The number of total answers by the author who gives the answer sentence. The more answers one gives, the more experience he or she acquires.
13. **Total Points:** The total points that the author who gives the answer sentence receives.

The previous literature (Shah et al., 2010) hinted that some cQA features, such as *Sentence Length*, *Has Link* and *Best Answer Star*, may be more im-

portant than others. We also expect that some feature may be redundant when their most related features are given, e.g., the *Author Level* feature is positively related with the *Total Points* received by answerers, and *Stopwords Rate* is of little help when both *Sentence Length* (not including stop words) and *Uppercase Rate* are given. Therefore, to explore the optimal combination of these features, we propose a group  $L_1$  regularization term in the general CRF model (Section 3.3) for feature learning.

All features presented here can be extracted automatically from the Yahoo! Answers website. We normalize all these feature values to real numbers between 0 and 1 by dividing them by the corresponding maximal value of these features. These sentence-level features can be easily utilized in the CRF framework. For instance, if the rate of uppercase words is prominent or the position is close to the beginning or end of the answer, then the probability of the label +1 (summary sentence) should be boosted by assigning it with a large value.

### Contextual Modeling Under Question Segmentation

For cQAs summarization, the semantic interactions between different sentence sites are crucial, that is, some context co-occurrences should be encouraged and others should be penalized for requirements of information novelty and non-redundancy in the generated summary. Here we consider both local (sentences from the same answer) and global (sentences from different answers) settings. This give rise to four contextual factors that we will explore for modeling the pairwise semantic interactions based on question segmentation. In this paper, we utilize a simple but effective lightweight question segmentation method (Ding et al., 2008; Wang et al., 2010). It mainly involves the following two steps:

**Step 1.** Question sentence detection: every sentence in the original multi-sentence question is classified into *question sentence* and *non-question (context) sentence*. The *question mark* and *5WIH* features are applied.

**Step 2.** Context assignment: every context sentence is assigned to the most relevant question sentence. We compute the semantic similarity (Simpson and Crowe, 2005) between sentences or sub ques-

Figure 1: Four kinds of the contextual factors are considered for answer summarization in our general CRF based models.

tions as:

$$sim(x, y) = 2 \times \sum_{(w_1, w_2) \in M(x, y)} \frac{sim(w_1, w_2)}{|x| + |y|} \quad (2)$$

where  $M(x, y)$  denotes synset pairs matched in sentences  $x$  and  $y$ ; and the similarity between the two synsets  $w_1$  and  $w_2$  is computed to be inversely proportional to the length of the path in Wordnet.

One answer sentence may related to more than one sub questions to some extent. Thus, we define the *replied question*  $Qr_i$  as the sub question with the maximal similarity to sentence  $x_i$ :  $Qr_i = \operatorname{argmax}_{Q_j} sim(x_i, Q_j)$ . It is intuitive that different summary sentences aim at answering different sub questions. Therefore, we design the following two contextual factors based on the similarity of replied questions.

**Dissimilar Replied Question Factor:** Given two answer sentences  $x_i$ ,  $x_j$  and their corresponding replied questions  $Qr_i$ ,  $Qr_j$ . If the similarity<sup>2</sup> of  $Qr_i$  and  $Qr_j$  is below some threshold  $\tau_{lq}$ , it means that  $x_i$  and  $x_j$  will present different viewpoints to answer different sub questions. In this case, it is likely that  $x_i$  and  $x_j$  are both summary sentences; we ensure this by setting the contextual factor  $cf_1$  with a large value of  $\exp \nu$ , where  $\nu$  is a positive real constant often assigned to value 1; otherwise we set  $cf_1$  to  $\exp - \nu$  for penalization.

$$cf_1 = \begin{cases} \exp \nu, & y_i = y_j = 1 \\ \exp - \nu, & \text{otherwise} \end{cases}$$

**Similar Replied Question Factor:** Given two an-

<sup>2</sup>We use the semantic similarity of Equation 2 for all our similarity measurement in this paper.

swer sentences  $x_i$ ,  $x_j$  and their corresponding replied questions  $Qr_i$ ,  $Qr_j$ . If the similarity of  $Qr_i$  and  $Qr_j$  is above some upper threshold  $\tau_{uq}$ , this means that  $x_i$  and  $x_j$  are very similar and likely to provide similar viewpoint to answer similar questions. In this case, we want to select either  $x_i$  or  $x_j$  as answer. This is done by setting the contextual factor  $cf_2$  such that  $x_i$  and  $x_j$  have opposite labels,

$$cf_2 = \begin{cases} \exp \nu, & y_i * y_j = -1 \\ \exp - \nu, & \text{otherwise} \end{cases}$$

Assuming that sentence  $x_i$  is selected as a summary sentence, and its next local neighborhood sentence  $x_{i+1}$  by the same author is dissimilar to it but it is relevant to the original multi-sentence question, then it is reasonable to also pick  $x_{i+1}$  as a summary sentence because it may offer new viewpoints by the author. Meanwhile, other local and non-local sentences which are similar to it at above the upper threshold will probably not be selected as summary sentences as they offer similar viewpoint as discussed above. Therefore, we propose the following two kinds of contextual factors for selecting the answer sentences in the CRF model.

**Local Novelty Factor:** If the similarity of answer sentence  $x_i$  and  $x_{i+1}$  given by the same author is below a lower threshold  $\tau_{ls}$ , but their respective similarities to the sub questions both exceed an upper threshold  $\tau_{us}$ , then we will boost the probability of selecting both as summary sentences by setting:

$$cf_3 = \begin{cases} \exp \nu, & y_i = y_{i+1} = 1 \\ \exp - \nu, & \text{otherwise} \end{cases}$$

**Redundance Factor:** If the similarity of answer

sentence  $x_i$  and  $x_j$  is greater than the upper threshold  $\tau_{us}$ , then they are likely to be redundant and hence should be given opposite labels. This is done by setting:

$$cf_4 = \begin{cases} \exp \nu, & y_i * y_j = -1 \\ \exp -\nu, & \text{otherwise} \end{cases}$$

Figure 1 gives an illustration of these four contextual factors in our proposed general CRF based model. The parameter estimation and model inference are discussed in the following subsection.

### 3.3 Group $L_1$ Regularization for Feature Learning

In the context of cQA summarization task, some features are intuitively to be more important than others. As a result, we group the parameters in our CRF model with their related features<sup>3</sup> and introduce a group  $L_1$ -regularization term for selecting the most useful features from the least important ones, where the regularization term becomes,

$$R(\theta) = C \sum_{g=1}^G \|\vec{\theta}_g\|_2, \quad (3)$$

where  $C$  controls the penalty magnitude of the parameters,  $G$  is the number of feature groups and  $\vec{\theta}_g$  denotes the parameters corresponding to the particular group  $g$ . Notice that this penalty term is indeed a  $L(1, 2)$  regularization because in every particular group we normalize the parameters in  $L_2$  norm while the weight of a whole group is summed in  $L_1$  form.

Given a set of training data  $D = (x^{(i)}, y^{(i)})$ ,  $i = 1, \dots, N$ , the parameters  $\theta = (\mu_l, \lambda_k)$  of the general CRF with the group  $L_1$ -regularization are estimated in using a maximum log likelihood function  $L$  as:

$$L = \sum_{i=1}^N \log(p_\theta(y^{(i)}|x^{(i)})) - C \sum_{g=1}^G \|\vec{\theta}_g\|_2, \quad (4)$$

<sup>3</sup>We note that every sentence-level feature discussed in Section 3.2 presents a variety of instances (e.g., the sentence with longer or shorter length is the different instance), and we may call it sub-feature of the original sentence-level feature in the micro view. Every sub-feature has its corresponding weight in our CRF model. Whereas in a macro view, those related sub-features can be considered as a group.

where  $N$  denotes the total number of training samples. we compute the log-likelihood gradient component of  $\theta$  in the first term of Equation 4 as in usual CRFs. However, the second term of Equation 4 is non-differentiable when some special  $\|\vec{\theta}_g\|_2$  becomes exactly zero. To tackle this problem, an additional variable is added for each group (Schmidt, 2010); that is, by replacing each norm  $\|\vec{\theta}_g\|_2$  with the variable  $\alpha_g$ , subject to the constraint  $\alpha_g \geq \|\vec{\theta}_g\|_2$ , i.e.,

$$L = \sum_{i=1}^N \log(p_\theta(y^{(i)}|x^{(i)})) - C \sum_{g=1}^G \alpha_g, \quad (5)$$

subject to  $\alpha_g \geq \|\vec{\theta}_g\|_2, \forall g$ .

This formulation transforms the non-differentiable regularizer to a simple linear function and maximizing Equation 5 will lead to a solution to Equation 4 because it is a lower bound of the latter. Then, we add a sufficient small positive constant  $\varepsilon$  when computing the  $L_2$  norm (Lee et al., 2006), i.e.,  $\|\vec{\theta}_g\|_2 = \sqrt{\sum_{j=1}^{|g|} \theta_{gj}^2 + \varepsilon}$ , where  $|g|$  denotes the number of features in group  $g$ . To obtain the optimal value of parameter  $\theta$  from the training data, we use an efficient L-BFGS solver to solve the problem, and the first derivative of every feature  $j$  in group  $g$  is,

$$\frac{\delta L}{\delta \theta_{gj}} = \sum_{i=1}^N C_{gj}(y^{(i)}, x^{(i)}) - \sum_{i=1}^N \sum_y p(y|x^{(i)}) C_{gj}(y, x^{(i)}) - 2C \frac{\theta_{gj}}{\sqrt{\sum_{l=1}^{|g|} \theta_{gl}^2 + \varepsilon}} \quad (6)$$

where  $C_{gj}(y, x)$  denotes the count of feature  $j$  in group  $g$  of observation-label pair  $(x, y)$ . The first two terms of Equation 6 measure the difference between the empirical and the model expected values of feature  $j$  in group  $g$ , while the third term is the derivative of group  $L_1$  priors.

For inference, the labeling sequence can be obtained by maximizing the probability of  $y$  conditioned on  $x$ ,

$$y^* = \operatorname{argmax}_y p_\theta(y|x). \quad (7)$$

We use a modification of the Viterbi algorithm to perform inference of the CRF with non-local edges

previously used in (Galley, 2006). That is, we replace the edge connection  $z_t = (y_{t-2}, y_{t-1}, y_t)$  of order-2 Markov model by  $z_t = (y_{N_t}, y_{t-1}, y_t)$ , where  $y_{N_t}$  represents the label at the source of the non-local edge. Although it is an approximation of the exact inference, we will see that it works well for our answer summarization task in the experiments.

## 4 Experimental Setting

### 4.1 Dataset

To evaluate the performance of our CRF based answer summarization model, we conduct experiments on the Yahoo! Answers archives dataset. The Yahoo! *Webscope*<sup>TM</sup> Program<sup>4</sup> opens up a number of Yahoo! Answers datasets for interested academics in different categories. Our original dataset contains 1,300,559 questions and 2,770,896 answers in ten taxonomies from Yahoo! Answers. After filtering the questions which have less than 5 answers and some trivial factoid questions using the features by (Tomasoni and Huang, 2010), we reduce the dataset to 55,132 questions. From this sub-set, we next select the questions with incomplete answers as defined in Section 2.1. Specifically, we select the questions where the average similarity between the best answer and all sub questions is less than 0.6 or when the star rating of the best answer is less than 4. We obtain 7,784 questions after this step. To evaluate the effectiveness of this method, we randomly choose 400 questions in the filtered dataset and invite 10 graduate candidate students (not in NLP research field) to verify whether a question suffers from the incomplete answer problem. We divide the students into five groups of two each. We consider the questions as the “incomplete answer questions” only when they are judged by both members in a group to be the case. As a result, we find that 360 (90%) of these questions indeed suffer from the incomplete answer problem, which indicates that our automatic detection method is efficient. This randomly selected 400 questions along with their 2559 answers are then further manually summarized for evaluation of automatically generated answer summaries by our model in experiments.

<sup>4</sup><http://sandbox.yahoo.com/>

## 4.2 Evaluation Measures

When taking the summarization as a sequential bi-classification problem, we can make use of the usual precision, recall and F1 measures (Shen et al., 2007) for classification accuracy evaluation.

In our experiments, we also compare the precision, recall and F1 score in the ROUGE-1, ROUGE-2 and ROUGE-L measures (Lin, 2004) for answer summarization performance.

## 5 Experimental Results

### 5.1 Summarization Results

We adapt the Support Vector Machine (SVM) and Logistic Regression (LR) which have been reported to be effective for classification and the Linear CRF (LCRF) which is used to summarize ordinary text documents in (Shen et al., 2007) as baselines for comparison. To better illustrate the effectiveness of question segmentation based contextual factors and the group  $L_1$  regularization term, we carry the tests in the following sequence: (a) we use only the contextual factors  $cf_3$  and  $cf_4$  with default  $L_2$  regularization (gCRF); (b) we add the reply question based factors  $cf_1$  and  $cf_2$  to the model (gCRF-QS); and (c) we replace default  $L_2$  regularization with our proposed group  $L_1$  regularization term (gCRF-QS-11). For linear CRF system, we use all our textual and non-textual features as well as the local (exact previous and next) neighborhood contextual factors instead of the features of (Shen et al., 2007) for fairness. For the thresholds used in the contextual factors, we enforce  $\tau_{lq}$  to be equal to  $\tau_{ls}$  and  $\tau_{uq}$  equal to  $\tau_{us}$  for the purpose of simplifying the parameters setting ( $\tau_{lq} = \tau_{ls} = 0.4$ ,  $\tau_{uq} = \tau_{us} = 0.8$  in our experiments). We randomly divide the dataset into ten subsets (every subset with 40 questions and the associated answers), and conduct a ten-fold cross validation and for each round where the nine subsets are used to train the model and the remaining one for testing. The precision, recall and F1 measures of these models are presented in Table 2.

Table 2 shows that our general CRF model based on question segmentation with group  $L_1$  regularization out-performs the baselines significantly in all three measures (gCRF-QS-11 is 13.99% better than SVM in precision, 9.77% better in recall and 11.72% better in F1 score). We note that both SVM and LR,

Model	R1_P	R1_R	R1_F1	R2_P	R2_R	R2_F1	RL_P	RL_R	RL_F1
SVM	79.2%	52.5%	63.1%	71.9%	41.3%	52.4%	67.1%	36.7%	47.4%
LR	75.2%↓	57.4%↑	65.1%↑	66.1%↓	48.5%↑	56.0%↑	61.6%↓	43.2%↑	50.8%↑
LCRF	78.7%-	61.8%↑	69.3%-	71.4%-	54.1%↑	61.6%↑	67.1%-	49.6%↑	57.0%↑
<b>gCRF</b>	81.9%↑	65.2%↑	72.6%↑	76.8%↑	57.3%↑	65.7%↑	73.9%↑	53.5%↑	62.1%↑

<b>gCRF-QS-II</b>	<b>86.6%</b> ↑	68.3%-	<b>76.4%</b> ↑	<b>82.6%</b> ↑	61.5%-	<b>70.5%</b> ↑	<b>80.4%</b> ↑	58.2%-	<b>67.5%</b> ↑

Table 3: The Precision, Recall and F1 of ROUGE-1, ROUGE-2, ROUGE-L in the baselines SVM,LR, LCRF and our general CRF based models (gCRF, gCRF-QS, gCRF-QS-II). The down-arrow means performance degradation with statistical significance.

Model	Precision	Recall	F1
SVM	65.93%	61.96%	63.88%
LR	66.92%-	61.31%-	63.99%-
LCRF	69.80%↑	63.91%-	66.73%↑
<b>gCRF</b>	73.77%↑	69.43%↑	71.53%↑
<b>gCRF-QS</b>	74.78%↑	<b>72.51%</b> ↑	73.63%↑
<b>gCRF-QS-II</b>	<b>79.92%</b> ↑	71.73%-	<b>75.60%</b> ↑

Table 2: The Precision, Recall and F1 measures of the baselines SVM,LR, LCRF and our general CRF based models (gCRF, gCRF-QS, gCRF-QS-II). The up-arrow denotes the performance improvement compared to the previous method (above) with statistical significance under p value of 0.05, the short line '-' denotes there is no difference in statistical significance.

which just utilize the independent sentence-level features, behave not vary well here, and there is no statistically significant performance difference between them. We also find that LCRF which utilizes the local context information between sentences perform better than the LR method in precision and F1 with statistical significance. While we consider the general local and non-local contextual factor  $cf_3$  and  $cf_4$  for novelty and non-redundancy constraints, the gCRF performs much better than LCRF in all three measures; and we obtain further performance improvement by adding the contextual factors based on QS, especially in the recall measurement. This is mainly because we have divided the question into several sub questions, and the system is able to select more novel sentences than just treating the original multi-sentence as a whole. In addition, when we replace the default  $L_2$  regularization by the group  $L_1$  regularization for more efficient feature weight learning, we obtain a much better performance in

precision while not sacrificing the recall measurement statistically.

We also compute the Precision, Recall and F1 in ROUGE-1, ROUGE-2 and ROUGE-L measurements, which are widely used to measure the quality of automatic text summarization. The experimental results are listed in Table 3. All results in the Table are the average of the ten-fold cross validation experiments on our dataset.

It is observed that our gCRF-QS-II model improves the performance in terms of precision, recall and F1 score on all three measurements of ROUGE-1, ROUGE-2 and ROUGE-L by a significant margin compared to other baselines due to the use of local and non-local contextual factors and factors based on QS with group  $L_1$  regularization. Since the ROUGE measures care more about the recall and precision of N-grams as well as common substrings to the reference summary rather than the whole sentence, they offer a better measurement in modeling the user’s information needs. Therefore, the improvements in these measures are more encouraging than those of the average classification accuracy for answer summarization.

From the viewpoint of ROUGE measures we observe that our question segmentation method can enhance the recall of the summaries significantly due to the more fine-grained modeling of sub questions. We also find that the precision of the group  $L_1$  regularization is much better than that of the default  $L_2$  regularization while not hurting the recall significantly. In general, the experimental results show that our proposed method is more effective than other baselines in answer summarization for addressing the incomplete answer problem in cQAs.

Figure 2: The accumulated weight of each site feature group in the group  $L_1$ -regularization to our Yahoo! Answer dataset. The horizontal axis corresponds to the name of each feature group.

## 5.2 Evaluation of Feature Learning

For group  $L_1$  regularization term, we set the  $\varepsilon = 10^{-4}$  in Equation 6. To see how much the different textual and non-textual features contribute to community answer summarization, the accumulated weight of each group of sentence-level features<sup>5</sup> is presented in Figure 2. It shows that the textual features such as 1 (*Sentence Length*), 2 (*Position*) 3 (*Answer Length*), 6 (*Has Link*) and non-textual features such as 8 (*Best Answer Star*), 12 (*Total Answer Number*) as well as 13 (*Total Points*) have larger weights, which play a significant role in the summarization task as we intuitively considered; features 4 (*Stopwords Rate*), 5 (*Uppercase Rate*) and 9 (*Thumbs Up*) have medium weights relatively; and the other features like 7 (*Similarity to Question*), 10 (*Author Level*) and 11 (*Best Answer Rate*) have the smallest accumulated weights. The main reasons that the feature 7 (*Similarity to Question*) has low contribution is that we have utilized the similarity to question in the contextual factors, and this similarity feature in the single site becomes redundant. Similarly, the features *Author Level* and *Best Answer Number* are likely to be redundant when other non-textual features (*Total Answer Number* and *Total Points*) are presented together. The experimental results demonstrate that with the use of group  $L_1$ -regularization we have learnt better combination of these features.

<sup>5</sup>Note that we have already evaluated the contribution of the contextual factors in Section 5.1.

## 5.3 An Example of Summarized Answer

To demonstrate the effectiveness of our proposed method, Table 4 shows the generated summary of the example question which is previously illustrated in Table 1 in the introduction section. The best answer available in the system and the summarized answer generated by our model are compared in Table 4. It is found that the summarized answer contains more valuable information about the original multi-sentence question, as it better answers the reason of teeth bleeding and offers some solution for it. Storing and indexing this summarized answer in question archives should provide a better choice for answer reuse in question retrieval of cQAs.

Question
Why do teeth bleed at night and how do you prevent/stop it? This morning I woke up with blood caked between my two front teeth.[...]
Best Answer - Chosen by Asker
Periodontal disease is a possibility, gingivitis, or some gum infection. Teeth don't bleed; gums bleed.
Summarized Answer Generated by Our Method
Periodontal disease is a possibility, gingivitis, or some gum infection. Teeth don't bleed; gums bleed. Gums that bleed could be a sign of a more serious issue like leukemia, an infection, gum disease, a blood disorder, or a vitamin deficiency. wash your mouth with warm water and salt, it will help to strengthen your gum and teeth, also salt avoid infection.

Table 4: Summarized answer by our general CRF based model for the question in Table 1.

## 6 Conclusions

We proposed a general CRF based community answer summarization method to deal with the incomplete answer problem for deep understanding of complex multi-sentence questions. Our main contributions are that we proposed a systematic way for modeling semantic contextual interactions between the answer sentences based on question segmentation and we explored both the textual and non-textual answer features learned via a group  $L_1$  regularization. We showed that our method is able to achieve significant improvements in performance of answer summarization compared to other baselines and previous methods on Yahoo! Answers dataset. We plan to extend our proposed model with more advanced feature learning as well as enriching our summarized answer with more available Web re-

sources.

## Abstract

In recent years, error mining approaches were developed to help identify the most likely sources of parsing failures in parsing systems using handcrafted grammars and lexicons. However the techniques they use to enumerate and count n-grams builds on the sequential nature of a text corpus and do not easily extend to structured data. In this paper, we propose an algorithm for mining trees and apply it to detect the most likely sources of generation failure. We show that this tree mining algorithm permits identifying not only errors in the generation system (grammar, lexicon) but also mismatches between the structures contained in the input and the input structures expected by our generator as well as a few idiosyncrasies/error in the input data.

## 1 Introduction

In recent years, error mining techniques have been developed to help identify the most likely sources of parsing failure (van Noord, 2004; Sagot and de la Clergerie, 2006; de Kok et al., 2009). First, the input data (text) is separated into two subcorpora, a corpus of sentences that could be parsed (PASS) and a corpus of sentences that failed to be parsed (FAIL). For each n-gram of words (and/or part of speech tag) occurring in the corpus to be parsed, a suspicion rate is then computed which, in essence, captures the likelihood that this n-gram causes parsing to fail.

These error mining techniques have been applied with good results on parsing output and shown to help improve the large scale symbolic grammars and

lexicons used by the parser. However the techniques they use (e.g., suffix arrays) to enumerate and count n-grams builds on the sequential nature of a text corpus and cannot easily extend to structured data.

There are some NLP applications though where the processed data is structured data such as trees or graphs and which would benefit from error mining. For instance, when generating sentences from dependency trees, as was proposed recently in the Generation Challenge Surface Realisation Task (SR Task, (Belz et al., 2011)), it would be useful to be able to apply error mining on the input trees to find the most likely causes of generation failure.

In this paper, we address this issue and propose an approach that supports error mining on trees. We adapt an existing algorithm for tree mining which we then use to mine the Generation Challenge dependency trees and identify the most likely causes of generation failure. We show in particular, that this tree mining algorithm permits identifying not only errors in the grammar and the lexicon used by generation but also a few idiosyncrasies/error in the input data as well as mismatches between the structures contained in the SR input and the input structures expected by our generator. The latter is an important point since, for symbolic approaches, a major hurdle to participation in the SR challenge is known to be precisely these mismatches i.e., the fact that the input provided by the SR task fails to match the input expected by the symbolic generation systems (Belz et al., 2011).

The paper is structured as follows. Section 2 presents the HybridTreeMiner algorithm, a complete and computationally efficient algorithm developed

Figure 1: Four unordered labelled trees. The rightmost is in Breadth-First Canonical Form

by (Chi et al., 2004) for discovering frequently occurring subtrees in a database of labelled unordered trees. Section 3 shows how to adapt this algorithm to mine the SR dependency trees for subtrees with high suspicion rate. Section 4 presents an experiment we made using the resulting tree mining algorithm on SR dependency trees and summarises the results. Section 5 discusses related work. Section 6 concludes.

## 2 Mining Trees

Mining for frequent subtrees is an important problem that has many applications such as XML data mining, web usage analysis and RNA classification. The HybridTreeMiner (HTM) algorithm presented in (Chi et al., 2004) provides a complete and computationally efficient method for discovering frequently occurring subtrees in a database of labelled unordered trees and counting them. We now sketch the intuition underlying this algorithm<sup>1</sup>. In the next section, we will show how to modify this algorithm to mine for errors in dependency trees.

Given a set of trees  $T$ , the HybridTreeMiner algorithm proceeds in two steps. First, the unordered labelled trees contained in  $T$  are converted to a canonical form called BFCF (Breadth-First Canonical Form). In that way, distinct instantiations of the same unordered trees have a unique representation. Second, the subtrees of the BFCF trees are enumerated in increasing size order using two tree operations called join and extension and their support (the number of trees in the database that contains each subtree) is recorded. In effect, the algorithm builds an enumeration tree whose nodes are the possible subtrees of  $T$  and such that, at depth  $d$  of this enumeration tree, all possible frequent subtrees consisting of  $d$  nodes are listed.

<sup>1</sup>For a more complete definition see (Chi et al., 2004).

The BFCF canonical form of an unordered tree is an ordered tree  $t$  such that  $t$  has the smallest breath-first canonical string (BFCS) encoding according to lexicographic order. The BFCS encoding of a tree is obtained by breadth-first traversal of the tree, recording the string labelling each node, “\$” to separate siblings with distinct parents and “#” to represent the end of the tree<sup>2</sup>. For instance, the BFCS encodings of the four trees shown in Figure 1 are ‘A\$BB\$C\$DC#’, ‘A\$BB\$C\$CD#’, ‘A\$BB\$DC\$C#’ and ‘A\$BB\$CD\$C#’ respectively. Hence, the rightmost tree is the BFCF of all four trees.

The join and extension operations used to iteratively enumerate subtrees are depicted in Figure 2 and can be defined as follows.

- A leg is a leaf of maximal depth.
- Extension: Given a tree  $t$  of height  $h_t$  and a node  $n$ , extending  $t$  with  $n$  yields a tree  $t'$  (a child of  $t$  in the enumeration tree) with height  $h_{t'}$  such that  $n$  is a child of one of  $t$ 's legs and  $h_{t'}$  is  $h_t + 1$ .
- Join: Given two trees  $t_1$  and  $t_2$  of same height  $h$  differing only in their rightmost leg and such that  $t_1$  sorts lower than  $t_2$ , joining  $t_1$  and  $t_2$  yields a tree  $t'$  (a child of  $t_1$  in the enumeration tree) of same height  $h$  by adding the rightmost leg of  $t_2$  to  $t_1$  at level  $h - 1$ .

Figure 2: Join and Extension Operations

To support counting, the algorithm additionally records for each subtree a list (called *occurrence list*)

<sup>2</sup>Assuming “#” sorts greater than “\$” and both sort greater than any other alphabets in node labels.

of all trees in which this subtree occurs and of its position in the tree (represented by the list of tree nodes mapped onto by the subtree). Thus for a given subtree  $t$ , the *support* of  $t$  is the number of elements in that list. Occurrence lists are also used to check that trees that are combined occur in the data. For the join operation, the subtrees being combined must occur in the same tree at the same position (the intersection of their occurrence lists must be non empty and the tree nodes must match except the last node). For the extension operation, the extension of a tree  $t$  is licensed for any given occurrence in the occurrence list only if the planned extension maps onto the tree identified by the occurrence.

### 3 Mining Dependency Trees

We develop an algorithm (called ErrorTreeMiner, ETM) which adapts the HybridTreeMiner algorithm to mine sources of generation errors in the Generation Challenge SR shallow input data. The main modification is that instead of simply counting trees, we want to compute their suspicion rate. Following (de Kok et al., 2009), we take the suspicion rate of a given subtree  $t$  to be the proportion of cases where  $t$  occurs in an input tree for which generation fails:

$$Sus(t) = \frac{count(t|FAIL)}{count(t)}$$

where  $count(t)$  is the number of occurrences of  $t$  in all input trees and  $count(t|FAIL)$  is the number of occurrences of  $t$  in input trees for which no output was produced.

Since we work with subtrees of arbitrary length, we also need to check whether constructing a longer subtree is useful that is, whether its suspicion rate is equal or higher than the suspicion rate of any of the subtrees it contains. In that way, we avoid computing all subtrees (thus saving time and space). As noted in (de Kok et al., 2009), this also permits bypassing *suspicion sharing* that is the fact that, if  $n_2$  is the cause of a generation failure, and if  $n_2$  is contained in larger trees  $n_3$  and  $n_4$ , then all three trees will have high suspicion rate making it difficult to identify the actual source of failure namely  $n_2$ . Because we use a milder condition however (we accept bigger trees whose suspicion rate is *equal* to the suspicion rate of any of their subtrees), some amount of

    return true  
  end if  
end if  
return false
```

---

suspicion sharing remains. As we shall see in Section 4.3.2, relaxing this check though allows us to extract frequent larger tree patterns and thereby get a more precise picture of the context in which highly suspicious items occur.

Finally, we only keep subtrees whose support is above a given threshold where the support  $Sup(t)$  of a tree  $t$  is defined as the ratio between the number of times it occurs in an input for which generation fails and the total number of generation failures:

$$Sup(t) = \frac{count(t|FAIL)}{count(FAIL)}$$

The modified algorithm we use for error mining is given in Algorithm 1, 2 and 3. It can be summarised as follows.

First, dependency trees are converted to Breadth-First Canonical Form whereby lexicographic order can apply to the word forms labelling tree nodes, to their part of speech, to their dependency relation or to any combination thereof<sup>3</sup>.

Next, the algorithm iteratively enumerates the subtrees occurring in the input data in increasing size order and associating each subtree  $t$  with two occurrence lists namely, the list of input trees in which  $t$  occurs and for which generation was successful ( $PASS(t)$ ); and the list of input trees in which  $t$  occurs and for which generation failed ( $FAIL(t)$ ).

This process is initiated by building trees of size one (i.e., one-node tree) and extending them to trees of size two. It is then continued by extending the trees using the join and extension operations. As explained in Section 2 above, join and extension only apply provided the resulting trees occur in the data (this is checked by looking up occurrence lists).

---

<sup>3</sup>For convenience, the dependency relation labelling the edges of dependency trees is brought down to the daughter node of the edge.

Each time an  $n$ -node tree  $t_n$ , is built, it is checked that (i) its support is above the set threshold and (ii) its suspicion rate is higher than or equal to the suspicion rate of all  $(n - 1)$ -node subtrees of  $t_n$ .

In sum, the ETM algorithm differs from the HTM algorithm in two main ways. First, while HTM explores the enumeration tree depth-first, ETM proceeds breadth-first to ensure that the suspicion rate of  $(n-1)$ -node trees is always available when checking whether an  $n$ -node tree should be introduced. Second, while the HTM algorithm uses support to prune the search space (only trees with a minimum support bigger than the set threshold are stored), the ETM algorithm drastically prunes the search space by additionally checking that the suspicion rate of all subtrees contained in a new tree  $t$  is smaller or equal to the suspicion rate of  $t$ . As a result, while ETM loses the space advantage of HTM by a small margin<sup>4</sup>, it benefits from a much stronger pruning of the search space than HTM through suspicion rate checking. In practice, the ETM algorithm allows us to process e.g., all NP chunks of size 4 and 6 present in the SR data (roughly 60 000 trees) in roughly 20 minutes on a PC.

## 4 Experiment and Results

Using the input data provided by the Generation Challenge SR Task, we applied the error mining algorithm described in the preceding Section to debug and extend a symbolic surface realiser developed for this task.

### 4.1 Input Data and Surface Realisation System

The shallow input data provided by the SR Task was obtained from the Penn Treebank using the LTH Constituent-to-Dependency Conversion Tool for Penn-style Treebanks (Pennconverter, (Johansson and Nugues, 2007)). It consists of a set of unordered labelled syntactic dependency trees whose nodes are labelled with word forms, part of speech categories, partial morphosyntactic information such as tense and number and, in some cases, a sense tag identifier. The edges are labelled with the syntactic labels provided by the Pennconverter. All words (including punctuation) of the original sen-

---

<sup>4</sup>ETM needs to store all  $(n-1)$ -node trees in queues before producing  $n$ -node trees.

tence are represented by a node in the tree and the alignment between nodes and word forms was provided by the organisers.

The surface realiser used is a system based on a Feature-Based Lexicalised Tree Adjoining Grammar (FB-LTAG) for English extended with a unification based compositional semantics. Both the grammars and the lexicon were developed in view of the Generation Challenge and the data provided by this challenge was used as a means to debug and extend the system. Unknown words are assigned a default TAG family/tree based on the part of speech they are associated with in the SR data. The surface realisation algorithm extends the algorithm proposed in (Gardent and Perez-Beltrachini, 2010) and adapts it to work on the SR dependency input rather than on flat semantic representations.

## 4.2 Experimental Setup

To facilitate interpretation, we first chunked the input data in NPs, PPs and Clauses and performed error mining on the resulting sets of data. The chunking was performed by retrieving from the Penn Treebank (PTB), for each phrase type, the yields of the constituents of that type and by using the alignment between words and dependency tree nodes provided by the organisers of the SR Task. For instance, given the sentence “*The most troublesome report may be the August merchandise trade deficit due out tomorrow*”, the NPs “*The most troublesome report*” and “*the August merchandise trade deficit due out tomorrow*” will be extracted from the PTB and the corresponding dependency structures from the SR Task data.

Using this chunked data, we then ran the generator on the corresponding SR Task dependency trees and stored separately, the input dependency trees for which generation succeeded and the input dependency trees for which generation failed. Using information provided by the generator, we then removed from the failed data, those cases where generation failed either because a word was missing in the lexicon or because a TAG tree/family was missing in the grammar but required by the lexicon and the input data. These cases can easily be detected using the generation system and thus do not need to be handled by error mining.

Finally, we performed error mining on the data

using different minimal support thresholds, different display modes (sorted first by size and second by suspicion rate vs sorted by suspicion rate) and different labels (part of speech, words and part of speech, dependency, dependency and part of speech).

## 4.3 Results

One feature of our approach is that it permits mining the data for tree patterns of arbitrary size using different types of labelling information (POS tags, dependencies, word forms and any combination thereof). In what follows, we focus on the NP chunk data and illustrate by means of examples how these features can be exploited to extract complementary debugging information from the data.

### 4.3.1 Mining on single labels (word form, POS tag or dependency)

Mining on a single label permits (i) assessing the relative impact of each category in a given label category and (ii) identifying different sources of errors depending on the type of label considered (POS tag, dependency or word form).

**Mining on POS tags** Table 1 illustrates how mining on a single label (in this case, POS tags) gives a good overview of how the different categories in that label type impact generation: two POS tags (POS and CC) have a suspicion rate of 0.99 indicating that these categories always lead generation to fail. Other POS tag with much lower suspicion rate indicate that there are unresolved issues with, in decreasing order of suspicion rate, cardinal numbers (CD), proper names (NNP), nouns (NN), prepositions (IN) and determiners (DT).

The highest ranking category (POS<sup>5</sup>) points to a mismatch between the representation of genitive NPs (e.g., *John’s father*) in the SR Task data and in the grammar. While our generator expects the representation of ‘John’s father’ to be FATHER(“S”(JOHN)), the structure provided by the SR Task is FATHER(JOHN(“S”)). Hence whenever a possessive appears in the input data, generation fails. This is in line with (Rajkumar et al., 2011)’s finding that the logical forms expected by their system for possessives differed from the shared task inputs.

<sup>5</sup>In the Penn Treebank, the POS tag is the category assigned to possessive ‘s.

POS	Sus	Sup	Fail	Pass
POS	0.99	0.38	3237	1
CC	0.99	0.21	1774	9
CD	0.39	0.16	1419	2148
NNP	0.35	0.32	2749	5014
NN	0.30	0.81	6798	15663
IN	0.30	0.16	1355	3128
DT	0.09	0.12	1079	10254

Table 1: Error Mining on POS tags with frequency cutoff 0.1 and displaying only trees of size 1 sorted by decreasing suspicion rate (Sus)

The second highest ranked category is CC for coordinations. In this case, error mining unveils a bug in the grammar trees associated with conjunction which made all sentences containing a conjunction fail. Because the grammar is compiled out of a strongly factorised description, errors in this description can propagate to a large number of trees in the grammar. It turned out that an error occurred in a class inherited by all conjunction trees thereby blocking the generation of any sentence requiring the use of a conjunction.

Next but with a much lower suspicion rate come cardinal numbers (CD), proper names (NNP), nouns (NN), prepositions (IN) and determiners (DT). We will see below how the richer information provided by mining for larger tree patterns with mixed labelling information permits identifying the contexts in which these POS tags lead to generation failure.

**Mining on Word Forms** Because we remove from the failure set all cases of errors due to a missing word form in the lexicon, a high suspicion rate for a word form usually indicates a missing or incorrect lexical entry: the word is present in the lexicon but associated with either the wrong POS tag and/or the wrong TAG tree/family. To capture such cases, we therefore mine not on word forms alone but on pairs of word forms and POS tag. In this way, we found for instance, that cardinal numbers induced many generation failures whenever they were categorised as determiners but not as nouns in our lexicon. As we will see below, larger tree patterns help identify the specific contexts inducing such failures.

One interesting case stood out which pointed to idiosyncrasies in the input data: The word form \$

(Sus=1) was assigned the POS tag \$ in the input data, a POS tag which is unknown to our system and not documented in the SR Task guidelines. The SR guidelines specify that the Penn Treebank tagset is used modulo the modifications which are explicitly listed. However for the \$ symbol, the Penn treebank used SYM as a POS tag and the SR Task \$, but the modification is not listed. Similarly, while in the Penn treebank, punctuations are assigned the SYM POS tag, in the SR data “,” is used for the comma, “(“ for an opening bracket and so on.

**Mining on Dependencies** When mining on dependencies, suspects can point to syntactic constructions (rather than words or word categories) that are not easily spotted when mining on words or parts of speech. Thus, while problems with coordination could easily be spotted through a high suspicion rate for the CC POS tag, some constructions are linked neither to a specific POS tag nor to a specific word. This is the case, for instance, for apposition which a suspicion rate of 0.19 (286F/1148P) identified as problematic. Similarly, a high suspicion rate (0.54, 183F/155P) on the TMP dependency indicates that temporal modifiers are not correctly handled either because of missing or erroneous information in the grammar or because of a mismatch between the input data and the format expected by the surface realiser.

Interestingly, the underspecified dependency relation DEP which is typically used in cases for which no obvious syntactic dependency comes to mind shows a suspicion rate of 0.61 (595F/371P).

#### 4.3.2 Mining on trees of arbitrary size and complex labelling patterns

While error mining with tree patterns of size one permits ranking and qualifying the various sources of errors, larger patterns often provide more detailed contextual information about these errors. For instance, Table 1 shows that the CD POS tag has a suspicion rate of 0.39 (1419F/2148P). The larger tree patterns identified below permits a more specific characterization of the context in which this POS tag co-occurs with generation failure:

TP1	CD(IN,RBR)	<i>more than 10</i>
TP2	IN(CD)	<i>of 1991</i>
TP3	NNP(CD)	<i>November 1</i>
TP4	CD(NNP(CD))	<i>Nov. 1, 1997</i>

Two patterns clearly emerge: a pattern where cardinal numbers are parts of a date (tree patterns TP2-TP4) and a more specific pattern (TP1) involving the comparative construction (e.g., *more than 10*). All these patterns in fact point to a missing category for cardinals in the lexicon: they are only associated with determiner TAG trees, not nouns, and therefore fail to combine with prepositions (e.g., *of 1991, than 10*) and with proper names (e.g., *November 1*).

For proper names (NNP), dates also show up because months are tagged as proper names (TP3,TP4) as well as addresses TP5:

TP5 NNP(“,”“,”) *Brooklyn, n.y.*,

For prepositions (IN), we find, in addition to the TP1-TP2, the following two main patterns:

TP6 DT(IN) *those with, some of*

TP7 RB(IN) *just under, little more*

Pattern TP6 points to a missing entry for words such as *those* and *some* which are categorised in the lexicon as determiners but not as nouns. TP7 points to a mismatch between the SR data and the format expected by the generator: while the latter expects the structure IN(RB), the input format provided by the SR Task is RB(IN).

#### 4.4 Improving Generation Using the Results of Error Mining

Table 2 shows how implementing some of the corrections suggested by error mining impacts the number of NP chunks (size 4) that can be generated. In this experiment, the total number of input (NP) dependency trees is 24995. Before error mining, generation failed on 33% of these input. Correcting the erroneous class inherited by all conjunction trees mentioned in Section 4.3.1 brings generation failure down to 26%. Converting the input data to the correct input format to resolve the mismatch induced by possessive 's (cf. Section 4.3.1) reduce generation failure to 21%<sup>6</sup> and combining both corrections results in a failure rate of 13%. In other words, error mining permits quickly identifying two issues which, once corrected, reduces generation failure by 20 points.

When mining on clause size chunks, other mismatches were identified such as in particular, mismatches introduced by subjects and auxiliaries:

<sup>6</sup>For NP of size 4, 3264 structures with possessive 's were rewritten.

NP 4	Before	After
SR Data	8361	6511
Rewritten SR Data	5255	3401

Table 2: Diminishing the number of errors using information from error mining. The table compares the number of failures on NP chunks of size 4 before (first row) and after (second row) rewriting the SR data to the format expected by our generator and before (second column) and after (third column) correcting the grammar and lexicon errors discussed in Section 4.3.1

while our generator expects both the subject and the auxiliary to be children of the verb, the SR data represent the subject and the verb as children of the auxiliary.

## 5 Related Work

We now relate our proposal (i) to previous proposals on error mining and (ii) to the use of error mining in natural language generation.

**Previous work on error mining.** (van Noord, 2004) initiated error mining on parsing results with a very simple approach computing the parsability rate of each n-gram in a very large corpus. The parsability rate of an n-gram  $w_1 \dots w_n$  is the ratio  $R(w_1 \dots w_n) = \frac{C(w_1 \dots w_n | OK)}{C(w_1 \dots w_n)}$  with  $C(w_1 \dots w_n)$  the number of sentences in which the n-gram  $w_1 \dots w_n$  occurs and  $C(w_1 \dots w_n | OK)$  the number of sentences containing  $w_1 \dots w_n$  which could be parsed. The corpus is stored in a suffix array and the sorted suffixes are used to compute the frequency of each n-grams in the total corpus and in the corpus of parsed sentences. The approach was later extended and refined in (Sagot and de la Clergerie, 2006) and (de Kok et al., 2009) whereby (Sagot and de la Clergerie, 2006) defines a suspicion rate for n-grams which takes into account the number of occurrences of a given word form and iteratively defines the suspicion rate of each word form in a sentence based on the suspicion rate of this word form in the corpus; (de Kok et al., 2009) combined the iterative error mining proposed by (Sagot and de la Clergerie, 2006) with expansion of forms to n-grams of words and POS tags of arbitrary length.

Our approach differs from these previous ap-

proaches in several ways. First, error mining is performed on trees. Second, it can be parameterised to use any combination of POS tag, dependency and/or word form information. Third, it is applied to generation input rather than parsing output. Typically, the input to surface realisation is a structured representation (i.e., a flat semantic representation, a first order logic formula or a dependency tree) rather than a string. Mining these structured representations thus permits identifying causes of undergeneration in surface realisation systems.

**Error Mining for Generation** Not much work has been done on mining the results of surface realisers. Nonetheless, (Gardent and Kow, 2007) describes an error mining approach which works on the output of surface realisation (the generated sentences), manually separates correct from incorrect output and looks for derivation items which systematically occur in incorrect output but not in correct ones. In contrast, our approach works on the input to surface realisation, automatically separates correct from incorrect items using surface realisation and targets the most likely sources of errors rather than the absolute ones.

More generally, our approach is the first to our knowledge, which mines a surface realiser for undergeneration. Indeed, apart from (Gardent and Kow, 2007), most previous work on surface realisation evaluation has focused on evaluating the performance and the coverage of surface realisers. Approaches based on reversible grammars (Carroll et al., 1999) have used the semantic formulae output by parsing to evaluate the coverage and performance of their realiser; similarly, (Gardent et al., 2010) developed a tool called GenSem which traverses the grammar to produce flat semantic representations and thereby provide a benchmark for performance and coverage evaluation. In both cases however, because it is produced using the grammar exploited by the surface realiser, the input produced can only be used to test for overgeneration (and performance). (Callaway, 2003) avoids this shortcoming by converting the Penn Treebank to the format expected by his realiser. However, this involves manually identifying the mismatches between two formats much like symbolic systems did in the Generation Challenge SR Task. The error mining approach we pro-

pose helps identifying such mismatches automatically.

## 6 Conclusion

Previous work on error mining has focused on applications (parsing) where the input data is sequential working mainly on words and part of speech tags. In this paper, we proposed a novel approach to error mining which permits mining trees. We applied it to the input data provided by the Generation Challenge SR Task. And we showed that this supports the identification of gaps and errors in the grammar and in the lexicon; and of mismatches between the input data format and the format expected by our realiser.

We applied our error mining approach to the input of a surface realiser to identify the most likely sources of *undergeneration*. We plan to also explore how it can be used to detect the most likely sources of *overgeneration* based on the output of this surface realiser on the SR Task data. Using the Penn Treebank sentences associated with each SR Task dependency tree, we will create the two tree sets necessary to support error mining by dividing the set of trees output by the surface realiser into a set of trees (FAIL) associated with overgeneration (the generated sentences do not match the original sentences) and a set of trees (SUCCESS) associated with success (the generated sentence matches the original sentences). Exactly which tree should populate the SUCCESS and FAIL set is an open question. The various evaluation metrics used by the SR Task (BLEU, NIST, METEOR and TER) could be used to determine a threshold under which an output is considered incorrect (and thus classified as FAIL). Alternatively, a strict matching might be required. Similarly, since the surface realiser is non deterministic, the number of output trees to be kept will need to be experimented with.

## Acknowledgments

We would like to thank Clément Jacq for useful discussions on the hybrid tree miner algorithm. The research presented in this paper was partially supported by the European Fund for Regional Development within the framework of the INTERREG IV A Allegro Project.

## Abstract

This paper studies the problem of sentence-level semantic coherence by answering SAT-style sentence completion questions. These questions test the ability of algorithms to distinguish sense from nonsense based on a variety of sentence-level phenomena. We tackle the problem with two approaches: methods that use local lexical information, such as the n-grams of a classical language model; and methods that evaluate global coherence, such as latent semantic analysis. We evaluate these methods on a suite of practice SAT questions, and on a recently released sentence completion task based on data taken from five Conan Doyle novels. We find that by fusing local and global information, we can exceed 50% on this task (chance baseline is 20%), and we suggest some avenues for further research.

## 1 Introduction

In recent years, standardized examinations have proved a fertile source of evaluation data for language processing tasks. They are valuable for many reasons: they represent facets of language understanding recognized as important by educational experts; they are organized in various formats designed to evaluate specific capabilities; they are yardsticks by which society measures educational progress; and they affect a large number of people.

Previous researchers have taken advantage of this material to test both narrow and general language processing capabilities. Among the narrower tasks, the identification of synonyms and antonyms has

been studied by (Landauer and Dumais, 1997; Mohammed et al., 2008; Mohammed et al., 2011; Turney et al., 2003; Turney, 2008), who used questions from the Test of English as a Foreign Language (TOEFL), Graduate Record Exams (GRE) and English as a Second Language (ESL) exams. Tasks requiring broader competencies include logic puzzles and reading comprehension. Logic puzzles drawn from the Law School Administration Test (LSAT) and the GRE were studied in (Lev et al., 2004), which combined an extensive array of techniques to solve the problems. The DeepRead system (Hirschman et al., 1999) initiated a long line of research into reading comprehension based on test prep material (Charniak et al., 2000; Riloff and Theilen, 2000; Wang et al., 2000; Ng et al., 2000).

In this paper, we study a new class of problems intermediate in difficulty between the extremes of synonym detection and general question answering - the sentence completion questions found on the Scholastic Aptitude Test (SAT). These questions present a sentence with one or two blanks that need to be filled in. Five possible words (or short phrases) are given as options for each blank. All possible answers except one result in a nonsense sentence. Two examples are shown in Figure 1.

The questions are highly constrained in the sense that all the information necessary is present in the sentence itself without any other context. Nevertheless, they vary widely in difficulty. The first of these examples is relatively simple: the second half of the sentence is a clear description of the type of behavior characterized by the desired adjective. The second example is more sophisticated; one must infer from

1. One of the characters in Milton Murayama's novel is considered \_\_\_\_\_ because he deliberately defies an oppressive hierarchical society.  
(A) rebellious (B) impulsive (C) artistic (D) industrious (E) tyrannical
  
2. Whether substances are medicines or poisons often depends on dosage, for substances that are \_\_\_\_\_ in small doses can be \_\_\_\_\_ in large.  
(A) useless .. effective  
(B) mild .. benign  
(C) curative .. toxic  
(D) harmful .. fatal  
(E) beneficial .. miraculous

Figure 1: Sample sentence completion questions (Educational-Testing-Service, 2011).

the contrast between medicine and poison that the correct answer involves a contrast, either *useless vs. effective* or *curative vs. toxic*. Moreover, the first, incorrect, possibility is perfectly acceptable in the context of the second clause alone; only irrelevance to the contrast between medicine and poison eliminates it. In general, the questions require a combination of semantic and world knowledge as well as occasional logical reasoning. We study the sentence completion task because we believe it is complex enough to pose a significant challenge, yet structured enough that progress may be possible.

As a first step, we have approached the problem from two points-of-view: first by exploiting local sentence structure, and secondly by measuring a novel form of global sentence coherence based on latent semantic analysis. To investigate the usefulness of local information, we evaluated n-gram language model scores, from both a conventional model with Good-Turing smoothing, and with a recently proposed maximum-entropy class-based n-gram model (Chen, 2009a; Chen, 2009b). Also in the language modeling vein, but with potentially global context, we evaluate the use of a recurrent neural network language model. In all the language modeling approaches, a model is used to compute a sentence probability with each of the potential completions. To measure global coherence, we propose

a novel method based on latent semantic analysis (LSA). We find that the LSA based method performs best, and that both local and global information can be combined to exceed 50% accuracy. We report results on a set of questions taken from a collection of SAT practice exams (Princeton-Review, 2010), and further validate the methods with the recently proposed MSR Sentence Completion Challenge set (Zweig and Burges, 2011).

Our paper thus makes the following contributions: First, we present the first published results on the SAT sentence completion task. Secondly, we evaluate the effectiveness of both local n-gram information, and global coherence in the form of a novel LSA-based metric. Finally, we illustrate that the local and global information can be effectively fused.

The remainder of this paper is organized as follows. In Section 2 we discuss related work. Section 3 describes the language modeling methods we have evaluated. Section 4 outlines the LSA-based methods. Section 5 presents our experimental results. We conclude with a discussion in Section 6.

## 2 Related Work

The past work which is most similar to ours is derived from the lexical substitution track of SemEval-2007 (McCarthy and Navigli, 2007). In this task, the challenge is to find a replacement for a word or phrase removed from a sentence. In contrast to our SAT-inspired task, the original answer is indicated. For example, one might be asked to find alternates for *match* in "After the *match*, replace any remaining fluid deficit to prevent problems of chronic dehydration throughout the tournament." Two consistently high-performing systems for this task are the KU (Yuret, 2007) and UNT (Hassan et al., 2007) systems. These operate in two phases: first they find a set of potential replacement words, and then they rank them. The KU system uses just an N-gram language model to do this ranking. The UNT system uses a large variety of information sources, and a language model score receives the highest weight. N-gram statistics were also very effective in (Giuliano et al., 2007). That paper also explores the use of Latent Semantic Analysis to measure the degree of similarity between a potential replacement and its context, but the results are poorer than others. Since the original word provides a strong hint as to the pos-

sible meanings of the replacements, we hypothesize that N-gram statistics are largely able to resolve the remaining ambiguities. The SAT sentence completion sentences do not have this property and thus are more challenging.

Related to, but predating the Semeval lexical substitution task are the ESL synonym questions proposed by Turney (2001), and subsequently considered by numerous research groups including Terra and Clarke (2003) and Pado and Lapata (2007). These questions are similar to the SemEval task, but in addition to the original word and the sentence context, the list of options is provided. Jarmasz and Szpakowicz (2003) used a sophisticated thesaurus-based method and achieved state-of-the-art performance, which is 82%.

Other work on standardized tests includes the synonym and antonym tasks mentioned in Section 1, and more recent work on a SAT analogy task introduced by (Turney et al., 2003) and extensively used by other researchers (Veale, 2004; Turney and Littman, 2005; D. et al., 2009).

### 3 Sentence Completion via Language Modeling

Perhaps the most straightforward approach to solving the sentence completion task is to form the complete sentence with each option in turn, and to evaluate its likelihood under a language model. As discussed in Section 2, this was found to be very effective in the ranking phase of several SemEval systems. In this section, we describe the suite of state-of-the-art language modeling techniques for which we will present results. We begin with n-gram models; first a classical n-gram backoff model (Chen and Goodman, 1999), and then a recently proposed class-based maximum-entropy n-gram model (Chen, 2009a; Chen, 2009b). N-gram models have the obvious disadvantage of using a very limited context in predicting word probabilities. Therefore we evaluate the recurrent neural net model of (Mikolov et al., 2010; Mikolov et al., 2011b). This model has produced record-breaking perplexity results in several tasks (Mikolov et al., 2011a), and has the potential to encode sentence-span information in the network hidden-layer activations. We have also evaluated the use of parse scores, using an off-the-shelf stochastic context free grammar parser. How-

ever, the grammatical structure of the alternatives is often identical. With scores differing only in the final non-terminal/terminal rewrites, this did little better than chance. The use of other syntactically derived features, for example based on a dependency parse, are likely to be more effective, but we leave this for future work.

#### 3.1 Backoff N-gram Language Model

Our baseline model is a Good-Turing smoothed model trained with the CMU language modeling toolkit (Clarkson and Rosenfeld, 1997). For the SAT task, we used a trigram language model trained on 1.1B words of newspaper data, described in Section 5.1. All bigrams occurring at least twice were retained in the model, along with all trigrams occurring at least three times. The vocabulary consisted of all words occurring at least 100 times in the data, along with every word in the development or test sets. This resulted in a 124k word vocabulary and 59M n-grams. For the Conan Doyle data, which we henceforth refer to as the *Holmes data* (see Section 5.1), the smaller amount of training data allowed us to use 4-grams and a vocabulary cutoff of 3. This resulted in 26M n-grams and a 126k word vocabulary.

#### 3.2 Maximum Entropy Class-Based N-gram Language Model

Word-class information provides a level of abstraction which is not available in a word-level language model; therefore we evaluated a state-of-the-art class based language model. Model M (Chen, 2009a; Chen, 2009b) is a recently proposed class based exponential n-gram language model which has shown improvements across a variety of tasks (Chen, 2009b; Chen et al., 2009; Emami et al., 2010). The key ideas are the modeling of word n-gram probabilities with a maximum entropy model, and the use of word-class information in the definition of the features. In particular, each word  $w$  is assigned deterministically to a class  $c$ , allowing the n-gram probabilities to be estimated as the product of class and word parts

$$P(w_i | w_{i-n+1} \dots w_{i-2} w_{i-1}) = P(c_i | c_{i-n+1} \dots c_{i-2} c_{i-1}, w_{i-n+1} \dots w_{i-2} w_{i-1}) P(w_i | w_{i-n+1} \dots w_{i-2} w_{i-1}, c_i).$$

Both components are themselves maximum entropy n-gram models in which the probability of a word or class label  $l$  given history  $h$  is determined by  $\frac{1}{Z} \exp(\sum_k f_k(h, l))$ . The features  $f_k(h, l)$  used are the presence of various patterns in the concatenation of  $hl$ , for example whether a particular suffix is present in  $hl$ .

### 3.3 Recurrent Neural Net Language Model

Many of the questions involve long-range dependencies between words. While n-gram models have no ability to explicitly maintain long-span context, the recently proposed recurrent neural-net model of (Mikolov et al., 2010) does. Related approaches have been proposed by (Sutskever et al., 2011; Socher et al., 2011). In this model, a set of neural net activations  $\mathbf{s}(t)$  is maintained and updated at each sentence position  $t$ . These activations encapsulate the sentence history up to the  $t^{\text{th}}$  word in a real-valued vector which typically has several hundred dimensions. The word at position  $t$  is represented as a binary vector  $\mathbf{w}(t)$  whose length is the vocabulary size, and with a “1” in a position uniquely associated with the word, and “0” elsewhere.  $\mathbf{w}(t)$  and  $\mathbf{s}(t)$  are concatenated to predict an output distribution over words,  $\mathbf{y}(t)$ . Updating is done with two weight matrices  $\mathbf{u}$  and  $\mathbf{v}$  and nonlinear functions  $f()$  and  $g()$  (Mikolov et al., 2011b):

$$\begin{aligned} \mathbf{x}(t) &= [\mathbf{w}(t)^T \mathbf{s}(t-1)^T]^T \\ s_j(t) &= f\left(\sum_i x_i(t) u_{ji}\right) \\ y_k(t) &= g\left(\sum_j s_j(t) v_{kj}\right) \end{aligned}$$

with  $f()$  being a sigmoid and  $g()$  a softmax:

$$f(x) = \frac{1}{1 + \exp(-x)}, g(z_m) = \frac{\exp(z_m)}{\sum_k \exp(z_k)}$$

The output  $\mathbf{y}(t)$  is a probability distribution over words, and the parameters  $\mathbf{u}$  and  $\mathbf{v}$  are trained with back-propagation to minimize the Kullback-Leibler (KL) divergence between the predicted and observed distributions. Because of the recurrent connections, this model is similar to a nonlinear infinite impulse response (IIR) filter, and has the potential to model long span dependencies. Theoretical considerations (Bengio et al., 1994) indicate that for many problems, this may not be possible, but in practice it is an empirical question.

## 4 Sentence Completion via Latent Semantic Analysis

Latent Semantic Analysis (LSA) (Deerwester et al., 1990) is a widely used method for representing words and documents in a low dimensional vector space. The method is based on applying singular value decomposition (SVD) to a matrix  $W$  representing the occurrence of words in documents. SVD results in an approximation of  $W$  by the product of three matrices, one in which each word is represented as a low-dimensional vector, one in which each document is represented as a low dimensional vector, and a diagonal scaling matrix. The similarity between two words can then be quantified as the cosine-similarity between their respective scaled vectors, and document similarity can be measured likewise. It has been used in numerous tasks, ranging from information retrieval (Deerwester et al., 1990) to speech recognition (Bellegarda, 2000; Coccaro and Jurafsky, 1998).

To perform LSA, one proceeds as follows. The input is a collection of  $n$  documents which are expressed in terms of words from a vocabulary of size  $m$ . These documents may be actual documents such as newspaper articles, or simply as in our case notional documents such as sentences. Next, a  $m \times n$  matrix  $W$  is formed. At its simplest, the  $ij^{\text{th}}$  entry contains the number of times word  $i$  has occurred in document  $j$  - its *term frequency* or TF value. More conventionally, the entry is weighted by some notion of the importance of word  $i$ , for example the negative logarithm of the fraction of documents that contain it, resulting in a TF-IDF weighting (Salton et al., 1975). Finally, to obtain a subspace representation of dimension  $d$ ,  $W$  is decomposed as

$$W \approx USV^T$$

where  $U$  is  $m \times d$ ,  $V^T$  is  $d \times n$ , and  $S$  is a  $d \times d$  diagonal matrix. In applications,  $d \ll n$  and  $d \ll m$ ; for example one might have a 50,000 word vocabulary and 1,000,000 documents and use a 300 dimensional subspace representation.

An important property of SVD is that the rows of  $US$  - which represents the words - behave similarly to the original rows of  $W$ , in the sense that the cosine similarity between two rows in  $US$  approximates the cosine similarity between the corre-

sponding rows in  $W$ . Cosine similarity is defined as  $\text{sim}(\mathbf{x}, \mathbf{y}) = \frac{\mathbf{x} \cdot \mathbf{y}}{\|\mathbf{x}\| \|\mathbf{y}\|}$ .

#### 4.1 Total Word Similarity

Perhaps the simplest way of doing sentence completion with LSA is to compute the total similarity of a potential answer  $a$  with the rest of the words in the sentence  $\mathcal{S}$ , and to choose the most related option. We define the total similarity as:

$$\text{tot sim}(a, \mathcal{S}) = \sum_{w \in \mathcal{S}} \text{sim}(a, w)$$

When the completion requires two words, total similarity is the sum of the contributions for both words. This is our baseline method for using LSA, and one of the best methods we have found.

#### 4.2 Sentence Reconstruction

Recall that LSA approximates a weighted word-document matrix  $W$  as the product of low rank matrices  $U$  and  $V$  along with a scaling matrix  $S$ :  $W \approx USV^T$ . Using singular value decomposition, this is done so as to minimize the mean square reconstruction error  $\sum_{ij} Q_{ij}^2$  where  $Q = W - USV^T$ . From the basic definition of LSA, each column of  $W$  (representing a document) is represented as

$$W_j = USV_j^T, \quad (1)$$

that is, as a linear combination of the set of basis functions formed by the columns of  $US$ , with the combination weights specified in  $V_j^T$ . When a new document is presented, it is also possible to represent it in terms of the same basis vectors. Moreover, we may take the reconstruction error induced by this representation to be a measure of how consistent the new document is with the original set of documents used to determine  $US$  and  $V$  (Bellegarda, 2000).

It remains to represent a new document in terms of the LSA bases. This is done as follows (Deerwester et al., 1990; Bellegarda, 2000), again with the objective of minimizing the reconstruction error. First, note that since  $U$  is column-orthonormal, (1) implies that

$$V_j = W_j^T US^{-1} \quad (2)$$

Thus, if we notionally index a new document by  $p$ , we proceed by forming a new column (document) vector  $W_p$  using the standard term-weighting, and

then find its LSA-space representation  $V_p$  using (2). We can evaluate the reconstruction quality by inserting the result in (1). The reconstruction error is then

$$\|(UU^T - I)W_p\|^2$$

Note that if all the dimensions are retained, the reconstruction error is zero; in the case that only the highest singular vectors are used, however, it is not. Due to the fact that the sentences vary in length we choose the number of retained singular vectors as a fraction  $f$  of the sentence length. If the answer has  $n$  words we use the top  $nf$  components. In practice, a  $f$  of 1.2 was selected on the basis of development set results.

#### 4.3 A LSA N-gram Language Model

In the context of speech recognition, LSA has been combined with classical n-gram language models in (Coccaro and Jurafsky, 1998; Bellegarda, 2000). The crux of this idea is to interpolate an n-gram language model probability with one based on LSA, with the intuition that the standard n-gram model will do a good job predicting function words, and the LSA model will do a good job on words predicted by their long-span context. This logic makes sense for the sentence completion task as well, motivating us to evaluate it.

To do this, we adopt the procedure of (Coccaro and Jurafsky, 1998), using linear interpolation between the n-gram and LSA probabilities:

$$p(w|history) = \alpha p_{ng}(w|history) + (1 - \alpha) p_{lsa}(w|history)$$

The probability of a word given its history is computed by the LSA model in the following way. Let  $h$  be the sum of all the LSA word vectors in the history. Let  $m$  be the smallest cosine similarity between  $h$  and any word in the vocabulary  $V$ :  $m = \min_{w \in V} \text{sim}(h, w)$ . The probability of a word  $w$  in the context of history  $h$  is given by

$$P_{lsa}(w|h) = \frac{\text{sim}(h, w) - m}{\sum_{q \in V} (\text{sim}(h, q) - m)}$$

Since similarity can be negative, subtracting the minimum ( $m$ ) ensures that all the estimated probabilities are between 0 and 1.

#### 4.4 Improving Efficiency and Expressiveness

Given the basic framework described above, a number of enhancements are possible. In terms of efficiency, recall that it is necessary to perform SVD on a term-document matrix. The data we used was grouped into paragraph “documents,” of which there were over 27 million, with 2.6 million unique words. While the resulting matrix is highly sparse, it is nevertheless impractical to perform SVD. We overcome this difficulty in two ways. First, we restrict the set of documents used to those which are “relevant” to a given test set. This is done by requiring that a document contain at least one of the potential answer-words. Secondly, we restrict the vocabulary to the set of words present in the test set. For the sentence-reconstruction method of Section 4.2, we have found it convenient to do data selection *per-sentence*.

To enhance the expressive power of LSA, the term vocabulary can be expanded from unigrams to bigrams or trigrams of words, thus adding information about word ordering. This was also used in the reconstruction technique.

### 5 Experimental Results

#### 5.1 Data Resources

We present results with two datasets. The first is taken from *11 Practice Tests for the SAT & PSAT 2011 Edition* (Princeton-Review, 2010). This book contains eleven practice tests, and we used all the sentence completion questions in the first five tests as a development set, and all the questions in the last six tests as the test set. This resulted in sets with 95 and 108 questions respectively. Additionally, we report results on the recently released *MSR Sentence Completion Challenge* (Zweig and Burges, 2011). This consists of a set of 1,040 sentence completion questions based on sentences occurring in five Conan Doyle Sherlock Holmes novels, and is identical in format to the SAT questions. Due to the source of this data, we refer to it as the *Holmes data*.

To train models, we have experimented with a variety of data sources. Since there is no publicly available collection of SAT questions suitable to training, our methods have all relied on unsupervised data. Early on, we ran a set of experiments to determine the relevance of different types of data. Thinking that data from an encyclopedia

Data	Dev % Correct	Test % Correct
Encarta	26	33
Wikipedia	32	31
LA Times	39	42

Table 1: Effectiveness of different types of training data.

might be useful, we evaluated an electronic version of the 2003 Encarta encyclopedia, which has approximately 29M words. Along similar lines, we used a collection of Wikipedia articles consisting of 709M words. This data is the entire Wikipedia as of January 2011, broken down into sentences, with filtering to remove sentences consisting of URLs and Wiki author comments. Finally, we used a commercial newspaper dataset consisting of all the Los Angeles Times data from 1985 to 2002, containing about 1.1B words. These data sources were evaluated using the baseline n-gram LM approach of Section 3.1. Initial experiments indicated that that the Los Angeles Times data is best suited to this task (see Table 1), and our SAT experiments use this source. For the MSR Sentence Completion data, we obtained the training data specified in (Zweig and Burges, 2011), consisting of approximately 500 19th-century novels available from Project Gutenberg, and comprising 48M words.

#### 5.2 Human Performance

To provide human benchmark performance, we asked six native speaking high school students and five graduate students to answer the questions on the development set. The high-schoolers attained 87% accuracy and the graduate students 95%. Zweig and Burges (2011) cite a human performance of 91% on the Holmes data. Statistics from a large cross-section of the population are not available. As a further point of comparison, we note that chance performance is 20%.

#### 5.3 Language Modeling Results

Table 2 summarizes our language modeling results on the SAT data. With the exception of the baseline backoff n-gram model, these techniques were too computationally expensive to utilize the full Los Angeles Times corpus. Instead, as with LSA, a “relevant” corpus was selected of the sentences which contain at least one answer option from either the

Method	Data (Dev / Test)	Dev	Test
3-gram GT	1.1B / 1.1B	39%	42%
Model M	193M / 236M	35	41
RNN	36M / 44M	37	42
LSA-LM	293M / 358 M	48	44

Table 2: Performance of language modeling methods on SAT questions.

Method	Dev ppl	Dev	Test ppl	Test
3-gram GT	195	36%	190	44%
Model M	178	36	175	42
RNN	147	37	144	42

Table 3: Performance of language modeling methods using identical training data and vocabularies.

development or test set. Separate subsets were made for development and test data. This data was further sub-sampled to obtain the training set sizes indicated in the second column. For the LSA-LM, an interpolation weight of 0.1 was used for the LSA score, determined through optimization on the development set. We see from this table that the language models perform similarly and achieve just above 40% on the test set.

To make a more controlled comparison that normalizes for the amount of training data, we have trained Model M, and the Good-Turing model on the same data subset as the RNN, and with the same vocabulary. In Table 3, we present perplexity results on a held-out set of dev/test-relevant Los Angeles Times data, and performance on the actual SAT questions. Two things are notable. First, the recurrent neural net has dramatically lower perplexity than the other methods. This is consistent with results in (Mikolov et al., 2011a). Secondly, despite the differences in perplexity, the methods show little difference on SAT performance. Because Model M was not better, only uses n-gram context, and was used in the construction of the Holmes data (Zweig and Burges, 2011), we do not consider it further.

## 5.4 LSA Results

Table 4 presents results for the methods of Sections 4.1 and 4.2. Of all the methods in isolation, the simple approach of Section 4.1 - to use the total cosine similarity between a potential answer and the other words in the sentence - has performed best. The ap-

Method	Dev	Test
Total Word Similarity	46%	46%
Reconstruction Error	53	41

LSA + Good-Turing LM + RNN	52

Table 5: SAT test set accuracy with combined methods.

proach of using reconstruction error performed very well on the development set, but unremarkably on the test set.

## 5.5 Combination Results

A well-known trick for obtaining best results from a machine learning system is to combine a set of diverse methods into a single ensemble (Dietterich, 2000). We use ensembles to get the highest accuracy on both of our data sets.

We use a simple linear combination of the outputs of the other models discussed in this paper. For the LSA model, the linear combination has three inputs: the total word similarity, the cosine similarity between the sum of the answer word vectors and the sum of the rest of sentence’s word vectors, and the number of out-of-vocabulary terms in the answer. Each additional language model beyond LSA contributes an additional input: the probability of the sentence under that language model.

We train the parameters of the linear combination on the SAT development set. The training minimizes a loss function of pairs of answers: one correct and one incorrect fill-in from the same question. We use the RankNet loss function (Burges et al., 2005):

$$\min_{\vec{w}} f(\vec{w} \cdot (\vec{x} - \vec{y})) + \lambda \|\vec{w}\|^2$$

where  $\vec{x}$  are the input features for the incorrect answer,  $\vec{y}$  are the features for the correct answer,  $\vec{w}$  are the weights for the combination, and  $f(z) = \log(1 + \exp(z))$ . We tune the regularizer via 5-fold cross validation, and minimize the loss using L-BFGS (Nocedal and Wright, 2006). The results on the SAT test set for combining various models are shown in Table 5.

## 5.6 Holmes Data Results

To measure the robustness of our approaches, we have applied them to the MSR Sentence Completion set (Zweig and Burges, 2011), termed the *Holmes data*. In Table 6, we present the results on this set, along with the comparable SAT results. Note that the latter are derived from models trained with the Los Angeles Times data, while the Holmes results are derived from models trained with 19th-century novels. We see from this table that the results are similar across the two tasks. The best performing single model is LSA total word similarity.

For the Holmes data, combining the models outperforms any single model. We train the linear combination function via 5-fold cross-validation: the model is trained five times, each time on 3/5 of the data, the regularization tuned on 1/5 of the data, and tested on 1/5. The test results are pooled across all 5 folds and are shown in Table 6. In this case, the best combination is to blend LSA, the Good-Turing language model, and the recurrent neural network.

## 6 Discussion

To verify that the differences in accuracy between the different algorithms are not statistical flukes, we perform a statistical significance test on the outputs of each algorithm. We use McNemar’s test, which is a matched test between two classifiers (Dietterich, 1998). We use the False Discovery Rate method (Benjamini and Hochberg, 1995) to control the false positive rate caused by multiple tests. If we allow 2% of our tests to yield incorrectly false results, then for the SAT data, the combination of the Good-Turing smoothed language model with an LSA-based global similarity model (52% accuracy) is better than the baseline alone (42% accuracy).

Secondly, for the Holmes data, we can state that LSA total similarity beats the recurrent neural network, which in turn is better than the baseline n-gram model. The combination of all three is significantly better than any of the individual models.

To better understand the system performance and gain insight into ways of improving it, we have examined the system’s errors. Encouragingly, one-third of the errors involve single-word questions which test the dictionary definition of a word. This is done either by stating the definition, or provid-

Method	SAT	Holmes

Combination	<b>53</b>	<b>52</b>
Human	87 to 95	91

Table 6: Performance of methods on the MSR Sentence Completion Challenge, contrasted with SAT test set.

ing a stereotypical use of the word. An example of the first case is: “Great artists are often *prophetic (visual)*: they perceive what we cannot and anticipate the future long before we do.” (The system’s incorrect answer is in parentheses.) An example of the second is: “One cannot help but be moved by Theresa’s *heartrending (therapeutic)* struggle to overcome a devastating and debilitating accident.”

At the other end of the difficulty spectrum are questions involving world knowledge and/or logical implications. An example requiring both is, “Many fear that the *ratification (withdrawal)* of more lenient tobacco advertising could be detrimental to public health.” About 40% of the errors require this sort of general knowledge to resolve. Based on our analysis, we believe that future research could profitably exploit the structured information present in a dictionary. However, the ability to identify and manipulate logical relationships and embed world knowledge in a manner amenable to logical manipulation may be necessary for a full solution. It is an interesting research question if this could be done implicitly with a machine learning technique, for example recurrent or recursive neural networks.

## 7 Conclusion

In this paper we have investigated methods for answering sentence-completion questions. These questions are intriguing because they probe the ability to distinguish semantically coherent sentences from incoherent ones, and yet involve no more context than the single sentence. We find that both local n-gram information and an LSA-based global coherence model do significantly better than chance, and that they can be effectively combined.

## Abstract

Sequential modeling has been widely used in a variety of important applications including named entity recognition and shallow parsing. However, as more and more real time large-scale tagging applications arise, decoding speed has become a bottleneck for existing sequential tagging algorithms. In this paper we propose 1-best A\*, 1-best iterative A\*,  $k$ -best A\* and  $k$ -best iterative Viterbi A\* algorithms for sequential decoding. We show the efficiency of these proposed algorithms for five NLP tagging tasks. In particular, we show that iterative Viterbi A\* decoding can be several times or orders of magnitude faster than the state-of-the-art algorithm for tagging tasks with a large number of labels. This algorithm makes real-time large-scale tagging applications with thousands of labels feasible.

## 1 Introduction

Sequence tagging algorithms including HMMs (Rabiner, 1989), CRFs (Lafferty et al., 2001), and Collins's perceptron (Collins, 2002) have been widely employed in NLP applications. Sequential decoding, which finds the best tag sequences for given inputs, is an important part of the sequential tagging framework. Traditionally, the Viterbi algorithm (Viterbi, 1967) is used. This algorithm is quite efficient when the label size of problem modeled is low. Unfortunately, due to its  $O(TL^2)$  time complexity, where  $T$  is the input token size and  $L$  is the label size, the Viterbi decoding can become prohibitively slow when the label size is large (say, larger than 200).

It is not uncommon that the problem modeled consists of more than 200 labels. The Viterbi algorithm cannot find the best sequences in tolerable

response time. To resolve this, Esposito and Radicioni (2009) have proposed a Carpediem algorithm which opens only necessary nodes in searching the best sequence. More recently, Kaji et al. (2010) proposed a staggered decoding algorithm, which proves to be very efficient on datasets with a large number of labels.

What the aforementioned literature does not cover is the  $k$ -best sequential decoding problem, which is indeed frequently required in practice. For example to pursue a high recall ratio, a named entity recognition system may have to adopt  $k$ -best sequences in case the true entities are not recognized at the best one. The  $k$ -best parses have been extensively studied in syntactic parsing context (Huang, 2005; Pauls and Klein, 2009), but it is not well accommodated in sequential decoding context. To our best knowledge, the state-of-the-art  $k$ -best sequential decoding algorithm is *Viterbi A\**<sup>1</sup>. In this paper, we generalize the *iterative process* from the work of (Kaji et al., 2010) and propose a  $k$ -best sequential decoding algorithm, namely *iterative Viterbi A\**. We show that the proposed algorithm is several times or orders of magnitude faster than the state-of-the-art in all tagging tasks which consist of more than 200 labels.

Our contributions can be summarized as follows. (1) We apply the A\* search framework to sequential decoding problem. We show that A\* with a proper heuristic can outperform the classic Viterbi decoding. (2) We propose 1-best A\*, 1-best iterative A\* decoding algorithms which are the second and third fastest decoding algorithms among the five decoding algorithms for comparison, although there is a significant gap to the fastest 1-best decoding algorithm. (3) We propose  $k$ -best A\* and  $k$ -best iterative Viterbi A\* algorithms. The latter is several times or orders of magnitude faster than the state-of-the-art

<sup>1</sup>Implemented in both CRFPP (<http://crfpp.sourceforge.net/>) and LingPipe (<http://alias-i.com/lingpipe/>) packages.

$k$ -best decoding algorithm. This algorithm makes real-time large-scale tagging applications with thousands of labels feasible.

## 2 Problem formulation

In this section, we formulate the sequential decoding problem in the context of perceptron algorithm (Collins, 2002) and CRFs (Lafferty et al., 2001). All the discussions apply to HMMs as well. Formally, a perceptron model is

$$f(\mathbf{y}, \mathbf{x}) = \sum_{t=1}^T \sum_{k=1}^K \theta_k f_k(y_t, y_{t-1}, \mathbf{x}_t), \quad (1)$$

and a CRFs model is

$$p(\mathbf{y}|\mathbf{x}) = \frac{1}{Z(\mathbf{x})} \exp\left\{\sum_{t=1}^T \sum_{k=1}^K \theta_k f_k(y_t, y_{t-1}, \mathbf{x}_t)\right\}, \quad (2)$$

where  $\mathbf{x}$  and  $\mathbf{y}$  is an observation sequence and a label sequence respectively,  $t$  is the sequence position,  $T$  is the sequence size,  $f_k$  are feature functions and  $K$  is the number of feature functions.  $\theta_k$  are the parameters that need to be estimated. They represent the importance of feature functions  $f_k$  in prediction. For CRFs,  $Z(\mathbf{x})$  is an instance-specific normalization function

$$Z(\mathbf{x}) = \sum_{\mathbf{y}} \exp\left\{\sum_{t=1}^T \sum_{k=1}^K \theta_k f_k(y_t, y_{t-1}, \mathbf{x}_t)\right\}. \quad (3)$$

If  $\mathbf{x}$  is given, the decoding is to find the best  $\mathbf{y}$  which maximizes the score of  $f(\mathbf{y}, \mathbf{x})$  for perceptron or the probability of  $p(\mathbf{y}|\mathbf{x})$  for CRFs. As  $Z(\mathbf{x})$  is a constant for any given input sequence  $\mathbf{x}$ , the decoding for perceptron or CRFs is identical, that is,

$$\arg \max_{\mathbf{y}} f(\mathbf{y}, \mathbf{x}). \quad (4)$$

To simplify the discussion, we divide the features into two groups: unigram label features and bigram label features. Unigram features are of form  $f_k(y_t, \mathbf{x}_t)$  which are concerned with the current label and arbitrary feature patterns from input sequence. Bigram features are of form  $f_k(y_t, y_{t-1}, \mathbf{x}_t)$  which are concerned with both the previous and the current labels. We thus rewrite the decoding problem as

$$\arg \max_{\mathbf{y}} \sum_{t=1}^T \left( \sum_{k=1}^{K_1} \theta_k^1 f_k^1(y_t, \mathbf{x}_t) + \sum_{k=1}^{K_2} \theta_k^2 f_k^2(y_t, y_{t-1}, \mathbf{x}_t) \right). \quad (5)$$

For a better understanding, one can interpret the term  $\sum_{k=1}^{K_1} \theta_k^1 f_k^1(y_t, \mathbf{x}_t)$  as node  $y_t$ 's score at position  $t$ , and interpret the term

$\sum_{k=1}^{K_2} \theta_k^2 f_k^2(y_t, y_{t-1}, \mathbf{x}_t)$  as edge  $(y_{t-1}, y_t)$ 's score. So the sequential decoding problem is cast as a max score pathfinding problem<sup>2</sup>. In the discussion hereafter, we assume scores of nodes and edges are pre-computed (denoted as  $n(y_t)$  and  $e(y_{t-1}, y_t)$ ), and we can thus focus on the analysis of different decoding algorithms.

## 3 Background

We present the existing algorithms for both 1-best and  $k$ -best sequential decoding in this section. These algorithms serve as basis for the proposed algorithms in Section 4.

### 3.1 1-Best Viterbi

The Viterbi algorithm is a classic dynamic programming based decoding algorithm. It has the computational complexity of  $O(TL^2)$ , where  $T$  is the input sequence size and  $L$  is the label size<sup>3</sup>. Formally, the Viterbi computes  $\alpha(y_t)$ , the best score from starting position to label  $y_t$ , as follows.

$$\max_{y_{t-1}} (\alpha_{y_{t-1}} + e(y_{t-1}, y_t)) + n(y_t), \quad (6)$$

where  $e(y_{t-1}, y_t)$  is the edge score between nodes  $y_{t-1}$  and  $y_t$ ,  $n(y_t)$  is the node score for  $y_t$ . Note that the terms  $\alpha_{y_{t-1}}$  and  $e(y_{t-1}, y_t)$  take value 0 for  $t = 0$  at initialization. Using the recursion defined above, we can compute the highest score at end position  $T - 1$  and its corresponding sequence. The recursive computation of  $\alpha_{y_t}$  is denoted as forward pass since the computing traverses the lattice from left to right. Conversely, the backward pass computes  $\beta_{y_t}$  as the follows.

$$\max_{y_{t+1}} (\beta_{y_{t+1}} + e(y_t, y_{t+1}) + n(y_{t+1})). \quad (7)$$

Note that  $\beta_{y_{T-1}} = 0$  at initialization. The max score can be computed using  $\max_{y_0} (\beta_0 + n(y_0))$ . We can use either forward or backward pass to compute the best sequence. Table 1 summarizes the computational complexity of all decoding algorithms including Viterbi, which has the complexity of  $TL^2$  for both best and worst cases. Note that N/A means the decoding algorithms are not applicable (for example, iterative Viterbi is not applicable to  $k$ -best decoding). The proposed algorithms (see Section 4) are highlighted in bold.

### 3.2 1-Best iterative Viterbi

Kaji et al. (Kaji et al., 2010) presented an efficient sequential decoding algorithm named *staggered decoding*. We use the name *iterative Viterbi* to describe

<sup>2</sup>With the constraint that the path consists of one and only one node at each position.

<sup>3</sup>We ignore the feature size terms for simplicity.

this algorithm for the reason that the iterative process plays a central role in this algorithm. Indeed, this iterative process is generalized in this paper to handle  $k$ -best sequential decoding (see Section 4.4).

The main idea is to start with a coarse lattice which consists of both *active* labels and *degenerate* labels. A label is referred to as an *active label* if it is not grouped (e.g., all labels in Fig. 1 (a) and label *A* at each position in Fig. 1 (b)), and otherwise as an *inactive label* (i.e., dotted nodes). The new label, which is made by grouping the inactive labels, is referred to as a *degenerate label* (i.e., large nodes covering the dotted ones). Fig. 1 (a) shows a lattice which consists of active labels only and (b) shows a lattice which consists of both active and degenerate ones. The score of a degenerate label is the max score of inactive labels which are included in the degenerate label. Similarly, the edge score between a degenerate label  $z$  and an active label  $y'$  is the max edge score between any inactive label  $y \in z$  and  $y'$ , and the score of two degenerate labels  $z$  and  $z'$  is the max edge score between any inactive label  $y \in z$  and  $y' \in z'$ . Using the above definitions, the best sequence derived from a degenerate lattice would be the upper bound of the sequence derived from the original lattice. If the best sequence does not include any degenerate labels, it is indeed the best sequence for the original lattice.

Figure 1: (a) A lattice consisting of active labels only. (b) A lattice consisting of both active labels and degenerate ones. Each position has one active label (A) and one degenerate label (consisting of B, C, D, E, and F).

The pseudo code for this algorithm is shown in Algorithm 1. The lattice is initialized to include one active label and one degenerate label at each position (see Figure 1 (b)). Note that the labels are ranked by the probabilities estimated from the training data. The Viterbi algorithm is applied to the lattice to find the best sequence. If the sequence consists of active labels only, the algorithm terminates and returns such a sequence. Otherwise, the lower bound  $lb^4$  of the active sequence in the lattice is updated and the lattice is expanded. The lower bound can be initialized to the best sequence score using a beam search (with beam size being 1). After either a forward or a backward pass, the lower bound is assigned with

<sup>4</sup>The maximum score of the active sequences found so far.

the best active sequence score  $best(lattice)^5$  if the former is less than the latter. The expansion of lattice ensures that the lattice has twice active labels as before at a given position. Figure 2 shows the column-wise expansion step. The number of active labels in the column is doubled only if the best sequence of the degenerate lattice passes through the degenerate label of that column.

---

### Algorithm 1 Iterative Viterbi Algorithm

---

```

1:  $lb =$  best score from beam search
2: init lattice
3: for  $i=0; i < T; i++$  do
4:   if  $i \% 2 == 0$  then
5:      $y =$  forward()
6:   else
7:      $y =$  backward()
8:   end if
9:   if  $y$  consists of active labels only then
10:    return  $y$ 
11:   end if
12:   if  $lb < best(lattice)$  then
13:      $lb = best(lattice)$ 
14:   end if
15:   expand lattice
16: end for

```

---

---

### Algorithm 2 Forward

---

```

1: for  $i=0; i < T; i++$  do
2:   Compute  $\alpha(y_i)$  and  $\beta(y_i)$  according to Equations (6) and (7)
3:   if  $\alpha(y_i) + \beta(y_i) < lb$  then
4:     prune  $y_i$  from the current lattice
5:   end if
6: end for
7:  $Node\ b = \arg \max_{y_{T-1}} \alpha(y_{T-1})$ 
8: return sequence back tracked by  $b$ 

```

---

Figure 2: Column-wise lattice expansion: (a) The best sequence of the initial degenerate lattice, which does not pass through the degenerate label in the first column. (b) Column-wise expansion is performed and the best sequence is searched again. Notice that the active label in the first column is not expanded. (c) The final result.

Algorithm 2 shows the forward pass in which the node pruning is performed. That is, for any node, if the best score of sequence which passes such a node is less than the lower bound  $lb$ , such a node is removed from the lattice. This removal is safe as such a node does not have a chance to form an optimal sequence. It is worth noting that, if a node is removed, it can no longer be added into the lattice.

<sup>5</sup>We do not update the lower bound  $lb$  if we cannot find an active sequence.

This property ensures the efficiency of the iterative Viterbi algorithm. The backward pass is similar to the forward one and it is thus omitted.

The alternative calls of forward and backward passes (in Algorithm 1) ensure the alternative updating/lowering of node forward and backward scores, which makes the node pruning in either forward pass (see Algorithm 2) or backward pass more efficient. The lower bound  $lb$  is updated once in each iteration of the main loop in Algorithm 1. While the forward and backwards scores of nodes gradually decrease and the lower bound  $lb$  increases, more and more nodes are pruned.

The iterative Viterbi algorithm has computational complexity of  $T$  and  $TL^2$  for best and worst cases respectively. This can be proved as follows (Kaji et al., 2010). At the  $m$ -th iteration in Algorithm 1, iterative Viterbi decoding requires order of  $T4^m$  time because there are  $2^m$  active labels (plus one degenerate label). Therefore, it has  $\sum_{i=0}^m T4^i$  time complexity if it terminates at the  $m$ -th iteration. In the best case in which  $m = 0$ , the time complexity is  $T$ . In the worst case in which  $m = \lceil \log_2 L \rceil - 1$  ( $\lceil \cdot \rceil$  is the ceiling function which maps a real number to the smallest following integer), the time complexity is order of  $TL^2$  because  $\sum_{i=0}^{\lceil \log_2 L \rceil - 1} T4^i < 4/3TL^2$ .

### 3.3 1-Best Carpediem

Esposito and Radicioni (2009) have proposed a novel 1-best<sup>6</sup> sequential decoding algorithm, *Carpediem*, which attempts to open only necessary nodes in searching the best sequence in a given lattice. Carpediem has the complexity of  $TL \log L$  and  $TL^2$  for the best and worst cases respectively. We skip the description of this algorithm due to space limitations. Carpediem is used as a baseline in our experiments for decoding speed comparison.

### 3.4 K-Best Viterbi

In order to produce  $k$ -best sequences, it is not enough to store 1-best label per node, as the  $k$ -best sequences may include suboptimal labels. The  $k$ -best sequential decoding gives up this 1-best label memorization in the dynamic programming paradigm. It stores up to  $k$ -best labels which are necessary to form  $k$ -best sequences. The  $k$ -best Viterbi algorithm thus has the computational complexity of  $KTL^2$  for both best and worst cases.

Once we store the  $k$ -best labels per node in a lattice, the  $k$ -best Viterbi algorithm calls either the forward or the backward passes just in the same way as the 1-best Viterbi decoding does. We can compute

the  $k$  highest score at the end position  $T - 1$  and the corresponding  $k$ -best sequences.

### 3.5 K-Best Viterbi A\*

To our best knowledge the most efficient  $k$ -best sequence algorithm is the Viterbi A\* algorithm as shown in Algorithm 3. The algorithm consists of one forward pass and an A\* backward pass. The forward pass computes and stores the Viterbi forward scores, which are the best scores from the start to the current nodes. In addition, each node stores a *backlink* which points to its predecessor.

The major part of Algorithm 3 describes the backward A\* pass. Before describing the algorithm, we note that each node in the agenda represents a sequence. So the operations on nodes (push or pop) correspond to the operations on sequences. Initially, the  $L$  nodes at position  $T - 1$  are pushed to an agenda. Each of the  $L$  nodes  $n_i$ ,  $i = 0, \dots, L - 1$ , represents a sequence. That is, node  $n_i$  represents the best sequence from the start to itself. The best of the  $L$  sequences is the globally best sequence. However, the  $i$ -th best,  $i = 2, \dots, k$ , of the  $L$  sequence may not be the globally  $i$ -th best sequence. The priority of each node is set as the score of the sequence which is derived by such a node. The algorithm then goes to a loop of  $k$ . In each loop, the best node is popped off from the agenda and is stored in a set  $r$ . The algorithm adds alternative candidate nodes (or sequences) to the agenda via a double nested loop. The idea is that, when an optimal node (or sequence) is popped off, we have to push to the agenda all nodes (sequences) which are slightly worse than the just popped one. The interpretation of slightly worse is to replace one edge from the popped node (sequence). The slightly worse sequences can be found by the exact heuristic derived from the first Viterbi forward pass.

Figure 3 shows an example of the push operations for a lattice of  $T = 4$ ,  $Y = 4$ . Suppose an optimal node  $2:B$  (in red, standing for node  $B$  at position 2, representing the sequence of  $0:A 1:D 2:B 3:C$ ) is popped off, new nodes of  $1:A$ ,  $1:B$ ,  $1:C$  and  $0:B$ ,  $0:C$  and  $0:D$  are pushed to the agenda according to the double nested for loop in Algorithm 3. Each of the pushed nodes represents a sequence, for example, node  $1:B$  represents a sequence which consists of three parts: Viterbi sequence from start to  $1:B$  ( $0:C 1:B$ ),  $2:B$  and forward link of  $2:B$  ( $3:C$  in this case). All of these pushed nodes (sequences) are served as candidates for the next agenda pop operation.

The algorithm terminates the loop once it has optimal  $k$  nodes. The  $k$ -best sequences can be derived by the  $k$  optimal nodes. This algorithm has

<sup>6</sup>They did not provide  $k$ -best solutions.

Figure 3: Alternative nodes push after popping an optimal node.

computation complexity of  $TL^2 + TL$  for both best and worst cases, with the first term accounting for Viterbi forward pass and the second term accounting for A\* backward process. The bottleneck is thus at the Viterbi forward pass.

---

**Algorithm 3** *K*-Best Viterbi A\* algorithm

---

```

1: forward()
2: push  $L$  best nodes to agenda  $q$ 
3:  $c = 0$ 
4:  $r = \{\}$ 
5: while  $c < K$  do
6:   Node  $n = q.pop()$ 
7:    $r = r \cup n$ 
8:   for  $i = n.t - 1; i \geq 0; i --$  do
9:     for  $j = 0; j < L; j ++$  do
10:      if  $j! = n.backlink.y$  then
11:        create new node  $s$  at position  $i$  and label  $j$ 
12:         $s.forwardlink = n$ 
13:         $q.push(s)$ 
14:      end if
15:    end for
16:     $n = n.backlink$ 
17:  end for
18:   $c ++$ 
19: end while
20: return  $K$  best sequences derived by  $r$ 

```

---

## 4 Proposed Algorithms

In this section, we propose A\* based sequential decoding algorithms that can efficiently handle datasets with a large number of labels. In particular, we first propose the A\* and the iterative A\* decoding algorithm for 1-best sequential decoding. We then extend the 1-best A\* algorithm to a  $k$ -best A\* decoding algorithm. We finally apply the iterative process to the Viterbi A\* algorithm, resulting in the *iterative Viterbi A\** decoding algorithm.

### 4.1 1-Best A\*

A\*(Hart et al., 1968; Russell and Norvig, 1995), as a classic search algorithm, has been successfully applied in syntactic parsing (Klein and Manning, 2003; Pauls and Klein, 2009). The general idea of A\* is to consider labels  $y_t$  which are likely to result in the best sequence using a score  $f$  as follows.

$$f(y) = g(y) + h(y), \quad (8)$$

where  $g(y)$  is the score from start to the current node and  $h(y)$  is a heuristic which estimates the score

from the current node to the target. A\* uses an agenda (based on the  $f$  score) to decide which nodes are to be processed next. If the heuristic satisfies the condition  $h(y_{t-1}) \geq e(y_{t-1}, y_t) + h(y_t)$ , then  $h$  is called *monotone* or *admissible*. In such a case, A\* is guaranteed to find the best sequence. We start with the naive (but admissible) heuristic as follows

$$h(y_t) = \sum_{i=t+1}^{T-1} (\max n(y_i) + \max e(y_{i-1}, y_i)). \quad (9)$$

That is, the heuristic of node  $y_t$  to the end is the sum of max edge scores between any two positions and max node scores per position. Similar to (Pauls and Klein, 2009) we explore the heuristic in different coarse levels. We apply the Viterbi backward pass to different degenerate lattices and use the Viterbi backward scores as different heuristics. Different degenerate lattices are generated from different iterations of Algorithm 1: The  $m$ -th iteration corresponds to a lattice of  $(2^m + 1) * T$  nodes. A larger  $m$  indicates a more accurate heuristic, which results in a more efficient A\* search (fewer nodes being processed). However, this efficiency comes with the price that such an accurate heuristic requires more computation time in the Viterbi backward pass. In our experiments, we try the naive heuristic and the following values of  $m$ : 0, 3, 6 and 9.

In the best case, A\* expands one node per position, and each expansion results in the push of all nodes at next position to the agenda. The search is similar to the beam search with beam size being 1. The complexity is thus  $TL$ . In the worst case, A\* expands every node per position, and each expansion results in the push of all nodes at next position to the agenda. The complexity thus becomes  $TL^2$ .

### 4.2 1-Best Iterative A\*

The iterative process as described in the iterative Viterbi decoding can be used to boost A\* algorithm, resulting in the *iterative A\** algorithm. For simplicity, we only make use of the naive heuristic in Equation (9) in the iterative A\* algorithm. We initialize the lattice with one active label and one degenerate label at each position (see Figure 1 (b)). We then run A\* algorithm on the degenerate lattice and get the best sequence. If the sequence is active we return it. Otherwise we expand the lattice in each iteration until we find the best active sequence. Similar to iterative Viterbi algorithm, iterative A\* has the complexity of  $T$  and  $TL^2$  for the best and worst cases respectively.

### 4.3 $K$ -Best A\*

The extension from 1-best A\* to  $k$ -best A\* is again due to the memorization of  $k$ -best labels per node.

Table 1: Best case and worst case computational complexity of various decoding algorithms.

	1-best decoding		$K$ -best decoding	
	best case	worst case	best case	worst case
beam	$TL$	$TL$	$KTL$	$KTL$
Viterbi	$TL^2$	$TL^2$	$KTL^2$	$KTL^2$
iterative Viterbi	$T$	$TL^2$	N/A	N/A
Carpediem	$TL \log L$	$TL^2$	N/A	N/A
A*	$TL$	$TL^2$	$KTL$	$KTL^2$
<b>iterative A*</b>	$T$	$TL^2$	N/A	N/A
Viterbi A*	N/A	N/A	$TL^2 + KTL$	$TL^2 + KTL$
<b>iterative Viterbi A*</b>	N/A	N/A	$T + KT$	$TL^2 + KTL$

We use either the naive heuristic (Equation (9)) or different coarse level heuristics by setting  $m$  to be 0, 3, 6 or 9 (see Section 4.1). The first  $k$  nodes which are popped off the agenda can be used to back track the  $k$ -best sequences. The  $k$ -best A\* algorithm has the computational complexity of  $KTL$  and  $KTL^2$  for best and worst cases respectively.

#### 4.4 $K$ -Best Iterative Viterbi A\*

We now present the  $k$ -best iterative Viterbi A\* algorithm (see Algorithm 4) which applies the iterative process to  $k$ -best Viterbi A\* algorithm. The major difference between 1-best iterative Viterbi A\* algorithm (Algorithm 1) and this algorithm is that the latter calls the  $k$ -best Viterbi A\* (Algorithm 3) after the best sequence is found. If the  $k$ -best sequences are all active, we terminate the algorithm and return the  $k$ -best sequences. If we cannot find either the best active sequence or the  $k$ -best active sequences, we expand the lattice to continue the search in the next iteration.

As in the iterative Viterbi algorithm (see Section 3.2), nodes are pruned at each position in forward or backward passes. Efficient pruning contributes significantly to speeding up decoding. Therefore, to have a tighter (higher) lower bound  $lb$  is important. We initialize the lower bound  $lb$  with the  $k$ -th best score from beam search (with beam size being  $k$ ) at line 1. Note that the beam search is performed on the original lattice which consists of  $L$  active labels per position. The beam search time is negligible compared to the total decoding time. At line 16, we update  $lb$  as follows. We enumerate the best active sequences backtracked by the nodes at position  $T - 1$ . If the current  $lb$  is less than the  $k$ -th active sequence score, we update the  $lb$  with the  $k$ -th active sequence score (we do not update  $lb$  if there are less than  $k$  active sequences). At line 19, we use the sequences returned from Viterbi A\* algorithm to update the  $lb$  in the same manner. To enable this update, we request the Viterbi A\* algorithm to return  $k'$ ,  $k' > k$ , sequences (line 10). A larger number of  $k'$  results in a higher chance to find the  $k$ -th active sequence,

which in turn offers a tighter (higher)  $lb$ , but it comes with the expense of additional time (the backward A\* process takes  $O(TL)$  time to return one more sequence). In experiments, we found the  $lb$  updates on line 1 and line 16 are essential for fast decoding. The updating of  $lb$  using Viterbi A\* sequences (line 19) can boost the decoding speed further. We experimented with different  $k'$  values ( $k' = nk$ , where  $n$  is an integer) and selected  $k' = 2k$  which results in the largest decoding speed boost.

---

```

---

## 5 Experiments

We compare aforementioned 1-best and  $k$ -best sequential decoding algorithms using five datasets in this section.

### 5.1 Experimental setting

We apply 1-best and  $k$ -best sequential decoding algorithms to five NLP tagging tasks: Penn TreeBank (PTB) POS tagging, CoNLL2000 joint POS tagging and chunking, CoNLL 2003 joint POS tagging, chunking and named entity tagging, HPSG supertagging (Matsuzaki et al., 2007) and a search query named entity recognition (NER) dataset. We used

sections 02-21 of PTB for training and section 23 for testing in POS task. As in (Kaji et al., 2010), we combine the POS tags and chunk tags to form joint tags for CoNLL 2000 dataset, e.g., NN|B-NP. Similarly we combine the POS tags, chunk tags, and named entity tags to form joint tags for CoNLL 2003 dataset, e.g., PRP\$|I-NP|O. Note that by such tag joining, we are able to offer different tag decodings (for example, chunking and named entity tagging) simultaneously. This indeed is one of the effective approaches for joint tag decoding problems. The search query NER dataset is an in-house annotated dataset which assigns semantic labels, such as *product*, *business* tags to web search queries.

Table 2 shows the training and test sets size (sentence #), the average token length of test dataset and the label size for the five datasets. POS and supertag datasets assign tags to tokens while CoNLL 2000, CoNLL 2003 and search query datasets assign tags to phrases. We use the standard BIO encoding for CoNLL 2000, CoNLL 2003 and search query datasets.

Table 2: Training and test datasets size, average token length of test set and label size for five datasets.

	training #	test #	token length	label size
POS	39831	2415	23	45
CoNLL2000	8936	2012	23	319
CoNLL2003	14987	3684	12	443
Supertag	37806	2291	22	2602
search query	79569	6867	3	323

Due to the long CRF training time (days to weeks even for stochastic gradient descent training) for these large label size datasets, we choose the perceptron algorithm for training. The models are averaged over 10 iterations (Collins, 2002). The training time takes minutes to hours for all datasets. We note that the selection of training algorithm does not affect the decoding process: the decoding is identical for both CRF and perceptron training algorithms. We use the common features which are adopted in previous studies, for example (Sha and Periera, 2003). In particular, we use the unigrams of the current and its neighboring words, word bigrams, prefixes and suffixes of the current word, capitalization, all-number, punctuation, and tag bigrams for POS, CoNLL2000 and CoNLL 2003 datasets. For supertag dataset, we use the same features for the word inputs, and the unigrams and bigrams for gold POS inputs. For search query dataset, we use the same features plus gazetteer based features.

## 5.2 Results

We report the token accuracy for all datasets to facilitate comparison to previous work. They are 97.00, 94.70, 95.80, 90.60 and 88.60 for POS, CoNLL 2000, CoNLL 2003, supertag, and search query re-

spectively. We note that all decoding algorithms as listed in Section 3 and Section 4 are exact. That is, they produce exactly the same accuracy. The accuracy we get for the first four tasks is comparable to the state-of-the-art. We do not have a baseline to compare with for the last dataset as it is not publicly available<sup>7</sup>. Higher accuracy may be achieved if more task specific features are introduced on top of the standard features. As this paper is more concerned with the decoding speed, the feature engineering is beyond the scope of this paper.

Table 3 shows how many iterations in average are required for iterative Viterbi and iterative Viterbi A\* algorithms. Although the max iteration size is bounded to  $\lceil \log_2 L \rceil$  for each position (for example, 9 for CoNLL 2003 dataset), the total iteration number for the whole lattice may be greater than  $\lceil \log_2 L \rceil$  as different positions may not expand at the same time. Despite the large number of iterations used in iterative based algorithms (especially iterative Viterbi A\* algorithm), the algorithms are still very efficient (see below).

Table 3: Iteration numbers of iterative Viterbi and iterative Viterbi A\* algorithms for five datasets.

	POS	CoNLL2000	CoNLL2003	Supertag	search query
iter Viter	6.32	8.76	9.18	10.63	6.71
iter Viter A*	14.42	16.40	15.41	18.62	9.48

Table 4 and 5 show the decoding speed (sentences per second) of 1-best and 5-best decoding algorithms respectively. The proposed decoding algorithms and the largest decoding speeds across different decoding algorithms (other than beam) are highlighted in bold. We exclude the time for feature extraction in computing the speed. The beam search decoding is also shown as a baseline. We note that beam decoding is the only approximate decoding algorithm in this table. All other decoding algorithms produce exactly the same accuracy, which is usually much better than the accuracy of beam decoding.

For 1-best decoding, iterative Viterbi always outperforms other ones. A\* with a proper heuristic denoted as A\* (*best*), that is, the best A\* using naive heuristic or the values of  $m$  being 0, 3, 6 or 9 (see Section 4.1), can be the second best choice (except for the POS task), although the gap between iterative Viterbi and A\* is significant. For example, for CoNLL 2003 dataset, the former can decode 2239 sentences per second while the latter only decodes 225 sentences per second. The iterative process successfully boosts the decoding speed of iterative Viterbi compared to Viterbi, but it slows down the decoding speed of iterative A\* compared

<sup>7</sup>The lower accuracy is due to the dynamic nature of queries: many of test query tokens are unseen in the training set.

to A\*(best). This is because in the Viterbi case, the iterative process has a node pruning procedure, while it does not have such pruning in A\*(best) algorithm. Take CoNLL 2003 data as an example, the removal of the pruning slows down the 1-best iterative Viterbi decoding from 2239 to 604 sentences/second. Carpediem algorithm performs poorly in four out of five tasks. This can be explained as follows. The Carpediem implicitly assumes that the node scores are the dominant factors to determine the best sequence. However, this assumption does not hold as the edge scores play an important role.

For 5-best decoding,  $k$ -best Viterbi decoding is very slow. A\* with a proper heuristic is still slow. For example, it only reaches 11 sentences per second for CoNLL 2003 dataset. The classic Viterbi A\* can usually obtain a decent decoding speed, for example, 40 sentences per second for CoNLL 2003 dataset. The only exception is supertag dataset, on which the Viterbi A\* decodes 0.1 sentence per second while the A\* decodes 3. This indicates the scalability issue of Viterbi A\* algorithm for datasets with more than one thousand labels. The proposed iterative Viterbi A\* is clearly the winner. It speeds up the Viterbi A\* to factors of 4, 7, 360, and 3 for CoNLL 2000, CoNLL 2003, supertag and query search data respectively. The decoding speed of iterative Viterbi A\* can even be comparable to that of beam search.

Figure 4 shows  $k$ -best decoding algorithms decoding speed with respect to different  $k$  values for CoNLL 2003 data. The Viterbi A\* and iterative Viterbi A\* algorithms are significantly faster than the Viterbi and A\*(best) algorithms. Although the iterative Viterbi A\* significantly outperforms the Viterbi A\* for  $k < 30$ , the speed of the former converges to the latter when  $k$  becomes 90 or larger. This is expected as the  $k$ -best sequences span over the whole lattice: the earlier iteration in iterative Viterbi A\* algorithm cannot provide the  $k$ -best sequences using the degenerate lattice. The overhead of multiple iterations slows down the decoding speed compared to the Viterbi A\* algorithm.

Figure 4: Decoding speed of  $k$ -best decoding algorithms for various  $k$  for CoNLL 2003 dataset.

## 6 Related work

The Viterbi algorithm is the only exact algorithm widely adopted in the NLP applications. Esposito and Radicioni (2009) proposed an algorithm which opens necessary nodes in a lattice in searching the best sequence. The staggered decoding (Kaji et al., 2010) forms the basis for our work on iterative based decoding algorithms. Apart from the exact decoding, approximate decoding algorithms such as beam search are also related to our work. Tsuruoka and Tsujii (2005) proposed easiest-first deterministic decoding. Siddiqi and Moore (2005) presented the parameter tying approach for fast inference in HMMs. A similar idea was applied to CRFs as well (Cohn, 2006; Jeong, 2009). We note that the exact algorithm always guarantees the optimality which cannot be attained in approximate algorithms.

In terms of  $k$ -best parsing, Huang and Chiang (2005) proposed an efficient algorithm which is similar to the  $k$ -best Viterbi A\* algorithm presented in this paper. Pauls and Klein (2009) proposed an algorithm which replaces the Viterbi forward pass with an A\* search. Their algorithm optimizes the Viterbi pass, while the proposed iterative Viterbi A\* algorithm optimizes both Viterbi and A\* passes.

This paper is also related to the coarse to fine PCFG parsing (Charniak et al., 2006) as the degenerate labels can be treated as coarse levels. However, the difference is that the coarse-to-fine parsing is an approximate decoding while ours is exact one. In terms of different coarse levels of heuristic used in A\* decoding, this paper is related to the work of hierarchical A\* framework (Raphael, 2001; Felzenszwalb et al., 2007). In terms of iterative process, this paper is close to (Burkett et al., 2011) as both exploit the search-and-expand approach.

## 7 Conclusions

We have presented and evaluated the A\* and iterative A\* algorithms for 1-best sequential decoding in this paper. In addition, we proposed A\* and iterative Viterbi A\* algorithm for  $k$ -best sequential decoding.  $K$ -best Iterative A\* algorithm can be several times or orders of magnitude faster than the state-of-the-art  $k$ -best decoding algorithm. It makes real-time large-scale tagging applications with thousands of labels feasible.

{mwhitney, anoop}@sfu.ca

## Abstract

Bootstrapping a classifier from a small set of seed rules can be viewed as the propagation of labels between examples via features shared between them. This paper introduces a novel variant of the Yarowsky algorithm based on this view. It is a bootstrapping learning method which uses a graph propagation algorithm with a well defined objective function. The experimental results show that our proposed bootstrapping algorithm achieves state of the art performance or better on several different natural language data sets.

## 1 Introduction

In this paper, we are concerned with a case of semi-supervised learning that is close to unsupervised learning, in that the labelled and unlabelled data points are from the same domain and only a small set of seed rules is used to derive the labelled points. We refer to this setting as *bootstrapping*. In contrast, typical semi-supervised learning deals with a large number of labelled points, and a domain adaptation task with unlabelled points from the new domain.

The two dominant discriminative learning methods for bootstrapping are self-training (Scudder, 1965) and co-training (Blum and Mitchell, 1998). In this paper we focus on a self-training style bootstrapping algorithm, the Yarowsky algorithm (Yarowsky, 1995). Variants of this algorithm have been formalized as optimizing an objective function in previous work by Abney (2004) and Haffari and Sarkar (2007), but it is not clear that any perform as well as the Yarowsky algorithm itself.

We take advantage of this formalization and introduce a novel algorithm called Yarowsky-prop which builds on the algorithms of Yarowsky (1995) and Subramanya et al. (2010). It is theoretically

\*This research was partially supported by an NSERC, Canada (RGPIN: 264905) grant. We would like to thank Gholamreza Haffari and the anonymous reviewers for their comments. We particularly thank Michael Collins, Jason Eisner, and Damianos Karakos for the data we used in our experiments.

$x$	denotes an example
$f, g$	denote features
$i, k$	denote labels
$X$	set of training examples
$F_x$	set of features for example $x$
$Y$	current labelling of $X$
$Y_x$	current label for example $x$
$\perp$	value of $Y_x$ for unlabelled examples
$L$	number of labels (not including $\perp$ )
$\Lambda$	set of currently labelled examples
$V$	set of currently unlabelled examples
$X_f$	set of examples with feature $f$
$\Lambda_f$	set of currently labelled examples with $f$
$V_f$	set of currently unlabelled examples with $f$
$\Lambda_j$	set of examples currently labelled with $j$
$\Lambda_{fj}$	set of examples with $f$ currently labelled with $j$

Table 1: Notation of Abney (2004).

well-understood as minimizing an objective function at each iteration, and it obtains state of the art performance on several different NLP data sets. To our knowledge, this is the first theoretically motivated self-training bootstrapping algorithm which performs as well as the Yarowsky algorithm.

## 2 Bootstrapping

Abney (2004) defines useful notation for semi-supervised learning, shown in table 1. Note that  $\Lambda$ ,  $V$ , etc. are relative to the current labelling  $Y$ . We additionally define  $F$  to be the set of all features, and use  $U$  to denote the uniform distribution. In the bootstrapping setting the learner is given an initial partial labelling  $Y^{(0)}$  where only a few examples are labelled (i.e.  $Y_x^{(0)} = \perp$  for most  $x$ ).

Abney (2004) defines three probability distributions in his analysis of bootstrapping:  $\theta_{fj}$  is the parameter for feature  $f$  with label  $j$ , taken to be normalized so that  $\theta_f$  is a distribution over labels.  $\phi_x$  is the labelling distribution representing the current  $Y$ ; it is a point distribution for labelled examples and uniform for unlabelled examples.  $\pi_x$  is the prediction distribution over labels for example  $x$ .

The approach of Haghighi and Klein (2006b) and Haghighi and Klein (2006a) also uses a small set of

---

Algorithm 1: The basic Yarowsky algorithm.

- 

seed rules but uses them to inject features into a joint model  $p(x, j)$  which they train using expectation-maximization for Markov random fields. We focus on discriminative training which does not require complex partition functions for normalization. Blum and Chawla (2001) introduce an early use of transductive learning using graph propagation. X. Zhu and Z. Ghahramani and J. Lafferty (2003)’s method of graph propagation is predominantly transductive, and the non-transductive version is closely related to Abney (2004) c.f. Haffari and Sarkar (2007).<sup>1</sup>

### 3 Existing algorithms

#### 3.1 Yarowsky

A decision list (DL) is a (ordered) list of feature-label pairs (rules) which is produced by assigning a score to each rule and sorting on this score. It chooses a label for an example from the first rule whose feature is a feature of the example. For a DL the prediction distribution is defined by  $\pi_x(j) \propto \max_{f \in F_x} \theta_{fj}$ . The basic Yarowsky algorithm is shown in algorithm 1. Note that at any point some training examples may be left unlabelled by  $Y^{(t)}$ .

We use Collins and Singer (1999) for our exact specification of Yarowsky.<sup>2</sup> It uses DL rule scores

$$\theta_{fj} \propto \frac{|\Lambda_{fj}| + \epsilon}{|\Lambda_f| + L\epsilon} \quad (1)$$

where  $\epsilon$  is a smoothing constant. When constructing a DL it keeps only the rules with (pre-normalized) score over a threshold  $\zeta$ . In our implementation we add the seed rules to each subsequent DL.<sup>3</sup>

---

<sup>1</sup>Large-scale information extraction, e.g. (Hearst, 1992), Snowball (Agichtein and Gravano, 2000), AutoSlog (Riloff and Shepherd, 1997), and Junto (Talukdar, 2010) among others, also have similarities to our approach. We focus on the formal analysis of the Yarowsky algorithm by Abney (2004).

<sup>2</sup>It is similar to that of Yarowsky (1995) but is better specified and omits word sense disambiguation optimizations. The general algorithm in Yarowsky (1995) is self-training with any kind of underlying supervised classifier, but we follow the convention of using Yarowsky to refer to the DL algorithm.

<sup>3</sup>This is not clearly specified in Collins and Singer (1999),

#### 3.2 Yarowsky-cautious

Collins and Singer (1999) also introduce a variant algorithm Yarowsky-cautious. Here the DL training step keeps only the top  $n$  rules  $(f, j)$  over the threshold for each label  $j$ , ordered by  $|\Lambda_f|$ . Additionally the threshold  $\zeta$  is checked against  $|\Lambda_{fj}|/|\Lambda_f|$  instead of the smoothed score.  $n$  begins at  $n_0$  and is incremented by  $\Delta n$  at each iteration. We add the seed DL to the new DL after applying the cautious pruning. Cautiousness limits not only the size of the DL but also the number of labelled examples, prioritizing decisions which are believed to be of high accuracy.

At the final iteration Yarowsky-cautious uses the current labelling to train a DL without a threshold or cautiousness, and this DL is used for testing. We call this the retraining step.<sup>4</sup>

#### 3.3 DL-CoTrain

Collins and Singer (1999) also introduce the co-training algorithm DL-CoTrain. This algorithm alternates between two DLs using disjoint views of the features in the data. At each step it trains a DL and then produces a new labelling for the other DL. Each DL uses thresholding and cautiousness as we describe for Yarowsky-cautious. At the end the DLs are combined, the result is used to label the data, and a retraining step is done from this single labelling.

#### 3.4 Y-1/DL-1-VS

One of the variant algorithms of Abney (2004) is Y-1/DL-1-VS (referred to by Haffari and Sarkar (2007) as simply DL-1). Besides various changes in the specifics of how the labelling is produced, this algorithm has two differences versus Yarowsky. Firstly, the smoothing constant  $\epsilon$  in (1) is replaced by  $1/|V_f|$ . Secondly,  $\pi$  is redefined as  $\pi_x(j) = \frac{1}{|F_x|} \sum_{f \in F_x} \theta_{fj}$ , which we refer to as the sum definition of  $\pi$ . This definition does not match a literal DL but is easier to analyze.

We are not concerned here with the details of Y-1/DL-1-VS, but we note that Haffari and Sarkar

---

but is used for DL-CoTrain in the same paper.

<sup>4</sup>The details of Yarowsky-cautious are not clearly specified in Collins and Singer (1999). Based on similar parts of DL-CoTrain we assume that the top  $n$  selection is per label rather than in total, that the thresholding value is unsmoothed, and that there is a retraining step. We also assume their notation  $Count'(x)$  to be equivalent to  $|\Lambda_f|$ .

(2007) provide an objective function for this algorithm using a generalized definition of cross-entropy in terms of Bregman distance, which motivates our objective in section 4. The Bregman distance between two discrete probability distributions  $p$  and  $q$  is defined as  $B_\psi(p, q) = \sum_i [\psi(p_i) - \psi(q_i) - \psi'(q_i)(p_i - q_i)]$ . As a specific case we have  $B_{t^2}(p, q) = \sum_i (p_i - q_i)^2 = \|p - q\|^2$ . Then Bregman distance-based entropy is  $H_{t^2}(p) = -\sum_i p_i^2$ , KL-Divergence is  $B_{t^2}$ , and cross-entropy follows the standard definition in terms of  $H_{t^2}$  and  $B_{t^2}$ . The objective minimized by Y-1/DL-1-VS is:

$$\sum_{\substack{x \in X \\ f \in F_x}} H_{t^2}(\phi_x || \theta_f) = \sum_{\substack{x \in X \\ f \in F_x}} \left[ B_{t^2}(\phi_x || \theta_f) - \sum_y \phi_x^2 \right]. \quad (2)$$

### 3.5 Yarowsky-sum

As a baseline for the sum definition of  $\pi$ , we introduce the Yarowsky-sum algorithm. It is the same as Yarowsky except that we use the sum definition when labelling: for example  $x$  we choose the label  $j$  with the highest (sum)  $\pi_x(j)$ , but set  $Y_x = \perp$  if the sum is zero. Note that this is a linear model similar to a conditional random field (CRF) (Lafferty et al., 2001) for unstructured multiclass problems.

### 3.6 Bipartite graph algorithms

Haffari and Sarkar (2007) suggest a bipartite graph framework for semi-supervised learning based on their analysis of Y-1/DL-1-VS and objective (2). The graph has vertices  $X \cup F$  and edges  $\{(x, f) : x \in X, f \in F_x\}$ , as in the graph shown in figure 1(a). Each vertex represents a distribution over labels, and in this view Yarowsky can be seen as alternately updating the example distributions based on the feature distributions and visa versa.

Based on this they give algorithm 2, which we call HS-bipartite. It is parametrized by two functions which are called features-to-example and examples-to-feature here. Each can be one of two choices: **average**( $S$ ) is the normalized average of the distributions of  $S$ , while **majority**( $S$ ) is a uniform distribution if all labels are supported by equal numbers of distributions of  $S$ , and otherwise a point distribution with mass on the best supported label. The **average-majority** form is similar

---

Algorithm 2: HS-bipartite.

---

```

1: apply  $\theta^{(0)}$  to  $X$  produce a labelling  $Y^{(0)}$ 
2: for iteration  $t$  to maximum or convergence do
3:   for  $f \in F$  do
4:     let  $p = \text{examples-to-feature}(\{\phi_x : x \in X_f\})$ 
5:     if  $p \neq U$  then let  $\theta_f = p$ 
6:   end for
7:   for  $x \in X$  do
8:     let  $p = \text{features-to-example}(\{\theta_f : f \in F_x\})$ 
9:     if  $p \neq U$  then let  $\phi_x = p$ 
10:  end for
11: end for

```

---

to Y-1/DL-1-VS, and the **majority-majority** form minimizes a different objective similar to (2).

In our implementation we label training data (for the convergence check) with the  $\phi$  distributions from the graph. We label test data by constructing new  $\phi_x = \text{examples-to-feature}(F_x)$  for the unseen  $x$ .

### 3.7 Semi-supervised learning algorithm of Subramanya et al. (2010)

Subramanya et al. (2010) give a semi-supervised algorithm for part of speech tagging. Unlike the algorithms described above, it is for domain adaptation with large amounts of labelled data rather than bootstrapping with a small number of seeds.

This algorithm is structurally similar to Yarowsky in that it begins from an initial partial labelling and repeatedly trains a classifier on the labelling and then relabels the data. It uses a CRF (Lafferty et al., 2001) as the underlying supervised learner. It differs significantly from Yarowsky in two other ways: First, instead of only training a CRF it also uses a step of graph propagation between distributions over the  $n$ -grams in the data. Second, it does the propagation on distributions over  $n$ -gram types rather than over  $n$ -gram tokens (instances in the data).

They argue that using propagation over types allows the algorithm to enforce constraints and find similarities that self-training cannot. We are not concerned here with the details of this algorithm, but it motivates our work firstly in providing the graph propagation which we will describe in more detail in section 4, and secondly in providing an algorithmic structure that we use for our algorithm in section 5.

### 3.8 Collins and Singer (1999)'s EM

We implemented the EM algorithm of Collins and Singer (1999) as a baseline for the other algorithms.

Method	$\mathcal{V}$	$\mathcal{N}(u)$	$q_u$
$\phi$ - $\theta$	$X \cup F$	$\mathcal{N}_x = F_x, \mathcal{N}_f = X_f$	$q_x = \phi_x, q_f = \theta_f$
$\pi$ - $\theta$	$X \cup F$	$\mathcal{N}_x = F_x, \mathcal{N}_f = X_f$	$q_x = \pi_x, q_f = \theta_f$
$\theta$ -only	$F$	$\mathcal{N}_f = \bigcup_{x \in X_f} F_x \setminus f$	$q_f = \theta_f$
$\theta^T$ -only	$F$	$\mathcal{N}_f = \bigcup_{x \in X_f} F_x \setminus f$	$q_f = \theta_f^T$

Table 2: Graph structures for propagation.

They do not specify tuning details, but to get comparable accuracy we found it was necessary to do smoothing and to include weights  $\lambda_1$  and  $\lambda_2$  on the expected counts of seed-labelled and initially unlabelled examples respectively (Nigam et al., 2000).

## 4 Graph propagation

The graph propagation of Subramanya et al. (2010) is a method for smoothing distributions attached to vertices of a graph. Here we present it with an alternate notation using Bregman distances as described in section 3.4.<sup>5</sup> The objective is

$$\mu \sum_{\substack{u \in \mathcal{V} \\ v \in \mathcal{N}(i)}} w_{uv} B_{t^2}(q_u, q_v) + \nu \sum_{u \in \mathcal{V}} B_{t^2}(q_u, U) \quad (3)$$

where  $\mathcal{V}$  is a set of vertices,  $\mathcal{N}(v)$  is the neighbourhood of vertex  $v$ , and  $q_v$  is an initial distribution for each vertex  $v$  to be smoothed. They give an iterative update to minimize (3). Note that (3) is independent of their specific graph structure, distributions, and semi-supervised learning algorithm.

We propose four methods for using this propagation with Yarowsky. These methods all use constant edge weights ( $w_{uv} = 1$ ). The distributions and graph structures are shown in table 2. Figure 1 shows example graphs for  $\phi$ - $\theta$  and  $\theta$ -only.  $\pi$ - $\theta$  and  $\theta^T$ -only are similar, and are described below.

The graph structure of  $\phi$ - $\theta$  is the bipartite graph of Haffari and Sarkar (2007). In fact,  $\phi$ - $\theta$  the propagation objective (3) and Haffari and Sarkar (2007)’s Y-1/DL-1-VS objective (2) are identical up to constant coefficients and an extra constant term.<sup>6</sup>  $\phi$ - $\theta$

<sup>5</sup>We omit the option to hold some of the distributions at fixed values, which would add an extra term to the objective.

<sup>6</sup>The differences are specifically: First, (3) adds the constant coefficients  $\mu$  and  $\nu$ . Second, (3) sums over each edge twice (once in each direction), while (2) sums over each only once. Since  $w_{uv} = w_{vu}$  and  $B_{t^2}(q_u, q_v) = B_{t^2}(q_v, q_u)$ , this can be folded into the constant  $\mu$ . Third, after expanding (2) there is a term  $|F_x|$  inside the sum for  $H_{t^2}(\phi_x)$  which is not present in (3). This does not effect the direction of minimization. Fourth,  $B_{t^2}(q_u, U)$  in (3) expands to  $H_{t^2}(q_u)$  plus a constant, adding an extra constant term to the total.

Figure 1: Example graphs for  $\phi$ - $\theta$  and  $\theta$ -only propagation.

therefore gives us a direct way to optimize (2).

The other three methods do not correspond to the objective of Haffari and Sarkar (2007). The  $\pi$ - $\theta$  method is like  $\phi$ - $\theta$  except for using  $\pi$  as the distribution for example vertices.

The bipartite graph of the first two methods differs from the structure used by Subramanya et al. (2010) in that it does propagation between two different kinds of distributions instead of only one kind. We also adopt a more comparable approach with a graph over only features. Here we define adjacency by co-occurrence in the same example. The  $\theta$ -only method uses this graph and  $\theta$  as the distribution.

Finally, we noted in section 3.7 that the algorithm of Subramanya et al. (2010) does one additional step in converting from token level distributions to type level distributions. The  $\theta^T$ -only method therefore uses the feature-only graph but for the distribution uses a type level version of  $\theta$  defined by  $\theta_{fj}^T = \frac{1}{|X_f|} \sum_{x \in X_f} \pi_x(j)$ .

## 5 Novel Yarowsky-prop algorithm

We call our graph propagation based algorithm Yarowsky-prop. It is shown with  $\theta^T$ -only propagation in algorithm 3. It is based on the Yarowsky algorithm, with the following changes: an added step to calculate  $\theta^T$  (line 4), an added step to calculate  $\theta^P$  (line 5), the use of  $\theta^P$  rather than the DL to update the labelling (line 6), and the use of the sum definition of  $\pi$ . Line 7 does DL training as we describe in sections 3.1 and 3.2. Propagation is done with the iterative update of Subramanya et al. (2010).

This algorithm is adapted to the other propagation methods described in section 4 by changing the type of propagation on line 5. In  $\theta$ -only, propagation is

Algorithm 3: Yarowsky-prop.

---

```

1: let  $\theta_{fj}$  be the scores of the seed rules // crf_train
2: for iteration  $t$  to maximum or convergence do
3:   let  $\pi_x(j) = \frac{1}{|F_x|} \sum_{f \in F_x} \theta_{fj}$  // post_decode
4:   let  $\theta_{fj}^T = \frac{\sum_{x \in X_f} \pi_x(j)}{|X_f|}$  // token_to_type
5:   propagate  $\theta^T$  to get  $\theta^P$  // graph_propagate
6:   label the data with  $\theta^P$  // viterbi_decode
7:   train a new DL  $\theta_{fj}$  // crf_train
8: end for

```

---

done on  $\theta$ , using the graph of figure 1(b). In  $\phi$ - $\theta$  and  $\pi$ - $\theta$  propagation is done on the respective bipartite graph (figure 1(a) or the equivalent with  $\pi$ ). Line 4 is skipped for these methods, and  $\phi$  is as defined in section 2. For the bipartite graph methods  $\phi$ - $\theta$  and  $\pi$ - $\theta$  only the propagated  $\theta$  values on the feature nodes are used for  $\theta^P$  (the distributions on the example nodes are ignored after the propagation itself).

The algorithm uses  $\theta_{fj}$  values rather than an explicit DL for labelling. The (pre-normalized) score for any  $(f, j)$  not in the DL is taken to be zero. Besides using the sum definition of  $\pi$  when calculating  $\theta^T$ , we also use a sum in labelling. When labelling an example  $x$  (at line 6 and also on testing data) we use  $\arg \max_j \sum_{f \in F_x: \theta_f^P \neq U} \theta_{fj}^P$ , but set  $Y_x = \perp$  if the sum is zero. Ignoring uniform  $\theta_f^P$  values is intended to provide an equivalent to the DL behaviour of using evidence only from rules that are in the list.

We include the cautiousness of Yarowsky-cautious (section 3.2) in the DL training on line 7. At the labelling step on line 6 we label only examples which the pre-propagated  $\theta$  would also assign a label (using the same rules described above for  $\theta^P$ ). This choice is intended to provide an equivalent to the Yarowsky-cautious behaviour of limiting the number of labelled examples; most  $\theta_f^P$  are non-uniform, so without it most examples become labelled early.

We observe further similarity between the Yarowsky algorithm and the general approach of Subramanya et al. (2010) by comparing algorithm 3 here with their algorithm 1. The comments in algorithm 3 give the corresponding parts of their algorithm. Note that each line has a similar purpose.

## 6 Evaluation

### 6.1 Tasks and data

For evaluation we use the tasks of Collins and Singer (1999) and Eisner and Karakos (2005), with data

Rank	Score	Feature	Label
<b>1</b>	0.999900	New-York	loc.
<b>2</b>	0.999900	California	loc.

		$\vdots$	

Figure 2: A DL from iteration 5 of Yarowsky on the named entity task. Scores are pre-normalized values from the expression on the left side of (1), not  $\theta_{fj}$  values. Context features are indicated by *italics*; all others are spelling features. Specific feature types are omitted. Seed rules are indicated by **bold** ranks.

kindly provided by the respective authors.

The task of Collins and Singer (1999) is named entity classification on data from New York Times text.<sup>7</sup> The data set was pre-processed by a statistical parser (Collins, 1997) and all noun phrases that are potential named entities were extracted from the parse tree. Each noun phrase is to be labelled as a person, organization, or location. The parse tree provides the surrounding context as *context features* such as the words in prepositional phrase and relative clause modifiers, etc., and the actual words in the noun phrase provide the *spelling features*. The test data additionally contains some noise examples which are not in the three named entity categories. We use the seed rules the authors provide, which are the first seven items in figure 2. For DL-CoTrain, we use their two views: one view is the spelling features, and the other is the context features. Figure 2 shows a DL from Yarowsky training on this task.

The tasks of Eisner and Karakos (2005) are word sense disambiguation on several English words which have two senses corresponding to two different words in French. Data was extracted from the Canadian Hansards, using the English side to produce training and test data and the French side to produce the gold labelling. Features are the original and lemmatized words immediately adja-

<sup>7</sup>We removed weekday and month examples from the test set as they describe. They note 88962 examples in their training set, but the file has 89305. We did not find any filtering criteria that produced the expected size, and therefore used all examples.

cent to the word to be disambiguated, and original and lemmatized context words in the same sentence. Their seeds are pairs of adjacent word features, with one feature for each label (sense). We use the ‘drug’, ‘land’, and ‘sentence’ tasks, and the seed rules from their best seed selection: ‘alcohol’/‘medical’, ‘acres’/‘court’, and ‘reads’/‘served’ respectively (they do not provide seeds for their other three tasks). For DL-CoTrain we use adjacent words for one view and context words for the other.

## 6.2 Experimental set up

Where applicable we use smoothing  $\epsilon = 0.1$ , a threshold  $\zeta = 0.95$ , and cautiousness parameters  $n_0 = \Delta n = 5$  as in Collins and Singer (1999) and propagation parameters  $\mu = 0.6, \nu = 0.01$  as in Subramanya et al. (2010). Initial experiments with different propagation parameters suggested that as long as  $\nu$  was set at this value changing  $\mu$  had relatively little effect on the accuracy. We did not find any propagation parameter settings that outperformed this choice. For the Yarowsky-prop algorithms we perform a single iteration of the propagation update for each iteration of the algorithm.

For EM we use weights  $\lambda_1 = 0.98$ , and  $\lambda_2 = 0.02$  (see section 3.8), which were found in initial experiments to be the best values, and results are averaged over 10 random initializations.

The named entity test set contains some examples that are neither person, organization, nor location. Collins and Singer (1999) define noise accuracy as accuracy that includes such instances, and clean accuracy as accuracy calculated across only the examples which are one of the known labels. We report only clean accuracy in this paper; noise accuracy tracks clean accuracy but is a little lower. There is no difference on the word sense data sets. We also report (clean) non-seeded accuracy, which we define to be clean accuracy over only examples which are not assigned a label by the seed rules. This is intended to evaluate what the algorithm has learned, rather than what it can achieve by using the input information directly (Daume, 2011).

We test Yarowsky, Yarowsky-cautious, Yarowsky-sum, DL-CoTrain, HS-bipartite in all four forms, and Yarowsky-prop cautious and non-cautious and in all four forms. For each algorithm except EM we perform a final retraining step

Gold	Spelling features	Context features

as described for Yarowsky-cautious (section 3.2). Our programs and experiment scripts have been made available.<sup>8</sup>

## 6.3 Accuracy

Table 3 shows the final test set accuracies for the all the algorithms. The seed DL accuracy is also included for reference.

The best performing form of our novel algorithm is Yarowsky-prop-cautious  $\theta$ -only. It numerically outperforms DL-CoTrain on the named entity task, is not (statistically) significantly worse on the drug and land tasks, and is significantly better on the sentence task. It also numerically outperforms Yarowsky-cautious on the named entity task and is significantly better on the drug task. Is significantly worse on the land task, where most algorithms converge at labelling all examples with the first sense. It is significantly worse on the sentence task, although it is the second best performing algorithm and several percent above DL-CoTrain on that task.

Figure 3 shows (all) three examples from the named entity test set where Yarowsky-prop-cautious  $\theta$ -only is correct but none of the other Yarowsky variants are. Note that it succeeds despite misleading features; “maker” and “company” might be taken to indicate a company and “president-of” an organization, but all three examples are locations.

Yarowsky-prop-cautious  $\phi$ - $\theta$  and  $\pi$ - $\theta$  also perform respectably, although not as well. Yarowsky-prop-cautious  $\theta^T$ -only and the non-cautious versions are significantly worse. Although  $\theta^T$ -only was intended to incorporate Subramanya et al. (2010)’s idea of type level distributions, it in fact performs worse than  $\theta$ -only. We believe that Collins and Singer (1999)’s definition (1) of  $\theta$  incorporates sufficient type level information that the creation of a separate distribution is unnecessary in this case.

Figure 4 shows the test set non-seeded accuracies as a function of the iteration for many of the algo-

Table 3: Test set percent accuracy and non-seeded test set percent accuracy (respectively) for the algorithms on all tasks. **Bold** items are a maximum in their column. *Italic* items have a statistically significant difference versus DL-CoTrain ( $p < 0.05$  with a McNemar test). For EM,  $\pm$  indicates one standard deviation but statistical significance was not measured.

rithms on the named entity task. The Yarowsky-prop non-cautious algorithms quickly converge to the final accuracy and are not shown. While the other algorithms (figure 4(a)) make a large accuracy improvement in the final retraining step, the Yarowsky-prop (figure 4(b)) algorithms reach comparable accuracies earlier and gain much less from retraining.

We did not implement Collins and Singer (1999)’s CoBoost; however, in their results it performs comparably to DL-CoTrain and Yarowsky-cautious. As with DL-CoTrain, CoBoost requires two views.

#### 6.4 Cautiousness

Cautiousness appears to be important in the performance of the algorithms we tested. In table 3, only the cautious algorithms are able to reach the 90% accuracy range.

To evaluate the effects of cautiousness we examine the Yarowsky-prop  $\theta$ -only algorithm on the named entity task in more detail. This algorithm has two classifiers which are trained in conjunction: the DL and the propagated  $\theta^P$ . Figure 5 shows the training set coverage (of the labelling on line 6 of algorithm 3) and the test set accuracy of both classifiers, for the cautious and non-cautious versions.

The non-cautious version immediately learns a DL over all feature-label pairs, and therefore has full

coverage after the first iteration. The DL and  $\theta^P$  converge to similar accuracies within a few more iterations, and the retraining step increases accuracy by less than one percent. On the other hand, the cautious version gradually increases the coverage over the iterations. The DL accuracy follows the coverage closely (similar to the behaviour of Yarowsky-cautious, not shown here), while the propagated classifier accuracy jumps quickly to near 90% and then increases only gradually.

Although the DL prior to retraining achieves a roughly similar accuracy in both versions, only the cautious version is able to reach the 90% accuracy range in the propagated classifier and retraining. Presumably the non-cautious version makes an early mistake, reaching a local minimum which it cannot escape. The cautious version avoids this by making only safe rule selection and labelling choices.

Figure 5(b) also helps to clarify the difference in retraining that we noted in section 6.3. Like the non-propagated DL algorithms, the DL component of Yarowsky-prop has much lower accuracy than the propagated classifier prior to the retraining step. But after retraining, the DL and  $\theta^P$  reach very similar accuracies.

(a) Collins & Singer algorithms (plus sum form)

(b) Yarowsky propagation cautious

Figure 4: Non-seeded test accuracy versus iteration for various algorithms on named entity. The results for the Yarowsky-prop algorithms are for the propagated classifier  $\theta^P$ , except for the final DL retraining iteration.

## 6.5 Objective function

The propagation method  $\phi$ - $\theta$  was motivated by optimizing the equivalent objectives (2) and (3) at each iteration. Figure 6 shows the graph propagation objective (3) along with accuracy for Yarowsky-prop  $\phi$ - $\theta$  without cautiousness. The objective value decreases as expected, and converges along with accuracy. Conversely, the cautious version (not shown here) does not clearly minimize the objective, since cautiousness limits the effect of the propagation.

## 7 Conclusions

Our novel algorithm achieves accuracy comparable to Yarowsky-cautious, but is better theoretically motivated by combining ideas from Haffari and Sarkar (2007) and Subramanya et al. (2010). It also achieves accuracy comparable to DL-CoTrain, but does not require the features to be split into two independent views.

As future work, we would like to apply our al-

(a) Non-cautious

(b) Cautious

Figure 5: Internal train set coverage and non-seeded test accuracy (same scale) for Yarowsky-prop  $\theta$ -only on named entity.

Figure 6: Non-seeded test accuracy (left axis), coverage (left axis, same scale), and objective value (right axis) for Yarowsky-prop  $\phi$ - $\theta$ . Iterations are shown on a log scale. We omit the first iteration (where the DL contains only the seed rules) and start the plot at iteration 2 where there is a complete DL.

gorithm to a structured task such as part of speech tagging. We also believe that our method for adapting Collins and Singer (1999)'s cautiousness to Yarowsky-prop can be applied to similar algorithms with other underlying classifiers, even to structured output models such as conditional random fields.

## Abstract

We present a novel algorithm for multilingual dependency parsing that uses annotations from a diverse set of source languages to parse a new unannotated language. Our motivation is to broaden the advantages of multilingual learning to languages that exhibit significant differences from existing resource-rich languages. The algorithm learns which aspects of the source languages are relevant for the target language and ties model parameters accordingly. The model factorizes the process of generating a dependency tree into two steps: *selection* of syntactic dependents and their *ordering*. Being largely language-universal, the selection component is learned in a supervised fashion from all the training languages. In contrast, the ordering decisions are only influenced by languages with similar properties. We systematically model this cross-lingual sharing using typological features. In our experiments, the model consistently outperforms a state-of-the-art multilingual parser. The largest improvement is achieved on the non Indo-European languages yielding a gain of 14.4%.<sup>1</sup>

## 1 Introduction

Current top performing parsing algorithms rely on the availability of annotated data for learning the syntactic structure of a language. Standard approaches for extending these techniques to resource-lean languages either use parallel corpora or rely on

annotated trees from other source languages. These techniques have been shown to work well for language families with many annotated resources (such as Indo-European languages). Unfortunately, for many languages there are no available parallel corpora or annotated resources in related languages. For such languages the only remaining option is to resort to unsupervised approaches, which are known to produce highly inaccurate results.

In this paper, we present a new multilingual algorithm for dependency parsing. In contrast to previous approaches, this algorithm can learn dependency structures using annotations from a diverse set of source languages, even if this set is not related to the target language. In our *selective sharing* approach, the algorithm learns which aspects of the source languages are relevant for the target language and ties model parameters accordingly. This approach is rooted in linguistic theory that characterizes the connection between languages at various levels of sharing. Some syntactic properties are universal across languages. For instance, nouns take adjectives and determiners as dependents, but not adverbs. However, the order of these dependents with respect to the parent is influenced by the typological features of each language.

To implement this intuition, we factorize generation of a dependency tree into two processes: selection of syntactic dependents and their ordering. The first component models the distribution of dependents for each part-of-speech tag, abstracting over their order. Being largely language-universal, this distribution can be learned in a supervised fashion from all the training languages. On the other hand,

<sup>1</sup>The source code for the work presented in this paper is available at <http://groups.csail.mit.edu/rbg/code/unidep/>

ordering of dependents varies greatly across languages and therefore should only be influenced by languages with similar properties. Furthermore, this similarity has to be expressed at the level of dependency types – i.e., two languages may share noun-adposition ordering, but differ in noun-determiner ordering. To systematically model this cross-lingual sharing, we rely on typological features that reflect ordering preferences of a given language. In addition to the known typological features, our parsing model embeds latent features that can capture cross-lingual structural similarities.

While the approach described so far supports a seamless transfer of shared information, it does not account for syntactic properties of the target language unseen in the training languages. For instance, in the CoNLL data, Arabic is the only language with the VSO ordering. To handle such cases, our approach augments cross-lingual sharing with unsupervised learning on the target languages.

We evaluated our selective sharing model on 17 languages from 10 language families. On this diverse set, our model consistently outperforms state-of-the-art multilingual dependency parsers. Performance gain, averaged over all the languages, is 5.9% when compared to the highest baseline. Our model achieves the most significant gains on non-Indo-European languages, where we see a 14.4% improvement. We also demonstrate that in the absence of observed typological information, a set of automatically induced latent features can effectively work as a proxy for typology.

## 2 Related Work

Traditionally, parallel corpora have been a mainstay of multilingual parsing (Wu, 1997; Kuhn, 2004; Smith and Smith, 2004; Hwa et al., 2005; Xi and Hwa, 2005; Burkett and Klein, 2008; Snyder et al., 2009). However, recent work in multilingual parsing has demonstrated the feasibility of transfer in the absence of parallel data. As a main source of guidance, these methods rely on the commonalities in dependency structure across languages. For instance, Naseem et al. (2010) explicitly encode these similarities in the form of universal rules which guide grammar induction in the target language. An alternative approach is to directly employ a non-lexicalized

parser trained on one language to process a target language (Zeman and Resnik, 2008; McDonald et al., 2011; Søgaard, 2011). Since many unlexicalized dependencies are preserved across languages, these approaches are shown to be effective for related languages. For instance, when applied to the language pairs within the Indo-European family, such parsers outperform unsupervised monolingual techniques by a significant margin.

The challenge, however, is to enable dependency transfer for target languages that exhibit structural differences from source languages. In such cases, the extent of multilingual transfer is determined by the relation between source and target languages. Berg-Kirkpatrick and Klein (2010) define such a relation in terms of phylogenetic trees, and use this distance to selectively tie the parameters of monolingual syntactic models. Cohen et al. (2011) do not use a predefined linguistic hierarchy of language relations, but instead learn the contribution of source languages to the training mixture based on the likelihood of the target language. Søgaard (2011) proposes a different measure of language relatedness based on perplexity between POS sequences of source and target languages. Using this measure, he selects a subset of training source sentences that are closer to the target language. While all of the above techniques demonstrate gains from modeling language relatedness, they still underperform when the source and target languages are unrelated.

Our model differs from the above approaches in its emphasis on the selective information sharing driven by language relatedness. This is further combined with monolingual unsupervised learning. As our evaluation demonstrates, this layered approach broadens the advantages of multilingual learning to languages that exhibit significant differences from the languages in the training mix.

## 3 Linguistic Motivation

### Language-Independent Dependency Properties

Despite significant syntactic differences, human languages exhibit striking similarity in dependency patterns. For a given part-of-speech tag, the set of tags that can occur as its dependents is largely consistent across languages. For instance, adverbs and nouns are likely to be dependents of verbs, while adjectives

are not. Thus, these patterns can be freely transferred across languages.

**Shared Dependency Properties** Unlike dependent selection, the ordering of dependents in a sentence differs greatly across languages. In fact, cross-lingual syntactic variations are primarily expressed in different ordering of dependents (Harris, 1968; Greenberg, 1963). Fortunately, the dimensions of these variations have been extensively studied in linguistics and are documented in the form of typological features (Comrie, 1989; Haspelmath et al., 2005). For instance, most languages are either dominantly prepositional like English or post-positional like Urdu. Moreover, a language may be close to different languages for different dependency types. For instance, Portuguese is a prepositional language like English, but the order of its noun-adjective dependency is different from English and matches that of Arabic. Therefore, we seek a model that can express parameter sharing at the level of dependency types and can benefit from known language relations.

**Language-specific Dependency Variations** Not every aspect of syntactic structure is shared across languages. This is particularly true given a limited number of supervised source languages; it is quite likely that a target language will have previously unseen syntactic phenomena. In such a scenario, the raw text in the target language might be the only source of information about its unique aspects.

## 4 Model

We propose a probabilistic model for generating dependency trees that facilitates parameter sharing across languages. We assume a setup where dependency tree annotations are available for a set of source languages and we want to use these annotations to infer a parser for a target language. Syntactic trees for the target language are not available during training. We also assume that both source and target languages are annotated with a coarse parts-of-speech tagset which is shared across languages. Such tagsets are commonly used in multilingual parsing (Zeman and Resnik, 2008; McDonald et al., 2011; Søgaard, 2011; Naseem et al., 2010).

The key feature of our model is a two-tier approach that separates the *selection* of dependents from their *ordering*:

1. *Selection Component*: Determines the dependent tags given the parent tag.
2. *Ordering Component*: Determines the position of each dependent tag with respect to its parent (right or left) and the order within the right and left dependents.

This factorization constitutes a departure from traditional parsing models where these decisions are tightly coupled. By separating the two, the model is able to support different degrees of cross-lingual sharing on each level.

For the selection component, a reasonable approximation is to assume that it is the same for all languages. This is the approach we take here.

As mentioned in Section 3, the ordering of dependents is largely determined by the typological features of the language. We assume that we have a set of such features for every language  $l$ , and denote this feature vector by  $v_l$ . We also experiment with a variant of our model where typological features are not observed. Instead, the model captures structural variations across languages by means of a small set of binary latent features. The values of these features are language dependent. We denote the set of latent features for language  $l$  by  $b_l$ .

Finally, based on the well known fact that long distance dependencies are less likely (Eisner and Smith, 2010), we bias our model towards short dependencies. This is done by imposing a corpus-level soft constraint on dependency lengths using the posterior regularization framework (Graça et al., 2007).

### 4.1 Generative Process

Our model generates dependency trees one fragment at a time. A *fragment* is defined as a subtree comprising the immediate dependents of any node in the tree. The process recursively generates fragments in a head outwards manner, where the distribution over fragments depends on the head tag. If the generated fragment is not empty then the process continues for each child tag in the fragment, drawing new fragments from the distribution associated with the tag. The process stops when there are no more non-empty fragments.

A fragment with head node  $h$  is generated in language  $l$  via the following stages:

Figure 1: The steps of the generative process for a fragment with head  $h$ . In step (a), the unordered set of dependents is chosen. In step (b) they are partitioned into left and right unordered sets. Finally, each set is ordered in step (c).

- Generate the set of dependents of  $h$  via a distribution  $P_{sel}(S|h)$ . Here  $S$  is an unordered set of POS tags. Note that this part is universal (i.e., it does not depend on the language  $l$ ).
- For each element in  $S$  decide whether it should go to the right or left of  $h$  as follows: for every  $a \in S$ , draw its direction from the distribution  $P_{ord}(d|a, h, l)$ , where  $d \in \{R, L\}$ . This results in two unordered sets  $S_R, S_L$ , the right and left dependents of  $h$ . This part *does* depend on the language  $l$ , since the relative ordering of dependents is not likely to be universal.
- Order the sets  $S_R, S_L$ . For simplicity, we assume that the order is drawn uniformly from all the possible unique permutations over  $S_R$  and  $S_L$ . We denote the number of such unique permutations of  $S_R$  by  $n(S_R)$ .<sup>2</sup> Thus the probability of each permutation of  $S_R$  is  $\frac{1}{n(S_R)}$ .<sup>3</sup>

Figure 1 illustrates the generative process. The first step constitutes the *selection* component and the last two steps constitute the *ordering* component. Given this generation scheme, the probability  $P(D)$  of generating a given fragment  $D$  with head  $h$  will be:

$$P_{sel}(\{D\}|h) \prod_{a \in D} P_{ord}(d_D(a)|a, h, l) \frac{1}{n(D_R)n(D_L)} \quad (1)$$

Where we use the following notations:

- $D_R, D_L$  denote the parts of the fragment that are to the left and right of  $h$ .

<sup>2</sup>This number depends on the count of each distinct tag in  $S_R$ . For example if  $S_R = \{N, N, N\}$  then  $n(S_R) = 1$ . If  $S_R = \{N, D, V\}$  then  $n(S_R) = 3!$ .

<sup>3</sup>We acknowledge that assuming a uniform distribution over the permutations of the right and left dependents is linguistically counterintuitive. However, it simplifies the model by greatly reducing the number of parameters to learn.

- $\{D\}$  is the unordered set of tags in  $D$ .
- $d_D(a)$  is the position (either  $R$  or  $L$ ) of the dependent  $a$  w.r.t. the head of  $D$ .

In what follows we discuss the parameterizations of the different distributions.

#### 4.1.1 Selection Component

The selection component draws an unordered set of tags  $S$  given the head tag  $h$ . We assume that the process is carried out in two steps. First the number of dependents  $n$  is drawn from a distribution:

$$P_{size}(n|h) = \theta_{size}(n|h) \quad (2)$$

where  $\theta_{size}(n|h)$  is a parameter for each value of  $n$  and  $h$ . We restrict the maximum value of  $n$  to four, since this is a reasonable bound on the total number of dependents for a single parent node in a tree. These parameters are non-negative and satisfy  $\sum_n \theta_{size}(n|h) = 1$ . In other words, the size is drawn from a categorical distribution that is fully parameterized.

Next, given the size  $n$ , a set  $S$  with  $|S| = n$  is drawn according to the following log-linear model:

$$P_{set}(S|h, n) = \frac{1}{Z_{set}(h, n)} e^{\sum_{S_i \in S} \theta_{sel}(S_i|h)}$$

$$Z_{set}(h, n) = \sum_{S: |S|=n} e^{\sum_{S_i \in S} \theta_{sel}(S_i|h)}$$

In the above,  $S_i$  is the  $i^{th}$  POS tag in the unordered set  $S$ , and  $\theta_{sel}(S_i|h)$  are parameters. Thus, large values of  $\theta_{sel}(S_i|h)$  indicate that POS  $S_i$  is more likely to appear in the subset with parent POS  $h$ .

Combining the above two steps we have the following distribution for selecting a set  $S$  of size  $n$ :

$$P_{sel}(S|h) = P_{size}(n|h) P_{set}(S|h, n) . \quad (3)$$

ID	Feature Description	Values
81A	Order of Subject, Object and Verb	SVO, SOV, VSO, VOS, OVS, OSV
85A	Order of Adposition and Noun	Postpositions, Prepositions, Inpositions
86A	Order of Genitive and Noun	Genitive-Noun, Noun-Genitive
87A	Order of Adjective and Noun	Adjective-Noun, Noun-Adjective
88A	Order of Demonstrative and Noun	Demonstrative-Noun, Noun-Demonstrative
89A	Order of Numeral and Noun	Numeral-Noun, Noun-Numeral

Table 1: The set of typological features that we use in our model. For each feature, the first column gives the ID of the feature as used in WALS, the second column describes the feature and the last column enumerates the allowable values for the feature. Besides these values, each feature can also have a value of ‘No dominant order’.

#### 4.1.2 Ordering Component

The ordering component consists of distributions  $P_{ord}(d|a, h, l)$  that determine whether tag  $a$  will be mapped to the left or right of the head tag  $h$ . We model it using the following log-linear model:

$$P_{ord}(d|a, h, l) = \frac{1}{Z_{ord}(a, h, l)} e^{\mathbf{w}_{ord} \cdot \mathbf{g}(d, a, h, \mathbf{v}_l)}$$

$$Z_{ord}(a, h, l) = \sum_{d \in \{R, L\}} e^{\mathbf{w}_{ord} \cdot \mathbf{g}(d, a, h, \mathbf{v}_l)}$$

Note that in the above equations the ordering component depends on the known typological features  $\mathbf{v}_l$ . In the setup when typological features are not known,  $\mathbf{v}_l$  is replaced with the latent ordering feature set  $\mathbf{b}_l$ .

The feature vector  $\mathbf{g}$  contains indicator features for combinations of  $a, h, d$  and individual features  $v_{li}$  (i.e., the  $i^{th}$  typological features for language  $l$ ).

#### 4.2 Typological Features

The typological features we use are a subset of order-related typological features from ‘‘The World Atlas of Language Structure’’ (Haspelmath et al., 2005). We include only those features whose values are available for all the languages in our dataset. Table 1 summarizes the set of features that we use. Note that we do not explicitly specify the correspondence between these features and the model parameters. Instead, we leave it for the model to learn this correspondence automatically.

#### 4.3 Dependency Length Constraint

To incorporate the intuition that long distance dependencies are less likely, we impose a posterior constraint on dependency length. In particular, we use the Posterior Regularization (PR) framework of Graça et al. (2007). The PR framework incorporates

constraints by adding a penalty term to the standard likelihood objective. This term penalizes the distance of the model posterior from a set  $\mathcal{Q}$ , where  $\mathcal{Q}$  contains all the posterior distributions that satisfy the constraints. In our case the constraint is that the expected dependency length is less than or equal to a pre-specified threshold value  $b$ . If we denote the latent dependency trees by  $z$  and the observed sentences by  $x$  then

$$\mathcal{Q} = \{q(z|x) : E_q[f(x, z)] \leq b\} \quad (4)$$

where  $f(x, z)$  computes the sum of the lengths of all dependencies in  $z$  with respect to the linear order of  $x$ . We measure the length of a dependency relation by counting the number of tokens between the head and its modifier. The PR objective penalizes the KL-divergence of the model posterior from the set  $\mathcal{Q}$ :

$$\mathcal{L}_\theta(x) - \text{KL}(\mathcal{Q} \parallel p_\theta(z|x))$$

where  $\theta$  denotes the model parameters and the first term is the log-likelihood of the data. This objective can be optimized using a modified version of the EM algorithm (Graça et al., 2007).

### 5 Parameter Learning

Our model is parameterized by the parameters  $\theta_{sel}$ ,  $\theta_{size}$  and  $\mathbf{w}_{ord}$ . We learn these by maximizing the likelihood of the training data. As is standard, we add  $\ell_2$  regularization on the parameters and tune it on source languages. The likelihood is marginalized over all latent variables. These are:

- For sentences in the target language: all possible derivations that result in the observed POS tag sequences. The derivations include the choice of unordered sets size  $n$ , the unordered sets themselves  $S$ , their left/right al-

locations and the orderings within the left and right branches.

- For all languages: all possible values of the latent features  $\mathbf{b}_l$ .<sup>4</sup>

Since we are learning with latent variables, we use the EM algorithm to monotonically improve the likelihood. At each E step, the posterior over latent variables is calculated using the current model. At the M step this posterior is used to maximize the likelihood over the fully observed data. To compensate for the differences in the amount of training data, the counts from each language are normalized before computing the likelihood.

The M step involves finding maximum likelihood parameters for log-linear models in Equations 3 and 4. This is done via standard gradient based search; in particular, we use the method of BFGS.

We now briefly discuss how to calculate the posterior probabilities. For estimating the  $\mathbf{w}_{ord}$  parameters we require marginals of the type  $P(b_{li}|\mathcal{D}_l; \mathbf{w}^t)$  where  $\mathcal{D}_l$  are the sentences in language  $l$ ,  $b_{li}$  is the  $i_{th}$  latent feature for the language  $l$  and  $\mathbf{w}^t$  are the parameter values at iteration  $t$ . Consider doing this for a source language  $l$ . Since the parses are known, we only need to marginalize over the other latent features. This can be done in a straightforward manner by using our probabilistic model. The complexity is exponential in the number of latent features, since we need to marginalize over all features other than  $b_{li}$ . This is feasible in our case, since we use a relatively small number of such features.

When performing unsupervised learning for the target language, we need to marginalize over possible derivations. Specifically, for the M step, we need probabilities of the form  $P(a \text{ modifies } h|\mathcal{D}_l; \mathbf{w}^t)$ . These can be calculated using a variant of the inside outside algorithm. The exact version of this algorithm would be exponential in the number of dependents due to the  $\frac{1}{n(S_r)}$  term in the permutation factor. Although it is possible to run this exact algorithm in our case, where the number of dependents is limited to 4, we use an approximation that works well in practice: instead of  $\frac{1}{n(S_r)}$  we use  $\frac{1}{|S_r|!}$ . In this case the runtime is no longer exponential in the number of children, so inference is much faster.

<sup>4</sup>This corresponds to the case when typological features are not known.

Finally, given the trained parameters we generate parses in the target language by calculating the maximum a posteriori derivation. This is done using a variant of the CKY algorithm.

## 6 Experimental Setup

**Datasets and Evaluation** We test the effectiveness of our approach on 17 languages: Arabic, Basque, Bulgarian, Catalan, Chinese, Czech, Dutch, English, German, Greek, Hungarian, Italian, Japanese, Portuguese, Spanish, Swedish and Turkish. We used datasets distributed for the 2006 and 2007 CoNLL Shared Tasks (Buchholz and Marsi, 2006; Nivre et al., 2007). Each dataset provides manually annotated dependency trees and POS tags. To enable crosslingual sharing, we map the gold part-of-speech tags in each corpus to a common coarse tagset (Zeman and Resnik, 2008; Sjøgaard, 2011; McDonald et al., 2011; Naseem et al., 2010). The coarse tagset consists of 11 tags: noun, verb, adjective, adverb, pronoun, determiner, adposition, numeral, conjunction, particle, punctuation mark, and X (a catch-all tag). Among several available fine-to-coarse mapping schemes, we employ the one of Naseem et al. (2010) that yields consistently better performance for our method and the baselines than the mapping proposed by Petrov et al. (2011).

As the evaluation metric, we use directed dependency accuracy. Following standard evaluation practices, we do not evaluate on punctuation. For both the baselines and our model we evaluate on all sentences of length 50 or less ignoring punctuation.

**Training Regime** Our model typically converges quickly and does not require more than 50 iterations of EM. When the model involves latent typological variables, the initialization of these variables can impact the final performance. As a selection criterion for initialization, we consider the performance of the final model averaged over the supervised source languages. We perform ten random restarts and select the best according to this criterion. Likewise, the threshold value  $b$  for the PR constraint on the dependency length is tuned on the source languages, using average test set accuracy as the selection criterion.

**Baselines** We compare against the state-of-the-art multilingual dependency parsers that do not use parallel corpora for training. All the systems were eval-

uated using the same fine-to-coarse tagset mapping. The first baseline, *Transfer*, uses direct transfer of a discriminative parser trained on all the source languages (McDonald et al., 2011). This simple baseline achieves surprisingly good results, within less than 3% difference from a parser trained using parallel data. In the second baseline (*Mixture*), parameters of the target language are estimated as a weighted mixture of the parameters learned from annotated source languages (Cohen et al., 2011). The underlying parsing model is the dependency model with valance (DMV) (Klein and Manning, 2004). Originally, the baseline methods were evaluated on different sets of languages using a different tag mapping. Therefore, we obtained new results for these methods in our setup. For the *Transfer* baseline, for each target language we trained the model on all other languages in our dataset. For the *Mixture* baseline, we trained the model on the same four languages used in the original paper — English, German, Czech and Italian. When measuring the performance on these languages, we selected another set of four languages with a similar level of diversity.<sup>5</sup>

## 7 Results

Table 2 summarizes the performance for different configurations of our model and the baselines.

**Comparison against Baselines** On average, the selective sharing model outperforms both baselines, yielding 8.9% gain over the weighted mixture model (Cohen et al., 2011) and 5.9% gain over the direct transfer method (McDonald et al., 2011). Our model outperforms the weighted mixture model on 15 of the 17 languages and the transfer method on 12 of the 17 languages. Most of the gains are obtained on non-Indo-European languages, that have little similarity with the source languages. For this set, the average gain over the transfer baseline is 14.4%. With some languages, such as Japanese, achieving gains of as much as 30%.

On Indo-European languages, the model performance is almost equivalent to that of the best performing baseline. To explain this result we con-

<sup>5</sup>We also experimented with a version of the Cohen et al. (2011) model trained on all the source languages. This setup resulted in decreased performance. For this reason, we chose to train the model on the four languages.

sider the performance of the supervised version of our model which constitutes an upper bound on the performance. The average accuracy of our supervised model on these languages is 66.8%, compared to the 76.3% of the unlexicalized MST parser. Since Indo-European languages are overrepresented in our dataset, a target language from this family is likely to exhibit more similarity to the training data. When such similarity is substantial, the transfer baseline will benefit from the power of a context-rich discriminative parser.

A similar trait can be seen by comparing the performance of our model to an oracle version of our model which selects the optimal source language for a given target language (column 7). Overall, our method performs similarly to this oracle variant. However, the gain for non Indo-European languages is 1.9% vs -1.3% for Indo-European languages.

**Analysis of Model Properties** We first test our hypothesis about the universal nature of the dependent selection. We compare the performance of our model (column 6) against a variant (column 8) where this component is trained from annotations on the target language. The performance of the two is very close – 1.8%, supporting the above hypothesis.

To assess the contribution of other layers of selective sharing, we first explore the role of typological features in learning the ordering component. When the model does not have access to observed typological features, and does not use latent ones (column 4), the accuracy drops by 2.6%<sup>6</sup>. For some languages (e.g., Turkish) the decrease is very pronounced. Latent typological features (column 5) do not yield the same gain as observed ones, but they do improve the performance of the typology-free model by 1.4%.

Next, we show the importance of using raw target language data in training the model. When the model has to make all the ordering decisions based on meta-linguistic features without account for unique properties of the target languages, the performance decreases by 0.9% (see column 3).

To assess the relative difficulty of learning the ordering and selection components, we consider model variants where each of these components is

<sup>6</sup>In this setup, the ordering component is trained in an unsupervised fashion on the target language.

Table 2: Directed dependency accuracy of different variants of our selective sharing model and the baselines. The first section of the table (column 1 and 2) shows the accuracy of the weighted mixture baseline (Cohen et al., 2011) (Mixture) and the multi-source transfer baseline (McDonald et al., 2011) (Transfer). The middle section shows the performance of our model in different settings. D± indicates the presence/absence of raw target language data during training. T<sub>o</sub> indicates the use of observed typological features for all languages and T<sub>l</sub> indicates the use of latent typological features for all languages. The last section shows results of our model with different levels of oracle supervision: a. (Best Pair) Model parameters are borrowed from the best source language based on the accuracy on the target language b. (Sup. Sel.) Selection component is trained using MLE estimates from target language c. (Sup. Ord.) Ordering component is trained using MLE estimates from the target language d. (MLE) All model parameters are trained on the target language in a supervised fashion. The horizontal partitions separate language families. The first three families are sub-divisions of the Indo-European language family.

trained using annotations in the target language. As shown in columns 8 and 9, these two variants outperform the original model, achieving 61.3% for supervised selection and 63.7% for supervised ordering. Comparing these numbers to the accuracy of the original model (column 6) demonstrates the difficulty inherent in learning the ordering information. This finding is expected given that ordering involves selective sharing from multiple languages.

Overall, the performance gap between the selective sharing model and its monolingual supervised counterpart is 7.3%. In contrast, the unsupervised monolingual variant of our model achieves a meager 26%.<sup>7</sup> This demonstrates that our model can effectively learn relevant aspects of syntactic structure from a diverse set of languages.

<sup>7</sup>This performance is comparable to other generative models such as DMV (Klein and Manning, 2004).

## 8 Conclusions

We present a novel algorithm for multilingual dependency parsing that uses annotations from a diverse set of source languages to parse a new unannotated language. Overall, our model consistently outperforms the multi-source transfer based dependency parser of McDonald et al. (2011). Our experiments demonstrate that the model is particularly effective in processing languages that exhibit significant differences from the training languages.

# The Creation of a Corpus of English Metalanguage

Shomir Wilson\*

Carnegie Mellon University  
Pittsburgh, PA 15213, USA  
shomir@cs.cmu.edu

## Abstract

Metalanguage is an essential linguistic mechanism which allows us to communicate explicit information about language itself. However, it has been underexamined in research in language technologies, to the detriment of the performance of systems that could exploit it. This paper describes the creation of the first tagged and delineated corpus of English metalanguage, accompanied by an explicit definition and a rubric for identifying the phenomenon in text. This resource will provide a basis for further studies of metalanguage and enable its utilization in language technologies.

## 1 Introduction

In order to understand the language that we speak, we sometimes must refer to the language itself. Language users do this through an understanding of the *use-mention distinction*, as exhibited by the mechanism of *metalanguage*: that is, language that describes language. The use-mention distinction is illustrated simply in Sentences (1) and (2) below:

(1) I watch football on weekends.

(2) Football may refer to one of several sports.

A reader understands that *football* in Sentence (1) refers to a sporting activity, while the same word in Sentence (2) refers to the term *football* itself. Evidence suggests that human communication frequently employs metalanguage (Anderson et al. 2002), and the phenomenon is essential for many activities, including the introduction of new

vocabulary, attribution of statements, explanation of meaning, and assignment of names (Saka 2003). Sentences (3) through (8) below further illustrate the phenomenon, highlighted in bold.

(3) This is sometimes called **tough love**.

(4) I wrote “**meet outside**” on the chalkboard.

(5) **Has** is a conjugation of the verb **have**.

(6) The button labeled **go** was illuminated.

(7) That bus, was its name **61C**?

(8) **Mississippi** is fun to spell.

Recognizing a wide variety of metalinguistic constructions is a skill that humans take for granted in fellow interlocutors (Perlis, Purang & Andersen 1998), and it is a core language skill that children demonstrate at an early age (Clark & Schaefer 1989). Regardless of context, topic, or mode of communication (spoken or written), we are able to refer directly to language, and we expect others to recognize and understand when we do so.

The study of the syntax and semantics of metalanguage is well developed for formal languages. However, the study of the phenomenon in natural language is relatively nascent, and its incorporation into language technologies is almost non-existent. Parsing the distinction is difficult, as shown in Figure 1 below: *go* does not function as a verb in Sentence (6), but it is tagged as such. *Delineating* an instance of metalanguage with quotation marks is a common convention, but this often fails to ameliorate the parsing problem. Quotation marks, italic text, and bold text—three common conventions used to highlight metalanguage—are inconsistently applied and are already “overloaded” with several distinct uses.

Moreover, applications of natural language processing generally lack the ability to recognize and interpret metalanguage (Anderson et al. 2002).

---

\* This research was performed during a prior affiliation with the University of Maryland at College Park.

Systems using sentiment analysis are affected, as sentiment-suggestive terms appearing in metalanguage (especially in quotation, a form of the phenomenon (Maier 2007)) are not necessarily reflective of the writer or speaker. Applications of natural language understanding cannot process metalanguage without detecting it, especially when upstream components (such as parsers) mangle its structure. Interactive systems that could leverage users' expectations of metalanguage competency currently fail to do so. Figure 2 below shows a fragment of conversation with the *Let's Go!* (Raux et al. 2005) spoken dialog system, designed to help users plan trips on Pittsburgh's bus system.

```
(ROOT
  (S
    (NP
      (NP (DT The) (NN button))
      (VP (VBN labeled)
        (S
          (VP (VB go))))))
    (VP (VBD was)
      (VP (VBN illuminated)))
    (. .)))
```

Figure 1. Output of the Stanford Parser (Klein & Manning 2003) for Sentence (6). Adding quotation marks around *go* alters the parser output slightly (not shown), but *go* remains labeled VB.

```
Let's Go!: Where do you wish to depart
from?
User: Arlington.
Let's Go!: Departing from Allegheny
West. Is this right?
User: No, I said "Arlington".
Let's Go!: Please say where you are
leaving from.
```

Figure 2: A conversation with *Let's Go!* in which the user responds to a speech recognition error.

The exchange shown in Figure 2 is representative of the reactions of nearly all dialog systems: in spite of the domain generality of metalanguage and the user's expectation of its availability, the system does not recognize it and instead "talks past" the user. In effect, language technologies that ignore metalanguage are discarding the most direct source of linguistic information that text or utterances can provide.

This paper describes the first substantial study to characterize and gather instances of English metalanguage. Section 2 presents a definition and a rubric for metalanguage in the form of *mentioned language*. Section 3 describes the procedure used to create the corpus and some notable properties of its contents, and Section 4 discusses insights gained into the phenomenon. The remaining sections discuss the context of these results and future directions for this research.

## 2 Metalanguage and the Use-Mention Distinction<sup>1</sup>

Although the reader is likely to be familiar with the terms *use-mention distinction* and *metalanguage*, the topic merits further explanation to precisely establish the phenomenon being studied. Intuitively, the vast majority of utterances are produced for use rather than mention, as the roles of language-mention are auxiliary (albeit indispensable) to language use. This paper will adopt the term *mentioned language* to describe the literal, delineable phenomenon illustrated in examples thus far. Other forms of metalanguage occur through deictic references to linguistic entities that do not appear in the relevant statement. (For example, consider "That word was misspelled" where the referred-to word resides outside of the sentence.) For technical tractability, this study focuses on mentioned language.

### 2.1 Definition

Although the use-mention distinction has enjoyed a long history of theoretical discussion, attempts to explicitly define one or both of the distinction's disjuncts are difficult (or impossible) to find. Below is the definition of mentioned language adopted by this study, followed by clarifications.

*Definition: For T a token or a set of tokens in a sentence, if T is produced to draw attention to a property of the token T or the type of T, then T is an instance of mentioned language.*

Here, a *token* is the specific, situated (i.e., as appearing in the sentence) instantiation of a linguistic entity: a letter, symbol, sound, word, phrase, or another related entity. A *property* might

<sup>1</sup> The definition and rubric in this section were originally introduced by Wilson (2011a). For brevity, their full justifications and the argument for equivalence between the two are not reproduced here.

be a token's spelling, pronunciation, meaning (for a variety of interpretations of *meaning*), structure, connotation, original source (in cases of quotation), or another aspect for which language is shown or demonstrated. The *type* of T is relevant in most instances of mentioned language, but the *token* itself is relevant in others, as in the sentence below:

(9) "The" appears between quote marks here.

Constructions like (9) are unusual and are of limited practical value, but the definition accommodates them for completeness.

The adoption of this definition was motivated by a desire to study mentioned language with precise, repeatable results. However, it was too abstract to consistently apply to large quantities of candidate phrases in sentences, a necessity for corpus creation. A brief attempt to train annotators using the definition was unsuccessful, and instead a rubric was created for this purpose.

## 2.2 Annotation Rubric

A human reader with some knowledge of the use-mention distinction can often intuit the presence of mentioned language in a sentence. However, to operationalize the concept and move toward corpus construction, it was necessary to create a rubric for labeling it. The rubric is based on substitution, and it may be applied, with caveats described below, to determine whether a linguistic entity is mentioned by the sentence in which it occurs.

*Rubric: Suppose X is a linguistic entity in a sentence S. Construct sentence S' as follows: replace X in S with a phrase X' of the form "that [item]", where [item] is the appropriate term for X in the context of S (e.g., "letter", "symbol", "word", "name", "phrase", "sentence", etc.). X is an instance of mentioned language if, when assuming that X' refers to X, the meaning of S' is equivalent to the meaning of S.*

To further operationalize the rubric, Figure 3 shows it rewritten in pseudocode form. To verify the rubric, the reader can follow a positive example and a negative example in Figure 4.

To maintain coherency, minor adjustments in sentence wording will be necessary for some candidate phrases. For instance, Sentence (10) below must be rewritten as (11):

(10) The word *cat* is spelled with three letters.

(11) *Cat* is spelled with three letters.

This is because S' for (10) and (11) are respectively (12) and (13):

(12) The word that word is spelled with three letters.

(13) That word is spelled with three letters.

```

Given S a sentence and X a copy of a
linguistic entity in S:
(1) Create X': the phrase "that [item]",
    where [item] is the appropriate term
    for linguistic entity X in the
    context of S.
(2) Create S': copy S and replace the
    occurrence of X with X'.
(3) Create W: the set of truth
    conditions of S.
(4) Create W': the set of truth
    conditions of S', assuming that X'
    in S' is understood to refer
    deictically to X.
(5) Compare W and W'. If they are equal,
    X is mentioned language in S. Else,
    X is not mentioned language in S.

```

Figure 3: Pseudocode equivalent of the rubric.

```

Positive Example
S: Spain is the name of a European
country.
X: Spain.
(1) X': that name
(2) S': That name is the name of a
European country.
(3) W: Stated briefly, Spain is the name
of a European country.
(4) W': Stated briefly, Spain is the
name of a European country.
(5) W and W' are equal. Spain is
mentioned language in S.

Negative Example
S: Spain is a European country.
X: Spain.
(1) X': that name
(2) S': That name is a European country.
(3) W: Stated briefly, Spain is a
European country.
(4) W': Stated briefly, the name Spain
is a European country.
(5) W and W' are not equal. Spain is not
mentioned language in S.

```

Figure 4: Examples of rubric application using the pseudocode in Figure 3.

Also, quotation marks around or inside of a candidate phrase require special attention, since their inclusion or exclusion in X can alter the meaning of S'. For this discussion, quotation marks

and other stylistic cues are considered informal cues which aid a reader in detecting mentioned language. Style conventions may call for them, and in some cases they might be strictly necessary, but a competent language user possesses sufficient skill to properly discard or retain them as each instance requires (Saka 1998).

### 3 The Mentioned Language Corpus

“Laboratory examples” of mentioned language (such as the examples thus far in this paper) only begin to illustrate the variation in the phenomenon. To conduct an empirical examination of mentioned language and to study the feasibility of automatic identification, it was necessary to gather a large, diverse set of samples. This section describes the process of building a series of three progressively more sophisticated corpora of mentioned language. The first two were previously constructed by Wilson (2010; 2011b) and will be described only briefly. The third was built with insights from the first two, and it will be described in greater detail. This third corpus is the first to *delineate* mentioned language: that is, it identifies precise subsequences of words in a sentence that are subject to the phenomenon. Doing so will enable analysis of the syntax and semantics of English metalanguage.

#### 3.1 Approach

The article set of *English Wikipedia*<sup>2</sup> was chosen as a source for text, from which instances were mined using a combination of automated and manual efforts. Four factors led to its selection:

- 1) *Wikipedia is collaboratively written*. Since any registered user can contribute to articles, Wikipedia reflects the language habits of a large sample of English writers (Adler et al. 2008).
- 2) *Stylistic cues that sometimes delimit mentioned language are present in article text*. Contributors tend to use quote marks, italic text, or bold text to delimit mentioned language<sup>3</sup>, thus following conventions respected across many domains of writing (Strunk & White 1979; Chicago Editorial Staff 2010; American Psychological Association. 2001). Discussion

<sup>2</sup> Described in detail at

[http://en.wikipedia.org/wiki/English\\_Wikipedia](http://en.wikipedia.org/wiki/English_Wikipedia).

<sup>3</sup> These conventions are stated in Wikipedia’s style manual, though it is unclear whether most contributors read the manual or follow the conventions out of habit.

boards and other sources of informal language were considered, but the lack of consistent (or any) stylistic cues would have made candidate phrase collection untenably time-consuming.

- 3) *Articles are written to introduce a wide variety of concepts to the reader*. Articles are written informatively and they generally assume the reader is unfamiliar with their topics, leading to frequent instances of mentioned language.
- 4) *Wikipedia is freely available*. Various language learning materials were also considered, but legal and technical obstacles made them unsuitable for creating a freely available corpus.

To construct each of the three corpora, a general procedure was followed. First, a set of current article revisions was downloaded from Wikipedia. Then, the main bodies of article text (excluding discussion pages, image captions, and other peripheral text) were scanned for sentences that contained instances of highlighted text (i.e., text inside of the previously mentioned stylistic cues). Since stylistic cues are also used for other language tasks, candidate instances were heuristically filtered and then annotated by human readers.

#### 3.2 Previous Efforts

In previous work, a pilot corpus was constructed to verify the fertility of Wikipedia as a source for mentioned language. From 1,000 articles, 1,339 sentences that contained stylistic cues were examined by a human reader, and 171 were found to contain at least one instance of mentioned language. Although this effort verified Wikipedia’s viability for the project, it also revealed that the hand-labeling procedure was time-consuming, and prior heuristic filtering would be necessary.

Next, the “Combined Cues” corpus was constructed to test the combination of stylistic filtering and a new lexical filter for selecting candidate instances. A set of 23 “mention-significant” words was gathered informally from the pilot corpus, consisting of nouns and verbs:

*Nouns: letter, meaning, name, phrase, pronunciation, sentence, sound, symbol, term, title, word*

*Verbs: ask, call, hear, mean, name, pronounce, refer, say, tell, title, translate, write*

Instances of highlighted text were only promoted to the hand annotation stage if they contained at least one of these words within the three-word phrase directly preceding the

highlighted text. From 3,831 articles, a set of 898 sentences were found to contain 1,164 candidate instances that passed the combination of stylistic and lexical filters. Hand annotation of those candidates yielded 1,082 instances of mentioned language. Although the goal of the filters was only to ease hand annotation, it could be stated that the filters had almost 93% precision in detecting the phenomenon. It did not seem plausible that the set of mention-significant words was complete enough to justify that high percentage, and concerns were raised that the lexical filter was rejecting many instances of mentioned language.

### 3.3 The “Enhanced Cues” Corpus

The construction of the present corpus (referred to as the “Enhanced Cues” Corpus) was similar to previous efforts but used a much-enlarged set of mention-significant nouns and verbs gathered from the *WordNet* (Fellbaum 1998) lexical ontology. For each of the 23 original mention-significant words, a human reader started with its containing synset and followed hypernym links until a synset was reached that did not refer to a linguistic entity. Then, backtracking one synset, all lemmas of all descendants of the most general linguistically-relevant synset were gathered. Figure 5 illustrates this procedure with an example.

Figure 5: Gathering mention-significant words from WordNet using the seed noun “term”. Here, “Language unit”, “word”, “syllable”, “anagram”, and all their descendants are gathered.

Using the combination of stylistic and lexical cues, 2,393 candidate instances were collected, and the researcher used the rubric and definition from Section 2 to identify 629 instances of mentioned language<sup>4</sup>. The researcher also identified four categories of mentioned language based on the nature of the substitution phrase X’ specified by the rubric. These categories will be discussed in the following subsection. Figure 6 summarizes this procedure and the numeric outcomes.

Figure 6: The procedure used to create the Enhanced Cues Corpus.

### 3.4 Corpus Composition

As stated previously, categories for mentioned language were identified based on intuitive relationships among the substitution phrases created for the rubric (e.g., “that word”, “that title”, “that symbol”). The categories are:

- 1) *Words as Words (WW)*: Within the context of the sentence, the candidate phrase is used to refer to the word or phrase itself and not what it usually refers to.

<sup>4</sup> This corpus is available at [http://www.cs.cmu.edu/~shomir/um\\_corpus.html](http://www.cs.cmu.edu/~shomir/um_corpus.html).

- 2) *Names as Names (NN)*: The sentence directly refers to the candidate phrase as a proper name, nickname, or title.
- 3) *Spelling or Pronunciation (SP)*: The candidate text appears only to illustrate spelling, pronunciation, or a character symbol.
- 4) *Other Mention/Interesting (OM)*: The candidate phrase is an instance of mentioned language that does not fit the above three categories.
- 5) *Not Mention (XX)*: The candidate phrase is not mentioned language.

Table 1 presents the frequencies of each category in the Enhanced Cues corpus, and Table 2 provides examples for each from the corpus. WW was by far the most common label to appear, which is perhaps an artifact of the use of Wikipedia as the text source. Although Wikipedia articles contain many names, NN was not as common, and informal observations suggested that names and titles are not as frequently introduced via metalanguage. Instead, their referents are introduced directly by the first appearance of the referring text. Spelling and pronunciation were particularly sparse; again, a different source might have yielded more examples for this category. The OM category was occupied mostly by instances of speech or language production by an agent, as illustrated by the two OM examples in Table 2.

Category	Code	Frequency
Words as Words	WW	438
Names as Names	NN	117
Spelling or Pronunciation	SP	48
Other Mention/Interesting	OM	26
Not Mention	XX	1,764

Table 1: The by-category composition of candidate instances in the Enhanced Cues corpus.

In the interest of revealing both lexical and syntactic cues for mentioned language, part-of-speech tags were computed (using NLTK (Loper & Bird 2002)) for words in all of the sentences containing candidate instances. Tables 3 and 4 list the ten most common words (as POS-tagged) in the three-word phrases before and after (respectively) candidate instances. Although the heuristics for collecting candidate instances were not intended to function as a classifier, figures for precision are shown for each word: these represent

the percentage of occurrences of the word which were associated with candidates identified as mentioned language. For example, 80% of appearances of the verb *call* preceded a candidate instance that was labeled as mentioned language.

Code	Example
WW	The IP Multimedia Subsystem architecture uses the term <u>transport plane</u> to describe a function roughly equivalent to the routing control plane.
NN	<u>Digeri</u> is the name of a Thracian tribe mentioned by Pliny the Elder, in The Natural History. Hazrat Syed Jalaluddin Bukhari's descendants are also called <u>Naqvi al-Bukhari</u> .
SP	The French changed the spelling to <u>bataillon</u> , whereupon it directly entered into German. Welles insisted on pronouncing the word apostles with a hard <u>t</u> .
OM	He kneels over Fil, and seeing that his <u>eyes are open whispers: brother</u> . During Christmas 1941, she typed <u>The end on the last page of Laura</u> .
XX	<u>NCR</u> was the first U.S. publication to write about the clergy sex abuse scandal. Many Croats reacted by <u>expelling</u> all words in the Croatian language that had, in their minds, even distant Serbian origin.

Table 2: Two examples from the corpus for each category. Candidate phrases appear underlined, with the original stylistic cues removed.

Many of these words appeared as mention words for the Combined Cues corpus, indicating that prior intuitions about framing metalanguage were correct. In particular, *call* (*v*), *word*(*n*), and *term* (*n*) were exceptionally frequent and effective at associating with mentioned language. In contrast, the distribution of frequencies for the words *following* candidate instances exhibited a “long tail”, indicating greater variation in vocabulary.

Rank	Word	Freq.	Precision (%)
1	call (v)	92	80
2	word (n)	68	95.8
3	term (n)	60	95.2
4	name (n)	31	67.4
5	use (v)	17	70.8
6	know (v)	15	88.2
7	also (rb)	13	59.1
8	name (v)	11	100
9	sometimes (rb)	9	81.9
10	Latin (n)	9	69.2

Table 3: The top ten words appearing in the three-word sequences *before* candidate instances, with precisions of association with mentioned language.

Rank	Word	Freq.	Precision (%)
1	mean (v)	31	83.4
2	name (n)	24	63.2
3	use (v)	11	55
4	meaning (n)	8	57.1
5	derive (v)	8	80
6	refers (n)	7	87.5
7	describe (v)	6	60
8	refer (v)	6	54.5
9	word (n)	6	50
10	may (md)	5	62.5

Table 4: The top ten words appearing in the three-word sequences *after* candidate instances, with precisions of association with mentioned language.

### 3.5 Reliability and Consistency of Annotation

To provide some indication of the reliability and consistency of the Enhanced Cues Corpus, three additional expert annotators were recruited to label a subset of the candidate instances. These additional annotators received guidelines for annotation that included the five categories, and they worked separately (from each other and from the primary annotator) to label 100 instances selected randomly with quotas for each category.

Calculations first were performed to determine the level of agreement on the mere presence of mentioned language, by mapping labels WW, NN, SP, and OM to *true* and XX to *false*. All four annotators agreed upon a *true* label for 46 instances and a *false* label for 30 instances, with an average pairwise Kappa (computed via NTLK) of 0.74. Kappa between the primary annotator and a

hypothetical “majority voter” of the three additional annotators was 0.90. These results were taken as moderate indication of the reliability of “simple” use-mention labeling.

However, the per-category results showed reduced levels of agreement. Kappa was calculated to be 0.61 for the original coding. Table 5 shows the Kappa statistic for binary re-mapping for each of the categories. This was done similarly to the “XX versus all others” procedure described above.

Code	Frequency	K
WW	17	0.38
NN	17	0.72
SP	16	0.66
OM	4	0.09
XX	46	0.74

Table 5: Frequencies of each category in the subset labeled by additional annotators and the values of the Kappa statistic for binary relabelings.

The low value for remapped OM was expected, since the category was small and intentionally not well-defined. The relatively low value for WW was not expected, though it seems possible that the redaction of specific stylistic cues made annotators less certain when to apply this category. Overall, these numbers suggest that, although annotators tend to agree whether a candidate instance is mentioned language or not, there is less of a consensus on how to qualify positive instances.

## 4 Discussion

The Enhanced Cues corpus confirms some of the hypothesized properties of metalanguage and yields some unexpected insights. Stylistic cues appear to be strongly associated with mentioned language; although the examination of candidate phrases was limited to “highlighted” text, informal perusal of the remainder of article text confirmed this association. Further evidence can be seen in examples from other texts, shown below with their original stylistic cues intact:

- Like so many words, the meaning of “addiction” has varied wildly over time, but the trajectory might surprise you.<sup>5</sup>

<sup>5</sup> News article from CNN.com:  
<http://www.cnn.com/2011/LIVING/03/23/addicted.to.addiction/index.html>

- Sending a signal in this way is called a **speech act**.<sup>6</sup>
- M1 and M2 are Slashdot shorthand for “moderation” and “metamoderation,” respectively.<sup>7</sup>
- He could explain foreordination thoroughly, and he used the terms “baptize” and “Athanasian.”<sup>8</sup>
- They use *Kabuki* precisely because they and everyone else have only a hazy idea of the word’s true meaning, and they can use it purely on the level of insinuation.<sup>9</sup>

However, the connection between mentioned language and stylistic cues is only valuable when stylistic cues are available. Still, even in their absence there appears to be an association between mentioned language and a core set of nouns and verbs. Recurring patterns were observed in how mention-significant words related to mentioned language. Two were particularly common:

- *Noun apposition between a mention-significant noun and mentioned language.* An example of this appears in Sentence (5), consisting of the noun *verb* and the mentioned word *have*.
- *Mentioned language appearing in appropriate semantic roles for mention-significant verbs.* Sentence (3) illustrates this, with the verb *call* assigning the label *tough love* as an attribute of the sentence subject.

With further study, it should be possible to exploit these relationships to automatically detect mentioned language in text.

## 5 Related Work

The use-mention distinction has enjoyed a long history of chiefly theoretical discussion. Beyond those authors already cited, many others have addressed it as the formal topic of *quotation* (Davidson 1979; Cappelen & Lepore 1997; García-Carpintero 2004; Partee 1973; Quine 1940; Tarski 1933). Nearly all of these studies have eschewed empirical treatments, instead hand-picking illustrations of the phenomenon.

<sup>6</sup> Page 684 of Russell and Norvig’s 1995 edition of *Artificial Intelligence*, a textbook.

<sup>7</sup> Frequently Asked Questions (FAQ) list on Slashdot.org: <http://slashdot.org/faq/metamod.shtml>

<sup>8</sup> Novel *Elmer Gantry* by Sinclair Lewis.

<sup>9</sup> Opinion column on Slate.com: <http://www.slate.com/id/2250081/>

One notable exception was a study by Anderson et al. (2004), who created a corpus of metalanguage from a subset of the British National Corpus, finding that approximately 11% of spoken utterances contained some form (whether explicit or implicit) of metalanguage. However, limitations in the Anderson corpus’ structure (particularly lack of word- or phrase-level annotations) and content (the authors admit it is noisy) served as compelling reasons to start afresh and create a richer resource.

## 6 Future Work

As explained in the introduction, the long-term goal of this research program is to apply an understanding of metalanguage to enhance language technologies. However, the more immediate goal for creating this corpus was to enable (and to begin) progress in research on metalanguage. Between these long-term and immediate goals lies an intermediate step: methods must be developed to detect and delineate metalanguage automatically.

Using the Enhanced Cues Corpus, a two-stage approach to automatic identification of mentioned language is being developed. The first stage is *detection*, the determination of whether a sentence contains an instance of mentioned language. Preliminary results indicate that approximately 70% of instances can be detected using simple machine learning methods (e.g., bag of words input to a decision tree). The remaining instances will require more advanced methods to detect, such as word sense disambiguation to validate occurrences of mention-significant words. The second stage is *delineation*, the determination of the subsequence of words in a sentence that functions as mentioned language. Early efforts have focused on the associations discussed in Section 5 between mentioned language and mention-significant words. The total number of such associations appears to be small, making their collection a tractable activity.

## Acknowledgements

# Crosslingual Induction of Semantic Roles

Ivan Titov      Alexandre Klementiev

Saarland University

Saarbrücken, Germany

{titov|aklement}@mmci.uni-saarland.de

## Abstract

We argue that multilingual parallel data provides a valuable source of indirect supervision for induction of shallow semantic representations. Specifically, we consider unsupervised induction of semantic roles from sentences annotated with automatically-predicted syntactic dependency representations and use a state-of-the-art generative Bayesian non-parametric model. At inference time, instead of only seeking the model which explains the monolingual data available for each language, we regularize the objective by introducing a soft constraint penalizing for disagreement in argument labeling on aligned sentences. We propose a simple approximate learning algorithm for our set-up which results in efficient inference. When applied to German-English parallel data, our method obtains a substantial improvement over a model trained without using the agreement signal, when both are tested on non-parallel sentences.

## 1 Introduction

Learning in the context of multiple languages simultaneously has been shown to be beneficial to a number of NLP tasks from morphological analysis to syntactic parsing (Kuhn, 2004; Snyder and Barzilay, 2010; McDonald et al., 2011). The goal of this work is to show that parallel data is useful in unsupervised induction of shallow semantic representations.

Semantic role labeling (SRL) (Gildea and Jurafsky, 2002) involves predicting predicate argument structure, i.e. both the identification of arguments

and their assignment to underlying semantic roles. For example, in the following sentences:

- (a) [<sub>A0</sub>Peter] blamed [<sub>A1</sub>Mary] [<sub>A2</sub>for planning a theft].
- (b) [<sub>A0</sub>Peter] blamed [<sub>A2</sub>planning a theft] [<sub>A1</sub>on Mary].
- (c) [<sub>A1</sub>Mary] was blamed [<sub>A2</sub>for planning a theft] [<sub>A0</sub>by Peter]

the arguments ‘*Peter*’, ‘*Mary*’, and ‘*planning a theft*’ of the predicate ‘*blame*’ take the agent (*A0*), patient (*A1*) and reason (*A2*) roles, respectively. In this work, we focus on predicting argument roles.

SRL representations have many potential applications in NLP and have recently been shown to benefit question answering (Shen and Lapata, 2007; Kaisser and Webber, 2007), textual entailment (Sammons et al., 2009), machine translation (Wu and Fung, 2009; Liu and Gildea, 2010; Wu et al., 2011; Gao and Vogel, 2011), and dialogue systems (Basili et al., 2009; van der Plas et al., 2011), among others. Though syntactic representations are often predictive of semantic roles (Levin, 1993), the interface between syntactic and semantic representations is far from trivial. Lack of simple deterministic rules for mapping syntax to shallow semantics motivates the use of statistical methods.

Most of the current statistical approaches to SRL are supervised, requiring large quantities of human annotated data to estimate model parameters. However, such resources are expensive to create and only available for a small number of languages and domains. Moreover, when moved to a new domain, performance of these models tends to degrade substantially (Pradhan et al., 2008). Sparsity of annotated data motivates the need to look to alternative

resources. In this work, we make use of unsupervised data along with parallel texts and learn to induce semantic structures in two languages simultaneously. As does most of the recent work on unsupervised SRL, we assume that our data is annotated with automatically-predicted syntactic dependency parses and aim to induce a model of linking between syntax and semantics in an unsupervised way.

We expect that both linguistic relatedness and variability can serve to improve semantic parses in individual languages: while the former can provide additional evidence, the latter can serve to reduce uncertainty in ambiguous cases. For example, in our sentences (a) and (b) representing so-called *blame* alternation (Levin, 1993), the same information is conveyed in two different ways and a successful model of semantic role labeling needs to learn the corresponding linkings from the data. Inducing them solely based on monolingual data, though possible, may be tricky as selectional preferences of the roles are not particularly restrictive; similar restrictions for patient and agent roles may further complicate the process. However, both sentences (a) and (b) are likely to be translated in German as ‘ $[_{A_0}Peter]$  *beschuldigte*  $[_{A_1}Mary]$   $[_{A_2}einen Diebstahl zu planen]$ ’. Maximizing agreement between the roles predicted for both languages would provide a strong signal for inducing the proper linkings in our examples.

In this work, we begin with a state-of-the-art monolingual unsupervised Bayesian model (Titov and Klementiev, 2012) and focus on improving its performance in the crosslingual setting. It induces a linking between syntax and semantics, encoded as a clustering of syntactic signatures of predicate arguments. The clustering implicitly defines the set of permissible alternations. For predicates present in both sides of a bitext, we guide models in both languages to prefer clusterings which maximize agreement between predicate argument structures predicted for each aligned predicate pair. We experimentally show the effectiveness of the crosslingual learning on the English-German language pair.

Our model admits efficient inference: the estimation time on CoNLL 2009 data (Hajič et al., 2009) and Europarl v.6 bitext (Koehn, 2005) does not exceed 5 hours on a single processor and the inference algorithm is highly parallelizable, reducing in-

ference time down to less than half an hour on multiple processors. This suggests that the models scale to much larger corpora, which is an important property for a successful unsupervised learning method, as unlabeled data is abundant.

In summary, our contributions are as follows.

- This work is the first to consider the crosslingual setting for unsupervised SRL.
- We propose a form of agreement penalty and show its efficacy on English-German language pair when used in conjunction with a state-of-the-art non-parametric Bayesian model.
- We demonstrate that efficient approximate inference is feasible in the multilingual setting.

The rest of the paper is organized as follows. Section 2 begins with a definition of the crosslingual semantic role induction task we address in this paper. In Section 3, we describe the base monolingual model, and in Section 4 we propose an extension for the crosslingual setting. In Section 5, we describe our inference procedure. Section 6 provides both evaluation and analysis. Finally, additional related work is presented in Section 7.

## 2 Problem Definition

As we mentioned in the introduction, in this work we focus on the labeling stage of semantic role labeling. Identification, though an important problem, can be tackled with heuristics (Lang and Lapata, 2011a; Grenager and Manning, 2006; de Marneffe et al., 2006) or potentially by using a supervised classifier trained on a small amount of data.

Instead of assuming the availability of role annotated data, we rely only on automatically generated syntactic dependency graphs in both languages. While we cannot expect that syntactic structure can trivially map to a semantic representation<sup>1</sup>, we can make use of syntactic cues. In the labeling stage, semantic roles are represented by clusters of arguments, and labeling a particular argument corresponds to deciding on its role cluster. However, instead of dealing with argument occurrences directly,

<sup>1</sup>Although it provides a strong baseline which is difficult to beat (Grenager and Manning, 2006; Lang and Lapata, 2010; Lang and Lapata, 2011a).

we represent them as predicate-specific syntactic signatures, and refer to them as *argument keys*. This representation aids our models in inducing high purity clusters (of argument keys) while reducing their granularity. We follow (Lang and Lapata, 2011a) and use the following syntactic features for English to form the argument key representation:

- Active or passive verb voice (ACT/PASS).
- Arg. position relative to predicate (LEFT/RIGHT).
- Syntactic relation to its governor.
- Preposition used for argument realization.

In the example sentences in Section 1, the argument keys for candidate arguments *Peter* for sentences (a) and (c) would be ACT:LEFT:SBJ and PASS:RIGHT:LGS->by,<sup>2</sup> respectively. While aiming to increase the purity of argument key clusters, this particular representation will not always produce a good match: e.g. *planning a theft* in sentence (b) will have the same key as *Mary* in sentence (a). Increasing the expressiveness of the argument key representation by using features of the syntactic frame would enable us to distinguish that pair of arguments. However, we keep this particular representation, in part to compare with the previous work. In German, we do not include the relative position features, because they are not very informative due to variability in word order.

In sum, we treat the unsupervised semantic role labeling task as clustering of argument keys. Thus, argument occurrences in the corpus whose keys are clustered together are assigned the same semantic role. The objective of this work is to improve argument key clusterings by inducing them simultaneously in two languages.

### 3 Monolingual Model

In this section we describe one of the Bayesian models for semantic role induction proposed in (Titov and Klementiev, 2012). Before describing our method, we briefly introduce the central components of the model: the Chinese Restaurant Processes (CRPs) and Dirichlet Processes (DPs) (Ferguson, 1973; Pitman, 2002). For more details we refer the reader to (Teh, 2007).

<sup>2</sup>LGS denotes a logical subject in a passive construction (Surdeanu et al., 2008).

### 3.1 Chinese Restaurant Processes

CRPs define probability distributions over partitions of a set of objects. An intuitive metaphor for describing CRPs is assignment of tables to restaurant customers. Assume a restaurant with a sequence of tables, and customers who walk into the restaurant one at a time and choose a table to join. The first customer to enter is assigned the first table. Suppose that when a client number  $i$  enters the restaurant,  $i - 1$  customers are sitting at each of the  $k \in (1, \dots, K)$  tables occupied so far. The new customer is then either seated at one of the  $K$  tables with probability  $\frac{N_k}{i-1+\alpha}$ , where  $N_k$  is the number of customers already sitting at table  $k$ , or assigned to a new table with the probability  $\frac{\alpha}{i-1+\alpha}$ ,  $\alpha > 0$ .

If we continue and assume that for each table every customer at a table orders the same meal, with the meal for the table chosen from an arbitrary base distribution  $H$ , then all ordered meals will constitute a sample from the Dirichlet Process  $DP(\alpha, H)$ .

An important property of the non-parametric processes is that a model designer does not need to specify the number of tables (i.e. clusters) a-priori as it is induced automatically on the basis of the data and also depending on the choice of the concentration parameter  $\alpha$ . This property is crucial for our task, as the intended number of roles cannot possibly be specified for every predicate.

### 3.2 The Generative Story

In Section 2 we defined our task as clustering of argument keys, where each cluster corresponds to a semantic role. If an argument key  $k$  is assigned to a role  $r$  ( $k \in r$ ), all of its occurrences are labeled  $r$ .

The Bayesian model encodes two common assumptions about semantic roles. First, it enforces the selectional restriction assumption: namely it stipulates that the distribution over potential argument fillers is sparse for every role, implying that ‘peaky’ distributions of arguments for each role  $r$  are preferred to flat distributions. Second, each role normally appears at most once per predicate occurrence. The inference algorithm will search for a clustering which meets the above requirements to the maximal extent.

The model associates two distributions with each predicate: one governs the selection of argument

fillers for each semantic role, and the other models (and penalizes) duplicate occurrence of roles. Each predicate occurrence is generated independently given these distributions. Let us describe the model by first defining how the set of model parameters and an argument key clustering are drawn, and then explaining the generation of individual predicate and argument instances. The generative story is formally presented in Figure 1.

For each predicate  $p$ , we start by generating a partition of argument keys  $B_p$  with each subset  $r \in B_p$  representing a single semantic role. The partitions are drawn from  $CRP(\alpha)$  independently for each predicate. The crucial part of the model is the set of selectional preference parameters  $\theta_{p,r}$ , the distributions of arguments  $x$  for each role  $r$  of predicate  $p$ . We represent arguments by lemmas of their syntactic heads.<sup>3</sup>

The preference for sparseness of the distributions  $\theta_{p,r}$  is encoded by drawing them from the DP prior  $DP(\beta, H^{(A)})$  with a small concentration parameter  $\beta$ , the base probability distribution  $H^{(A)}$  is just the normalized frequencies of arguments in the corpus. The geometric distribution  $\psi_{p,r}$  is used to model the number of times a role  $r$  appears with a given predicate occurrence. The decision whether to generate at least one role  $r$  is drawn from the uniform Bernoulli distribution. If 0 is drawn then the semantic role is not realized for the given occurrence, otherwise the number of additional roles  $r$  is drawn from the geometric distribution  $Geom(\psi_{p,r})$ . The Beta priors over  $\psi$  can indicate the preference towards generating at most one argument for each role.

Now, when parameters and argument key clusterings are chosen, we can summarize the remainder of the generative story as follows. We begin by independently drawing occurrences for each predicate. For each predicate role we independently decide on the number of role occurrences. Then each of the arguments is generated (see **GenArgument**) by choosing an argument key  $k_{p,r}$  uniformly from the set of argument keys assigned to the cluster  $r$ , and finally choosing its filler  $x_{p,r}$ , where the filler is the lemma of the syntactic head of the argument.

<sup>3</sup>For prepositional phrases, the head noun of the object noun phrase is taken as it encodes crucial lexical information. However, the preposition is not ignored but rather encoded in the corresponding argument key, as explained in Section 2.

Clustering of argument keys:	
for each predicate $p = 1, 2, \dots$ :	
$B_p \sim CRP(\alpha)$	[partition of arg keys]
Parameters:	
for each predicate $p = 1, 2, \dots$ :	
for each role $r \in B_p$ :	
$\theta_{p,r} \sim DP(\beta, H^{(A)})$	[distrib of arg fillers]
$\psi_{p,r} \sim Beta(\eta_0, \eta_1)$	[geom distr for dup roles]
Data generation:	
for each predicate $p = 1, 2, \dots$ :	
for each occurrence $s$ of $p$ :	
for every role $r \in B_p$ :	
if $[n \sim Unif(0, 1)] = 1$ :	[role appears at least once]
<b>GenArgument</b> ( $p, r$ )	[draw one arg]
while $[n \sim \psi_{p,r}] = 1$ :	[continue generation]
<b>GenArgument</b> ( $p, r$ )	[draw more args]
<b>GenArgument</b> ( $p, r$ ):	
$k_{p,r} \sim Unif(1, \dots,  r )$	[draw arg key]
$x_{p,r} \sim \theta_{p,r}$	[draw arg filler]

Figure 1: The generative story for predicate-argument structure.

## 4 Multilingual Extension

As we argued in Section 1, our goal is to penalize for disagreement in semantic structures predicted for each language on parallel data. In doing so, as in much of previous work on unsupervised induction of linguistic structures, we rely on automatically produced word alignments. In Section 6, we describe how we use word alignment to decide if two arguments are aligned; for now, we assume that (noisy) argument alignments are given.

Intuitively, when two arguments are aligned in parallel data, we expect them to be labeled with the same semantic role in both languages. This correspondence is simpler than the one expected in multilingual induction of syntax and morphology where systematic but unknown relation between structures in two language is normally assumed (e.g., (Snyder et al., 2008)). A straightforward implementation of this idea would require us to maintain one-to-one mapping between semantic roles across languages. Instead of assuming this correspondence, we penalize for the lack of isomorphism between the sets of roles in aligned predicates with the penalty dependent on the degree of violation. This softer approach

is more appropriate in our setting, as individual argument keys do not always deterministically map to gold standard roles<sup>4</sup> and strict penalization would result in the propagation of the corresponding over-coarse clusters to the other language. Empirically, we observed this phenomenon on the held-out set with the increase of the penalty weight.

Encoding preference for the isomorphism directly in the generative story is problematic: sparse Dirichlet priors can be used in a fairly trivial way to encode sparsity of the mapping in one direction or another but not in both. Instead, we formalize this preference with a penalty term similar to the expectation criteria in KL-divergence form introduced in McCallum et al. (2007). Specifically, we augment the joint probability with a penalty term computed on parallel data:

$$\sum_{p^{(1)}, p^{(2)}} \left( -\gamma^{(1)} \sum_{r^{(1)} \in B_{p^{(1)}}} f_{r^{(1)}} \arg \max_{r^{(2)} \in B_{p^{(2)}}} \log \hat{P}(r^{(2)} | r^{(1)}) - \gamma^{(2)} \sum_{r^{(2)} \in B_{p^{(2)}}} f_{r^{(2)}} \arg \max_{r^{(1)} \in B_{p^{(1)}}} \log \hat{P}(r^{(1)} | r^{(2)}) \right),$$

where  $\hat{P}(r^{(l)} | r^{(l')})$  is the proportion of times the role  $r^{(l')}$  of predicate  $p^{(l')}$  in language  $l'$  is aligned to the role  $r^{(l)}$  of predicate  $p^{(l)}$  in language  $l$ , and  $f_{r^{(l)}}$  is the total number of times the role is aligned,  $\gamma^{(l)}$  is a non-negative constant. The rationale for introducing the individual weighting  $f_{r^{(l)}}$  is two-fold. First, the proportions  $\hat{P}(r^{(l)} | r^{(l')})$  are more ‘reliable’ when computed from larger counts. Second, more frequent roles should have higher penalty as they compete with the joint probability term, the likelihood part of which scales linearly with role counts.

Space restrictions prevent us from discussing the close relation between this penalty formulation and the existing work on injecting prior and side information in learning objectives in the form of constraints (McCallum et al., 2007; Ganchev et al., 2010; Chang et al., 2007).

In order to support efficient and parallelizable inference, we simplify the above penalty by considering only disjoint pairs of predicates, instead of summing over all pairs  $p^{(1)}$  and  $p^{(2)}$ . When choosing

<sup>4</sup>The average purity for argument keys with automatic argument identification and using predicted syntactic trees, before any clustering, is approximately 90.2% on English and 87.8% on German.

the pairs, we aim to cover the maximal number of alignment counts so as to preserve as much information from parallel corpora as possible. This objective corresponds to the classic maximum weighted bipartite matching problem with the weight for each edge  $p^{(1)}$  and  $p^{(2)}$  equal to the number of times the two predicates were aligned in parallel data. We use the standard polynomial algorithm (the Hungarian algorithm, (Kuhn, 1955)) to find an optimal solution.

## 5 Inference

An inference algorithm for an unsupervised model should be efficient enough to handle vast amounts of unlabeled data, as it can easily be obtained and is likely to improve results. We use a simple approximate inference algorithm based on greedy search. We start by discussing search for the maximum a-posteriori clustering of argument keys in the monolingual set-up and then discuss how it can be extended to accommodate the role alignment penalty.

### 5.1 Monolingual Setting

In the model, a linking between syntax and semantics is induced independently for each predicate. Nevertheless, searching for a MAP clustering can be expensive: even a move involving a single argument key implies some computations for all its occurrences in the corpus. Instead of more complex MAP search algorithms (see, e.g., (Daume III, 2007)), we use a greedy procedure where we start with each argument key assigned to an individual cluster, and then iteratively try to merge clusters. Each move involves (1) choosing an argument key and (2) deciding on a cluster to reassign it to. This is done by considering all clusters (including creating a new one) and choosing the most probable one.

Instead of choosing argument keys randomly at the first stage, we order them by corpus frequency. This ordering is beneficial as getting clustering right for frequent argument keys is more important and the corresponding decisions should be made earlier.<sup>5</sup> We used a single iteration in our experiments, as we have not noticed any benefit from using multiple iterations.

<sup>5</sup>This has been explored before for shallow semantic representations (Lang and Lapata, 2011a; Titov and Klementiev, 2011).

## 5.2 Incorporating the Alignment Penalty

Inference in the monolingual setting is done independently for each predicate, as the model factorizes over the predicates. The role alignment penalty introduces interdependencies between the objectives for each bilingual predicate pair chosen by the assignment algorithm as discussed in Section 4. For each pair of predicates, we search for clusterings to maximize the sum of the log-probability and the negated penalty term.

At first glance it may seem that the alignment penalty can be easily integrated into the greedy MAP search algorithm: instead of considering individual argument keys, one could use pairs of argument keys and decide on their assignment to clusters jointly. However, given that there is no isomorphic mapping between argument keys across languages, this solution is unlikely to be satisfactory.<sup>6</sup> Instead, we use an approximate inference procedure similar in spirit to annotation projection techniques.

For each predicate, we first induce semantic roles independently for the first language, as described in Section 5.1, and then use the same algorithm for the second language but take the penalty term into account. Then we repeat the process in the reverse direction. Among these two solutions, we choose the one which yields the higher objective value. In this way, we begin with producing a clustering for the side which is easier to cluster and provides more clues for the other side.<sup>7</sup>

## 6 Empirical Evaluation

We begin by describing the data and evaluation metrics we use before discussing results.

### 6.1 Data

We run our main experiments on the English-German section of Europarl v6 parallel corpus

---

<sup>6</sup>We also considered a variation of this idea where a pair of argument keys is chosen randomly proportional to their alignment frequency and multiple iterations are repeated. Despite being significantly slower than our method, it did not provide any improvement in accuracy.

<sup>7</sup>In preliminary experiments, we studied an even simpler inference method where the projection direction was fixed for all predicates. Though this approach did outperform the monolingual model, the results were substantially worse than achieved with our method.

(Koehn, 2005) and the CoNLL 2009 distributions of the Penn Treebank WSJ corpus (Marcus et al., 1993) for English and the SALSA corpus (Burchardt et al., 2006) for German. As standard for unsupervised SRL, we use the entire CoNLL training sets for evaluation, and use held-out sets for model selection and parameter tuning.

*Syntactic annotation.* Although the CoNLL 2009 dataset already has predicted dependency structures, we could not reproduce them so that we could use the same parser to annotate Europarl. We chose to reannotate it, since using different parsing models for both datasets would be undesirable. We used MaltParser (Nivre et al., 2007) for English and the syntactic component of the LTH system (Johansson and Nugues, 2008) for German.

*Predicate and argument identification.* We select all non-auxiliary verbs as predicates. For English, we identify their arguments using a heuristic proposed in (Lang and Lapata, 2011a). It is comprised of a list of 8 rules, which use nonlexicalized properties of syntactic paths between a predicate and a candidate argument to iteratively discard non-arguments from the list of all words in a sentence. For German, we use the LTH argument identification classifier. Accuracy of argument identification on CoNLL 2009 using predicted syntactic analyses was 80.7% and 86.5% for English and German, respectively.

*Argument alignment.* We use GIZA++ (Och and Ney, 2003) to produce word alignments in Europarl: we ran it in both directions and kept the intersection of the induced word alignments. For every argument identified in the previous stage, we chose a set of words consisting of the argument’s syntactic head and, for prepositional phrases, the head noun of the object noun phrase. We mark arguments in two languages as aligned if there is any word alignment between the corresponding sets and if they are arguments of aligned predicates.

### 6.2 Evaluation Metrics

We use the standard purity (PU) and collocation (CO) metrics as well as their harmonic mean (F1) to measure the quality of the resulting clusters. Purity measures the degree to which each cluster contains arguments sharing the same gold role:

$$PU = \frac{1}{N} \sum_i \max_j |G_j \cap C_i|$$

where  $C_i$  is the set of arguments in the  $i$ -th induced cluster,  $G_j$  is the set of arguments in the  $j$ th gold cluster, and  $N$  is the total number of arguments. Collocation evaluates the degree to which arguments with the same gold roles are assigned to a single cluster:

$$CO = \frac{1}{N} \sum_j \max_i |G_j \cap C_i|$$

We compute the aggregate PU, CO, and F1 scores over all predicates in the same way as (Lang and Lapata, 2011a) by weighting the scores of each predicate by the number of its argument occurrences. Since our goal is to evaluate the clustering algorithms, we *do not* include incorrectly identified arguments when computing these metrics.

### 6.3 Parameters and Set-up

Our models are robust to parameter settings; the parameters were tuned (to an order of magnitude) to optimize the  $F1$  score on the held-out development set and were as follows. Parameters governing duplicate role generation,  $\eta_0^{(\cdot)}$  and  $\eta_1^{(\cdot)}$ , and penalty weights  $\gamma^{(\cdot)}$  were set to be the same for both languages, and are 100,  $1.e-3$  and 10, respectively. The concentration parameters were set as follows: for English, they were set to  $\alpha^{(1)} = 1.e-3$ ,  $\beta^{(1)} = 1.e-3$ , and, for German, they were  $\alpha^{(2)} = 0.1$ ,  $\beta^{(2)} = 1$ .

Domains of Europarl (parliamentary proceedings) and German/English CoNLL data (newswire) are substantially different. Since the influence of domain shift is not the focus of work, we try to minimize its effect by computing the likelihood part of the objective on CoNLL data alone. This also makes our setting more comparable to prior work.<sup>8</sup>

### 6.4 Results

*Base monolingual model.* We begin by evaluating our base monolingual model *MonoBayes* alone against the current best approaches to unsupervised semantic role induction. Since we do not have access to the systems, we compare on the marginally different English CoNLL 2008 (Surdeanu et al.,

<sup>8</sup>Preliminary experiments on the entire dataset show a slight degradation in performance.

	PU	CO	F1
<i>LLogistic</i>	79.5	76.5	78.0
<i>GraphPart</i>	88.6	70.7	78.6
<i>SplitMerge</i>	88.7	73.0	80.1
<i>MonoBayes</i>	88.1	77.1	<b>82.2</b>
<i>SyntF</i>	81.6	77.5	79.5

2008) shared task dataset used in their experiments. We report the results using gold argument identification and gold syntactic parses in order to focus the evaluation on the argument labeling stage and to minimize the noise due to automatic syntactic annotations. The methods are Latent Logistic classification (Lang and Lapata, 2010), Split-Merge clustering (Lang and Lapata, 2011a), and Graph Partitioning (Lang and Lapata, 2011b) (labeled *LLogistic*, *SplitMerge*, and *GraphPart*, respectively) achieving the current best unsupervised SRL results in this setting. Additionally, we compute the syntactic function baseline (*SyntF*), which simply clusters predicate arguments according to the dependency relation to their head. Following (Lang and Lapata, 2010), we allocate a cluster for each of 20 most frequent relations in the CoNLL dataset and one cluster for all other relations. Our model substantially outperforms other models (see Table 1).

*Multilingual extensions.* Next, we improve our model performance using agreement as an additional supervision signal during training (see Section 4). We compare the performance of individual English and German models induced separately (*MonoBayes*) with the jointly induced models (*MultiBayes*) as well as the syntactic baseline, see Table 2.<sup>9</sup> While we see little improvement in F1 for English, the German system improves by 1.8%. For German, the crosslingual learning also results in 1.5% improvement over the syntactic baseline, which is considered difficult to outperform (Grenager and Manning, 2006; Lang and Lapata, 2010). Note that recent unsupervised SRL meth-

<sup>9</sup>Note that the scores are computed on correctly identified arguments only, and tend to be higher in these experiments probably because the complex arguments get discarded by the argument identifier.

ods do not always improve on it, see Table 1.

The relatively low expressivity and limited purity of our argument keys (see discussion in Section 4) are likely to limit potential improvements when using them in crosslingual learning. The natural next step would be to consider crosslingual learning with a more expressive model of the syntactic frame and syntax-semantics linking.

## 7 Related Work

Unsupervised learning in crosslingual setting has been an active area of research in recent years. However, most of this research has focused on induction of syntactic structures (Kuhn, 2004; Snyder et al., 2009) or morphologic analysis (Snyder and Barzilay, 2008) and we are not aware of any previous work on induction of semantic representations in the crosslingual setting. Learning of semantic representations in the context of monolingual weakly-parallel data was studied in Titov and Kozhevnikov (2010) but their setting was semi-supervised and they experimented only on a restricted domain.

Most of the SRL research has focused on the supervised setting, however, lack of annotated resources for most languages and insufficient coverage provided by the existing resources motivates the need for using unlabeled data or other forms of weak supervision. This includes methods based on graph alignment between labeled and unlabeled data (Fürstenu and Lapata, 2009), using unlabeled data to improve lexical generalization (Deschacht and Moens, 2009), and projection of annotation across languages (Pado and Lapata, 2009; van der Plas et al., 2011). Semi-supervised and weakly-supervised techniques have also been explored for other types of semantic representations but these studies again have mostly focused on restricted domains (Kate and Mooney, 2007; Liang et al., 2009; Goldwasser et al., 2011; Liang et al., 2011).

Early unsupervised approaches to the SRL task include (Swier and Stevenson, 2004), where the VerbNet verb lexicon was used to guide unsupervised learning, and a generative model of Grenager and Manning (2006) which exploits linguistic priors on syntactic-semantic interface.

More recently, the role induction problem has been studied in Lang and Lapata (2010) where it has been reformulated as a problem of detecting alternations and mapping non-standard linkings to the canonical ones. Later, Lang and Lapata (2011a) proposed an algorithmic approach to clustering argument signatures which achieves higher accuracy and outperforms the syntactic baseline. In Lang and Lapata (2011b), the role induction problem is formulated as a graph partitioning problem: each vertex in the graph corresponds to a predicate occurrence and edges represent lexical and syntactic similarities between the occurrences. Unsupervised induction of semantics has also been studied in Poon and Domingos (2009) and Titov and Klementiev (2011) but the induced representations are not entirely compatible with the PropBank-style annotations and they have been evaluated only on a question answering task for the biomedical domain. Also, a related task of unsupervised argument identification has been considered in Abend et al. (2009).

## 8 Conclusions

This work adds unsupervised semantic role labeling to the list of NLP tasks benefiting from the crosslingual induction setting. We show that an agreement signal extracted from parallel data provides indirect supervision capable of substantially improving a state-of-the-art model for semantic role induction.

Although in this work we focused primarily on improving performance for each individual language, cross-lingual semantic representation could be extracted by a simple post-processing step. In future work, we would like to model cross-lingual semantics explicitly.

## Abstract

This paper presents a novel top-down head-driven parsing algorithm for data-driven projective dependency analysis. This algorithm handles global structures, such as clause and coordination, better than shift-reduce or other bottom-up algorithms. Experiments on the English Penn Treebank data and the Chinese CoNLL-06 data show that the proposed algorithm achieves comparable results with other data-driven dependency parsing algorithms.

## 1 Introduction

Transition-based parsing algorithms, such as shift-reduce algorithms (Nivre, 2004; Zhang and Clark, 2008), are widely used for dependency analysis because of the efficiency and comparatively good performance. However, these parsers have one major problem that they can handle only local information. Isozaki et al. (2004) pointed out that the drawbacks of shift-reduce parser could be resolved by incorporating top-down information such as root finding.

This work presents an  $O(n^2)$  top-down head-driven transition-based parsing algorithm which can parse complex structures that are not trivial for shift-reduce parsers. The deductive system is very similar to Earley parsing (Earley, 1970). The Earley prediction is tied to a particular grammar rule, but the proposed algorithm is data-driven, following the current trends of dependency parsing (Nivre, 2006; McDonald and Pereira, 2006; Koo et al., 2010). To do the prediction without any grammar rules, we introduce a weighted prediction that is to predict lower nodes from higher nodes with a statistical model.

To improve parsing flexibility in deterministic parsing, our top-down parser uses beam search algorithm with dynamic programming (Huang and Sagae, 2010). The complexity becomes  $O(n^2 * b)$  where  $b$  is the beam size. To reduce prediction errors, we propose a lookahead technique based on a FIRST function, inspired by the LL(1) parser (Aho and Ullman, 1972). Experimental results show that the proposed top-down parser achieves competitive results with other data-driven parsing algorithms.

## 2 Definition of Dependency Graph

A dependency graph is defined as follows.

**Definition 2.1 (Dependency Graph)** Given an input sentence  $W = \mathbf{n}_0 \dots \mathbf{n}_n$  where  $\mathbf{n}_0$  is a special root node  $\$,$  a directed graph is defined as  $G_W = (V_W, A_W)$  where  $V_W = \{0, 1, \dots, n\}$  is a set of (indices of) nodes and  $A_W \subseteq V_W \times V_W$  is a set of directed arcs. The set of arcs is a set of pairs  $(x, y)$  where  $x$  is a head and  $y$  is a dependent of  $x.$   $x \rightarrow^* l$  denotes a path from  $x$  to  $l.$  A directed graph  $G_W = (V_W, A_W)$  is **well-formed** if and only if:

- There is no node  $x$  such that  $(x, 0) \in A_W.$
- If  $(x, y) \in A_W$  then there is no node  $x'$  such that  $(x', y) \in A_W$  and  $x' \neq x.$
- There is no subset of arcs  $\{(x_0, x_1), (x_1, x_2), \dots, (x_{l-1}, x_l)\} \subseteq A_W$  such that  $x_0 = x_l.$

These conditions are referred to **ROOT, SINGLE-HEAD, and ACYCLICITY,** and we call an **well-formed** directed graph as a **dependency graph.**

**Definition 2.2 (PROJECTIVITY)** A dependency graph  $G_W = (V_W, A_W)$  is **projective** if and only if,

$$\begin{array}{l}
\text{input:} \quad W = \mathbf{n}_0 \dots \mathbf{n}_n \\
\text{axiom}(p_0): \quad 0 : \langle 1, 0, n + 1, \mathbf{n}_0 \rangle : \emptyset \\
\text{pred}_{\curvearrowright}: \quad \frac{\overbrace{\ell : \langle i, h, j, s_d | \dots | s_0 \rangle : -}^{\text{state } p}}{\ell + 1 : \langle i, k, h, s_{d-1} | \dots | s_0 | \mathbf{n}_k \rangle : \{p\}} \exists k : i \leq k < h \\
\text{pred}_{\frown}: \quad \frac{\overbrace{\ell : \langle i, h, j, s_d | \dots | s_0 \rangle : -}^{\text{state } p}}{\ell + 1 : \langle i, k, j, s_{d-1} | \dots | s_0 | \mathbf{n}_k \rangle : \{p\}} \exists k : i \leq k < j \wedge h < i \\
\text{scan:} \quad \frac{\ell : \langle i, h, j, s_d | \dots | s_0 \rangle : \pi}{\ell + 1 : \langle i + 1, h, j, s_d | \dots | s_0 \rangle : \pi} i = h \\
\text{comp:} \quad \frac{\overbrace{- : \langle -, h', j', s'_d | \dots | s'_0 \rangle : \pi'}^{\text{state } q} \quad \overbrace{\ell : \langle i, h, j, s_d | \dots | s_0 \rangle : \pi}^{\text{state } p}}{\ell + 1 : \langle i, h', j', s'_d | \dots | s'_1 | s'_0 \frown s_0 \rangle : \pi'} q \in \pi, h < i \\
\text{goal:} \quad 3n : \langle n + 1, 0, n + 1, s_0 \rangle : \emptyset
\end{array}$$

Figure 1: The non-weighted deductive system of top-down dependency parsing algorithm:  $_-$  means “take anything”.

for every arc  $(x, y) \in A_W$  and node  $l$  in  $x < l < y$  or  $y < l < x$ , there is a path  $x \rightarrow^* l$  or  $y \rightarrow^* l$ .

The proposed algorithm in this paper is for projective dependency graphs. If a projective dependency graph is connected, we call it a **dependency tree**, and if not, a **dependency forest**.

### 3 Top-down Parsing Algorithm

Our proposed algorithm is a transition-based algorithm, which uses stack and queue data structures. This algorithm formally uses the following state:

$$\ell : \langle i, h, j, S \rangle : \pi$$

where  $\ell$  is a step size,  $S$  is a stack of trees  $s_d | \dots | s_0$  where  $s_0$  is a top tree and  $d$  is a window size for feature extraction,  $i$  is an index of node on the top of the input node queue,  $h$  is an index of root node of  $s_0$ ,  $j$  is an index to indicate the right limit ( $j - 1$  inclusive) of  $\text{pred}_{\curvearrowright}$ , and  $\pi$  is a set of pointers to **predictor states**, which are states just before putting the node in  $h$  onto stack  $S$ . In the deterministic case,  $\pi$  is a singleton set except for the initial state.

This algorithm has four actions,  $\text{predict}_{\curvearrowright}(\text{pred}_{\curvearrowright})$ ,  $\text{predict}_{\frown}(\text{pred}_{\frown})$ , scan and complete(comp). The deductive system of the top-down algorithm is shown in Figure 1. The initial state  $p_0$  is a state initialized by an artificial root node  $\mathbf{n}_0$ . This algorithm

applies one action to each state selected from applicable actions in each step. Each of three kinds of actions, pred, scan, and comp, occurs  $n$  times, and this system takes  $3n$  steps for a complete analysis.

Action  $\text{pred}_{\curvearrowright}$  puts  $\mathbf{n}_k$  onto stack  $S$  selected from the input queue in the range,  $i \leq k < h$ , which is to the left of the root  $\mathbf{n}_h$  in the stack top. Similarly, action  $\text{pred}_{\frown}$  puts a node  $\mathbf{n}_k$  onto stack  $S$  selected from the input queue in the range,  $h < i \leq k < j$ , which is to the right of the root  $\mathbf{n}_h$  in the stack top. The node  $\mathbf{n}_i$  on the top of the queue is scanned if it is equal to the root node  $\mathbf{n}_h$  in the stack top. Action comp creates a directed arc  $(h', h)$  from the root  $h'$  of  $s'_0$  on a predictor state  $q$  to the root  $h$  of  $s_0$  on a current state  $p$  if  $h < i$ <sup>1</sup>.

The precondition  $i < h$  of action  $\text{pred}_{\curvearrowright}$  means that the input nodes in  $i \leq k < h$  have not been predicted yet.  $\text{Pred}_{\curvearrowright}$ , scan and  $\text{pred}_{\frown}$  do not conflict with each other since their preconditions  $i < h$ ,  $i = h$  and  $h < i$  do not hold at the same time. However, this algorithm faces a  $\text{pred}_{\frown}$ -comp conflict because both actions share the same precondition  $h < i$ , which means that the input nodes in  $1 \leq k \leq h$  have been predicted and scanned. This

<sup>1</sup>In a single root tree, the special root symbol  $\$_0$  has exactly one child node. Therefore, we do not apply comp action to a state if its condition satisfies  $s_1 \cdot \mathbf{h} = \mathbf{n}_0 \wedge \ell \neq 3n - 1$ .

step	state	stack	queue	action	state information

Figure 2: Stages of the top-down deterministic parsing process for a sentence “I saw a girl”. We follow a convention and write the stack with its topmost element to the right, and the queue with its first element to the left. In this example, we set the window size  $d$  to 1, and write the descendants of trees on stack elements  $s_0$  and  $s_1$  within depth 1.

parser constructs left and right children of a head node in a left-to-right direction by scanning the head node prior to its right children. Figure 2 shows an example for parsing a sentence “I saw a girl”.

#### 4 Correctness

To prove the *correctness* of the system in Figure 1 for the **projective** dependency graph, we use the proof strategy of (Nivre, 2008a). The correct deductive system is both *sound* and *complete*.

**Theorem 4.1** *The deductive system in Figure 1 is correct for the class of dependency forest.*

**Proof 4.1** *To show soundness, we show that  $G_{p_0} = (V_W, \emptyset)$ , which is a directed graph defined by the axiom, is well-formed and projective, and that every transition preserves this property.*

- **ROOT:** *The node 0 is a root in  $G_{p_0}$ , and the node 0 is on the top of stack of  $p_0$ . The two  $\text{pred}$  actions put a word onto the top of stack, and predict an arc from root or its descendant to the child. The  $\text{comp}$  actions add the predicted arcs which include no arc of  $(x, 0)$ .*
- **SINGLE-HEAD:**  *$G_{p_0}$  is single-head. A node  $y$  is no longer in stack and queue after a  $\text{comp}$  action creates an arc  $(x, y)$ . The node  $y$  cannot make any arc  $(x', y)$  after the removal.*
- **ACYCLICITY:**  *$G_{p_0}$  is acyclic. A cycle is created only if an arc  $(x, y)$  is added when there is a directed path  $y \rightarrow^* x$ . The node  $x$  is no*

*longer in stack and queue when the directed path  $y \rightarrow^* x$  was made by adding an arc  $(l, x)$ . There is no chance to add the arc  $(x, y)$  on the directed path  $y \rightarrow^* x$ .*

- **PROJECTIVITY:**  *$G_{p_0}$  is projective. Projectivity is violated by adding an arc  $(x, y)$  when there is a node  $l$  in  $x < l < y$  or  $y < l < x$  with the path to or from the outside of the span  $x$  and  $y$ . When  $\text{pred}_{\curvearrowright}$  creates an arc relation from  $x$  to  $y$ , the node  $y$  cannot be scanned before all nodes  $l$  in  $x < l < y$  are scanned and completed. When  $\text{pred}_{\curvearrowright}$  creates an arc relation from  $x$  to  $y$ , the node  $y$  cannot be scanned before all nodes  $k$  in  $k < y$  are scanned and completed, and the node  $x$  cannot be scanned before all nodes  $l$  in  $y < l < x$  are scanned and completed. In those processes, the node  $l$  in  $x < l < y$  or  $y < l < x$  does not make a path to or from the outside of the span  $x$  and  $y$ , and a path  $x \rightarrow^* l$  or  $y \rightarrow^* l$  is created.  $\square$*

*To show completeness, we show that for any sentence  $W$ , and dependency forest  $G_W = (V_W, A_W)$ , there is a transition sequence  $C_{0,m}$  such that  $G_{p_m} = G_W$  by an inductive method.*

- *If  $|W| = 1$ , the projective dependency graph for  $W$  is  $G_W = (\{0\}, \emptyset)$  and  $G_{p_0} = G_W$ .*
- *Assume that the claim holds for sentences with length less or equal to  $t$ , and assume that  $|W| = t + 1$  and  $G_W = (V_W, A_W)$ . The subgraph  $G_{W'}$  is defined as  $(V_W - t, A^{-t})$  where*

Figure 3: Feature window of trees on stack  $S$ : The window size  $d$  is set to 2. Each  $x.h$ ,  $x.l$  and  $x.r$  denotes root, left and right child nodes of a stack element  $x$ .

$A^{-t} = A_W - \{(x, y) | x = t \vee y = t\}$ . If  $G_W$  is a dependency forest, then  $G_{W'}$  is also a dependency forest. It is obvious that there is a transition sequence for constructing  $G_W$  except arcs which have a node  $t$  as a head or a dependent<sup>2</sup>. There is a state  $p_q = q : \langle i, x, t + 1 \rangle : -$  for  $i$  and  $x$  ( $0 \leq x < i < t + 1$ ). When  $x$  is the head of  $t$ ,  $\text{pred}_{\curvearrowright}$  to  $t$  creates a state  $p_{q+1} = q + 1 : \langle i, t, t + 1 \rangle : \{p_q\}$ . At least one node  $y$  in  $i \leq y < t$  becomes the dependent of  $t$  by  $\text{pred}_{\curvearrowright}$  and there is a transition sequence for constructing a tree rooted by  $y$ . After constructing a subtree rooted by  $t$  and spanned from  $i$  to  $t$ ,  $t$  is scanned, and then  $\text{comp}$  creates an arc from  $x$  to  $t$ . It is obvious that the remaining transition sequence exists. Therefore, we can construct a transition sequence  $C_{0,m}$  such that  $G_{p_m} = G_W$ .  $\square$

The deductive system in Figure 1 is both sound and complete. Therefore, it is correct.  $\square$

## 5 Weighted Parsing Model

### 5.1 Stack-based Model

The proposed algorithm employs a stack-based model for scoring hypothesis. The cost of the model is defined as follows:

$$c_s(i, h, j, S) = \theta_s \cdot \mathbf{f}_{s,act}(i, h, j, S) \quad (1)$$

where  $\theta_s$  is a weight vector,  $\mathbf{f}_s$  is a feature function, and  $act$  is one of the applicable actions to a state  $\ell : \langle i, h, j, S \rangle : \pi$ . We use a set of feature templates of (Huang and Sagae, 2010) for the model. As shown in Figure 3, left children  $s_0.l$  and  $s_1.l$  of trees on

<sup>2</sup>This transition sequence is defined for  $G_{W'}$ , but it is possible to be regarded as the definition for  $G_W$  as long as the transition sequence is indifferent from the node  $t$ .

---

### Algorithm 1 Top-down Parsing with Beam Search

---

```

1: input  $W = \mathbf{n}_0, \dots, \mathbf{n}_n$ 
2:  $start \leftarrow \langle 1, 0, n + 1, \mathbf{n}_0 \rangle$ 
3:  $buf[0] \leftarrow \{start\}$ 
4: for  $\ell \leftarrow 1 \dots 3n$  do
5:    $hypo \leftarrow \{\}$ 
6:   for each  $state$  in  $buf[\ell - 1]$  do
7:     for  $act \leftarrow \text{applicableAct}(state)$  do
8:        $newstates \leftarrow \text{actor}(act, state)$ 
9:       addAll  $newstates$  to  $hypo$ 
10:  add top  $b$  states to  $buf[\ell]$  from  $hypo$ 
11: return best candidate from  $buf[3n]$ 

```

---

stack for extracting features are different from those of Huang and Sagae (2010) because in our parser the left children are generated from left to right.

As mentioned in Section 1, we apply beam search and Huang and Sagae (2010)’s DP techniques to our top-down parser. Algorithm 1 shows the our beam search algorithm in which top most  $b$  states are preserved in a buffer  $buf[\ell]$  in each step. In line 10 of Algorithm 1, equivalent states in the step  $\ell$  are merged following the idea of DP. Two states  $\langle i, h, j, S \rangle$  and  $\langle i', h', j', S' \rangle$  in the step  $\ell$  are equivalent, notated  $\langle i, h, j, S \rangle \sim \langle i', h', j', S' \rangle$ , iff

$$\mathbf{f}_{s,act}(i, h, j, S) = \mathbf{f}_{s,act}(i', h', j', S'). \quad (2)$$

When two equivalent predicted states are merged, their predictor states in  $\pi$  get combined. For further details about this technique, readers may refer to (Huang and Sagae, 2010).

### 5.2 Weighted Prediction

The step 0 in Figure 2 shows an example of prediction for a head node “\$0”, where the node “saw<sub>2</sub>” is selected as its child node. To select a probable child node, we define a statistical model for the prediction. In this paper, we integrate the cost from a graph-based model (McDonald and Pereira, 2006) which directly models dependency links. The cost of the 1st-order model is defined as the relation between a child node  $\mathbf{c}$  and a head node  $\mathbf{h}$ :

$$c_p(\mathbf{h}, \mathbf{c}) = \theta_p \cdot \mathbf{f}_p(\mathbf{h}, \mathbf{c}) \quad (3)$$

where  $\theta_p$  is a weight vector and  $\mathbf{f}_p$  is a features function. Using the cost  $c_p$ , the top-down parser selects a probable child node in each prediction step.

When we apply beam search to the top-down parser, then we no longer use  $\exists$  but  $\forall$  on  $\text{pred}_{\curvearrowright}$  and

Figure 4: An example of tree structure: Each  $\mathbf{h}$ ,  $\mathbf{l}_l$  and  $\mathbf{r}_1$  denotes head, left and right child nodes.

$\text{pred}_{\curvearrowright}$  in Figure 1. Therefore, the parser may predict many nodes as an appropriate child from a single state, causing many predicted states. This may cause the beam buffer to be filled only with the states, and these may exclude other states, such as scanned or completed states. Thus, we limit the number of predicted states from a single state by **prediction size** implicitly in line 10 of Algorithm 1.

To improve the prediction accuracy, we introduce a more sophisticated model. The cost of the sibling 2nd-order model is defined as the relationship between  $\mathbf{c}$ ,  $\mathbf{h}$  and a sibling node **sib**:

$$c_p(\mathbf{h}, \mathbf{sib}, \mathbf{c}) = \theta_p \cdot \mathbf{f}_p(\mathbf{h}, \mathbf{sib}, \mathbf{c}). \quad (4)$$

The 1st- and sibling 2nd-order models are the same as McDonald and Pereira (2006)'s definitions, except the cost factors of the sibling 2nd-order model. The cost factors for a tree structure in Figure 4 are defined as follows:

$$c_p(\mathbf{h}, -, \mathbf{l}_1) + \sum_{y=1}^{l-1} c_p(\mathbf{h}, \mathbf{l}_y, \mathbf{l}_{y+1}) \\ + c_p(\mathbf{h}, -, \mathbf{r}_1) + \sum_{y=1}^{m-1} c_p(\mathbf{h}, \mathbf{r}_y, \mathbf{r}_{y+1}).$$

This is different from McDonald and Pereira (2006) in that the cost factors for left children are calculated from left to right, while those in McDonald and Pereira (2006)'s definition are calculated from right to left. This is because our top-down parser generates left children from left to right. Note that the cost of weighted prediction model in this section is incrementally calculated by using only the information on the current state, thus the condition of state merge in Equation 2 remains unchanged.

### 5.3 Weighted Deductive System

We extend deductive system to a weighted one, and introduce **forward cost** and **inside cost** (Stolcke,

1995; Huang and Sagae, 2010). The forward cost is the total cost of a sequence from an initial state to the end state. The inside cost is the cost of a top tree  $s_0$  in stack  $S$ . We define these costs using a combination of stack-based model and weighted prediction model. The forward and inside costs of the combination model are as follows:

$$\begin{cases} c^{\text{fw}} = c_s^{\text{fw}} + c_p^{\text{fw}} \\ c^{\text{in}} = c_s^{\text{in}} + c_p^{\text{in}} \end{cases} \quad (5)$$

where  $c_s^{\text{fw}}$  and  $c_s^{\text{in}}$  are a forward cost and an inside cost for stack-based model, and  $c_p^{\text{fw}}$  and  $c_p^{\text{in}}$  are a forward cost and an inside cost for weighted prediction model. We add the following tuple of costs to a state:

$$(c_s^{\text{fw}}, c_s^{\text{in}}, c_p^{\text{fw}}, c_p^{\text{in}}).$$

For each action, we define how to efficiently calculate the forward and inside costs<sup>3</sup>, following Stolcke (1995) and Huang and Sagae (2010)'s works. In either case of  $\text{pred}_{\curvearrowleft}$  or  $\text{pred}_{\curvearrowright}$ ,

$$\frac{(c_s^{\text{fw}}, -, c_p^{\text{fw}}, -)}{(c_s^{\text{fw}} + \lambda, 0, c_p^{\text{fw}} + c_p(s_0 \cdot \mathbf{h}, \mathbf{n}_k), 0)}$$

where

$$\lambda = \begin{cases} \theta_s \cdot \mathbf{f}_{s, \text{pred}_{\curvearrowleft}}(i, h, j, S) & \text{if } \text{pred}_{\curvearrowleft} \\ \theta_s \cdot \mathbf{f}_{s, \text{pred}_{\curvearrowright}}(i, h, j, S) & \text{if } \text{pred}_{\curvearrowright} \end{cases} \quad (6)$$

In the case of scan,

$$\frac{(c_s^{\text{fw}}, c_s^{\text{in}}, c_p^{\text{fw}}, c_p^{\text{in}})}{(c_s^{\text{fw}} + \xi, c_s^{\text{in}} + \xi, c_p^{\text{fw}}, c_p^{\text{in}})}$$

where

$$\xi = \theta_s \cdot \mathbf{f}_{s, \text{scan}}(i, h, j, S). \quad (7)$$

In the case of comp,

$$\frac{(c_s^{\text{fw}}, c_s^{\text{in}}, c_p^{\text{fw}}, c_p^{\text{in}})}{(c_s^{\text{fw}} + c_s^{\text{in}} + \mu, c_s^{\text{in}} + c_s^{\text{in}} + \mu, \\ c_p^{\text{fw}} + c_p^{\text{in}} + c_p(s'_0 \cdot \mathbf{h}, s_0 \cdot \mathbf{h}), \\ c_p^{\text{in}} + c_p^{\text{in}} + c_p(s'_0 \cdot \mathbf{h}, s_0 \cdot \mathbf{h}))}$$

where

$$\mu = \theta_s \cdot \mathbf{f}_{s, \text{comp}}(i, h, j, S) + \theta_s \cdot \mathbf{f}_{s, \text{pred}_{\curvearrowleft}}(-, h', j', S'). \quad (8)$$

<sup>3</sup>For brevity, we present the formula not by 2nd-order model as equation 4 but a 1st-order one for weighted prediction.

Pred<sub>∧</sub> takes either pred<sub>∧</sub> or pred<sub>∨</sub>. Beam search is performed based on the following linear order for the two states  $p$  and  $p'$  at the same step, which have  $(c^{\text{fw}}, c^{\text{in}})$  and  $(c'^{\text{fw}}, c'^{\text{in}})$  respectively:

$$p \succ p' \text{ iff } c^{\text{fw}} < c'^{\text{fw}} \text{ or } c^{\text{fw}} = c'^{\text{fw}} \wedge c^{\text{in}} < c'^{\text{in}}. \quad (9)$$

We prioritize the forward cost over the inside cost since forward cost pertains to longer action sequence and is better suited to evaluate hypothesis states than inside cost (Nederhof, 2003).

#### 5.4 FIRST Function for Lookahead

Top-down backtrack parser usually reduces backtracking by precomputing the set FIRST( $\cdot$ ) (Aho and Ullman, 1972). We define the set FIRST( $\cdot$ ) for our top-down dependency parser:

$$\text{FIRST}(t') = \{\text{ld.t} \mid \text{ld} \in \text{Imdescendant}(\text{Tree}, t') \\ \text{Tree} \in \text{Corpus}\} \quad (10)$$

where  $t'$  is a POS-tag,  $\text{Tree}$  is a correct dependency tree which exists in  $\text{Corpus}$ , a function  $\text{Imdescendant}(\text{Tree}, t')$  returns the set of the leftmost descendant node  $\text{ld}$  of each nodes in  $\text{Tree}$  whose POS-tag is  $t'$ , and  $\text{ld.t}$  denotes a POS-tag of  $\text{ld}$ . Though our parser does not backtrack, it looks ahead when selecting possible child nodes at the prediction step by using the function FIRST. In case of pred<sub>∧</sub>:

$$\forall k : i \leq k < h \wedge \mathbf{n}_i.t \in \text{FIRST}(\mathbf{n}_k.t) \\ \frac{\overbrace{\ell : \langle i, h, j, s_d | \dots | s_0 \rangle : -}^{\text{state } p}}{\ell + 1 : \langle i, k, h, s_{d-1} | \dots | s_0 | \mathbf{n}_k \rangle : \{p\}}$$

where  $\mathbf{n}_i.t$  is a POS-tag of the node  $\mathbf{n}_i$  on the top of the queue, and  $\mathbf{n}_k.t$  is a POS-tag in  $k$ th position of an input nodes. The case for pred<sub>∨</sub> is the same. If there are no nodes which satisfy the condition, our top-down parser creates new states for all nodes, and pushes them into *hypo* in line 9 of Algorithm 1.

#### 6 Time Complexity

Our proposed top-down algorithm has three kinds of actions which are scan, comp and predict. Each scan and comp actions occurs  $n$  times when parsing a sentence with the length  $n$ . Predict action also occurs  $n$  times in which a child node is selected from

a node sequence in the input queue. Thus, the algorithm takes the following times for prediction:

$$n + (n - 1) + \dots + 1 = \sum_i^n i = \frac{n(n + 1)}{2}. \quad (11)$$

As  $n^2$  for prediction is the most dominant factor, the time complexity of the algorithm is  $O(n^2)$  and that of the algorithm with beam search is  $O(n^2 * b)$ .

#### 7 Related Work

Alshawi (1996) proposed head automaton which recognizes an input sentence top-down. Eisner and Satta (1999) showed that there is a cubic-time parsing algorithm on the formalism of the head automaton grammars, which are equivalently converted into split-head bilexical context-free grammars (SBCFGs) (McAllester, 1999; Johnson, 2007). Although our proposed algorithm does not employ the formalism of SBCFGs, it creates left children before right children, implying that it does not have spurious ambiguities as well as parsing algorithms on the SBCFGs. Head-corner parsing algorithm (Kay, 1989) creates dependency tree top-down, and in this our algorithm has similar spirit to it.

Yamada and Matsumoto (2003) applied a shift-reduce algorithm to dependency analysis, which is known as arc-standard transition-based algorithm (Nivre, 2004). Nivre (2003) proposed another transition-based algorithm, known as arc-eager algorithm. The arc-eager algorithm processes right-dependent top-down, but this does not involve the prediction of lower nodes from higher nodes. Therefore, the arc-eager algorithm is a totally bottom-up algorithm. Zhang and Clark (2008) proposed a combination approach of the transition-based algorithm with graph-based algorithm (McDonald and Pereira, 2006), which is the same as our combination model of stack-based and prediction models.

#### 8 Experiments

Experiments were performed on the English Penn Treebank data and the Chinese CoNLL-06 data. For the English data, we split WSJ part of it into sections 02-21 for training, section 22 for development and section 23 for testing. We used Yamada and Matsumoto (2003)'s head rules to convert phrase structure to dependency structure. For the Chinese data,

Table 1: Results for test data: Time measures the parsing time per sentence in seconds. Accuracy is an unlabeled attachment score, complete is a sentence complete rate, and root is a correct root rate. \* indicates our experiments.

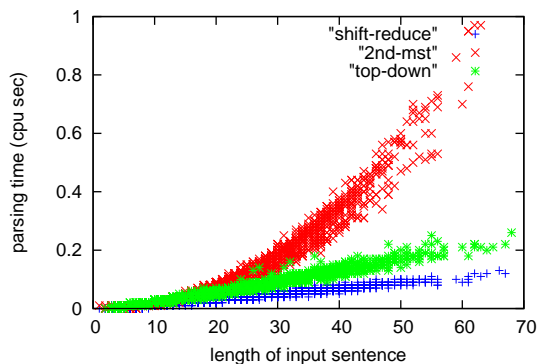

Figure 5: Scatter plot of parsing time against sentence length, comparing with top-down, 2nd-MST and shift-reduce parsers (beam size: 8, pred size: 5)

we used the information of words and fine-grained POS-tags for features. We also implemented and experimented Huang and Sagae (2010)’s arc-standard shift-reduce parser. For the 2nd-order Eisner-Satta algorithm, we used MSTParser (McDonald, 2012).

We used an early update version of averaged perceptron algorithm (Collins and Roark, 2004) for training of shift-reduce and top-down parsers. A set of feature templates in (Huang and Sagae, 2010) were used for the stack-based model, and a set of feature templates in (McDonald and Pereira, 2006) were used for the 2nd-order prediction model. The weighted prediction and stack-based models of top-down parser were jointly trained.

### 8.1 Results for English Data

During training, we fixed the prediction size and beam size to 5 and 16, respectively, judged by pre-

	accuracy	complete	root
oracle (sh+mst)	94.3	52.3	97.7
oracle (top+sh)	94.2	51.7	97.6
oracle (top+mst)	93.8	50.7	97.1
oracle (top+sh+mst)	94.9	55.3	98.1

Table 2: Oracle score, choosing the highest accuracy parse for each sentence on test data from results of top-down (beam 8, pred 5) and shift-reduce (beam 8) and MST(2nd) parsers in Table 1.

	accuracy	complete	root
top-down (beam:8, pred:5)	90.9	80.4	93.0
shift-reduce (beam:8)	90.8	77.6	93.5
2nd-MST	91.4	79.3	94.2
oracle (sh+mst)	94.0	85.1	95.9
oracle (top+sh)	93.8	84.0	95.6
oracle (top+mst)	93.6	84.2	95.3
oracle (top+sh+mst)	94.7	86.5	96.3

Table 3: Results for Chinese Data (CoNLL-06)

liminary experiments on development data. After 25 iterations of perceptron training, we achieved 92.94 unlabeled accuracy for top-down parser with the FIRST function and 93.01 unlabeled accuracy for shift-reduce parser on development data by setting the beam size to 8 for both parsers and the prediction size to 5 in top-down parser. These trained models were used for the following testing.

We compared top-down parsing algorithm with other data-driven parsing algorithms in Table 1. Top-down parser achieved comparable unlabeled accuracy with others, and outperformed them on the sentence complete rate. On the other hand, top-down parser was less accurate than shift-reduce

Table 4: Two examples on which top-down parser is superior to two bottom-up parsers: In correct analysis, the boxed portion is the head of the underlined portion. Bottom-up parsers often mistake to capture the relation.

parser on the correct root measure. In step 0, top-down parser predicts a child node, a root node of a complete tree, using little syntactic information, which may lead to errors in the root node selection. Therefore, we think that it is important to seek more suitable features for the prediction in future work.

Figure 5 presents the parsing time against sentence length. Our proposed top-down parser is theoretically slower than shift-reduce parser and Figure 5 empirically indicates the trends. The dominant factor comes from the score calculation, and we will leave it for future work. Table 2 shows the oracle score for test data, which is the score of the highest accuracy parse selected for each sentence from results of several parsers. This indicates that the parses produced by each parser are different from each other. However, the gains obtained by the combination of top-down and 2nd-MST parsers are smaller than other combinations. This is because top-down parser uses the same features as 2nd-MST parser, and these are more effective than those of stack-based model. It is worth noting that as shown in Figure 5, our  $O(n^2 * b)$  ( $b = 8$ ) top-down parser is much faster than  $O(n^3)$  Eisner-Satta CKY parsing.

## 8.2 Results for Chinese Data (CoNLL-06)

We also experimented on the Chinese data. Following English experiments, shift-reduce parser was trained by setting beam size to 16, and top-down parser was trained with the beam size and the prediction size to 16 and 5, respectively. Table 3 shows the results on the Chinese test data when setting beam size to 8 for both parsers and prediction size to 5 in top-down parser. The trends of the results are almost

the same as those of the English results.

## 8.3 Analysis of Results

Table 4 shows two interesting results, on which top-down parser is superior to either shift-reduce parser or 2nd-MST parser. The sentence No.717 contains an adverbial clause structure between the subject and the main verb. Top-down parser is able to handle the long-distance dependency while shift-reduce parser cannot correctly analyze it. The effectiveness on the clause structures implies that our head-driven parser may handle non-projective structures well, which are introduced by Johansson’s head rule (Johansson and Nugues, 2007). The sentence No.127 contains a coordination structure, which it is difficult for bottom-up parsers to handle, but, top-down parser handles it well because its top-down prediction globally captures the coordination.

## 9 Conclusion

This paper presents a novel head-driven parsing algorithm and empirically shows that it is as practical as other dependency parsing algorithms. Our head-driven parser has potential for handling non-projective structures better than other non-projective dependency algorithms (McDonald et al., 2005; Attardi, 2006; Nivre, 2008b; Koo et al., 2010). We are in the process of extending our head-driven parser for non-projective structures as our future work.

## Acknowledgments

We would like to thank Kevin Duh for his helpful comments and to the anonymous reviewers for giving valuable comments.

## Abstract

The language MIX consists of all strings over the three-letter alphabet  $\{a, b, c\}$  that contain an equal number of occurrences of each letter. We prove Joshi's (1985) conjecture that MIX is not a tree-adjoining language.

## 1 Introduction

The language

$$\text{MIX} = \{ w \in \{a, b, c\}^* \mid |w|_a = |w|_b = |w|_c \}$$

has attracted considerable attention in computational linguistics.<sup>1</sup> This language was used by Bach (1981) in an exercise to show that the permutation closure of a context-free language is not necessarily context-free.<sup>2</sup> MIX may be considered a prototypical example of *free word order language*, but, as remarked by Bach (1981), it seems that no human language “has such complete freedom for order”, because “typically, certain constituents act as ‘boundary domains’ for scrambling”. Joshi (1985) refers to MIX as representing “an extreme case of the degree of free word order permitted in a language”, which is “linguistically not relevant”. Gazdar (1988) adopts a similar position regarding the relation between MIX

<sup>1</sup>If  $w$  is a string and  $d$  is a symbol, we write  $|w|_d$  to mean the number of occurrences of  $d$  in  $w$ . We will use the notation  $|w|$  to denote the length of  $w$ , i.e., the total number of occurrences of symbols in  $w$ .

<sup>2</sup>According to Gazdar (1988), “MIX was originally described by Emmon Bach and was so-dubbed by students in the 1983 Hampshire College Summer Studies in Mathematics”. According to Bach (1988), the name MIX was “the happy invention of Bill Marsh”.

and natural languages, noting that “it seems rather unlikely that any natural language will turn out to have a MIX-like characteristic”.

It therefore seems natural to assume that languages such as MIX should be excluded from any class of formal languages that purports to be a tight formal characterization of the possible natural languages. It was in this spirit that Joshi et al. (1991) suggested that MIX should not be in the class of so-called *mildly context-sensitive* languages:

“[mildly context-sensitive grammars] capture only certain kinds of dependencies, e.g., nested dependencies and certain limited kinds of cross-serial dependencies (for example, in the subordinate clause constructions in Dutch or some variations of them, but perhaps not in the so-called MIX (or Bach) language) . . .”

Mild context-sensitivity is an informally defined notion first introduced by Joshi (1985); it consists of the three conditions of *limited cross-serial dependencies*, *constant growth*, and *polynomial parsing*. The first condition is only vaguely formulated, but the other two conditions are clearly satisfied by tree-adjoining grammars. The suggestion of Joshi et al. (1991) was that MIX should be regarded as a violation of the condition of limited cross-serial dependencies.

Joshi (1985) conjectured rather strongly that MIX is not a tree-adjoining language: “TAGs cannot generate this language, although for TAGs the proof is not in hand yet”. An even stronger conjecture was made by Marsh (1985), namely, that MIX is not an

*indexed language*.<sup>3</sup> (It is known that the indexed languages properly include the tree-adjoining languages.) Joshi et al. (1991), however, expressed a more pessimistic view about the conjecture:

“It is not known whether TAG ... can generate MIX. This has turned out to be a very difficult problem. In fact, it is not even known whether an IG [(indexed grammar)] can generate MIX.”

This open question has become all the more pressing after a recent result by Salvati (2011). This result says that MIX is in the class of *multiple context-free languages* (Seki et al., 1991), or equivalently, languages of *linear context-free rewriting systems* (Vijay-Shanker et al., 1987; Weir, 1988), which has been customarily regarded as a formal counterpart of the informal notion of a mildly context-sensitive language.<sup>4</sup> It means that either we have to abandon the identification of multiple context-free languages with mildly context-sensitive languages, or we should revise our conception of limited cross-serial dependencies and stop regarding MIX-like languages as violations of this condition. Surely, the resolution of Joshi’s (1985) conjecture should crucially affect the choice between these two alternatives.

In this paper, we prove that MIX is not a tree-adjoining language. Our proof is cast in terms of the formalism of *head grammar* (Pollard, 1984; Roach, 1987), which is known to be equivalent to TAG (Vijay-Shanker and Weir, 1994). The key to our proof is the notion of an *n-decomposition* of a string over  $\{a, b, c\}$ , which is similar to the notion of a derivation in head grammars, but independent of any particular grammar. The parameter  $n$  indicates how unbalanced the occurrence counts of the three letters can be at any point in a decomposition. We first

<sup>3</sup>The relation of MIX with indexed languages is also of interest in combinatorial group theory. Gilman (2005) remarks that “it does not ... seem to be known whether or not the word problem of  $Z \times Z$  is indexed”, alluding to the language  $O_2 = \{w \in \{a, \bar{a}, b, \bar{b}\}^* \mid |w|_a = |w|_{\bar{a}}, |w|_b = |w|_{\bar{b}}\}$ . Since  $O_2$  and MIX are rationally equivalent,  $O_2$  is indexed if and only if MIX is indexed (Salvati, 2011).

<sup>4</sup>Joshi et al. (1991) presented linear context-free rewriting systems as mildly context-sensitive grammars. Groenink (1997) wrote “The class of mildly context-sensitive languages seems to be most adequately approached by LCFRS.”

show that if MIX is generated by some head grammar, then there is an  $n$  such that every string in MIX has an  $n$ -decomposition. We then prove that if every string in MIX has an  $n$ -decomposition, then every string in MIX must have a 2-decomposition. Finally, we exhibit a particular string in MIX that has no 2-decomposition. The length of this string is 87, and the fact that it has no 2-decomposition was first verified by a computer program accompanying this paper. We include here a rigorous, mathematical proof of this fact not relying on the computer verification.

## 2 Head Grammars

A *head grammar* is a quadruple  $G = (N, \Sigma, P, S)$ , where  $N$  is a finite set of nonterminals,  $\Sigma$  is a finite set of terminal symbols (alphabet),  $S$  is a distinguished element of  $N$ , and  $P$  is a finite set of rules. Each nonterminal is interpreted as a binary predicate on strings in  $\Sigma^*$ . There are four types of rules:

$$\begin{aligned} A(x_1 x_2 y_1, y_2) &\leftarrow B(x_1, x_2), C(y_1, y_2) \\ A(x_1, x_2 y_1 y_2) &\leftarrow B(x_1, x_2), C(y_1, y_2) \\ A(x_1 y_1, y_2 x_2) &\leftarrow B(x_1, x_2), C(y_1, y_2) \\ A(w_1, w_2) &\leftarrow \end{aligned}$$

Here,  $A, B, C \in N$ ,  $x_1, x_2, y_1, y_2$  are *variables*, and  $w_1, w_2 \in \Sigma \cup \{\varepsilon\}$ .<sup>5</sup> Rules of the first three types are *binary rules* and rules of the last type are *terminating rules*. This definition of a head grammar actually corresponds to a normal form for head grammars that appears in section 3.3 of Vijay-Shanker and Weir’s (1994) paper.<sup>6</sup>

The rules of head grammars are interpreted as implications from right to left, where variables can be instantiated to any terminal strings. Each binary

<sup>5</sup>We use  $\varepsilon$  to denote the empty string.

<sup>6</sup>This normal form is also mentioned in chapter 5, section 4 of Kracht’s (2003) book. The notation we use to express rules of head grammars is borrowed from *elementary formal systems* (Smullyan, 1961; Arikawa et al., 1992), also known as *literal movement grammars* (Groenink, 1997; Kracht, 2003), which are logic programs over strings. In Vijay-Shanker and Weir’s (1994) notation, the four rules are expressed as follows:

$$\begin{aligned} A &\rightarrow C_{2,2}(B, C) \\ A &\rightarrow C_{1,2}(B, C) \\ A &\rightarrow W(B, C) \\ A &\rightarrow C_{1,1}(w_1 \uparrow w_2) \end{aligned}$$

rule involves an operation that combines two pairs of strings to form a new pair. The operation involved in the third rule is known as *wrapping*; the operations involved in the first two rules we call *left concatenation* and *right concatenation*, respectively. If  $G = (N, \Sigma, P, S)$  is a head grammar,  $A \in N$ , and  $w_1, w_2 \in \Sigma^*$ , then we say that a *fact*  $A(w_1, w_2)$  is *derivable* and write  $\vdash_G A(w_1, w_2)$ , if  $A(w_1, w_2)$  can be inferred using the rules in  $P$ . More formally, we have  $\vdash_G A(w_1, w_2)$  if one of the following conditions holds:

- $A(w_1, w_2) \leftarrow$  is a terminating rule in  $P$ .
- $\vdash_G B(u_1, u_2)$ ,  $\vdash_G C(v_1, v_2)$ , and there is a binary rule  $A(\alpha_1, \alpha_2) \leftarrow B(x_1, x_2), C(y_1, y_2)$  in  $P$  such that  $(w_1, w_2)$  is the result of substituting  $u_1, u_2, v_1, v_2$  for  $x_1, x_2, y_1, y_2$ , respectively, in  $(\alpha_1, \alpha_2)$ .

The language of  $G$  is

$$L(G) = \{ w_1 w_2 \mid \vdash_G S(w_1, w_2) \}.$$

**Example 1.** Let  $G = (N, \Sigma, P, S)$ , where  $N = \{S, A, A', C, D, E, F\}$ ,  $\Sigma = \{a, \bar{a}, \#\}$ , and  $P$  consists of the following rules:

$$\begin{aligned} S(x_1 y_1, y_2 x_2) &\leftarrow D(x_1, x_2), C(y_1, y_2) \\ C(\varepsilon, \#) &\leftarrow \\ D(\varepsilon, \varepsilon) &\leftarrow \\ D(x_1 y_1, y_2 x_2) &\leftarrow F(x_1, x_2), D(y_1, y_2) \\ F(x_1 y_1, y_2 x_2) &\leftarrow A(x_1, x_2), E(y_1, y_2) \\ A(a, a) &\leftarrow \\ E(x_1 y_1, y_2 x_2) &\leftarrow D(x_1, x_2), A'(y_1, y_2) \\ A'(\bar{a}, \bar{a}) &\leftarrow \end{aligned}$$

We have  $L(G) = \{ w \# w^R \mid w \in D_{\{a, \bar{a}\}} \}$ , where  $D_{\{a, \bar{a}\}}$  is the Dyck language over  $\{a, \bar{a}\}$  and  $w^R$  is the reversal of  $w$ . All binary rules of this grammar are wrapping rules.

If  $\vdash_G A(w_1, w_2)$ , a *derivation tree* for  $A(w_1, w_2)$  is a finite binary tree whose nodes are labeled by facts that are derived during the derivation of  $A(w_1, w_2)$ . A derivation tree for  $A(w_1, w_2)$  represents a “proof” of  $\vdash_G A(w_1, w_2)$ , and is formally defined as follows:

- If  $A(w_1, w_2) \leftarrow$  is a terminating rule, then a tree with a single node labeled by  $A(w_1, w_2)$  is a derivation tree for  $A(w_1, w_2)$ .

Figure 1: An example of a derivation tree of a head grammar.

- If  $\vdash_G A(w_1, w_2)$  is derived from  $\vdash_G B(u_1, u_2)$  and  $\vdash_G C(v_1, v_2)$  by some binary rule, then a binary tree whose root is labeled by  $A(w_1, w_2)$  and whose immediate left (right) subtree is a derivation tree for  $B(u_1, u_2)$  (for  $C(v_1, v_2)$ , respectively) is a derivation tree for  $A(w_1, w_2)$ .

If  $w \in L(G)$ , a derivation tree for  $w$  is a derivation tree for some  $S(w_1, w_2)$  such that  $w_1 w_2 = w$ .

**Example 1 (continued).** Figure 1 shows a derivation tree for  $aaāāāā\#āāāāāā$ .

The following lemma should be intuitively clear from the definition of a derivation tree:

**Lemma 1.** Let  $G = (N, \Sigma, P, S)$  be a head grammar and  $A$  be a nonterminal in  $N$ . Suppose that  $w \in L(G)$  has a derivation tree in which a fact  $A(v_1, v_2)$  appears as a label of a node. Then there are strings  $z_0, z_1, z_2$  with the following properties:

- $w = z_0 v_1 z_1 v_2 z_2$ , and
- $\vdash_G A(u_1, u_2)$  implies  $z_0 u_1 z_1 u_2 z_2 \in L(G)$ .

*Proof.* We can prove by straightforward induction on the height of derivation trees that whenever  $A(v_1, v_2)$  appears on a node in a derivation tree for  $B(w_1, w_2)$ , then there exist  $z_0, z_1, z_2, z_3$  that satisfy one of the following conditions:

- $w_1 = z_0 v_1 z_1 v_2 z_2$ ,  $w_2 = z_3$ , and  $\vdash_G A(u_1, u_2)$  implies  $\vdash_G B(z_0 u_1 z_1 u_2 z_2, z_3)$ .
- $w_1 = z_0$ ,  $w_2 = z_1 v_1 z_2 v_2 z_3$ , and  $\vdash_G A(u_1, u_2)$  implies  $\vdash_G B(z_0, z_1 u_1 z_2 u_2 z_3)$ .

(c)  $w_1 = z_0v_1z_1$ ,  $w_2 = z_2v_2z_3$ , and  $\vdash_G A(u_1, u_2)$  implies  $\vdash_G B(z_0u_1z_1, z_2u_2z_3)$ .

We omit the details.  $\square$

We call a nonterminal  $A$  of a head grammar  $G$  *useless* if  $A$  does not appear in any derivation trees for strings in  $L(G)$ . Clearly, useless nonterminals can be eliminated from any head grammar without affecting the language of the grammar.

### 3 Decompositions of Strings in MIX

Henceforth,  $\Sigma = \{a, b, c\}$ . Let  $\mathbb{Z}$  denote the set of integers. Define functions  $\psi_1, \psi_2: \Sigma^* \rightarrow \mathbb{Z}$ ,  $\psi: \Sigma^* \rightarrow \mathbb{Z} \times \mathbb{Z}$  by

$$\begin{aligned}\psi_1(w) &= |w|_a - |w|_c, \\ \psi_2(w) &= |w|_b - |w|_c, \\ \psi(w) &= (\psi_1(w), \psi_2(w)).\end{aligned}$$

Clearly, we have  $\psi(a) = (1, 0)$ ,  $\psi(b) = (0, 1)$ ,  $\psi(c) = (-1, -1)$ , and

$$w \in \text{MIX} \quad \text{iff} \quad \psi(w) = (0, 0).$$

Note that for all strings  $w_1, w_2 \in \Sigma^*$ ,  $\psi(w_1w_2) = \psi(w_1) + \psi(w_2)$ . In other words,  $\psi$  is a homomorphism from the free monoid  $\Sigma^*$  to  $\mathbb{Z} \times \mathbb{Z}$  with addition as the monoid operation and  $(0, 0)$  as identity.

**Lemma 2.** *Suppose that  $G = (N, \Sigma, P, S)$  is a head grammar without useless nonterminals such that  $L(G) \subseteq \text{MIX}$ . There exists a function  $\Psi_G: N \rightarrow \mathbb{Z} \times \mathbb{Z}$  such that  $\vdash_G A(u_1, u_2)$  implies  $\psi(u_1u_2) = \Psi_G(A)$ .*

*Proof.* Since  $G$  has no useless nonterminals, for each nonterminal  $A$  of  $G$ , there is a derivation tree for some string in  $L(G)$  in which  $A$  appears in a node label. By Lemma 1, there are strings  $z_0, z_1, z_2$  such that  $\vdash_G A(u_1, u_2)$  implies  $z_0u_1z_1u_2z_2 \in L(G)$ . Since  $L(G) \subseteq \text{MIX}$ , we have  $\psi(z_0u_1z_1u_2z_2) = (0, 0)$ , and hence

$$\psi(u_1u_2) = -\psi(z_0z_1z_2). \quad \square$$

A *decomposition* of  $w \in \Sigma^*$  is a finite binary tree satisfying the following conditions:

- the root is labeled by some  $(w_1, w_2)$  such that  $w = w_1w_2$ ,

- each internal node whose left and right children are labeled by  $(u_1, u_2)$  and  $(v_1, v_2)$ , respectively, is labeled by one of  $(u_1u_2v_1, v_2)$ ,  $(u_1, u_2v_1v_2)$ ,  $(u_1v_1, v_2u_2)$ .
- each leaf node is labeled by some  $(s_1, s_2)$  such that  $s_1s_2 \in \{b, c\}^* \cup \{a, c\}^* \cup \{a, b\}^*$ .

Thus, the label of an internal node in a decomposition is obtained from the labels of its children by left concatenation, right concatenation, or wrapping. It is easy to see that if  $G$  is a head grammar over the alphabet  $\Sigma$ , any derivation for  $w \in L(G)$  induces a decomposition of  $w$ . (Just strip off nonterminals.) Note that unlike with derivation trees, we have placed no bound on the length of a string that may appear on a leaf node of a decomposition. This will be convenient in some of the proofs below.

When  $p$  and  $q$  are integers, we write  $[p, q]$  for the set  $\{r \in \mathbb{Z} \mid p \leq r \leq q\}$ . We call a decomposition of  $w$  an *n-decomposition* if each of its nodes is labeled by some  $(v_1, v_2)$  such that  $\psi(v_1v_2) \in [-n, n] \times [-n, n]$ .

**Lemma 3.** *If  $\text{MIX} = L(G)$  for some head grammar  $G = (\Sigma, N, P, S)$ , then there exists an  $n$  such that each  $w \in \text{MIX}$  has an  $n$ -decomposition.*

*Proof.* We may suppose without loss of generality that  $G$  has no useless nonterminal. Since  $\text{MIX} = L(G)$ , there is a function  $\Psi_G$  satisfying the condition of Lemma 2. Since the set  $N$  of nonterminals of  $G$  is finite, there is an  $n$  such that  $\Psi_G(A) \in [-n, n] \times [-n, n]$  for all  $A \in N$ . Then it is clear that a derivation tree for  $w \in L(G)$  induces an  $n$ -decomposition of  $w$ .  $\square$

If  $w = d_1 \dots d_m \in \Sigma^m$ , then for  $0 \leq i \leq j \leq m$ , we write  $w[i, j]$  to refer to the substring  $d_{i+1} \dots d_j$  of  $w$ . (As a special case, we have  $w[i, i] = \varepsilon$ .) The following is a key lemma in our proof:

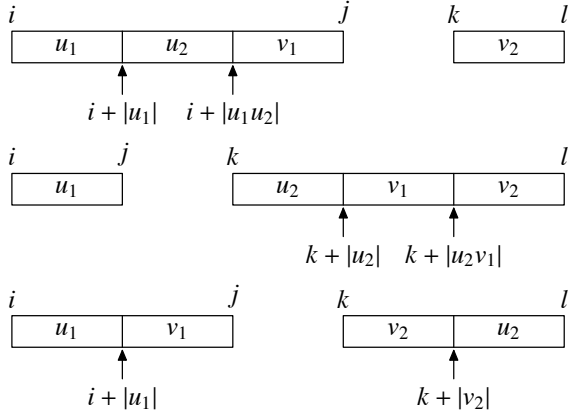

**Lemma 4.** *If each  $w \in \text{MIX}$  has an  $n$ -decomposition, then each  $w \in \text{MIX}$  has a 2-decomposition.*

*Proof.* Assume that each  $w \in \text{MIX}$  has an  $n$ -decomposition. Define a homomorphism  $\gamma_n: \Sigma^* \rightarrow \Sigma^*$  by

$$\begin{aligned}\gamma_n(a) &= a^n, \\ \gamma_n(b) &= b^n, \\ \gamma_n(c) &= c^n.\end{aligned}$$

Clearly,  $\gamma_n$  is an injection, and we have  $\psi(\gamma_n(v)) = n \cdot \psi(v)$  for all  $v \in \Sigma^*$ .

Let  $w \in \text{MIX}$  with  $|w| = m$ . Then  $w' = \gamma_n(w) \in \text{MIX}$  and  $|w'| = mn$ . By assumption,  $w'$  has an  $n$ -decomposition  $\mathcal{D}$ . We assign a 4-tuple  $(i, j, k, l)$  of natural numbers to each node of  $\mathcal{D}$  in such a way that  $(w'[i, j], w'[k, l])$  equals the label of the node. This is done recursively in an obvious way, starting from the root. If the root is labeled by  $(w_1, w_2)$ , then it is assigned  $(0, |w_1|, |w_1|, |w_1 w_2|)$ . If a node is assigned a tuple  $(i, j, k, l)$  and has two children labeled by  $(u_1, u_2)$  and  $(v_1, v_2)$ , respectively, then the 4-tuples assigned to the children are determined according to how  $(u_1, u_2)$  and  $(v_1, v_2)$  are combined at the parent node:

Now define a function  $f: [0, mn] \rightarrow \{kn \mid 0 \leq k \leq m\}$  by

$$f(i) = \begin{cases} i & \text{if } n \text{ divides } i, \\ n \cdot \lfloor i/n \rfloor & \text{if } n \text{ does not divide } i \text{ and} \\ & w'[i-1, i] \in \{a, b\}, \\ n \cdot \lceil i/n \rceil & \text{if } n \text{ does not divide } i \text{ and} \\ & w'[i-1, i] = c. \end{cases}$$

Clearly,  $f$  is weakly increasing in the sense that  $i \leq j$  implies  $f(i) \leq f(j)$ . Let  $\mathcal{D}'$  be the result of replacing the label of each node in  $\mathcal{D}$  by

$$(w'[f(i), f(j)], w'[f(k), f(l)]),$$

where  $(i, j, k, l)$  is the 4-tuple of natural numbers assigned to that node by the above procedure. It is easy to see that  $\mathcal{D}'$  is another decomposition of  $w'$ . Note that since each of  $f(i), f(j), f(k), f(l)$  is an integral multiple of  $n$ , we always have

$$(w'[f(i), f(j)], w'[f(k), f(l)]) = (\gamma_n(u), \gamma_n(v))$$

for some substrings  $u, v$  of  $w$ . This implies that for  $h = 1, 2$ ,

$$\psi_h(w'[f(i), f(j)]w'[f(k), f(l)])$$

is an integral multiple of  $n$ .

*Claim.*  $\mathcal{D}'$  is a  $2n$ -decomposition.

We have to show that every node label  $(v_1, v_2)$  in  $\mathcal{D}'$  satisfies  $\psi(v_1 v_2) \in [-2n, 2n] \times [-2n, 2n]$ . For  $h = 1, 2$ , define  $\varphi_h: [0, mn] \times [0, mn] \rightarrow \mathbb{Z}$  as follows:

$$\varphi_h(i, j) = \begin{cases} \psi_h(w'[i, j]) & \text{if } i \leq j, \\ -\psi_h(w'[j, i]) & \text{otherwise.} \end{cases}$$

Then it is easy to see that for all  $i, j, i', j' \in [0, mn]$ ,

$$\varphi_h(i', j') = \varphi_h(i', i) + \varphi_h(i, j) + \varphi_h(j, j').$$

Inspecting the definition of the function  $f$ , we can check that

$$\varphi_h(f(i), i) \in [0, n-1]$$

always holds. Suppose that  $(i, j, k, l)$  is assigned to a node in  $\mathcal{D}$ . By assumption, we have  $\psi_h(w'[i, j]w'[k, l]) \in [-n, n]$ , and

$$\begin{aligned} & \psi_h(w'[f(i), f(j)]w'[f(k), f(l)]) \\ &= \psi_h(w'[f(i), f(j)]) + \psi_h(w'[f(k), f(l)]) \\ &= \varphi_h(f(i), f(j)) + \varphi_h(f(k), f(l)) \\ &= \varphi_h(f(i), i) + \varphi_h(i, j) + \varphi_h(j, f(j)) \\ & \quad + \varphi_h(f(k), k) + \varphi_h(k, l) + \varphi_h(l, f(l)) \\ &= \varphi_h(f(i), i) + \psi_h(w'[i, j]) + \varphi_h(j, f(j)) \\ & \quad + \varphi_h(f(k), k) + \psi_h(w'[k, l]) + \varphi_h(l, f(l)) \\ &= \psi_h(w'[i, j]w'[k, l]) + \varphi_h(f(i), i) + \varphi_h(f(k), k) \\ & \quad + \varphi_h(j, f(j)) + \varphi_h(l, f(l)) \\ &\in \{p + q_1 + q_2 + r_1 + r_2 \mid p \in [-n, n], \\ & \quad q_1, q_2 \in [0, n-1], r_1, r_2 \in [-n+1, 0]\} \\ &= [-3n+2, 3n-2]. \end{aligned}$$

Since  $\psi_h(w'[f(i), f(j)]w'[f(k), f(l)])$  must be an integral multiple of  $n$ , it follows that

$$\psi_h(w'[f(i), f(j)]w'[f(k), f(l)]) \in \{-2n, -n, 0, n, 2n\}.$$

This establishes the claim.

We have shown that each node of  $\mathcal{D}'$  is labeled by a pair of strings of the form  $(\gamma_n(u), \gamma_n(v))$  such that

$$\psi(\gamma_n(u)\gamma_n(v)) \in \{-2n, -n, 0, n, 2n\} \times \{-2n, -n, 0, n, 2n\}.$$

Now it is easy to see that inverting the homomorphism  $\gamma_n$  at each node of  $\mathcal{D}'$

$$(\gamma_n(u), \gamma_n(v)) \mapsto (u, v)$$

gives a 2-decomposition of  $w$ . □

#### 4 A String in MIX That Has No 2-Decomposition

By Lemmas 3 and 4, in order to prove that there is no head grammar for MIX, it suffices to exhibit a string in MIX that has no 2-decomposition. The following is such a string:

$$z = a^5 b^{14} a^{19} c^{29} b^{15} a^5.$$

In this section, we prove that the string  $z$  has no 2-decomposition.<sup>7</sup>

It helps to visualize strings in MIX as closed curves in a plane. If  $w$  is a string in MIX, by plotting the coordinates of  $\psi(v)$  for each prefix  $v$  of  $w$ , we can represent  $w$  by a closed curve  $C$  together with a map  $t: [0, |w|] \rightarrow C$ . The representation of the string  $z$  is given in Figure 2.

Let us call a string  $w \in \{a, b, c\}^*$  such that  $\psi(w) \in [-2, 2] \times [-2, 2]$  *long* if  $w$  contains all three letters, and *short* otherwise. (If  $\psi(w) \notin [-2, 2] \times [-2, 2]$ , then  $w$  is neither short nor long.) It is easy to see that a short string  $w$  always satisfies

$$|w|_a \leq 4, \quad |w|_b \leq 4, \quad |w|_c \leq 2.$$

The maximal length of a short string is 6. (For example,  $a^4 c^2$  and  $b^4 c^2$  are short strings of length 6.) We also call a pair of strings  $(v_1, v_2)$  *long* (or *short*) if  $v_1 v_2$  is long (or short, respectively).

According to the definition of an  $n$ -decomposition, a leaf node in a 2-decomposition

<sup>7</sup>This fact was first verified by the computer program accompanying this paper. The program, written in C, implements a generic, memoized top-down recognizer for the language  $\{w \in \text{MIX} \mid w \text{ has a 2-decomposition}\}$ , and does not rely on any special properties of the string  $z$ .

Figure 2: Graphical representation of the string  $z = a^5 b^{14} a^{19} c^{29} b^{15} a^5$ . Note that every point  $(i, j)$  on the diagonal segment has  $i > 7$  or  $j < -2$ .

must be labeled by a short pair of strings. We call a 2-decomposition *normal* if the label of every internal node is long. Clearly, any 2-decomposition can be turned into a normal 2-decomposition by deleting all nodes that are descendants of nodes with short labels.

One important property of the string  $z$  is the following:

**Lemma 5.** *If  $z = x_1 v x_2$  and  $\psi(v) \in [-2, 2] \times [-2, 2]$ , then either  $v$  or  $x_1 x_2$  is short.*

*Proof.* This is easy to see from the graphical representation in Figure 2. If a substring  $v$  of  $z$  has  $\psi(v) \in [-2, 2] \times [-2, 2]$ , then the subcurve corresponding to  $v$  must have initial and final coordinates whose difference lies in  $[-2, 2] \times [-2, 2]$ . If  $v$  contains all three letters, then it must contain as a substring at least one of  $ba^{19}c$ ,  $ac^{29}b$ , and  $cb^{15}a$ . The only way to satisfy both these conditions is to have the subcurve corresponding to  $v$  start and end very close to the origin, so that  $x_1 x_2$  is short. (Note that the distance between the coordinate  $(5, 0)$  corresponding to position 5 of  $z$  and the diagonal segment corresponding to the substring  $c^{29}$  is large enough that it is impossible for  $v$  to start at position 5 and end in the middle of  $c^{29}$  without violating the condition  $\psi(v) \in [-2, 2] \times [-2, 2]$ .) □

Lemma 5 leads to the following observation. Let us call a decomposition of a string *concatenation-free* if each of its non-leaf labels is the wrapping of the labels of the children.

**Lemma 6.** *If  $z$  has a 2-decomposition, then  $z$  has a normal, concatenation-free 2-decomposition.*

*Proof.* Let  $\mathcal{D}$  be a 2-decomposition of  $z$ . Without loss of generality, we may assume that  $\mathcal{D}$  is normal. Suppose that  $\mathcal{D}$  contains a node  $\mu$  whose label is the left or right concatenation of the labels of its children,  $(u_1, u_2)$  and  $(v_1, v_2)$ . We only consider the case of left concatenation since the case of right concatenation is entirely analogous; so we suppose that the node  $\mu$  is labeled by  $(u_1u_2v_1, v_2)$ . It follows that  $z = x_1u_1u_2x_2$  for some  $x_1, x_2$ , and by Lemma 5, either  $u_1u_2$  or  $x_1x_2$  is short. If  $u_1u_2$  is short, then the left child of  $\mu$  is a leaf because  $\mathcal{D}$  is normal. We can replace its label by  $(u_1u_2, \varepsilon)$ ; the label  $(u_1u_2v_1, v_2)$  of  $\mu$  will now be the wrapping (as well as left concatenation) of the two child labels,  $(u_1u_2, \varepsilon)$  and  $(v_1, v_2)$ . If  $x_1x_2$  is short, then we can combine by wrapping a single node labeled by  $(x_1, x_2)$  with the subtree of  $\mathcal{D}$  rooted at the left child of  $\mu$ , to obtain a new 2-decomposition of  $z$ . In either case, the result is a normal 2-decomposition of  $z$  with fewer instances of concatenation. Repeating this procedure, we eventually obtain a normal, concatenation-free 2-decomposition of  $z$ .  $\square$

Another useful property of the string  $z$  is the following:

**Lemma 7.** *Suppose that the following conditions hold:*

- (i)  $z = x_1u_1v_1yv_2u_2x_2$ ,
- (ii)  $x_1yx_2$  is a short string, and
- (iii) both  $\psi(u_1u_2)$  and  $\psi(v_1v_2)$  are in  $[-2, 2] \times [-2, 2]$ .

*Then either  $(u_1, u_2)$  or  $(v_1, v_2)$  is short.*

*Proof.* Suppose  $(u_1, u_2)$  and  $(v_1, v_2)$  are both long. Since  $(u_1, u_2)$  and  $(v_1, v_2)$  must both contain  $c$ , either  $u_1$  ends in  $c$  and  $v_1$  starts in  $c$ , or else  $v_2$  ends in  $c$  and  $u_2$  starts in  $c$ .

*Case 1.*  $u_1$  ends in  $c$  and  $v_1$  starts in  $c$ . Since  $(v_1, v_2)$  must contain at least one occurrence of  $a$ , the string  $v_1yv_2$  must contain  $cb^{15}a$  as a substring.

$$\begin{array}{|c|c|c|c|c|} \hline a^5b^{14} & a^{19} & c^{29} & b^{15} & a^5 \\ \hline \end{array}$$

$\underbrace{\hspace{10em}}_{v_1yv_2}$

Since  $x_1yx_2$  is short, we have  $|y|_b \leq 4$ . It follows that  $|v_1v_2|_b \geq 11$ . But  $v_1yv_2$  is a substring of  $c^{28}b^{15}a^5$ , so  $|v_1v_2|_a \leq 5$ . This clearly contradicts  $\psi(v_1v_2) \in [-2, 2] \times [-2, 2]$ .

*Case 2.*  $v_2$  ends in  $c$  and  $u_2$  starts in  $c$ . In this case,  $cb^{15}a^5$  is a suffix of  $u_2x_2$ . Since  $x_1yx_2$  is short,  $|x_2|_a \leq 4$ . This means that  $cb^{15}a$  is a substring of  $u_2$  and hence  $|u_2|_b = 15$ .

$$\begin{array}{|c|c|c|c|c|} \hline a^5b^{14} & a^{19} & c^{29} & b^{15} & a^5 \\ \hline \end{array}$$

$\underbrace{\hspace{10em}}_{v_1yv_2}$

On the other hand, since  $(v_1, v_2)$  must contain at least one occurrence of  $b$ , the string  $v_1yv_2$  must contain  $ba^{19}c$  as a substring. This implies that  $|u_1u_2|_a \leq 10$ . But since  $|u_2|_b = 15$ , we have  $|u_1u_2|_b \geq 15$ . This clearly contradicts  $\psi(u_1u_2) \in [-2, 2] \times [-2, 2]$ .  $\square$

We now assume that  $z$  has a normal, concatenation-free 2-decomposition  $\mathcal{D}$  and derive a contradiction. We do this by following a certain path in  $\mathcal{D}$ . Starting from the root, we descend in  $\mathcal{D}$ , always choosing a non-leaf child, as long as there is one. We show that this path will never terminate.

The  $i$ -th node on the path will be denoted by  $\mu_i$ , counting the root as the 0-th node. The label of  $\mu_i$  will be denoted by  $(w_{i,1}, w_{i,2})$ . With each  $i$ , we associate three strings  $x_{i,1}, y_i, x_{i,2}$  such that  $x_{i,1}w_{i,1}y_iw_{i,2}x_{i,2} = z$ , analogously to Lemma 1. Since  $\psi(w_{i,1}w_{i,2}) \in [-2, 2] \times [-2, 2]$  and  $\psi(z) = (0, 0)$ , we will always have  $\psi(x_{i,1}y_ix_{i,2}) \in [-2, 2] \times [-2, 2]$ .

Initially,  $(w_{0,1}, w_{0,2})$  is the label of the root  $\mu_0$  and  $x_{0,1} = y_0 = x_{0,2} = \varepsilon$ . If  $\mu_i$  is not a leaf node, let  $(u_{i,1}, u_{i,2})$  and  $(v_{i,1}, v_{i,2})$  be the labels of the left and right children of  $\mu_i$ , respectively. If the left child is not a leaf node, we let  $\mu_{i+1}$  be the left child, in which case we have  $(w_{i+1,1}, w_{i+1,2}) = (u_{i,1}, u_{i,2})$ ,  $x_{i+1,1} = x_{i,1}$ ,  $x_{i+1,2} = x_{i,2}$ , and  $y_{i+1} = v_{i,1}yv_{i,2}$ . Otherwise,  $\mu_{i+1}$  will be the right child of  $\mu_i$ , and we have  $(w_{i+1,1}, w_{i+1,2}) = (v_{i,1}, v_{i,2})$ ,  $x_{i+1,1} = x_{i,1}u_{i,1}$ ,  $x_{i+1,2} = u_{i,2}x_{i,2}$ , and  $y_{i+1} = y_i$ .

The path  $\mu_0, \mu_1, \mu_2, \dots$  is naturally divided into two parts. The initial part of the path consists of nodes where  $x_{i,1}y_ix_{i,2}$  is short. Note that  $x_{0,1}y_0x_{0,2} = \varepsilon$  is short. As long as  $x_{i,1}y_ix_{i,2}$  is short,  $(w_{i,1}, w_{i,2})$  must be long and  $\mu_i$  has two children labeled by  $(u_{i,1}, u_{i,2})$  and  $(v_{i,1}, v_{i,2})$ . By Lemma 7, either  $(u_{i,1}, u_{i,2})$  or  $(v_{i,1}, v_{i,2})$  must be short. Since the length

of  $z$  is 87 and the length of a short string is at most 6, exactly one of  $(u_{i,1}, u_{i,2})$  and  $(v_{i,1}, v_{i,2})$  must be long.

We must eventually enter the second part of the path, where  $x_{i,1}y_ix_{i,2}$  is no longer short. Let  $\mu_m$  be the first node belonging to this part of the path. Note that at  $\mu_m$ , we have  $\psi(x_{m,1}y_mx_{m,2}) = \psi(x_{m-1,1}y_{m-1}x_{m-1,2}) + \psi(v)$  for some short string  $v$ . (Namely,  $v = u_{m-1,1}u_{m-1,2}$  or  $v = v_{m-1,1}v_{m-1,2}$ .)

**Lemma 8.** *If  $u$  and  $v$  are short strings and  $\psi(uv) \in [-2, 2] \times [-2, 2]$ , then  $|uv|_d \leq 4$  for each  $d \in \{a, b, c\}$ .*

*Proof.* Since  $u$  and  $v$  are short, we have  $|u|_a \leq 4, |u|_b \leq 4, |u|_c \leq 2$  and  $|v|_a \leq 4, |v|_b \leq 4, |v|_c \leq 2$ . It immediately follows that  $|uv|_c \leq 4$ . We distinguish two cases.

*Case 1.*  $|uv|_c \leq 2$ . Since  $\psi(uv) \in [-2, 2] \times [-2, 2]$ , we must have  $|uv|_a \leq 4$  and  $|uv|_b \leq 4$ .

*Case 2.*  $|uv|_c \geq 3$ . Since  $|u|_c \leq 2$  and  $|v|_c \leq 2$ , we must have  $|u|_c \geq 1$  and  $|v|_c \geq 1$ . Also,  $\psi(uv) \in [-2, 2] \times [-2, 2]$  implies that  $|uv|_a \geq 1$  and  $|uv|_b \geq 1$ . Since  $u$  and  $v$  are short, it follows that one of the following two conditions must hold:

- (i)  $|u|_a \geq 1, |u|_b = 0$  and  $|v|_a = 0, |v|_b \geq 1$ .
- (ii)  $|u|_a = 0, |u|_b \geq 1$  and  $|v|_a \geq 1, |v|_b = 0$ .

In the former case,  $|uv|_a = |u|_a \leq 4$  and  $|uv|_b = |v|_b \leq 4$ . In the latter case,  $|uv|_a = |v|_a \leq 4$  and  $|uv|_b = |u|_b \leq 4$ .  $\square$

By Lemma 8, the number of occurrences of each letter in  $x_{m,1}y_mx_{m,2}$  is in  $[1, 4]$ . This can only be if

$$\begin{aligned} x_{m,1}x_{m,2} &= a^j, \\ y_m &= c^k b^l, \end{aligned}$$

for some  $j, k, l \in [1, 4]$ . This means that the string  $z$  must have been split into two strings  $(w_{0,1}, w_{0,2})$  at the root of  $\mathcal{D}$  somewhere in the vicinity of position 67 (see Figure 2).

It immediately follows that for all  $i \geq m$ ,  $w_{i,1}$  is a substring of  $a^5 b^{14} a^{19} c^{28}$  and  $w_{i,2}$  is a substring of  $b^{14} a^5$ . We show by induction that for all  $i \geq m$ , the following condition holds:

( $\dagger$ )  $ba^{19}c^{17}$  is a substring of  $w_{i,1}$ .

The condition ( $\dagger$ ) clearly holds for  $i = m$ . Now assume ( $\dagger$ ). Then  $(w_{i,1}, w_{i,2})$  is long, and  $\mu_i$  has left and

right children, labeled by  $(u_{i,1}, u_{i,2})$  and  $(v_{i,1}, v_{i,2})$ , respectively, such that  $w_{i,1} = u_{i,1}v_{i,1}$  and  $w_{i,2} = v_{i,2}u_{i,2}$ . We consider two cases.

*Case 1.*  $u_{i,1}$  contains  $c$ . Then  $ba^{19}c$  is a substring of  $u_{i,1}$ . Since  $u_{i,2}$  is a substring of  $b^{14}a^5$ , it cannot contain any occurrences of  $c$ . Since  $\psi_1(u_{i,1}u_{i,2}) \in [-2, 2]$ , it follows that  $u_{i,1}$  must contain at least 17 occurrences of  $c$ ; hence  $ba^{19}c^{17}$  is a substring of  $u_{i,1}$ . Since  $(u_{i,1}, u_{i,2})$  is long,  $(w_{i+1,1}, w_{i+1,2}) = (u_{i,1}, u_{i,2})$ . Therefore, the condition ( $\dagger$ ) holds with  $i + 1$  in place of  $i$ .

*Case 2.*  $u_{i,1}$  does not contain  $c$ . Then  $(u_{i,1}, u_{i,2})$  is short and  $(w_{i+1,1}, w_{i+1,2}) = (v_{i,1}, v_{i,2})$ . Note that  $v_{i,1}$  must contain at least 17 occurrences of  $c$ , but  $v_{i,2}$  is a substring of  $b^{14}a^5$  and hence cannot contain more than 14 occurrences of  $b$ . Since  $\psi_2(v_{i,1}v_{i,2}) \in [-2, 2]$ , it follows that  $v_{i,1}$  must contain at least one occurrence of  $b$ . Therefore,  $ba^{19}c^{17}$  must be a substring of  $v_{i,1} = w_{i+1,1}$ , which shows that ( $\dagger$ ) holds with  $i + 1$  in place of  $i$ .

We have proved that ( $\dagger$ ) holds for all  $i \geq m$ . It follows that for all  $i$ ,  $\mu_i$  has two children and hence  $\mu_{i+1}$  is defined. This means that the path  $\mu_0, \mu_1, \mu_2, \dots$  is infinite, contradicting the assumption that  $\mathcal{D}$  is a 2-decomposition of  $z$ .

We have proved the following:

**Lemma 9.** *There is a string in MIX that has no 2-decomposition.*

**Theorem 10.** *There is no head grammar  $G$  such that  $L(G) = \text{MIX}$ .*

*Proof.* Immediate from Lemmas 3, 4, and 9.  $\square$

School of Computer Science and Technology  
Harbin Institute of Technology, China  
{lzh, tliu, car}@ir.hit.edu.cn

## Abstract

We present a simple and effective framework for exploiting multiple monolingual treebanks with different annotation guidelines for parsing. Several types of *transformation patterns* (TP) are designed to capture the systematic annotation inconsistencies among different treebanks. Based on such TPs, we design *quasi-synchronous grammar* features to augment the baseline parsing models. Our approach can significantly advance the state-of-the-art parsing accuracy on two widely used target treebanks (Penn Chinese Treebank 5.1 and 6.0) using the Chinese Dependency Treebank as the source treebank. The improvements are respectively 1.37% and 1.10% with automatic part-of-speech tags. Moreover, an indirect comparison indicates that our approach also outperforms previous work based on treebank conversion.

## 1 Introduction

The scale of available labeled data significantly affects the performance of statistical data-driven models. As a structural classification problem that is more challenging than binary classification and sequence labeling problems, syntactic parsing is more prone to suffer from the data sparseness problem. However, the heavy cost of treebanking typically limits one single treebank in both scale and genre. At present, learning from one single treebank seems inadequate for further boosting parsing accuracy.<sup>1</sup>

\*Correspondence author: tliu@ir.hit.edu.cn

<sup>1</sup>Incorporating an increased number of global features, such as third-order features in graph-based parsers, slightly affects parsing accuracy (Koo and Collins, 2010; Li et al., 2011).

Treebanks	# of Words	Grammar
CTB5	0.51 million	Phrase structure
CTB6	0.78 million	Phrase structure
CDT	1.11 million	Dependency structure
Sinica	0.36 million	Phrase structure
TCT	about 1 million	Phrase structure

Table 1: Several publicly available Chinese treebanks.

Therefore, studies have recently resorted to other resources for the enhancement of parsing models, such as large-scale unlabeled data (Koo et al., 2008; Chen et al., 2009; Bansal and Klein, 2011; Zhou et al., 2011), and bilingual texts or cross-lingual treebanks (Burkett and Klein, 2008; Huang et al., 2009; Burkett et al., 2010; Chen et al., 2010).

The existence of multiple monolingual treebanks opens another door for this issue. For example, table 1 lists a few publicly available Chinese treebanks that are motivated by different linguistic theories or applications. In the current paper, we utilize the first three treebanks, i.e., the Chinese Penn Treebank 5.1 (CTB5) and 6.0 (CTB6) (Xue et al., 2005), and the Chinese Dependency Treebank (CDT) (Liu et al., 2006). The Sinica treebank (Chen et al., 2003) and the Tsinghua Chinese Treebank (TCT) (Qiang, 2004) can be similarly exploited with our proposed approach, which we leave as future work.

Despite the divergence of annotation philosophy, these treebanks contain rich human knowledge on the Chinese syntax, thereby having a great deal of common ground. Therefore, exploiting multiple treebanks is very attractive for boosting parsing accuracy. Figure 1 gives an example with different an-

Figure 1: Example with annotations from CTB5 (upper) and CDT (under).

notations from CTB5 and CDT.<sup>2</sup> This example illustrates that the two treebanks annotate coordination constructions differently. In CTB5, the last noun is the head, whereas the first noun is the head in CDT.

One natural idea for multiple treebank exploitation is *treebank conversion*. First, the annotations in the source treebank are converted into the style of the target treebank. Then, both the converted treebank and the target treebank are combined. Finally, the combined treebank are used to train a better parser. However, the inconsistencies among different treebanks are normally nontrivial, which makes rule-based conversion infeasible. For example, a number of inconsistencies between CTB5 and CDT are lexicon-sensitive, that is, they adopt different annotations for some particular lexicons (or word senses). Niu et al. (2009) use sophisticated strategies to reduce the noises of the converted treebank after automatic treebank conversion.

The present paper proposes a simple and effective framework for this problem. The proposed framework avoids directly addressing the difficult annotation transformation problem, but focuses on modeling the annotation inconsistencies using *transformation patterns* (TP). The TPs are used to compose *quasi-synchronous grammar* (QG) features, such that the knowledge of the source treebank can inspire the target parser to build better trees. We conduct extensive experiments using CDT as the source treebank to enhance two target treebanks (CTB5 and CTB6). Results show that our approach can significantly boost state-of-the-art parsing accuracy. Moreover, an indirect comparison indicates that our ap-

<sup>2</sup>CTB5 is converted to dependency structures following the standard practice of dependency parsing (Zhang and Clark, 2008b). Notably, converting a phrase-structure tree into its dependency-structure counterpart is straightforward and can be performed by applying heuristic head-finding rules.

proach also outperforms the treebank conversion approach of Niu et al. (2009).

## 2 Related Work

The present work is primarily inspired by Jiang et al. (2009) and Smith and Eisner (2009). Jiang et al. (2009) improve the performance of word segmentation and part-of-speech (POS) tagging on CTB5 using another large-scale corpus of different annotation standards (People’s Daily). Their framework is similar to ours. However, handling syntactic annotation inconsistencies is significantly more challenging in our case of parsing. Smith and Eisner (2009) propose effective QG features for parser adaptation and projection. The first part of their work is closely connected with our work, but with a few important differences. First, they conduct simulated experiments on one treebank by manually creating a few trivial annotation inconsistencies based on two heuristic rules. They then focus on better adapting a parser to a new annotation style with few sentences of the target style. In contrast, we experiment with two real large-scale treebanks, and boost the state-of-the-art parsing accuracy using QG features. Second, we explore much richer QG features to fully exploit the knowledge of the source treebank. These features are tailored to the dependency parsing problem. In summary, the present work makes substantial progress in modeling structural annotation inconsistencies with QG features for parsing.

Previous work on treebank conversion primarily focuses on converting one grammar formalism of a treebank into another and then conducting a study on the converted treebank (Collins et al., 1999; Xia et al., 2008). The work by Niu et al. (2009) is, to our knowledge, the only study to date that combines the converted treebank with the existing target treebank. They automatically convert the dependency-structure CDT into the phrase-structure style of CTB5 using a statistical constituency parser trained on CTB5. Their experiments show that the combined treebank can significantly improve the performance of constituency parsers. However, their method requires several sophisticated strategies, such as corpus weighting and score interpolation, to reduce the influence of conversion errors. Instead of using the noisy converted treebank as additional training data, our approach allows the QG-

enhanced parsing models to softly learn the systematic inconsistencies based on QG features, making our approach simpler and more robust.

Our approach is also intuitively related to *stacked learning* (SL), a machine learning framework that has recently been applied to dependency parsing to integrate two main-stream parsing models, i.e., graph-based and transition-based models (Nivre and McDonald, 2008; Martins et al., 2008). However, the SL framework trains two parsers on the same treebank and therefore does not need to consider the problem of annotation inconsistencies.

### 3 Dependency Parsing

Given an input sentence  $\mathbf{x} = w_0 w_1 \dots w_n$  and its POS tag sequence  $\mathbf{t} = t_0 t_1 \dots t_n$ , the goal of dependency parsing is to build a dependency tree as depicted in Figure 1, denoted by  $\mathbf{d} = \{(h, m, l) : 0 \leq h \leq n, 0 < m \leq n, l \in \mathcal{L}\}$ , where  $(h, m, l)$  indicates an directed arc from the *head word* (also called *father*)  $w_h$  to the *modifier* (also called *child* or *dependent*)  $w_m$  with a dependency label  $l$ , and  $\mathcal{L}$  is the label set. We omit the label  $l$  because we focus on unlabeled dependency parsing in the present paper. The artificial node  $w_0$ , which always points to the root of the sentence, is used to simplify the formalizations.

In the current research, we adopt the graph-based parsing models for their state-of-the-art performance in a variety of languages.<sup>3</sup> Graph-based models view the problem as finding the highest scoring tree from a directed graph. To guarantee the efficiency of the decoding algorithms, the score of a dependency tree is factored into the scores of some small parts (subtrees).

$$\begin{aligned} \text{Score}_{bs}(\mathbf{x}, \mathbf{t}, \mathbf{d}) &= \mathbf{w}_{bs} \cdot \mathbf{f}_{bs}(\mathbf{x}, \mathbf{t}, \mathbf{d}) \\ &= \sum_{p \subseteq \mathbf{d}} \mathbf{w}_{part} \cdot \mathbf{f}_{part}(\mathbf{x}, \mathbf{t}, p) \end{aligned}$$

where  $p$  is a scoring part which contains one or more dependencies of  $\mathbf{d}$ , and  $\mathbf{f}_{bs}(\cdot)$  denotes the *basic parsing features*, as opposed to the *QG features*. Figure 2 lists the scoring parts used in our work, where  $g$ ,  $h$ ,  $m$ , and  $s$ , are word indices.

We implement three parsing models of varying strengths in capturing features to better understand the effect of the proposed QG features.

<sup>3</sup>Our approach can equally be applied to transition-based parsing models (Yamada and Matsumoto, 2003; Nivre, 2003) with minor modifications.

Figure 2: Scoring parts used in our graph-based parsing models.

- **The first-order model (O1)** only incorporates dependency parts (McDonald et al., 2005), and requires  $O(n^3)$  parsing time.
- **The second-order model using only sibling parts (O2sib)** includes both dependency and sibling parts (McDonald and Pereira, 2006), and needs  $O(n^3)$  parsing time.
- **The second-order model (O2)** uses all the scoring parts in Figure 2 (Koo and Collins, 2010). The time complexity of the decoding algorithm is  $O(n^4)$ .

For the O2 model, the score function is rewritten as:

$$\begin{aligned} \text{Score}_{bs}(\mathbf{x}, \mathbf{t}, \mathbf{d}) &= \sum_{\{(h,m)\} \subseteq \mathbf{d}} \mathbf{w}_{dep} \cdot \mathbf{f}_{dep}(\mathbf{x}, \mathbf{t}, h, m) \\ &+ \sum_{\{(h,s),(h,m)\} \subseteq \mathbf{d}} \mathbf{w}_{sib} \cdot \mathbf{f}_{sib}(\mathbf{x}, \mathbf{t}, h, s, m) \\ &+ \sum_{\{(g,h),(h,m)\} \subseteq \mathbf{d}} \mathbf{w}_{grad} \cdot \mathbf{f}_{grad}(\mathbf{x}, \mathbf{t}, g, h, m) \end{aligned}$$

where  $\mathbf{f}_{dep}(\cdot)$ ,  $\mathbf{f}_{sib}(\cdot)$  and  $\mathbf{f}_{grad}(\cdot)$  correspond to the features for the three kinds of scoring parts. We adopt the standard features following Li et al. (2011). For the O1 and O2sib models, the above formula is modified by deactivating the extra parts.

### 4 Dependency Parsing with QG Features

Smith and Eisner (2006) propose the QG for machine translation (MT) problems, allowing greater syntactic divergences between the two languages. Given a source sentence  $\mathbf{x}'$  and its syntactic tree  $\mathbf{d}'$ , a QG defines a monolingual grammar that generates translations of  $\mathbf{x}'$ , which can be denoted by  $p(\mathbf{x}, \mathbf{d}, \mathbf{a} | \mathbf{x}', \mathbf{d}')$ , where  $\mathbf{x}$  and  $\mathbf{d}$  refer to a translation and its parse, and  $\mathbf{a}$  is a cross-language alignment. Under a QG, any portion of  $\mathbf{d}$  can be aligned to any

<sup>4</sup>We use the coarse-to-fine strategy to prune the search space, which largely accelerates the decoding procedure (Koo and Collins, 2010).

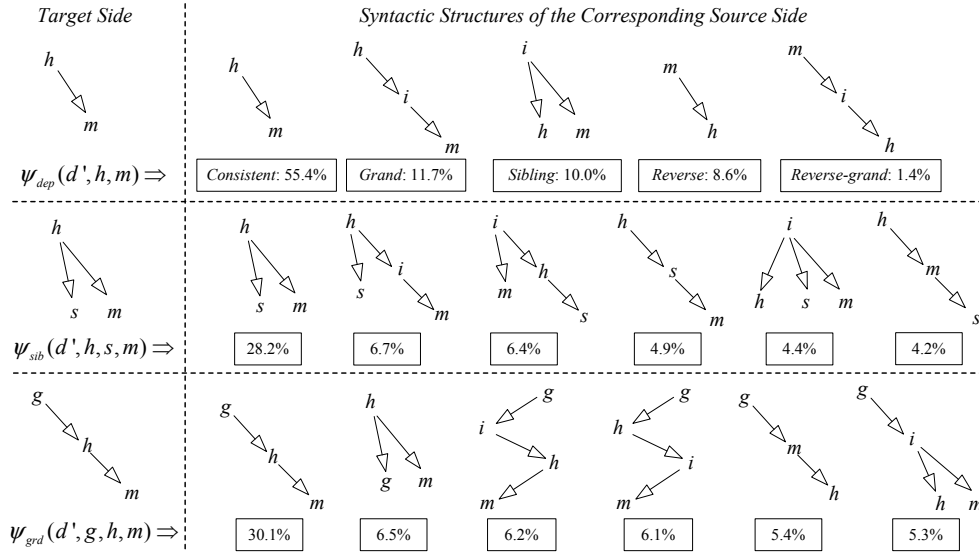

Figure 4: Most frequent transformation patterns (TPs) when using CDT as the source treebank and CTB5 as the target. A TP comprises two syntactic structures, one in the source side and the other in the target side, and denotes the process by which the left-side subtree is transformed into the right-side structure. Functions  $\psi_{dep}(\cdot)$ ,  $\psi_{sib}(\cdot)$ , and  $\psi_{grd}(\cdot)$  return the specific TP type for a candidate scoring part according to the source tree  $d'$ .

Figure 3: Framework of our approach.

portion of  $d'$ , and the construction of  $d$  can be inspired by arbitrary substructures of  $d'$ . To date, QGs have been successfully applied to various tasks, such as word alignment (Smith and Eisner, 2006), machine translation (Gimpel and Smith, 2011), question answering (Wang et al., 2007), and sentence simplification (Woodsend and Lapata, 2011).

In the present work, we utilize the idea of the QG for the exploitation of multiple monolingual treebanks. The key idea is to let the parse tree of one style inspire the parsing process of another style. Different from a MT process, our problem consid-

ers one single sentence ( $\mathbf{x} = \mathbf{x}'$ ), and the alignment  $\mathbf{a}$  is trivial. Figure 3 shows the framework of our approach. First, we train a statistical parser on the source treebank, which is called the source parser. The source parser is then used to parse the whole target treebank. At this point, the target treebank contains two sets of annotations, one conforming to the source style, and the other conforming to the target style. During both the training and test phases, the target parser are inspired by the source annotations, and the score of a target dependency tree becomes

$$Score(\mathbf{x}, \mathbf{t}, \mathbf{d}', \mathbf{d}) = Score_{bs}(\mathbf{x}, \mathbf{t}, \mathbf{d}) + Score_{qg}(\mathbf{x}, \mathbf{t}, \mathbf{d}', \mathbf{d})$$

The first part corresponds to the baseline model, whereas the second part is affected by the source tree  $d'$  and can be rewritten as

$$Score_{qg}(\mathbf{x}, \mathbf{t}, \mathbf{d}', \mathbf{d}) = \mathbf{w}_{qg} \cdot \mathbf{f}_{qg}(\mathbf{x}, \mathbf{t}, \mathbf{d}', \mathbf{d})$$

where  $\mathbf{f}_{qg}(\cdot)$  denotes the QG features. We expect the QG features to encourage or penalize certain scoring parts in the target side according to the source tree  $d'$ . Taking Figure 1 as an example, suppose that the upper structure is the target. The target parser can raise the score of the candidate dependence “and”  $\leftarrow$  “industry”, because the depen-

dependency also appears in the source structure, and evidence in the training data shows that both annotation styles handle conjunctions in the same manner. Similarly, the parser may add weight to “*trade*” ← “*industry*”, considering that the *reverse* arc is in the source structure. Therefore, the QG-enhanced model must learn the systematic consistencies and inconsistencies from the training data.

To model such consistency or inconsistency systematicness, we propose the use of TPs for encoding the structural correspondence between the source and target styles. Figure 4 presents the three kinds of TPs used in our model, which correspond to the three scoring parts of our parsing models.

Dependency TPs shown in the first row consider how one dependency in the target side is transformed in the source annotations. We only consider the five cases shown in the figure. The percentages in the lower boxes refer to the proportion of the corresponding pattern, which are counted from the training data of the target treebank with source annotations  $T^{+S}$ . We can see that the noisy source structures and the gold-standard target structures have 55.4% common dependencies. If the source structure does not belong to any of the listed five cases,  $\psi_{dep}(\mathbf{d}', h, m)$  returns “*else*” (12.9%). We could consider more complex structures, such as  $h$  being the grand grand father of  $m$ , but statistics show that more complex transformations become very scarce in the training data.

For the reason that dependency TPs can only model how one dependency in the target structure is transformed, we consider more complex transformations for the other two kinds of scoring parts of the target parser, i.e., the sibling and grand TPs shown in the bottom two rows. We only use high-frequency TPs of a proportion larger than 1.0%, aggregate others as “*else*”, which leaves us with 21 sibling TPs and 22 grand TPs.

Based on these TPs, we propose the QG features for enhancing the baseline parsing models, which are shown in Table 2. The type of the TP is conjoined with the related words and POS tags, such that the QG-enhanced parsing models can make more elaborate decisions based on the context. Then, the score contributed by the QG features can

be redefined as

$$\begin{aligned} Score_{qg}(\mathbf{x}, \mathbf{t}, \mathbf{d}', \mathbf{d}) = & \sum_{\{(h,m)\} \subseteq \mathbf{d}} \mathbf{w}_{qg-dep} \cdot \mathbf{f}_{qg-dep}(\mathbf{x}, \mathbf{t}, \mathbf{d}', h, m) \\ & + \sum_{\{(h,s),(h,m)\} \subseteq \mathbf{d}} \mathbf{w}_{qg-sib} \cdot \mathbf{f}_{qg-sib}(\mathbf{x}, \mathbf{t}, \mathbf{d}', h, s, m) \\ & + \sum_{\{(g,h),(h,m)\} \subseteq \mathbf{d}} \mathbf{w}_{qg-grd} \cdot \mathbf{f}_{qg-grd}(\mathbf{x}, \mathbf{t}, \mathbf{d}', g, h, m) \end{aligned}$$

which resembles the baseline model and can be naturally handled by the decoding algorithms.

## 5 Experiments and Analysis

We use the CDT as the source treebank (Liu et al., 2006). CDT consists of 60,000 sentences from the People’s Daily in 1990s. For the target treebank, we use two widely used versions of Penn Chinese Treebank, i.e., CTB5 and CTB6, which consist of Xinhua newswire, Hong Kong news and articles from Sinarama news magazine (Xue et al., 2005). To facilitate comparison with previous results, we follow Zhang and Clark (2008b) for data split and constituency-to-dependency conversion of CTB5. CTB6 is used as the Chinese data set in the CoNLL 2009 shared task (Hajič et al., 2009). Therefore, we adopt the same setting.

CDT and CTB5/6 adopt different POS tag sets, and converting from one tag set to another is difficult (Niu et al., 2009).<sup>5</sup> To overcome this problem, we use the People’s Daily corpus (PD),<sup>6</sup> a large-scale corpus annotated with word segmentation and POS tags, to train a statistical POS tagger. The tagger produces a universal layer of POS tags for both the source and target treebanks. Based on the common tags, the source parser projects the source annotations into the target treebanks. PD comprises approximately 300 thousand sentences of with approximately 7 million words from the first half of 1998 of People’s Daily.

Table 3 summarizes the data sets used in the present work. CTB5X is the same with CTB5 but follows the data split of Niu et al. (2009). We use CTB5X to compare our approach with their treebank conversion method (see Table 9).

<sup>5</sup>The word segmentation standards of the two treebanks also slightly differs, which are not considered in this work.

Table 2: QG features used to enhance the baseline parsing models.  $\text{dir}(h, m)$  denotes the direction of the dependency  $(h, m)$ , whereas  $\text{dist}(h, m)$  is the distance  $|h - m|$ .  $\oplus \text{dir}(h, m) \circ \text{dist}(h, m)$  indicates that the features listed in the corresponding column are also conjoined with  $\text{dir}(h, m) \circ \text{dist}(h, m)$  to form new features.

Corpus	Train	Dev	Test
PD	281,311	5,000	10,000
CDT	55,500	1,500	3,000
CTB5	16,091	803	1,910
CTB5X	18,104	352	348
CTB6	22,277	1,762	2,556

Table 3: Data used in this work (in sentence number).

We adopt *unlabeled attachment score* (UAS) as the primary evaluation metric. We also use *Root accuracy* (RA) and *complete match rate* (CM) to give more insights. All metrics exclude punctuation. We adopt Dan Bikel’s randomized parsing evaluation comparator for significance test (Noreen, 1989).<sup>7</sup>

For all models used in current work (POS tagging and parsing), we adopt averaged perceptron to train the feature weights (Collins, 2002). We train each model for 10 iterations and select the parameters that perform best on the development set.

## 5.1 Preliminaries

This subsection describes how we project the source annotations into the target treebanks. First, we train a statistical POS tagger on the training set of PD, which we name *Tagger<sup>PD</sup>*.<sup>8</sup> The tagging accuracy on the test set of PD is 98.30%.

We then use *Tagger<sup>PD</sup>* to produce POS tags for all the treebanks (CDT, CTB5, and CTB6).

Based on the common POS tags, we train a second-order source parser (O2) on CDT, denoted by *Parser<sup>CDT</sup>*. The UAS on CDT-test is 84.45%. We then use *Parser<sup>CDT</sup>* to parse CTB5 and CTB6.

<sup>7</sup>[http://www.cis.upenn.edu/\[normal-wave~\]dbikel/software.html](http://www.cis.upenn.edu/[normal-wave~]dbikel/software.html)

<sup>8</sup>We adopt the Chinese-oriented POS tagging features proposed in Zhang and Clark (2008a).

Models	without QG	with QG
O2	86.13	86.44 (+0.31, $p = 0.06$ )
O2sib	85.63	86.17 (+0.54, $p = 0.003$ )
O1	83.16	84.40 (+1.24, $p < 10^{-5}$ )
Li11	86.18	—
Z&N11	86.00	—

Table 4: Parsing accuracy (UAS) comparison on CTB5-test with gold-standard POS tags. Li11 refers to the second-order graph-based model of Li et al. (2011), whereas Z&N11 is the feature-rich transition-based model of Zhang and Nivre (2011).

At this point, both CTB5 and CTB6 contain dependency structures conforming to the style of CDT.

## 5.2 CTB5 as the Target Treebank

Table 4 shows the results when the gold-standard POS tags of CTB5 are adopted by the parsing models. We aim to analyze the efficacy of QG features under the ideal scenario wherein the parsing models suffer from no error propagation of POS tagging. We determine that our baseline O2 model achieves comparable accuracy with the state-of-the-art parsers. We also find that QG features can boost the parsing accuracy by a large margin when the baseline parser is weak (O1). The improvement shrinks for stronger baselines (O2sib and O2). This phenomenon is understandable. When gold-standard POS tags are available, the baseline features are very reliable and the QG features becomes less helpful for more complex models. The p-values in parentheses present the statistical significance of the improvements.

We then turn to the more realistic scenario wherein the gold-standard POS tags of the target treebank are unavailable. We train a POS tagger on the training set of CTB5 to produce the automatic

Models	without QG	with QG
O2	79.67	81.04 (+1.37)

O1	76.73	79.04 (+2.31)
Li11 joint	80.79	—
Li11 pipeline	79.29	—

Table 5: Parsing accuracy (UAS) comparison on CTB5-test with automatic POS tags. The improvements shown in parentheses are all statistically significant ( $p < 10^{-5}$ ).

Setting	UAS	CM	RA
$\mathbf{f}_{bs}(\cdot)$	79.67	26.81	73.82
$\mathbf{f}_{qg}(\cdot)$	79.15	26.34	74.71
$\mathbf{f}_{bs}(\cdot) + \mathbf{f}_{qg}(\cdot)$	81.04	29.63	77.17
$\mathbf{f}_{bs}(\cdot) + \mathbf{f}_{qg-dep}(\cdot)$	80.82	28.80	76.28
$\mathbf{f}_{bs}(\cdot) + \mathbf{f}_{qg-sib}(\cdot)$	80.86	28.48	76.18
$\mathbf{f}_{bs}(\cdot) + \mathbf{f}_{qg-grd}(\cdot)$	80.88	28.90	76.34

Table 6: Feature ablation for Parser-O2 on CTB5-test with automatic POS tags.

POS tags for the development and test sets of CTB5. The tagging accuracy is 93.88% on the test set. The automatic POS tags of the training set are produced using 10-fold cross-validation.<sup>9</sup>

Table 5 shows the results. We find that QG features result in a surprisingly large improvement over the O1 baseline and can also boost the state-of-the-art parsing accuracy by a large margin. Li et al. (2011) show that a joint POS tagging and dependency parsing model can significantly improve parsing accuracy over a pipeline model. Our QG-enhanced parser outperforms their best joint model by 0.25%. Moreover, the QG features can be used to enhance a joint model and achieve higher accuracy, which we leave as future work.

### 5.3 Analysis Using Parser-O2 with AUTO-POS

We then try to gain more insights into the effect of the QG features through detailed analysis. We select the state-of-the-art O2 parser and focus on the realistic scenario with automatic POS tags.

Table 6 compares the efficacy of different feature sets. The first major row analyzes the efficacy of

<sup>9</sup>We could use the POS tags produced by *Tagger<sup>PD</sup>* in Section 5.1, which however would make it difficult to compare our results with previous ones. Moreover, inferior results may be gained due to the differences between CTB5 and PD in word segmentation standards and text sources.

the basic features  $\mathbf{f}_{bs}(\cdot)$  and the QG features  $\mathbf{f}_{qg}(\cdot)$ . When using the few QG features in Table 2, the accuracy is very close to that when using the basic features. Moreover, using both features generates a large improvement. The second major row compares the efficacy of the three kinds of QG features corresponding to the three types of scoring parts. We can see that the three feature sets are similarly effective and yield comparable accuracies. Combining these features generate an additional improvement of approximately 0.2%. These results again demonstrate that all the proposed QG features are effective.

Figure 5 describes how the performance varies when the scale of CTB5 and CDT changes. In the left subfigure, the parsers are trained on part of the CTB5-train, and “16” indicates the use of all the training instances. Meanwhile, the source parser  $Parser^{CDT}$  is trained on the whole CDT-train. We can see that QG features render larger improvement when the target treebank is of smaller scale, which is quite reasonable. More importantly, the curves indicate that **a QG-enhanced parser trained on a target treebank of 16,000 sentences may achieve comparable accuracy with a baseline parser trained on a treebank that is double the size (32,000)**, which is very encouraging.

In the right subfigure, the target treebank is trained on the whole CTB5-train, whereas the source parser is trained on part of the CDT-train, and “55.5” indicates the use of all. The curve clearly demonstrates that the QG features are more helpful when the source treebank gets larger, which can be explained as follows. A larger source treebank can teach a source parser of higher accuracy; then, the better source parser can parse the target treebank more reliably; and finally, the target parser can better learn the annotation divergences based on QG features. These results demonstrate the effectiveness and stability of our approach.

Table 7 presents the detailed effect of the QG features on different dependency patterns. A pattern “VV  $\rightarrow$  NN” refers to a right-directed dependency with the head tagged as “VV” and the modifier tagged as “NN”. whereas “ $\leftarrow$ ” means left-directed. The “w/o QG” column shows the number of the corresponding dependency pattern that appears in the gold-standard trees but misses in the results of the baseline parser, whereas the signed figures in the “+QG” column are the changes made by the QG-

Figure 5: Parsing accuracy (UAS) comparison on CTB5-test when the scale of CDT and CTB5 varies (thousands in sentence number).

Dependency	w/o QG	+QG	Descriptions
NN ← NN	858	-78	noun modifier or coordinating nouns
VV → VV	777	-41	object clause or coordinating verbs
VV ← VV	570	-38	subject clause
VV → NN	509	-79	verb and its object
w <sub>0</sub> → VV	357	-57	verb as sentence root
VV ← NN	328	-32	attributive clause
P ← VV	278	-37	preposition phrase attachment
VV → DEC	233	-33	attributive clause and auxiliary DE
P → NN	175	-35	preposition and its object

Table 7: Detailed effect of QG features on different dependency patterns.

enhanced parser. We only list the patterns with an absolute change larger than 30. We find that the QG features can significantly help a variety of dependency patterns (i.e., reducing the missing number).

#### 5.4 CTB6 as the Target Treebank

We use CTB6 as the target treebank to further verify the efficacy of our approach. Compared with CTB5, CTB6 is of larger scale and is converted into dependency structures according to finer-grained head-finding rules (Hajič et al., 2009). We directly adopt the same transformation patterns and features tuned on CTB5. Table 8 shows results. The improvements are similar to those on CTB5, demonstrating that our approach is effective and robust. We list the top three systems of the CoNLL 2009 shared task in Table 8, showing that our approach also advances the state-of-the-art parsing accuracy on this data set.<sup>10</sup>

<sup>10</sup>We reproduce their UASs using the data released by the organizer: <http://ufal.mff.cuni.cz/conll2009-st/results/results.php>. The parsing accuracies of the top systems may be underestimated since the accuracy of the provided POS tags in CoNLL 2009 is only 92.38% on the test set, while the POS tagger used in our experiments reaches 94.08%.

Table 9: Parsing accuracy (UAS) comparison on the test set of CTB5X. Niu et al. (2009) use the maximum entropy inspired generative parser (GP) of Charniak (2000) as their constituent parser.

#### 5.5 Comparison with Treebank Conversion

As discussed in Section 2, Niu et al. (2009) automatically convert the dependency-structure CDT to the phrase-structure annotation style of CTB5X and use the converted treebank as additional labeled data. We convert their phrase-structure results on CTB5X-test into dependency structures using the same head-finding rules. To compare with their results, we run our baseline and QG-enhanced O2 parsers on CTB5X. Table 9 presents the results.<sup>11</sup> The indirect comparison indicates that our approach can achieve larger improvement than their treebank conversion based method.

## 6 Conclusions

The current paper proposes a simple and effective framework for exploiting multiple large-scale treebanks of different annotation styles. We design rich TPs to model the annotation inconsistencies and consequently propose QG features based on these TPs. Extensive experiments show that our approach can effectively utilize the syntactic knowledge from another treebank and significantly improve the state-of-the-art parsing accuracy.

<sup>11</sup>We thank the authors for sharing their results. Niu et al. (2009) also use the reranker (RP) of Charniak and Johnson (2005) as a stronger baseline, but the results are missing. They find a less improvement on F score with RP than with GP (0.9% vs. 1.1%). We refer to their Table 5 and 6 for details.

## Abstract

We present a statistical model for canonicalizing named entity mentions into a table whose rows represent entities and whose columns are attributes (or parts of attributes). The model is novel in that it incorporates entity context, surface features, first-order dependencies among attribute-parts, and a notion of noise. Transductive learning from a few seeds and a collection of mention tokens combines Bayesian inference and conditional estimation. We evaluate our model and its components on two datasets collected from political blogs and sports news, finding that it outperforms a simple agglomerative clustering approach and previous work.

## 1 Introduction

Proper handling of mentions in text of real-world entities—identifying and resolving them—is a central part of many NLP applications. We seek an algorithm that infers a set of real-world entities from mentions in a text, mapping each entity mention token to an entity, and discovers general categories of words used in names (e.g., titles and last names). Here, we use a probabilistic model to infer a structured representation of canonical forms of entity attributes through transductive learning from named entity mentions with a small number of seeds (see Table 1). The input is a collection of mentions found by a named entity recognizer, along with their contexts, and, following Eisenstein et al. (2011), the output is a table in which entities are rows (the number of which is not pre-specified) and attribute words are organized into columns.

This paper contributes a model that builds on the approach of Eisenstein et al. (2011), but also:

- incorporates context of the mention to help with disambiguation and to allow mentions that do not share words to be merged liberally;
- conditions against shape features, which improve the assignment of words to columns;

- is designed to explicitly handle some noise; and
- is learned using elements of Bayesian inference with conditional estimation (see §2).

We experiment with variations of our model, comparing it to a baseline clustering method and the model of Eisenstein et al. (2011), on two datasets, demonstrating improved performance over both at recovering a gold standard table. In a political blogs dataset, the mentions refer to political figures in the United States (e.g., Mrs. Obama and Michelle Obama). As a result, the model discovers parts of names—(Mrs., Michelle, Obama)—while simultaneously performing coreference resolution for named entity mentions. In the sports news dataset, the model is provided with named entity mentions of heterogeneous types, and success here consists of identifying the correct team for every player (e.g., Kobe Bryant and Los Angeles Lakers). In this scenario, given a few seed examples, the model begins to identify simple relations among named entities (in addition to discovering attribute structures), since attributes are expressed as named entities across multiple mentions. We believe this adaptability is important, as the salience of different kinds of names and their usages vary considerably across domains.

Table 1: Seeds for politics (above) and sports (below).

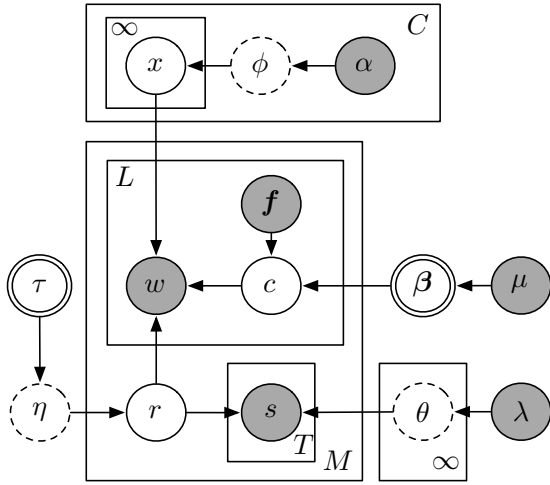

Figure 1: Graphical representation of our model. Top, the generation of the table:  $C$  is the number of attributes/columns, the number of rows is infinite,  $\alpha$  is a vector of concentration parameters,  $\phi$  is a multinomial distribution over strings, and  $x$  is a word in a table cell. Lower left, for choosing entities to be mentioned:  $\tau$  determines the stick lengths and  $\eta$  is the distribution over entities to be selected for mention. Middle right, for choosing attributes to use in a mention:  $f$  is the feature vector, and  $\beta$  is the weight vector drawn from a Laplace distribution with mean zero and variance  $\mu$ . Center, for generating mentions:  $M$  is the number of mentions in the data,  $w$  is a word token set from an entity/row  $r$  and attribute/column  $c$ . Lower right, for generating contexts:  $s$  is a context word, drawn from a multinomial distribution  $\theta$  with a Dirichlet prior  $\lambda$ . Variables that are known or fixed are shaded; variables that are optimized are double circled. Others are latent; dashed lines imply collapsing.

## 2 Model

We begin by assuming as input a set of mention tokens, each one or more words. In our experiments these are obtained by running a named entity recognizer. The output is a table in which rows are understood to correspond to entities (types, not mention tokens) and columns are fields, each associated with an attribute or a part of it. Our approach is based on a probabilistic graphical model that generates the mentions, which are observed, and the table, which is mostly unobserved, similar to Eisenstein et al. (2011). Our learning procedure is a hybrid of Bayesian inference and conditional estimation. The generative story, depicted in Figure 1, is:

- For each column  $j \in \{1, \dots, C\}$ :
  - Draw a multinomial distribution  $\phi_j$  over the

- vocabulary from a Dirichlet process:  $\phi_j \sim \text{DP}(\alpha_j, G_0)$ . This is the lexicon for field  $j$ .
- Generate table entries. For each row  $i$  (of which there are infinitely many), draw an entry  $x_{i,j}$  for cell  $i, j$  from  $\phi_j$ . A few of these entries (the seeds) are observed; we denote those  $\tilde{x}$ .
- Draw weights  $\beta_j$  that associate shape and positional features with columns from a 0-mean,  $\mu$ -variance Laplace distribution.
- Generate the distribution over entities to be mentioned in general text:  $\eta \sim \text{GEM}(\tau)$  (“stick-breaking” distribution).
- Generate context distributions. For each row  $r$ :
  - Draw a multinomial over the context vocabulary (distinct from mention vocabulary) from a Dirichlet distribution,  $\theta_r \sim \text{Dir}(\lambda)$ .
- For each mention token  $m$ :
  - Draw an entity/row  $r \sim \eta$ .
  - For each word in the mention  $w$ , given some of its features  $f$  (assumed observed):
    - ▷ Choose a column  $c \sim \frac{1}{Z} \exp(\beta_c^\top f)$ . This uses a log-linear distribution with partition function  $Z$ . In one variation of our model, first-order dependencies among the columns are enabled; these introduce a dynamic character to the graphical model that is not shown in Figure 1.
    - ▷ With probability  $1 - \epsilon$ , set the text  $w_{ml}$  to be  $x_{rc}$ . Otherwise, generate any word from a unigram-noise distribution.
  - Generate mention context. For each of the  $T = 10$  context positions (five before and five after the mention), draw the word  $s$  from  $\theta_r$ .

Our choices of prior distributions reflect our beliefs about the shapes of the various distributions. We expect field lexicons  $\phi_j$  and the distributions over mentioned entities  $\eta$  to be “Zipfian” and so use tools from nonparametric statistics to model them. We expect column-feature weights  $\beta$  to be mostly zero, so a sparsity-inducing Laplace prior is used (Tibshirani, 1996).

Our goal is to maximize the *conditional* likelihood of most of the evidence (mentions, contexts, and seeds),  $p(w, s, \tilde{x} \mid \alpha, \beta, \lambda, \tau, \mu, \epsilon, f) =$

$$\sum_r \sum_c \sum_{x \setminus \tilde{x}} \int d\theta \int d\eta \int d\phi p(w, s, r, c, x, \theta, \eta, \phi \mid \alpha, \beta, \lambda, \tau, \mu, \epsilon, f)$$

with respect to  $\beta$  and  $\tau$ . We fix  $\alpha$  (see §3.3 for the values of  $\alpha$  for each dataset),  $\lambda = 2$  (equivalent to add-one smoothing),  $\mu = 2 \times 10^{-8}$ ,  $\epsilon = 10^{-10}$ , and each mention word’s  $f$ . Fixing  $\lambda$ ,  $\mu$ , and  $\alpha$  is essentially just “being Bayesian,” or fixing a hyperparameter based on prior beliefs. Fixing  $f$  is quite different; it is conditioning our model on some observable features of the data, in this case word shape features. We do this to avoid integrating over feature vector values. These choices highlight that the design of a probabilistic model can draw from both Bayesian and discriminative tools. Observing some of  $x$  as seeds ( $\tilde{x}$ ) renders this approach transductive.

Exact inference in this model is intractable, so we resort to an approximate inference technique based on Markov Chain Monte Carlo simulation. The optimization of  $\beta$  can be described as “contrastive” estimation (Smith and Eisner, 2005), in which some aspects of the data are conditioned against for computational convenience. The optimization of  $\tau$  can be described as “empirical Bayesian” estimation (Morris, 1983) in which the parameters of a prior are fit to data. Our overall learning procedure is a Monte Carlo Expectation Maximization algorithm (Wei and Tanner, 1990).

### 3 Learning and Inference

Our learning procedure is an iterative algorithm consisting of two steps. In the E-step, we perform collapsed Gibbs sampling to obtain distributions over row and column indices for every mention, given the current value of the hyperparameters. In the M-step, we obtain estimates for the hyperparameters, given the current posterior distributions.

#### 3.1 E-step

For the  $m$ th mention, we sample row index  $r$ , then for each word  $w_{m\ell}$ , we sample column index  $c$ .

##### 3.1.1 Sampling Rows

Similar to Eisenstein et al. (2011), when we sample the row for a mention, we use Bayes’ rule and marginalize the columns. We further incorporate context information and a notion of noise.

$$p(r_m = r \mid \dots) \propto p(r_m = r \mid r_{-m}, \eta) \left( \prod_{\ell} \sum_c p(w_{m\ell} \mid x, r_m = r, c_{m\ell} = c) \right) \left( \prod_t p(s_{mt} \mid r_m = r) \right)$$

We consider each quantity in turn.

**Prior.** The probability of drawing a row index follows a stick breaking distribution. This allows us to have an unbounded number of rows and let the model infer the optimal value from data. A standard marginalization of  $\eta$  gives us:

$$p(r_m = r \mid r_{-m}, \tau) = \begin{cases} \frac{N_r^{-m}}{N + \tau} & \text{if } N_r^{-m} > 0 \\ \frac{\tau}{N + \tau} & \text{otherwise,} \end{cases}$$

where  $N$  is the number of mentions,  $N_r$  is the number of mentions assigned to row  $r$ , and  $N_r^{-m}$  is the number of mentions assigned to row  $r$ , excluding  $m$ .

**Mention likelihood.** In order to compute the likelihood of observing mentions in the dataset, we have to consider a few cases. If a cell in a table has already generated a word, it can only generate that word. This hard constraint was a key factor in the inference algorithm of Eisenstein et al. (2011); we speculate that softening it may reduce MCMC mixing time, so introduce a notion of noise. With probability  $\epsilon = 10^{-10}$ , the cell can generate any word. If a cell has not generated any word, its probability still depends on other elements of the table. With base distribution  $G_0$ ,<sup>1</sup> and marginalizing  $\phi$ , we have:

$$p(w_{m\ell} \mid x, r_m = r, c_{m\ell} = c, \alpha_c) = \begin{cases} 1 - \epsilon & \text{if } x_{rc} = w_{m\ell} \\ \epsilon & \text{if } x_{rc} \notin \{w_{m\ell}, \emptyset\} \\ \frac{N_{cw}^{-m\ell}}{N_c^{-m\ell} + \alpha_c} & \text{if } x_{rc} = \emptyset \text{ and } N_{cw} > 0 \\ G_0(w_{m\ell}) \frac{\alpha_c}{N_c^{-m\ell} + \alpha_c} & \text{if } x_{rc} = \emptyset \text{ and } N_{cw} = 0 \end{cases} \quad (1)$$

where  $N_c^{-m\ell}$  is the number of cells in column  $c$  that are not empty and  $N_{cw}^{-m\ell}$  is the number of cells in column  $c$  that are set to the word  $w_{m\ell}$ ; both counts excluding the current word under consideration.

**Context likelihood.** It is important to be able to use context information to determine which row a mention should go into. As a novel extension, our model also uses surrounding words of a mention as its “context”—similar context words can encourage two mentions that do not share any words to be merged. We choose a Dirichlet-multinomial distribution for our context distribution. For every row in the table, we have a multinomial distribution over context vocabulary  $\theta_r$  from a Dirichlet prior  $\lambda$ .

<sup>1</sup>We let  $G_0$  be a uniform distribution over the vocabulary.

Therefore, the probability of observing the  $t$ th context word for mention  $m$  is  $p(s_{mt} | r_m = r, \lambda)$

$$= \begin{cases} \frac{N_r^{-mt} + \lambda_s - 1}{N_r^{-mt} + \sum_v \lambda_v - V} & \text{if } N_r^{-mt} > 0 \\ \frac{\lambda_s - 1}{\sum_v \lambda_v - V} & \text{otherwise,} \end{cases}$$

where  $N_r^{-mt}$  is the number of context words of mentions assigned to row  $r$ ,  $N_{rs}^{-mt}$  is the number of context words of mentions assigned to row  $r$  that are  $s_{mt}$ , both excluding the current context word, and  $v$  ranges over the context vocabulary of size  $V$ .

### 3.1.2 Sampling Columns

Our column sampling procedure is novel to this work and substantially differs from that of Eisenstein et al. (2011). First, we note that when we sample column indices for each word in a mention, the row index for the mention  $r$  has already been sampled. Also, our model has interdependencies among column indices of a mention.<sup>2</sup> Standard Gibbs sampling procedure breaks down these dependencies. For faster mixing, we experiment with first-order dependencies between columns when sampling column indices. This idea was suggested by Eisenstein et al. (2011, footnote 1) as a way to learn structure in name conventions. We suppressed this aspect of the model in Figure 1 for clarity.

We sample the column index  $c_1$  for the first word in the mention, marginalizing out probabilities of other words in the mention. After we sample the column index for the first word, we sample the column index  $c_2$  for the second word, fixing the previous word to be in column  $c_1$ , and marginalizing out probabilities of  $c_3, \dots, c_L$  as before. We repeat the above procedure until we reach the last word in the mention. In practice, this can be done efficiently using backward probabilities computed via dynamic programming. This kind of blocked Gibbs sampling was proposed by Jensen et al. (1995) and used in NLP by Mochihashi et al. (2009). We have:

$$p(c_{ml} = c | \mathbf{f}_{ml}, \beta) p(c_{ml} = c | c_{ml_-} = c_-) \left( \sum_{c_+} p_b(c_{ml} = c | c_{ml_+} = c_+) \right) p(w_{ml} | x, r_m = r, c_{ml} = c, \alpha_c),$$

<sup>2</sup>As shown in Figure 1, column indices in a mention form “v-structures” with the row index  $r$ . Since every  $w_\ell$  is observed, there is an active path that goes through all these nodes.

where  $\ell_-$  is the preceding word and  $c_-$  is its sampled index,  $\ell_+$  is the following word and  $c_+$  is its possible index, and  $p_b(\cdot)$  are backward probabilities. Alternatively, we can perform standard Gibbs sampling and drop the dependencies between columns, which makes the model rely more heavily on the features. For completeness, we detail the computations.

**Featurized log linear distribution.** Our model can use arbitrary features to choose a column index. These features are incorporated as a log-linear distribution,  $p(c_{ml} = c | \mathbf{f}_{ml}, \beta) = \frac{\exp(\beta_c^\top \mathbf{f}_{ml})}{\sum_{c'} \exp(\beta_{c'}^\top \mathbf{f}_{ml})}$ . The list of features used in our experiments is:  $\mathbf{1}\{w$  is the first word in the mention};  $\mathbf{1}\{w$  ends with a period};  $\mathbf{1}\{w$  is the last word in the mention};  $\mathbf{1}\{w$  is a Roman numeral};  $\mathbf{1}\{w$  starts with an upper-case letter};  $\mathbf{1}\{w$  is an Arabic number};  $\mathbf{1}\{w \in \{\text{mr, mrs, ms, miss, dr, mdm}\}$ };  $\mathbf{1}\{w$  contains  $\geq 1$  punctuation symbol};  $\mathbf{1}\{w \in \{\text{jr, sr}\}$ };  $\mathbf{1}\{w \in \{\text{is, in, of, for}\}$ };  $\mathbf{1}\{w$  is a person entity};  $\mathbf{1}\{w$  is an organization entity}.

**Forward and backward probabilities.** Since we introduce first-order dependencies between columns, we have forward and backward probabilities, as in HMMs. However, we always sample from left to right, so we do not need to marginalize random variables to the left of the current variable because their values are already sampled. Our transition probabilities are as follows:

$$p(c_{ml} = c | c_{ml_-} = c_-) = \frac{N_{c_-,c}^{-m}}{\sum_{c'_-} N_{c'_-,c}^{-m}},$$

where  $N_{c_-,c}^{-m}$  is the number of times we observe transitions from column  $c_-$  to  $c$ , excluding mention  $m$ . The forward and backward equations are simple (we omit them for space).

**Mention likelihood.** Mention likelihood  $p(w_{ml} | x, r_m = r, c_{ml} = c, \alpha_c)$  is identical to when we sample the row index (Eq. 1).

## 3.2 M-step

In the M-step, we use gradient-based optimization routines, L-BFGS (Liu and Nocedal, 1989) and OWL-QN (Andrew and Gao, 2007) respectively, to maximize with respect to  $\tau$  and  $\beta$ .

### 3.3 Implementation Details

We ran Gibbs sampling for 500 iterations,<sup>3</sup> discarding the first 200 for burn-in and averaging counts over every 10th sample to reduce autocorrelation.

For each word in a mention  $w$ , we introduced 12 binary features  $f$  for our featurized log-linear distribution (§3.1.2).

We then downcased all words in mentions for the purpose of defining the table and the mention words  $w$ . Ten context words (5 each to the left and right) define  $s$  for each mention token.

For non-convex optimization problems like ours, initialization is important. To guide the model to reach a good local optimum without many restarts, we manually initialized feature weights and put a prior on transition probabilities to reflect phenomena observed in the initial seeds. The initializer was constructed once and not tuned across experiments.<sup>4</sup> The M-step was performed every 50 Gibbs sampling iterations. After inference, we filled each cell with the word that occurred at least 80% of the time in the averaged counts for the cell, if such a word existed.

## 4 Experiments

We compare several variations of our model to Eisenstein et al. (2011) (the authors provided their implementation to us) and a clustering baseline.

### 4.1 Datasets

We collected named entity mentions from two corpora: political blogs and sports news. The political blogs corpus is a collection of blog posts about politics in the United States (Eisenstein and Xing, 2010), and the sports news corpus contains news summaries of major league sports games (National Basketball

<sup>3</sup>On our moderate-sized datasets (see §4.1), each iteration takes approximately three minutes on a 2.2GHz CPU.

<sup>4</sup>For the politics dataset, we set  $C = 6$ ,  $\alpha = \langle 1.0, 1.0, 10^{-12}, 10^{-15}, 10^{-12}, 10^{-8} \rangle$ , initialized  $\tau = 1$ , and used a Dirichlet prior on transition counts such that before observing any data:  $N_{0,1} = 10, N_{0,5} = 5, N_{2,0} = 10, N_{2,1} = 10, N_{2,3} = 10, N_{2,4} = 5, N_{3,0} = 10, N_{3,1} = 10, N_{5,1} = 15$  (others are set to zero). For the sports dataset, we set  $C = 5$ ,  $\alpha = \langle 1.0, 1.0, 10^{-15}, 10^{-6}, 10^{-6} \rangle$ , initialized  $\tau = 1$ , and used a Dirichlet prior on transition counts  $N_{0,1} = 10, N_{2,3} = 20, N_{3,4} = 10$  (others are set to zero). We also manually initialized the weights of some features  $\beta$  for both datasets. These values were obtained from preliminary experiments on a smaller sample of the datasets, and updated on the first EM iteration.

	Politics	Sports
# source documents	3,000	700
# mentions	10,647	13,813
# unique mentions	528	884
size of mention vocabulary	666	1,177
size of context vocabulary	2,934	2,844

Table 2: Descriptive statistics about the datasets.

Association, National Football League, and Major League Baseball) in 2009. Due to the large size of the corpora, we uniformly sampled a subset of documents for each corpus and ran the Stanford NER tagger (Finkel et al., 2005), which tagged named entities mentions as person, location, and organization. We used named entity of type person from the political blogs corpus, while we are interested in person and organization entities for the sports news corpus. Mentions that appear less than five times are discarded. Table 2 summarizes statistics for both datasets of named entity mentions.

**Reference tables.** We use Eisenstein et al.’s manually built 125-entity (282 vocabulary items) reference table for the politics dataset. Each entity in the table is represented by the set of all tokens that appear in its references, and the tokens are placed in its correct column. For the sports data, we obtained a roster of all NBA, NFL, and MLB players in 2009. We built our sports reference table using the players’ names, teams and locations, to get 3,642 players and 15,932 vocabulary items. The gold standard table for the politics dataset is incomplete, whereas it is complete for the sports dataset.

**Seeds.** Table 1 shows the seeds for both datasets.

### 4.2 Evaluation Scores

We propose both a row evaluation to determine how well a model disambiguates entities and merges mentions of the same entity and a column evaluation to measure how well the model relates words used in different mentions. Both scores are new for this task.

The first step in evaluation is to find a maximum score bipartite matching between rows in the response and reference table.<sup>5</sup> Given the response and

<sup>5</sup>Treating each row as a set of words, we can optimize the matching using the Jonker and Volgenant (1987) algorithm. The column evaluation is identical, except that sets of words that are matched are defined by columns. We use the Jaccard similarity—for two sets  $A$  and  $B$ ,  $\frac{|A \cap B|}{|A \cup B|}$ —for our similarity function,  $\text{Sim}(i, j)$ .

reference tables,  $x_{res}$  and  $x_{ref}$ , we can compute:

$$S_{res} = \frac{1}{|x_{res}|} \sum_{i \in x_{res}, j \in x_{ref}: \text{Match}(i, j) = 1} \text{Sim}(i, j)$$

$$S_{ref} = \frac{1}{|x_{ref}|} \sum_{i \in x_{res}, j \in x_{ref}: \text{Match}(i, j) = 1} \text{Sim}(i, j)$$

where  $i$  and  $j$  denote rows,  $\text{Match}(i, j)$  is one if  $i$  and  $j$  are matched to each other in the optimal matching or zero otherwise.  $S_{res}$  is a precision-like score, and  $S_{ref}$  is a recall-like score.<sup>6</sup> Column evaluation is the same, but compares columns instead.

### 4.3 Baselines

Our simple baseline is an agglomerative clustering algorithm that clusters mentions into entities using the single-linkage criterion. Initially, each unique mention forms its own cluster that we incrementally merge together to form rows in the table. This method requires a similarity score between two clusters. For the politics dataset, we follow Eisenstein et al. (2011) and use the string edit distance between mention strings in each cluster to define the score. For the sports dataset, since mentions contain person and organization named entity types, our score for clustering uses the Jaccard distance between context words of the mentions. However, such clusterings do not produce columns. Therefore, we first match words in mentions of type person against a regular expression to recognize entity attributes from a fixed set of titles and suffixes, and the first, middle and last names. We treat words in mentions of type organization as a single attribute.<sup>7</sup> As we merge clusters together, we arrange words such that

<sup>6</sup>Eisenstein et al. (2011) used precision and recall for their similarity function. Precision prefers a more compact response row (or column), which unfairly penalizes situations like those of our sports dataset, where rows are heterogeneous (e.g., including people and organizations). Consider a response table made up of two rows: (Kobe, Bryant) and (Los, Angeles, Lakers), and a reference table containing all NBA players and their team names, e.g., (Kobe, Bryant, Los, Angeles, Lakers). Evaluating with the precision similarity function, we will have perfect precision by matching the first row to the reference row for Kobe Bryant and the latter row to any Lakers player. The system is not rewarded for merging the two rows together, even if they are describing the same entity. Our evaluation scores, however, reward the system for accurately filling in more cells.

<sup>7</sup>Note that the baseline system uses NER tags, list of titles and suffixes; which are also provided to our model through the features in §3.1.2.

all words within a column belong to the same attribute, creating columns as necessary to accommodate multiple similar attributes as a result of merging. We can evaluate the tables produced by each step of the clustering to obtain the entire sequence of response-reference scores.

As a strong baseline, we also compare our approach with the original implementation of the model of Eisenstein et al. (2011), denoted by EEA.

### 4.4 Results

For both the politics and sports dataset, we run the procedure in §3.3 three times and report the results.

**Politics.** The results for the politics dataset are shown in Figure 2. Our model consistently outperformed both baselines. We also analyze how much each of our four main extensions (shape features, context information, noise, and first-order column dependencies) to EEA contributes to overall performance by ablating each in turn (also shown in Fig. 2). The best-performing complete model has 415 rows, of which 113 were matched to the reference table. Shape features are useful: removing them was detrimental, and they work even better without column dependencies. Indeed, the best model did not have column dependencies. Removing context features had a strong negative effect, though perhaps this could be overcome with a more carefully tuned initializer.

In row evaluation, the baseline system can achieve a high reference score by creating one entity row per unique string, but as it merges strings, the clusters encompass more word tokens, improving response score at the expense of reference score. With fewer clusters, there are fewer entities in the response table for matching and the response score suffers. Although we use the same seed table in both experiments, the results from EEA are below the baseline curve because it has the additional complexity of inferring the number of columns from data. Our model is simpler in this regard since it assumes that the number of columns is known ( $C = 6$ ). In column evaluation, our method without column dependencies was best.

**Sports.** The results for the sports dataset are shown in Figure 3. Our best-performing complete model’s response table contains 599 rows, of which 561 were matched to the reference table. In row eval-

Figure 2: Row (left) and column (right) scores for the politics dataset. For all but “baseline” (clustering), each point denotes a unique sampling run. Note the change in scale in the left plot at  $y = 0.25$ . For the clustering baseline, points correspond to iterations.

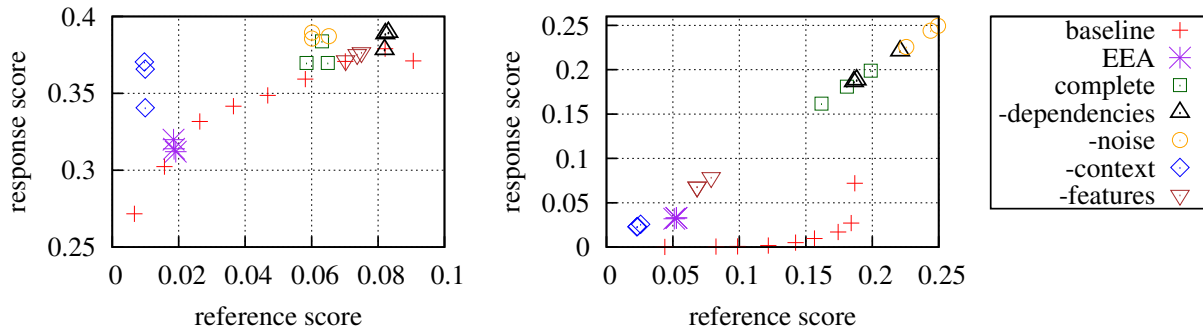

Figure 3: Row (left) and column (right) scores for the sports dataset. Each point denotes a unique sampling run. The reference score is low since the reference set includes all entities in the NBA, NFL, and MLB, but most of them were not mentioned in our dataset.

uation, our model lies above the baseline response-reference score curve, demonstrating its ability to correctly identify and combine player mentions with their team names. Similar to the previous dataset, our model is also substantially better in column evaluation, indicating that it mapped mention words into a coherent set of five columns.

#### 4.5 Discussion

The two datasets illustrate that our model adapts to somewhat different tasks, depending on its input. Furthermore, fixing  $C$  (unlike EEA) does appear to have benefits.

In the politics dataset, most of the mentions contain information about people. Therefore, besides canonicalizing named entities, the model also resolves within-document and cross-document coreference, since it assigned a row index for every mention. For example, our model learned that most mentions of John McCain, Sen. John McCain, Sen. McCain, and Mr. McCain refer to the same entity. Table 3 shows a few noteworthy entities from our complete model’s output table.

Barack	Obama	Mr.	Sen.		Hussein
Michelle	Obama	Mrs.			
Norm	Coleman		Sen.		
Sarah	Palin	Ms.			
John	McCain	Mr.	Sen.		Hussein

Table 3: A small segment of the output table for the politics dataset, showing a few noteworthy correct (blue) and incorrect (red) examples. Black indicates seeds. Though Ms. is technically correct, there is variation in preferences and conventions. Our data include eight instances of Ms. Palin and none of Mrs. Palin or Mrs. Sarah Palin.

The first entity is an easy example since it only had to complete information provided in the seed table. The model found the correct gender-specific title for Barack Obama, Mr.. The rest of the examples were fully inferred from the data. The model was essentially correct for the second, third, and fourth entities. The last row illustrates a partially erroneous example, in which the model confused the middle name of John McCain, possibly because of a combination of a strong prior to reuse this row and the

Derek	Jeter	New	York	
Ben	Roethlisberger		Pittsburgh	Steelers
Alex	Rodriguez	New	York	Yankees
Michael	Vick		Philadelphia	Eagles
Kevin	Garnett	Los	Angeles	Lakers
Dave	Toub		The	Bears

Table 4: A small segment of the output table for the sports dataset, showing a few noteworthy correct (blue) and incorrect (red) examples. Black indicates seed examples.

introduction of a notion of noise.

In the sports dataset, persons and organizations are mentioned. Recall that success here consists of identifying the correct team for every player. The EEA model is not designed for this and performed poorly. Our model can do better, since it makes use of context information and features, and it can put a person and an organization in one row even though they do not share common words. Table 4 shows a few noteworthy entities from our complete model’s output.

Surprisingly, the model failed to infer that Derek Jeter plays for New York Yankees, although mentions of the organization New York Yankees can be found in our dataset. This is because the model did not see enough evidence to put them in the same row. However, it successfully inferred the missing information for Ben Roethlisberger. The next two rows show cases where our model successfully matched players with their teams and put each word token to its respective column. The most frequent error, by far, is illustrated in the fifth row, where a player is matched with a wrong team. Kevin Garnett plays for the Boston Celtics, not the Los Angeles Lakers. It shows that in some cases context information is not adequate, and a possible improvement might be obtained by providing more context to the model. The sixth row is interesting because Dave Toub is indeed affiliated with the Chicago Bears. However, when the model saw a mention token The Bears, it did not have any other columns to put the word token The, and decided to put it in the fourth column although it is not a location. If we added more columns, determiners could become another attribute of the entities that might go into one of these new columns.

## 5 Related Work

There has been work that attempts to fill predefined templates using Bayesian nonparametrics (Haghighi and Klein, 2010) and automatically learns template structures using agglomerative clustering (Chambers and Jurafsky, 2011). Charniak (2001) and El-sner et al. (2009) focused specifically on names and discovering their structure, which is a part of the problem we consider here. More similar to our work, Eisenstein et al. (2011) introduced a non-parametric Bayesian approach to extract structured databases of entities. A fundamental difference of our approach from any of the previous work is it maximizes conditional likelihood and thus allows beneficial incorporation of arbitrary features.

Our model is focused on the problem of canonicalizing mention strings into their parts, though its  $r$  variables (which map mentions to rows) could be interpreted as (within-document and cross-document) coreference resolution, which has been tackled using a range of probabilistic models (Li et al., 2004; Haghighi and Klein, 2007; Poon and Domingos, 2008; Singh et al., 2011). We have not evaluated it as such, believing that further work should be done to integrate appropriate linguistic cues before such an application.

## 6 Conclusions

We presented an improved probabilistic model for canonicalizing named entities into a table. We showed that the model adapts to different tasks depending on its input and seeds, and that it improves over state-of-the-art performance on two corpora.

## Acknowledgements

The authors thank Jacob Eisenstein and Tae Yano for helpful discussions and providing us with the implementation of their model, Tim Hawes for helpful discussions, Naomi Saphra for assistance in developing the gold standard for the politics dataset, and three anonymous reviewers for comments on an earlier draft of this paper. ## Abstract

In this paper we propose a method to automatically label multi-lingual data with named entity tags. We build on prior work utilizing Wikipedia metadata and show how to effectively combine the weak annotations stemming from Wikipedia metadata with information obtained through English-foreign language parallel Wikipedia sentences. The combination is achieved using a novel semi-CRF model for foreign sentence tagging in the context of a parallel English sentence. The model outperforms both standard annotation projection methods and methods based solely on Wikipedia metadata.

## 1 Introduction

Named Entity Recognition (NER) is a frequently needed technology in NLP applications. State-of-the-art statistical models for NER typically require a large amount of training data and linguistic expertise to be sufficiently accurate, which makes it nearly impossible to build high-accuracy models for a large number of languages.

Recently, there have been two lines of work which have offered hope for creating NER analyzers in many languages. The first has been to devise an algorithm to tag foreign language entities using metadata from the semi-structured Wikipedia repository: inter-wiki links, article categories, and cross-language links (Richman and Schone, 2008). The second has been to use parallel English-foreign language data, a high-quality NER tagger for English, and projected annotations for the foreign language (Yarowsky et al., 2001; Das and Petrov, 2011). Parallel data has also been used to improve existing monolingual taggers or other analyzers in two languages (Burkett et al., 2010a; Burkett et al., 2010b).

---

This research was conducted during the author's internship at Microsoft Research

The goal of this work is to create high-accuracy NER annotated data for foreign languages. Here we combine elements of both Wikipedia metadata-based approaches and projection-based approaches, making use of parallel sentences extracted from Wikipedia. We propose a statistical model which can combine the two types of information. Similarly to the joint model of Burkett et al. (2010a), our model can incorporate both monolingual and bilingual features in a log-linear framework. The advantage of our model is that it is much more efficient as it does not require summing over matchings of source and target entities. It is a conditional model for target sentence annotation given an aligned English source sentence, where the English sentence is used only as a source of features. Exact inference is performed using standard semi-markov CRF model inference techniques (Sarawagi and Cohen, 2004).

Our results show that the semi-CRF model improves on the performance of projection models by more than 10 points in F-measure, and that we can achieve tagging F-measure of over 91 using a very small number of annotated sentence pairs.

The paper is organized as follows: We first describe the datasets and task setting in Section 2. Next, we present our two baseline methods: A Wikipedia metadata-based tagger and a cross-lingual projection tagger in Sections 3 and 4, respectively. We present our direct semi-CRF tagging model in Section 5.

## 2 Data and task

As a case study, we focus on two very different foreign languages: Korean and Bulgarian. The English and foreign language sentences that comprise our training and test data are extracted from Wikipedia (<http://www.wikipedia.org>). Currently there are more than 3.8 million articles in the English Wikipedia, 125,000 in the Bulgarian Wikipedia, and 131,000 in the Korean Wikipedia.

Figure 1: A parallel sentence-pair showing gold-standard NE labels and word alignments.

To create our dataset, we followed Smith et al. (2010) to find parallel-foreign sentences using comparable documents linked by inter-wiki links. The approach uses a small amount of manually annotated article-pairs to train a document-level CRF model for parallel sentence extraction. A total of 13,410 English-Bulgarian and 8,832 English-Korean sentence pairs were extracted.

Of these, we manually annotated 91 English-Bulgarian and 79 English-Korean sentence pairs with source and target named entities as well as word-alignment links among named entities in the two languages. Figure 1 illustrates a Bulgarian-English sentence pair with alignment.

The named entity annotation scheme followed has the labels GPE (Geopolitical entity), PER (Person), ORG (Organization), and DATE. It is based on the MUC-7 annotation guidelines, and GPE is synonymous with Location. The annotation process was not as rigorous as one might hope, due to lack of resources. The English-Bulgarian and English-Korean datasets were labeled by one annotator each and then annotations on the English sentences were double-checked by the other annotator. Disagreements were rare and were resolved after discussion.

The task we evaluate on is tagging of foreign language sentences. We measure performance by labeled precision, recall, and F-measure. We give partial credit if entities partially overlap on their span of words and match on their labels.

Table 1 shows the total number of English, Bulgarian and Korean entities and the percentage of entities that were manually aligned to an entity of the same type in the other language. The data sizes are fairly small as the data is

Language	Entities	Aligned %
English	342	93.9%
Bulgarian	344	93.3%
English	414	88.4%
Korean	423	86.5%

Table 1: English-Bulgarian and English-Korean data characteristics.

used only to train models with very few coarse-grained features and for evaluation. These datasets are available at <http://research.microsoft.com/en-us/people/kristout/nerwikidownload.aspx>.

As we can see, less than 100% of entities have parallels in the other language. This is due to two phenomena: one is that the parallel sentences sometimes contain different amounts of information and one language might use more detail than the other. The other is that the same information might be expressed using a named entity in one language, and using a non-entity phrase in the other language (e.g. “He is from Bulgaria” versus “He is Bulgarian”). Both of these causes of divergence are much more common in the English-Korean dataset than in the English-Bulgarian one.

### 3 Wiki-based tagger: annotating sentences based on Wikipedia metadata

We followed the approach of Richman and Schone (2008) to derive named entity annotations of both English and foreign phrases in Wikipedia, using Wikipedia metadata. The following sources of information were used from Wikipedia: *category* annotations on English documents, *article links* which link from phrases in an article to another article in the same language, and *interwiki links* which link

### English candidate entities

*Local-wiki-links:* [Igor Tudor]-PER [16 April 1978]-DATE [Croatian]-GPE

*Global-wiki-links:* [Igor Tudor]-PER\* [16]-DATE\* [16]-GPE [April]-DATE [1978]-DATE\* [1978]-GPE [Split]-GPE [Croatian]-GPE\* [Croatian]-ORG [Igor]-PER

*Stanford tagger:* [Igor Tudor]-PER [April 1978]-DATE

### Bulgarian candidate entities

*Local-wiki-links:* [Игор Тудор]-PER [16 април]-DATE

*Global-wiki-links:* : [Игор Тудор]-PER [Игор]-PER [16]-DATE [16 април]-DATE

Figure 2: Candidate NEs for the English and Bulgarian sentences according to baseline taggers.

from articles in one language to comparable (semantically equivalent) articles in the other language. In addition to the Wikipedia-derived resources, the approach requires a manually specified map from English category key-phrases to NE tags, but does not require expert knowledge for any non-English language. We implemented the main ideas of the approach but some implementation details may differ.

To tag English language phrases, we first derived named entity categorizations of English article titles, by assigning a tag based on the article’s category information. The category-to-NE map used for the assignment is a small manually specified map from phrases appearing in category titles to NE tags. For example, if an article has categories “People by”, “People from”, “Surnames” etc., it is classified as PER. Looking at the example in Figure 1, the article with title “Igor Tudor” is classified as PER because one of its categories is “Living people”. The full map we use is taken from the paper (Richman and Schone, 2008).

Using the article-level annotations and *article links* we define a local English wiki-based tagger and a global English wiki-based tagger, which will be described in detail next.

**Local English Wiki-based tagger.** This Wiki-based tagger tags phrases in an English article based on the *article links* from these phrases to NE-tagged articles. For example, suppose that the phrase “Split” in the article with title “Igor Tudor” is linked to the article with title “Split”, which is classified as GPE. Thus the local English Wiki-based tagger can tag this phrase as GPE. If, within the same article, the phrase “Split” occurs again, it can be tagged again even if it is not linked to a tagged article (this is the one sense per document assumption). Addition-

ally, the tagger tags English phrases as DATE if they match a set of manually specified regular expressions. As a filter, phrases that do not contain a capitalized word or a number are not tagged with NE tags.

**Global English Wiki-based tagger.** This tagger tags phrases with NE tags if these phrases have ever been linked to a categorized article (the most frequent label is used). For example, if “Split” does not have a link anywhere in the current article, but has been linked to the GPE-labeled article with title “Split” in another article, it will still be tagged as GPE. We also apply a local+global Wiki-tagger, which tags entities according to the local Wiki-tagger and additionally tags any non-conflicting entities according to the global tagger.

**Local foreign Wiki-based tagger.** The idea is the same as for the local English tagger, with the difference that we first assign NE tags to foreign language articles by using the NE tags assigned to English articles to which they are connected with inter-wiki links. Because we do not have maps from category phrases to NE tags for foreign languages, using inter-wiki links is a way to transfer this knowledge to the foreign languages. After we have categorized foreign language articles we follow the same algorithm as for the local English Wiki-based tagger. For Bulgarian we also filtered out entities based on capitalization and numbers, but did not do that for Korean as it has no concept of capitalization.

**Global foreign Wiki-based tagger** The global and local+global taggers are analogous, using the categorization of foreign articles as above.

Figure 2 shows the tags assigned to English and Bulgarian strings according to the local and global Wiki-based taggers. The global Wiki-based tagger could assign multiple labels to the same string (corresponding to different senses in different occurrences). In case of multiple possible labels, the most frequent one is denoted by \* in the Figure. The Figure also shows the results of the Stanford NER tagger for English (Finkel et al., 2005) (we used the MUC-7 classifier).

Table 2 reports the performance of the local (L Wiki-tagger), local+global (LG Wiki tagger) and the Stanford tagger. We can see that the local Wiki taggers have higher precision but lower recall than the local+global Wiki taggers. The local+global taggers

Language	L Wiki-tagger			LG Wiki-tagger			Stanford Tagger		
	Prec	Rec	F1	Prec	Rec	F1	Prec	Rec	F1
English	92.8	75.1	83.0	79.7	89.5	<b>84.3</b>	86.5	77.5	81.7
Bulgarian	94.1	48.7	64.2	86.8	79.9	<b>83.2</b>			
English	92.6	75.6	83.2	84.1	86.7	<b>85.4</b>	82.2	71.9	76.7
Korean	89.5	57.3	<b>69.9</b>	43.2	78.0	55.6			

Table 2: English-Bulgarian and English-Korean Wiki-based tagger performance.

are overall best for English and Bulgarian. The local tagger is best for Korean, as the precision suffers too much due to the global tagger. This is perhaps due in part to the absence of the capitalization filter for Korean which improved precision for Bulgarian and English. The Stanford tagger is worse than the Wiki-based tagger, but it is different enough that it contributes useful information to the task.

## 4 Projection Model

From Table 2 we can see that the English Wiki-based taggers are better than the Bulgarian and Korean ones, which is due to the abundance and completeness of English data in Wikipedia. In such circumstances, previous research has shown that one can project annotations from English to the more resource-poor language (Yarowsky et al., 2001). Here we follow the approach of Feng et al. (2004) to train a log-linear model for projection.

Note that the Wiki-based taggers do not require training data and can be applied to any sentences from Wikipedia articles. The projection model described in this section and the Semi-CRF model described in Section 5 are trained using annotated data. They can be applied to tag foreign sentences in English-foreign sentence pairs extracted from Wikipedia.

The task of projection is re-cast as a ranking task, where for each source entity  $S_i$ , we rank all possible candidate target entity spans  $T_j$  and select the best span as corresponding to this source entity. Each target span is labeled with the NE label of the corresponding source entity. The probability distribution over target spans  $T_j$  for a given source entity  $S_i$  is defined as follows:

$$p(S_i|T_j) = \frac{\exp(\lambda f(S_i, T_j))}{\sum_{j'} \exp(\lambda f(S_i, T'_j))}$$

where  $\lambda$  is a parameter vector, and  $\mathbf{f}(S_i, T_j)$  is a fea-

ture vector for the candidate entity pair.

From this formulation we can see that a fixed set of English source entities  $S_i$  is required as input. The model projects these entities to corresponding foreign entities. We train and evaluate the projection model using 10-fold cross-validation on the dataset from Table 1. For training, we use the human-annotated gold English entities and the manually-specified entity alignments to derive corresponding target entities. At test time we use the local+global Wiki-based tagger to define the English entities and we don't use the manually annotated alignments.

### 4.1 Features

We present the features for this model in a lot of detail since analogous feature types are also used in our final direct semi-CRF model. The features are grouped into four categories.

#### Word alignment features

We exploit a feature set based on HMM word alignments in both directions (Och and Ney, 2000). To define the features we make use of the posterior alignment link probabilities as well as the most likely (Viterbi) alignments. The posterior probabilities are the probabilities of links in both directions given the source and target sentences:  $P(a_i = j|s, t)$  and  $P(a_j = i|s, t)$ .

If a source entity consists of positions  $i_1, \dots, i_m$  and a potential corresponding target entity consists of positions  $j_1, \dots, j_n$ , the word-alignment derived features are:

- Probability that each word from one of the entities is aligned to a word from the other entity, estimated as:

$\prod_{i \in i_1 \dots i_m} \sum_{j \in j_1 \dots j_n} P(a_i = j|s, t)$  We use an analogous estimate for the probability in the other direction.

- Sum of posterior probabilities of links from words inside one entity to words outside another entity  $\sum_{i \in i_1 \dots i_m} (1 - \sum_{j \in j_1 \dots j_n} P(a_i = j | s, t))$ . Probabilities from the other HMM direction are estimated analogously.
- Indicator feature for whether the source and target entity can be extracted as a phrase pair according to the combined Viterbi alignments (grow-diag-final) and the standard phrase extraction heuristic (Koehn et al., 2003).

### Phonetic similarity features

These features measure the similarity between a source and target entity based on pronunciation. We utilize a transliteration model (Cherry and Suzuki, 2009), trained from pairs of English person names and corresponding foreign language names, extracted from Wikipedia. The transliteration model can return an  $n$ -best list of transliterations of a foreign string, together with scores. For example the top 3 transliterations in English of the Bulgarian equivalent of “Igor Tudor” from Figure 1 are *Igor Twoodor*, *Igor Twoodore*, and *Igore Twoodore*.

We estimate phonetic similarity between a source and target entity by computing Levenshtein and other distance metrics between the source entity and the closest transliteration of the target (out of a 10-best list of transliterations). We use normalized and un-normalized Levenshtein distance. We also use a BLEU-type measure which estimates character  $n$ -gram overlap.

### Position/Length features

These report relative length and position of the English and foreign entity following (Feng et al., 2004).

### Wiki-based tagger features

These features look at the degree of match between the source and target entities based on the tags assigned to them by the local and global Wiki-taggers for English and the foreign language, and by the Stanford tagger for English. These are indicator features separate for the different source-target tagger combinations, looking at whether the taggers agree in their assignments to the candidate entities.

## 4.2 Model Evaluation

We evaluate the tagging F-measure for projection models on the English-Bulgarian and English-Korean datasets. 10-fold cross-validation was used to estimate model performance. The foreign language NE F-measure is reported in Table 3. The best Wiki-based tagger performance is shown on the last line as a baseline (repeated from Table 2).

We present a detailed evaluation of the model to gain understanding of the strengths and limitations of the projection approach and to motivate our direct semi-CRF model. To give an estimate of the upper bound on performance for the projection model, we first present two oracles. The goal of the oracles is to estimate the impact of two sources of error for the projection model: the first is the error in detecting English entities, and the second is the error in determining the corresponding foreign entity for a given English entity.

The first oracle ORACLE1 has access to the gold-standard English entities and gold-standard word alignments among English and foreign words. For each source entity, ORACLE1 selects the longest foreign language sequence of words that could be extracted in a phrase pair coupled with the source entity word sequence (according the standard phrase extraction heuristic (Koehn et al., 2003)), and labels it with the label of the source entity. Note that the word alignments do not uniquely identify the corresponding foreign phrase for each English phrase and some error is possible due to this. The performance of this oracle is closely related to the percentage of linked source-target entities reported in Table 1. The second oracle ORACLE2 provides the performance of the projection model when gold-standard source entities are known, but the corresponding target entities still have to be determined by the projection model (gold-standard alignments are not known). In other words, ORACLE2 is the projection model with all features, where in the test set we provide the gold standard English entities as input. The performance of ORACLE2 is determined by the error in automatic word alignment and in determining phonetic correspondence. As we can see the drop due to this error is very large, especially on Korean, where performance drops from 90.0 to 81.9 F-measure.

The next section in the Table presents the perfor-

Method	English-Bulgarian			English-Korean		
	Prec	Rec	F1	Prec	Rec	F1
ORACLE1	98.3	92.9	95.5	95.5	85.1	90.0
ORACLE2	96.7	86.3	91.2	90.5	74.7	81.9
PM-WF	71.7	80.0	75.7	85.1	72.2	78.1
PM+WF	73.6	81.3	77.2	87.6	74.9	<b>80.8</b>
Wiki-tagger	86.8	79.9	<b>83.2</b>	89.5	57.3	69.9

Table 3: English-Bulgarian and English-Korean Projection tagger performance.

mance of non-oracle projection models, which do not have access to any manually labeled information. The local+global Wiki-based tagger is used to define English entities, and only automatically derived alignment information is used. PM+WF is the projection model using all features. The line above, PM-WF represents the projection model without the Wiki-tagger derived features, and is included to show that the gain from using these features is substantial. The difference in accuracy between the projection model and ORACLE2 is very large, and is due to the error of the Wiki-based English taggers. The drop for Bulgarian is so large that the best projection model PM+WF does not reach the performance of 83.2 achieved by the baseline Wiki-based tagger. When source entities are assigned with error for this language pair, projecting entity annotations from the source is not better than using the target Wiki-based annotations directly. For Korean while the trend in model performance is similar as oracle information is removed, the projection model achieves substantially better performance (80.8 vs 69.9) due to the much larger difference in performance between the English and Korean Wiki-based taggers.

The drawback of the projection model is that it determines target entities only by assigning the best candidate for each source entity. It cannot create target entities that do not correspond to source entities, it is not able to take into account multiple conflicting source NE taggers as sources of information, and it does not make use of target sentence context and entity consistency constraints. To address these shortcomings we propose a direct semi-CRF model, described in the next section.

## 5 Semi-CRF Model

Semi-Markov conditional random fields (semi-CRFs) are a generalization of CRFs. They assign labels to segments of an input sequence  $\mathbf{x}$ , rather than

to individual elements  $x_i$  and features can be defined on complete segments. We apply Semi-CRFs to learn a NE tagger for labeling foreign sentences in the context of corresponding source sentences with existing NE annotations.

The semi-CRF defines a distribution over foreign sentence labeled segmentations (where the segments are named entities with their labels, or segments of length one with label “NONE”). To formally define the distribution, we introduce some notation following Sarawagi and Cohen (2005):

Let  $\mathbf{s} = \langle s_1, \dots, s_p \rangle$  denote a segmentation of the foreign sentence  $\mathbf{x}$ , where a segment  $s_j = \langle t_j, u_j, y_j \rangle$  is determined by its start position  $t_j$ , end position  $u_j$ , and label  $y_j$ . Features are defined on segments and adjacent segment labels. In our application, we only use features on segments. The features on segments can also use information from the corresponding English sentence  $\mathbf{e}$  along with external annotations on the sentence pair  $\mathbf{A}$ .

The feature vector for each segment can be denoted by  $F(j, \mathbf{s}, \mathbf{x}, \mathbf{e}, \mathbf{A})$  and the weight vector for features by  $\mathbf{w}$ . The probability of a segmentation is then defined as:

$$P(\mathbf{s}|\mathbf{x}, \mathbf{e}, \mathbf{A}) = \frac{\sum_j \exp \mathbf{w}' F(j, \mathbf{s}, \mathbf{x}, \mathbf{e}, \mathbf{A})}{Z(\mathbf{x}, \mathbf{e}, \mathbf{A})}$$

In the equation above  $Z$  represents a normalizer summing over valid segmentations.

### 5.1 Features

We use both boolean and real-valued features in the semi-CRF model. Example features and their values are given in Table 4. The features are the ones that fire on the segment of length 1 containing the Bulgarian equivalent of the word “Split” and labeled with label GPE ( $t_j=13, u_j=13, y_j=GPE$ ), from the English-Bulgarian sentence pair in Figure 1.

The features look at the English and foreign sentence as well as external annotations **A**. Note that the semi-CRF model formulation does not require a fixed labeling of the English sentence. Different and possibly conflicting NE tags for candidate English and foreign sentence substrings according to the Wiki-based taggers and the Stanford tagger are specified as one type of external annotations (see Figure 2). Another annotation type is derived from HMM-based word alignments and the transliteration model described in Section 4. They provide two kinds of alignment links between English and foreign tokens: one based on the HMM-word alignments (posterior probability of the link in both directions), and another based on different character-based distance metrics between transliterations of foreign words and English words. The transliteration model and distance metrics were described in Section 4 as well. For the example Bulgarian correspondent of “Split” in the figure, the English “Split” is linked to it according to both the forward and backward HMM, and according to two out of the three transliteration distance measures. A third annotation type is automatically derived links between foreign candidate entity strings (sequences of tokens) and best corresponding English candidate entities. The candidate English entities are defined by the union of entities proposed by the Wiki-based taggers and the Stanford tagger. Note that these English candidate entities can be overlapping and inconsistent without harming the model. We link foreign candidate segments with English candidate entities based on the projection model described in Section 4 and trained on the same data. The projection model scores every source-target entity pair and selects the best source for each target candidate entity. For our example target segment, the corresponding source candidate entity is “Split”, labeled GPE by the local+global Wiki-tagger and by the global Wiki-tagger.

The features are grouped into three categories:

**Group 1. Foreign Wiki-based tagger features.** These features look at target segments and extract indicators of whether the label of the segment agrees with the label assigned by the local, global, and/or local+global wiki tagger. For the example segment from the sentence in Figure 1, since neither the local nor global tagger have assigned a label GPE, the first three features have value zero. In addition to tags on

the whole segment, we look at tag combinations for individual words within the segment as well as two words to the left and right outside the segment. In the first section in Table 4 we can see several feature types and their values for our example.

**Group 2. Foreign surface-based features.** These features look at orthographic properties of the words and distinguish several word types. The types are based on capitalization and also distinguish numbers and punctuation. In addition, we make use of word-clusters generated by JCluster.<sup>1</sup>

We look at properties of the individual words as well as the concatenation for all words in the segment. In addition, there are features for words two words to the left and two words to the right outside the segment. The second section in the Table shows several features of this type with their values.

**Group 3. Label match between English and aligned foreign entities.** These features look at the linked English segment for the candidate target segment and compare the tags assigned to the English segment by the different English taggers to the candidate target label. In addition to segment-level comparisons, they also look at tag assignments for individual source tokens linked to the individual target tokens (by word alignment and transliteration links). The last section in the Table contains sample features with their values. The feature SOURCE-E-WIKI-TAG-MATCH looks at whether the corresponding source entity has the same local+global Wiki-tagger assigned tag as the candidate target entity. The next two features look at the Stanford tagger and the global Wiki-tagger. The real-valued features like SCORE-SOURCE-E-WIKI-TAG-MATCH return the score of the matching between the source and target candidate entities (according to the projection model), if the labels match. In this way, more confident matchings can impact the target tags more than less confident ones.

## 5.2 Experimental results

Our main results are listed in Table 5. We perform 10-fold cross-validation as in the projection experiments. The best Wiki-based and projection models are listed as baselines at the bottom of the table.

Table 4: Features with example values.

We look at performance using four sets of features: (i) Monolingual Wiki-tagger based, using only the features in Group 1 (MONO); (ii) Bilingual label match and Wiki-tagger based, using features in Groups 1 and 3 (BI); (iii) Monolingual all, using features in Groups 1 and 2 (MONO-ALL), and (iv) Bilingual all, using all features (BI-ALL). Additionally, we report performance of the full bilingual model with all features, but when English candidate entities are generated only according to the local+global Wiki-tagger (BI-ALL-WT).

The main results show that the full semi-CRF model greatly outperforms the baseline projection and Wiki-taggers. For Bulgarian, the F-measure of the full model is 92.8 compared to the best baseline result of 83.2. For Korean, the F-measure of the semi-CRF is 91.2, more than 10 points higher than the performance of the projection model.

Within the semi-CRF model, the contribution of English sentence context was substantial, leading to 2.5 point increase in F-measure for Bulgarian (92.8 versus 90.3 F-measure), and 4.0 point increase for Korean (91.2 versus 87.2).

The additional gain due to considering candidate source entities generated from all English taggers was 1.3 F-measure points for both language pairs (comparing models BI-ALL and BI-ALL-WT).

If we restrict the semi-CRF to use only features similar to the ones used by the projection model, we still obtain performance much better than that of the projection model: comparing BI to the projection model, we see gains of 9.4 points for Bulgarian, and 4 points for Korean. This is due to the fact that the semi-CRF is able to relax the assumption of one-to-one correspondence between source and target entities, and can effectively combine information from multiple source and target taggers.

We should note that the proposed method can only tag foreign sentences in English-foreign sentence pairs. The next step for this work is to train monolingual NE taggers for the foreign languages, which can work on text within or outside of Wikipedia. Preliminary results show performance of over 80 F-measure for such monolingual models.

## 6 Related Work

As discussed throughout the paper, our model builds upon prior work on Wikipedia metadata-based NE tagging (Richman and Schone, 2008) and cross-lingual projection for named entities (Feng et al., 2004). Other interesting work on aligning named entities in two languages is reported in (Huang and Vogel, 2002; Moore, 2003).

Our direct semi-CRF tagging approach is related to bilingual labeling models presented in previous

work (Burkett et al., 2010a; Smith and Smith, 2004; Snyder and Barzilay, 2008). All of these models jointly label aligned source and target sentences. In contrast, our model is not concerned with tagging English sentences but only tags foreign sentences in the context of English sentences. Compared to the joint log-linear model of Burkett et al. (2010a), our semi-CRF approach does not require enumeration of  $n$ -best candidates for the English sentence and is not limited to  $n$ -best candidates for the foreign sentence. It enables the use of multiple unweighted and overlapping entity annotations on the English sentence.

## 7 Conclusions

In this paper we showed that using resources from Wikipedia, it is possible to combine metadata-based approaches and projection-based approaches for inducing named entity annotations for foreign languages. We presented a direct semi-CRF tagging model for labeling foreign sentences in parallel sentence pairs, which outperformed projection by more than 10 F-measure points for Bulgarian and Korean.

## Abstract

In this paper, we propose a computational approach to generate neologisms consisting of homophonic puns and metaphors based on the category of the service to be named and the properties to be underlined. We describe all the linguistic resources and natural language processing techniques that we have exploited for this task. Then, we analyze the performance of the system that we have developed. The empirical results show that our approach is generally effective and it constitutes a solid starting point for the automation of the naming process.

## 1 Introduction

A catchy, memorable and creative name is an important key to a successful business since the name provides the first image and defines the identity of the service to be promoted. A good name is able to state the area of competition and communicate the promise given to customers by evoking semantic associations. However, finding such a name is a challenging and time consuming activity, as only few words (in most cases only one or two) can be used to fulfill all these objectives at once. Besides, this task requires a good understanding of the service to be promoted, creativity and high linguistic skills to be able to play with words. Furthermore, since many new products and companies emerge every year, the naming style is continuously changing and creativity standards need to be adapted to rapidly changing requirements.

The creation of a name is both an art and a science (Keller, 2003). Naming has a precise methodology

and effective names do not come out of the blue. Although it might not be easy to perceive all the effort behind the naming process just based on the final output, both a training phase and a long process consisting of many iterations are certainly required for coming up with a good name.

From a practical point of view, naming agencies and branding firms, together with automatic name generators, can be considered as two alternative services that facilitate the naming process. However, while the first type is generally expensive and processing can take rather long, the current automatic generators are rather naïve in the sense that they are based on straightforward combinations of random words. Furthermore, they do not take semantic reasoning into account.

To overcome the shortcomings of these two alternative ways (i.e. naming agencies and naïve generators) that can be used for obtaining name suggestions, we propose a system which combines several linguistic resources and natural language processing (NLP) techniques to generate creative names, more specifically neologisms based on homophonic puns and metaphors. In this system, similarly to the previously mentioned generators, users are able to determine the category of the service to be promoted together with the features to be emphasized. Our improvement lies in the fact that instead of random generation, we take semantic, phonetic, lexical and morphological knowledge into consideration to automatize the naming process.

Although various resources provide distinct tips for inventing creative names, no attempt has been made to combine all means of creativity that can be used during the naming process. Furthermore, in addition to the devices stated by copywriters, there

might be other latent methods that these experts unconsciously use. Therefore, we consider the task of discovering and accumulating all crucial features of creativity to be essential before attempting to automatize the naming process. Accordingly, we create a gold standard of creative names and the corresponding creative devices that we collect from various sources. This resource is the starting point of our research in linguistic creativity for naming.

The rest of the paper is structured as follows. First, we review the state-of-the-art relevant to the naming task. Then, we give brief information about the annotation task that we have conducted. Later on, we describe the model that we have designed for the automatization of the naming process. Afterwards, we summarize the annotation task that we have carried out and analyze the performance of the system with concrete examples by discussing its virtues and limitations. Finally, we draw conclusions and outline ideas for possible future work.

## 2 Related Work

In this section, we will analyze the state of the art concerning the naming task from three different aspects: i) linguistic ii) computational iii) commercial.

### 2.1 Linguistic

Little research has been carried out to investigate the linguistic aspects of the naming mechanism. B. V. Bergh (1987) built a four-fold linguistic topology consisting of phonetic, orthographic, morphological and semantic categories to evaluate the frequency of linguistic devices in brand names. Bao et al. (2008) investigated the effects of relevance, connotation, and pronunciation of brand names on preferences of consumers. Klink (2000) based his research on the area of sound symbolism (i.e. “the direct linkage between sound and meaning” (Leanne Hinton, 2006)) by investigating whether the sound of a brand name conveys an inherent meaning and the findings showed that both vowels and consonants of brand names communicate information related to products when no marketing communications are available. Kohli et al. (2005) analyzed consumer evaluations of meaningful and non-meaningful brand names and the results suggested that non-meaningful brand names are evaluated less favorably than meaningful ones even after repeated exposure. Lastly, cog (2011) focused on the semantics of branding and based on the analysis of several

international brand names, it was shown that cognitive operations such as domain reduction/expansion, mitigation, and strengthening might be used unconsciously while creating a new brand name.

### 2.2 Computational

To the best of our knowledge, there is only one computational study in the literature that can be applied to the automatization of name generation. Stock and Strapparava (2006) introduce an acronym ironic re-analyzer and generator called HAHAcronym. This system both makes fun of existing acronyms, and produces funny acronyms that are constrained to be words of the given language by starting from concepts provided by users. HAHAcronym is mainly based on lexical substitution via semantic field opposition, rhyme, rhythm and semantic relations such as antonyms retrieved from WordNet (Stark and Riesefeld, 1998) for adjectives.

As more naïve solutions, automatic name generators can be used as a source of inspiration in the brainstorming phase to get ideas for good names. As an example, [www.business-name-generators.com](http://www.business-name-generators.com) randomly combines abbreviations, syllables and generic short words from different domains to obtain creative combinations. The domain generator on [www.namestation.com](http://www.namestation.com) randomly generates name ideas and available domains based on alliterations, compound words and custom word lists. Users can determine the prefix and suffix of the names to be generated. The brand name generator on [www.netsubstance.com](http://www.netsubstance.com) takes keywords as inputs and here users can configure the percentage of the shifting of keyword letters. Lastly, the mechanism of [www.naming.net](http://www.naming.net) is based on name combinations among common words, Greek and Latin prefixes, suffixes and roots, beginning and ending word parts and rhymes. A shortcoming of these kinds of automatic generators is that random generation can output so many bad suggestions and users have to be patient to find the name that they are looking for. In addition, these generations are based on straightforward combinations of words and they do not include a mechanism to also take semantics into account.

### 2.3 Commercial

Many naming agencies and branding firms<sup>1</sup> provide professional service to aid with the naming of new

<sup>1</sup>e.g. [www.eatmywords.com](http://www.eatmywords.com), [www.designbridge.com](http://www.designbridge.com), [www.ahundredmonkeys.com](http://www.ahundredmonkeys.com)

products, domains, companies and brands. Such services generally require customers to provide brief information about the business to be named, fill in questionnaires to learn about their markets, competitors, and expectations. In the end, they present a list of name candidates to be chosen from. Although the resulting names can be successful and satisfactory, these services are very expensive and the processing time is rather long.

### 3 Dataset and Annotation

In order to create a gold standard for linguistic creativity in naming, collect the common creativity devices used in the naming process and determine the suitable ones for automation, we conducted an annotation task on a dataset of 1000 brand and company names from various domains (Özbal et al., 2012). These names were compiled from a book dedicated to brand naming strategies (Botton and Cegarra, 1990) and various web resources related to creative naming such as [adslogans.co.uk](http://adslogans.co.uk) and [brandsandtags.com](http://brandsandtags.com).

Our list contains names which were invented via various creativity methods. While the creativity in some of these names is independent of the context and the names themselves are sufficient to realize the methods used (e.g. alliteration in *Peak Performance*, modification of one letter in *Vimeo*), for some of them the context information such as the description of the product or the area of the company is also necessary to fully understand the methods used. For instance, *Thanks a Latte* is a coffee bar name where the phonetic similarity between “lot” and “latte” (a coffee type meaning “milk” in Italian) is exploited. The name *Caterpillar*, which is an earth-moving equipment company, is used as a metaphor. Therefore, we need extra information regarding the domain description in addition to the names. Accordingly, while building our dataset, we conducted two separate branches of annotation. The first branch required the annotators to fill in the domain description of the names in question together with their etymologies if required, while the second asked them to determine the devices of creativity used in each name.

In order to obtain the list of creativity devices, we collected a total of 31 attributes used in the naming process from various resources including academic papers, naming agents, branding and advertisement experts. To facilitate the task for the annotators,

we subsumed the most similar attributes when required. Adopting the four-fold linguistic topology suggested by Bergh et al. (B. V. Bergh, 1987), we mapped these attributes into phonetic, orthographic, morphological and semantic categories. The phonetic category includes attributes such as rhyme (i.e. repetition of similar sounds in two or more words - e.g. *Etch-a-sketch*) and reduplication (i.e. repeating the root or stem of a word or part of it exactly or with a slight change - e.g. *Teenie Weenie*), while the orthographic category consists of devices such as acronyms (e.g. *BMW*) and palindromes (i.e. words, phrases, numbers that can be read the same way in either direction e.g. *Honda “Civic”*). The third category is the morphology which contains affixation (i.e. forming different words by adding morphemes at the beginning, middle or end of words - e.g. *Nutella*) and blending (i.e. forming a word by blending sounds from two or more distinct words and combining their meanings - e.g. *Wikipedia* by blending “Wiki” and “encyclopedia”). Finally, the semantic category includes attributes such as metaphors (i.e. Expressing an idea through the image of another object - e.g. *Virgin*) and punning (i.e. using a word in different senses or words with sound similarity to achieve specific effect such as humor - e.g. *Thai Me Up* for a Thai restaurant).

### 4 System Description

The resource that we have obtained after the annotation task provides us with a starting point to study and try to replicate the linguistic and cognitive processes behind the creation of a successful name. Accordingly, we have made a systematic attempt to replicate these processes, and implemented a system which combines methods and resources used in various areas of Natural Language Processing (NLP) to create neologisms based on homophonic puns and metaphors. While the variety of creativity devices is actually much bigger, our work can be considered as a starting point to investigate which kinds of technologies can successfully be exploited in which way to support the naming process. The task that we deal with requires: 1) reasoning of relations between entities and concepts; 2) understanding the desired properties of entities determined by users; 3) identifying semantically related terms which are also consistent with the objectives of the advertisement; 4) finding terms which are suitable metaphors for the properties that need to be emphasized; 5) reasoning

about phonetic properties of words; 6) combining all this information to create natural sounding neologisms.

In this section, we will describe in detail the work flow of the system that we have designed and implemented to fulfill these requirements.

#### 4.1 Specifying the category and properties

Our design allows users to determine the category of the product/brand/company to be advertised (e.g. shampoo, car, chocolate) optionally together with the properties (e.g. softening, comfortable, additive) that they want to emphasize. In the current implementation, categories are required to be nouns while properties are required to be adjectives. These inputs that are specified by users constitute the main *ingredients* of the naming process. After the determination of these ingredients, several techniques and resources are utilized to enlarge the ingredient list, and thereby to increase the variety of new and creative names.

#### 4.2 Adding common sense knowledge

After the word defining the category is determined by the user, we need to automatically retrieve more information about this word. For instance, if the category has been determined as “shampoo”, we need to learn that “it is used for washing hair” or “it can be found in the bathroom”, so that all this extra information can be included in the naming process. To achieve that, we use ConceptNet (Liu and Singh, 2004), which is a semantic network containing common sense, cultural and scientific knowledge. This resource consists of nodes representing concepts which are in the form of words or short phrases of natural language, and labeled relations between them.

ConceptNet has a closed class of relations expressing connections between concepts. After the analysis of these relations according to the requirements of the task, we have decided to use the ones listed in Table 1 together with their description in the second column. The third column states whether the category word should be the first or second argument of the relation in order for us to consider the new word that we discover with that relation. Since, for instance, the relations *MadeOf(milk, \*)* and *MadeOf(\*, milk)* can be used for different goals (the former to obtain the ingredients of milk, and the latter to obtain products containing milk), we

Relation	Description	#	POS
HasA	What does it possess?	1	n
PartOf	What is it part of?	2	n
UsedFor	What do you use it for?	1	n,v
AtLocation	Where would you find it?	2	n
MadeOf	What is it made of?	1	n
CreatedBy	How do you bring it into existence?	1	n
HasSubevent	What do you do to accomplish it?	2	v
Causes	What does it make happen?	1	n,v
Desires	What does it want?	1	n,v
CausesDesire	What does it make you want to do?	1	n,v
HasProperty	What properties does it have?	1	a
ReceivesAction	What can you do to it?	1	v

Table 1: ConceptNet relations.

need to make this differentiation. Via ConceptNet 5, the latest version of ConceptNet, we obtain a list of relations such as *AtLocation(shampoo, bathroom)*, *UsedFor(shampoo, clean)* and *MadeOf(shampoo, perfume)* with the query word “shampoo”. We add all the words appearing in relations with the category word to our ingredient list. Among these new words, multiwords are filtered out since most of them are noisy and for our task a high precision is more important than a high recall.

Since sense information is not provided, one of the major problems in utilizing ConceptNet is the difficulty in disambiguating the concepts. In our current design, we only consider the most common senses of words. As another problem, the part-of-speech (POS) information is not available in ConceptNet. To handle this problem, we have determined the required POS tags of the new words that can be obtained from the relations with an additional goal of filtering out the noise. These tags are stated in the fourth column of Table 1.

#### 4.3 Adding semantically related words

To further increase the size of the ingredient list, we utilize another resource called WordNet (Miller, 1995), which is a large lexical database for English. In WordNet, nouns, verbs, adjectives and adverbs are grouped into sets of cognitive synonyms called synsets. Each synset in WordNet expresses a different concept and they are connected to each other with lexical, semantic and conceptual relations.

We use the *direct hypernym* relation of WordNet to retrieve the superordinates of the category word (e.g. *cleansing agent*, *cleanser* and *cleaner* for the category word *shampoo*). We prefer to use this relation of WordNet instead of the relation “IsA” in

ConceptNet to avoid getting too general words. Although we can obtain only the direct hypernyms in WordNet, no such mechanism exists in ConceptNet. In addition, while WordNet has been built by linguists, ConceptNet is built from the contributions of many thousands of people across the Web and naturally it also contains a lot of noise.

In addition to the direct hypernyms of the category word, we increase the size of the ingredient list by adding synonyms of the category word, the new words coming from the relations and the properties determined by the user.

It should be noted that we do not consider any other statistical or knowledge based techniques for semantic relatedness. Although they would allow us to discover more concepts, it is difficult to understand if and how these concepts pertain to the context. In WordNet we can decide what relations to explore, with the result of a more precise process with possibly less recall.

#### 4.4 Retrieving metaphors

A metaphor is a figure of speech in which an implied comparison is made to indicate how two things that are not alike in most ways are similar in one important way. Metaphors are common devices for evocation, which has been found to be a very important technique used in naming according to the analysis of our dataset.

In order to generate metaphors, we start with the set of properties determined by the user and adopt a similar technique to the one proposed by (Veale, 2011). In this work, to metaphorically ascribe a property to a term, stereotypes for which the property is culturally salient are intersected with stereotypes to which the term is pragmatically comparable. The stereotypes for a property are found by querying on the web with the simile pattern “as  $\langle property \rangle$  as \*”. Unlike the proposed approach, we do not apply any intersection with comparable stereotypes since the naming task should favor further terms to the category word in order to exaggerate, to evoke and thereby to be more effective.

The first constituent of our approach uses the pattern “as  $\langle property \rangle$  as \*” with the addition of “ $\langle property \rangle$  like \*”, which is another important block for building similes. Given a property, these patterns are harnessed to make queries through the web api of Google Suggest. This service performs auto-completion of search queries based on popu-

lar searches. Although top 10 (or fewer) suggestions are provided for any query term by Google Suggest, we expand these sets by adding each letter of the alphabet at the end of the provided phrase. Thereby, we obtain 10 more suggestions for each of these queries. Among the metaphor candidates that we obtain, we filter out multiwords to avoid noise as much as possible. Afterwards, we conduct a lemmatization process on the rest of the candidates. From the list of lemmas, we only consider the ones which appear in WordNet as a noun. Although the list that we obtain in the end has many potentially valuable metaphors (e.g. *sun*, *diamond*, *star*, *neon* for the property *bright*), it also contains a lot of uncommon and unrelated words (e.g. *downlaod*, *myspace*, *house*). Therefore, we need a filtering mechanism to remove the noise and keep only the best metaphors.

To achieve that, the second constituent of the metaphor retrieval mechanism makes a query in ConceptNet with the given property. Then, all the nouns coming from the relations in the form of *HasProperty*(\* , *property*) are collected to find words having that property. The POS check to obtain only nouns is conducted with a look-up in WordNet as before. It should be noted that this technique would not be enough to retrieve metaphors alone since it can also return noise (e.g. *blouse*, *idea*, *color*, *homeschooler* for the property *bright*).

After we obtain two different lists of metaphor candidates with the two mechanisms mentioned above, we take the intersection of these lists and consider only the words appearing in both lists as metaphors. In this manner, we aim to remove the noise coming from each list and obtain more reliable metaphors. To illustrate, for the same example property *bright*, the metaphors obtained at the end of the process are *sun*, *light* and *day*.

#### 4.5 Generating neologisms

After the ingredient list is complete, the phonetic module analyzes all ingredient pairs to generate neologisms with possibly homophonic puns based on phonetic similarity.

To retrieve the pronunciation of the ingredients, we utilize the CMU Pronouncing Dictionary (Lenzo, 2007). This resource is a machine-readable pronunciation dictionary of English which is suitable for uses in speech technology, and it contains over 125,000 words together with their transcriptions. It has mappings from words to their pronunciations

Input		Successful output		Unsuccessful output	
Category	Properties	Word	Ingredients	Word	Ingredients
bar	irish lively wooden traditional warm hospitable friendly	beertender barty giness	bartender, beer party, bar guinness, gin	barkplace barl bark	workplace, bar girl, bar work, bar
perfume	attractive strong intoxicating unforgettable feminine mystic sexy audacious provocative	mysticious bussling mysteelious	mysterious, mystic buss, puzzling mysterious, steel	provocadeepe	provocative, deep
sunglasses	cool elite though authentic cheap sporty	spectacools electacles polarice	spectacles, cool spectacles, elect polarize, ice	spocleang	sporting, clean
restaurant	warm elegant friendly original italian tasty cozy modern	eatalian pastarant peatza	italian, eat restaurant, pasta pizza, eat	dusta hometess	pasta, dust hostess, home
shampoo	smooth bright soft volumizing hydrating quality	fragrinse cleansun	fragrance, rinse cleanser, sun	furl sasun	girl, fur satin, sun

Table 2: A selection of succesful and unsuccessful neologisms generated by the model.

and the current phoneme set contains 39 phonemes based on the ARPAbet symbol set, which has been developed for speech recognition uses. We conducted a mapping from the ARPAbet phonemes to the international phonetic alphabet (IPA) phonemes and we grouped the IPA phonemes based on the phoneme classification documented in IPA. More specifically, we grouped the ones which appear in the same category such as p-b, t-d and s-z for the consonants; i-y and e-ø for the vowels.

After having the pronunciation of each word in the ingredient list, shorter pronunciation strings are compared against the substrings of longer ones. Among the different possible distance metrics that can be applied for calculating the phonetic similarity between two pronunciation strings, we have chosen the Levenshtein distance (Levenshtein, 1966). This distance is a metric for measuring the amount of difference between two sequences, defined as the minimum number of edits required for the transformation of one sequence into the other. The allowable edit operations for this transformation are insertion, deletion, or substitution of a single character. For example, the Levenshtein distance between the strings “kitten” and “sitting” is 3, since the following three edits change one into the other, and there is no way to do it with fewer than three edits: kitten → sitten (substitution of ‘k’ with ‘s’), sitten → sittin (substitution of ‘e’ with ‘i’), sittin → sitting (insertion of ‘g’ at the end). For the distance calculation, we employ relaxation by giving a smaller penalty for the

phonemes appearing in the same phoneme groups mentioned previously. We normalize each distance by the length of the pronunciation string considered for the distance calculation and we only allow the combination of word pairs that have a normalized distance score less than 0.5, which was set empirically.

Since there is no one-to-one relationship between letters and phonemes and no information about which phoneme is related to which letter(s) is available, it is not straightforward to combine two words after determining the pairs via Levenshtein distance calculation. To solve this issue, we use the Berkeley word aligner<sup>2</sup> for the alignment of letters and phonemes. The Berkeley Word Aligner is a statistical machine translation tool that automatically aligns words in a sentence-aligned parallel corpus. To adapt this tool according to our needs, we split all the words in our dictionary into letters and their mapped pronunciation to their phonemes, so that the aligner could learn a mapping from phonemes to characters. The resulting alignment provides the information about from which index to which index the replacement of the substring of a word should occur. Accordingly, the substring of the word which has a high phonetic similarity with a specific word is replaced with that word. As an example, if the first ingredient is *bright* and the second ingredient is *light*, the name *blight* can be obtained at the end of

<sup>2</sup><http://code.google.com/p/berkeleyaligner/>

this process.

#### 4.6 Checking phonetic likelihood

To check the likelihood and well-formedness of the new string after the replacement, we learn a 3-gram language model with absolute smoothing. For learning the language model, we only consider the words in the CMU pronunciation dictionary which also exist in WordNet. This filtering is required in order to eliminate a large number of non-English trigrams which would otherwise cause too high probabilities to be assigned to very unlikely sequences of characters. We remove the words containing at least one trigram which is very unlikely according to the language model. The threshold to determine the unlikely words is set to the probability of the least frequent trigram observed in the training data.

### 5 Evaluation

We evaluated the performance of our system with a manual annotation in which 5 annotators judged a set of neologisms along 4 dimensions: 1) appropriateness, i.e. the number of ingredients (0, 1 or 2) used to generate the neologism which are appropriate for the input; 2) pleasantness, i.e. a binary decision concerning the conformance of the neologism to the sound patterns of English; 3) humor/wittiness, i.e. a binary decision concerning the wittiness of the neologism; 4) success, i.e. an assessment of the fitness of the neologism as a name for the target category/properties (unsuccessful, neutral, successful).

To create the dataset, we first compiled a list of 50 categories by selecting 50 hyponyms of the synset *consumer goods* in WordNet. To determine the properties to be underlined, we asked two annotators to state the properties that they would expect to have in a product or company belonging to each category in our category list. Then, we merged the answers coming from the two annotators to create the final set of properties for each category.

Although our system is actually able to produce a limitless number of results for a given input, we limited the number of outputs for each input to reduce the effort required for the annotation task. Therefore, we implemented a ranking mechanism which used a hybrid scoring method by giving equal weights to the language model and the normalized phonetic similarity. Among the ranked neologisms for each input, we only selected the top 20 to build the dataset. It should be noted that for some input

	Dimension			
	APP	PLE	HUM	SUX
2	9.54	0	0	27.04
3	33.3	25.34	32.77	49.52
4	41.68	38.6	34.57	18.77
5	15.48	36.06	32.66	4.67
3+	90.46	100	100	72.96

Table 3: Inter-annotator agreement (in terms of majority class, MC) on the four annotation dimensions.

combinations the system produced less than 20 neologisms. Accordingly, our dataset consists of a total number of 50 inputs and 943 neologisms.

To have a concrete idea about the agreement between annotators, we calculated the majority class for each dimension. With 5 annotators, a majority class greater than or equal to 3 means that the absolute majority of the annotators agreed on the same decision. Table 3 shows the distribution of majority classes along the four dimensions of the annotation. For pleasantness (PLE) and humor (HUM), the absolute majority of the annotators (i.e. 3/5) agreed on the same decision in 100% of the cases, while for appropriateness (APP) the figure is only slightly lower. Concerning success, arguably the most subjective of the four dimensions, in 27% of the cases it is not possible to take a majority decision. Nevertheless, in almost 73% of the cases the absolute majority of the annotators agreed on the annotation of this dimension.

Table 4 shows the micro and macro-average of the percentage of cases in which at least 3 annotators have labeled the ingredients as appropriate (APP), and the neologisms as pleasant (PLE), humorous (HUM) or successful (SUX). The system selects appropriate ingredients in approximately 60% of the cases, and outputs pleasant, English-sounding names in  $\sim 87\%$  of the cases. Almost one name out of four is labeled as successful by the majority of the annotators, which we regard as a very positive result considering the difficulty of the task. Even though we do not explicitly try to inject humor in the neologisms, more than 15% of the generated names turn out to be witty or amusing. The system managed to generate at least one successful name for all 50 input categories and at least one witty name for 42. As expected, we found out that there is a very high correlation (91.56%) between the appropriateness of the

Accuracy	Dimension			
	APP	PLE	HUM	SUX
micro	59.60	87.49	16.33	23.86
macro	60.76	87.01	15.86	24.18

Table 4: Accuracy of the generation process along the four dimensions.

ingredients and the success of the name. A successful name is also humorous in 42.67% of the cases, while 62.34% of the humorous names are labeled as successful. This finding confirms our intuition that amusing names have the potential to be very appealing to the customers. In more than 76% of the cases, a humorous name is the product of the combination of appropriate ingredients.

In Table 2, we show a selection of successful and unsuccessful outputs generated for the category and the set of properties listed under the block of columns labeled as *Input* according to the majority of annotators (i.e. 3 or more). As an example of positive outcomes, we can focus on the columns under *Successful output* for the input target word *restaurant*. The model correctly selects the ingredients *eat* (a restaurant is *UsedFor* eating), *pizza* and *pasta* (which are found *AtLocation* restaurant) to generate an appropriate name. The three “palatable” neologisms generated are *eatalian* (from the combination of *eat* and *Italian*), *pastarant* (*pasta* + *restaurant*) and *peatza* (*pizza* + *eat*). These three suggestions are amusing and have a nice ring to them. As a matter of fact, it turns out that the name *Eatalian* is actually used by at least one real Italian restaurant located in Los Angeles, CA<sup>3</sup>.

For the same set of stimuli, the model also selects some ingredients which are not really related to the use-case, e.g., *dust* and *hostess* (both of which can be found *AtLocation* restaurant) and *home* (a synonym for *plate*, which can be found *AtLocation* restaurant, in the baseball jargon). With these ingredients, the model produces the suggestion *dusta* which sounds nice but has a negative connotation, and *hometess* which can hardly be associated to the input category.

A rather common class of unsuccessful outputs include words that, by pure chance, happen to be already existing in English. In these cases, no actual neologism is generated. Sometimes, the generated

words have rather unpleasant or irrelevant meanings, as in the case of *bark* for *bar*. Luckily enough, these kinds of outputs can easily be eliminated by filtering out all the output words which can already be found in an English dictionary or which are found to have a negative valence with state-of-the-art techniques (e.g. SentiWordNet (Esuli and Sebastiani, 2006)). Another class of negative results includes neologisms generated from ingredients that the model cannot combine in a good English-sounding neologism (e.g. *spocleang* from *sporting* and *clean* for *sunglasses* or *sasun* from *satin* and *sun* for *shampoo*).

## 6 Conclusion

In this paper, we have focused on the task of automating the naming process and described a computational approach to generate neologisms with homophonic puns based on phonetic similarity. This study is our first step towards the systematic emulation of the various creative devices involved in the naming process by means of computational methods.

Due to the complexity of the problem, a unified model to handle all the creative devices at the same time seems outside the reach of the current state-of-the-art NLP techniques. Nevertheless, the resource that we collected, together with the initial implementation of this model should provide a good starting point for other researchers in the area. We believe that our contribution will motivate other research teams to invest more effort in trying to tackle the related research problems.

As future work, we plan to improve the quality of the output by considering word sense disambiguation techniques to reduce the effect of inappropriate ingredients. We also want to extend the model to include multiword ingredients and to generate not only words but also short phrases. Then, we would like to focus on other classes of creative devices, such as affixation or rhyming. Lastly, we plan to make the system that we have developed publicly available and collect user feedback for further development and improvement.

# Unsupervised Relation Discovery with Sense Disambiguation

Limin Yao    Sebastian Riedel    Andrew McCallum

Department of Computer Science

University of Massachusetts, Amherst

{lmyao, riedel, mccallum}@cs.umass.edu

## Abstract

To discover relation types from text, most methods cluster shallow or syntactic patterns of relation mentions, but consider only one possible sense per pattern. In practice this assumption is often violated. In this paper we overcome this issue by inducing clusters of pattern senses from feature representations of patterns. In particular, we employ a topic model to partition entity pairs associated with patterns into sense clusters using local and global features. We merge these sense clusters into semantic relations using hierarchical agglomerative clustering. We compare against several baselines: a generative latent-variable model, a clustering method that does not disambiguate between path senses, and our own approach but with only local features. Experimental results show our proposed approach discovers dramatically more accurate clusters than models without sense disambiguation, and that incorporating global features, such as the document theme, is crucial.

## 1 Introduction

Relation extraction (RE) is the task of determining semantic relations between entities mentioned in text. RE is an essential part of information extraction and is useful for question answering (Ravichandran and Hovy, 2002), textual entailment (Szpektor et al., 2004) and many other applications.

A common approach to RE is to assume that relations to be extracted are part of a predefined ontology. For example, the relations are given in knowledge bases such as Freebase (Bollacker et al., 2008) or DBpedia (Bizer et al., 2009). However, in many applications, ontologies do not yet exist or have low

coverage. Even when they do exist, their maintenance and extension are considered to be a substantial bottleneck. This has led to considerable interest in unsupervised relation discovery (Hasegawa et al., 2004; Banko and Etzioni, 2008; Lin and Pantel, 2001; Bollegala et al., 2010; Yao et al., 2011). Here, the relation extractor simultaneously discovers facts expressed in natural language, and the ontology into which they are assigned.

Many relation discovery methods rely exclusively on the notion of either shallow or syntactic patterns that appear between two named entities (Bollegala et al., 2010; Lin and Pantel, 2001). Such patterns could be sequences of lemmas and Part-of-Speech tags, or lexicalized dependency paths. Generally speaking, relation discovery attempts to cluster such patterns into sets of equivalent or similar meaning. Whether we use sequences or dependency paths, we will encounter the problem of polysemy. For example, a pattern such as “A beat B” can mean that person A wins over B in competing for a political position, as pair “(Hillary Rodham Clinton, Jonathan Tasini)” in “Sen Hillary Rodham Clinton beats rival Jonathan Tasini for Senate.” It can also indicate that an athlete A beat B in a sports match, as pair “(Dmitry Tursunov, Andy Roddick)” in “Dmitry Tursunov beat the best American player Andy Roddick.” Moreover, it can mean “physically beat” as pair “(Mr. Harris, Mr. Simon)” in “On Sept. 7, 1999, Mr. Harris fatally beat Mr. Simon.” This is known as *polysemy*. If we work with patterns alone, our extractor will not be able to differentiate between these cases.

Most previous approaches do not explicitly address this problem. Lin and Pantel (2001) assumes only one sense per path. In (Pantel et al., 2007), they augment each relation with its selectional pref-

erences, i.e. fine-grained entity types of two arguments, to handle polysemy. However, such fine-grained entity types come at a high cost. It is difficult to discover a high-quality set of fine-grained entity types due to unknown criteria for developing such a set. In particular, the optimal granularity of entity types depends on the particular pattern we consider. For example, a pattern like “A beat B” could refer to A winning a sports competition against B, or a political election. To differentiate between these senses we need types such as “Politician” or “Athlete”. However, for “A, the parent of B” we only need to distinguish between persons and organizations (for the case of the sub-organization relation). In addition, there are senses that just cannot be determined by entity types alone: Take the meaning of “A beat B” where A and B are both persons; this could mean A physically beats B, or it could mean that A defeated B in a competition.

In this paper we address the problem of polysemy, while we circumvent the problem of finding fine-grained entity types. Instead of mapping entities to fine-grained types, we directly induce pattern senses by clustering feature representations of pattern contexts, i.e. the entity pairs associated with a pattern. This allows us to employ not only local features such as words, but also global features such as the document and sentence themes.

To cluster the entity pairs of a single relation pattern into senses, we develop a simple extension to Latent Dirichlet Allocation (Blei et al., 2003). Once we have our pattern senses, we merge them into clusters of different patterns with a similar sense. We employ hierarchical agglomerative clustering with a similarity metric that considers features such as the entity arguments, and the document and sentence themes.

We perform experiments on New York Times articles and consider lexicalized dependency paths as patterns in our data. In the following we shall use the term path and pattern exchangeably. We compare our approach with several baseline systems, including a generative model approach, a clustering method that does not disambiguate between senses, and our approach with different features. We perform both automatic and manual evaluations. For automatic evaluation, we use relation instances in Freebase as ground truth, and employ two clustering

metrics, pairwise F-score and  $B^3$  (as used in coference). Experimental results show that our approach improves over the baselines, and that using global features achieves better performance than using entity type based features. For manual evaluation, we employ a set intrusion method (Chang et al., 2009). The results also show that our approach discovers relation clusters that human evaluators find coherent.

## 2 Our Approach

We induce pattern senses by clustering the entity pairs associated with a pattern, and discover semantic relations by clustering these sense clusters. We represent each pattern as a list of entity pairs and employ a topic model to partition them into different sense clusters using local and global features. We take each sense cluster of a pattern as an atomic cluster, and use hierarchical agglomerative clustering to organize them into semantic relations. Therefore, a semantic relation comprises a set of sense clusters of patterns. Note that one pattern can fall into different semantic relations when it has multiple senses.

### 2.1 Sense Disambiguation

In this section, we discuss the details of how we discover senses of a pattern. For each pattern, we form a clustering task by collecting all entity pairs the pattern connects. Our goal is to partition these entity pairs into sense clusters. We represent each pair by the following features.

**Entity names:** We use the surface string of the entity pair as features. For example, for pattern “A play B”, pairs which contain B argument “Mozart” could be in one sense, whereas pairs which have “Mets” could be in another sense.

**Words:** The words between and around the two entity arguments can disambiguate the sense of a path. For example, “A’s parent company B” is different from “A’s largest company B” although they share the same path “A’s company B”. The former describes the sub-organization relationship between two companies, while the latter describes B as the largest company in a location A. The two words to the left of the source argument, and to the right of the destination argument also help sense discovery. For example, in “Mazurkas played by Anna Kijanowska, pianist”, “pianist” tells us pattern “A played by B”

takes the “music” sense.

**Document theme:** Sometimes, the same pattern can express different relations in different documents, depending on the document’s theme. For instance, in a document about politics, “A defeated B” is perhaps about a politician that won an election against another politician. While in a document about sports, it could be a team that won against another team in a game, or an athlete that defeated another athlete. In our experiments, we use the meta-descriptors of a document as side information and train a standard LDA model to find the theme of a document. See Section 3.1 for details.

**Sentence theme:** A document may cover several themes. Moreover, sometimes the theme of a document is too general to disambiguate senses. We therefore also extract the theme of a sentence as a feature. Details are in 3.1.

We call entity name and word features local, and the two theme features global.

We employ a topic model to discover senses for each path. Each path  $p_i$  forms a document, and it contains a list of entity pairs co-occurring with the path in the tuples. Each entity pair is represented by a list of features  $f_k$  as we described. For each path, we draw a multinomial distribution  $\theta$  over topics/senses. For each feature of an entity pair, we draw a topic/sense from  $\theta_{p_i}$ . Formally, the generative process is as follows:

$$\begin{aligned} \theta_{p_i} &\sim \text{Dirichlet}(\alpha) \\ \phi_z &\sim \text{Dirichlet}(\beta) \\ z_e &\sim \text{Multinomial}(\theta_{p_i}) \\ f_k &\sim \text{Multinomial}(\phi_{z_e}) \end{aligned}$$

Assume we have  $m$  paths and  $l$  entity pairs for each path. We denote each entity pair of a path as  $e(p_i) = (f_1, \dots, f_n)$ . Hence we have:

$$\begin{aligned} P(e_1(p_i), e_2(p_i), \dots, e_l(p_i) | z_1, z_2, \dots, z_l) \\ = \prod_{j=1}^l \prod_{k=1}^n p(f_k | z_j) p(z_j) \end{aligned}$$

We assume the features are conditionally independent given the topic assignments. Each feature is generated from a multinomial distribution  $\phi$ . We use Dirichlet priors on  $\theta$  and  $\phi$ . Figure 1 shows the graphical representation of this model.

Figure 1: Sense-LDA model.

This model is a minor variation on standard LDA and the difference is that instead of drawing an observation from a hidden topic variable, we draw multiple observations from a hidden topic variable. Gibbs sampling is used for inference. After inference, each entity pair of a path is assigned to one topic. One topic is one sense. Entity pairs which share the same topic assignments form one sense cluster.

## 2.2 Hierarchical Agglomerative Clustering

After discovering sense clusters of paths, we employ hierarchical agglomerative clustering (HAC) to discover semantic relations from these sense clusters. We apply the complete linkage strategy and take cosine similarity as the distance function. The cutting threshold is set to 0.1.

We represent each sense cluster as one vector by summing up features from each entity pair in the cluster. The weight of a feature indicates how many entity pairs in the cluster have the feature. Some features may get larger weights and dominate the cosine similarity. We down-weight these features. For example, we use binary features for word “defeat” in sense clusters of pattern “A defeat B”. The two theme features are extracted from generative models, and each is a topic number.

Our approach produces sense clusters for each path and semantic relation clusters of the whole data. Table 1 and 2 show some example output.

## 3 Experiments

We carry out experiments on New York Times articles from years 2000 to 2007 (Sandhaus, 2008). Following (Yao et al., 2011), we filter out noisy documents and use natural language packages to annotate the documents, including NER tagging (Finkel et al., 2005) and dependency parsing (Nivre et al., 2004). We extract dependency paths for each pair of named entities in one sentence. We use their lemmas

Path	20:sports	30:entertainment	25:music/art
A play B	Americans, Ireland Yankees, Angels Ecuador, England Redskins, Detroit Red Bulls, F.C. Barcelona	Jean-Pierre Bacri, Jacques Rita Benton, Gay Head Dance Jeanie, Scrabble Meryl Streep, Leilah Kevin Kline, Douglas Fairbanks	Daniel Barenboim, recital of Mozart Mr. Rose, Ballade Gil Shaham, Violin Romance Ms. Golabek, Steinways Bruce Springsteen, Saints
<b>doc theme</b>	sports	music books television	music theater
<b>sen theme</b>	game yankees	theater production book film show	music reviews opera
<b>lexical words</b>	beat victory num-num won	played plays directed artistic	director conducted production
<b>entity names</b>	-	r:theater	r:theater r:hall r:york l:opera

Table 1: Example sense clusters produced by sense disambiguation. For each sense, we randomly sample 5 entity pairs. We also show top features for each sense. Each row shows one feature type, where “num” stands for digital numbers, and prefix “l:” for source argument, prefix “r:” for destination argument. Some features overlap with each other. We manually label each sense for easy understanding. We can see the last two senses are close to each other. For two theme features, we replace the theme number with the top words. For example, the document theme of the first sense is Topic30, and Topic30 has top words “sports”.

relation	paths
entertainment	A, who play B:30; A play B:30; star A as B:30
sports	lead A to victory over B:20; A play to B:20; A play B:20; A’s loss to B:20; A beat B:20; A trail B:20; A face B:26; A hold B:26; A play B:26; A acquire (X) from B:26; A send (X) to B:26;
politics	A nominate B:39; A name B:39; A select B:39; A name B:42; A select B:42; A ask B:42; A choose B:42; A nominate B:42; A turn to B:42;
law	A charge B:39; A file against B:39; A accuse B:39; A sue B:39

Table 2: Example semantic relation clusters produced by our approach. For each cluster, we list the top paths in it, and each is followed by “:number”, indicating its sense obtained from sense disambiguation. They are ranked by the number of entity pairs they take. The column on the left shows sense of each relation. They are added manually by looking at the sense numbers associated with each path.

for words on the dependency paths. Each entity pair and the dependency path which connects them form a tuple.

We filter out paths which occur fewer than 200 times and use some heuristic rules to filter out paths which are unlikely to represent a relation, for example, paths in which both arguments take the syntactic role “doj” (direct objective) in the dependency path. In such cases both arguments are often part of a coordination structure, and it is unlikely that they are related. In summary, we collect about one million tuples, 1300 patterns and half million named entities. In terms of named entities, the data is very sparse. On average one named entity occurs four times.

### 3.1 Feature Extraction

For the entity name features, we split each entity string of a tuple into tokens. Each token is a fea-

ture. The source argument tokens are augmented with prefix “l:”, and the destination argument tokens with prefix “r:”. We use tokens to encourage overlap between different entities.

For the word features, we extract all the words between the two arguments, removing stopwords and the words with capital letters. Words with capital letters are usually named entities, and they do not tend to indicate relations. We also extract neighboring words of source and destination arguments. The two words to the left of the source argument are added with prefix “lc:”. Similarly the two words to the right of the destination arguments are added with prefix “rc:”.

Each document in the NYT corpus is associated with many descriptors, indicating the topic of the document. For example, some documents are labeled as “Sports”, “Dallas Cowboys”, “New York Giants”, “Pro Football” and so on. Some are labeled

as “Politics and Government”, and “Elections”. We shall extract a theme feature for each document from these descriptors. To this end we interpret the descriptors as words in documents, and train a standard LDA model based on these documents. We pick the most frequent topic as the theme of a document.

We also train a standard LDA model to obtain the theme of a sentence. We use a bag-of-words representation for a document and ignore sentences from which we do not extract any tuples. The LDA model assigns each word to a topic. We count the occurrences of all topics in one sentence and pick the most frequent one as its theme. This feature captures the intuition that different words can indicate the same sense, for example, “film”, “show”, “series” and “television” are about “entertainment”, while “coach”, “game”, “jets”, “giants” and “season” are about “sports”.

### 3.2 Sense clusters and relation clusters

For the sense disambiguation model, we set the number of topics (senses) to 50. We experimented with other numbers, but this setting yielded the best results based on our automatic evaluation measures. Note that a path has a multinomial distribution over 50 senses but only a few senses have non-zero probabilities.

We look at some sense clusters of paths. For path “A play B”, we examine the top three senses, as shown in Table 1. The last two senses “entertainment” and “music” are close. Randomly sampling some entity pairs from each of them, we find that the two sense clusters are precise. Only 1% of pairs from the sense cluster “entertainment” should be assigned to the “music” sense. For the path “play A in B” we discover two senses which take the most probabilities: “sports” and “art”. Both clusters are precise. However, the “sports” sense may still be split into more fine-grained sense clusters. In “sports”, 67% pairs mean “play another team in a location” while 33% mean “play another team in a game”.

We also closely investigate some relation clusters, shown in Table 2. Both the first and second relation contain path “A play B” but with different senses. For the second relation, most paths state “play” relations between two teams, while a few of them express relations of teams acquiring players from

other teams. For example, the entity pair “(Atlanta Hawks, Dallas Mavericks)” mentioned in sentence “The Atlanta Hawks acquired point guard Anthony Johnson from the Dallas Mavericks.” This is due to that they share many entity pairs of team-team.

### 3.3 Baselines

We compare our approach against several baseline systems, including a generative model approach and variations of our own approach.

**Rel-LDA:** Generative models have been successfully applied to unsupervised relation extraction (Rink and Harabagiu, 2011; Yao et al., 2011). We compare against one such model: An extension to standard LDA that falls into the framework presented by Yao et al. (2011). Each document consists of a list of tuples. Each tuple is represented by features of the entity pair, as listed in 2.1, and the path. For each document, we draw a multinomial distribution over relations. For each tuple, we draw a relation topic and independently generate all the features. The intuition is that each document discusses one domain, and has a particular distribution over relations.

In our experiments, we test different numbers of relation topics. As the number goes up, precision increases whereas recall drops. We report results with 300 and 1000 relation topics.

**One sense per path (HAC):** This system uses only hierarchical clustering to discover relations, skipping sense disambiguation. This is similar to DIRT (Lin and Pantel, 2001). In DIRT, each path is represented by its entity arguments. DIRT calculates distributional similarities between different paths to find paths which bear the same semantic relation. It does not employ global topic model features extracted from documents and sentences.

**Local:** This system uses our approach (both sense clustering with topic models and hierarchical clustering), but without global features.

**Local+Type** This system adds entity type features to the previous system. This allows us to compare performance of using global features against entity type features. To determine entity types, we link named entities to Wikipedia pages using the Wikifier (Ratinov et al., 2011) package and extract categories from the Wikipedia page. Generally Wikipedia provides many types for one entity. For example, “Mozart” is

a *person*, *musician*, *pianist*, *composer*, and *catholic*. As we argued in Section 1, it is difficult to determine the right granularity of the entity types to use. In our experiments, we use all of them as features. In hierarchical clustering, for each sense cluster of a path, we pick the most frequent entity type as a feature. This approach can be seen as a proxy to ISP (Pantel et al., 2007), since selectional preferences are one way of distinguishing multiple senses of a path.

**Our Approach+Type** This system adds Wikipedia entity type features to our approach. The Wikipedia feature is the same as used in the previous system.

## 4 Evaluations

### 4.1 Automatic Evaluation against Freebase

We evaluate relation clusters discovered by all approaches against Freebase. Freebase comprises a large collection of entities and relations which come from varieties of data sources, including Wikipedia infoboxes. Many users also contribute to Freebase by annotating relation instances. We use coreference evaluation metrics: pairwise F-score and  $B^3$  (Bagga and Baldwin, 1998). Pairwise metrics measure how often two tuples which are clustered in one semantic relation are labeled with the same Freebase label. We evaluate approximately 10,000 tuples which occur in both our data and Freebase. Since our system predicts fine-grained clusters comparing against Freebase relations, the measure of recall is underestimated. The precision measure is more reliable and we employ F-0.5 measure, which places more emphasis on precision.

Matthews correlation coefficient (MCC) (Baldi et al., 2000) is another measure used in machine learning, which takes into account true and false positives and negatives and is generally regarded as a balanced measure which can be used when the classes are of very different sizes. In our case, the true negative number is 100 times larger than the true positive number. Therefore we also employ MCC, calculated as

$$\text{MCC} = \frac{TP \times TN - FP \times FN}{\sqrt{(TP + FP)(TP + FN)(TN + FP)(TN + FN)}}$$

The MCC score is between -1 and 1. The larger the better. In perfect predictions,  $FP$  and  $FN$  are 0, and the MCC score is 1. A random prediction results in score 0.

Table 3 shows the results of all systems. Our approach achieves the best performance in most measures. Without using sense disambiguation, the performance of hierarchical clustering decreases significantly, losing 17% in precision in the pairwise measure, and 15% in terms of  $B^3$ . The generative model approach with 300 topics achieves similar precision to the hierarchical clustering approach. With more topics, the precision increases, however, the recall of the generative model is much lower than those of other approaches. We also show the results of our approach without global document and sentence theme features (Local). In this case, both precision and recall decrease. We compare global features (Our approach) against Wikipedia entity type features (Local+Type). We see that using global features achieves better performance than using entity type based features. When we add entity type features to our approach, the performance does not increase. The entity type features do not help much is due to that we cannot determine which particular type to choose for an entity pair. Take pair “(Hillary Rodham Clinton, Jonathan Tasini)” as an example, choosing *politician* for both arguments instead of *person* will help.

We should note that these measures provide comparison between different systems although they are not accurate. One reason is the following: some relation instances should have multiple labels but they have only one label in Freebase. For example, instances of a relation that a person “was born in” a country could be labeled as “/people/person/place\_of\_birth” and as “/people/person/nationality”. This decreases the pairwise precision. Further discussion is in Section 4.3.

### 4.2 Path Intrusion

We also evaluate coherence of relation clusters produced by different approaches by creating path intrusion tasks (Chang et al., 2009). In each task, some paths from one cluster and an intruding path from another are shown, and the annotator’s job is to identify one single path which is out of place. For each path, we also show the annotators one example sentence. Three graduate students in natural language processing annotate intruding paths. For disagreements, we use majority voting. Table 4 shows one example intrusion task.

System	Pairwise				$B^3$		
	Prec.	Rec.	F-0.5	MCC	Prec.	Rec.	F-0.5
Rel-LDA/300	0.593	0.077	0.254	0.191	0.558	0.183	0.396
Rel-LDA/1000	0.638	0.061	0.220	0.177	0.626	0.160	0.396
HAC	0.567	0.152	0.367	0.261	0.523	<b>0.248</b>	0.428
Local	0.625	0.136	0.364	0.264	0.626	0.225	0.462
Local+Type	0.718	0.115	0.350	0.265	<b>0.704</b>	0.201	0.469
Our Approach	<b>0.736</b>	<b>0.156</b>	<b>0.422</b>	<b>0.314</b>	0.677	0.233	<b>0.490</b>
Our Approach+Type	0.682	0.110	0.334	0.250	0.687	0.199	0.460

Table 3: Pairwise and  $B^3$  evaluation for various systems. Since our systems predict more fine-grained clusters than Freebase, the recall measure is underestimated.

Path	Example sentence
A beat B	<b>Dmitry Tursunov</b> beat the best American player, <b>Andy Roddick</b>
A, who lose to B	<b>Sluman</b> , Loren Roberts (who lost a 1994 Open playoff to <b>Ernie Els</b> at Oakmont ...
A, who beat B	... offender seems to be the Russian <b>Mariya Sharapova</b> , who beat <b>Jelena Dokic</b>
<i>A, a broker at B</i>	<i><b>Robert Bewkes</b>, a broker at <b>UBS</b> for 12 years</i>
A meet B	<b>Howell</b> will meet <b>Geoff Ogilvy</b> , Harrington will face Davis Love III

Table 4: A path intrusion task. We show 5 paths and ask the annotator to identify one path which does not belong to the cluster. And we show one example sentence for each path. The entities (As and Bs) in the sentences are bold. And the italic row here indicates the intruder.

System	Correct
Rel-LDA/300	0.737
Rel-LDA/1000	0.821
HAC	0.852
Local+Type	0.773
Our approach	0.887

Table 5: Results of intruding tasks of all systems.

From Table 5, we see that our approach achieves the best performance. We concentrate on some intrusion tasks and compare the clusters produced by different systems.

The clusters produced by HAC (without sense disambiguation) is coherent if all the paths in one relation take a particular sense. For example, one task contains paths “A, director at B”, “A, specialist at B”, “A, researcher at B”, “A, B professor” and “A’s program B”. It is easy to identify “A’s program B” as an intruder when the annotators realize that the other four paths state the relation that people work in an educational institution. The generative model approach produces more coherent clusters when the number of relation topics increases.

The system which employs local and entity type features (Local+Type) produces clusters with low

coherence because the system puts high weight on types. For example, (*United States*, A talk with B, *Syria*) and (*Canada*, A defeat B, *United States*) are clustered into one relation since they share the argument types “country”-“country”. Our approach using the global theme features can correct such errors.

### 4.3 Error Analysis

We also closely analyze the pairwise errors that we encounter when comparing against Freebase labels. Some errors arise because one instance can have multiple labels, as we explained in Section 4.1. One example is the following: Our approach predicts that (*News Corporation*, buy, *MySpace*) and (*Dow Jones & Company*, the parent of, *The Wall Street Journal*) are in one relation. In Freebase, one is labeled as “/organization/parent/child”, the other is labeled as “/book/newspaper\_owner/newspapers\_owned”. The latter is a sub-relation of the former. We can overcome this issue by introducing hierarchies in relation labels.

Some errors are caused by selecting the incorrect sense for an entity pair of a path. For instance, we put (*Kenny Smith*, who grew up in, *Queens*) and (*Phil Jackson*, return to, *Los Angeles Lakers*) into

the “/people/person/place\_of\_birth” relation cluster since we do not detect the “sports” sense for the entity pair “(Phil Jackson, Los Angeles Lakers)”.

## 5 Related Work

There has been considerable interest in unsupervised relation discovery, including clustering approach, generative models and many other approaches.

Our work is closely related to DIRT (Lin and Pantel, 2001). Both DIRT and our approach represent dependency paths using their arguments. Both use distributional similarity to find patterns representing similar semantic relations. Based on DIRT, Pantel et al. (2007) addresses the issue of multiple senses per path by automatically learning admissible argument types where two paths are similar. They cluster arguments to fine-grained entity types and rank the associations of a relation with these entity types to discover selectional preferences. Selectional preferences discovery (Ritter et al., 2010; Seaghdha, 2010) can help path sense disambiguation, however, we show that using global features performs better than entity type features.

Our approach is also related to feature partitioning in cross-cutting model of lexical semantics (Reisinger and Mooney, 2011). And our sense disambiguation model is inspired by this work. There they partition features of words into views and cluster words inside each view. In our case, each sense of a path can be seen as one view. However, we allow different views to be merged since some views overlap with each other.

Hasegawa et al. (2004) cluster pairs of named entities according to the similarity of context words intervening between them. Hachey (2009) uses topic models to perform dimensionality reduction on features when clustering entity pairs into relations. Bollegala et al. (2010) employ co-clustering to find clusters of entity pairs and patterns jointly. All the approaches above neither deal with polysemy nor incorporate global features, such as sentence and document themes.

Open information extraction aims to discover relations independent of specific domains (Banko et al., 2007; Banko and Etzioni, 2008). They employ a self-learner to extract relation instances, but no attempt is made to cluster instances into relations.

Yates and Etzioni (2009) present RESOLVER for discovering relational synonyms as a post processing step. Our approach falls into the same category. Moreover, we explore path senses and global features for relation discovery.

Many generative probabilistic models have been applied to relation extraction. For example, varieties of topic models are employed for both open domain (Yao et al., 2011) and in-domain relation discovery (Chen et al., 2011; Rink and Harabagiu, 2011). Our approach employs generative models for path sense disambiguation, which achieves better performance than directly applying generative models to unsupervised relation discovery.

## 6 Conclusion

We explore senses of paths to discover semantic relations. We employ a topic model to partition entity pairs of a path into different sense clusters and use hierarchical agglomerative clustering to merge senses into semantic relations. Experimental results show our approach discovers precise relation clusters and outperforms a generative model approach and a clustering method which does not address sense disambiguation. We also show that using global features improves the performance of unsupervised relation discovery over using entity type based features.

## Abstract

In relation extraction, distant supervision seeks to extract relations between entities from text by using a knowledge base, such as Freebase, as a source of supervision. When a sentence and a knowledge base refer to the same entity pair, this approach heuristically labels the sentence with the corresponding relation in the knowledge base. However, this heuristic can fail with the result that some sentences are labeled wrongly. This noisy labeled data causes poor extraction performance. In this paper, we propose a method to reduce the number of wrong labels. We present a novel generative model that directly models the heuristic labeling process of distant supervision. The model predicts whether assigned labels are correct or wrong via its hidden variables. Our experimental results show that this model detected wrong labels with higher performance than baseline methods. In the experiment, we also found that our wrong label reduction boosted the performance of relation extraction.

## 1 Introduction

Machine learning approaches have been developed to address relation extraction, which is the task of extracting semantic relations between entities expressed in text. Supervised approaches are limited in scalability because labeled data is expensive to produce. A particularly attractive approach, called distant supervision (DS), creates labeled data by heuristically aligning entities in text with those in a knowledge base, such as Freebase (Mintz et al., 2009).

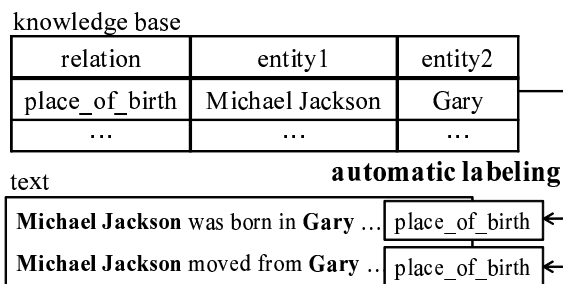

Figure 1: Automatic labeling by distant supervision. Upper sentence: correct labeling; lower sentence: incorrect labeling.

With DS it is assumed that if a sentence contains an entity pair in a knowledge base, such a sentence actually expresses the corresponding relation in the knowledge base.

However, the DS assumption can fail, which results in noisy labeled data and this causes poor extraction performance. An entity pair in a target text generally expresses more than one relation while a knowledge base stores a subset of the relations. The assumption ignores this possibility. For instance, consider the *place\_of\_birth* relation between *Michael Jackson* and *Gary* in Figure 1. The upper sentence indeed expresses the *place\_of\_birth* relation between the two entities. In DS *place\_of\_birth* is assigned to the sentence, and it becomes a useful training example. On the other hand, the lower sentence does not express this relation between the two entities, but the DS heuristic wrongly labels the sentence as expressing it.

Riedel et al. (2010) relax the DS assumption as at least one sentence containing an entity pair ex-

pressing the corresponding relation in the knowledge base. They cast the relaxed assumption as multi-instance learning. However, even the relaxed assumption can fail. The relaxation is equivalent to the DS assumption when a labeled pair of entities is mentioned once in a target corpus (Riedel et al., 2010). In fact, 91.7% of entity pairs appear only once in Wikipedia articles (see Section 7).

In this paper, we propose a method to reduce the number of wrong labels generated by DS without using either of these assumptions. Given the labeled corpus created with the DS assumption, we first predict whether each *pattern*, which frequently appears in text to express a relation (see Section 4), expresses a target relation. Patterns that are predicted not to express the relation are used to form a negative pattern list for removing wrong labels of the relation.

The main contributions of this paper are as follows:

- To make the pattern prediction, we propose a generative model that directly models the process of automatic labeling in DS. Without any strong assumptions like Riedel et al. (2010)'s, the model predicts whether each pattern expresses each relation via hidden variables (see Section 5).
- Our variational inference for our generative model lets us automatically calibrate parameters for each relation, which are sensitive to the performance (see Section 6).
- We applied our method to Wikipedia articles using Freebase as a knowledge base and found that (i) our model identified patterns expressing a given relation more accurately than baseline methods and (ii) our method led to better extraction performance than the original DS (Mintz et al., 2009) and MultiR (Hoffmann et al., 2011), which is a state-of-the-art multi-instance learning system for relation extraction (see Section 7).

## 2 Related Work

The increasingly popular approach, called distant supervision (DS), or weak supervision, utilizes a knowledge base to heuristically label a corpus (Wu and Weld, 2007; Bellare and McCallum, 2007; Pal

et al., 2007). Our work was inspired by Mintz et al. (2009) who used Freebase as a knowledge base by making the DS assumption and trained relation extractors on Wikipedia. Previous works (Hoffmann et al., 2010; Yao et al., 2010) have pointed out that the DS assumption generates noisy labeled data, but did not directly address the problem. Wang et al. (2011) applied a rule-based method to the problem by using popular entity types and keywords for each relation. In (Bellare and McCallum, 2007; Riedel et al., 2010; Hoffmann et al., 2011), they used multi-instance learning, which deals with uncertainty of labels, to relax the DS assumption. However, the relaxed assumption can fail when a labeled entity pair is mentioned only once in a corpus (Riedel et al., 2010). Our approach relies on neither of these assumptions.

Bootstrapping for relation extraction (Riloff and Jones, 1999; Pantel and Pennacchiotti, 2006; Carlson et al., 2010) is related to our method. In bootstrapping, seed entity pairs of the target relation are given in order to select reliable patterns, which are used to extract new entity pairs. To avoid the selection of unreliable patterns, bootstrapping introduces scoring functions for each pattern candidate. This can be applied to our approach, which seeks to reduce the number of unreliable patterns by using a set of given entity pairs. However, the bootstrapping-like approach suffers from sensitive parameters that are critical to its performance. Ideally, the parameters such as a threshold for scoring function should be determined for each relation, but there are no principled methods (Komachi et al., 2008). In our approach, parameters are calibrated for each relation by maximizing the likelihood of our generative model.

## 3 Knowledge-based Distant Supervision

In this section, we describe DS for relation extraction. We use the term *relation* as the relation between two entities. A *relation instance* is a tuple consisting of two entities and relation  $r$ . For example, *place\_of\_birth(Michael Jackson, Gary)* in Figure 1 is a relation instance.

Relation extraction seeks to extract relation instances from text. An entity is mentioned as a named entity in text. We extract a relation instance from a

single sentence. For example, from the upper sentence in Figure 1 we extract *place\_of\_birth*(*Michael Jackson, Gary*). Since two entities mentioned in a sentence do not always have a relation, we select entity pairs from a corpus when: (i) the path of the dependency parse tree between the corresponding two named entities in the sentence is no longer than 4 and (ii) the path does not contain a sentence-like boundary, such as a relative clause<sup>1</sup> (Banko et al., 2007; Banko and Etzioni, 2008). Banko and Etzioni (2008) found that a set of eight lexico-syntactic forms covers nearly 95% of relation phrases in their corpus. (Fader et al. (2011) found that this set covers 69% of their corpus). Our rule is designed to cover at least the eight lexico-syntactic forms. We use the entity pairs extracted by this rule.

DS uses a knowledge base to create labeled data for relation extraction by heuristically matching entity pairs. A *knowledge base* is a set of relation instances about predefined relations. For each sentence in the corpus, we extract all of its entity pairs. Then, for each entity pair, we try to retrieve the relation instances about the entity pair from the knowledge base. If we found such a relation instance, then the set of its relation, the entity pair, and the sentence is stored as a positive example. If not, then the set of the entity pair and the sentence is stored as a negative example. Features of an entity pair are extracted from the sentence containing the entity pair.

As mentioned in Section 1, the assumption of DS can fail, resulting in wrong assignments of a relation to sentences that do not express the relation. We call such assignments *wrong labels*. An example of a wrong label is *place\_of\_birth* assigned to the lower sentence in Figure 1.

## 4 Wrong Label Reduction

We define a *pattern* as the entity types of an entity pair<sup>2</sup> as well as the sequence of words on the path of the dependency parse tree from the first entity to the second one. For example, from “Michael Jackson was born in Gary” in Figure 1, the pattern “[Person] born in [Location]” is extracted. We use entity

<sup>1</sup>We reject sentence-like dependencies such as *ccomp*, *complm* and *mark*

<sup>2</sup>If we use a standard named entity tagger, the entity types are Person, Location, and Organization.

for each entry  $(r, Pair, Sentence)$  in  $LD$  do
  pattern  $Pat \leftarrow$  the pattern from  $(Pair, Sentence)$ 
  if  $Pat \in NegPat(r)$  then
    remove  $(r, Pair, Sentence)$  from  $LD$ 
  end if
end for
return  $LD$ 

```

---

types to distinguish the sentences that express different relations with the same dependency path, such as “ABBA was formed in Stockholm.” and “ABBA was formed in 1970.”

Our aim is to remove wrong labels assigned to frequent patterns, which cause poor precision. Indeed, in our Wikipedia corpus, more than 6% of the sentences containing the pattern “[Person] moved to [Location]”, which does not express *place\_of\_death*, are labeled as *place\_of\_death*, and the labels assigned to these sentences hurt extraction performance (see Section 7.3.3). We would like to remove *place\_of\_death* from the sentences that contain this pattern.

In our method, we reduce the number of wrong labels as follows: (i) given a labeled corpus with the DS assumption, we first predict whether a pattern expresses a relation and then (ii) remove wrong labels using the negative pattern list, which is defined as patterns that are predicted not to express the relation. In the first step, we introduce the novel generative model that directly models DS’s labeling process and make the prediction (see Section 5). The second step is formally described in Algorithm 1. For relation extraction, we train a classifier for entity pairs using the resultant labeled data.

## 5 Generative Model

We now describe our generative model, which predicts whether a pattern expresses relation  $r$  or not via hidden variables. In this section, we consider relation  $r$  since parameters are conditionally independent if relation  $r$  and the hyperparameter are given.

An observation of our model is whether entity pair  $i$  appearing with pattern  $s$  in the corpus is labeled with relation  $r$  or not. Our binary observations are written as  $\mathbf{X}_r = \{(x_{rsi}) | s = 1, \dots, S, i =$

Figure 2: Graphical model representation of our model.  $R$  indicates the number of relations.  $S$  is the number of patterns.  $N_s$  is the number of entity pairs that appear with pattern  $s$  in the corpus.  $x_{rsi}$  is the observed variables. The circled variables except  $x_{rsi}$  are parameters or hidden variables.  $\lambda$  is the hyperparameter and  $m_{st}$  is constant. The boxes are “plates” representing replicates.

$1, \dots, N_s\}$ ,<sup>3</sup> where we define  $S$  to be the number of patterns and  $N_s$  to be the number of entity pairs appearing with pattern  $s$ . Note that we count an entity pair for given pattern  $s$  once even if the entity pair is mentioned with pattern  $s$  more than once in the corpus, because DS assigns the same relation to all mentions of the entity pair.

Given relation  $r$ , our model assumes the following generative process:

1. For each pattern  $s$ 
  - Choose whether  $s$  expresses relation  $r$  or not
$$z_{rs} \sim Be(\theta_r)$$
2. For each entity pair  $i$  appearing with pattern  $s$ 
  - Choose whether  $i$  is labeled or not
$$x_{rsi} \sim P(x_{rsi} | \mathbf{Z}_r, a_r, d_r, \lambda, \mathbf{M}),$$

where  $Be(\theta_r)$  is a Bernoulli distribution with parameter  $\theta_r$ ,  $z_{rs}$  is a binary hidden variable that is 1 if pattern  $s$  expresses relation  $r$  and 0 otherwise, and  $\mathbf{Z}_r = \{(z_{rs}) | s = 1, \dots, S\}$ . Given a value of  $z_{rs}$ , we model two kinds of probabilities: one for patterns that actually express relation  $r$ , i.e.,  $P(x_{rsi} = 1 | z_{rs} = 1)$ , and one for patterns that do not express  $r$ , i.e.,  $P(x_{rsi} = 1 | z_{rs} = 0)$ . The former is simply parameterized as  $0 \leq a_r \leq 1$ . We express the latter as  $b_{rs} = P(x_{rsi} = 1 | \mathbf{Z}_r, a_r, d_r, \lambda, \mathbf{M})$ , which is a function of  $\mathbf{Z}_r, a_r, d_r, \lambda$  and  $\mathbf{M}$ ; we explain its modeling in the following two subsections.

<sup>3</sup>Since a set of entity pairs appearing with pattern  $s$  is different,  $i$  should be written as  $i_s$ . For simplicity, however, we use  $i$  for each pattern.

Figure 3: Venn diagram-like description.  $E_1$  and  $E_2$  are sets of entity pairs.  $E_1/E_2$  has 6/4 entity pairs because the 6/4 entity pairs appear with pattern 1/2 in the target corpus. Pattern 1 expresses relation  $r$  and pattern 2 does not. Elements in  $E_1$  are labeled with probability  $a_r = 3/6 = 0.5$ . Those in  $E_2$  are labeled with probability  $b_{r2} = a_r(|E_1 \cap E_2|/|E_2|) = 0.5(2/4) = 0.25$ .

The graphical model of our model is shown in Figure 2.

### 5.1 Example of Wrong Labeling

Using a simple example, we describe how we model  $b_{rs}$ , the probability with which DS assigns relation  $r$  to pattern  $s$  via entity pairs when pattern  $s$  does not express relation  $r$ .

Consider two patterns: pattern 1 that expresses relation  $r$  and pattern 2 that does not (i.e.,  $z_{r1} = 1$  and  $z_{r2} = 0$ ). We also assume that there are entity pairs that appear with pattern 1 as well as with pattern 2 in different places in the corpus (for example, *Michael Jackson* and *Gary* in Figure 1). When such entity pairs are labeled, relation  $r$  is assigned to pattern 1 and at the same time to wrong pattern 2. Such entity pairs are observed as elements in the intersection of the two sets of entity pairs,  $E_1$  and  $E_2$ . Here,  $E_s$  is the set of entity pairs that appear with pattern  $s$  in the corpus. This situation is described in Figure 3.

We model probability  $b_{r2}$  as follows. In  $E_1$ , an entity pair is labeled with probability  $a_r$ . We assume that entity pairs in the intersection,  $E_1 \cap E_2$ , are also labeled with  $a_r$ . From the viewpoint of  $E_2$ , entity pairs in its subset,  $E_1 \cap E_2$ , are labeled with  $a_r$ . Therefore,  $b_{r2}$  is modeled as

$$b_{r2} = a_r \frac{|E_1 \cap E_2|}{|E_2|},$$

where  $|E|$  denotes the number of elements in set  $E$ . An example of this calculation is shown in Figure 3.

We generalize the example in the next subsection.

## 5.2 Modeling of Probability $b_{rs}$

We model  $b_{rs}$  so that it is proportional to the number of entity pairs that are shared with correct patterns whose  $z_{rs} = 1$ , i.e.,

$$b_{rs} = a_r \frac{\left| \left( \bigcap_{\{t|z_{rt}=1, t \neq s\}} E_t \right) \cap E_s \right|}{|E_s|}, \quad (1)$$

where  $\cap$  indicates set intersections. However, the enumeration in Eq.1 requires  $O(SN_s^2)$  computational cost and a huge amount of memory to store all of the entity pairs. We approximate the right-hand side of Eq.1 as

$$b_{rs} \approx a_r \left( 1 - \prod_{t=1, t \neq s}^S \left( 1 - \frac{|E_t \cap E_s|}{|E_s|} \right)^{z_{rt}} \right).$$

This approximation is made, given the sizes of all  $E_s$ s and those of all intersections of two  $E_s$ s. This has a lower computational cost of  $O(S)$  and let us use less memory. We define  $S \times S$  matrix  $\mathbf{M}$  whose elements are  $m_{st} = |E_t \cap E_s|/|E_s|$ .

In reality, factors other than the process described in the previous subsection can cause wrong labeling (for example, errors in the knowledge base). We introduce a parameter  $0 \leq d_r \leq 1$  that covers such factors. Finally, we define  $b_{rs}$  as

$$b_{rs} \equiv a_r \left( \lambda \left( 1 - \prod_{t=1, t \neq s}^S (1 - m_{st})^{z_{rt}} \right) + (1 - \lambda) d_r \right), \quad (2)$$

where  $0 \leq \lambda \leq 1$  is the hyperparameter that controls how strongly  $b_{rs}$  is affected by the main labeling process explained in the previous subsection.

## 5.3 Likelihood

Given observation  $\mathbf{X}_r$ , the likelihood of our model is

$$\begin{aligned} P(\mathbf{X}_r | \theta_r, a_r, d_r, \lambda, \mathbf{M}) \\ = \sum_{\mathbf{Z}_r} P(\mathbf{Z}_r | \theta_r) P(\mathbf{X}_r | \mathbf{Z}_r, a_r, d_r, \lambda, \mathbf{M}), \end{aligned}$$

where

$$P(\mathbf{Z}_r | \theta_r) = \prod_{s=1}^S \theta_r^{z_{rs}} (1 - \theta_r)^{1 - z_{rs}}.$$

For each pattern  $s$ , we define  $n_{rs}$  as the number of entity pairs to which relation  $r$  is assigned (i.e.,  $n_{rs} = \sum_i x_{rsi}$ ).

$$\begin{aligned} p(\mathbf{X}_r | \mathbf{Z}_r, a_r, d_r, \lambda, \mathbf{M}) = \\ \prod_{s=1}^S \left\{ a_r^{n_{rs}} (1 - a_r)^{N_s - n_{rs}} \right\}^{z_{rs}} \\ \left\{ b_{rs}^{n_{rs}} (1 - b_{rs})^{N_s - n_{rs}} \right\}^{1 - z_{rs}}, \quad (3) \end{aligned}$$

where  $b_{rs}$  is in Eq.2.

## 6 Learning

We learn parameters  $a_r$ ,  $\theta_r$ , and  $d_r$  and infer hidden variables  $\mathbf{Z}_r$  by maximizing the log likelihood given  $\mathbf{X}_r$ . Estimated  $\mathbf{Z}_r$  is used to predict which patterns express relation  $r$ .

To infer  $z_{rs}$ , we would like to calculate the posterior probability of  $z_{rs}$ . However, this calculation is intractable because each  $z_{rs}$  depends on the others,  $\{(z_{rt}) | t \neq s\}$ , as shown in Eqs.2 and 3. This prevents us from using the EM algorithm. Instead, we apply variational approximation to the posterior distribution by using the following trial distribution:

$$Q(\mathbf{Z}_r | \Phi_r) = \prod_{s=1}^S \phi_{rs}^{z_{rs}} (1 - \phi_{rs})^{1 - z_{rs}},$$

where  $0 \leq \phi_{rs} \leq 1$  is a parameter for the trial distribution.

The following function  $F_r$  is a lower bound of the log likelihood, and maximizing this function with respect to  $\Phi_r$  is equivalent to minimizing the KL divergence between the trial distribution and the posterior distribution of  $\mathbf{Z}_r$ .

$$\begin{aligned} F_r = E_Q[\log P(\mathbf{Z}_r, \mathbf{X}_r | \theta_r, a_r, d_r, \lambda, \mathbf{M})] \\ - E_Q[\log Q(\mathbf{Z}_r | \Phi_r)]. \quad (4) \end{aligned}$$

$E_Q[\bullet]$  represents the expectation over trial distribution  $Q$ . We maximize function  $F_r$  with respect to the parameters instead of the log likelihood.

However, we need further approximation for two terms on expanding Eq.4. Both of the terms are expressed as  $E_Q[\log(f(\mathbf{Z}_r))]$ , where  $f(\mathbf{Z}_r)$  is a function of  $\mathbf{Z}_r$ . We apply the following approximation (Asuncion et al., 2009).

$$E_Q[\log(f(\mathbf{Z}_r))] \approx \log(E_Q[f(\mathbf{Z}_r)]).$$

This is based on the Taylor series of  $\log$  at  $E_Q[f(\mathbf{Z}_r)]$ . In our problem, since the second derivative is sufficiently small, we use the zeroth-order approximation.<sup>4</sup>

Our learning algorithm is derived by calculating the stationary condition of the resultant evaluation function with respect to each parameter. We have the exact solution for  $\theta_r$ . For each  $\phi_{rs}$  and  $d_r$ , we derive a fixed point iteration. We update  $a_r$  by using the steepest ascent. We update each parameter in turn while keeping the other parameters fixed. Parameter updating proceeds until a termination condition is met.

After learning, we have  $\phi_{rs}$  for each pair of relation  $r$  and pattern  $s$ . The greater the value of  $\phi_{rs}$  is, the more likely it is that pattern  $s$  expresses relation  $r$ . We set a threshold and determine  $z_{rs} = 0$  when  $\phi_{rs}$  is less than the threshold.

## 7 Experiments

We performed two sets of experiments.

**Experiment 1** aimed to evaluate the performance of our generative model itself, which predicts whether a pattern expresses a relation, given a labeled corpus created with the DS assumption.

**Experiment 2** aimed to evaluate how much our wrong label reduction in Section 4 improved the performance of relation extraction. In our method, we trained a classifier with a labeled corpus cleaned by Algorithm 1 using the negative pattern list predicted by the generative model.

### 7.1 Dataset

Following Mintz et al. (2009), we carried out our experiments using Wikipedia as the target corpus and Freebase (September, 2009, (Google, 2009)) as the knowledge base. We used more than 1,300,000 Wikipedia articles in the wex dump data (September, 2009, (Metaweb Technologies, 2009)). The properties of our data are shown in Table 1.

In Wikipedia articles, named entities were identified by anchor text linking to another article and starting with a capital letter (Yan et al., 2009). We applied Open NLP POS tagger<sup>5</sup> and MaltParser (Nivre et al., 2007) to sentences containing more

Table 1: Properties of Wikipedia dataset

documents	1,303,000
entity pairs	2,017,000
(matched to Freebase)	129,000
(with entity types)	913,000
frequent patterns	3,084
relations	24

than one named entity. We then extracted sentences containing related entity pairs with the method explained in Section 3. To match entity pairs, we used ID mapping between the dump data and Freebase. We used the most frequent 24 relations.

### 7.2 Experiment 1: Pattern Prediction

We compared our model with baseline methods in terms of ability to predict patterns that express a given relation.

The input of this task was  $\mathbf{X}_{r,s}$ , which expresses whether or not each entity pair appearing with each pattern is labeled with relation  $r$ , as explained in Section 5. In Experiment 1, since we needed entity types for patterns, we restricted ourselves to entities matched with Freebase, which also provides entity types for entities. We used patterns that appear more than 20 times in the corpus.

#### 7.2.1 Evaluation

We split the data into training data and test data. The training data was  $\mathbf{X}_{r,s}$  for 12 relations and the test data was that for the remaining 12 relations. The training data was used to calibrate parameters (see the following subsection for details). The test data was used for evaluation. We randomly split the data five times and took the average of the following evaluation values.

We evaluated the performance by precision, recall, and F value. They were calculated using gold standard data, which was constructed by hand. We manually selected patterns that actually express a target relation as positive patterns for the relation.<sup>6</sup> We averaged the evaluation values in terms of macro average over relations before averaging over the data splits.

<sup>6</sup>Patterns that ambiguously express the relation, for instance “[Person] in [Location]” for *place\_of\_birth*, were not selected as positive patterns.

<sup>4</sup>The first-order information becomes zero in this case.

<sup>5</sup><http://opennlp.sourceforge.net/>

Table 2: Averages of precision, recall, and F value in Experiment 1. The averages of threshold of RS(rank) and RS(value) were  $6.2 \pm 3.2$  and  $0.10 \pm 0.06$ , respectively. The averages of hyperparameters of PROP were  $0.84 \pm 0.05$  for  $\lambda$  and  $0.85 \pm 0.10$  for the threshold.

	Precision	Recall	F value
Baseline	0.339	1.000	0.458
RS(rank)	0.749	0.549	0.467
RS(value)	0.601	0.647	0.545
PROP	0.782	0.688	0.667

## 7.2.2 Methods

We compared the following methods:

**Baseline:** This method assigns relation  $r$  to a pattern when the pattern is mentioned with at least one entity pair corresponding to relation  $r$  in Freebase. This method is based on the DS assumption.

**Ratio-based Selection (RS):** Given relation  $r$  and pattern  $s$ , this method calculates  $n_{rs}/N_s$ , which is the ratio of the number of labeled entity pairs appearing with pattern  $s$  to the number of entity pairs including unlabeled ones. RS then selects the top  $n$  patterns (RS(rank)). We also tested a version using a real-valued threshold (RS(value)). In training, we selected the threshold that maximized the F value. Some bootstrapping approaches (Carlson et al., 2010) use a rank-based threshold like RS(rank).

**Proposed Model (PROP):** Using the training data, we determined the two hyperparameters,  $\lambda$  and the threshold to round  $\phi_{rs}$  to 1 or 0, so that they maximized the F value. When  $\phi_{rs}$  is greater than the threshold, we select pattern  $s$  as one expressing relation  $r$ .

## 7.2.3 Result and Discussion

The results of Experiment 1 are shown in Table 2. Our model achieved the best precision, recall, and F value. RS(value) had the second best F value, but it completely removed more than one infrequent relation on average in test sets. This is problematic for real situations. RS(rank) achieved the second highest precision. However, its recall, which is also important in our task, was the lowest and its F value was almost the same as naive Baseline.

The thresholds of RS, which directly affect their performance, should be calibrated for each relation, but it is hard to do this in advance. On the other

Table 3: Example of estimated  $\phi_{rs}$  for  $r = \textit{place\_of\_birth}$ . Entity types are omitted in patterns.  $n_{rs}/N_s$  is the ratio of the number of labeled entity pairs to the number of entity pairs appearing with pattern  $s$ .

pattern $s$	$n_{rs}/N_s$	$\phi_{rs}$	expresses $r$ ?
born in	0.512	0.999	true
actor from	0.480	0.999	true
elected Mayor of	0.384	0.855	false
family moved from	0.344	0.055	false
native of	0.327	0.999	true
grew in	0.162	0.000	false

hand, our model learns parameters such as  $a_r$  for each relation and thus the hyperparameter of our model does not directly affect its performance. This results in a high prediction performance.

Examples of estimated  $\phi_{rs}$ , the probability with which pattern  $s$  expresses relation  $r$ , are shown in Table 3. The pattern, “[Person] family moved from [Location]”, which does not express *place\_of\_birth*, had low  $\phi_{rs}$  in spite of having higher  $n_{rs}/N_s$  than the valid pattern “[Person] native of [Location]”. The former pattern had higher  $b_{rs}$ , the probability with which relation  $r$  is wrongly assigned to pattern  $s$  via entity pairs, because there were more entity pairs that appeared not only with this pattern but also with patterns that was predicted to express *place\_of\_birth*.

## 7.3 Experiment 2: Relation Extraction

We investigated the performance of relation extraction using our wrong label reduction, which uses the results of the pattern prediction.

Following Mintz et al. (2009), we performed an automatic held-out evaluation and a manual evaluation. In both cases, we used 400,000 articles for testing and the remaining 903,000 for training.

### 7.3.1 Configuration of Classifiers

Following Mintz et al. (2009), we used a multi-class logistic classifier optimized using L-BFGS with Gaussian regularization to classify entity pairs to the predefined 24 relations and NONE. In order to train the NONE class, we randomly picked 100,000 examples that did not match to Freebase as pairs. (Several entities in the examples matched and had entity types of Freebase.) In this experiment, we

Figure 4: Precision-recall curves in held-out evaluation. Precision is reported at recall levels from 5 to 50,000.

used not only entity pairs matched to Freebase but also ones not matched to Freebase (i.e., entity pairs that do not have entity types). We used syntactic features (i.e., features obtained from the dependency parse tree of a sentence) and lexical features, and entity types, which essentially correspond to the ones developed by Mintz et al. (2009).

We compared the following methods: logistic regression with the labeled data cleaned by the proposed method (PROP), logistic regression with the standard DS labeled data (LR), and MultiR proposed in (Hoffmann et al., 2011) as a state-of-the-art multi-instance learning system.<sup>7</sup> For logistic regression, when more than one relation is assigned to a sentence, we simply copied the feature vector and created a training example for each relation. In PROP, we used training articles for pattern prediction.<sup>8</sup>

### 7.3.2 Held-out Evaluation

In the held-out evaluation, relation instances discovered from testing articles were automatically compared with those in Freebase. This let us calculate the precision of each method for the best  $n$  relation instances. The precisions are underestimated because this evaluation suffers from false negatives due to the incompleteness of Freebase. We changed  $n$  from 5 to 50,000 and measured precision and recall. Precision-recall curves for the held-out data are

<sup>7</sup>For MultiR, we used the authors’ implementation from <http://www.cs.washington.edu/homes/raphaelh/mr/>

<sup>8</sup>In Experiment 2 we set  $\lambda = 0.85$  and the threshold at 0.95.

Table 4: Averages of precisions at 50 for the most frequent 15 relations as well as example relations.

	PROP	MultiR	LR
<i>place_of_birth</i>	1.0	1.0	0.56
<i>place_of_death</i>	1.0	0.7	0.84
average	$0.89 \pm 0.14$	$0.83 \pm 0.21$	$0.82 \pm 0.23$

shown in Figure 4.

PROP achieved comparable or higher precision at most recall levels compared with LR and MultiR. Its performance at  $n = 50,000$  is much higher than that of the others. While our generative model does not use unlabeled examples as negative ones in detecting wrong labels, classifier-based approaches including MultiR do, suffering from false negatives.

### 7.3.3 Manual Evaluation

For manual evaluation, we picked the top ranked 50 relation instances for the most frequent 15 relations. The manually evaluated precisions averaged over the 15 relations are shown in table 4.

PROP achieved the best average precision. For *place\_of\_birth*, LR wrongly extracted entity pairs with “[Person] played with club [Location]”, which does not express the relation. PROP and MultiR avoided this mistake. For *place\_of\_death*, LR and MultiR wrongly extracted entity pairs with “[Person] moved to [Location]”. Multi-instance learning does not work for wrong labels assigned to entity pairs that appear only once in a corpus. In fact, 72% of entity pairs that appeared with this pattern and were wrongly labeled as *place\_of\_death* appeared only once in the corpus. Only PROP avoided mistakes of this kind because our method works in such situations.

## 8 Conclusion

We proposed a method that reduces the number of wrong labels created with the DS assumption, which is widely applied. Our generative model directly models the labeling process of DS and predicts patterns that are wrongly labeled with a relation. The predicted patterns are used for wrong label reduction. The experimental results show that this method successfully reduced the number of wrong labels and boosted the performance of relation extraction.

## Abstract

We present an approach for detecting salient (important) dates in texts in order to automatically build event timelines from a search query (e.g. the name of an event or person, etc.). This work was carried out on a corpus of newswire texts in English provided by the Agence France Presse (AFP). In order to extract salient dates that warrant inclusion in an event timeline, we first recognize and normalize temporal expressions in texts and then use a machine-learning approach to extract salient dates that relate to a particular topic. We focused only on extracting the dates and not the events to which they are related.

## 1 Introduction

Our aim here was to build thematic timelines for a general domain topic defined by a user query. This task, which involves the extraction of important events, is related to the tasks of *Retrospective Event Detection* (Yang et al., 1998), or *New Event Detection*, as defined for example in Topic Detection and Tracking (TDT) campaigns (Allan, 2002).

The majority of systems designed to tackle this task make use of textual information in a bag-of-words manner. They use little temporal information, generally only using document metadata, such as the document creation time (DCT). The few systems that do make use of temporal information (such as the now discontinued Google timeline), only extract absolute, full dates (that feature a day, month and year). In our corpus, described in Section 3.1, we found that only 7% of extracted temporal expressions are absolute dates.

We distinguish our work from that of previous researchers in that we have focused primarily on extracted temporal information as opposed to other textual content. We show that using linguistic temporal processing helps extract important events in texts. Our system extracts a maximum of temporal information and uses only this information to detect salient dates for the construction of event timelines. Other types of content are used for initial thematic document retrieval. Output is a list of dates, ranked from most important to least important with respect to the given topic. Each date is presented with a set of relevant sentences.

We can see this work as a new, easily evaluable task of “date extraction”, which is an important component of timeline summarization.

In what follows, we first review some of the related work in Section 2. Section 3 presents the resources used and gives an overview of the system. The system used for temporal analysis is described in Section 4, and the strategy used for indexing and finding salient dates, as well as the results obtained, are given in Section 5<sup>1</sup>.

## 2 Related Work

The ISO-TimeML language (Pustejovsky et al., 2010) is a specification language for manual annotation of temporal information in texts, but, to the best of our knowledge, it has not yet actually been used in information retrieval systems. Neverthe-

<sup>1</sup>This work has been partially funded by French National Research Agency (ANR) under project Chronolines (ANR-10-CORD-010). We would like to thank the French News Agency (AFP) for providing us with the corpus.

less, (Alonso et al., 2007; Alonso, 2008; Kanhabua, 2009) and (Mestl et al., 2009), among others, have highlighted that the analysis of temporal information is often an essential component in text understanding and is useful in a wide range of information retrieval applications. (Harabagiu and Bejan, 2005; Saquete et al., 2009) highlight the importance of processing temporal expressions in Question Answering systems. For example, in the TREC-10 QA evaluation campaign, more than 10% of questions required an element of temporal processing in order to be correctly processed (Li et al., 2005a). In multi-document summarization, temporal processing enables a system to detect redundant excerpts from various texts on the same topic and to present results in a relevant chronological order (Barzilay and Elhadad, 2002). Temporal processing is also useful for aiding medical decision-making. (Kim and Choi, 2011) present work on the extraction of temporal information in clinical narrative texts. Similarly, (Jung et al., 2011) present an end-to-end system that processes clinical records, detects events and constructs timelines of patients' medical histories.

The various editions of the TDT task have given rise to the development of different systems that detect novelty in news streams (Allan, 2002; Kumaran and Allen, 2004; Fung et al., 2005). Most of these systems are based on statistical bag-of-words models that use similarity measures to determine proximity between documents (Li et al., 2005b; Brants et al., 2003). (Smith, 2002) used spatio-temporal information from texts to detect events from a digital library. His method used place/time collocations and ranked events according to statistical measures.

Some efforts have been made for automatically building textual and graphical timelines. For example, (Allan et al., 2001) present a system that uses measures of pertinence and novelty to construct timelines that consist of one sentence per date. (Chieu and Lee, 2004) propose a similar system that extracts events relevant to a query from a collection of documents. Important events are those reported in a large number of news articles and each event is constructed according to one single query and represented by a set of sentences. (Swan and Allen, 2000) present an approach to generating graphical timelines that involves extracting clusters of noun phrases and named entities. More recently, (Yan et

al., 2011b; Yan et al., 2011a) used a summarization-based approach to automatically generate timelines, taking into account the evolutionary characteristics of news.

### 3 Resources and System Overview

#### 3.1 AFP Corpus

For this work, we used a corpus of newswire texts provided by the AFP French news agency. The English AFP corpus is composed of 1.3 million texts that span the 2004-2011 period (511 documents/day in average and 426 millions words). Each document is an XML file containing a title, a date of creation (DCT), set of keywords, and textual content split into paragraphs.

#### 3.2 AFP Chronologies

AFP "chronologies" (textual event timelines) are a specific type of articles written by AFP journalists in order to contextualize current events. These chronologies may concern any topic discussed in the media, and consist in a list of dates (typically between 10 and 20) associated with a text describing the related event(s). Figure 1 shows an example of such a chronology. Further examples are given in Figure 2. We selected 91 chronologies satisfying the following constraints:

- All dates in the chronologies are between 2004 and 2011 to be sure that the related events are described in the corpus. For example, "*Chronology of climax to Vietnam War*" was excluded because its corresponding dates do not appear in the content of the articles.
- All dates in the chronology are anterior to the chronology's creation date. For example, the chronology "*Space in 2005: A calendar*", published in January 2005 and listing scheduled events, was not selected (because almost no rocket launches finally happened on the expected day).
- The temporal granularity of the chronology is the day. For example, "*A timeline of how the London transport attacks unfolded*", relating the events hour by hour, is not in our focus.

```

Figure 1: Example of an AFP manual chronology.

For learning and evaluation purposes, all chronologies were converted to a single XML format. Each document was manually associated with a user search query made up of the keywords required to retrieve the chronology.

### 3.3 System Overview

Figure 3 shows the general architecture of the system. First, pre-processing of the AFP corpus tags and normalizes temporal expressions in each of the articles (step ① in the Figure). Next, the corpus is indexed by the Lucene search engine<sup>2</sup> (step ②).

Given a query, a number of documents are retrieved by Lucene (③). These documents can be filtered (④), and dates are extracted from the remaining documents. These dates are then ranked in order to show the most important ones to the user (⑤), to-

## 4 Temporal and Linguistic Processing

In this section, we describe the linguistic and temporal information extracted during the pre-processing phase and how the extraction is carried out. We rely on the powerful linguistic analyzer XIP (Ait-Mokhtar et al., 2002), that we adapted for our purposes.

### 4.1 XIP

The linguistic analyzer we use performs a deep syntactic analysis of running text. It takes as input XML files and analyzes the textual content enclosed in the various XML tags in different ways that are specified in an XML guide (a file providing instructions to the parser, see (Roux, 2004) for details). XIP performs complete linguistic processing ranging from tokenization to deep grammatical dependency analysis. It also performs named entity recog-

nition (NER) of the most usual named entity categories and recognizes temporal expressions. Linguistic units manipulated by the parser are either terminal categories or chunks. Each of these units is associated with an attribute-value matrix that contains the unit's relevant morphological, syntactic and semantic information. Linguistic constituents are linked by oriented and labelled n-ary relations denoting syntactic or semantic properties of the input text. A Java API is provided with the parser so that all linguistic structures and relations can be easily manipulated by Java code.

In the following subsections, we give details of the linguistic information that is used for the detection of salient dates.

## 4.2 Named Entity Recognition

Named Entity (NE) Recognition is one of the outputs provided by XIP. NEs are represented as unary relations in the parser output. We used the existing NE recognition module of the English grammar which tags the following NE types: **location names**, **person names** and **organization names**. Ambiguous NE types (ambiguity between type **location** or **organization** for country names for instance) are also considered.

## 4.3 Temporal Analysis

A previous module for temporal analysis was developed and integrated into the English grammar (Hagège and Tannier, 2008), and evaluated during TempEval campaign (Verhagen et al., 2007). This module was adapted for tagging salient dates. Our goal with temporal analysis is to be able to tag and normalize<sup>3</sup> a selected subset of temporal expressions (TEs) which we consider to be relevant for our task. This subset of expressions is described in the following sections.

### 4.3.1 Absolute Dates

Absolute dates are dates that can be normalized without external or contextual knowledge. This is the case, for instance, of “*On January 5th 2003*”. In these expressions, all information needed for normalization is contained in the linguistic expression.

<sup>3</sup>We call *normalization* the operation of turning a temporal expression into a formatted, fully specified representation. This includes finding the absolute value of relative dates.

However, absolute dates are relatively infrequent in our corpus (7%), so in order to broaden the coverage for the detection of salient dates, we decided to consider relative dates, which are far more frequent.

### 4.3.2 DCT-relative Dates

DCT-relative temporal expressions are those which are relative to the creation date of the document. This class represents 40% of dates extracted from the AFP corpus. Unlike the absolute dates, the linguistic expression does not provide all the information needed for normalization. External information is required, in particular, the date which corresponds to the moment of utterance. In news articles, this is the DCT. Two sub-classes of relative TEs can be distinguished. The first sub-class only requires knowledge of the DCT value to perform the normalization. This is the case of expressions like *next Friday*, which correspond to the calendar date of the first Friday following the DCT. The second sub-class requires further contextual knowledge for normalization. For example, *on Friday* will correspond either to *last Friday* or to *next Friday* depending on the context where this expression appears (e.g. *He is expected to come on Friday* corresponds to *next Friday* while *He arrived on Friday* corresponds to *last Friday*). In such cases, the tense of the verb that governs the TE is essential for normalization. This information is provided by the linguistic analysis carried out by XIP.

### 4.3.3 Underspecified Dates

Considering the kind of corpus we deal with (news), we decided to consider TEs whose granularity is at least equal to a day. As a result, TEs were normalized to a numerical YYYYMMDD format (where YYYY corresponds to the year, MM to the month and DD to the day). In case of TEs with a granularity superior to the day or month, DD and MM fields remain unspecified accordingly. However, these underspecified dates are not used in our experiments.

## 4.4 Modality and Reported Speech

An important issue that can affect the calculation of salient dates is the modality associated with timestamped events in text. For instance, the status of a salient date candidate in a sentence like “*The meet-*

ing takes place on Friday” has to be distinguished from the one in “The meeting should take place on Friday” or “The meeting will take place on Friday, Mr. Hong said”. The time-stamped event *meeting takes place* is factual in the first example and can be taken as granted. In the second and third examples, however, the event does not necessarily occur. This is expressed by the modality introduced by the modal auxiliary *should* (second example), or by the use of the future tense or reported speech (third example). We annotate TEs with information regarding the factuality of the event they modify. More specifically, we consider the following features:

**Events that are mentioned in the future:** If a time-stamped event is in the future tense, we add a specific attribute MODALITY with value FUTURE to the corresponding TE annotation.

**Events used with a modal verb:** If a time-stamped event is introduced by a modal verb such as *should* or *would*, then attribute MODALITY to the corresponding TE annotation has the value MODAL.

**Reported speech verbs:** Reported speech verbs (or verbs of speaking) introduce indirect or reported speech. We dealt with time-stamped events governed by a reported speech verb, or otherwise appearing in reported speech. Once again, XIP’s linguistic analysis provided the necessary information, including the marking of reported speech verbs and clause segmentation of complex sentences. If a relevant TE modifies a reported speech verb, the annotation of this TE contains a specific attribute, DECLARATION=“YES”. If the relevant TE modifies a verb that appears in a clause introduced by a reported speech verb then the annotation contains the attribute REPORTED=“YES”.

Note that the different annotations can be combined (e.g. modality and reported speech can occur for a same time-stamped event). For example, the TE *Friday* in “The meeting should take place on Friday, Mr. Hong said” is annotated with both modality and reported speech attributes.

#### 4.5 Corpus-dependent Special Cases

While we developed the linguistic and temporal annotators, we took into account some specificities of our corpus. We decided that the TEs *today* and

```
<DCT value="20050105"/>
<EC TYPE="TIMEX" value="unknown">The year
2004</EC> was the deadliest <EC TYPE="TIMEX"
value="unknown">in a decade</EC> for journalists
around the world, mainly because of the number of reporters
killed in <EC TYPE="LOCORG">Iraq</EC>, the
media rights group <EN TYPE="ORG">Reporters
Sans Frontieres</EN> (Reporters Without Bor-
ders) said <EC TYPE="DATE" SUBTYPE="REL"
REF="ST" DECLARATION="YES" value
="20050105">Wednesday</EC>.
```

Figure 4: Example of XIP output for a sample article.

*now* were not relevant for the detection of salient dates. In the AFP news corpus, these expressions are mostly generic expressions synonymous with *nowadays* and do not really time-stamp an event with respect to the DCT. Another specificity of the corpus is the fact that if the DCT corresponds to a Monday, and if an event in a past tense is described with the associated TE *on Monday* or *Monday*, it means that this event occurs on the DCT day itself, and not on the Monday before. We adapted the TE normalizer to these special cases.

#### 4.6 Implementation and Example

As said previously, a NER module is integrated into the XIP parser, which we used “as is”. The TE tagger and normalizer was adapted from (Hagège and Tannier, 2008). We used the Java API provided with the parser to perform the annotation and normalization of TEs. The output for the linguistic and temporal annotation consists in XML files where only selected information is kept (structural information distinguishing headlines from news content, DCT), and enriched with the linguistic annotations described before (NEs and TEs with relevant attributes corresponding to the normalization and typing). Information concerning modality, future tense and reported speech, appears as attributes on the TE tag. Figure 4 shows an example of an analyzed excerpt of a news article.

In this news excerpt, only one TE (*Wednesday*) is normalized as both *The year 2004* and *in a decade* are not considered to be relevant. The first one being a generic TE and the second one being of granularity superior to a year. The annotation of the relevant TE has the attribute indicating that it time-stamps an event realized by a reported speech verb. The nor-

malized value of the TE corresponds to the 5th of January 2005, which is a Wednesday. NEs are also annotated.

In the entire AFP corpus, 11.5 millions temporal expressions were detected, among which 845,000 absolute dates (7%) and 4.6 millions normalized relative dates (40%). Although we have not yet evaluated our tagging of relative dates, the system on which our current date normalization is based achieved good results in the TempEval (Verhagen et al., 2007) campaign.

## 5 Experiments and Results

In Section 5.1, we propose two baseline approaches in order to give a good idea of the difficulty of the task (Section 5.4 also discusses this point). In Section 5.2, we present our experiments using simple filtering and statistics on dates calculated by Lucene. Finally, Section 5.3 gives details of our experiments with a learning approach. In our experiments, we used three different values to rank dates:

- $occ(d)$  is the number of textual units (documents or sentences) containing the date  $d$ .
- Lucene provides ranked documents together with their relevance score.  $luc(d)$  is the sum of Lucene scores for textual units containing the date  $d$ .
- An adaptation of classical  $tf.idf$  for dates:

$$tf.idf(d) = f(d) \cdot \log \frac{N}{df(d)}$$

where  $f(d)$  is the number of occurrences of date  $d$  in the sentence (generally,  $f(d) = 1$ ),  $N$  is the number of indexed sentences and  $df(d)$  is the number of sentences containing date  $d$ .

In all experiments (including baselines), timelines have been built by considering only dates between the first and the last dates of the corresponding manual chronology. Processing runs were evaluated on manually-written chronologies (see Section 3.2) according to Mean Average Precision (MAP), which is a widely accepted metric for ranked lists. MAP gives a higher weight to higher ranked elements than lower ranked elements. Significance of evaluation results are indicated by the  $p$ -value results of the Student’s t-test ( $t(90) = 1.9867$ ).

Baselines “only DCTs”			
Model	$BL_{DCT}^{occ}$	$BL_{DCT}^{luc}$	$BL_{DCT}^{tf.idf}$
MAP Score	0.5036	0.5521	0.5523
Baselines “only absolute dates”			
Model	$BL_{abs}^{occ}$	$BL_{abs}^{luc}$	$BL_{abs}^{tf.idf}$
MAP Score	0.2627	0.2782	0.2778
Baselines “absolute dates or alternatively DCTs”			
Model	$BL_{mix}^{occ}$	$BL_{mix}^{luc}$	$BL_{mix}^{tf.idf}$
MAP Score	0.4005	0.4110	0.4135

Table 1: MAP results for baseline runs.

### 5.1 Baseline Runs

$BL_{DCT}$ . Indexing and search were done at **document level** (*i.e.* each AFP article, with its title and keywords, is a document). Given a query, the top 10,000 documents were retrieved. In these runs, **only the DCT** for each document was considered. Dates were ranked by one of the three values described above ( $occ$ ,  $luc$  or  $tf.idf$ ) leading to runs  $BL_{DCT}^{occ}$ ,  $BL_{DCT}^{luc}$  and  $BL_{DCT}^{tf.idf}$ .

$BL_{abs}$ . Indexing and search were done at **sentence level** (document title and keywords are added to sentence text). Given a query, the top 10,000 sentences were retrieved. **Only absolute dates** in these sentences were considered. We thus obtained runs  $BL_{abs}^{occ}$ ,  $BL_{abs}^{luc}$  and  $BL_{abs}^{tf.idf}$ .

Note that in this baseline, as well as in all the subsequent runs, the information unit was the sentence because a date was associated to a small part of the text. The rest of the document generally contained text that was not related to the specific date.

$BL_{mix}$ . Same as  $BL_{abs}$ , except that sentences containing no absolute dates were considered and associated to the DCT.

Table 1 shows results for these baseline runs. Using only DCTs with Lucene scores or  $tf.idf(d)$  already yielded interesting results, with MAP around 0.55.

### 5.2 Salient Date Extraction with XIP Results and Simple Filtering

In these experiments, we considered a Lucene index to be built as follows: each document was taken to

Model	MAP Score	Model	MAP Score
<i>Salient date runs with all dates</i>			
$SD^{luc}$	0.6962	$SD^{tf.idf}$	0.6982
<i>Salient dates runs with filtering</i>			
$SD_R^{luc}$	0.6975	$SD_R^{tf.idf}$	0.6996
$SD_F^{luc}$	0.6967	$SD_F^{tf.idf}$	0.6993 **
$SD_M^{luc}$	0.6978	$SD_M^{tf.idf}$	0.7005 *
$SD_D^{luc}$	0.7066 **	$SD_D^{tf.idf}$	0.7091 **
$SD_{FMD}^{luc}$	0.7086 **	$SD_{FMD}^{tf.idf}$	0.7112 **
$SD_{RFMD}^{luc}$	0.7127 **	$SD_{RFMD}^{tf.idf}$	0.7146 **

Table 2: MAP results for salient date extraction with XIP and simple filtering. The significance of the improvement due to filtering wrt no filtering is indicated by the Student t-test (\*:  $p < 0.05$  (significant); \*\*:  $p < 0.01$  (highly significant)). The improvement due to using  $tf.idf(d)$  as opposed to  $occ(d)$  is also highly significant.

be a **sentence** containing a **normalized date**. This sentence was indexed with the title and keywords of the AFP article containing it. Given a query, the top 10,000 documents were retrieved. Combinations between the following filtering operations were possible, by removing all dates associated with a reported speech verb ( $R$ ), a modal verb ( $M$ ) and/or a future verb ( $F$ ). All these filtering operations were intended to remove references to events that were not certain, thereby minimizing noise in results.

These processing runs are named  $SD$  runs, with indices representing the filtering operations. For example, a run obtained by filtering modal and future verbs is called  $SD_{M,F}$ . In all combinations, dates were ranked by the sum of Lucene scores for these sentences ( $luc$ ) or by  $tf.idf^4$ .

Table 2 presents the results for this series of experiments. MAP values are much higher than for baselines. Using  $tf.idf(d)$  is only very slightly better than  $luc$ . Filtering operations bring significant improvement but the benefits of these different techniques have to be further investigated.

### 5.3 Machine-Learning Runs

We used our set of manually-written chronologies as a training corpus to perform machine learning experiments. We used IcsiBoost<sup>5</sup>, an implementa-

<sup>4</sup>We do not present runs where dates are ranked by the number of times they appear in retrieved sentences ( $occ$ ), as we did for baselines, since results are systematically lower.

<sup>5</sup><http://code.google.com/p/icsiboost/>

tion of adaptative boosting (AdaBoost (Freund and Schapire, 1997)).

In our approach, we consider two classes: *salient dates* are dates that have an entry in the manual chronologies, while *non-salient dates* are all other dates. This choice does, however, represent an important bias. The choices of journalists are indeed very subjective, and chronologies must not exceed a certain length, which means that relevant dates can be thrown away. These issues will be discussed in Section 5.4.

The classifier instances were not all sentences retrieved by the search engine. Using all sentences would not yield a useful feature set. We rather aggregated all sentences corresponding to the same date before learning the classifier. Therefore, each instance corresponded to a single date, and features were figures concerning the set of sentences containing this date.

Features used in this series of runs are as follows:

1. Features representing the fact that the more a date is mentioned, the more important it is likely to be: 1) Sum of the Lucene scores for all sentences containing the date 2) Number of sentences containing the date 3) Ratio between the total weights of the date and weights of all returned dates 4) Ratio between the frequency of the date and frequency of all returned dates;
2. Features representing the fact that an important event is still written about, a long time after it occurs: 1) Distance between the date and the most recent mention of this date 2) Distance between the date and the DCT;
3. Other features: 1) Lucene's best ranking of the date 2) Number of times where the date is absolute in the text 3) Number of times where the date is relative (but normalized) in the text 4) Total number of keywords of the query in the title, sentence and named entities of retrieved documents 5) Number of times where the date modifies a reported speech verb or is extracted from reported speech.

We did not aim to classify dates, but rather to rank them. Instead, we used the predicted probability  $P(d)$  returned by the classifier, and mixed it with the Lucene score of sentences, or with date  $tf.idf$ :

Model	MAP Score
<i>Machine-Learning Runs</i>	
$ML_{base}^{luc}$	0.7033
$ML^{luc}$	0.7905 **
$ML^{tf.idf}$	0.7918 **

Table 3: MAP results for salient date extraction with machine-learning.  $ML_{base}^{luc}$  used Lucene scores and only the first set of features described above.  $ML^{luc}$  and  $ML^{tf.idf}$  used the three sets of features. They are both highly significant under the *t-test* ( $p \approx 6.10^{-4}$ ) wrt respectively  $SD^{luc}$  and  $SD^{tf.idf}$ .

$$score(d) = P(d) \times val(d)$$

where  $val(d)$  is either  $luc(d)$  or  $tf.idf(d)$ .

Because the task is very subjective and (above all) because of the low quantity of learning data, we preferred not to opt for a “learning to rank” approach.

We evaluated this approach with a classic 4-fold cross-validation. Our 91 chronologies were randomly divided into 4 sub-samples, each of them being used once as test data. The final scores, presented in Table 3, are the average of these 4 processes. As shown in this table, the learning approach improves MAP results by about 0.05 point.

#### 5.4 Discussion and Final Experiment

Chronologies hand-written by journalists are a very useful resources for evaluation of our system, as they are completely dissociated from our research and are an exact representation of the output we aim to obtain. However, assembling such a chronology is a very subjective task, and no clear method for evaluation agreement between two journalists seems immediately apparent. Only experts can build such chronologies, and calculating this agreement would require at least two experts from each domain, which are hard to come by. One may then consider our system as a useful tool for building a chronology more objectively.

To illustrate this point, we chose four specific topics<sup>6</sup> and showed one of our runs on each topic to an AFP expert for these subjects. We asked him to assess the first 30 dates of these runs.

<sup>6</sup>Namely, “Arab revolt timeline for Morocco”, “Kyrgyzstan unrest timeline”, “Lebanon’s new government: a timeline”, “Libya timeline”.

Topic	$AP_C$	$AP_E$
<i>Morocco</i>	0.5847	0.5718
<i>Kyrgyzstan</i>	0.6125	0.9989
<i>Libya</i>	0.7856	1
<i>Lebanon</i>	0.4673	0.7652

Table 4: Average precision results for manual evaluation on 4 topics, against the original chronologies ( $AP_C$ ), and the expert assessment ( $AP_E$ ).

Table 4 presents results for this evaluation, comparing average precision values obtained 1) against the original, manual chronologies ( $AP_C$ ), and 2) against the expert assessment ( $AP_E$ ). These values show that, for 3 runs out of 4, many dates returned by the system are considered as valid by the expert, even if not presented in the original chronology.

Even if this experiment is not strong enough to lead to a formal conclusion (*post-hoc* evaluation with only 4 topics and a single assessor), this tends to show that our system produces usable outputs and that our system can be of help to journalists by providing them with chronologies that are as useful and objective as possible.

## 6 Conclusion and Future Work

This article presents a task of “date extraction” and shows the importance of taking temporal information into consideration and how with relatively simple temporal processing, we were able to indirectly point to important events using the temporal information associated with these events. Of course, as our final goal consists in the detection of important events, we need to take into account the textual content. In future work, we envisage providing, together with the detection of salient dates, a semantic analysis that will help determine the importance of events. Another interesting direction in which we soon aim to work is to consider all textual excerpts that are associated with salient dates, and use clustering techniques to determine if textual excerpts correspond to the same event or not. Finally, as our news corpus is available both for English and French (comparable corpus, not necessarily translations), we aim to investigate cross-lingual extraction of salient dates and salient events.

## Abstract

We propose a latent variable model to enhance historical analysis of large corpora. This work extends prior work in topic modelling by incorporating metadata, and the interactions between the components in metadata, in a general way. To test this, we collect a corpus of slavery-related United States property law judgements sampled from the years 1730 to 1866. We study the language use in these legal cases, with a special focus on shifts in opinions on controversial topics across different regions. Because this is a longitudinal data set, we are also interested in understanding how these opinions change over the course of decades. We show that the joint learning scheme of our sparse mixed-effects model improves on other state-of-the-art generative and discriminative models on the region and time period identification tasks. Experiments show that our sparse mixed-effects model is more accurate quantitatively and qualitatively interesting, and that these improvements are robust across different parameter settings.

## 1 Introduction

Many scientific subjects, such as psychology, learning sciences, and biology, have adopted computational approaches to discover latent patterns in large scale datasets (Chen and Lombardi, 2010; Baker and Yacef, 2009). In contrast, the primary methods for historical research still rely on individual judgement and reading primary and secondary sources, which are time consuming and expensive. Furthermore, traditional human-based methods might have good precision when searching for relevant information, but suffer from low recall. Even when language technologies have been applied to historical problems, their focus has often been on information retrieval (Gotscharek et al., 2009), to improve accessibility of texts. Empirical methods for analysis and interpretation of these texts is therefore a burgeoning new field.

Court opinions form one of the most important parts of the legal domain, and can serve as an excellent resource to understand both legal and political history (Popkin, 2007). Historians often use court opinions as a primary source for constructing interpretations of the past. They not only report the proceedings of a court, but also express a judges' views toward the issues at hand in a case, and reflect the legal and political environment of the region and period. Since there exists many thousands of early court opinions, however, it is difficult for legal historians to manually analyze the documents case by case. Instead, historians often restrict themselves to discussing a relatively small subset of legal opinions that are considered decisive. While this approach has merit, new technologies should allow extraction of patterns from large samples of opinions.

Latent variable models, such as latent Dirichlet allocation (LDA) (Blei et al., 2003) and probabilistic latent semantic analysis (PLSA) (Hofmann, 1999), have been used in the past to facilitate social science research. However, they have numerous drawbacks, as many topics are uninterpretable, overwhelmed by uninformative words, or represent background language use that is unrelated to the dimensions of analysis that qualitative researchers are interested in.

SAGE (Eisenstein et al., 2011a), a recently proposed sparse additive generative model of language, addresses many of the drawbacks of LDA. SAGE assumes a background distribution of language use, and enforces sparsity in individual topics. Another advantage, from a social science perspective, is that SAGE can be derived from a standard logit random-utility model of judicial opinion writing, in contrast to LDA. In this work we extend SAGE to the supervised case of joint region and time period prediction. We formulate the resulting sparse mixed-effects (SME) model as being made up of mixed effects that not only contain random effects from sparse topics, but also mixed effects from available metadata. To do this we augment SAGE with two sparse latent variables that model the region and time of a document, as well as a third sparse latent

variable that captures the interactions among the region, time and topic latent variables. We also introduce a multiclass perceptron-style weight estimation method to model the contributions from different sparse latent variables to the word posterior probabilities in this predictive task. Importantly, the resulting distributions are still sparse and can therefore be qualitatively analyzed by experts with relatively little noise.

In the next two sections, we overview work related to qualitative social science analysis using latent variable models, and introduce our slavery-related early United States court opinion data. We describe our sparse mixed-effects model for joint modeling of region, time, and topic in section 4. Experiments are presented in section 5, with a robust analysis from qualitative and quantitative standpoints in section 5.2, and we discuss the conclusions of this work in section 6.

## 2 Related Work

Natural Language Processing (NLP) methods for automatically understanding and identifying key information in historical data have not yet been explored until recently. Related research efforts include using the LDA model for topic modeling in historical newspapers (Yang et al., 2011), a rule-based approach to extract verbs in historical Swedish texts (Pettersson and Nivre, 2011), a system for semantic tagging of historical Dutch archives (Cybulska and Vossen, 2011).

Despite our historical data domain, our approach is more relevant to text classification and topic modelling. Traditional discriminative methods, such as support vector machine (SVM) and logistic regression, have been very popular in various text categorization tasks (Joachims, 1998; Wang and McKeown, 2010) in the past decades. However, the main problem with these methods is that although they are accurate in classifying documents, they do not aim at helping us to understand the documents.

Another problem is lack of expressiveness. For example, SVM does not have latent variables to model the subtle differences and interactions of features from different domains (e.g. text, links, and date), but rather treats them as a “bag-of-features”. Generative methods, by contrast, can show the causes to effects, have attracted attentions in recent years due to the rich expressiveness of the models and competitive performances in predictive tasks (Wang et al., 2011). For example, Nguyen et al. (2010) study the effect of the context of interaction in blogs using a standard LDA model. Guo and Diab (2011) show the effectiveness of using se-

mantic information in multifaceted topic models for text categorization. Eisenstein et al. (2010) use a latent variable model to predict geolocation information of Twitter users, and investigate geographic variations of language use. Temporally, topic models have been used to show the shift in language use over time in online communities (Nguyen and Rosé, 2011) and the evolution of topics over time (Shubhankar et al., 2011).

When evaluating understandability, however, dense word distributions are a serious issue in many topic models as well as other predictive tasks. Such topic models are often dominated by function words and do not always effectively separate topics. Recent work have shown significant gains in both predictiveness and interpretability by enforcing sparsity, such as in the task of discovering sociolinguistic patterns of language use (Eisenstein et al., 2011b).

Our proposed sparse mixed-effects model balances the pros and cons the above methods, aiming at higher classification accuracies using the SME model for joint geographic and temporal aspects prediction, as well as richer interaction of components from metadata to enhance historical analysis in legal opinions. To the best of our knowledge, this study is the first of its kind to discover region and time specific topical patterns jointly in historical texts.

## 3 Data

We have collected a corpus of slavery-related United States supreme court legal opinions from Lexis Nexis. The dataset includes 5,240 slavery-related state supreme court cases from 24 states, during the period of 1730 - 1866. Optical character recognition (OCR) software was used by Lexis Nexis to digitize the original documents. In our region identification task, we wish to identify whether an opinion was written in a free state<sup>1</sup> (R1) or a slave state (R2)<sup>2</sup>. In our time identification experiment, we approximately divide the legal documents into four time quartiles (Q1, Q2, Q3, and Q4), and predict which quartile the testing document belongs to. Q1 contains cases from 1837 or earlier, where as Q2 is for 1838-1848, Q3 is for 1849-1855, and Q4 is for 1856 and later.

## 4 The Sparse Mixed-Effects Model

To address the over-parameterization, lack of expressiveness and robustness issues in LDA, the SAGE (Eisenstein et al., 2011a) framework draws a

<sup>1</sup>Including border states, this set includes CT, DE, IL, KY, MA, MD, ME, MI, NH, NJ, NY, OH, PA, and RI.

<sup>2</sup>These states include AR, AL, FL, GA, MS, NC, TN, TX, and VA.

- For each document  $d$ 
  - Draw the region label  $y_d^{(R)}$
  - Draw the time quartile label  $y_d^{(Q)}$
  - For each word  $n$ , draw  $w_n^{(d)} \sim \beta_{y_d}$

#### 4.1 Parameter Estimation

We follow the MAP estimation method that Eisenstein et al. (2011a) used to train all sparse latent variables  $\eta$ , and perform Bayesian inference on other latent variables. The estimation of all variance variables  $\tau$  remains as plugging the compound distribution of Normal-Jeffrey’s prior, where the latter is a replacement of the Exponential prior. When performing Expectation-Maximization (EM) algorithm to infer the latent variables in SME, we derive the following likelihood function:

$$\begin{aligned}
\mathcal{L} = & \sum_d \langle \log P(\theta_d | \alpha) \rangle + \langle \log P(Z_n^{(d)} | \theta_d) \rangle \\
& + \sum_n^{N_d} \langle \log P(w_n^{(d)} | z_n^{(d)}, \eta, m, y_d^{(R)}, y_d^{(Q)}) \rangle \\
& + \sum_k \langle \log P(\eta_k^{(T)} | 0, \tau_k^{(T)}) \rangle + \sum_k \langle \log P(\tau_k^{(T)} | \gamma) \rangle \\
& + \sum_j \langle \log P(\eta_j^{(R)} | 0, \tau_j^{(R)}) \rangle + \sum_j \langle \log P(\tau_j^{(R)} | \gamma) \rangle \\
& + \sum_q \langle \log P(\eta_q^{(Q)} | 0, \tau_q^{(Q)}) \rangle + \sum_q \langle \log P(\tau_q^{(Q)} | \gamma) \rangle \\
& + \sum_q \sum_j \sum_k \langle \log P(\eta_{q,j,k}^{(I)} | 0, \tau_{q,j,k}^{(I)}) \rangle \\
& + \sum_q \sum_j \sum_k \langle \log P(\tau_{q,j,k}^{(I)} | \gamma) \rangle \\
& - \langle \log Q(\tau, z, \theta) \rangle
\end{aligned}$$

The above E step likelihood score can be intuitively interpreted as the sum of topic proportion scores, latent topic scores, the word scores, the  $\eta$  scores with their priors, and minus the joint variance. In the M step, when we use Newton’s method to optimize the sparse deviation  $\eta_k$  parameter, we need to modify the original likelihood function in SAGE and its corresponding first and second order derivatives when deriving the gradient and Hessian matrix. The likelihood function for sparse topic deviation  $\eta_k$  is:

$$\begin{aligned}
\mathcal{L}(\eta_k) = & \langle c_k^{(T)} \rangle \top \eta_k \\
& - C_d \log \sum_q \sum_j \sum_i \exp(\lambda^{(Q)} \eta_{qi} + \lambda^{(R)} \eta_{ji}) \\
& + \eta_{ki} + \eta_{qjk i} + m_i - \eta_k \top \text{diag}(\langle (\tau_k^{(T)})^{-1} \rangle) \eta_k^{(T)} / 2
\end{aligned}$$

and we can derive the gradient when taking the first order partial derivative:

$$\begin{aligned}
\frac{\partial \mathcal{L}}{\partial \eta_k^{(T)}} = & \langle c_k^{(T)} \rangle - \sum_q \sum_j \langle C_{qjk} \rangle \beta_{qjk} \\
& - \text{diag}(\langle (\tau_k^{(T)})^{-1} \rangle) \eta_k^{(T)}
\end{aligned}$$

where  $c_k^{(T)}$  is the true count, and  $\beta_{qjk}$  is the log word likelihood in the original likelihood function.  $C_{qjk}$  is the expected count from combinations of time, region and topic.  $\sum_q \sum_j \langle C_{qjk} \rangle \beta_{qjk}$  will then be taken the second order derivative to form the Hessian matrix, instead of  $\langle C_k \rangle \beta_k$  in the previous SAGE setting.

To learn the weight parameters  $\lambda^{(R)}$  and  $\lambda^{(Q)}$ , we can approximate the weights using a multiclass perceptron-style (Collins, 2002) learning method. If we say that the notation of  $\sum V^{(\bar{R})}$  is to marginalize out all other variables in  $\beta$  except  $\eta^{(R)}$ , and  $P(y_d^{(R)})$  is the prior for the region prediction task, we can predict the expected region value  $\hat{y}_d^{(R)}$  of a document  $d$ :

$$\begin{aligned}
\hat{y}_d^{(R)} & \propto \arg \max_{\hat{y}_d^{(R)}} \exp \left( \sum V^{(\bar{R})} \log \beta + \log P(y_d^{(R)}) \right) \\
= \arg \max_{\hat{y}_d^{(R)}} & \left( \exp \left( \sum V^{(\bar{R})} (m + \eta_{z_n^{(d)}}^{(T)} + \lambda^{(R)} \eta_{y_d^{(R)}}^{(R)} \right. \right. \\
& \left. \left. + \lambda^{(Q)} \eta_{y_d^{(Q)}}^{(Q)} + \eta_{y_d^{(R)}, y_d^{(Q)}, z_n^{(d)}}^{(I)} \right) P(y_d^{(R)}) \right)
\end{aligned}$$

If the symbol  $\delta$  is the hyperprior for the learning rate and  $\hat{y}_d^{(R)}$  is the true label, the update procedure for the weights becomes:

$$\lambda_d^{(R')} = \lambda_d^{(R)} + \delta (\hat{y}_d^{(R)} - y_d^{(R)})$$

Similarly, we derive the  $\lambda^{(Q)}$  parameter using the above formula. It is necessary to normalize the weights in each EM loop to preserve the sparsity property of latent variables. The weight update of  $\lambda^{(R)}$  and  $\lambda^{(Q)}$  is bound by the averaged accuracy of the two classification tasks in the training data, which is similar to the notion of minimizing empirical risk (Bahl et al., 1988). Our goal is to choose the two weight parameters that minimize the empirical classification error rate on training data when learning the word posterior probability.

#### 5 Prediction Experiments

We perform three quantitative experiments to evaluate the predictive power of the sparse mixed-effects model. In these experiments, to predict the region and time period labels of a given document, we

jointly learn the two labels in the SME model, and choose the pair which maximizes the probability of the document.

In the first experiment, we compare the prediction accuracy of our SME model to a widely used discriminative learner in NLP – the linear kernel support vector machine (SVM)<sup>3</sup>. In the second experiment, in addition to the linear kernel SVM, we also compare our SME model to a state-of-the-art sparse generative model of text (Eisenstein et al., 2011a), and vary the size of input vocabulary  $W$  exponentially from  $2^9$  to the full size of our training vocabulary<sup>4</sup>. In the third experiment, we examine the robustness of our model by examining how the number of topics influences the prediction accuracy when varying the  $K$  from 10 to 50.

Our data consists of 4615 training documents and 625 held-out documents for testing. While individual judges wrote multiple opinions in our corpus, no judges overlapped between training and test sets. When measuring by the majority class in the testing condition, the chance baseline for the region identification task is 57.1% and the time identification task is 32.3%. We use three-fold cross-validation to infer the learning rate  $\delta$  and cost  $C$  hyperpriors in the SME and SVM model respectively. We use the paired student  $t$ -test to measure the statistical significance.

## 5.1 Quantitative Results

### 5.1.1 Comparing SME to SVM

We show in this section the predictive power of our sparse mixed-effects model, comparing to a linear kernel SVM learner. To compare the two models in different settings, we first empirically set the number of topics  $K$  in our SME model to be 25, as this setting was shown to yield a promising result in a previous study (Eisenstein et al., 2011a) on sparse topic models. In terms of the size of vocabulary  $W$  for both the SME and SVM learner, we select three values to represent dense, medium or sparse feature spaces:  $W_1 = 2^9$ ,  $W_2 = 2^{12}$ , and the full vocabulary size of  $W_3 = 2^{13.8}$ . Table 1 shows the accuracy of both models, as well as the relative improvement (gain) of SME over SVM.

When looking at the experiment results under different settings, we see that the SME model always outperforms the SVM learner. In the time quartile prediction task, the advantage of SME model

<sup>3</sup>In our implementation, we use LibSVM (Chang and Lin, 2011).

<sup>4</sup>To select the vocabulary size  $W$ , we rank the vocabulary by word frequencies in a descending order, and pick the top- $W$  words.

Method	Time	Gain	Region	Gain
SVM ( $W_1$ )	33.2%	–	69.7%	–
SME ( $W_1$ )	36.4%	9.6%	71.4%	2.4%
SVM ( $W_2$ )	35.8%	–	72.3%	–
SME ( $W_2$ )	40.9%	14.2%	74.0%	2.4%
SVM ( $W_3$ )	36.1%	–	73.5%	–
SME ( $W_3$ )	41.9%	16.1%	74.8%	1.8%

Table 1: Compare the accuracy of the linear kernel support vector machine to our sparse mixed-effects model in the region and time identification tasks ( $K = 25$ ). *Gain: the relative improvement of SME over SVM.*

is more salient. For example, with a medium density feature space of  $2^{12}$ , SVM obtained an accuracy of 35.8%, but SME achieved an accuracy of 40.9%, which is a 14.2% relative improvement ( $p < 0.001$ ) over SVM. When the feature space becomes sparser, the SME obtains an increased relative improvement ( $p < 0.001$ ) of 16.1%, using full size of vocabulary. The performance of SVM in the binary region classification is stronger than in the previous task, but SME is able to outperform SVM in all three settings, with tightened advantages ( $p < 0.05$  in  $W_2$  and  $p < 0.001$  in  $W_3$ ). We hypothesize that it might be because that SVM, as a strong large margin learner, is a more natural approach in a binary classification setting, but might not be the best choice in a four-way or multiclass classification task.

### 5.1.2 Comparing SME to SAGE

In this experiment, we compare SME with a state-of-the-art sparse generative model: SAGE (Eisenstein et al., 2011a).

Most studies on topic modelling have not been able to report results when using different sizes of vocabulary for training. Because of the importance of interpretability for social science research, the choice of vocabulary size is critical to ensure understandable topics. Thus we report our results at various vocabulary sizes  $W$  on SME and SAGE. To better validate the performance of SME, we also include the performance of SVM in this experiment, and fix the number of topics  $K = 10$  for the SME and SAGE models, which is a different value for the number of topics  $K$  than the empirical  $K$  we used in the experiment of Section 5.1.1. Figure 2 and Figure 3 show the experiment results in both time and region classification task.

In Figure 2, we evaluate the impacts of  $W$  on our time quartile prediction task. The advantage of the SME model is very obvious throughout the experiments. Interestingly, when we continue to increase

Figure 2: Accuracy on predicting the time quartile varying the vocabulary size  $W$ , while  $K$  is fixed to 10.

Figure 3: Accuracy on predicting the region varying the vocabulary size  $W$ , while  $K$  is fixed to 10.

the vocabulary size  $W$  exponentially and make the feature space more sparse, SME obtains its best result at  $W = 2^{13}$ , where the relative improvement over SAGE and SVM is 16.8% and 22.9% respectively ( $p < 0.001$  under all comparisons).

Figure 3 shows the impacts of  $W$  on the accuracy of SAGE and SME in the region identification task. In this experiment, the results of SME model are in line with SAGE and SVM when the feature space is dense. However, when  $W$  reaches the full vocabulary size, we have observed significantly better results ( $p < 0.001$  in the comparison to SAGE and  $p < 0.05$  with SVM). We hypothesize that there might be two reasons: first, the  $K$  parameter is set to 10 in this experiment, which is much denser than the experiment setting in Section 5.1.1. Under this condition, the sparse topic advantage of SME might be less salient. Secondly, in the two tasks, it is observed that the accuracy of the binary region classification task is much higher than the four-way task, thus while the latter benefits significantly from this joint learning scheme of the SME model, but the former might not have the equivalent gain<sup>5</sup>.

<sup>5</sup>We hypothesize that this problem might be eliminated if

### 5.1.3 Influence of the number of topics $K$

Figure 4: Accuracy on predicting the time quartile varying the number of topics  $K$ , while  $W$  is fixed to  $2^9$ .

Figure 5: Accuracy on predicting the region varying the number of topics  $K$ , while  $W$  is fixed to  $2^9$ .

Unlike hierarchical Dirichlet processes (Teh et al., 2006), in parametric Bayesian generative models, the number of topics  $K$  is often set manually, and can influence the model’s accuracy significantly. In this experiment, we fix the input vocabulary  $W$  to  $2^9$ , and compare the mixed-effect model with SAGE in both region and time identification tasks.

Figure 4 shows how the variations of  $K$  can influence the system performance in the time quartile prediction task. We can see that the sparse mixed-effects model (SME) reaches its best performance when the  $K$  is 40. After increasing the number of topics  $K$ , we can see SAGE consistently increase its accuracy, obtaining its best result when  $K = 30$ . When comparing these two models, SME’s best performance outperforms SAGE’s with an absolute improvement of 3%, which equals to a relative improvement ( $p < 0.001$ ) of 8.4%. Figure 5 demonstrates the impacts of  $K$  on the predictive power of SME and SAGE in the region identification task.

the two tasks in SME have similar difficulties and accuracies, but this needs to be verified in future work.

Keywords discovered by the SME model	
Prior to 1837 (Q1)	pauperis, footprints, American Colonization Society, manumissions, 1797
1838 - 1848 (Q2)	indentured, borrowers, orphan's, 1841, vendee's, drawer's, copartners
1849 - 1855 (Q3)	Frankfort, negro trader, 1851, Kentucky Assembly, marshaled, classed
After 1856 (Q4)	railroadco, statute, Alabama, steamboats, Waterman's, mulattoes, man-trap
Free Region (R1)	apprenticed, overseer's, Federal Army, manumitting, Illinois constitution
Slave Region (R2)	Alabama, Clay's Digest, oldest, cotton, reinstatement, sanction, plantation's
Topic 1 in Q1 R1	imported, comaker, runs, writ's, remainderman's, converters, runaway
Topic 1 in Q1 R2	comaker, imported, deceitful, houston, send, bright, remainderman's
Topic 2 in Q1 R1	descendent, younger, administrator's, documentary, agreeable, emancipated
Topic 2 in Q1 R2	younger, administrator's, grandmother's, plaintiffs, emancipated, learnedly
Topic 3 in Q2 R1	heir-at-law, reconsidered, manumissions, birthplace, mon, mother-in-law
Topic 3 in Q2 R2	heir-at-law, reconsideration, mon, confessions, birthplace, father-in-law's
Topic 4 in Q2 R1	indentured, apprenticed, deputy collector, stepfather's, traded, seizes
Topic 4 in Q2 R2	deputy collector, seizes, traded, hiring, stepfather's, indentured, teaching
Topic 5 in Q4 R1	constitutionality, constitutional, unconstitutionally, Federal Army, violated
Topic 5 in Q4 R2	petition, convictions, criminal court, murdered, constitutionality, man-trap

Table 2: A partial listing of an example for early United States state supreme court opinion keywords generated from the time quartile  $\eta^{(Q)}$ , region  $\eta^{(R)}$  and topic-region-time  $\eta^{(I)}$  interactive variables in the sparse mixed-effects model.

Except that the two models tie up when  $K = 10$ , SME outperforms SAGE for all subsequent variations of  $K$ . Similar to the region task, SME achieves the best result when  $K$  is sparser ( $p < 0.01$  when  $K = 40$  and  $K = 50$ ).

## 5.2 Qualitative Analysis

In this section, we qualitatively evaluate the topics generated vis-a-vis the secondary literature on the legal and political history of slavery in the United States. The effectiveness of SME could depend not just on its predictive power, but also in its ability to generate topics that will be useful to historians of the period. Supreme court opinions on slavery are of significant interest for American political history. The conflict over slave property rights was at the heart of the “cold war” (Wright, 2006) between North and South leading up to the U.S. Civil War. The historical importance of this conflict between Northern and Southern legal institutions is one of the motivations for choosing our data domain.

We conduct qualitative analyses on the top-ranked keywords<sup>6</sup> that are associated with different geographical locations and different temporal frames, generated by our SME model. In our analysis, for

each interaction of topic, region, and time period, a list of the most salient vocabulary words was generated. These words were then analyzed in the context of existing historical literature on the shift in attitudes and views over time and across regions. Table 2 shows an example of relevant keywords and topics.

This difference between Northern and Southern opinion can be seen in some of the topics generated by the SME. Topic 1 deals with transfers of human beings as slave property. The keyword “remainderman” designates a person who inherits or is entitled to inherit property upon the termination of an estate, typically after the death of a property owner, and appears in Northern and Southern cases. However, in Topic 1 “runaway” appears as a keyword in decisions from free states but not in decisions from slave states. The fact that “runaway” is not a top word in the same topic in the Southern legal opinions is consistent with a spatial (geolocational) division in which the property claims of slave owners over runaways were not heavily contested in Southern courts.

Topic 3 concerns bequests, as indicated by the term “heir-at-law”, but again the term “manumissions”, ceases to show up in the slave states after the first time quartile, perhaps reflecting the hostility to

<sup>6</sup>Keywords were ranked by word posterior probabilities.

manumissions that southern courts exhibited as the conflict over slavery deepened.

Topic 4 concerns indentures and apprentices. Interestingly, the terms indentures and apprenticeships are more prominent in the non-slave states, reflecting the fact that apprenticeships and indentures were used in many border states as a substitute for slavery, and these were often governed by continued usage of Master and Servant law (Orren, 1992).

Topic 5 shows the constitutional crisis in the states. In particular, the anti-slavery state courts are prone to use the term “unconstitutional” much more often than the slave states. The word “man-trap”, a term used to refer to states where free blacks could be kidnapped purpose of enslaving them. The fugitive slave conflicts of the mid-19th century that led to the civil war were precisely about this aversion of the northern states to having to return runaway slaves to the Southern states.

Besides these subjective observations about the historical significance of the SME topics, we also conduct a more formal analysis comparing the SME classification to that conducted by a legal historian. Wahl (2002) analyses and classifies by hand 10989 slave cases in the US South into 6 categories: “Hires”, “Sales”, “Transfers”, “Common Carrier”, “Black Rights” and “Other”. An example of “Hires” is Topic 4. Topics 1, 2, and 3 concern “Transfers” of slave property between inheritors, descendants and heirs-at-law. Topic 5 would be classified as “Other”.

We take each of our 25 modelled topics and classify them along Wahl’s categories, using “Other” when a classification could not be obtained. The classifications are quite transparent in virtually all cases, as certain words (such as “employer” or “bequest”) clearly designate certain categories (respectively, such as “Hires” or “Transfers”). We then calculate the probability of each of Wahl’s categories in Region 2. We then compare these to the relative frequencies of Wahl’s categorization in the states that overlap with our Region 2 in Figure 6 and do a  $\chi^2$  test for goodness of fit, which allows us to reject difference at 0.1% confidence.

The SME model thus delivers topics that, at a first pass, are consistent with the history of the period as well as previous work by historians, showing the qualitative benefits of the model. We plan to conduct more vertical and temporal analyses using SME in the future.

## 6 Conclusion and Future Work

In this work, we propose a sparse mixed-effects model for historical analysis of text. This model is built on the state-of-the-art in latent variable mod-

Figure 6: Comparison with Wahl (2002) classification.

elling and extends that model to a setting where metadata is available for analysis. We jointly model those observed labels as well as unsupervised topic modelling. In our experiments, we have shown that the resulting model jointly predicts the region and the time of a given court document. Across vocabulary sizes and number of topics, we have achieved better system accuracy than state-of-the-art generative and discriminative models of text. Our quantitative analysis shows that early US state supreme court opinions are predictable, and contains distinct views towards slave-related topics, and the shifts among opinions depending on different periods of time. In addition, our model has been shown to be effective for qualitative analysis of historical data, revealing patterns that are consistent with the history of the period.

This approach to modelling text is not limited to the legal domain. A key aspect of future work will be to extend the Sparse Mixed-Effects paradigm to other problems within the social sciences where metadata is available but qualitative analysis at a large scale is difficult or impossible. In addition to historical documents, this can include humanities texts, which are often sorely lacking in empirical justifications, and analysis of online communities, which are often rife with available metadata but produce content far faster than it can be analyzed by experts.

## Abstract

Previous work using topic model for statistical machine translation (SMT) explore topic information at the word level. However, SMT has been advanced from word-based paradigm to phrase/rule-based paradigm. We therefore propose a topic similarity model to exploit topic information at the synchronous rule level for hierarchical phrase-based translation. We associate each synchronous rule with a topic distribution, and select desirable rules according to the similarity of their topic distributions with given documents. We show that our model significantly improves the translation performance over the baseline on NIST Chinese-to-English translation experiments. Our model also achieves a better performance and a faster speed than previous approaches that work at the word level.

## 1 Introduction

Topic model (Hofmann, 1999; Blei et al., 2003) is a popular technique for discovering the underlying topic structure of documents. To exploit topic information for statistical machine translation (SMT), researchers have proposed various topic-specific lexicon translation models (Zhao and Xing, 2006; Zhao and Xing, 2007; Tam et al., 2007) to improve translation quality.

Topic-specific lexicon translation models focus on word-level translations. Such models first estimate word translation probabilities conditioned on topics, and then adapt lexical weights of phrases

by these probabilities. However, the state-of-the-art SMT systems translate sentences by using sequences of synchronous rules or phrases, instead of translating word by word. Since a synchronous rule is rarely factorized into individual words, we believe that it is more reasonable to incorporate the topic model directly at the rule level rather than the word level.

Consequently, we propose a **topic similarity** model for hierarchical phrase-based translation (Chiang, 2007), where each synchronous rule is associated with a topic distribution. In particular,

- Given a document to be translated, we calculate the topic similarity between a rule and the document based on their topic distributions. We augment the hierarchical phrase-based system by integrating the proposed topic similarity model as a new feature (Section 3.1).
- As we will discuss in Section 3.2, the similarity between a generic rule and a given source document computed by our topic similarity model is often very low. We don't want to penalize these generic rules. Therefore we further propose a topic sensitivity model which rewards generic rules so as to complement the topic similarity model.
- We estimate the topic distribution for a rule based on both the source and target side topic models (Section 4.1). In order to calculate similarities between target-side topic distributions of rules and source-side topic distributions of given documents during decoding, we project

\*Corresponding author

Figure 1: Four synchronous rules with topic distributions. Each sub-graph shows a rule with its topic distribution, where the X-axis means topic index and the Y-axis means the topic probability. Notably, the rule (b) and rule (c) shares the same source Chinese string, but they have different topic distributions due to the different English translations.

the target-side topic distributions of rules into the space of source-side topic model by one-to-many projection (Section 4.2).

Experiments on Chinese-English translation tasks (Section 6) show that, our method outperforms the baseline hierarchical phrase-based system by +0.9 BLEU points. This result is also +0.5 points higher and 3 times faster than the previous topic-specific lexicon translation method. We further show that both the source-side and target-side topic distributions improve translation quality and their improvements are complementary to each other.

## 2 Background: Topic Model

A topic model is used for discovering the topics that occur in a collection of documents. Both Latent Dirichlet Allocation (LDA) (Blei et al., 2003) and Probabilistic Latent Semantic Analysis (PLSA) (Hofmann, 1999) are types of topic models. LDA is the most common topic model currently in use, therefore we exploit it for mining topics in this paper. Here, we first give a brief description of LDA.

LDA views each document as a mixture proportion of various topics, and generates each word by multinomial distribution conditioned on a topic. More specifically, as a generative process, LDA first samples a document-topic distribution for each document. Then, for each word in the document, it samples a topic index from the document-topic distribution and samples the word conditioned on the topic index according the topic-word distribution.

Generally speaking, LDA contains two types of parameters. The first one relates to the document-topic distribution, which records the topic distribution of each document. The second one is used for topic-word distribution, which represents each topic

as a distribution over words. Based on these parameters (and some hyper-parameters), LDA can infer a topic assignment for each word in the documents. In the following sections, we will use these parameters and the topic assignments of words to estimate the parameters in our method.

## 3 Topic Similarity Model

Sentences should be translated in consistence with their topics (Zhao and Xing, 2006; Zhao and Xing, 2007; Tam et al., 2007). In the hierarchical phrase based system, a synchronous rule may be related to some topics and unrelated to others. In terms of probability, a rule often has an uneven probability distribution over topics. The probability over a topic is high if the rule is highly related to the topic, otherwise the probability will be low. Therefore, we use topic distribution to describe the relatedness of rules to topics.

Figure 1 shows four synchronous rules (Chiang, 2007) with topic distributions, some of which contain nonterminals. We can see that, although the source part of rule (b) and (c) are identical, their topic distributions are quite different. Rule (b) contains a highest probability on the topic about “China-U.S. relationship”, which means rule (b) is much more related to this topic. In contrast, rule (c) contains an even distribution over various topics. Thus, given a document about “China-U.S. relationship”, we hope to encourage the system to apply rule (b) but penalize the application of rule (c). We achieve this by calculating similarity between the topic distributions of a rule and a document to be translated.

More formally, we associate each rule with a **rule-topic distribution**  $P(z|r)$ , where  $r$  is a rule, and  $z$  is a topic. Suppose there are  $K$  topics, this distribution

can be represented by a  $K$ -dimension vector. The  $k$ -th component  $P(z = k|r)$  means the probability of topic  $k$  given the rule  $r$ . The estimation of such distribution will be described in Section 4.

Analogously, we represent the topic information of a document  $d$  to be translated by a **document-topic distribution**  $P(z|d)$ , which is also a  $K$ -dimension vector. The  $k$ -th dimension  $P(z = k|d)$  means the probability of topic  $k$  given document  $d$ . Different from rule-topic distribution, the document-topic distribution can be directly inferred by an off-the-shelf LDA tool.

Consequently, based on these two distributions, we select a rule for a document to be translated according to their **topic similarity** (Section 3.1), which measures the relatedness of the rule to the document. In order to encourage the application of generic rules which are often penalized by our similarity model, we also propose a topic sensitivity model (Section 3.2).

### 3.1 Topic Similarity

By comparing the similarity of their topic distributions, we are able to decide whether a rule is suitable for a given source document. The topic similarity computes the distance of two topic distributions. We calculate the topic similarity by Hellinger function:

$$\begin{aligned} & \text{Similarity}(P(z|d), P(z|r)) \\ &= \sum_{k=1}^K \left( \sqrt{P(z = k|d)} - \sqrt{P(z = k|r)} \right)^2 \quad (1) \end{aligned}$$

Hellinger function is used to calculate distribution distance and is popular in topic model (Blei and Lafferty, 2007).<sup>1</sup> By topic similarity, we aim to encourage or penalize the application of a rule for a given document according to their topic distributions, which then helps the SMT system make better translation decisions.

### 3.2 Topic Sensitivity

Domain adaptation (Wu et al., 2008; Bertoldi and Federico, 2009) often distinguishes general-domain data from in-domain data. Similarly, we divide the rules into topic-insensitive rules and topic-sensitive

<sup>1</sup>We also try other distance functions, including Euclidean distance, Kullback-Leibler divergence and cosine function. They produce similar results in our preliminary experiments.

rules according to their topic distributions. Let's revisit Figure 1. We can easily find that the topic distribution of rule (c) distribute evenly. This indicates that it is insensitive to topics, and can be applied in any topics. We call such a rule a topic-insensitive rule. In contrast, the distributions of the rest rules peak on a few topics. Such rules are called topic-sensitive rules. Generally speaking, a topic-insensitive rule has a fairly flat distribution, while a topic-sensitive rule has a sharp distribution.

A document typically focuses on a few topics, and has a sharp topic distribution. In contrast, the distribution of topic-insensitive rule is fairly flat. Hence, a topic-insensitive rule is always less similar to documents and is punished by the similarity function.

However, topic-insensitive rules may be more preferable than topic-sensitive rules if neither of them are similar to given documents. For a document about the "military" topic, the rule (b) and (c) in Figure 1 are both dissimilar to the document, because rule (b) relates to the "China-U.S. relationship" topic and rule (c) is topic-insensitive. Nevertheless, since rule (c) occurs more frequently across various topics, it may be better to apply rule (c).

To address such issue of the topic similarity model, we further introduce a topic sensitivity model to describe the topic sensitivity of a rule using entropy as a metric:

$$\begin{aligned} & \text{Sensitivity}(P(z|r)) \\ &= - \sum_{k=1}^K P(z = k|r) \times \log(P(z = k|r)) \quad (2) \end{aligned}$$

According to the Eq. (2), a topic-insensitive rule has a large entropy, while a topic-sensitive rule has a smaller entropy. By incorporating the topic sensitivity model with the topic similarity model, we enable our SMT system to balance the selection of these two types of rules. Given rules with approximately equal values of Eq. (1), we prefer topic-insensitive rules.

## 4 Estimation

Unlike document-topic distribution that can be directly learned by LDA tools, we need to estimate the rule-topic distribution according to our requirement. In this paper, we try to exploit the topic information

of both source and target language. To achieve this goal, we use both source-side and target-side monolingual topic models, and learn the correspondence between the two topic models from word-aligned bilingual corpus.

Specifically, we use two types of rule-topic distributions: one is source-side rule-topic distribution and the other is target-side rule-topic distribution. These two rule-topic distributions are estimated by corresponding topic models in the same way (Section 4.1). Notably, only source language documents are available during decoding. In order to compute the similarity between the target-side topic distribution of a rule and the source-side topic distribution of a given document, we need to project the target-side topic distribution of a synchronous rule into the space of the source-side topic model (Section 4.2).

A more principle way is to learn a bilingual topic model from bilingual corpus (Mimno et al., 2009). However, we may face difficulty during decoding, where only source language documents are available. It requires a marginalization to infer the monolingual topic distribution using the bilingual topic model. The high complexity of marginalization prohibits such a summation in practice. Previous work on bilingual topic model avoid this problem by some monolingual assumptions. Zhao and Xing (2007) assume that the topic model is generated in a monolingual manner, while Tam et al., (2007) construct their bilingual topic model by enforcing a one-to-one correspondence between two monolingual topic models. We also estimate our rule-topic distribution by two monolingual topic models, but use a different way to project target-side topics onto source-side topics.

#### 4.1 Monolingual Topic Distribution Estimation

We estimate rule-topic distribution from word-aligned bilingual training corpus with document boundaries explicitly given. The source and target side distributions are estimated in the same way. For simplicity, we only describe the estimation of source-side distribution in this section.

The process of rule-topic distribution estimation is analogous to the traditional estimation of rule translation probability (Chiang, 2007). In addition to the word-aligned corpus, the input for estimation also contains the source-side topic-document distri-

bution of every documents inferred by LDA tool.

We first extract synchronous rules from training data in a traditional way. When a rule  $r$  is extracted from a document  $d$  with topic distribution  $P(z|d)$ , we collect an instance  $(r, P(z|d), c)$ , where  $c$  is the fraction count of an instance as described in Chiang, (2007). After extraction, we get a set of instances  $\mathcal{I} = \{(r, P(z|d), c)\}$  with different document-topic distributions for each rule. Using these instances, we calculate the topic probability  $P(z = k|r)$  as follows:

$$P(z = k|r) = \frac{\sum_{I \in \mathcal{I}} c \times P(z = k|d)}{\sum_{k'=1}^K \sum_{I \in \mathcal{I}} c \times P(z = k'|d)} \quad (3)$$

By using both source-side and target-side document-topic distribution, we obtain two rule-topic distributions for each rule in total.

#### 4.2 Target-side Topic Distribution Projection

As described in the previous section, we also estimate the target-side rule-topic distribution. However, only source document-topic distributions are available during decoding. In order to calculate the similarity between the target-side rule-topic distribution of a rule and the source-side document-topic distribution of a source document, we need to project target-side topics into the source-side topic space. The projection contains two steps:

- In the first step, we learn the topic-to-topic correspondence probability  $p(z_f|z_e)$  from target-side topic  $z_e$  to source-side topic  $z_f$ .
- In the second step, we project the target-side topic distribution of a rule into source-side topic space using the correspondence probability.

In the first step, we estimate the correspondence probability by the co-occurrence of the source-side and the target-side topic assignment of the word-aligned corpus. The topic assignments are output by LDA tool. Thus, we denotes each sentence pair by  $(\mathbf{z}_f, \mathbf{z}_e, \mathbf{a})$ , where  $\mathbf{z}_f$  and  $\mathbf{z}_e$  are the topic assignments of source-side and target-side sentences respectively, and  $\mathbf{a}$  is a set of links  $\{(i, j)\}$ . A link  $(i, j)$  means a source-side position  $i$  aligns to a target-side position  $j$ . Thus, the co-occurrence of a source-side topic with index  $k_f$  and a target-side

e-topic	f-topic 1	f-topic 2	f-topic 3
enterprises	农业(agricultural)	企业(enterprise)	发展(develop)
rural	农村(rural)	市场(market)	经济(economic)
state	农民(peasant)	国有(state)	科技(technology)
agricultural	改革(reform)	公司(company)	我国(China)
market	财政(finance)	金融(finance)	技术(technique)
reform	社会(social)	银行(bank)	产业(industry)
production	保障(safety)	投资(investment)	结构(structure)
peasants	调整(adjust)	管理(manage)	创新(innovation)
owned	政策(policy)	改革(reform)	加快(accelerate)
enterprise	收入(income)	经营(operation)	改革(reform)
$p(z_f z_e)$	0.38	0.28	0.16

Table 1: Example of topic-to-topic correspondence. The last line shows the correspondence probability. Each column means a topic represented by its top-10 topical words. The first column is a target-side topic, while the rest three columns are source-side topics.

topic  $k_e$  is calculated by:

$$\sum_{(\mathbf{z}_f, \mathbf{z}_e, \mathbf{a})} \sum_{(i, j) \in \mathbf{a}} \delta(z_{f_i}, k_f) * \delta(z_{e_j}, k_e) \quad (4)$$

where  $\delta(x, y)$  is the Kronecker function, which is 1 if  $x = y$  and 0 otherwise. We then compute the probability of  $P(z = k_f | z = k_e)$  by normalizing the co-occurrence count. Overall, after the first step, we obtain an correspondence matrix  $\mathbf{M}_{K_e \times K_f}$  from target-side topic to source-side topic, where the item  $M_{i,j}$  represents the probability  $P(z_f = i | z_e = j)$ .

In the second step, given the correspondence matrix  $\mathbf{M}_{K_e \times K_f}$ , we project the target-side rule-topic distribution  $P(z_e|r)$  to the source-side topic space by multiplication as follows:

$$T(P(z_e|r)) = P(z_e|r) \otimes \mathbf{M}_{K_e \times K_f} \quad (5)$$

In this way, we get a second distribution for a rule in the source-side topic space, which we called projected target-side topic distribution  $T(P(z_e|r))$ .

Obviously, our projection method allows one target-side topic to align to multiple source-side topics. This is different from the one-to-one correspondence used by Tam et al., (2007). From the training result of the correspondence matrix  $\mathbf{M}_{K_e \times K_f}$ , we find that the topic correspondence between source and target language is not necessarily one-to-one. Typically, the probability  $P(z = k_f | z = k_e)$  of a target-side topic mainly distributes on two or three source-side topics. Table 1 shows an example of a target-side topic with its three mainly aligned source-side topics.

## 5 Decoding

We incorporate our topic similarity model as a new feature into a traditional hiero system (Chiang, 2007) under discriminative framework (Och and Ney, 2002). Considering there are a source-side rule-topic distribution and a projected target-side rule-topic distribution, we add four features in total:

- *Similarity* ( $P(z_f|d), P(z_f|r)$ )
- *Similarity* ( $P(z_f|d), T(P(z_e|r))$ )
- *Sensitivity* ( $P(z_f|r)$ )
- *Sensitivity* ( $T(P(z_e|r))$ )

To calculate the total score of a derivation on each feature listed above during decoding, we sum up the correspondent feature score of each applied rule.<sup>2</sup>

The source-side and projected target-side rule-topic distribution are calculated before decoding. During decoding, we first infer the topic distribution  $P(z_f|d)$  for a given document on source language. When applying a rule, it is straightforward to calculate these topic features. Obviously, the computational cost of these features is rather small.

In the topic-specific lexicon translation model, given a source document, it first calculates the topic-specific translation probability by normalizing the entire lexicon translation table, and then adapts the lexical weights of rules correspondingly. This makes the decoding slower. Therefore, comparing with the previous topic-specific lexicon translation method, our method provides a more efficient way for incorporating topic model into SMT.

## 6 Experiments

We try to answer the following questions by experiments:

1. Is our topic similarity model able to improve translation quality in terms of BLEU? Furthermore, are source-side and target-side rule-topic distributions complementary to each other?

<sup>2</sup>Since glue rule and rules of unknown words are not extracted from training data, here, we just ignore the calculation of the four features for them.

System	MT06	MT08	Avg	Speed
Baseline	30.20	21.93	26.07	12.6
TopicLex	30.65	22.29	26.47	3.3
SimSrc	30.41	<b>22.69</b>	26.55	11.5
SimTgt	30.51	22.39	26.45	11.7
SimSrc+SimTgt	30.73	<b>22.69</b>	<b>26.71</b>	11.2
Sim+Sen	<b>30.95</b>	<b>22.92</b>	<b>26.94</b>	10.2

Table 2: Result of our topic similarity model in terms of BLEU and speed (words per second), comparing with the traditional hierarchical system (“Baseline”) and the topic-specific lexicon translation method (“TopicLex”). “SimSrc” and “SimTgt” denote similarity by source-side and target-side rule-distribution respectively, while “Sim+Sen” activates the two similarity and two sensitivity features. “Avg” is the average BLEU score on the two test sets. Scores marked in bold mean significantly (Koehn, 2004) better than *Baseline* ( $p < 0.01$ ).

2. Is it helpful to introduce the topic sensitivity model to distinguish topic-insensitive and topic-sensitive rules?
3. Is it necessary to project topics by one-to-many correspondence instead of one-to-one correspondence?
4. What is the effect of our method on various types of rules, such as phrase rules and rules with non-terminals?

## 6.1 Data

We present our experiments on the NIST Chinese-English translation tasks. The bilingual training data contains 239K sentence pairs with 6.9M Chinese words and 9.14M English words, which comes from the FBIS portion of LDC data. There are 10,947 documents in the FBIS corpus. The monolingual data for training English language model includes the Xinhua portion of the GIGAWORD corpus, which contains 238M English words. We used the NIST evaluation set of 2005 (MT05) as our development set, and sets of MT06/MT08 as test sets. The numbers of documents in MT05, MT06, MT08 are 100, 79, and 109 respectively.

We obtained symmetric word alignments of training data by first running GIZA++ (Och and Ney, 2003) in both directions and then applying refinement rule “grow-diag-final-and” (Koehn et al., 2003). The SCFG rules are extracted from this word-aligned training data. A 4-gram language model was trained on the monolingual data by the SRILM toolkit (Stolcke, 2002). Case-insensitive NIST BLEU (Papineni et al., 2002) was used to mea-

sure translation performance. We used minimum error rate training (Och, 2003) for optimizing the feature weights.

For the topic model, we used the open source LDA tool GibbsLDA++ for estimation and inference.<sup>3</sup> GibbsLDA++ is an implementation of LDA using gibbs sampling for parameter estimation and inference. The source-side and target-side topic models are estimated from the Chinese part and English part of FBIS corpus respectively. We set the number of topic  $K = 30$  for both source-side and target-side, and use the default setting of the tool for training and inference.<sup>4</sup> During decoding, we first infer the topic distribution of given documents before translation according to the topic model trained on Chinese part of FBIS corpus.

## 6.2 Effect of Topic Similarity Model

We compare our method with two baselines. In addition to the traditional hiero system, we also compare with the topic-specific lexicon translation method in Zhao and Xing (2007). The lexicon translation probability is adapted by:

$$\begin{aligned}
 p(f|e, D_F) &\propto p(e|f, D_F)P(f|D_F) & (6) \\
 &= \sum_k p(e|f, z = k)p(f|z = k)p(z = k|D_F) & (7)
 \end{aligned}$$

However, we simplify the estimation of  $p(e|f, z = k)$  by directly using the word alignment corpus with

<sup>3</sup><http://gibbslda.sourceforge.net/>

<sup>4</sup>We determine  $K$  by testing {15, 30, 50, 100, 200} in our preliminary experiments. We find that  $K = 30$  produces a slightly better performance than other values.

Type	Count	Src%	Tgt%
Phrase-rule	3.9M	83.4	84.4
Monotone-rule	19.2M	85.3	86.1
Reordering-rule	5.7M	85.9	86.8
All-rule	28.8M	85.1	86.0

Table 3: Percentage of topic-sensitive rules of various types of rule according to source-side (“Src”) and target-side (“Tgt”) topic distributions. Phrase rules are fully lexicalized, while monotone and reordering rules contain nonterminals (Section 6.5).

topic assignment that is inferred by the GibbsL-DA++. Despite the simplification of estimation, the improvement of our implementation is comparable with the improvement in Zhao et al.,(2007). Given a new document, we need to adapt the lexical translation weights of the rules based on topic model. The adapted lexicon translation model is added as a new feature under the discriminative framework.

Table 2 shows the result of our method comparing with the traditional system and the topic-lexicon specific translation method described as above. By using all the features (last line in the table), we improve the translation performance over the baseline system by 0.87 BLEU point on average. Our method also outperforms the topic-lexicon specific translation method by 0.47 points. This verifies that topic similarity model can improve the translation quality significantly.

In order to gain insights into why our model is helpful, we further investigate how many rules are topic-sensitive. As described in Section 3.2, we use entropy to measure the topic sensitivity. If the entropy of a rule is smaller than a certain threshold, then the rule is topic sensitive. Since documents often focus on some topics, we use the average entropy of document-topic distribution of all training documents as the threshold. We compare both source-side and target-side distribution shown in Table 3. We find that more than 80 percents of the rules are topic-sensitive, thus provides us a large space to improve the translation by exploiting topics.

We also compare these methods in terms of the decoding speed (words/second). The baseline translates 12.6 words per second, while the topic-specific lexicon translation method only translates 3.3 words in one second. The overhead of the topic-specific

System	MT06	MT08	Avg
Baseline	30.20	21.93	26.07
One-to-One	30.27	22.12	26.20
One-to-Many	30.51	22.39	26.45

Table 4: Effects of one-to-one and one-to-many topic projection.

lexicon translation method mainly comes from the adaptation of lexical weights. It takes 72.8% of the time to do the adaptation, despite only lexical weights of the used rules are adapted. In contrast, our method has a speed of 10.2 words per second for each sentence on average, which is three times faster than the topic-specific lexicon translation method.

Meanwhile, we try to separate the effects of source-side topic distribution from the target-side topic distribution. From lines 4-6 of Table 2. We clearly find that the two rule-topic distributions improve the performance by 0.48 and 0.38 BLEU points over the baseline respectively. It seems that the source-side topic model is more helpful. Furthermore, when combine these two distributions, the improvement is increased to 0.64 points. This indicates that the effects of source-side and target-side distributions are complementary.

### 6.3 Effect of Topic Sensitivity Model

As described in Section 3.2, because the similarity features always punish topic-insensitive rules, we introduce topic sensitivity features as a complement. In the last line of Table 2, we obtain a further improvement of 0.23 points, when incorporating topic sensitivity features with topic similarity features. This suggests that it is necessary to distinguish topic-insensitive and topic-sensitive rules.

### 6.4 One-to-One Vs. One-to-Many Topic Projection

In Section 4.2, we find that source-side topic and target-side topics may not exactly match, hence we use one-to-many topic correspondence. Yet another method is to enforce one-to-one topic projection (Tam et al., 2007). We achieve one-to-one projection by aligning a target topic to the source topic with the largest correspondence probability as calculated in Section 4.2.

Table 4 compares the effects of these two method-

System	MT06	MT08	Avg
Baseline	30.20	21.93	26.07
Phrase-rule	30.53	22.29	26.41
Monotone-rule	30.72	22.62	26.67
Reordering-rule	30.31	22.40	26.36
All-rule	30.95	22.92	26.94

Table 5: Effect of our topic model on three types of rules. Phrase rules are fully lexicalized, while monotone and reordering rules contain nonterminals.

s. We find that the enforced one-to-one topic method obtains a slight improvement over the baseline system, while one-to-many projection achieves a larger improvement. This confirms our observation of the non-one-to-one mapping between source-side and target-side topics.

### 6.5 Effect on Various Types of Rules

To get a more detailed analysis of the result, we further compare the effect of our method on different types of rules. We divide the rules into three types: phrase rules, which only contain terminals and are the same as the phrase pairs in phrase-based system; monotone rules, which contain non-terminals and produce monotone translations; reordering rules, which also contain non-terminals but change the order of translations. We define the monotone and reordering rules according to Chiang et al., (2008).

Table 5 show the results. We can see that our method achieves improvements on all the three types of rules. Our topic similarity method on monotone rule achieves the most improvement which is 0.6 BLEU points, while the improvement on reordering rules is the smallest among the three types. This shows that topic information also helps the selections of rules with non-terminals.

## 7 Related Work

In addition to the topic-specific lexicon translation method mentioned in the previous sections, researchers also explore topic model for machine translation in other ways.

Foster and Kunh (2007) describe a mixture-model approach for SMT adaptation. They first split a training corpus into different domains. Then, they train separate models on each domain. Finally, they

combine a specific domain translation model with a general domain translation model depending on various text distances. One way to calculate the distance is using topic model.

Gong et al. (2010) introduce topic model for filtering topic-mismatched phrase pairs. They first assign a specific topic for the document to be translated. Similarly, each phrase pair is also assigned with one specific topic. A phrase pair will be discarded if its topic mismatches the document topic.

Researchers also introduce topic model for cross-lingual language model adaptation (Tam et al., 2007; Ruiz and Federico, 2011). They use bilingual topic model to project latent topic distribution across languages. Based on the bilingual topic model, they apply the source-side topic weights into the target-side topic model, and adapt the n-gram language model of target side.

Our topic similarity model uses the document topic information. From this point, our work is related to context-dependent translation (Carpuat and Wu, 2007; He et al., 2008; Shen et al., 2009). Previous work typically use neighboring words and sentence level information, while our work extents the context into the document level.

## 8 Conclusion and Future Work

We have presented a topic similarity model which incorporates the rule-topic distributions on both the source and target side into traditional hierarchical phrase-based system. Our experimental results show that our model achieves a better performance with faster decoding speed than previous work on topic-specific lexicon translation. This verifies the advantage of exploiting topic model at the rule level over the word level. Further improvement is achieved by distinguishing topic-sensitive and topic-insensitive rules using the topic sensitivity model.

In the future, we are interesting to find ways to exploit topic model on bilingual data without document boundaries, thus to enlarge the size of training data. Furthermore, our training corpus mainly focus on news, it is also interesting to apply our method on corpus with more diverse topics. Finally, we hope to apply our method to other translation models, especially syntax-based models.

## Abstract

In this paper, we encode topic dependencies in hierarchical multi-label Text Categorization (TC) by means of rerankers. We represent reranking hypotheses with several innovative kernels considering both the structure of the hierarchy and the probability of nodes. Additionally, to better investigate the role of category relationships, we consider two interesting cases: (i) traditional schemes in which node-fathers include all the documents of their child-categories; and (ii) more general schemes, in which children can include documents not belonging to their fathers. The extensive experimentation on Reuters Corpus Volume 1 shows that our rerankers inject effective structural semantic dependencies in multi-classifiers and significantly outperform the state-of-the-art.

## 1 Introduction

Automated Text Categorization (TC) algorithms for hierarchical taxonomies are typically based on flat schemes, e.g., one-vs.-all, which do not take topic relationships into account. This is due to two major problems: (i) complexity in introducing them in the learning algorithm and (ii) the small or no advantage that they seem to provide (Rifkin and Klautau, 2004).

We speculate that the failure of using hierarchical approaches is caused by the inherent complexity of modeling all possible topic dependencies rather than the uselessness of such relationships. More precisely, although hierarchical multi-label classifiers can exploit machine learning algorithms for structural output, e.g., (Tsochantaridis et al., 2005; Riezler and Vasserman, 2010; Lavergne et al., 2010),

they often impose a number of simplifying restrictions on some category assignments. Typically, the probability of a document  $d$  to belong to a subcategory  $C_i$  of a category  $C$  is assumed to depend only on  $d$  and  $C$ , but not on other subcategories of  $C$ , or any other categories in the hierarchy. Indeed, the introduction of these long-range dependencies lead to computational intractability or more in general to the problem of how to select an effective subset of them. It is important to stress that (i) there is no theory that can suggest which are the dependencies to be included in the model and (ii) their exhaustive explicit generation (i.e., the generation of all hierarchy subparts) is computationally infeasible. In this perspective, kernel methods are a viable approach to implicitly and easily explore feature spaces encoding dependencies. Unfortunately, structural kernels, e.g., tree kernels, cannot be applied in structured output algorithms such as (Tsochantaridis et al., 2005), again for the lack of a suitable theory.

In this paper, we propose to use the combination of *reranking* with kernel methods as a way to handle the computational and feature design issues. We first use a basic hierarchical classifier to generate a hypothesis set of limited size, and then apply reranking models. Since our rerankers are simple binary classifiers of hypothesis pairs, they can encode complex dependencies thanks to kernel methods. In particular, we used tree, sequence and linear kernels applied to structural and feature-vector representations describing hierarchical dependencies.

Additionally, to better investigate the role of topical relationships, we consider two interesting cases: (i) traditional categorization schemes in which node-

fathers include all the documents of their child-categories; and (ii) more general schemes, in which children can include documents not belonging to their fathers. The intuition under the above setting is that shared documents between categories create semantic links between them. Thus, if we remove common documents between father and children, we reduce the dependencies that can be captured with traditional bag-of-words representation.

We carried out experiments on two entire hierarchies TOPICS (103 nodes organized in 5 levels) and INDUSTRIAL (365 nodes organized in 6 levels) of the well-known Reuters Corpus Volume 1 (RCV1). We first evaluate the accuracy as well as the efficiency of several reranking models. The results show that all our rerankers consistently and significantly improve on the traditional approaches to TC up to 10 absolute percent points. Very interestingly, the combination of structural kernels with the linear kernel applied to vectors of category probabilities further improves on reranking: such a vector provides a more effective information than the joint global probability of the reranking hypothesis.

In the rest of the paper, Section 2 describes the hypothesis generation algorithm, Section 3 illustrates our reranking approach based on tree kernels, Section 4 reports on our experiments, Section 5 illustrates the related work and finally Section 6 derives the conclusions.

## 2 Hierarchy classification hypotheses from binary decisions

The idea of the paper is to build efficient models for hierarchical classification using global dependencies. For this purpose, we use reranking models, which encode global information. This necessitates of a set of initial hypotheses, which are typically generated by *local classifiers*. In our study, we used  $n$  one-vs.-all binary classifiers, associated with the  $n$  different nodes of the hierarchy. In the following sections, we describe a simple framework for hypothesis generation.

### 2.1 Top $k$ hypothesis generation

Given  $n$  categories,  $C_1, \dots, C_n$ , we can define  $p_{C_i}^1(d)$  and  $p_{C_i}^0(d)$  as the probabilities that the classifier  $i$  assigns the document  $d$  to  $C_i$  or not, respectively. For example,  $p_{C_i}^h(d)$  can be computed from

Figure 1: A subhierarchy of Reuters.

Figure 2: A tree representing a category assignment hypothesis for the subhierarchy in Fig. 1.

the SVM classification output (i.e., the example margin). Typically, a large margin corresponds to high probability for  $d$  to be in the category whereas small margin indicates low probability<sup>1</sup>. Let us indicate with  $\mathbf{h} = \{h_1, \dots, h_n\} \in \{0, 1\}^n$  a classification hypothesis, i.e., the set of  $n$  binary decisions for a document  $d$ . If we assume independence between the SVM scores, the most probable hypothesis on  $d$  is

$$\tilde{\mathbf{h}} = \operatorname{argmax}_{\mathbf{h} \in \{0,1\}^n} \prod_{i=1}^n p_i^{\mathbf{h}_i}(d) = \left( \operatorname{argmax}_{h \in \{0,1\}} p_i^h(d) \right)_{i=1}^n.$$

Given  $\tilde{\mathbf{h}}$ , the second best hypothesis can be obtained by changing the label on the least probable classification, i.e., associated with the index  $j = \operatorname{argmin}_{i=1, \dots, n} p_i^{\tilde{\mathbf{h}}_i}(d)$ . By storing the probability of the  $k-1$  most probable configurations, the next  $k$  best hypotheses can be efficiently generated.

## 3 Structural Kernels for Reranking Hierarchical Classification

In this section we describe our hypothesis reranker. The main idea is to represent the hypotheses as a tree structure, naturally derived from the hierarchy and then to use tree kernels to encode such a structural description in a learning algorithm. For this purpose, we describe our hypothesis representation, kernel methods and the kernel-based approach to preference reranking.

### 3.1 Encoding hypotheses in a tree

Once hypotheses are generated, we need a representation from which the dependencies between the dif-

<sup>1</sup>We used the conversion of margin into probability provided by LIBSVM.

Figure 3: A compact representation of the hypothesis in Fig. 2.

ferent nodes of the hierarchy can be learned. Since we do not know in advance which are the important dependencies and not even the scope of the interaction between the different structure subparts, we rely on automatic feature engineering via structural kernels. For this paper, we consider tree-shaped hierarchies so that tree kernels, e.g. (Collins and Duffy, 2002; Moschitti, 2006a), can be applied.

In more detail, we focus on the Reuters categorization scheme. For example, Figure 1 shows a subhierarchy of the *Markets* (MCAT) category and its subcategories: *Equity Markets* (M11), *Bond Markets* (M12), *Money Markets* (M13) and *Commodity Markets* (M14). These also have subcategories: *Interbank Markets* (M131), *Forex Markets* (M132), *Soft Commodities* (M141), *Metals Trading* (M142) and *Energy Markets* (M143).

As the input of our reranker, we can simply use a tree representing the hierarchy above, marking the *negative* assignments of the current hypothesis in the node labels with “-”, e.g., -M142 means that the document was not classified in *Metals Trading*. For example, Figure 2 shows the representation of a classification hypothesis consisting in assigning the target document to the categories MCAT, M11, M13, M14 and M143.

Another more compact representation is the hierarchy tree from which all the nodes associated with a negative classification decision are removed. As only a small subset of nodes of the full hierarchy will be positively classified the tree will be much smaller. Figure 3 shows the compact representation of the hypothesis in Fig. 2. The next sections describe how to exploit these kinds of representations.

### 3.2 Structural Kernels

In kernel-based machines, both learning and classification algorithms only depend on the inner product between instances. In several cases, this can be efficiently and implicitly computed by kernel functions by exploiting the following dual formulation:

$\sum_{i=1..l} y_i \alpha_i \phi(o_i) \phi(o) + b = 0$ , where  $o_i$  and  $o$  are two objects,  $\phi$  is a mapping from the objects to feature vectors  $\vec{x}_i$  and  $\phi(o_i) \phi(o) = K(o_i, o)$  is a kernel function implicitly defining such a mapping. In case of structural kernels,  $K$  determines the shape of the substructures describing the objects above. The most general kind of kernels used in NLP are string kernels, e.g. (Shawe-Taylor and Cristianini, 2004), the Syntactic Tree Kernels (Collins and Duffy, 2002) and the Partial Tree Kernels (Moschitti, 2006a).

#### 3.2.1 String Kernels

The String Kernels (SK) that we consider count the number of subsequences shared by two strings of symbols,  $s_1$  and  $s_2$ . Some symbols during the matching process can be skipped. This modifies the weight associated with the target substrings as shown by the following SK equation:

$$SK(s_1, s_2) = \sum_{u \in \Sigma^*} \phi_u(s_1) \cdot \phi_u(s_2) = \sum_{u \in \Sigma^*} \sum_{\vec{I}_1: u=s_1[\vec{I}_1]} \sum_{\vec{I}_2: u=s_2[\vec{I}_2]} \lambda^{d(\vec{I}_1)+d(\vec{I}_2)}$$

where,  $\Sigma^* = \bigcup_{n=0}^{\infty} \Sigma^n$  is the set of all strings,  $\vec{I}_1$  and  $\vec{I}_2$  are two sequences of indexes  $\vec{I} = (i_1, \dots, i_{|u|})$ , with  $1 \leq i_1 < \dots < i_{|u|} \leq |s|$ , such that  $u = s_{i_1} \dots s_{i_{|u|}}$ ,  $d(\vec{I}) = i_{|u|} - i_1 + 1$  (distance between the first and last character) and  $\lambda \in [0, 1]$  is a decay factor.

It is worth noting that: (a) longer subsequences receive lower weights; (b) some characters can be omitted, i.e. gaps; (c) gaps determine a weight since the exponent of  $\lambda$  is the number of characters and gaps between the first and last character; and (c) the complexity of the SK computation is  $O(mnp)$  (Shawe-Taylor and Cristianini, 2004), where  $m$  and  $n$  are the lengths of the two strings, respectively and  $p$  is the length of the largest subsequence we want to consider.

In our case, given a hypothesis represented as a tree like in Figure 2, we can visit it and derive a linearization of the tree. SK applied to such a node sequence can derive useful dependencies between category nodes. For example, using the Breadth First Search on the compact representation, we get the sequence [MCAT, M11, M13, M14, M143], which generates the subsequences, [MCAT, M11], [MCAT, M11, M13, M14], [M11, M13, M143], [M11, M13, M143] and so on.

Figure 4: The tree fragments of the hypothesis in Fig. 2 generated by STK

Figure 5: Some tree fragments of the hypothesis in Fig. 2 generated by PTK

### 3.2.2 Tree Kernels

Convolution Tree Kernels compute the number of common substructures between two trees  $T_1$  and  $T_2$  without explicitly considering the whole fragment space. For this purpose, let the set  $\mathcal{F} = \{f_1, f_2, \dots, f_{|\mathcal{F}|}\}$  be a tree fragment space and  $\chi_i(n)$  be an indicator function, equal to 1 if the target  $f_i$  is rooted at node  $n$  and equal to 0 otherwise. A tree-kernel function over  $T_1$  and  $T_2$  is  $TK(T_1, T_2) = \sum_{n_1 \in N_{T_1}} \sum_{n_2 \in N_{T_2}} \Delta(n_1, n_2)$ ,  $N_{T_1}$  and  $N_{T_2}$  are the sets of the  $T_1$ 's and  $T_2$ 's nodes, respectively and  $\Delta(n_1, n_2) = \sum_{i=1}^{|\mathcal{F}|} \chi_i(n_1) \chi_i(n_2)$ . The latter is equal to the number of common fragments rooted in the  $n_1$  and  $n_2$  nodes. The  $\Delta$  function determines the richness of the kernel space and thus different tree kernels. Hereafter, we consider the equation to evaluate STK and PTK.<sup>2</sup>

**Syntactic Tree Kernels (STK)** To compute STK, it is enough to compute  $\Delta_{STK}(n_1, n_2)$  as follows (recalling that since it is a syntactic tree kernels, each node can be associated with a production rule): (i) if the productions at  $n_1$  and  $n_2$  are different then  $\Delta_{STK}(n_1, n_2) = 0$ ; (ii) if the productions at  $n_1$  and  $n_2$  are the same, and  $n_1$  and  $n_2$  have only leaf children then  $\Delta_{STK}(n_1, n_2) = \lambda$ ; and (iii) if the productions at  $n_1$  and  $n_2$  are the same, and  $n_1$  and  $n_2$  are not pre-terminals then  $\Delta_{STK}(n_1, n_2) = \lambda \prod_{j=1}^{l(n_1)} (1 + \Delta_{STK}(c_{n_1}^j, c_{n_2}^j))$ , where  $l(n_1)$  is the

<sup>2</sup>To have a similarity score between 0 and 1, a normalization in the kernel space, i.e.  $\frac{TK(T_1, T_2)}{\sqrt{TK(T_1, T_1) \times TK(T_2, T_2)}}$  is applied.

number of children of  $n_1$  and  $c_n^j$  is the  $j$ -th child of the node  $n$ . Note that, since the productions are the same,  $l(n_1) = l(n_2)$  and the computational complexity of STK is  $O(|N_{T_1}| |N_{T_2}|)$  but the average running time tends to be linear, i.e.  $O(|N_{T_1}| + |N_{T_2}|)$ , for natural language syntactic trees (Moschitti, 2006a; Moschitti, 2006b).

Figure 4 shows the five fragments of the hypothesis in Figure 2. Such fragments satisfy the constraint that each of their nodes includes all or none of its children. For example,  $[M13 [-M131 -M132]]$  is an STF, which has two non-terminal symbols,  $-M131$  and  $-M132$ , as leaves while  $[M13 [-M131]]$  is not an STF.

**The Partial Tree Kernel (PTK)** The computation of PTK is carried out by the following  $\Delta_{PTK}$  function: if the labels of  $n_1$  and  $n_2$  are different then  $\Delta_{PTK}(n_1, n_2) = 0$ ; else  $\Delta_{PTK}(n_1, n_2) =$

$$\mu \left( \lambda^2 + \sum_{\vec{I}_1, \vec{I}_2, l(\vec{I}_1) = l(\vec{I}_2)} \lambda^{d(\vec{I}_1) + d(\vec{I}_2)} \prod_{j=1}^{l(\vec{I}_1)} \Delta_{PTK}(c_{n_1}(\vec{I}_{1j}), c_{n_2}(\vec{I}_{2j})) \right)$$

where  $d(\vec{I}_1) = \vec{I}_{1l(\vec{I}_1)} - \vec{I}_{11}$  and  $d(\vec{I}_2) = \vec{I}_{2l(\vec{I}_2)} - \vec{I}_{21}$ . This way, we penalize both larger trees and child subsequences with gaps. PTK is more general than STK as if we only consider the contribution of shared subsequences containing all children of nodes, we implement STK. The computational complexity of PTK is  $O(p\rho^2 |N_{T_1}| |N_{T_2}|)$  (Moschitti, 2006a), where  $p$  is the largest subsequence of children that we want consider and  $\rho$  is the maximal out-degree observed in the two trees. However the average running time again tends to be linear for natural language syntactic trees (Moschitti, 2006a).

Given a target  $T$ , PTK can generate any subset of connected nodes of  $T$ , whose edges are in  $T$ . For example, Fig. 5 shows the tree fragments from the hypothesis of Fig. 2. Note that each fragment captures dependencies between different categories.

### 3.3 Preference reranker

When training a reranker model, the task of the machine learning algorithm is to learn to select the best candidate from a given set of hypotheses. To use SVMs for training a reranker, we applied Preference Kernel Method (Shen et al., 2003). The reduction method from ranking tasks to binary classification is an active research area; see for instance (Balcan et al., 2008) and (Ailon and Mohri, 2010).

Table 1: Instance distributions of RCV1: the most populated categories are on the top, the medium sized ones follow and the smallest ones are at the bottom. There are some difference between child-free and child-full setting since for the former, from each node, we removed all the documents in its children.

In the Preference Kernel approach, the reranking problem – learning to pick the correct candidate  $h_1$  from a candidate set  $\{h_1, \dots, h_k\}$  – is reduced to a binary classification problem by creating *pairs*: positive training instances  $\langle h_1, h_2 \rangle, \dots, \langle h_1, h_k \rangle$  and negative instances  $\langle h_2, h_1 \rangle, \dots, \langle h_k, h_1 \rangle$ . This training set can then be used to train a binary classifier. At classification time, pairs are not formed (since the correct candidate is not known); instead, the standard one-versus-all binarization method is still applied.

The kernels are then engineered to implicitly represent the *differences* between the objects in the pairs. If we have a valid kernel  $K$  over the candidate space  $\mathcal{T}$ , we can construct a preference kernel  $P_K$  over the space of pairs  $\mathcal{T} \times \mathcal{T}$  as follows:  $P_K(x, y) =$

$$P_K(\langle x_1, x_2 \rangle, \langle y_1, y_2 \rangle) = K(x_1, y_1) + K(x_2, y_2) - K(x_1, y_2) - K(x_2, y_1), \quad (1)$$

where  $x, y \in \mathcal{T} \times \mathcal{T}$ . It is easy to show (Shen et al., 2003) that  $P_K$  is also a valid Mercer’s kernel. This makes it possible to use kernel methods to train the reranker.

We explore innovative kernels  $K$  to be used in Eq. 1:

$K_J = p(x_1) \times p(y_1) + S$ , where  $p(\cdot)$  is the global joint probability of a target hypothesis and  $S$  is a structural kernel, i.e., SK, STK and PTK.

$K_P = \vec{x}_1 \cdot \vec{y}_1 + S$ , where  $\vec{x}_1 = \{p(x_1, j)\}_{j \in x_1}$ ,  $\vec{y}_1 = \{p(y_1, j)\}_{j \in y_1}$ ,  $p(t, n)$  is the classification probability of the node (category)  $n$  in the

$F_1$	BL	BOL	SK	STK	PTK

tree  $t \in \mathcal{T}$  and  $S$  is again a structural kernel, i.e., SK, STK and PTK.

For comparative purposes, we also use for  $S$  a linear kernel over the bag-of-labels (BOL). This is supposed to capture non-structural dependencies between the category labels.

## 4 Experiments

The aim of the experiments is to demonstrate that our reranking approach can introduce semantic dependencies in the hierarchical classification model, which can improve accuracy. For this purpose, we show that several reranking models based on tree kernels improve the classification based on the *flat* one-vs.-all approach. Then, we analyze the efficiency of our models, demonstrating their applicability.

### 4.1 Setup

We used two full hierarchies, TOPICS and INDUSTRY of Reuters Corpus Volume 1 (RCV1)<sup>3</sup> TC cor-

<sup>3</sup>[trec.nist.gov/data/reuters/reuters.html](http://trec.nist.gov/data/reuters/reuters.html)

pus. For most experiments, we randomly selected two subsets of 10k and 5k of documents for training and testing from the total 804,414 Reuters news from TOPICS by still using all the 103 categories organized in 5 levels (hereafter SAM). The distribution of the data instances of some of the different categories in such samples can be observed in Table 1. The training set is used for learning the binary classifiers needed to build the multiclass-classifier (MCC). To compare with previous work we also considered the Lewis’ split (Lewis et al., 2004), which includes 23,149 news for training and 781,265 for testing.

Additionally, we carried out some experiments on INDUSTRY data from RCV1. This contains 352,361 news assigned to 365 categories, which are organized in 6 levels. The Lewis’ split for INDUSTRY includes 9,644 news for training and 342,117 for testing. We used the above datasets with two different settings: the *child-free* setting, where we removed all the document belonging to the child nodes from the parent nodes, and the normal setting which we refer to as *child-full*.

To implement the baseline model, we applied the state-of-the-art method used by (Lewis et al., 2004) for RCV1, i.e.: SVMs with the default parameters (trade-off and cost factor = 1), linear kernel, normalized vectors, stemmed bag-of-words representation,  $\log(TF + 1) \times IDF$  weighting scheme and stop list<sup>4</sup>. We used the LIBSVM<sup>5</sup> implementation, which provides a probabilistic outcome for the classification function. The classifiers are combined using the one-vs.-all approach, which is also state-of-the-art as argued in (Rifkin and Klautau, 2004). Since the task requires us to assign multiple labels, we simply collect the decisions of the  $n$  classifiers: this constitutes our MCC baseline.

Regarding the reranker, we divided the training set in two chunks of data: Train1 and Train2. The binary classifiers are trained on Train1 and tested on Train2 (and vice versa) to generate the hypotheses on Train2 (Train1). The union of the two sets constitutes the training data for the reranker. We imple-

<sup>4</sup>We have just a small difference in the number of tokens, i.e., 51,002 vs. 47,219 but this is both not critical and rarely achievable because of the diverse stop lists or tokenizers.

<sup>5</sup><http://www.csie.ntu.edu.tw/~cjlin/libsvm/>

Figure 6: Learning curves of the reranking models using STK in terms of MicroAverage-F1, according to increasing training set (child-free setting).

Figure 7: Learning curves of the reranking models using STK in terms of MacroAverage-F1, according to increasing training set (child-free setting).

mented two rerankers: RR, which use the representation of hypotheses described in Fig. 2; and FRR, i.e., fast RR, which uses the compact representation described in Fig. 3.

The rerankers are based on SVMs and the Preference Kernel ( $P_K$ ) described in Sec. 1 built on top of SK, STK or PTK (see Section 3.2.2). These are applied to the tree-structured hypotheses. We trained the rerankers using SVM-light-TK<sup>6</sup>, which enables the use of structural kernels in SVM-light (Joachims, 1999). This allows for applying kernels to pairs of trees and combining them with vector-based kernels. Again we use default parameters to facilitate replicability and preserve generality. The rerankers always use 8 best hypotheses.

All the performance values are provided by means of Micro- and Macro-Average F1, evaluated on test

data over all categories (103 or 363). Additionally, the F1 of some binary classifiers are reported.

## 4.2 Classification Accuracy

In the first experiments, we compared the different kernels using the  $K_J$  combination (which exploits the joint hypothesis probability, see Sec. 3.3) on SAM. Tab. 2 shows that the baseline (state-of-the-art flat model) is largely improved by all rerankers. BOL cannot capture the same dependencies as the structural kernels. In contrast, when we remove the dependencies generated by shared documents between a node and its descendants (child-free setting) BOL improves on BL. Very interestingly, TK and PTK in this setting significantly improves on SK suggesting that the hierarchical structure is more important than the sequential one.

To study how much data is needed for the reranker, the figures 6 and 7 report the Micro and Macro Average F1 of our rerankers over 103 categories, according to different sets of training data. This time,  $K_J$  is applied to only STK. We note that (i) a few thousands of training examples are enough to deliver most of the RR improvement; and (ii) the FRR produces similar results as standard RR. This is very interesting since, as it will be shown in the next section, the compact representation produces much faster models.

Table 4 reports the F1 of some individual categories as well as global performance. In these experiments we used STK in  $K_J$  and  $K_P$ . We note that

Figure 8: Training and test time of the rerankers trained on data of increasing size.

$K_P$  highly improves on the baseline on child-free setting by about 7.1 and 9.9 absolute percent points in Micro-and Macro-F1, respectively. Also the improvement on child-full is meaningful, i.e., 4.6 percent points. This is rather interesting as BOL (not reported in the table) achieved a Micro-average of 80.4% and a Macro-average of 57.2% when used in  $K_P$ , i.e., up to 2 points below STK. This means that the use of probability vectors and combination with structural kernels is a very promising direction for reranker design.

To definitely assess the benefit of our rerankers we tested them on the Lewis’ split of two different datasets of RCV1, i.e., TOPIC and INDUSTRY. Table 5 shows impressive results, e.g., for INDUSTRY, the improvement is up to 5.2 percent points. We carried out statistical significance tests, which certified the significance at 99%. This was expected as the size of the Lewis’ test sets is in the order of several hundreds thousands.

Finally, to better understand the potential of reranking, Table 6 shows the oracle performance with respect to the increasing number of hypotheses. The outcome clearly demonstrates that there is large margin of improvement for the rerankers.

## 4.3 Running Time

To study the applicability of our rerankers, we have analyzed both the training and classification time. Figure 8 shows the minutes required to train the different models as well as to classify the test set according to data of increasing size.

It can be noted that the models using the compact hypothesis representation are much faster than those

F1	Topic					Industry				
	BL (Lewis)	BL (Ours)	$K_J$ (BOL)	$K_J$	$K_P$	BL (Lewis)	BL (Ours)	$K_J$ (BOL)	$K_J$	$K_P$
Micro-F1	0.816	0.815	0.818	0.827	0.849	0.512	0.562	0.566	0.576	0.628
Macro-F1	0.567	0.566	0.571	0.590	0.615	0.263	0.289	0.243	0.314	0.341

Table 5: Comparison between rankers using STK or BOL (when indicated) with the  $K_J$  and  $K_P$  schema. 32k examples are used for training the rerankers with child-full setting.

$k$	Micro- $F_1$	Macro- $F_1$
1	0.640	0.408
2	0.758	0.504
4	0.821	0.566
8	0.858	0.610
16	0.898	0.658

Table 6: Oracle performance according to the number of hypotheses (child-free setting).

using the complete hierarchy as representation, i.e., up to five times in training and eight time in testing. This is not surprising as, in the latter case, each kernel evaluation requires to perform tree kernel evaluation on trees of 103 nodes. When using the compact representation the number of nodes is upper-bounded by the maximum number of labels per documents, i.e., 6, times the depth of the hierarchy, i.e., 5 (the positive classification on the leaves is the worst case). Thus, the largest tree would contain 30 nodes. However, we only have 1.82 labels per document on average, therefore the trees have an average size of only about 9 nodes.

## 5 Related Work

Tree and sequence kernels have been successfully used in many NLP applications, e.g.: parse reranking and adaptation (Collins and Duffy, 2002; Shen et al., 2003; Toutanova et al., 2004; Kudo et al., 2005; Titov and Henderson, 2006), chunking and dependency parsing (Kudo and Matsumoto, 2003; Daumé III and Marcu, 2004), named entity recognition (Cumby and Roth, 2003), text categorization (Cancedda et al., 2003; Gliozzo et al., 2005) and relation extraction (Zelenko et al., 2002; Bunescu and Mooney, 2005; Zhang et al., 2006).

To our knowledge, ours is the first work exploring structural kernels for reranking hierarchical text categorization hypotheses. Additionally, there is a substantial lack of work exploring reranking for hierarchical text categorization. The work mostly related to ours is (Rousu et al., 2006) as they directly encoded global dependencies in a gradient descent learning approach. This kind of algorithm is less efficient than ours so they could experiment

with only the CCAT subhierarchy of RCV1, which only contains 34 nodes. Other relevant work such as (McCallum et al., 1998) and (Dumais and Chen, 2000) uses a rather different datasets and a different idea of dependencies based on feature distributions over the linked categories. An interesting method is SVM-struct (Tsochantaridis et al., 2005), which has been applied to model dependencies expressed as category label subsets of flat categorization schemes but no solution has been attempted for hierarchical settings. The approaches in (Finley and Joachims, 2007; Riezler and Vasserman, 2010; Lavergne et al., 2010) can surely be applied to model dependencies in a tree, however, they need that feature templates are specified in advance, thus the meaningful dependencies must be already known. In contrast, kernel methods allow for automatically generating all possible dependencies and reranking can efficiently encode them.

## 6 Conclusions

In this paper, we have described several models for reranking the output of an MCC based on SVMs and structural kernels, i.e., SK, STK and PTK. We have proposed a simple and efficient algorithm for hypothesis generation and their kernel-based representations. The latter are exploited by SVMs using preference kernels to automatically derive features from the hypotheses. When using tree kernels such features are tree fragments, which can encode complex semantic dependencies between categories. We tested our rerankers on the entire well-known RCV1. The results show impressive improvement on the state-of-the-art flat TC models, i.e., 3.3 absolute percent points on the Lewis' split (same setting) and up to 10 absolute points on samples using child-free setting.

epitler@seas.upenn.edu

## Abstract

*Prepositions* and *conjunctions* are two of the largest remaining bottlenecks in parsing. Across various existing parsers, these two categories have the lowest accuracies, and mistakes made have consequences for downstream applications. Prepositions and conjunctions are often assumed to depend on lexical dependencies for correct resolution. As lexical statistics based on the training set only are sparse, unlabeled data can help ameliorate this sparsity problem. By including unlabeled data features into a factorization of the problem which matches the representation of prepositions and conjunctions, we achieve a new state-of-the-art for English dependencies with 93.55% correct attachments on the current standard. Furthermore, conjunctions are attached with an accuracy of 90.8%, and prepositions with an accuracy of 87.4%.

## 1 Introduction

*Prepositions* and *conjunctions* are two large remaining bottlenecks in parsing. Across various existing parsers, these two categories have the lowest accuracies, and mistakes made on these have consequences for downstream applications. Machine translation is sensitive to parsing errors involving prepositions and conjunctions, because in some languages different attachment decisions in the parse of the source language sentence produce different translations. Preposition attachment mistakes are particularly bad when translating into Japanese (Schwartz et al., 2003) which uses a different post-position for different attachments; conjunction mis-

takes can cause word ordering mistakes when translating into Chinese (Huang, 1983).

Prepositions and conjunctions are often assumed to depend on *lexical dependencies* for correct resolution (Jurafsky and Martin, 2008). However, lexical statistics based on the training set only are typically sparse and have only a small effect on overall parsing performance (Gildea, 2001). *Unlabeled data* can help ameliorate this sparsity problem. Backing off to cluster membership features (Koo et al., 2008) or by using association statistics from a larger corpus, such as the web (Bansal and Klein, 2011; Zhou et al., 2011), have both improved parsing.

Unlabeled data has been shown to improve the accuracy of conjunctions within complex noun phrases (Pitler et al., 2010; Bergsma et al., 2011). However, it has so far been less effective within full parsing — while first-order web-scale counts noticeably improved overall parsing in Bansal and Klein (2011), the accuracy on conjunctions actually decreased when the web-scale features were added (Table 4 in that paper).

In this paper we show that unlabeled data *can* help prepositions and conjunctions, *provided that the dependency representation is compatible with how the parsing problem is decomposed for learning and inference*. By incorporating unlabeled data into factorizations which capture the relevant dependencies for prepositions and conjunctions, we produce a parser for English which has an unlabeled attachment accuracy of 93.5%, over an 18% reduction in error over the best previously published parser (Bansal and Klein, 2011) on the current standard for dependency parsing. The best model for conjunctions at-

taches them with 90.8% accuracy (42.5% reduction in error over MSTParser), and the best model for prepositions with 87.4% accuracy (18.2% reduction in error over MSTParser).

We describe the dependency representations of prepositions and conjunctions in Section 2. We discuss the implications of these representations for how learning and inference for parsing are decomposed (Section 3) and how unlabeled data may be used (Section 4). We then present experiments exploring the connection between representation, factorization, and unlabeled data in Sections 5 and 6.

## 2 Dependency Representations

A dependency tree is a rooted, directed tree (or arborecence), in which the vertices are the words in the sentence plus an artificial root node, and each edge  $(h, m)$  represents a directed dependency relation from the head  $h$  to the modifier  $m$ . Throughout this section, we will use  $Y$  to denote a particular parse tree, and  $(h, m) \in Y$  to denote a particular edge in  $Y$ .

The Wall Street Journal Penn Treebank (PTB) (Marcus et al., 1993) contains parsed constituency trees (where each sentence is represented as a context-free-grammar derivation). Dependency parsing requires a conversion from these constituency trees to dependency trees. The Treebank constituency trees left noun phrases (NPs) flat, although there have been subsequent projects which annotate the internal structure of noun phrases (Vadas and Curran, 2007; Weischedel et al., 2011). The presence or absence of these noun phrase internal annotations interacts with constituency-to-dependency conversion program in ways which have effects on conjunctions and prepositions.

We consider two such mapping regimes here:

1. PTB trees  $\rightarrow$  *Penn2Malt*<sup>1</sup>  $\rightarrow$  Dependencies
2. PTB trees patched with NP-internal annotations (Vadas and Curran, 2007)  $\rightarrow$  *pennconverter*<sup>2</sup>  $\rightarrow$  Dependencies

<sup>1</sup><http://w3.msi.vxu.se/~nivre/research/Penn2Malt.html>

<sup>2</sup>Johansson and Nugues (2007) [http://nlp.cs.lth.se/software/treebank\\_converter/](http://nlp.cs.lth.se/software/treebank_converter/)

Regime (1) is very commonly done in papers which report dependency parsing experiments (e.g., (McDonald and Pereira, 2006; Nivre et al., 2007; Zhang and Clark, 2008; Huang and Sagae, 2010; Koo and Collins, 2010)). *Penn2Malt* uses the head finding table from Yamada and Matsumoto (2003).

Regime (2) is based on the recommendations of the two converter tools; as of the date of this writing, the *Penn2Malt* website says: “Penn2Malt has been superseded by the more sophisticated *pennconverter*, which we strongly recommend”. The *pennconverter* website “strongly recommends” patching the Treebank with the NP annotations of Vadas and Curran (2007). A version of *pennconverter* was used to prepare the data for the CoNLL Shared Tasks of 2007-2009, so the trees produced by Regime 2 are similar (but not identical)<sup>3</sup> to these shared tasks. As far as we are aware, Bansal and Klein (2011) is the only published work which uses both steps in Regime (2).

The dependency representations produced by Regime 2 are designed to be more useful for extracting semantics (Johansson and Nugues, 2007). The parsing attachment accuracy of MALTPARSER (Nivre et al., 2007) was lower using *pennconverter* than *Penn2Malt*, but using the output of MALTPARSER under the new format parses produces a much better semantic role labeler than using its output with *Penn2Malt* (Johansson and Nugues, 2007).

Figures 1 and 2 show how conjunctions and prepositions, respectively, are represented after the two different conversion processes. *These differences are not rare*—70.7% of conjunctions and 5.2% of prepositions in the development set have a different parent under the two conversion types. These representational differences have serious implications for how well various factorizations will be able to capture these two phenomena.

## 3 Implications of Representations on the Scope of Factorization

Parsing requires a) learning to score potential parse trees, and b) given a particular scoring function, finding the highest scoring tree according to that function. The number of potential trees for a sen-

<sup>3</sup>The CoNLL data does not include the NP annotations; it does include annotations of named entities (Weischedel and Brunstein, 2005) so had some internal NP edges.

Figure 1: Examples of conjunctions: *the House Ways and Means Committee*, *notes and other debt*, and *sell or merge 600 by*. The conjunction is bolded, the left conjunct (in the linear order of the sentence) is underlined, and the right conjunct is italicized.

tence is exponential, so parsing is made tractable by decomposing the problem into a set of local substructures which can be combined using dynamic programming. Four possible factorizations are: single edges (edge-based), pairs of edges which share a parent (siblings), pairs of edges where the child of one is the parent of the other (grandparents), and triples of edges where the child of one is the parent of two others (grandparent+sibling). In this section, we discuss these factorizations and their relevance to conjunction and preposition representations.

### 3.1 Edge-based Scoring

One possible factorization corresponds to first-order parsing, in which the score of a parse tree  $Y$  decomposes completely across the edges in the tree:

$$S(Y) = \sum_{(h,m) \in Y} S(h,m) \quad (1)$$

Figure 2: Examples of prepositions: *plan in the S&L bailout law*, *opening of trading here yesterday*, and *whose plans for major rights issues*. The preposition is bolded and the (semantic) head is underlined.

**Conjunctions:** Under Conversion 1, we can see three different representations of conjunctions in Figures 1(a), 1(c), and 1(e). Under edge-based scoring, the conjunction would be scored along with *neither* of its conjuncts in 1(a). In Figure 1(c), the conjunction is scored along with its right conjunct only; in figure 1(e) along with its left conjunct only. The inconsistency here is likely to make learning more difficult, as what is learned is split across these three cases. Furthermore, the conjunction is connected with an edge to either zero or one of its two arguments; at least one of the arguments is completely ignored in terms of scoring the conjunction.

In Figures 1(c) and 1(e), the words being conjoined are connected to *each other* by an edge. This overloads the meaning of an edge; an edge indicates both a head-modifier relationship and a conjunction relationship. For example, compare the two natural phrases *dogs and cats* and *really nice dogs*. *dogs* and *cats* are a good pair to conjoin, but *cats* is not a good modifier for *dogs*, so there is a tension when scoring an edge like *(dogs, cats)*: it should get a high score

when actually indicating a conjunction and low otherwise. (*nice, really*) shows the opposite pattern—*really* is a good modifier for *nice*, but *nice* and *really* are not two words which should be conjoined. This may be partially compensated for by including features about the surrounding words (McDonald et al., 2005), but any feature templates which would be identical across the two contexts will be in tension.

In Figures 1(b), 1(d) and 1(f), the conjunction participates in a directed edge with each of the conjuncts. Thus, in edge-based scoring, at least under Conversion 2 neither of the conjuncts is being ignored; however, the factorization scores each edge independently, so how compatible these two conjuncts are with each other cannot be included in the scoring of a tree.

**Prepositions:** For all of the examples in Figure 2, there is a directed edge from the head of the phrase that the preposition modifies to the preposition. Differences in head finding rules account for the differences in preposition representations. In the second example, the first conversion scheme chooses *yesterday* as the head of the overall NP, resulting in the edge *yesterday*→*of*, while the second conversion scheme ignores temporal phrases when finding the head, resulting in the more semantically meaningful *opening*→*of*. Similarly, in the third example, the preposition *for* attaches to the pronoun *whose* in the first conversion scheme, while it attaches to the noun *plans* in the second.

With edge-based scoring, the object is not accessible when scoring where the preposition should attach, and PP-attachment is known to depend on the object of the preposition (Hindle and Rooth, 1993).

### 3.2 Sibling Scoring

Another alternative factorization is to score *siblings* as well as parent-child edges (McDonald and Pereira, 2006). Scores decompose as:

$$S(Y) = \sum_{(h, m, s)} S(h, m, s) \quad (2)$$

$$\left\{ (h, m, s) \mid \begin{array}{l} (h, m) \in Y, (h, s) \in Y, \\ (m, s) \in Sib(Y) \end{array} \right\}$$

where  $Sib(Y)$  is the set containing *ordered* and *adjacent* sibling pairs in  $Y$ : if  $(m, s) \in Sib(Y)$ , there must exist a shared parent  $h$  such that  $(h, m) \in Y$  and  $(h, s) \in Y$ ,  $m$  and  $s$  must be on the same side of  $h$ ,  $m$  must be closer to  $h$  than  $s$  in the linear order

of the sentence, and there must not exist any other children of  $h$  in between  $m$  and  $s$ .

Under this factorization, two of the three examples in Conversion 1 (and none of the examples in Conversion 2) in Figure 1 now include the conjunction and both conjuncts in the same score (Figures 1(c) and 1(e)). The scoring for head-modifier dependencies and conjunction dependencies are again being overloaded: (*debt, notes, and*) and (*debt, and, other*) are both sibling parts in Figure 1(c), yet only one of them represents a conjunction. The position of the conjunction in the sibling is not enough to determine whether one is scoring a true conjunction relation or just the conjunction and a different sibling; in 1(c) the conjunction is on the right of its sibling argument, while in 1(e) the conjunction is on the left.

For none of the other preposition or conjunction examples does a sibling factorization bring more of the arguments into the scope of what is scored along with the preposition/conjunction. Sibling scoring may have some benefit in that prepositions/conjunctions should have only one argument, so for prepositions (under both conversions) and conjunctions (under Conversion 2), the model can learn to disprefer the existence of any siblings and thus enforce choosing a single child.

### 3.3 Grandparent Scoring

Another alternative over pairs of edges scores grandparents instead of siblings, with factorization:

$$S(Y) = \sum_{\{ (h, m, c) \mid (h, m) \in Y, (m, c) \in Y \}} S(h, m, c) \quad (3)$$

Under Conversion 2, we would expect this factorization to perform much better on conjunctions and prepositions than edge-based or sibling-based factorizations. Both conjunctions and prepositions are consistently represented by exactly one grandparent relation (with one relevant argument as the grandparent, the preposition/conjunction as the parent, and the other argument as the child), so this is the first factorization that has allowed the compatibility of the two arguments to affect the attachment of the preposition/conjunction.

Under Conversion 1, this factorization is particularly appropriate for prepositions, but would be unlikely to help conjunctions, which have no children.

### 3.4 Grandparent-Sibling Scoring

A further widening of the factorization takes grandparents and siblings simultaneously:

$$S(Y) = \sum_{(g, h, m, s)} S(g, h, m, s) \quad (4)$$
$$\left\{ (g, h, m, s) \mid \begin{array}{l} (g, h) \in Y, (h, m) \in Y, \\ (h, s) \in Y, (m, s) \in \text{Sib}(Y) \end{array} \right\}$$

For projective parsing, dynamic programming for this factorization was derived in Koo and Collins (2010) (Model 1 in that paper), and for non-projective parsing, dual decomposition was used for this factorization in Koo et al. (2010).

This factorization should combine all the benefits of the sibling and grandparent factorizations described above—for Conversion 1, sibling scoring may help conjunctions and grandparent scoring may help prepositions, and for Conversion 2, grandparent scoring should help both, while sibling scoring may or may not add some additional gains.

## 4 Using Unlabeled Data Effectively

Associations from unlabeled data have the potential to improve both conjunctions and prepositions. We predict that web counts which include both conjuncts (for conjunctions), or which include both the attachment site and the object of a preposition (for prepositions) will lead to the largest improvements.

For the phrase *dogs and cats*, edge-based counts would measure the associations between *dogs* and *and*, and *and* and *cats*, but never any web counts that include both *dogs* and *cats*. For the phrase *ate spaghetti with a fork*, edge-based scoring would not use any web counts involving both *ate* and *fork*.

We use *associations* rather than raw counts. The phrases *trading and transacting* versus *trading and what* provide an example of the difference between associations and counts. The phrase *trading and what* has a higher count than the phrase *trading and transacting*, but *trading and transacting* are more highly associated. In this paper, we use point-wise mutual information (PMI) to measure the strength of associations of words participating in potential conjunctions or prepositions.<sup>4</sup> For three words  $h, m, c$ , this is calculated with:

$$PMI(h, m, c) = \log \frac{P(h * m * c)}{P(h)P(m)P(c)} \quad (5)$$

<sup>4</sup>PMI can be unreliable when frequency counts are small (Church and Hanks, 1990), however the data used was thresholded, so all counts used are at least 10.

The probabilities are estimated using web-scale n-gram counts, which are looked up using the tools and web-scale n-grams described in Lin et al. (2010). Defining the joint probability using wild-cards (rather than the exact sequence  $h m c$ ) is crucially important, as determiners, adjectives, and other words may naturally intervene between the words of interest.

Approaches which cluster words (i.e., Koo et al. (2008)) are also designed to identify words which are semantically related. As manually labeled parsed data is sparse, this may help generalize across similar words. However, if edges are not connected to the semantic head, cluster-based methods may be less effective. For example, the choice of *yesterday* as the head of *opening of trading here yesterday* in Figure 2(c) or *whose* in 2(e) may make cluster-based features less useful than if the semantic heads were chosen (*opening* and *plans*, respectively).

## 5 Experiments

The previous section motivated the use of unlabeled data for attaching prepositions and conjunctions. We have also hypothesized that these features will be most effective when the *data representation* and the *learning representation* both capture relevant properties of prepositions and conjunctions. We predict that Conversion 2 and a factorization which includes grand-parent scoring will achieve the highest performance. In this section, we investigate the impact of unlabeled data on parsing accuracy using the two conversions and using each of the factorizations described in Section 3.1-3.4.

### 5.1 Unlabeled Data Feature Set

**Clusters:** We replicate the cluster-based features from Koo et al. (2008), which includes features over *all* edges  $(h, m)$ , grand-parent triples  $(h, m, c)$ , and parent sibling triples  $(h, m, s)$ . The features were all derived from the publicly available clusters produced by running the Brown clustering algorithm (Brown et al., 1992) over the BLLIP corpus with the Penn Treebank sentences excluded.<sup>5</sup>

Preposition and conjunction-inspired features (motivated by Section 4) are described below:

<sup>5</sup>[people.csail.mit.edu/maestro/papers/bllip-clusters.gz](http://people.csail.mit.edu/maestro/papers/bllip-clusters.gz)

**Web Counts:** For each set of words of interest, we compute the PMI between the words, and then include binary features for whether the mutual information is undefined, if it is negative, and whether it is greater than each positive integer.

For conjunctions, we only do this for triples of both conjunct and the conjunction (and if the conjunction is *and* or *or* and the two potential conjuncts are the same coarse grained part-of-speech). For prepositions, we consider only cases in which the parent is a noun or a verb and the child is a noun (this corresponds to the cases considered by Hindle and Rooth (1993) and others). Prepositions use association features to score both the triple (parent, preposition, child) and all pairs within that triple. The counts features are not used if all the words involved are stopwords. For the scope of this paper we use *only* the above counts related to prepositions and conjunctions.

## 5.2 Parser

We use the Model 1 version of *dpo3*, a state-of-the-art third-order dependency parser (Koo and Collins, 2010)<sup>6</sup>. We augment the feature set used with the web-counts-based features relevant to prepositions and conjunctions and the cluster-based features. The only other change to the parser’s existing feature set was the addition of binary features for the part-of-speech tag of the child of the root node, alone and conjoined with the tags of its children. For further details about the parser, see Koo and Collins (2010).

## 5.3 Experimental Set-up

Training was done on Section 2-21 of the Penn Treebank. Section 22 was used for development, and Section 23 for test. We use automatic part-of-speech tags for both training and testing (Ratnaparkhi, 1996). The set of potential edges was pruned using the marginals produced by a first-order parser trained using exponentiated gradient descent (Collins et al., 2008) as in Koo and Collins (2010). We train the full parser for 15 iterations of averaged perceptron training (Collins, 2002), choose the iteration with the best unlabeled attachment score (UAS) on the development set, and apply the model after that iteration to the test set.

<sup>6</sup><http://groups.csail.mit.edu/nlp/dpo3/>

We also ran MSTParser (McDonald and Pereira, 2006), the Berkeley constituency parser (Petrov and Klein, 2007), and the unmodified *dpo3* Model 1 (Koo and Collins, 2010) using Conversion 2 (the current recommendations) for comparison. Since the converted Penn Treebank now contains a few non-projective sentences, we ran both the projective and non-projective versions of the second order (sibling) MSTParser. The Berkeley parser was trained on the constituency trees of the PTB patched with Vadas and Curran (2007), and then the predicted parses were converted using *pennconverter*.

## 6 Results and Discussion

Table 1 shows the unlabeled attachment scores, complete sentence exact match accuracies, and the accuracies of conjunctions and prepositions under Conversion 2.<sup>7</sup> The incorporation of the unlabeled data features (clusters and web counts) into the *dpo3* parser yields a significantly better parser than *dpo3* alone (93.54 UAS versus 93.21)<sup>8</sup>, and is more than a 1.5% improvement over MSTParser.

### 6.1 Impact of Factorization

In all four metrics (attachment of all non-punctuation tokens, sentence accuracy, prepositions, and conjunctions), there is no significant difference between the version of the parser which uses the grandparent and sibling factorization (Grand+Sib) and the version which uses just the grandparent factorization (Grand). A parser which uses only grandparents (referred to as Model 0 in Koo and Collins (2010)) may therefore be preferable, as it contains far fewer parameters than a third-order parser.

While the grandparent factorization and the sibling factorization (Sib) are both “second-order” parsers, scoring up to two edges (involving three words) simultaneously, their results are quite different, with the sibling factorization scoring much worse. This is particularly notable in the conjunction case, where the sibling model is over 5% absolute worse in accuracy than the grandparent model.

<sup>7</sup>As is standard for English dependency parsing, five punctuation symbols :, , “ ”, and . are excluded from the results (Yamada and Matsumoto, 2003).

<sup>8</sup>If the (deprecated) Conversion 1 is used, the new features improve the UAS of *dpo3* from 93.04 to 93.51.

Model	UAS	Exact Match	Conjunctions	Prepositions
MSTParser (proj)	91.96	38.9	84.0	84.2
MSTParser (non-proj)	91.98	38.7	83.8	84.6
Berkeley (converted)	90.98	36.0	85.6	84.3
dpo3 (Grand+Sib)	93.21	<b>44.8</b>	<b>89.6</b>	<b>86.9</b>
dpo3+Unlabeled (Edges)	93.12	43.6	85.3	<b>87.0</b>
dpo3+Unlabeled (Sib)	93.15	43.7	85.5	86.8
dpo3+Unlabeled (Grand)	<b>93.55</b>	<b>46.1</b>	<b>90.6</b>	<b>87.5</b>
dpo3+Unlabeled (Grand+Sib)	<b>93.54</b>	<b>46.0</b>	<b>90.8</b>	<b>87.4</b>
- Clusters	93.10	<b>45.0</b>	<b>90.5</b>	<b>87.5</b>
- Prep,Conj Counts	<b>93.52</b>	<b>45.8</b>	<b>89.9</b>	<b>87.1</b>

Table 1: Test set accuracies under Conversion 2 of unlabeled attachment scores, complete sentence exact match accuracies, conjunction accuracy, and preposition accuracy. Bolded items are the best in each column, or not significantly different from the best in that column (sign test,  $p < .05$ ).

## 6.2 Impact of Unlabeled Data

The unlabeled data features improved the already state-of-the-art *dpo3* parser in UAS, complete sentence accuracy, conjunctions, and prepositions. However, because the sample sizes are much smaller for the latter three cases, only the UAS improvement is statistically significant.<sup>9</sup> Overall, the results in Table 1 show that while the inclusion of unlabeled data improves parser performance, increasing the size of factorization matters even more. Ablation experiments showed that cluster features have a larger impact on overall UAS, while count features have a larger impact on prepositions and conjunctions.

## 6.3 Comparison with Other Parsers

The resulting *dpo3*+Unlabeled parser is significantly better than both versions of MSTParser and the Berkeley parser converted to dependencies across all four evaluations. *dpo3*+Unlabeled has an UAS 1.5% higher than MSTParser, which has an UAS 1.0% higher than the converted constituency parser. The MSTParser uses sibling scoring, so it is unsurprising that it performs less well on the new conversion.

While the converted constituency parser is not as good on dependencies as MSTParser overall, note that it is over a percent and a half better than MSTParser on attaching conjunctions (85.6% versus 84.0%). Conjunction scope may benefit from parallelism and higher-level structure, which is easily accessible when joining two matching non-terminals

<sup>9</sup>There are 52,308 non-punctuation tokens in the test set, compared with 2416 sentences, 1373 conjunctions, and 5854 prepositions.

in a context-free grammar, but much harder to determine in the local views of graph-based dependency parsers. The dependencies arising from the Berkeley constituency trees have higher conjunction accuracies than either the edge-based or sibling-based *dpo3*+Unlabeled parser. However, once grandparents are included in the factorization, the *dpo3*+Unlabeled is significantly better at attaching conjunctions than the constituency parser, attaching conjunctions with an accuracy over 90%. Therefore, some of the disadvantages of dependency parsing compared with constituency parsing can be compensated for with larger factorizations.

Scoring	Conjunctions	
	Conversion 1 (deprecated)	Conversion 2
Edge	86.3	85.3
Sib	<b>87.8</b>	85.5
Grand	<b>87.2</b>	<b>90.6</b>
Grand+Sib	<b>88.3</b>	<b>90.8</b>

Table 2: Unlabeled attachment accuracy for conjunctions. Bolded items are the best in each column, or not significantly different (sign test,  $p < .05$ ).

## 6.4 Impact of Data Representation

Tables 2 and 3 show the results of the *dpo3*+Unlabeled parser for conjunctions and prepositions, respectively, under the two different conversions. The data representation has an impact on which factorizations perform best. Under Conversion 1, conjunctions are more accurate under a sibling parser than a grandparent parser, while the

Scoring	Prepositions	
	Conversion 1 (deprecated)	Conversion 2
Edge	87.4	<b>87.0</b>
Sib	87.5	86.8
Grand	<b>87.9</b>	<b>87.5</b>
Grand+Sib	<b>88.4</b>	<b>87.4</b>

Table 3: Unlabeled attachment accuracy for prepositions. Bolded items are the best in each column, or not significantly different (sign test,  $p < .05$ ).

pattern is reversed for Conversion 2.

Conjunctions show a much stronger need for higher order factorizations than prepositions do. This is not too surprising, as prepositions have more of a selectional preference than conjunctions, and so the preposition itself is more informative about where it should attach. While prepositions do improve with larger factorizations, the improvement beyond edge-based is not significant for Conversion 2. One hypothesis for why Conversion 1 shows more of an improvement is that the wider scope leads to the semantic head being included; in Conversion 2, the semantic head is chosen as the parent of the preposition, so the wider scope is less necessary.

### 6.5 Preposition Error Analysis

Prepositions are *still* the largest source of errors in the dpo3+Unlabeled parser. We therefore analyze the errors made on the development set to determine whether the difficult remaining cases for parsers correspond to the Hindle and Rooth (1993) style PP-attachment classification task. In the PP-attachment classification task, the two choices for where the preposition attaches are the previous verb or the previous noun, and the preposition itself has a noun object. The ones that *do* attach to the preceding noun or verb (not necessarily the preceding word) and have a noun object (2323 prepositions) are attached by the dpo3+Unlabeled grandparent-scoring parser with 92.4% accuracy, while those that do not fit that categorization (1703 prepositions) have the correct parent only 82.7% of the time.

Local attachments are more accurate — prepositions are attached with 94.8% accuracy if the correct parent is the immediately preceding word (2364 cases) and only 79.1% accuracy if it is not (1662 cases). The preference is not necessarily for low

attachments though: the prepositions whose parent is not the preceding word are attached more accurately if the parent is the root word (usually corresponding to the main verb) of the sentence (90.8%, 587 cases) than if the parent is lower in the tree (72.7%, 1075 cases).

## 7 Conclusion

Features derived from unlabeled data (clusters and web counts) significantly improve a state-of-the-art dependency parser for English. We showed how well various factorizations are able to take advantage of these unlabeled data features, focusing our analysis on conjunctions and prepositions. Including grandparents in the factorization increases the accuracy of conjunctions over 5% absolute over edge-based or sibling-based scoring. The representation of the data is extremely important for how the problem should be factored—under the old Penn2Malt dependency representation, a sibling parser was more accurate than a grandparent parser. As some important relationships were represented as siblings and some as grandparents, there was a need to develop third-order parsers which could exploit both simultaneously (Koo and Collins, 2010). Under the new pennconverter standard, a grandparent parser is significantly better than a sibling parser, and there is no significant improvement when including both.

## Acknowledgments

I would like to thank Terry Koo for making the *dpo3* parser publically available and for his help with using the parser. I would also like to thank Mitch Marcus and Kenneth Church for useful discussions. This material is based upon work supported under a National Science Foundation Graduate Research Fellowship.

## Abstract

Treebanks are not large enough to reliably model precise lexical phenomena. This deficiency provokes attachment errors in the parsers trained on such data. We propose in this paper to compute lexical affinities, on large corpora, for specific lexico-syntactic configurations that are hard to disambiguate and introduce the new information in a parser. Experiments on the French Treebank showed a relative decrease of the error rate of 7.1% Labeled Accuracy Score yielding the best parsing results on this treebank.

## 1 Introduction

Probabilistic parsers are usually trained on treebanks composed of few thousands sentences. While this amount of data seems reasonable for learning syntactic phenomena and, to some extent, very frequent lexical phenomena involving closed parts of speech (POS), it proves inadequate when modeling lexical dependencies between open POS, such as nouns, verbs and adjectives. This fact was first recognized by (Bikel, 2004) who showed that bilexical dependencies were barely used in Michael Collins' parser.

The work reported in this paper aims at a better modeling of such phenomena by using a raw corpus that is several orders of magnitude larger than the treebank used for training the parser. The raw corpus is first parsed and the computed *lexical affinities* between lemmas, in specific lexico-syntactic configurations, are then injected back in the parser. Two outcomes are expected from this procedure, the first

is, as mentioned above, a better modeling of bilexical dependencies and the second is a method to adapt a parser to new domains.

The paper is organized as follows. Section 2 reviews some work on the same topic and highlights their differences with ours. In section 3, we describe the parser that we use in our experiments and give a detailed description of the frequent attachment errors. Section 4 describes how lexical affinities between lemmas are calculated and their impact is then evaluated with respect to the attachment errors made by the parser. Section 5 describes three ways to integrate the lexical affinities in the parser and reports the results obtained with the three methods.

## 2 Previous Work

Coping with lexical sparsity of treebanks using raw corpora has been an active direction of research for many years.

One simple and effective way to tackle this problem is to put together words that share, in a large raw corpus, similar linear contexts, into word *clusters*. The word occurrences of the training treebank are then replaced by their cluster identifier and a new parser is trained on the transformed treebank. Using such techniques (Koo et al., 2008) report significant improvement on the Penn Treebank (Marcus et al., 1993) and so do (Candito and Seddah, 2010; Candito and Crabbé, 2009) on the French Treebank (Abeillé et al., 2003).

Another series of papers (Volk, 2001; Nakov and Hearst, 2005; Pitler et al., 2010; Zhou et al., 2011) directly model word co-occurrences. Co-occurrences of pairs of words are first collected in a

raw corpus or internet  $n$ -grams. Based on the counts produced, lexical affinity scores are computed. The detection of pairs of words co-occurrences is generally very simple, it is either based on the direct adjacency of the words in the string or their co-occurrence in a window of a few words. (Bansal and Klein, 2011; Nakov and Hearst, 2005) rely on the same sort of techniques but use more sophisticated patterns, based on simple paraphrase rules, for identifying co-occurrences.

Our work departs from those approaches by the fact that we do not extract the lexical information directly on a raw corpus, but we first parse it and then extract the co-occurrences on the parse trees, based on some predetermined lexico-syntactic patterns. The first reason for this choice is that the linguistic phenomena that we are interested in, such as as PP attachment, coordination, verb subject and object can range over long distances, beyond what is generally taken into account when working on limited windows. The second reason for this choice was to show that the performances that the NLP community has reached on parsing, combined with the use of confidence measures allow to use parsers to extract accurate lexico-syntactic information, beyond what can be found in limited annotated corpora.

Our work can also be compared with self training approaches to parsing (McClosky et al., 2006; Suzuki et al., 2009; Steedman et al., 2003; Sagae and Tsujii, 2007) where a parser is first trained on a treebank and then used to parse a large raw corpus. The parses produced are then added to the initial treebank and a new parser is trained. The main difference between these approaches and ours is that we do not directly add the output of the parser to the training corpus, but extract precise lexical information that is then re-injected in the parser. In the self training approach, (Chen et al., 2009) is quite close to our work: instead of adding new parses to the treebank, the occurrence of simple interesting subtrees are detected in the parses and introduced as new features in the parser.

The way we introduce lexical affinity measures in the parser, in 5.1, shares some ideas with (Anguiano and Candito, 2011), who modify some attachments in the parser output, based on lexical information. The main difference is that we only take attachments that appear in an  $n$ -best parse list into account, while

they consider the first best parse and compute all potential alternative attachments, that may not actually occur in the  $n$ -best forests.

### 3 The Parser

The parser used in this work is the second order graph based parser (McDonald et al., 2005; Kübler et al., 2009) implementation of (Bohnet, 2010). The parser was trained on the French Treebank (Abeillé et al., 2003) which was transformed into dependency trees by (Candito et al., 2009). The size of the treebank and its decomposition into train, development and test sets is represented in table 1.

	nb of sentences	nb of words
FTB_TRAIN	9 881	278 083
FTB_DEV	1 239	36 508
FTB_TEST	1 235	36 340

Table 1: Size and decomposition of the French Treebank

The part of speech tagging was performed with the MELT tagger (Denis and Sagot, 2010) and lemmatized with the MACAON tool suite (Nasr et al., 2011). The parser gave state of the art results for parsing of French, reported in table 2.

	pred. POS tags		gold POS tags	
	punct	no punct	punct	no punct
LAS	88.02	90.24	88.88	91.12
UAS	90.02	92.50	90.71	93.20

Table 2: Labeled and unlabeled accuracy score for automatically predicted and gold POS tags with and without taking into account punctuation on FTB\_TEST.

Figure 1 shows the distribution of the 100 most common error types made by the parser. In this figure, x axis shows the error types and y axis shows the error ratio of the related error type ( $\frac{\text{number of errors of the specific type}}{\text{total number of errors}}$ ). We define an error type by the POS tag of the governor and the POS tag of the dependent. The figure presents a typical Zipfian distribution with a low number of frequent error types and a large number of unfrequent error types. The shape of the curve shows that concentrating on some specific frequent errors in order to increase the parser accuracy is a good strategy.

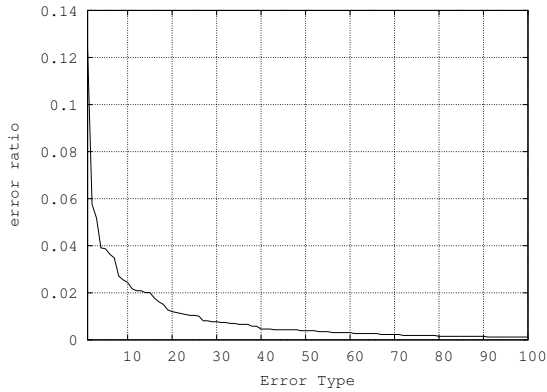

Figure 1: Distribution of the types of errors

Table 3 gives a finer description of the most common types of error made by the parser. Here we define more precise patterns for errors, where some lexical values are specified (for prepositions) and, in some cases, the nature of the dependency is taken into account. Every line of the table corresponds to one type of error. The first column describes the error type. The second column indicates the frequency of this type of dependency in the corpus. The third one displays the accuracy for this type of dependency (the number of dependencies of this type correctly analyzed by the parser divided by the total number of dependencies of this type). The fourth column shows the contribution of the errors made on this type of dependency to the global error rate. The last column associates a name with some of the error types that will prove useful in the remainder of the paper to refer to the error type.

Table 3 shows two different kinds of errors that impact the global error rate. The first one concerns very common dependencies that have a high accuracy but, due to their frequency, hurt the global error rate of the parser. The second one concerns low frequency, low accuracy dependency types. Lines 2 and 3, respectively attachment of the preposition  $\grave{a}$  to a verb and the subject dependency illustrate such a contrast. They both impact the total error rate in the same way (2.53% of the errors). But the first one is a low frequency low accuracy type (respectively 0.88% and 69.11%) while the second is a high frequency high accuracy type (respectively 3.43% and 93.03%). We will see in 4.2.2 that our method behaves quite differently on these two types of error.

dependency	freq.	acc.	contrib.	name

## 4 Creating the Lexical Resource

The lexical resource is a collection of tuples  $\langle C, g, d, s \rangle$  where  $C$  is a lexico-syntactic configuration,  $g$  is a lemma, called the governor of the configuration,  $d$  is another lemma called the dependent and  $s$  is a numerical value between 0 and 1, called the lexical affinity score, which accounts for the strength of the association between  $g$  and  $d$  in the context  $C$ . For example the tuple  $\langle (V, g) \xrightarrow{obj} (N, d), eat, oyster, 0.23 \rangle$  defines a simple configuration  $(V, g) \xrightarrow{obj} (N, d)$  that is an object dependency between verb  $g$  and noun  $d$ . When replacing variables  $g$  and  $d$  in  $C$  respectively with  $eat$  and  $oyster$ , we obtain the fully specified lexico syntactic pattern  $(V, eat) \xrightarrow{obj} (N, oyster)$ , that we call an instantiated configuration. The numerical value 0.23 accounts for how much  $eat$  and  $oyster$  like to co-occur in the verb-object configuration. Configurations can be of arbitrary complexity but they have to be generic enough in order to occur frequently in a corpus yet be specific enough to model a precise lexico syntactic phenomenon. The context  $(*, g) \xrightarrow{*} (*, d)$ , for example is very generic but does not model a precise linguistic phenomenon, as selectional preferences of a verb, for example. Moreover, configurations need to be error-prone. In the perspective of increasing a parser performances, there is no point in computing lexical affinity scores between words that appear in a configuration for which

the parser never makes mistakes.

The creation of the lexical resource is a three stage process. The first step is the definition of configurations, the second one is the collection of raw counts from the machine parsed corpora and the third one is the computation of lexical affinities based on the raw counts. The three steps are described in the following subsection while the evaluation of the created resource is reported in subsection 4.2.

#### 4.1 Computing Lexical Affinities

A set of 9 configurations have been defined. Their selection is a manual process based on the analysis of the errors made by the parser, described in section 3, as well as on the linguistic phenomena they model. The list of the 9 configurations is described in Table 4. As one can see on this table, configurations are usually simple, made up of one or two dependencies. Linguistically, configurations OBJ and SBJ concern subject and object attachments, configuration ADJ is related to attachments of adjectives to nouns and configurations NdeN, VdeN, VaN, and NaN indicate prepositional attachments. We have restricted ourselves here to two common French prepositions *à* and *de*. Configurations NcN and VcV deal respectively with noun and verb coordination.

Name	Description
OBJ	$(V, g) \xrightarrow{obj} (N, d)$
SBJ	$(V, g) \xrightarrow{subj} (N, d)$
ADJ	$(N, g) \rightarrow ADJ$
NdeN	$(N, g) \rightarrow (P, de) \rightarrow (N, d)$
VdeN	$(V, g) \rightarrow (P, de) \rightarrow (N, d)$
NaN	$(N, g) \rightarrow (P, \grave{a}) \rightarrow (N, d)$
VaN	$(V, g) \rightarrow (P, \grave{a}) \rightarrow (N, d)$
NcN	$(N, g) \rightarrow (CC, *) \rightarrow (N, d)$
VcV	$(V, g) \rightarrow (CC, *) \rightarrow (V, d)$

Table 4: List of the 9 configurations.

The computation of the number of occurrences of an instantiated configuration in the corpus is quite straightforward, it consists in traversing the dependency trees produced by the parser and detect the occurrences of this configuration.

At the end of the counts collection, we have gath-

CORPUS	Sent. nb.	Tokens nb.
AFP	1 024 797	31 486 618
EST REP	1 103 630	19 635 985
WIKI	1 592 035	33 821 460
TOTAL	3 720 462	84 944 063

Table 5: sizes of the corpora used to gather lexical counts

ered for every lemma  $l$  its number of occurrences as governor (resp. dependent) of configuration  $C$  in the corpus, noted  $\mathcal{C}(C, l, *)$  (resp.  $\mathcal{C}(C, *, l)$ ), as well as the number of occurrences of configuration  $C$  with lemma  $l_g$  as a governor and lemma  $l_d$  as a dependent, noted  $\mathcal{C}(C, l_g, l_d)$ . We are now in a position to compute the score  $s(C, l_g, l_d)$ . This score should reflect the tendency of  $l_g$  and  $l_d$  to appear together in configuration  $C$ . It should be maximal if whenever  $l_g$  occurs as the governor of configuration  $C$ , the dependent position is occupied by  $l_d$  and, symmetrically, if whenever  $l_d$  occurs as the dependent of configuration  $C$ , the governor position is occupied by  $l_g$ . A function that conforms such a behavior is the following:

$$s(C, l_g, l_d) = \frac{1}{2} \left( \frac{\mathcal{C}(C, l_g, l_d)}{\mathcal{C}(C, l_g, *)} + \frac{\mathcal{C}(C, l_g, l_d)}{\mathcal{C}(C, *, l_d)} \right)$$

it takes its values between 0 ( $l_g$  and  $l_d$  never co-occur) and 1 ( $g$  and  $d$  always co-occur). This function is close to pointwise mutual information (Church and Hanks, 1990) but takes its values between 0 and 1.

#### 4.2 Evaluation

Lexical affinities were computed on three corpora of slightly different genres. The first one, is a collection of news report of the French press agency *Agence France Presse*, the second is a collection of newspaper articles from a local French newspaper : *l'Est Républicain*. The third one is a collection of articles from the French Wikipedia. The size of the different corpora are detailed in table 5. The corpus was first POS tagged, lemmatized and parsed in order to get the 50 best parses for every sentence. Then the lexical resource was built, based on the 9 configurations described in table 4.

The lexical resource has been evaluated on FTB\_DEV with respect to two measures: coverage

and correction rate, described in the next two sections.

#### 4.2.1 Coverage

Coverage measures the instantiated configurations present in the evaluation corpus that are in the resource. The results are presented in table 6. Every line represents a configuration, the second column indicates the number of different instantiations of this configuration in the evaluation corpus, the third one indicates the number of instantiated configurations that were actually found in the lexical resource and the fourth column shows the coverage for this configuration, which is the ratio third column over the second. Last column represents the coverage of the training corpus (the lexical resource is extracted on the training corpus) and the last line represents the same quantities computed on all configurations.

Table 6 shows two interesting results: firstly the high variability of coverage with respect to configurations, and secondly the low coverage when the lexical resource is computed on the training corpus, this fact being consistent with the conclusions of (Bikel, 2004). A parser trained on a treebank cannot be expected to reliably select the correct governor in lexically sensitive cases.

#### 4.2.2 Correction Rate

While coverage measures how many instantiated configurations that occur in the treebank are actually present in the lexical resource, it does not measure if the information present in the lexical resource can actually help correcting the errors made by the parser.

We define *Correction Rate* (CR) as a way to approximate the usefulness of the data. Given a word  $d$  present in a sentence  $S$  and a configuration  $C$ , the set of all potential governors of  $d$  in configuration  $C$ , in all the  $n$ -best parses produced by the parser is computed. This set is noted  $\mathcal{G} = \{g_1, \dots, g_j\}$ . Let us note  $G_L$  the element of  $\mathcal{G}$  that maximizes the lexical affinity score. When the lexical resource gives no score to any of the elements of  $\mathcal{G}$ ,  $G_L$  is left unspecified.

Ideally,  $\mathcal{G}$  should not be the set of governors in the  $n$ -best parses but the set of all possible governors for  $d$  in sentence  $S$ . Since we have no simple way to compute the latter, we will content ourselves with the former as an approximation of the latter.

Let us note  $G_H$  the governor of  $d$  in the (first) best parse produced and  $G_R$  the governor of  $d$  in the correct parse. CR measures the effect of replacing  $G_H$  with  $G_L$ .

We have represented in table 7 the different scenarios that can happen when comparing  $G_H$ ,  $G_R$  and  $G_L$ .

$G_H = G_R$	$G_L = G_R$ or $G_L$ unspec.	CC
	$G_L \neq G_R$	CE
$G_H \neq G_R$	$G_L = G_R$	EC
	$G_L \neq G_R$ or $G_L$ unspec.	EE
	$G_R \notin \mathcal{G}$	NA

Table 7: Five possible scenarios when comparing the governor of a word produced by the parser ( $G_H$ ), in the reference parse ( $G_R$ ) and according to the lexical resource ( $G_L$ ).

In scenarios CC and CE, the parser did not make a mistake (the first letter, C, stands for correct). In scenario CC, the lexical affinity score was compatible with the choice of the parser or the lexical resource did not select any candidate. In scenario CE, the lexical resource introduced an error. In scenarios EC and EE, the parser made an error. In EC, the error was corrected by the lexical resource while in EE, it wasn't. Either because the lexical resource candidate was not the correct governor or it was unspecified. The last case, NA, indicates that the correct governor does not appear in any of the  $n$ -best parses. Technically this case could be integrated in EE (an error made by the parser was not corrected by the lexical resource) but we chose to keep it apart

since it represents a case where the right solution could not be found in the  $n$ -best parse list (the correct governor is not a member of set  $\mathcal{G}$ ).

Let's note  $n_S$  the number of occurrences of scenario  $S$  for a given configuration. We compute CR for this configuration in the following way:

$$\begin{aligned} CR &= \frac{\text{old error number} - \text{new error number}}{\text{old error number}} \\ &= \frac{n_{EC} - n_{CE}}{n_{EE} + n_{EC} + n_{NA}} \end{aligned}$$

When CR is equal to 0, the correction did not have any impact on the error rate. When  $CR > 0$ , the error rate is reduced and if  $CR < 0$  it is increased<sup>1</sup>.

CR for each configuration is reported in table 8. The counts of the different scenarios have also been reported.

Conf.	$n_{CC}$	$n_{CE}$	$n_{EC}$	$n_{EE}$	$n_{NA}$	CR
OBJ	992	30	51	5	17	0.29

VcN	120	21	14	11	5	-0.23
$\Sigma$	7223	264	398	146	121	0.20

Table 8: Correction Rate of the lexical resource with respect to FTB.DEV.

Table 8 shows very different results among configurations. Results for PP attachments VdeN, VaN and NaN are quite good (a CR of 75% for a given configuration, as VdeN indicates that the number of errors on such a configuration is decreased by 25%). It is interesting to note that the parser behaves quite badly on these attachments: their accuracy (as reported in table 3) is, respectively 74.68, 69.1 and 70.64. Lexical affinity helps in such cases. On the other hand, some attachments like configuration ADJ and NdeN, for which the parser showed very good accuracy (96.6 and 92.2) show very poor performances. In such cases, taking into account lexical affinity creates new errors.

<sup>1</sup>One can note, that contrary to coverage, CR does not measure a characteristic of the lexical resource alone, but the lexical resource combined with a parser.

On average, using the lexical resource with this simple strategy of systematically replacing  $G_H$  with  $G_L$  allows to decrease by 20% the errors made on our 9 configurations and by 2.5% the global error rate of the parser.

### 4.3 Filtering Data with Ambiguity Threshold

The data used to extract counts is noisy: it contains errors made by the parser. Ideally, we would like to take into account only non ambiguous sentences, for which the parser outputs a single parse hypothesis, hopefully the good one. Such an approach is obviously doomed to fail since almost every sentence will be associated to several parses. Another solution would be to select sentences for which the parser has a high confidence, using confidence measures as proposed in (Sánchez-Sáez et al., 2009; Hwa, 2004). But since we are only interested in some parts of sentences (usually one attachment), we don't need high confidence for the whole sentence. We have instead used a parameter, defined on single dependencies, called the *ambiguity measure*.

Given the  $n$  best parses of a sentence and a dependency  $\delta$ , present in at least one of the  $n$  best parses, let us note  $\mathcal{C}(\delta)$  the number of occurrences of  $\delta$  in the  $n$  best parse set. We note  $AM(\delta)$  the ambiguity measure associated to  $\delta$ . It is computed as follows:

$$AM(\delta) = 1 - \frac{\mathcal{C}(\delta)}{n}$$

An ambiguity measure of 0 indicates that  $\delta$  is non ambiguous in the set of the  $n$  best parses (the word that constitutes the dependent in  $\delta$  is attached to the word that constitutes the governor in  $\delta$  in all the  $n$ -best analyses). When  $n$  gets large enough this measure approximates the non ambiguity of a dependency in a given sentence.

Ambiguity measure is used to filter the data when counting the number of occurrences of a configuration: only occurrences that are made of dependencies  $\delta$  such that  $AM(\delta) \leq \tau$  are taken into account.  $\tau$  is called the ambiguity threshold.

The results of coverage and CR given above were computed for  $\tau$  equal to 1, which means that, when collecting counts, all the dependencies are taken into account whatever their ambiguity is. Table 9 shows coverage and CR for different values of  $\tau$ . As expected, coverage decreases with  $\tau$ . But, interest-

ingly, decreasing  $\tau$ , from 1 down to 0.2 has a positive influence on CR. Ambiguity threshold plays the role we expected: it allows to reduce noise in the data, and corrects more errors.

	$\tau = 1.0$	$\tau = 0.4$	$\tau = 0.2$	$\tau = 0.0$

## 5 Integrating Lexical Affinity in the Parser

We have devised three methods for taking into account lexical affinity scores in the parser. The first two are post-processing methods, that take as input the  $n$ -best parses produced by the parser and modify some attachments with respect to the information given by the lexical resource. The third method introduces the lexical affinity scores as new features in the parsing model. The three methods are described in 5.1, 5.2 and 5.3. They are evaluated in 5.4.

### 5.1 Post Processing Method

The post processing method is quite simple. It is very close to the method that was used to compute the Correction Rate of the lexical resource, in 4.2.2: it takes as input the  $n$ -best parses produced by the parser and, for every configuration occurrence  $C$  found in the first best parse, the set ( $\mathcal{G}$ ) of all potential governors of  $C$ , in the  $n$ -best parses, is computed and among them, the word that maximizes the lexical affinity score ( $G_L$ ) is identified.

Once  $G_L$  is identified, one can replace the choice of the parser ( $G_H$ ) with  $G_L$ . This method is quite crude since it does not take into account the confidence the parser has in the solution proposed. We observed, in 4.2.2 that CR was very low for configurations for which the parser achieves good accuracy. In order to introduce the parser confidence in the final choice of a governor, we compute  $\mathcal{C}(G_H)$  and

$\mathcal{C}(G_L)$  which respectively represent the number of times  $G_H$  and  $G_L$  appear as the governor of configuration  $C$ . The choice of the final governor, noted  $\hat{G}$ , depends on the ratio of  $\mathcal{C}(G_H)$  and  $\mathcal{C}(G_L)$ . The complete selection strategy is the following:

1. if  $G_H = G_L$  or  $G_L$  is unspecified,  $\hat{G} = G_H$ .
2. if  $G_H \neq G_L$ ,  $\hat{G}$  is determined as follows:

$$\hat{G} = \begin{cases} G_H & \text{if } \frac{\mathcal{C}(G_H)}{\mathcal{C}(G_L)} > \alpha \\ G_L & \text{otherwise} \end{cases}$$

where  $\alpha$  is a coefficient that is optimized on the development data set.

We have reported, in table 10 the values of CR, for the 9 different features, using this strategy, for  $\tau = 1$ . We do not report the values of CR for other values of  $\tau$  since they are very close to each other. The table shows several noticeable facts. First, the new strategy performs much better than the former one (crudely replacing  $G_H$  by  $G_L$ ), the value of CR increased from 0.2 to 0.4, which means that the errors made on the nine configurations are now decreased by 40%. Second, CR is now positive for every configuration: the number of errors is decreased for every configuration.

Conf.	OBJ	SUJ	ADJ	NdeN	VdeN
CR	0.45	0.46	0.14	0.05	0.73
Conf.	NaN	VaN	NcN	VcV	$\Sigma$
CR	0.12	0.8	0.12	0.1	0.4

Table 10: Correction Rate on FTB.DEV when taking into account parser confidence.

### 5.2 Double Parsing Method

The post processing method performs better than the naive strategy that was used in 4.2.2. But it has an important drawback: it creates inconsistent parses. Recall that the parser we are using is based on a second order model, which means that the score of a dependency depends on some neighboring ones. Since with the post processing method only a subset of the dependencies are modified, the resulting parse is inconsistent: the score of some dependencies is computed on the basis of other dependencies that have been modified.

In order to compute a new optimal parse tree that preserves the modified dependencies, we have used a technique proposed in (Mirroshandel and Nasr, 2011) that modifies the scoring function of the parser in such a way that the dependencies that we want to keep in the parser output get better scores than all competing dependencies.

The double parsing method is therefore a three stage method. First, sentence  $S$  is parsed, producing the  $n$ -best parses. Then, the post processing method is used, modifying the first best parse. Let's note  $\mathcal{D}$  the set of dependencies that were changed in this process. In the last stage, a new parse is produced, that preserves  $\mathcal{D}$ .

### 5.3 Feature Based Method

In the feature based method, new features are added to the parser that rely on lexical affinity scores. These features are of the following form:  $\langle C, l_g, l_d, \delta_C(s) \rangle$ , where  $C$  is a configuration number,  $s$  is the lexical affinity score ( $s = s(C, l_g, l_d)$ ) and  $\delta_C(\cdot)$  is a discretization function.

Discretization of the lexical affinity scores is necessary in order to fight against data sparseness. In this work, we have used Weka software (Hall et al., 2009) to discretize the scores with unsupervised binning. Binning is a simple process which divides the range of possible values a parameter can take into subranges called bins. Two methods are implemented in Weka to find the optimal number of bins: equal-frequency and equal-width. In equal-frequency binning, the range of possible values are divided into  $k$  bins, each of which holds the same number of instances. In equal-width binning, which is the method we have used, the range are divided into  $k$  subranges of the same size. The optimal number of bins is the one that minimizes the entropy of the data. Weka computes different number of bins for different configurations, ranging from 4 to 10. The number of new features added to the parser is equal to  $\sum_C B(C)$  where  $C$  is a configuration and  $B(C)$  is the number of bins for configuration  $C$ .

### 5.4 Evaluation

The three methods described above have been evaluated on FTB\_TEST. Results are reported in table 11. The three methods outperformed the baseline (the state of the art parser for French which is a second

order graph based method) (Bohnet, 2010). The best performances were obtained by the Double Parsing method that achieved a labeled relative error reduction of 7,1% on predicted POS tags, yielding the best parsing results on the French Treebank. It performs better than the Post Processing method, which means that the second parsing stage corrects some inconsistencies introduced in the Post Processing method. The performances of the Feature Based method are disappointing, it achieves an error reduction of 1.4%. This result is not easy to interpret. It is probably due to the limited number of new features introduced in the parser. These new features probably have a hard time competing with the large number of other features in the training process.

		pred. POS tags		gold POS tags

## 6 Conclusion

Computing lexical affinities, on large corpora, for specific lexico-syntactic configurations that are hard to disambiguate has shown to be an effective way to increase the performances of a parser. We have proposed in this paper one method to compute lexical affinity scores as well as three ways to introduce this new information in a parser. Experiments on a French corpus showed a relative decrease of the error rate of 7.1% Labeled Accuracy Score.

## Abstract

The Chinese comma signals the boundary of discourse units and also anchors discourse relations between adjacent text spans. In this work, we propose a discourse structure-oriented classification of the comma that can be automatically extracted from the Chinese Treebank based on syntactic patterns. We then experimented with two supervised learning methods that automatically disambiguate the Chinese comma based on this classification. The first method integrates comma classification into parsing, and the second method adopts a “post-processing” approach that extracts features from automatic parses to train a classifier. The experimental results show that the second approach compares favorably against the first approach.

## 1 Introduction

The Chinese comma, which looks graphically very similar to its English counterpart, is functionally quite different. It has attracted a significant amount of research that studied the problem from the viewpoint of natural language processing. For example, Jin et al (2004) and Li et al (2005) view the disambiguation of the Chinese comma as a way of breaking up long Chinese sentences into shorter ones to facilitate parsing. The idea is to split a long sentence into multiple comma-separated segments, parse them individually, and reconstruct the syntactic parse for the original sentence. Although both studies show a positive impact of this approach, comma disambiguation is viewed merely as a convenient tool to help achieve a more important goal.

Xue and Yang (2011) point out that the very reason for the existence of these long Chinese sentences is because the Chinese comma is ambiguous and in some context, it identifies the boundary of a sentence just as a period, a question mark, or an exclamation mark does. The disambiguation of comma is viewed as a necessary step to detect sentence boundaries in Chinese and it can benefit a whole range of downstream NLP applications such as syntactic parsing and Machine Translation. In Machine Translation, for example, it is very typical for “one” Chinese sentence to be translated into multiple English sentences, with each comma-separated segment corresponding to one English sentence. In the present work, we expand this view and propose to look at the Chinese comma in the context of discourse analysis. The Chinese comma is viewed as a delimiter of elementary discourse units (EDUs), in the sense of the Rhetorical Structure Theory (Carlson et al., 2002; Mann et al., 1988). It is also considered to be the anchor of discourse relations, in the sense of the Penn Discourse Treebank (PDT) (Prasad et al., 2008). Disambiguating the comma is thus necessary for the purpose of discourse segmentation, the identification of EDUs, a first step in building up the discourse structure of a Chinese text.

Developing a supervised or semi-supervised model of discourse segmentation would require ground truth annotated based on a well-established representation scheme, but as of right now no such annotation exists for Chinese to the best of our knowledge. However, syntactically annotated treebanks often contain important clues that can be used to infer discourse-level information. We present

a method of automatically deriving a preliminary form of discourse structure anchored by the Chinese comma from the Penn Chinese Treebank (CTB) (Xue et al., 2005), and using this information to train and test supervised models. This discourse information is formalized as a classification of the Chinese comma, with each class representing the boundary of an elementary discourse unit as well as the anchor of a coarse-grained discourse relation between the two discourse units that it delimits. We then develop two comma classification methods. In the first method, we replace the part-of-speech (POS) tag of each comma in the CTB with a derived discourse category and retrain a state-of-the-art Chinese parser on the relabeled data. We then evaluate how accurately the commas are classified in the parsing process. In the second method, we parse these sentences and extract lexical and syntactic information as features to predict these new discourse categories. The second approach gives us more control over what features to extract and our results show that it compares favorably against the first approach.

The rest of the paper is organized as follows. In Section 2, we present our approach to automatically extract discourse information from a syntactically annotated treebank and present our classification scheme. In Section 3, we describe our supervised learning methods and the features we extracted. Section 4 presents our experiment setup and experimental results. Related work is reviewed in Section 5. We conclude in Section 6.

## 2 Chinese comma classification

There are many ways to conceptualize the discourse structure of a text (Mann et al., 1988; Prasad et al., 2008), but there is more of a consensus among researchers about the fundamental building blocks of the discourse structure. For the Rhetorical Discourse Theory, the building blocks are Elementary Discourse Units (EDUs). For the PDT, the building blocks are abstract objects such as propositions, facts. Although they are phrased in different ways, syntactically these discourse units are generally realized as clauses or built on top of clauses. So the first step in building the discourse structure of a text is to identify these discourse units.

In Chinese, these elementary discourse units are generally delimited by the comma, but not all commas mark the boundaries of a discourse unit. In (1), for example, Comma [1] marks the boundary of a discourse unit while Comma [2] does not. This is reflected in its English translation: while the first comma corresponds to an English comma, the second comma is not translated at all, as it marks the boundary between a subject and its predicate, where no comma is needed in English. Disambiguating these two types of commas is thus an important first step in identifying elementary discourse units and building up the discourse structure of a text.

- (1) 王翔 虽 年 过 半 百, [1] 但

thinking , give people one CL challenger  
的 印 象 。  
DE impression .

“Although Wang Xiang is over 50 years old, his abundant energy and quick thinking leave people the impression of a challenger.”

Although to the best of our knowledge, no such discourse segmented data for Chinese exists in the public domain, this information can be extracted from the syntactic annotation of the CTB. In the syntactic annotation of the sentence, illustrated in (a), it is clear that while the first comma in the sentence marks the boundary of a clause, the second one marks the demarcation between the subject NP and the predicate VP and thus is not an indicator of a discourse boundary.

In addition to a binary distinction of whether a comma marks the boundary of a discourse unit, the CTB annotation also allows the extraction of a more elaborate classification of commas based on coordination and subordination relations of comma-separated clauses. This classification of the Chinese

comma can be viewed as a first approximation of the discourse relations anchored by the comma that can be refined later via a manual annotation process.

Based on the syntactic annotation in the CTB, we classify the Chinese comma into seven hierarchically organized categories, as illustrated in Figure 1. The first distinction is made between commas that indicate a discourse boundary (RELATION) and those that do not (OTHER). Commas that indicate discourse boundaries are further divided into commas that separate coordinated discourse units (COORD) vs commas that separate discourse units in a subordination relation (SUBORD). Based on the levels of embedding and the syntactic category of the coordinated structures, we define three different types of coordination (SB, IP\_COORD and VP\_COORD). We also define three types of subordination relations (ADJ, COMP, Sent\_SBJ), based on the syntactic structure. As we will show below, each of the six relations has a clear syntactic pattern that can be exploited for their automatic detection.

Figure 1: Comma classification

**Sentence Boundary (SB):** Following (Xue and Yang, 2011), we consider the loosely coordinated IPs that are the immediate children of the root IP to be independent sentences, and the commas separating them to be delimiters of sentence boundary. This is illustrated in (2), where a Chinese sentence can be split into two independent shorter sentences at the comma. We view this comma to be a marker of the sentence boundary and it serves the same function as the unambiguous sentence boundary delimiters (periods, question marks, exclamation marks) in Chinese. The syntactic pattern that is used to infer this relation is illustrated in (b).

- (2) 广东省 建立 了 自然  
Guangdong province establish ASP natural

科学 基金 , [3] 每年  
science foundation , every year  
投入 在一亿 元  
investment at one hundred million yuan  
以上 。  
above .

“Natural Science Foundation is established in Guangdong Province. More than one hundred million yuan is invested every year.”

**IP Coordination (IP\_COORD):** Coordinated IPs that are not the immediate children of the root IP are also considered to be discourse units and the commas linking them are labeled IP\_COORD. Different from the sentence boundary cases, these coordinated IPs are often embedded in a larger structure. An example is given in (3) and its typical syntactic pattern is illustrated in (c).

- (3) 据 陆仁法 介绍 , [4]  
According to Lu Renfa presentation ,  
全国 税收 任务已  
the whole country revenue goal already  
超额 完成 , [5] 总体  
exceeding quota complete , overall  
情况 比较 好 。  
situation fairly good .

“According to Lu Renfa, the national revenue goal is met and exceeded, and the overall situation is fairly good.”

**VP Coordination (VP\_COORD):** Coordinated VPs, when separated by the comma, are not semantically different from coordinated IPs. The only difference is that in the latter case, the coordinated VPs

share a subject, while coordinated IPs tend to have different subjects. Maintaining this distinction allow us to model subject (dis)continuity, which helps recover a subject when it is dropped, a prevalent phenomenon in Chinese. As shown in (4), the VPs in the text spans separated by Comma [6] have the same subject, thus the subject in the second VP is dropped. The syntactic pattern that allows us to extract this structure is given in (d).

- (4) 中国 银行 是四大 国有  
 China Bank is four major state-owned  
 商业 银行之一 , [6] 也 是  
 commercial bank one of these , also is  
 中国 的 主要 外汇 银行 。  
 China DE major foreign exchange bank .

“Bank of China is one of the four major state-owned commercial banks, and it is also China’s major foreign exchange bank.”

**Adjunction (ADJ):** Adjunction is one of three types of subordination relations we define. It holds between a subordinate clause and its main clause. The subordinate clause is normally introduced by a subordinating conjunction and it typically provides the cause, purpose, manner, or condition for the main clause. In the PDT terms, these subordinate conjunctions are discourse connectives that anchor a discourse relation between the subordinate clause and the main clause. In Chinese, with few exceptions, the subordinate clause comes before the main clause. (5) is an example of this relation.

- (5) 若工程 发生 保险 责任 范围  
 if project happen insurance liability scope  
 内 的 自然 灾害 , [7]  
 inside DE natural disaster ,  
 中保 财产 保险 公司  
 China Insurance property insurance company

将 按 规定 进行  
 will according to provision execute  
 赔偿 。  
 compensation .

“If natural disasters within the scope of the insurance liability happen in the project, PICC Property Insurance Company will provide compensations according to the provisions.”

(e) shows how (5) is represented in the syntactic structure in the CTB. Extracting this relation requires more than just the syntactic configuration between these two clauses. We also take advantage of the functional (dash) tags provided in the treebank. The functional tags are attached to the subordinate clause and they include CND (conditional), PRP (purpose or reason), MNR (manner), or ADV (other types of subordinate clauses that are adjuncts to the main clause).

**Complementation (COMP):** When a comma separates a verb governor and its complement clause, this verb and its subject generally describe the attribution of the complement clause. Attribution is an important notion in discourse analysis in both the RST framework and in the PDT. An example of this is given in (6), and the syntactic pattern used to extract this relation is illustrated in (f).

- (6) 该 公司 介绍 , [8] 在 未来 的  
 The company present , at future DE  
 五 年 内 他们 将 追加 投资  
 five year within they will additionally invest  
 九 千 万 美 元 , [9] 预 计  
 ninety million U.S. dollars , estimate  
 年 产 值 可 达  
 annual output will reach  
 三 亿 美 元 。  
 three hundred million U.S. dollars .

“According to the the company’s presentation, they will invest an additional ninety million

U.S. dollars in the next five years, and the estimated annual output will reach \$ 300 million.”

**Sentential Subject (SBJ):** This category is for commas that separate a sentential subject from its predicate VP. An example is given in (7) and the syntactic pattern used to extract this relation is illustrated in (g).

(7) 出口 快速 增长 , [10] 成为 推动  
 export rapid grow , become promote  
 经济 增长 的 重要 力量 。  
 economy growth DE important force .

“The rapid growth of export becomes an important force in promoting economic growth.”

**Others (OTHER):** The remaining cases of comma receive the OTHER label, indicating they do not mark the boundary of a discourse segment.

Our proposed comma classification scheme serves the dual purpose of identifying elementary discourse units and at the same time detecting coarse-grained discourse relations anchored by the comma. The discourse relations identified in this manner by no means constitute the full discourse analysis of a text, they are, however, a good first approximation. The advantage of our approach is that we do not require manual discourse annotations, and all the information we need is automatically extracted from the syntactic annotation of the CTB and attached to instances of the comma in the corpus. This makes it possible for us to train supervised models to automatically classify the commas in any Chinese text.

### 3 Two comma classification methods

Given the gold standard parses, based on the syntactic patterns described in Section 2, we can map the POS tag of each comma instance in the CTB to one of the seven classes described in Section 2. Using this relabeled data as training data, we experimented with two automatic comma disambiguation methods. In the first method, we simply retrained the Berkeley parser (Petrov and Klein, 2007) on the relabeled data and computed how accurately the commas are labeled in a held-out test set. In the second method, we trained a Maximum Entropy classifier with the Mallet (McCallum et al., 2002) machine learning package to classify the commas. The features are extracted from the CTB data automatically parsed with the Berkeley parser. We implemented features described in (Xue and Yang, 2011), and also experimented with a set of new features as follows. In general, these new features are extracted from the two text spans surrounding the comma. Given a comma, we define the preceding text span as  $i$  span and the following text span as  $j$  span. We also collected a number of subject-predicate pairs from a large corpus that doesn't overlap with the CTB. We refer to this corpus as the auxiliary corpus.

**Subject and Predicate features:** We explored various combinations of the subject ( $sbj$ ), predicate ( $pred$ ) and object ( $obj$ ) of the two spans. The subject of  $i$  span is represented as  $sbj_i$ , etc.

1. The existence of  $sbj_i$ ,  $sbj_j$ , both, or neither.
2. The lemma of  $pred_i$ , the lemma of  $pred_j$ , the conjunction of  $sbj_i$  and  $pred_j$ , the conjunction of  $pred_i$  and  $sbj_j$
3. whether the conjunction of  $sbj_i$  and  $pred_j$  occurs more than 2 times in the auxiliary corpus when  $j$  does not have a subject.
4. whether the conjunction of  $obj_i$  and  $pred_j$  occurs more than 2 times in the auxiliary corpus when  $j$  does not have a subject
5. Whether the conjunction of  $pred_i$  and  $sbj_j$  occurs more than 2 times in the auxiliary corpus when  $i$  does not have a subject.

**Mutual Information features:** Mutual information is intended to capture the association strength between the subject of a previous span and the predicate of the current span. We use Mutual Information

(Church and Hanks, 1989) as shown in Equation (1) and the frequency count computed based on the auxiliary corpus to measure such constraints.

$$MI = \log_2 \frac{\# \text{ co-occur of S and P * corpus size}}{\# \text{ S occur} * \# \text{ P occur}} \quad (1)$$

1. The conjunction of  $sbj_i$  and  $pred_j$  when  $j$  does not have a subject if their  $MI$  value is greater than -8.0, an empirically established threshold.
2. Whether  $obj_i$  and  $pred_j$  has an MI value greater than 5.0 if  $j$  does not have a subject.
3. Whether the MI value of  $sbj_i$  and  $pred_j$  is greater than 0.0, and they occur 2 times in the auxiliary corpus when  $j$  doesn't have a subject.
4. Whether the MI value of  $obj_i$  and  $pred_j$  is greater than 0.0 and they occur 2 times in the auxiliary corpus when  $j$  doesn't have a subject.
5. Whether the MI value of  $pred_i$  and  $sbj_j$  is greater than 0.0 and they occur more than 2 times in the auxiliary corpus when  $i$  does not have a subject.

**Span features:** We used span features to capture syntactic information, e.g. the comma separated spans are constituents in Tree (b) but not in Tree (d).

1. Whether  $i$  forms a single constituent, whether  $j$  forms a single constituent.
2. The conjunction and hierarchical relation of all constituent labels in  $i/j$ , if  $i/j$  does not form a single constituent. The conjunction of all constituent labels in both spans, if neither span form a single constituent.

**Lexical features:**

1. The first word in  $i$  if it is an adverb, the first word in  $j$  if it is an adverb.
2. The first word in  $i$  span if it is a coordinating conjunction, the first word in  $j$  if it is a coordinating conjunction.

## 4 Experiments

### 4.1 Datasets

We use the CTB 6.0 in our experiments and divide it into training, development and test sets using the data split recommended in the CTB 6.0 documentation, as shown in Table 1. There are 5436 commas

in the test set, including 1327 commas that are sentence boundaries (SB), 539 commas that connect coordinated IPs (IP\_COORD), 1173 commas that join coordinated VPs (VP\_COORD), 379 commas that delimit a subordinate clause and its main clause (ADJ), 314 commas that anchor complementation relations (COMP), and 1625 commas that belong to the OTHER category.

### 4.2 Results

As mentioned in Section 3, we experimented with two comma classification methods. In the first method, we replace the part-of-speech (POS) tags of the commas with the seven classes defined in Section 2. We then retrain the Berkeley parser (Petrov and Klein, 2007) using the training set as presented in Table 1, parse the test set, and evaluate the comma classification accuracy.

In the second method, we use the relabeled commas as the gold-standard data to train a supervised classifier to automatically classify the commas. As shown in the previous section, syntactic structures are an important source of information for our classifier. For feature extraction purposes, the entire CTB6.0 is automatically parsed in a round-robin fashion. We divided CTB 6.0 into 10 portions, and parsed each portion with a model trained on other portions, using the Berkeley parser (Petrov and Klein, 2007). Measured by the ParsEval metric (Black et al., 1991), the parsing accuracy on the CTB test set stands at 83.29% (F-score), with a precision of 85.18% and a recall of 81.49%.

The results are presented in Table 2, which shows the overall accuracy of the two methods as well as the results for each individual category. As should be clear from Table 2, the results for the two methods are very comparable, with the second method performing modestly better than the first method.

#### 4.2.1 Subject continuity

One of the goals for this classification scheme is to model subject continuity, which answers the question of how accurately we can predict whether two comma-separated text spans have the same subject or different subjects. When the two spans share the same subject, the comma belongs to the category VP\_COORD. When they have different subjects, they belong to the categories IP\_COORD or

Data	Train	Dev	Test
CTB-6.0	81-325, 400-454, 500-554	41-80	(1-40,901-931 newswire)
	590-596, 600-885, 900	1120-1129	(1018, 1020, 1036, 1044
	1001-1017, 1019, 1021-1035	2140-2159	1060-1061,
	1037-1043, 1045-1059,1062-1071	2280-2294	1072, 1118-1119, 1132
	1073-1078, 1100-1117, 1130-1131	2550-2569	1141-1142, 1148 magazine)
	1133-1140, 1143-1147, 1149-1151	2775-2799	(2165-2180, 2295-2310
	2000-2139, 2160-2164, 2181-2279	3080-3109	2570-2602, 2800-2819
	2311-2549, 2603-2774, 2820-3079		3110-3145 broadcast news)

Table 1: CTB 6.0 data set division.

SB. When this question is meaningless, e.g., when one of the span does not even have a subject, the comma belongs to other categories. To evaluate the performance of our model on this problem, we re-computed the results by putting IP\_COORD and SB in one category, putting VP\_COORD in another category and the rest of the labels in a third category. The results are presented in Table 3.

#### 4.2.2 The effect of genre

CTB 6.0 consists of data from three different genres, including newswire, magazine and broadcast news. Data genres may have very different characteristics. To evaluate how our model works on different genres, we train a model using training and development sets, and test the model on different genres as described in Table 1. The results on these three genres are presented in Table 4, and they shows a significant fluctuation across genres. Our model works the best on newswire, but not as good on broadcast news and magazine articles.

#### 4.2.3 Comparison with prior work

(Xue and Yang, 2011) presented results on a binary classification of whether or not a comma marks a sentence boundary, while the present work addresses a multi-category classification problem aimed at identifying discourse segments and preliminary discourse relations anchored by the comma. However, since we also have a SB category, comparison is possible. For comparison purposes, we retrained our model on their data sets, and computed the results of SB vs other categories. The results are shown in Table 5. Our results are very comparable with (Xue and Yang, 2011) despite that we are performing a multicategory classification.

#### 4.3 Error analysis

Even though our feature-based approach can theoretically “correct” parsing errors, meaning that a comma can in theory be classified correctly even if a sentence is incorrectly parsed, when examining the system output, errors in automatic parses often lead to errors in comma classification. A common parsing error is the confusion between Structures (h) and (i). If the subject of the text span after a comma is dropped as shown in (h), the parser often produces a VP coordination structure as shown in (i) and vice versa. This kind of parsing errors would lead to errors in our syntactic features and thus directly affect the accuracy of our model.

### 5 Related Work

There is a large body of work on discourse analysis in the field of Natural Language Processing. Most of the work, however, are on English. An unsupervised approach was proposed to recognize discourse relations in (Marcu and Echiabi, 2002), which extracts discourse relations that hold between arbitrary spans of text making use of cue phrases. Like the present work, a lot of research on discourse analysis is carried out at the sentence level. (Soricut and Marcu, 2003; Sporleder and Lapata, 2005; Polanyi et al., 2004). (Soricut and Marcu, 2003) and (Polanyi et al., 2004) implement models to perform discourse parsing, while (Sporleder and Lapata, 2005) introduces discourse chunking as an alternative to full-

scale discourse parsing.

The emergence of linguistic corpora annotated with discourse structure such as the RST Discourse Treebank (Carlson et al., 2002) and PDT (Miltsakaki et al., 2004; Prasad et al., 2008) have changed the landscape of discourse analysis. More robust, data-driven models are starting to emerge.

Compared with English, much less work has been done in Chinese discourse analysis, presumably due to the lack of discourse resources in Chinese. (Huang and Chen, 2011) constructs a small corpus following the PDT annotation scheme and

trains a statistical classifier to recognize discourse relations. Their work, however, is only concerned with discourse relations between adjacent sentences, thus side-stepping the hard problem of disambiguating the Chinese comma and analyzing intra-sentence discourse relations. To the best of our knowledge, our work is the first in attempting to disambiguating the Chinese comma as the first step in performing Chinese discourse analysis.

## 6 Conclusions and future work

We proposed a approach to disambiguate the Chinese comma as a first step toward discourse analysis. Training and testing data are automatically derived from a syntactically annotated corpus. We presented two automatic comma disambiguation methods that perform comparably. In the first method, comma disambiguation is integrated into the parsing process while in the second method we train a supervised classifier to classify the Chinese comma, using features extracted from automatic parses. Much needs to be done in the area, but we believe our work provides insight into the intricacy and complexity of discourse analysis in Chinese.

## Abstract

Previous work on classifying information status (Nissim, 2006; Rahman and Ng, 2011) is restricted to coarse-grained classification and focuses on conversational dialogue. We here introduce the task of classifying fine-grained information status and work on written text. We add a fine-grained information status layer to the Wall Street Journal portion of the OntoNotes corpus. We claim that the information status of a mention depends not only on the mention itself but also on other mentions in the vicinity and solve the task by collectively classifying the information status of all mentions. Our approach strongly outperforms reimplementations of previous work.

## 1 Introduction

Speakers present already known and yet to be established information according to principles referred to as *information structure* (Prince, 1981; Lambrecht, 1994; Kruijff-Korbayová and Steedman, 2003, inter alia). While information structure affects all kinds of constituents in a sentence, we here adopt the more restricted notion of *information status* which concerns only discourse entities realized as noun phrases, i.e. *mentions*<sup>1</sup>. Information status (*IS* henceforth) describes the degree to which a discourse entity is available to the hearer with regard to the speaker’s assumptions about the hearer’s knowledge and beliefs (Nissim et al., 2004). Old mentions are known to the hearer and have been referred

<sup>1</sup>Since not all noun phrases are referential, we call noun phrases which carry information status *mentions*.

to previously. Mediated mentions have not been mentioned before but are also not autonomous, i.e., they can only be correctly interpreted by reference to another mention or to prior world knowledge. All other mentions are *new*.

IS can be beneficial for a number of NLP tasks, though the results have been mixed. Nenkova et al. (2007) used IS as a feature for generating pitch accent in conversational speech. As IS is restricted to noun phrases, while pitch accent can be assigned to any word in an utterance, the experiments were not conclusive. For determining constituent order of German sentences, Cahill and Riester (2009) incorporate features modeling IS to good effect. Rahman and Ng (2011) showed that IS is a useful feature for coreference resolution.

Previous work on learning IS (Nissim, 2006; Rahman and Ng, 2011) is restricted in several ways. It deals with conversational dialogue, in particular with the corpus annotated by Nissim et al. (2004). However, many applications that can profit from IS concentrate on written texts, such as summarization. For example, Siddharthan et al. (2011) show that solving the IS subproblem of whether a person proper name is already known to the reader improves automatic summarization of news. Therefore, we here model IS in written text, creating a new dataset which adds an IS layer to the already existing comprehensive annotation in the OntoNotes corpus (Weischedel et al., 2011). We also report the first results on fine-grained IS classification by modelling further distinctions within the category of mediated mentions, such as comparative and bridging anaphora (see Examples 1 and 2, re-

spectively).<sup>2</sup> Fine-grained IS is a prerequisite to full bridging/comparative anaphora resolution, and therefore necessary to fill gaps in entity grids (Barzilay and Lapata, 2008) based on coreference only. Thus, Examples 1 and 2 do not exhibit any coreferential entity coherence but coherence can be established when the comparative anaphor *others* is resolved to *others than freeway survivor Buck Helm*, and the bridging anaphor *the streets* is resolved to *the streets of Oranjemund*, respectively.

- (1) the condition of *freeway survivor Buck Helm* . . . , improved, hospital officials said. Rescue crews, however, gave up hope that **others** would be found.
- (2) *Oranjemund, the mine headquarters*, is a lonely corporate oasis of 9,000 residents. Jackals roam **the streets** at night . . .

We approach the challenge of modeling IS via collective classification, using several novel linguistically motivated features. We reimplement Nissim’s (2006) and Rahman and Ng’s (2011) approaches as baselines and show that our approach outperforms these by a large margin for both coarse- and fine-grained IS classification.

## 2 Related Work

**IS annotation schemes and corpora.** We enhance the approach in Nissim et al. (2004) in two major ways (see also Section 3.1). First, comparative anaphora are not specifically handled in Nissim et al. (2004) (and follow-on work such as Ritz et al. (2008) and Riester et al. (2010)), although some of them might be included in their respective *bridging* subcategories. Second, we apply the annotation scheme reliably to a new genre, namely news. This is a non-trivial extension: Ritz et al. (2008) applied a variation of the Nissim et al. (2004) scheme to a small set of 220 NPs in a German news/commentary corpus but found that reliability then dropped significantly to the range of  $\kappa = 0.55$  to 0.60. They attributed this to the higher syntactic complexity and semantic vagueness in the commentary corpus. Riester et al. (2010) annotated a

<sup>2</sup>All examples in this paper are from the OntoNotes corpus. The mention in question is typed in boldface; antecedents, where applicable, are displayed in italics.

German news corpus marginally reliable ( $\kappa = 0.66$ ) for their overall scheme but their confusion matrix shows even lower reliability for several subcategories, most importantly deixis and bridging.

While standard coreference corpora do not contain IS annotation, some corpora annotated for bridging are emerging (Poesio, 2004; Korzen and Buch-Kromann, 2011) but they are (i) not annotated for comparative anaphora or other IS categories, (ii) often not tested for reliability or reach only low reliability, (iii) often very small (Poesio, 2004).

To the best of our knowledge, we therefore present the first English corpus reliably annotated for a wide range of IS categories as well as full anaphoric information for three main anaphora types (coreference, bridging, comparative).

**Automatic recognition of IS.** Vieira and Poesio (2000) describe heuristics for processing definite descriptions in news text. As their approach is restricted to definites, they only analyse a subset of the mentions we consider carrying IS. Siddharthan et al. (2011) also concentrate on a subproblem of IS only, namely the hearer-old/hearer-new distinctions for person proper names.

Nissim (2006) and Rahman and Ng (2011) both present algorithms for IS detection on Nissim et al.’s (2004) Switchboard corpus. Both papers treat IS classification as a local classification problem whereas we look at dependencies between the IS status of different mentions, leading to collective classification. In addition, they only distinguish the three main categories *old*, *mediated* and *new*. Finally, we work on news corpora which poses different problems from dialogue.

Anaphoricity determination (Ng, 2009; Zhou and Kong, 2009) identifies many or most *old* mentions. However, no distinction between *mediated* and *new* mentions is made. Most approaches to bridging resolution (Meyer and Dale, 2002; Poesio et al., 2004) or comparative anaphora (Modjeska et al., 2003; Markert and Nissim, 2005) address only the selection of the antecedent for the bridging/comparative anaphor, not its recognition. Sasano and Kurohashi (2009) do also tackle bridging recognition, but they depend on language-specific non-transferrable features for Japanese.

### 3 Corpus Creation

#### 3.1 Annotation Scheme

Our scheme follows Nissim et al. (2004) in distinguishing three major IS categories *old*, *new* and *mediated*. A mention is *old* if it is either coreferential with an already introduced entity or a generic or deictic pronoun. We follow the OntoNotes (Weischedel et al., 2011) definition of coreference to be able to integrate our annotations with it. This definition includes coreference with noun phrase as well as verb phrase antecedents<sup>3</sup>.

*Mediated* refers to entities which have not yet been introduced in the text but are inferrable via other mentions or are known via world knowledge. We distinguish the following six subcategories: The category *mediated/comparative* comprises mentions compared via either a contrast or similarity to another one (see Example 1). This category is novel in our scheme. We also include a category *mediated/bridging* (see Examples 2, 3 and 4). Bridging anaphora can be any noun phrase and are not limited to definite NPs as in Poesio et al. (2004), Gardent and Manuélian (2005), Riester et al. (2010). In contrast to Nissim et al. (2004), antecedents for both comparative and bridging categories are annotated and can be noun phrases, verb phrases or even clauses. The category *mediated/knowledge* is inspired by the hearer-old distinction introduced by Prince (1992) and covers entities generally known to the hearer. It includes many proper names, such as *Poland*.<sup>4</sup> Mentions that are syntactically linked via a possessive relation or a PP modification to other, *old* or *mediated* mentions fall into the type *mediated/synt* (see Examples 5 and 6).<sup>5</sup> With no change to Nissim et al.'s scheme, coordinated mentions where at least one element in the conjunction is *old* or *mediated* are covered by the category *mediated/aggregate*, and mentions referring to a value of a previously mentioned function by the type *mediated/func*.

All other mentions are annotated as *new*, includ-

<sup>3</sup>In contrast to Nissim et al. (2004), but in accordance with OntoNotes, we do not consider generics for coreference.

<sup>4</sup>This class corresponds roughly to Nissim et al.'s (2004) *mediated/general*.

<sup>5</sup>This class expands Nissim et al.'s (2004) *poss* category that only considers possessives but not PP modification.

ing most generics as well as newly introduced, specific mentions such as Example 7.

- (3) Initial steps were taken at *Poland's first environmental conference, which I attended last month*. ... it was no accident that **participants** urged the free flow of information
- (4) The Bakersfield supermarket *went out of business* last May. **The reason** was ...
- (5) One Washington couple sold *their liquor store*
- (6) *the main artery into San Francisco*
- (7) the owner was murdered by *robbers*

#### 3.2 Agreement Study

We carried out an agreement study with 3 annotators, of which Annotator A was the scheme developer and first author of this paper. All texts used were from the Wall Street Journal (WSJ) portion of OntoNotes. There were no restrictions on which texts to include apart from (i) exclusion of letters to the editor as they contain cross-document links and (ii) a preference for longer texts with potentially richer discourse structure.

Mentions were automatically preselected for the annotators using the gold-standard syntactic annotation.<sup>6</sup> The existing coreference annotation was automatically carried over to the IS task by marking all mentions in a coreference chain (apart from the first mention in the chain) as *old*. The annotation task consisted of marking all mentions for their IS (*old*, *mediated* or *new*) as well as marking *mediated* subcategories (see Section 3.1) and the antecedents for comparative and bridging anaphora.

The scheme was developed on 9 texts, which were also used for training the annotators. Inter-annotator agreement was measured on 26 new texts, which included 5905 pre-marked potential mentions. The annotations of 1499 of these were carried over from OntoNotes, leaving 4406 potential mentions for annotation and agreement measurement. In addition to

<sup>6</sup>Some non-mentions such as idioms could not be filtered out via the syntactic annotation and had to be excluded during human annotation.

	A-B	A-C	B-C
Overall Percentage coarse	87.5	86.3	86.5
Overall $\kappa$ coarse	77.3	75.2	74.7
Overall Percentage fine	86.6	85.3	85.7
Overall $\kappa$ fine	80.1	77.7	77.3

Table 1: Agreement Results

	A-B	A-C	B-C
$\kappa$ Non-mention	81.5	78.9	86.0
$\kappa$ Old	80.5	83.2	79.3
$\kappa$ New	76.6	74.0	74.3
$\kappa$ Mediated/Knowledge	82.1	78.4	74.1
$\kappa$ Mediated/Synt	88.4	87.8	87.6
$\kappa$ Mediated/Aggregate	87.0	85.4	86.0
$\kappa$ Mediated/Func	6.0	83.2	6.9
$\kappa$ Mediated/Comp	81.8	78.3	81.2
$\kappa$ Mediated/Bridging	70.8	60.6	62.3

Table 2: Agreement Results for individual categories

percentage agreement, we measured Cohen’s  $\kappa$  (Artstein and Poesio, 2008) between all 3 possible annotator pairings. We also report single-category agreement for each category, where all categories but one are merged and then  $\kappa$  is computed as usual. Table 1 shows agreement results for the overall scheme at the coarse-grained (4 categories: *non-mention*, *old*, *new*, *mediated*) and the fine-grained level (9 categories: *non-mention*, *old*, *new* and the 6 *mediated* subtypes). The results show that the scheme is overall reliable, with not too many differences between the different annotator pairings.<sup>7</sup>

Table 2 shows the individual category agreement for all 9 categories. We achieve high reliability for most categories.<sup>8</sup> Particularly interesting is the fact that hearer-old entities (*mediated/knowledge*) can be identified reliably although all annotators had substantially different backgrounds. The reliability of the category *bridging* is more annotator-dependent, although still higher, sometimes considerably, than other previous attempts at bridg-

<sup>7</sup>Often, annotation is considered highly reliable when  $\kappa$  exceeds 0.80 and marginally reliable when between 0.67 and 0.80 (Carletta, 1996). However, the interpretation of  $\kappa$  is still under discussion (Artstein and Poesio, 2008).

<sup>8</sup>The low reliability of the rare category *func*, when involving Annotator B, was explained by Annotator B forgetting about this category after having used it once. Pair A-C achieved high reliability ( $\kappa$  83.2 for pair A-C).

ing annotation (Poesio et al., 2004; Gardent and Manuélian, 2005; Riestler et al., 2010).

### 3.3 Gold Standard

Our final gold standard corpus consists of 50 texts from the WSJ portion of the OntoNotes corpus. The corpus will be made publically available as OntoNotes annotation layer via <http://www.h-its.org/nlp/download>.

Disagreements in the 35 texts used for annotator training (9 texts) and testing (26 texts) were resolved via discussion between the annotators. An additional 15 texts were annotated by Annotator A. Finally, Annotator A carried out consistency checks over all texts. – The gold standard includes 10,980 true mentions (see Table 3).

Texts	50
Mentions	10,980
old	3237

generic_deictic_pr	94
mediated	3,708
world knowledge	924
syntactic	1,592
aggregate	211
func	65
comparative	253
bridging	663
new	4,035

Table 3: Gold Standard Distribution

## 4 Features

In this Section, we describe both the local as well as the relational features we use.

### 4.1 Features for Local Classification

We use the following local features, including the features in Nissim (2006) and Rahman and Ng (2011) to be able to gauge how their systems fare on our corpus and as a comparison point for our novel collective classification approach.

The features developed by Nissim (2006) are shown in Table 4. Nissim shows clearly that these features are useful for IS classification. Thus, subjects are more likely to be *old* as assumed by, e.g., centering theory (Grosz et al.,

Feature	Value
full prev mention	{yes, no, NA} <sup>9</sup>
mention time	{first, second, more}
partial prev mention	{yes, no, NA}
determiner	{bare, def, dem, indef, poss, NA}
NP type	{pronoun, common, proper, other}
NP length	numeric
grammatical role	{subject, subjpass, pp, other}

Table 4: Nissim’s (2006) feature set

1995). Also, previously unmentioned proper names are more likely to be hearer-old and therefore mediated/knowledge, although their exact status will depend on how well known a particular proper name is.

Rahman and Ng (2011) add all *unigrams* appearing in any mention in the training set as features. They also integrated (via a convolution tree-kernel SVM (Collins and Duffy, 2001)) partial parse trees that capture the generalised syntactic context of a mention  $e$  and include the mention’s parent and sibling nodes without lexical leaves. However, they use no structure underneath the mention node  $e$  itself, assuming that “any NP-internal information has presumably been captured by the flat features”.

To these feature sets, we add a small set of other local features *otherlocal*. These track partial previous mentions by also counting partial previous mention time as well as the previous mention of content words only. We also add a mention’s number as one of singular, plural or unknown, and whether the mention is modified by an adjective. Another feature encapsulates whether the mention is modified by a comparative marker, using a small set of 10 markers such as *another*, *such*, *similar* ... and the presence of adjectives or adverbs in the comparative. Finally, we include the mention’s semantic class as one of 12 coarse-grained classes, including location, organisation, person and several classes for numbers (such as date, money or percent).

## 4.2 Relations for Collective Classification

Both Nissim (2006) and Rahman and Ng (2011) classify each mention individually in a standard supervised ML setting, not considering potential dependencies between the IS categories of different

<sup>9</sup>We changed the value of “full prev mention” from “numeric” to {yes, no, NA}.

mentions. However, collective or joint classification has made substantial impact in other NLP tasks, such as opinion mining (Pang and Lee, 2004; Somasundaran et al., 2009), text categorization (Yang et al., 2002; Taskar et al., 2002) and the related task of coreference resolution (Denis and Baldridge, 2007). We investigate two types of relations between mentions that might impact on IS classification.

**Syntactic parent-child relations.** Two mediated subcategories account for accessibility via syntactic links to another old or mediated mention: *mediated/synt* is used when at least one child of a mention is *mediated* or *old*, with child relations restricted to pre- or postnominal possessives as well as PP children in our scheme (see Section 3.1). *mediated/aggregate* is for coordinations in which at least one of the children is *old* or *mediated*. In these two cases, a mention’s IS depends directly on the IS of its children. We therefore link a mention  $m_1$  to a mention  $m_2$  via a *hasChild* relation if (i)  $m_2$  is a possessive or prepositional modification of  $m_1$ , or (ii)  $m_1$  is a coordination and  $m_2$  is one of its children.

Using such a relational feature catches two birds with one stone: firstly, it integrates the internal structure of a mention into the algorithm, which Rahman and Ng (2011) ignore; secondly, it captures dependencies between parent and child classification, which would not be possible if we integrated the internal structure via flat features or additional tree kernels. We hypothesise that the higher syntactic complexity of our news genre (14.5% of all mentions are *mediated/synt*) will make this feature highly effective in distinguishing between *new* and *mediated* categories.

**Syntactic precedence relations.** IS is said to influence word order (Birner and Ward, 1998; Cahill and Riester, 2009) and this fact has been exploited in work on generation (Prevost, 1996; Filippova and Strube, 2007; Cahill and Riester, 2009). Therefore, we integrate dependencies between the IS classification of mentions in precedence relations.

$m_1$  precedes  $m_2$  if (i)  $m_1$  and  $m_2$  are in the same clause, allowing for trace subjects in gerund and infinitive constructions, (ii)  $m_1$  and  $m_2$  are dependent on the same verb or noun, allowing for intervening nodes via modal, auxiliary, gerund and infinitive

constructions, (iii)  $m_1$  is neither a child nor a parent of  $m_2$ , and (iv)  $m_1$  occurs before  $m_2$ .

For Example 8 (slightly simplified) we extract the precedence relations shown in Table 5.

- (8) She was sent by her mother to a white woman’s house to do chores in exchange for meals and a place to sleep.

(She)<sub>old</sub> ><sub>p</sub> (her mother)<sub>med/synt</sub>  
 (She)<sub>old</sub> ><sub>p</sub> (a white-woman’s house)<sub>new</sub>  
 (She)<sub>old</sub> ><sub>p</sub> (chores)<sub>new</sub>  
 (She)<sub>old</sub> ><sub>p</sub> (exchange .....sleep)<sub>new</sub>  
 (her mother)<sub>med/synt</sub> ><sub>p</sub> (a white woman’s house)<sub>new</sub>  
 (chores)<sub>new</sub> ><sub>p</sub> (exchange ... sleep)<sub>new</sub>  
 (meals)<sub>new</sub> ><sub>p</sub> (a place to sleep)<sub>new</sub>

Table 5: Precedence Relations for Example 8. *She* is a trace subject for *do*.

Proper names behave differently from common nouns. For example, they can occur at many different places in the clause when functioning as spatial or temporal scene-setting elements, such as *In New York*. We therefore exclude all precedence relations where one element of the pair is a proper name.

We extract 2855 precedence relations. Table 6 shows the statistics on precedence with the first mention in a pair in rows and the second in columns. Mediated and new mentions indeed rarely precede old mentions, so that precedence should improve separating of `old` vs other mentions.

	old	mediated	new
old	136	387	519
mediated	88	357	379
new	85	291	613

Table 6: Precedence relations in our corpus

## 5 Experiments

### 5.1 Experimental Setup

We use our gold standard corpus (see Section 3.3) via 10-fold cross-validation on documents for all experiments. Following Nissim (2006) and Rahman and Ng (2011), we perform all experiments on gold standard mentions and use the human WSJ syntactic annotation for feature extraction, when necessary. For the extraction of semantic class, we use

OntoNotes entity type annotation for proper names and an automatic assignment of semantic class via WordNet hypernyms for common nouns.

Coarse-grained versions of all algorithms distinguish only between the three `old`, `mediated`, `new` categories. Fine-grained versions distinguish between the categories `old`, the six `mediated` subtypes, and `new`. We report overall accuracy as well as precision, recall and F-measure per category. Significance tests are conducted using McNemar’s test on overall algorithm accuracy, at the level of 1%.

### 5.2 Local Classifiers

We reimplemented the algorithms in Nissim (2006) and Rahman and Ng (2011) as comparison baselines, using their feature and algorithm choices. Algorithm *Nissim* is therefore a decision tree J48 with standard settings in WEKA with the features in Table 4. Algorithm *RahmanNg* is an SVM with a composite kernel and one-vs-all training/testing (toolkit SVMLight). They use the features in Table 4 plus unigram and tree kernel features, described in Section 4.1. We add our additional set of *otherlocal* features to both baseline algorithms (yielding *Nissim+ol* and *RahmanNg+ol*) as they aim specifically at improving fine-grained classification.

### 5.3 Collective Classification

For incorporating our inter-mention links, we use a variant of Iterative Collective classification (ICA), which has shown good performance over a variety of tasks (Lu and Getoor, 2003) and has been used in NLP for example for opinion mining (Somasundaran et al., 2009). ICA is normally faster than Gibbs sampling and — in initial experiments — did not yield significantly different results from it.

ICA initializes each mention with its most likely IS, according to the local classifier and features. It then iterates a relational classifier, which uses both local and relational features (our *hasChild* and *precedes* features) taking IS assignments to neighbouring mentions into account. We use the *exist* aggregator to define the dependence between mentions.

We use NetKit (Macskassy and Provost, 2007) with its standard ICA settings for collective inference, as it allows direct comparison between local and collective classification. The relational classifiers are always exactly the same classifiers as the

Table 7: Collective classification compared to Nissim’s local classifier. Best performing algorithms are bolded.

local ones with the relational features added: thus, if the local classifier is a tree kernel SVM so is the relational one. One problem when using the SVM Tree kernel as relational classifier is that it allows only for binary classification so that we need to train several binary networks in a one-vs-all paradigm (see also (Rahman and Ng, 2011)), which will not be able to use the multiclass dependencies of the relational features to optimum effect.

#### 5.4 Results

Table 7 shows the comparison of collective classification to local classification, using Nissim’s framework and features, and Table 8 the equivalent table for Rahman and Ng’s approach.

The improvements using the additional local features over the original local classifiers are statistically significant in all cases. In particular, the inclusion of semantic classes improves mediated/knowledge and mediated/func, and comparative anaphora are recognised highly reliably via a small set of comparative markers.

The *hasChild* relation leads to significant improvement in accuracy over local classification in all cases, showing the value of collective classification. The improvement here is centered on the categories of mediated/synt (for both cases) and mediated/aggregate (for *Nissim+ol+hasChild*) as well as their distinction from

new.<sup>10</sup> It is also interesting that collective classification with a concise feature set and a simple decision tree as used in *Nissim+ol+hasChild*, performs equally well as *RahmanNg+ol+hasChild*, which uses thousands of unigram and tree features and a more sophisticated local classifier. It also shows more consistent improvements over all fine-grained classes.

The *precedes* relation does not lead to any further improvement. We investigated several variations of the precedence link, such as restricting it to certain grammatical relations, taking into account definiteness or NP type but none of them led to any improvement. We think there are two reasons for this lack of success. First, the precedence of mediated vs. new mentions does not follow a clear order and is therefore not a very predictive feature (see Table 6). At first, this seems to contradict studies such as Cahill and Riester (2009) that find a variety of precedences according to information status. However, many of the clearest precedences they find are more specific variants of the  $\text{old} >_p \text{mediated}$  or  $\text{old} >_p \text{new}$  precedence or they are preferences at an even finer level than the one we annotate, including for example the identification of generics. Second, the clear  $\text{old} >_p \text{mediated}$

<sup>10</sup>For *RahmanNg+ol+hasChild*, the aggregate class suffers from collective classification. We hypothesise that this is an artefact of the one-vs-all training/testing for rare categories.

Table 8: Collective classification compared to Rahman and Ng’s local classifier. Best performing algorithms are bolded.

and  $\text{old} >_p \text{new}$  preferences are partially already captured by the local features, especially the grammatical role, as, for example, subjects are often both old as well as early on in a sentence.

With regard to fine-grained classification, many categories including comparative anaphora, are identified quite reliably, especially in the multiclass classification setting (*Nissim+ol+hasChild*). Bridging seems to be the by far most difficult category to identify with final best F-measures still very low. Most bridging mentions do not have any clear internal structure or external syntactic contexts that signal their presence. Instead, they rely more on lexical and world knowledge for recognition. Unigrams could potentially encapsulate some of this lexical knowledge but — without generalization — are too sparse for a relatively rare category such as bridging (6% of all mentions) to perform well. The difficulty of bridging recognition is an important insight of this paper as it casts doubt on the strategy in previous research to concentrate almost exclusively on antecedent selection (see Section 2).

## 6 Conclusions

We presented a new approach to information status classification in written text, for which we also provide the first reliably annotated English language corpus. Based on linguistic intuition, we define fea-

tures for classifying mentions collectively. We show that our collective classification approach outperforms the state-of-the-art in coarse-grained IS classification by about 10% (Nissim, 2006) and 5% (Rahman and Ng, 2011) accuracy. The gain is almost entirely due to improvements in distinguishing between *new* and *mediated* mentions. For the latter, we also report the – to our knowledge – first fine-grained IS classification results.

Since the work reported in this paper relied – following Nissim (2006) and Rahman and Ng (2011) – on gold standard mentions and syntactic annotations, we plan to perform experiments with predicted mentions as well. We also have to improve the recognition of bridging, ideally combining recognition and antecedent selection for a complete resolution component. In addition, we plan to integrate IS resolution with our coreference resolution system (Cai et al., 2011) to provide us with a more comprehensive discourse processing system.

## Abstract

Large e-commerce enterprises feature millions of items entered daily by a large variety of sellers. While some sellers provide rich, structured descriptions of their items, a vast majority of them provide unstructured natural language descriptions. In the paper we present a 2 steps method for structuring items into descriptive properties. The first step consists in unsupervised property discovery and extraction. The second step involves supervised property synonym discovery using a maximum entropy based clustering algorithm. We evaluate our method on a year worth of e-commerce data and show that it achieves excellent precision with good recall.

## 1 Introduction

Online commerce has gained a lot of popularity over the past decade. Large on-line C2C marketplaces like eBay and Amazon, feature a very large and long-tail inventory with millions of *items* (product offers) entered into the marketplace every day by a large variety of sellers. While some sellers (generally large professional ones) provide rich, structured description of their products (using schemas or via a global trade item number), the vast majority only provide unstructured natural language descriptions.

To manage items effectively and provide the best user experience, it is critical for these marketplaces to structure their inventory into descriptive name-value pairs (called properties) and ensure that items of the same kind (digital cameras for instance) are described using a unique set of property names

(brand, model, zoom, resolution, etc.) and values. For example, this is important for measuring item similarity and complementarity in merchandising, providing faceted navigation and various business intelligence applications. Note that structuring items does not necessarily mean identifying products as not all e-commerce inventory is manufactured (animals for examples).

Structuring inventory in the e-commerce domain raises several challenges. First, one needs to identify and extract the names and the values used by individual sellers from unstructured textual descriptions. Second, different sellers may describe the same product in very different ways, using different terminologies. For example, Figure 1 shows 3 item descriptions of hard drives from 3 different sellers. The left description mentions "rotational speed" in a specification table while the other two descriptions use the synonym "spindle speed" in a bulleted list (top right) or natural language specifications (bottom right). This requires discovering semantically equivalent property names and values across inventories from multiple sellers. Third, the scale at which on-line marketplaces operate makes impractical to solve any of these problems manually. For instance, eBay reported 99 million active users in 2011, many of whom are sellers, which may translate into thousands or even millions of synonyms to discover across more than 20,000 categories ranging from consumer electronics to collectible and art.

This paper describes a two step process for structuring items in the e-commerce domain. The first step consists in an unsupervised property extraction technique which allows discovering name-value

pairs from unstructured item descriptions. The second step consists in identifying semantically equivalent property names amongst these extracted properties. This is accomplished using supervised maximum entropy based clustering. Note that, although value synonym discovery is an equally important task for structuring items, this is still an area of ongoing research and is not addressed in this paper.

The remainder of this paper is structured as follows. We first review related work. We then describe the two steps of our approach: 1) unsupervised property discovery and extraction and 2) property name synonym discovery. Finally, we present experimental results on real large-scale e-commerce data.

## 2 Related Work

This section reviews related work for the two components of our method, namely unsupervised property extraction and supervised property name synonym discovery.

### 2.1 Unsupervised Property Extraction

A lot of progress has been accomplished in the area of property discovery from product reviews since the pioneering work by (Hu and Liu, 2004). Most of this work is based on the observation, later formalized as *double propagation* by (Qiu et al., 2009), that in reviews, opinion words are usually associated with product properties in some ways, and thus product properties can be identified from opinion words and opinion words from properties alternately and iteratively. While (Hu and Liu, 2004) initially used association mining techniques; (Liu et al., 2005) used Part-Of-Speech and supervised rule mining to generate language patterns and identify product properties; (Popescu and Etzioni, 2005) used point wise mutual information between candidate properties and meronymy discriminators; (Zhuang et al., 2006; Qiu et al., 2009) improved on previous work by using dependency parsing; (Kobayashi et al., 2007) mined property-opinion patterns using statistical and contextual cues; (Wang and Wang, 2008) leveraged property-opinion mutual information and linguistic rules to identify infrequent properties; and (Zhang et al., 2010) proposed a ranking scheme to improve double propagation precision. In this paper, we are focusing on extracting properties from

product descriptions which do not contain opinion words.

In a sense, item properties can be viewed as slots of product templates and our work bears similarities with template induction methods. (Chambers and Jurafsky, 2011) proposed a method for inferring event templates based on word clustering according to their proximity in the corpus and syntactic function clustering. Unfortunately, this technique cannot be applied to our problem due to the lack of discourse redundancy within item descriptions.

(Putthividhya and Hu, 2011) and (Sachan et al., 2011) also addressed the problem of structuring items in the e-commerce domain. However, these works assume that property names are known in advance and focus on discovering values for these properties from very short product titles.

Although we are primarily concerned with unsupervised property discovery, it is worth mentioning (Peng and McCallum, 2004) and (Ghani et al., 2006) who approached the problem using supervised machine learning techniques and require labeled data.

### 2.2 Property Name Synonym Discovery

Our work is related to the synonym discovery research which aims at identifying groups of words that are semantically identical based on some defined similarity metric. The body of work on this problem can be divided into two major approaches (Agirre et al., 2009): methods that are based on the available knowledge resources (e.g., WordNet, or available taxonomies) (Yang and Powers, 2005; Alvarez and Lim, 2007; Hughes and Ramage, ), and methods that use contextual/property distribution around the words (Pereira et al., 1993; Chen et al., 2006; Sahami and Heilman, 2006; Pantel et al., 2009). (Zhai et al., 2010) propose a constrained semi-supervised learning method using a naive Bayes formulation of EM seeded by a small set of labeled data and a set of soft constraints based on the prior knowledge of the problem. There has been also some recent work on applying topic modeling (e.g., LDA) for solving this problem (Guo et al., 2009).

Our work is also related to the existing research on schema matching problem where the objective is to identify objects that are semantically related cross schemas. There has been an extensive study on the

**Ineo I-NA215U+ 640GB Stylish Design Slim Palm-Size SuperSpeed USB 3.0 External Hard Drive** featuring with latest technology SuperSpeed USB 3.0 interface with **transfer rate up to 5Gbps**, (10 times faster than USB 2.0). Expand your PC/Laptop hard drive capacity instantly! SuperSpeed USB 3.0 era has arrived! Imagine you can store and access your data in 5.0Gbps (10 times faster than USB 2.0) with INeo I-NA215U+ External Hard Drive. 5.0Gbps SuperSpeed performance is perfect for ultra speed data backup or video editing and more applications. Also I-NA215U+ is ultra slim, lightweight, stylish design, "highly glossy white" chassis and also for quiet operation.

**Feature**

- **Build-in Capacity: 640GB**
- **SuperSpeed USB 3.0 Interface**
- 10 times faster than USB 2.0
- Fully backwards compatible with USB 2.0/1.1
- USB bus powered, no power adapter required
- No driver required, plug and play!
- Fan-less with silent operation

**Specifications :**

Data Storage	Formatted Capacity	640GB
Data Transfer Rate	To/From Media	USB 3.0 (5.0Gbps) USB 2.0 (480Mbps)
Buffer		8 MB
Seek Time	Average	11 ms
Rotational Speed		5400 RPM
External Interface		USB 3.0 / USB 2.0
Dimensions		5.4(L) x 3.1(W) x 0.5(H)
Warranty		1 Year Warranty

**General Features:**

- 250 GB formatted capacity
- 7200 RPM spindle speed
- 16 MB buffer
- USB 2.0 interface
- Maxtor SafetyDrill software included
- Back up all your files
- Two levels of data security
- Sync data between 2 or more computers
- Customizable Maxtor OneTouch button
- PC and Mac compatible

**Unit Dimensions:**

- 6.75 x 2.5 x 6-inches (H x W x D)
- 2.5 lbs

**Power Specifications:**

- 100-240 VAC, 1.0A, 50-60 VAC, 50-60 Hz; +12V 2.0A
- 24-watt maximum output power

**Description**

The Seagate 500 GB is a slim and portable external hard drive that solves all your data storage problems. Highly energy efficient, this Seagate 2.5-inch HDD consumes less power. The storage capacity of 500GB in this Seagate external HDD stores all your media large files and applications as well. The Seagate 500 GB provides you with an amazing transfer performance from the spindle speed of 5400rpm. The fast USB 2.0 interface of this Seagate 2.5-inch HDD gives you a speedy and reliable performance.

Figure 1: Three examples of item descriptions containing a specification table (left image), a bulleted list (top right) and natural language specifications (bottom right).

problem of schema matching (for a comprehensive survey see (Rahm and Bernstein, 2001; Bellahsene et al., 2011; Bernstein et al., 2011)). In general the work can be classified into rule-based and learning-based approaches. Rule-based systems (Castano and de Antonellis, 1999; Milo and Zohar, 1998; L. Palopoul and Ursino, 1998) often utilize only the schema information (e.g., elements, domain types of schema elements, and schema structure) to define a similarity metric for performing matching among the schema elements in a hard coded fashion. In contrast learning based approaches learn a similarity metric based on both the schema information and the data. Earlier learning based systems (Li and Clifton, 2000; Perkowitz and Etzioni, 1995; Clifton et al., 1997) often rely on one type of learning (e.g., schema meta-data, statistics of the data content, properties of the objects shared between the schemas, etc). These systems do not exploit the complete textual information in the data content therefore have limited applicability. Most recent systems attempt to incorporate the textual contents of the data sources into the system. Doan et

al. (2001) introduce *LSD* which is a semi-automatic machine learning based matching framework that trains a set of base learners using a set of user provided semantic mappings over a small data sources. Each base learner exploits a different type of information, e.g. source schema information and information in the data source. Given a new data source, the base learners are used to discover semantic mappings and their prediction is combined using a meta-learner. Similar to *LSD*, *GLUE* (Doan et al., 2003) also uses a set of base learners combined into a meta-learner for solving the matching problem between two ontologies. Our work is mostly related to (Wick et al., 2008) where they propose a general framework for performing jointly schema matching, co-reference and canonicalization using a supervised machine learning approach. In this approach the matching problem is treated as a clustering problem in the schema attribute space, where a cluster captures a matched set of attributes. A conditional random field (CRF) (Lafferty et al., 2001) is trained using user provided mappings between example schemas, or ontologies. CRF bene-

fits from first order logic features that capture both schema/ontology information as well as textual features in the related data sources.

### 3 Unsupervised Property Extraction

The first step of our solution to structuring e-commerce inventory aims at discovering and extracting relevant properties from items.

Our method is unsupervised and requires no prior knowledge of relevant properties or any domain knowledge as it operates the exact same way for all items and categories. It maintains a set of previously discovered properties called *known properties* with *popularity* information. The popularity of a given property name  $N$  (resp. value  $V$ ) is defined as the number of sellers who are using  $N$  (resp.  $V$ ). A seller is said to use a name or a value if we are able to extract the property name or value from at least one of its item descriptions. The method is incremental in that it starts with an empty set of known properties, mines individual items independently and incrementally builds and updates the set of known properties.

The key intuition is that the abundance of data in e-commerce allows simple and scalable heuristic to perform very well. For property extraction this translates into the following observation: although we may need complex natural language processing for extracting properties from each and every item, simple patterns can extract most of the relevant properties from a subset of the items due to redundancy between sellers. In other words, popular properties are used by many sellers and some of them write their descriptions in a manner that makes these properties easy to extract. For example one pattern that some sellers use to describe product properties often starts by a property name followed by a colon and then the property value (we refer to this pattern as the *colon pattern*). Using this pattern we can mine colon separated short strings like "size : 20 inches" or "color : light blue" which enables us to discover most relevant property names. However, such a pattern extracts properties from a fraction of the inventory only and does not suffice. We are using 4 patterns which are formally defined in Table 1.

All patterns run on the entire item description. Pattern 1 skips the html markers and scripts and

applies only to the content sentences. It ignores any candidate property which name is longer than 30 characters and values longer than 80 characters. These length thresholds may be domain dependent. They have been chosen empirically. Pattern 2, 3 and 4 search for known property names. Pattern 2 extracts the closest value to the right of the name. It allows the name and the value to be separated by special characters or some html markups (like "<TR>", "<TD>", etc.). It captures a wide range of name value pair occurrences including rows of specification tables.

Syntactic cleaning and validation is performed on all the extracted properties. Cleaning consists mainly in removing bullets from the beginning of names and punctuation at the end of names and values. Validation rejects properties which names are pure numbers, properties that contain some special characters and names which are less than 3 characters long. All discovered properties are added to the set of known properties and their popularity counts are updated.

Note that for efficiency reasons, Part-Of-Speech (POS) tagging is performed only on sentences containing the *anchor* of a pattern. The anchor of pattern 1 is the colon sign while the anchor of the other patterns is the known property name KN. We use (Toutanova et al., 2003) for POS tagging.

### 4 Property Synonym Discovery

In this section we briefly overview a probabilistic pairwise property synonym model inspired by (Culotta et al., 2007).

#### 4.1 Probabilistic Model

Given a category  $\mathcal{C}$ , let  $\mathcal{X}_{\mathcal{C}} = \{x_1, x_2, \dots, x_n\}$  be the raw set of  $n$  property names (prior to synonym discovery) extracted from a corpus of data associated with that category. Every property name is associated with pairs of values and popularity count (as defined in Section 3)  $\mathcal{V}_{x_i} = \{(v_j^i, c^i(v_j^i))\}_{j=1}^m$ , where  $v_j^i$  is the  $j^{th}$  value associated for the property name  $x_i$  and  $c^i(v_j^i)$  is the popularity of value  $v_j^i$ . Given a pair of property names  $x_{ij} = \{x_i, x_j\}$ , let the binary random variable  $y_{ij}$  be 1 if  $x_i$  and  $x_j$  are synonyms. Let  $\mathcal{F} = \{f_k(x_{ij}, y)\}$  be a set of features over  $x_{ij}$ . For example,  $f_k(x_{ij}, y)$  may indicate

#	Pattern	Example
1	[NP] [:] [optional DT] [NP]	"color : light blue"
2	[KN] [optional html] [NP]	"size</TD><TD><FONT COLOR="red">20 inches"
3	[!IN] [KN] ["is" or "are"] [NP]	"color is red"
4	[NP] [KN]	"red color"

Table 1: Patterns used to extract properties from item description. The macro tag NP denotes any of the tags NN, NNP, NNS, NNPS, JJ, JJS or CD. The KN tag is defined as a NP tag over a known property name. Pattern 1 only can discover new names; patterns 2 to 4 aim at capturing values for known property names.

whether  $x_i$  and  $x_j$  have both numerical values. Each feature  $f_k$  has an associated real-valued parameter  $\lambda_k$ . The *pairwise* model is given by:

$$\mathcal{P}(y_{ij}|x_{ij}) = \frac{1}{Z_{x_{ij}}} \exp \sum_k \lambda_k f_k(x_{ij}, y_{ij}) \quad (1)$$

where  $Z_{x_{ij}}$  is a normalizer that sums over the two settings of  $y_{ij}$ . This is a maximum-entropy classifier (i.e. logistic regression) in which  $\mathcal{P}(y_{ij}|x_{ij})$  is the probability that  $x_i$  and  $x_j$  are synonyms. To estimate  $\Lambda = \{\lambda_k\}$  from labeled training data, we perform gradient ascent to maximize the log-likelihood of the labeled data.

Given a data set in which property names are manually clustered, the training data can be created by simply enumerating over each pair of synonym property names  $x_{ij}$ , where  $y_{ij}$  is true if  $x_i$  and  $x_j$  are in the same cluster. More practically, given the raw set of extracted properties, first we manually cluster them. Positive examples are then pairs of property names from the same cluster. Negative examples are pairs of names cross two different clusters randomly selected. For example, let assume that the following four property name clusters have been constructed:  $\{color, shade\}$ ,  $\{size, dimension\}$ ,  $\{weight\}$ ,  $\{features\}$ . These clusters implies that "color" and "shade" are synonym; that "size" and "dimension" are synonym and that "weight" and "features" don't have any synonym. The pair  $(color, shade)$  is a positive examples, while  $(size, shade)$  and  $(weight, features)$  are negative examples.

Now, given an unseen category  $\mathcal{C}'$  and the set of raw properties (property names and values) mined from that category, we can construct an undirected-weighted graph in which vertices correspond to the property names  $\mathcal{N}_{\mathcal{C}'}$  and edge weights are propor-

tional to  $\mathcal{P}(y_{ij}|x_{ij})$ . The problem is now reduced to finding the maximum a posteriori (MAP) setting of  $y_{ij}$ s in the new graph. The inference in such models is generally intractable, therefore we apply approximate graph partitioning methods where we partition the graph into clusters with high intra-cluster edge weights and low inter-cluster edge weights. In this work we employ the standard *greedy agglomerative clustering*, in which each noun phrase would be assigned to the most probable cluster according to  $\mathcal{P}(y_{ij}|x_{ij})$ .

## 4.2 Features

Given a pair of property names  $x_{ij} = \{x_i, x_j\}$  we have designed a set of features as follows:

**Property name string similarity/distance:** This measures string similarity between two names. We have included various string edit distances such as *Jaccard* distance over *n-grams* extracted from the property names, and also *Levenstein* distance. We have also included a feature that compares the two property names after their commoner morphological and inflectional endings have been removed using the *Porter Stemmer* algorithm.

**Property value set coverage:** We compute a weighted *Jaccard* measure given the values and the value frequencies associated with a property name.

$$\mathcal{J}(\mathcal{V}_{x_i}, \mathcal{V}_{x_j}) = \frac{\sum_{v \in (\mathcal{V}_{x_i} \cap \mathcal{V}_{x_j})} \min(c^i(v), c^j(v))}{\sum_{v \in (\mathcal{V}_{x_i} \cap \mathcal{V}_{x_j})} \max(c^i(v), c^j(v))}$$

This feature essentially computes how many property values are common between the two property names, weighted by their popularity.

**Property name co-occurrence:** This is an interesting feature which is based on the observation that

two property names that are synonyms, rarely occur together within the same description. This is based on the assumption that sellers are consistent when using property names throughout a single description. For example when they are specifying the size of an item, they either use *size* or *dimensions* exclusively in a single description. However, it is more likely that two property names that are not synonyms appear together within a single description. To conform this assumption, we ran a separate experiment that measures the co-occurrence frequency of the property names in a single category. Table 2 shows a measurement of pairwise co-occurrence of a few example property names computed over the *Audio books* eBay category. Given a property name  $x$  let  $\mathcal{I}(x)$  be the total number of descriptions that contain the name  $x$ . Now, given two property names  $x_i$  and  $x_j$ , we define a measure of co-occurrence of these names as:

$$\text{CO}(x_i, x_j) = \frac{\mathcal{I}(x_i) \cap \mathcal{I}(x_j)}{\mathcal{I}(x_i) \cup \mathcal{I}(x_j)}$$

In Table 2 it can be seen that synonym property names such as "author" and "by" have a zero co-occurrence measure, while semantically different property names such as "format" and "read by" have a non-zero co-occurrence measure.

## 5 Experimental results

This section presents experimental results on a real dataset. We first describe the dataset used for these experiments and then provide results for property extraction and property name synonym discovery.

### 5.1 Data set and methodology

All the results we are reporting in this paper were obtained from a dataset of several billion descriptions corresponding to a year worth of eBay item (no sampling was performed).

For listing an item on eBay, a seller must provide a short descriptive title (up to 80 characters) and can optionally provide a few descriptive name value pairs called item specifics, and a free-form html description. Contrary to item specifics, a vast majority of sellers provide a rich description containing very useful information about the property of their item. Figure 1 shows 3 examples of eBay descriptions.

eBay organizes items into a six-level category structure similar to a topic hierarchy comprising 20,000 leaf categories and covering most of the goods in the world. An item is typically listed in one category but some items may be suitable for and listed in two categories.

Although this dataset is not publicly available, very similar data can be obtained from the eBay web site and through eBay Developers API <sup>1</sup>.

In the following, we report precision and recall results. Evaluation was performed by two annotators (non expert of the domain). For property extraction, they were asked to decide whether or not an extracted property is relevant for the corresponding items; for synonym discovery to decide whether or not sellers refer to the same semantic entity. Annotators were asked to reject the null hypothesis only beyond reasonable doubt and we found the annotator agreement to be extremely high.

### 5.2 Property Extraction Results

We have been running the property extraction method described in Section 3 on our entire dataset. The properties extracted have been aggregated at the leaf category level and ranked by popularity (as defined in Section 3). Because no gold standard data is available for this task, evaluation has to be performed manually. However, it is impractical to review results for 20,000 categories and we uniformly sampled 20 categories randomly.

**Precision.** Table 3 shows the weighted (by category size) average precision of the extracted property names up to rank 20. Precision at rank  $k$  for a given category is defined as the number of relevant properties in the top  $k$  properties of that categories, divided by  $k$ . Table 4 shows the top 15 properties extracted for five eBay categories.

Although we did not formally evaluate the precision of the discovered values, informal reviews have shown that this method extracts good quality values. Examples are "n/a", "well", "storage or well", "would be by well" and "by well" for the property name "Water" in the Land category; "metal", "plastic", "nylon", "acetate" and "durable o matter" for "Frame material" in Sunglasses; or "acrylic",

<sup>1</sup>See <https://www.x.com/developers/eBay/> for details.

Table 3: Weighted average precision of the top 20 extracted property names.

”oil”, ”acrylic on canvas” and ”oil on canvas” for ”Medium” in Paintings.

Sets of values tend to contain more synonyms than names. Also, we observed that some names exhibit polysemy issues in that their values clearly belong to several semantic clusters. An example of polysemy is the name ”Postmark” in the ”Postcards” categories which contains values like ”none, postally used, no, unused” and years (”1909, 1908, 1910...”). Cleaning and normalizing values is ongoing research effort.

**Recall.** Evaluating recall of our method requires comparing for each category, the number of relevant properties extracted to the number of relevant properties the descriptions in this category contain. It is dauntingly expensive. As a proxy for name recall, we examined 20 categories and found that our method discovered all the relevant popular property names.

It is quite remarkable that an unsupervised method like ours achieves results of that quality and is able to cover most of the good of the world with descriptive properties. To our knowledge, this has never been accomplished before in the e-commerce domain.

### 5.3 Synonym discovery results

To train our name synonym discovery algorithm, we manually clustered properties from 27 randomly se-

lected categories as described in Section 4. This resulted in 178 clusters, 113 of them containing a single property (no synonym) and 65 containing 2 or more properties and capturing actual synonym information. Note that although estimating the co-occurrence table (see Table 2) can be computationally expensive, it is very manageable for such a small set of clusters. Scalability issues due to the large number of eBay categories (nearly 20,000) made impractical to use the solutions proposed in the past to solve that problem as baselines.

Results were produced by applying the trained model to the top 20 discovered properties for each and every eBay categories. The algorithm discovered 10672 synonyms spanning 2957 categories.

**Precision.** To measure the precision of our algorithm, we manually labeled 6618 synonyms as *correct* or *incorrect*. 6076 synonyms were found to be correct and 542 incorrect, a precision of 91.8%. Table 5 shows examples of synonyms and one of the categories where they have been discovered. Some of them are very category specific. For instance, while ”hp” means ”horsepower” for air compressors, it is an acronym of a well known brand in consumer electronics.

**Recall.** Evaluating recall is a more labor intensive task as it involves comparing, for each of the 2957 categories, the number of synonyms discovered to the number of synonyms the category con-

Land	Aquariums	iPod & MP3 Players	Acoustic Guitars	Postcards
State	Dimensions	Weight	Top	Condition
Zoning	Height	Width	Scale length	Publisher

Paper Calendar	{Time period, Calendars era}

Table 5: Examples of discovered property name synonyms.

tains. As a proxy we labeled 40 randomly selected categories. For these categories, we found the recall to be 51%. As explained in Section 4, the overlap of values between two names is an important feature for our algorithm. The fact that we are not cleaning and normalizing the values discovered by our property extraction algorithm clearly impacts recall. This is definitively an important direction for further improvements.

## 6 Conclusion

We presented a method for structuring e-commerce inventory into descriptive properties. This method

is based on unsupervised property discovery and extraction from unstructured item descriptions, and on property name synonym discovery achieved using a supervised maximum entropy based clustering algorithm. Experiments on a large real e-commerce dataset showed that both techniques achieve very good results. However, we did not address the issue of property value cleaning and normalization. This is an important direction for future work.

## Abstract

The named entity disambiguation task is to resolve the many-to-many correspondence between ambiguous names and the unique real-world entity. This task can be modeled as a classification problem, provided that positive and negative examples are available for learning binary classifiers. High-quality sense-annotated data, however, are hard to be obtained in streaming environments, since the training corpus would have to be constantly updated in order to accommodate the fresh data coming on the stream. On the other hand, few positive examples plus large amounts of unlabeled data may be easily acquired. Producing binary classifiers directly from this data, however, leads to poor disambiguation performance. Thus, we propose to enhance the quality of the classifiers using finer-grained variations of the well-known Expectation-Maximization (EM) algorithm. We conducted a systematic evaluation using Twitter streaming data and the results show that our classifiers are extremely effective, providing improvements ranging from 1% to 20%, when compared to the current state-of-the-art biased SVMs, being more than 120 times faster.

## 1 Introduction

Human language is not exact. For instance, an entity<sup>1</sup> may be referred by multiple names (i.e., polysemy), and also the same name may refer to different entities depending on the surrounding context (i.e.,

<sup>1</sup>The term entity refers to anything that has a distinct, separate (materialized or not) existence.

homonymy). The task of named entity disambiguation is to identify which names refer to the same entity in a textual collection (Sarmiento et al., 2009; Yosef et al., 2011; Hoffart et al., 2011). The emergence of new communication technologies, such as micro-blog platforms, brought a humongous amount of textual mentions with ambiguous entity names, raising an urgent need for novel disambiguation approaches and algorithms.

In this paper we address the named entity disambiguation task under a particularly challenging scenario. We are given a stream of messages from a micro-blog channel such as Twitter<sup>2</sup> and a list of names  $n_1, n_2, \dots, n_N$  used for mentioning a specific entity  $e$ . Our problem is to monitor the stream and predict whether an incoming message containing  $n_i$  indeed refers to  $e$  (positive example) or not (negative example). This scenario brings challenges that must be overcome. First, micro-blog messages are composed of a small amount of words and they are written in informal, sometimes cryptic style. These characteristics make hard the identification of entities and the semantics of their relationships (Liu et al., 2011). Further, the scarcity of text in the messages makes it even harder to properly characterize a common context for the entities. Second, as we need to monitor messages that keep coming at a fast pace, we cannot afford to gather information from external sources on-the-fly. Finally, fresh data coming in the stream introduces new patterns, quickly invalidating static disambiguation models.

<sup>2</sup>Twitter is one of the fastest-growing micro-blog channels, and an authoritative source for breaking news (Jansen et al., 2009).

We hypothesize that the lack of information in each individual message and from external sources can be compensated by using information obtained from the large and diverse amount of text in a stream of messages taken as a whole, that is, thousands of messages per second coming from distinct sources.

The information embedded in such a stream of messages may be exploited for entity disambiguation through the application of supervised learning methods, for instance, with the application of binary classifiers. Such methods, however, suffer from a data acquisition bottleneck, since they are based on training datasets that are built by skilled human annotators who manually inspect the messages. This annotation process is usually lengthy and laborious, being clearly unfeasible to be adopted in data streaming scenarios. As an alternative to such manual process, a large amount of unlabeled data, augmented with a small amount of (likely) positive examples, can be collected automatically from the message stream (Liu et al., 2003; Denis, 1998; Comité et al., 1999; Letouzey et al., 2000).

Binary classifiers may be learned from such data by considering unlabeled data as negative examples. This strategy, however, leads to classifiers with poor disambiguation performance, due to a potentially large number of false-negative examples. In this paper we propose to refine binary classifiers iteratively, by performing Expectation-Maximization (EM) approaches (Dempster et al., 1977). Basically, a partial classifier is used to evaluate the likelihood of an unlabeled example being a positive example or a negative example, thus automatically and (continuously) creating a labeled training corpus. This process continues iteratively by changing the label of some examples (an operation we call label-transition), so that, after some iterations, the combination of labels is expected to converge to the one for which the observed data is most likely. Based on such an approach, we introduce novel disambiguation algorithms that differ among themselves on the granularity in which the classifier is updated, and on the label-transition operations that are allowed.

An important feature of the proposed approach is that, at each iteration of the EM-process, a new classifier (an improved one) is produced in order to account for the current set of labeled examples. We introduce a novel strategy to maintain the classifiers

up-to-date incrementally after each iteration, or even after each label-transition operation. Indeed, we theoretically show that our classifier needs to be updated just partially and we are able to determine exactly which parts must be updated, making our disambiguation methods extremely fast.

To evaluate the effectiveness of the proposed algorithms, we performed a systematic set of experiments using large-scale Twitter data containing messages with ambiguous entity names. In order to validate our claims, disambiguation performance is investigated by varying the proportion of false-negative examples in the unlabeled dataset. Our algorithms are compared against a state-of-the-art technique for named entity disambiguation based on classifiers, providing performance gains ranging from 1% to 20% and being roughly 120 times faster.

## 2 Related Work

In the context of databases, traditional entity disambiguation methods rely on similarity functions over attributes associated to the entities (de Carvalho et al., 2012). Obviously, such an approach is unfeasible for the scenario we consider here. Still on databases, Bhattacharya and Getoor (2007) and Dong et. al (2005) propose graph-based disambiguation methods that generate clusters of co-referent entities using known relationships between entities of several types. Methods to disambiguate person names in e-mail (Minkov et al., 2006) and Web pages (Bekkerman and McCallum, 2005; Wan et al., 2005) have employed similar ideas. In e-mails, information taken from the header of the messages leads to establish relationships between users and building a co-reference graph. In Web pages, reference information come naturally from links. Such graph-based approach could hardly be applied to the context we consider, in which the implied relationships between entities mentioned in a given micro-blog message are not clearly defined.

In the case of textual corpora, traditional disambiguation methods represent entity names and their context (Hasegawa et al., 2004) (i.e., words, phrases and other names occurring near them) as weighted vectors (Bagga and Baldwin, 1998; Pedersen et al., 2005). To evaluate whether two names refer to the same entity, these methods compute the similar-

ity between these vectors. Clusters of co-referent names are then built based on such similarity measure. Although effective for the tasks considered in these papers, the simplistic BOW-based approaches they adopt are not suitable for cases in which the context is harder to capture due to the small number of terms available or to informal writing style. To address these problems, some authors argue that contextual information may be enriched with knowledge from external sources, such as search results and the Wikipedia (Cucerzan, 2007; Bunescu and Pasca, 2006; Han and Zhao, 2009). While such a strategy is feasible in an off-line setting, two problems arise when monitoring streams of micro-blog messages. First, gathering information from external sources through the Internet can be costly and, second, informal mentions to named entities make it hard to look for related information in such sources.

The disambiguation methods we propose fall into a learning scenario known as PU (positive and unlabeled) learning (Liu et al., 2003; Denis, 1998; Comité et al., 1999; Letouzey et al., 2000), in which a classifier is built from a set of positive examples plus unlabeled data. Most of the approaches for PU learning, such as the biased-SVM approach (Li and Liu, 2003), are based on extracting negative examples from unlabeled data. We notice that existing approaches for PU learning are not likely to scale given the restrictions imposed by streaming data. Thus, we propose highly incremental approaches, which are able to process large-scale streaming data.

### 3 Disambiguation in Streaming Data

Consider a stream of messages from a micro-blog channel such as Twitter and let  $n_1, n_2, \dots, n_N$  be names used for mentioning a specific entity  $e$  in these messages. Our problem is to continually monitor the stream and predict whether an incoming message containing  $n_i$  indeed refers to  $e$  or not.

This task may be accomplished through the application of classification techniques. In this case, we are given an input data set called the training corpus (denoted as  $\mathcal{D}$ ) which consists of examples of the form  $\langle e, m, c \rangle$ , where  $e$  is the entity,  $m$  is a message containing the entity name (i.e., any  $n_i$ ), and  $c \in \{\ominus, \oplus\}$  is a binary variable that specifies whether or not the entity name in  $m$  refers to the

desired real-world entity  $e$ . The training corpus is used to produce a classifier that relates textual patterns (i.e., terms and sets of terms) in  $m$  to the value of  $c$ . The test set (denoted as  $\mathcal{T}$ ) consists of a set of records of the form  $\langle e, m, ? \rangle$ , and the classifier is used to indicate which messages in  $\mathcal{T}$  refer to (or not) the desired entity.

Supervised classifiers, however, are subject to a data acquisition bottleneck, since the creation of a training corpus requires skilled human annotators to manually inspect the messages. The cost associated with this annotation process may render vast amounts of examples unfeasible. In many cases, however, the acquisition of some positive examples is relatively inexpensive. For instance, as we are dealing with messages collected from micro-blog channels, we may exploit profiles (or hashtags) that are known to be strongly associated with the desired entity. Let us consider, as an illustrative example, the profile associated with a company (i.e., @bayer). Although the entity name is ambiguous, the sense of messages that are posted in this profile is biased towards the entity as being a company. Clearly, other tricks like this one can be used, but, unfortunately, they do not guarantee the absence of false-positives, and they are not complete since the majority of messages mentioning the entity name may appear outside its profile. Thus, the collected examples are not totally reliable, and disambiguation performance would be seriously compromised if classifiers were built upon these uncertain examples directly.

#### 3.1 Expectation-Maximization Approach

In this paper we hypothesize that it is worthwhile to enhance the reliability of unlabeled examples, provided that this type of data is inexpensive and the enhancement effort will be then rewarded with an improvement in disambiguation performance. Thus, we propose a new approach based on the Expectation-Maximization (EM) algorithm (Dempster et al., 1977). We assume two scenarios:

- the training corpus  $\mathcal{D}$  is composed of a small set of *truly* positive examples plus a large amount of unlabeled examples.
- the training corpus  $\mathcal{D}$  is composed of a small set of *potentially* positive examples plus a large amount of unlabeled examples.

In both scenarios, unlabeled examples are initially treated as negative ones, so that classifiers can be built from  $\mathcal{D}$ . Therefore, in both scenarios,  $\mathcal{D}$  may contain false-negatives. In the second scenario, however,  $\mathcal{D}$  may also contain false-positives.

**Definition 3.1:** *The label-transition operation  $x^{\ominus \rightarrow \oplus}$  turns a negative example  $x^{\ominus} \in \mathcal{D}$  into a positive one  $x^{\oplus}$ . The training corpus  $\mathcal{D}$  becomes  $\{(\mathcal{D} - x^{\ominus}) \cup x^{\oplus}\}$ . Similarly, the label-transition operation  $x^{\oplus \rightarrow \ominus}$ , turns a positive example  $x^{\oplus} \in \mathcal{D}$  into a negative one  $x^{\ominus}$ . The training corpus  $\mathcal{D}$  becomes  $\{(\mathcal{D} - x^{\oplus}) \cup x^{\ominus}\}$ .*

Our Expectation Maximization (EM) methods employ a classifier which assigns to each example  $x \in \mathcal{D}$  a probability  $\alpha(x, \ominus)$  of being negative. Then, as illustrated in Algorithm 1, label-transition operations are performed, so that, in the end of the process, it is expected that the assigned labels converge to the combination for which the data is most likely. In the first scenario only operations  $x^{\ominus \rightarrow \oplus}$  are allowed, while in the second scenario operations  $x^{\oplus \rightarrow \ominus}$  are also allowed. In both cases, a crucial issue that affects the effectiveness of our EM-based methods concerns the decision of whether or not performing the label-transition operation. Typically, a transition threshold  $\alpha_{min}$  is employed, so that a label-transition operation  $x^{\ominus \rightarrow \oplus}$  is always performed if  $x$  is a negative example and  $\alpha(x, \ominus) \leq \alpha_{min}$ . Similarly, operation  $x^{\oplus \rightarrow \ominus}$  is always performed if  $x$  is a positive example and  $\alpha(x, \ominus) > \alpha_{min}$ .

---

**Algorithm 1** Expectation-Maximization Approach.

---

**Given:**

$\mathcal{D}$ : training corpus

$\mathcal{R}$ : a binary classifier learned from  $\mathcal{D}$

**Expectation step:**

perform transition operations on examples in  $\mathcal{D}$

**Maximization step:**

update  $\mathcal{R}$  and  $\alpha(x, \ominus) \forall x \in \mathcal{D}$

---

The optimal value for  $\alpha_{min}$  is not known in advance. Fortunately, data distribution may provide hints about proper values for  $\alpha_{min}$ . In our approach, instead of using a single value for  $\alpha_{min}$ , which would be applied to all examples indistinctly, we use a specific  $\alpha_{min}^x$  threshold for each example  $x \in \mathcal{D}$ . Based on such an approach, we in-

troduce fine-grained EM-based methods for named entity disambiguation under streaming data. A specific challenge is that the proposed methods perform several transition operations during each EM iteration, and each transition operation may invalidate parts of the current classifier, which must be properly updated. We take into consideration two possible update granularities:

- the classifier is updated after each EM iteration.
- the classifier is updated after each label-transition operation.

**Incremental Classifier:** As already discussed, the classifier must be constantly updated during the EM process. In this case, well-established classifiers, such as SVMs (Joachims, 2006), have to be learned entirely from scratch, replicating work by large. Thus, we propose as an alternative the use of *Lazy Associative Classifiers* (Velooso et al., 2006).

**Definition 3.2:** *A classification rule is a specialized association rule  $\{\mathcal{X} \rightarrow c\}$  (Agrawal et al., 1993), where the antecedent  $\mathcal{X}$  is a set of terms (i.e., a termset), and the consequent  $c$  indicates if the prediction is positive or negative (i.e.,  $c \in \{\oplus, \ominus\}$ ). The domain for  $\mathcal{X}$  is the vocabulary of  $\mathcal{D}$ . The cardinality of rule  $\{\mathcal{X} \rightarrow c\}$  is given by the number of terms in the antecedent, that is  $|\mathcal{X}|$ . The support of  $\mathcal{X}$  is denoted as  $\sigma(\mathcal{X})$ , and is the number of examples in  $\mathcal{D}$  having  $\mathcal{X}$  as a subset. The confidence of rule  $\{\mathcal{X} \rightarrow c\}$  is denoted as  $\theta(\mathcal{X} \rightarrow c)$ , and is the conditional probability of  $c$  given the termset  $\mathcal{X}$ , that is,  $\theta(\mathcal{X} \rightarrow c) = \frac{\sigma(\mathcal{X} \cup c)}{\sigma(\mathcal{X})}$ .*

In this context, a classifier is denoted as  $\mathcal{R}$ , and it is composed of a set of rules  $\{\mathcal{X} \rightarrow c\}$  extracted from  $\mathcal{D}$ . Specifically,  $\mathcal{R}$  is represented as a pool of entries with the form  $\langle key, properties \rangle$ , where  $key = \{\mathcal{X}, c\}$  and  $properties = \{\sigma(\mathcal{X}), \sigma(\mathcal{X} \cup c), \theta(\mathcal{X} \rightarrow c)\}$ . Each entry in the pool corresponds to a rule, and the key is used to facilitate fast access to rule properties.

Once the classifier  $\mathcal{R}$  is extracted from  $\mathcal{D}$ , rules are collectively used to approximate the likelihood of an arbitrary example being positive ( $\oplus$ ) or negative ( $\ominus$ ). Basically,  $\mathcal{R}$  is interpreted as a poll, in which each rule  $\{\mathcal{X} \rightarrow c\} \in \mathcal{R}$  is a vote given by  $\mathcal{X}$  for  $\oplus$  or  $\ominus$ . Given an example  $x$ , a rule  $\{\mathcal{X} \rightarrow c\}$  is only considered a valid vote if it is applicable to  $x$ .

**Definition 3.3:** A rule  $\{\mathcal{X} \rightarrow c\} \in \mathcal{R}$  is said to be applicable to example  $x$  if  $\mathcal{X} \subseteq x$ , that is, if all terms in  $\mathcal{X}$  are present in example  $x$ .

We denote as  $\mathcal{R}_x$  the set of rules in  $\mathcal{R}$  that are applicable to example  $x$ . Thus, only and all the rules in  $\mathcal{R}_x$  are considered as valid votes when classifying  $x$ . Further, we denote as  $\mathcal{R}_x^c$  the subset of  $\mathcal{R}_x$  containing only rules predicting  $c$ . Votes in  $\mathcal{R}_x^c$  have different weights, depending on the confidence of the corresponding rules. Weighted votes for  $c$  are averaged, giving the score for  $c$  with regard to  $x$  (Equation 1). Finally, the likelihood of  $x$  being a negative example is given by the normalized score (Equation 2).

$$s(x, c) = \sum \frac{\theta(\mathcal{X} \rightarrow c)}{|\mathcal{R}_x^c|}, \text{ with } c \in \{\ominus, \oplus\} \quad (1)$$

$$\alpha(x, \ominus) = \frac{s(x, \ominus)}{s(x, \ominus) + s(x, \oplus)} \quad (2)$$

### Training Projection and Demand-Driven Rule

**Extraction:** Demand-driven rule extraction (Velo et al., 2006) is a recent strategy used to avoid the huge search space for rules, by projecting the training corpus according to the example being processed. More specifically, rule extraction is delayed until an example  $x$  is given for classification. Then, terms in  $x$  are used as a filter that configures the training corpus  $\mathcal{D}$  so that just rules that are applicable to  $x$  can be extracted. This filtering process produces a projected training corpus, denoted as  $\mathcal{D}_x$ , which contains only terms that are present in  $x$ . As shown in (Silva et al., 2011), the number of rules extracted using this strategy grows polynomially with the size of the vocabulary.

**Extending the Classifier Dynamically:** With demand-driven rule extraction, the classifier  $\mathcal{R}$  is extended dynamically as examples are given for classification. Initially  $\mathcal{R}$  is empty; a subset  $\mathcal{R}_{x_i}$  is appended to  $\mathcal{R}$  every time an example  $x_i$  is processed. Thus, after processing a sequence of  $m$  examples  $\{x_1, x_2, \dots, x_m\}$ ,  $\mathcal{R} = \{\mathcal{R}_{x_1} \cup \mathcal{R}_{x_2} \cup \dots \cup \mathcal{R}_{x_m}\}$ .

Before extracting rule  $\{\mathcal{X} \rightarrow c\}$ , it is checked whether this rule is already in  $\mathcal{R}$ . In this case, while processing an example  $x$ , if an entry is found with a key matching  $\{\mathcal{X}, c\}$ , then the rule in  $\mathcal{R}$  is used instead of extracting it from  $\mathcal{D}_x$ . Otherwise, the rule is extracted from  $\mathcal{D}_x$  and then it is inserted into  $\mathcal{R}$ .

**Incremental Updates:** Entries in  $\mathcal{R}$  may become invalid when  $\mathcal{D}$  is modified due to a label-transition operation. Given that  $\mathcal{D}$  has been modified, the classifier  $\mathcal{R}$  must be updated properly. We propose to maintain  $\mathcal{R}$  up-to-date incrementally, so that the updated classifier is exactly the same one that would be obtained by re-constructing it from scratch.

**Lemma 3.1:** Operation  $x^{\ominus \rightarrow \oplus}$  (or  $x^{\oplus \rightarrow \ominus}$ ) does not change the value of  $\sigma(\mathcal{X})$ , for any termset  $\mathcal{X}$ .

**Proof:** The operation  $x^{\ominus \rightarrow \oplus}$  changes only the label associated with  $x$ , but not its terms. Thus, the number of examples in  $\mathcal{D}$  having  $\mathcal{X}$  as a subset is essentially the same as in  $\{(\mathcal{D} - x^{\ominus}) \cup x^{\oplus}\}$ . The same holds for operation  $x^{\oplus \rightarrow \ominus}$ . ■

**Lemma 3.2:** Operation  $x^{\ominus \rightarrow \oplus}$  (or  $x^{\oplus \rightarrow \ominus}$ ) changes the value of  $\sigma(\mathcal{X} \cup c)$  iff termset  $\mathcal{X} \subset x$ .

**Proof:** For operation  $x^{\ominus \rightarrow \oplus}$ , if  $\mathcal{X} \subset x$ , then  $\{\mathcal{X} \cup \ominus\}$  appears once less in  $\{(\mathcal{D} - x^{\ominus}) \cup x^{\oplus}\}$  than in  $\mathcal{D}$ . Similarly,  $\{\mathcal{X} \cup \oplus\}$  appears once more in  $\{(\mathcal{D} - x^{\ominus}) \cup x^{\oplus}\}$  than in  $\mathcal{D}$ . Clearly, if  $\mathcal{X} \not\subset x$ , the number of times  $\{\mathcal{X} \cup \ominus\}$  (and  $\{\mathcal{X} \cup \oplus\}$ ) appears in  $\{(\mathcal{D} - x^{\ominus}) \cup x^{\oplus}\}$  remains the same as in  $\mathcal{D}$ . The same holds for operation  $x^{\oplus \rightarrow \ominus}$ . ■

**Lemma 3.3:** Operation  $x^{\ominus \rightarrow \oplus}$  (or  $x^{\oplus \rightarrow \ominus}$ ) changes the value of  $\theta(\mathcal{X} \rightarrow c)$  iff termset  $\mathcal{X} \subset x$ .

**Proof:** Comes directly from Lemmas 3.1 and 3.2. ■

From Lemmas 3.1 to 3.3, the number of rules that have to be updated due to a label-transition operation is bounded by the number of possible termsets in  $x$ . The following theorem states exactly the rules in  $\mathcal{R}$  that have to be updated due to a transition operation.

**Theorem 3.4:** All rules in  $\mathcal{R}$  that must be updated due to  $x^{\ominus \rightarrow \oplus}$  (or  $x^{\oplus \rightarrow \ominus}$ ) are those in  $\mathcal{R}_x$ .

**Proof:** From Lemma 3.3, all rules  $\{\mathcal{X} \rightarrow c\} \in \mathcal{R}$  that have to be updated due to operation  $x^{\ominus \rightarrow \oplus}$  (or  $x^{\oplus \rightarrow \ominus}$ ) are those for which  $\mathcal{X} \subseteq x$ . By definition,  $\mathcal{R}_x$  contains only and all such rules. ■

Updating  $\theta(\mathcal{X} \rightarrow \ominus)$  and  $\theta(\mathcal{X} \rightarrow \oplus)$  is straightforward. For operation  $x^{\ominus \rightarrow \oplus}$ , it suffices to iterate on  $\mathcal{R}_x$ , incrementing  $\sigma(\mathcal{X} \cup \oplus)$  and decrementing  $\sigma(\mathcal{X} \cup \ominus)$ . Similarly, for operation  $x^{\oplus \rightarrow \ominus}$ , it suffices to iterate on  $\mathcal{R}_x$ , incrementing  $\sigma(\mathcal{X} \cup \ominus)$  and decrementing  $\sigma(\mathcal{X} \cup \oplus)$ . The corresponding values for  $\theta(\mathcal{X} \rightarrow \ominus)$  and  $\theta(\mathcal{X} \rightarrow \oplus)$  are simply obtained by computing  $\frac{\sigma(\mathcal{X} \cup \ominus)}{\sigma(\mathcal{X})}$  and  $\frac{\sigma(\mathcal{X} \cup \oplus)}{\sigma(\mathcal{X})}$ , respectively.

### 3.2 Best Entropy Cut Method

In this section we propose a method for finding the activation threshold,  $\alpha_{min}^x$ , which is a fundamental step of our Expectation-Maximization approach.

**Definition 3.4:** Let  $c^y \in \{\ominus, \oplus\}$  be the label associated with an example  $y \in \mathcal{D}_x$ . Consider  $N_{\ominus}(\mathcal{D}_x)$  the number of examples in  $\mathcal{D}_x$  for which  $c^y = \ominus$ . Similarly, consider  $N_{\oplus}(\mathcal{D}_x)$  the number of examples in  $\mathcal{D}_x$  for which  $c^y = \oplus$ .

**Entropy Minimization:** Our method searches for a threshold  $\alpha_{min}^x$  that provides the best entropy cut in the probability space induced by  $\mathcal{D}_x$ . Specifically, given examples  $\{y_1, y_2, \dots, y_k\}$  in  $\mathcal{D}_x$ , our method first calculates  $\alpha(y_i, \ominus)$  for all  $y_i \in \mathcal{D}_x$ . Then, the values for  $\alpha(y_i, \ominus)$  are sorted in ascending order. In an ideal case, there is a cut  $\alpha_{min}^x$  such that:

$$c^{y_i} = \begin{cases} \oplus & \text{if } \alpha(y_i, \ominus) \leq \alpha_{min}^x \\ \ominus & \text{otherwise} \end{cases}$$

However, there are more difficult cases, for which it is not possible to obtain a perfect separation in the probability space. Thus, we propose a more general method to find the best cut in the probability space. The basic idea is that any value for  $\alpha_{min}^x$  induces two partitions over the space of values for  $\alpha(y_i, \ominus)$  (i.e., one partition with values that are lower than  $\alpha_{min}^x$ , and another partition with values that are higher than  $\alpha_{min}^x$ ). Our method sets  $\alpha_{min}^x$  to the value that minimizes the average entropy of these two partitions. Once  $\alpha_{min}^x$  is calculated, it can be used to activate a label-transition operation. Next we present the basic definitions in order to detail this method.

**Definition 3.5:** Consider a list of pairs  $\mathcal{O} = \{\dots, \langle c^{y_i}, \alpha(y_i, \ominus) \rangle, \langle c^{y_j}, \alpha(y_j, \ominus) \rangle, \dots\}$ , such that  $\alpha(y_i, \ominus) \leq \alpha(y_j, \ominus)$ . Also, consider  $f$  a candidate value for  $\alpha_{min}^x$ . In this case,  $\mathcal{O}_f(\leq)$  is a sub-list of  $\mathcal{O}$ , that is,  $\mathcal{O}_f(\leq) = \{\dots, \langle c^{y_i}, \alpha(y_i, \ominus) \rangle, \dots\}$ , such that for all pairs in  $\mathcal{O}_f(\leq)$ ,  $\alpha(y, \ominus) \leq f$ . Similarly,  $\mathcal{O}_f(>) = \{\dots, \langle c^{y_j}, \alpha(y_j, \ominus) \rangle, \dots\}$ , such that for all pairs in  $\mathcal{O}_f(>)$ ,  $\alpha(y, \ominus) > f$ . In other words,  $\mathcal{O}_f(\leq)$  and  $\mathcal{O}_f(>)$  are partitions of  $\mathcal{O}$  induced by  $f$ .

Our method works as follows. Firstly, it calculates the entropy in  $\mathcal{O}$ , as shown in Equation 3. Then, it calculates the sum of the entropies in each partition induced by  $f$ , according to Equation 4. Finally, it sets  $\alpha_{min}^x$  to the value of  $f$  that minimizes  $E(\mathcal{O}) - E(\mathcal{O}_f)$ , as illustrated in Figure 1.

Figure 1: Looking for the minimum entropy cut point.

$$E(\mathcal{O}) = - \left( \frac{N_{\ominus}(\mathcal{O})}{|\mathcal{O}|} \times \log \frac{N_{\ominus}(\mathcal{O})}{|\mathcal{O}|} \right) - \left( \frac{N_{\oplus}(\mathcal{O})}{|\mathcal{O}|} \times \log \frac{N_{\oplus}(\mathcal{O})}{|\mathcal{O}|} \right) \quad (3)$$

$$E(\mathcal{O}_f) = \frac{|\mathcal{O}_f(\leq)|}{|\mathcal{O}|} \times E(\mathcal{O}_f(\leq)) + \frac{|\mathcal{O}_f(>)|}{|\mathcal{O}|} \times E(\mathcal{O}_f(>)) \quad (4)$$

### 3.3 Disambiguation Algorithms

In this section we discuss four algorithms based on our incremental EM approach and following our Best Entropy Cut method. They differ among themselves on the granularity in which the classifier is updated and on the label-transition operations allowed:

- A1: the classifier is updated incrementally after each EM iteration (which may comprise several label-transition operations). Only operation  $x^{\ominus \rightarrow \oplus}$  is allowed.
- A2: the classifier is updated incrementally after each EM iteration. Both operations  $x^{\ominus \rightarrow \oplus}$  and  $x^{\oplus \rightarrow \ominus}$  are allowed.
- A3: the classifier is updated incrementally after each label-transition operation. Only operation  $x^{\ominus \rightarrow \oplus}$  is allowed.
- A4: the classifier is updated incrementally after each label-transition operation. Both operations  $x^{\ominus \rightarrow \oplus}$  and  $x^{\oplus \rightarrow \ominus}$  are allowed.

## 4 Experimental Evaluation

In this section we analyze our algorithms using standard measures such as AUC values. For each positive+unlabeled (PU) corpus used in our evaluation we randomly selected  $x\%$  of the positive examples (P) to become unlabeled ones (U). This procedure enables us to control the uncertainty level of the corpus. For each level we have a different TPR-FPR combination, enabling us to draw ROC curves. We repeated this procedure five times, so that five executions were performed for each uncertainty level. Tables 2–5 show the average for the five runs. Wilcoxon significance tests were performed ( $p < 0.05$ ) and best results, including statistical ties, are shown in bold.

### 4.1 Baselines and Collections

Our baselines include namely SVMs (Joachims, 2006) and Biased SVMs (B-SVM (Liu et al., 2003)). Although the simple SVM algorithm does not adapt itself with unlabeled data, we decided to use it in order to get a sense of the performance achieved by simple baselines (in this case, unlabeled data is simply used as negative examples). The B-SVM algorithm uses a soft-margin SVM as the underlying classifier, which is re-constructed from scratch after each EM iteration. B-SVM employs a single transition threshold  $\alpha_{min}$  for the entire corpus, instead of a different threshold  $\alpha_{min}^x$  for each  $x \in \mathcal{D}$ . It is representative of the state-of-the-art for learning classifiers from PU data.

We employed two different Twitter collections. The first collection, ORGANIZATIONS, is composed of 10 corpora<sup>3</sup> ( $O_1$  to  $O_{10}$ ). Each corpus contains messages in English mentioning the name of an organization (Bayer, Renault, among others). All messages were labeled by five annotators. Label  $\oplus$  means that the message is associated with the organization, whereas label  $\ominus$  means the opposite.

The other collection, SOCCER TEAMS, contains 6 large-scale PU corpora ( $ST_1$  to  $ST_6$ ), taken from a platform for real time event monitoring (the link to this platform is omitted due to blind review). Each corpus contains messages in Portuguese mentioning the name/mascot of a Brazilian soccer team. Both collections are summarized in Table 1.

<sup>3</sup><http://nlp.uned.es/weps/>

Table 1: Characteristics of each collection.

	P	U		P	U
$O_1$	404	10	$ST_1$	216,991	251,198
$O_2$	404	55	$ST_2$	256,027	504,428
$O_3$	349	116	$ST_3$	160,706	509,670
$O_4$	329	119	$ST_4$	147,706	633,357
$O_5$	335	133	$ST_5$	35,021	168,669
$O_6$	314	143	$ST_6$	5,993	351,882
$O_7$	292	148	–	–	–
$O_8$	295	172	–	–	–
$O_9$	273	165	–	–	–
$O_{10}$	33	425	–	–	–

### 4.2 Results

All experiments were performed on a Linux PC with an Intel Core 2 Duo 2.20GHz and 4GBytes RAM. Next we discuss the disambiguation performance and the computational efficiency of our algorithms.

**ORGANIZATIONS Corpora:** Table 2 shows average AUC values for each algorithm. Algorithm A4 was the best performer in all cases, suggesting the benefits of (i) enabling both types of label-transition operations and (ii) keeping the classifier up-to-date after each label-transition operation. Further, algorithm A3 performed better than algorithm A2 in most of the cases, indicating the importance of keeping the classifier always up-to-date. On average A1 provides gains of 4% when compared against B-SVM, while A4 provides gains of more than 20%.

**SOCCER TEAMS Corpora:** Table 3 shows average AUC values for each algorithm. Again, algorithm A4 was the best performer, providing gains that are up to 13% when compared against the baseline. Also, algorithm A3 performed better than algorithm A2, and the effectiveness of Algorithm A1 is similar to the effectiveness of the baseline.

Since the SOCCER TEAMS collection is composed of large-scale corpora, in addition to high effectiveness, another important issue to be evaluated is computational performance. Table 4 shows the results obtained for the evaluation of our algorithms. As it can be seen, algorithm A1 is the fastest one, since it is the simplest one. Even though being slower than algorithm A1, algorithm A4 runs, on average, 120 times faster than B-SVM.

Table 2: Average AUC values for each algorithm.

	A1	A2	A3	A4	SVM	B-SVM

## 5 Conclusions

In this paper we have introduced a novel EM approach, which employs a highly incremental underlying classifier based on association rules, completely avoiding work replication. Further, two label-transition operations are allowed, enabling the correction of false-negatives and false-positives. We proposed four algorithms based on our EM approach. Our algorithms employ an entropy min-

imization method, which finds the best transition threshold for each example in  $\mathcal{D}$ . All these properties make our algorithms appropriate for named entity disambiguation under streaming data scenarios. Our experiments involve Twitter data mentioning ambiguous named entities. These datasets were obtained from real application scenarios and from platforms currently in operation. We have shown that three of our algorithms achieve significantly higher disambiguation performance when compared against a strong baseline (B-SVM), providing gains ranging from 1% to 20%. Also importantly, for large-scale streaming data, our algorithms are more than 120 times faster than the baseline.

## Abstract

Classically, training relation extractors relies on high-quality, manually annotated training data, which can be expensive to obtain. To mitigate this cost, NLU researchers have considered two newly available sources of less expensive (but potentially lower quality) labeled data from distant supervision and crowd sourcing. There is, however, no study comparing the relative impact of these two sources on the precision and recall of post-learning answers. To fill this gap, we empirically study how state-of-the-art techniques are affected by scaling these two sources. We use corpus sizes of up to 100 million documents and tens of thousands of crowd-source labeled examples. Our experiments show that increasing the corpus size for distant supervision has a statistically significant, positive impact on quality (F1 score). In contrast, human feedback has a positive and statistically significant, but lower, impact on precision and recall.

## 1 Introduction

Relation extraction is the problem of populating a *target relation* (representing an entity-level relationship or attribute) with facts extracted from natural-language text. Sample relations include people’s titles, birth places, and marriage relationships.

Traditional relation-extraction systems rely on manual annotations or domain-specific rules provided by experts, both of which are scarce resources that are not portable across domains. To remedy these problems, recent years have seen interest in the *distant supervision* approach for rela-

tion extraction (Wu and Weld, 2007; Mintz et al., 2009). The input to distant supervision is a set of *seed facts* for the target relation together with an (unlabeled) text corpus, and the output is a set of (noisy) annotations that can be used by any machine learning technique to train a statistical model for the target relation. For example, given the target relation `birthPlace(person, place)` and a seed fact `birthPlace(John, Springfield)`, the sentence “*John and his wife were born in Springfield in 1946*” (S1) would qualify as a positive training example.

Distant supervision replaces the expensive process of manually acquiring annotations that is required by direct supervision with resources that already exist in many scenarios (seed facts and a text corpus). On the other hand, distantly labeled data may not be as accurate as manual annotations. For example, “*John left Springfield when he was 16*” (S2) would also be considered a positive example about place of birth by distant supervision as it contains both John and Springfield. The hypothesis is that the broad coverage and high redundancy in a large corpus would compensate for this noise. For example, with a large enough corpus, a distant supervision system may find that patterns in the sentence S1 strongly correlate with seed facts of `birthPlace` whereas patterns in S2 do not qualify as a strong indicator. Thus, intuitively the quality of distant supervision should improve as we use larger corpora. However, there has been no study on the impact of corpus size on distant supervision for relation extraction. Our goal is to fill this gap.

Besides “big data,” another resource that may be valuable to distant supervision is crowdsourc-

ing. For example, one could employ crowd workers to provide feedback on whether distant supervision examples are correct or not (Gormley et al., 2010). Intuitively the crowd workforce is a perfect fit for such tasks since many erroneous distant labels could be easily identified and corrected by humans. For example, distant supervision may mistakenly consider “*Obama took a vacation in Hawaii*” a positive example for `birthPlace` simply because a database says that Obama was born in Hawaii; a crowd worker would correctly point out that this sentence is not actually indicative of this relation.

It is unclear however which strategy one should use: scaling the text corpus or the amount of human feedback. Our primary contribution is to empirically assess how scaling these inputs to distant supervision impacts its result quality. We study this question with input data sets that are orders of magnitude larger than those in prior work. While the largest corpus (Wikipedia and New York Times) employed by recent work on distant supervision (Mintz et al., 2009; Yao et al., 2010; Hoffmann et al., 2011) contain about 2M documents, we run experiments on a 100M-document (50X more) corpus drawn from ClueWeb.<sup>1</sup> While prior work (Gormley et al., 2010) on crowdsourcing for distant supervision used thousands of human feedback units, we acquire tens of thousands of human-provided labels. Despite the large scale, we follow state-of-the-art distant supervision approaches and use deep linguistic features, e.g., part-of-speech tags and dependency parsing.<sup>2</sup>

Our experiments shed insight on the following two questions:

1. *How does increasing the corpus size impact the quality of distant supervision?*
2. *For a given corpus size, how does increasing the amount of human feedback impact the quality of distant supervision?*

We found that increasing corpus size consistently and significantly improves recall and F1, despite reducing precision on small corpora; in contrast, human feedback has relatively small impact on precision and recall. For example, on a TAC corpus with 1.8M documents, we found that increasing the corpus size ten-fold consistently results in statistically

significant improvement in F1 on two standardized relation extraction metrics (t-test with  $p=0.05$ ). On the other hand, increasing human feedback amount ten-fold results in statistically significant improvement on F1 only when the corpus contains at least 1M documents; and the magnitude of such improvement was only one fifth compared to the impact of corpus-size increment.

We find that the quality of distant supervision tends to be *recall gated*, that is, for any given relation, distant supervision fails to find all possible linguistic signals that indicate a relation. By expanding the corpus one can expand the number of patterns that occur with a known set of entities. Thus, as a rule of thumb for developing distant supervision systems, one should first attempt to expand the training corpus and then worry about precision of labels only after having obtained a broad-coverage corpus.

Throughout this paper, it is important to understand the difference between *mentions* and *entities*. Entities are conceptual objects that exist in the world (e.g., Barack Obama), whereas authors use a variety of wordings to refer to (which we call “mention”) entities in text (Ji et al., 2010).

## 2 Related Work

The idea of using entity-level structured data (e.g., facts in a database) to generate mention-level training data (e.g., in English text) is a classic one: researchers have used variants of this idea to extract entities of a certain type from webpages (Hearst, 1992; Brin, 1999). More closely related to relation extraction is the work of Lin and Patel (2001) that uses dependency paths to find answers that express the same relation as in a question.

Since Mintz et al. (2009) coined the name “*distant supervision*,” there has been growing interest in this technique. For example, distant supervision has been used for the TAC-KBP slot-filling tasks (Surdeanu et al., 2010) and other relation-extraction tasks (Hoffmann et al., 2010; Carlson et al., 2010; Nguyen and Moschitti, 2011a; Nguyen and Moschitti, 2011b). In contrast, we study how increasing input size (and incorporating human feedback) improves the result quality of distant supervision.

We focus on logistic regression, but it is interesting future work to study more sophisticated prob-

<sup>1</sup><http://lemurproject.org/clueweb09.php/>

<sup>2</sup>We used 100K CPU hours to run such tools on ClueWeb.

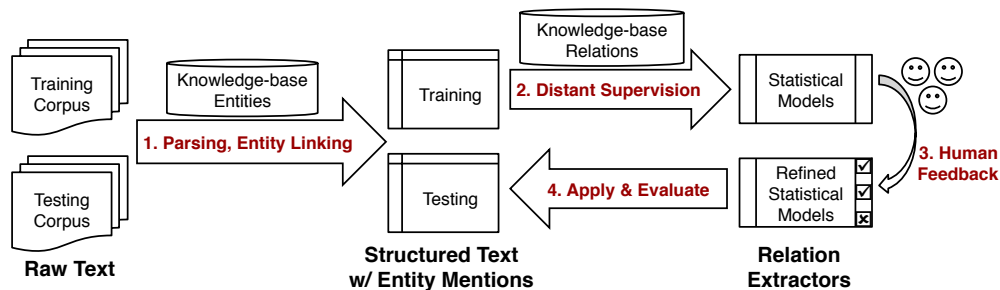

Figure 1: The workflow of our distant supervision system. Step 1 is preprocessing; step 4 is final evaluation. The key steps are distant supervision (step 2), where we train a logistic regression (LR) classifier for each relation using (noisy) examples obtained from sentences that match Freebase facts, and human feedback (step 3) where a crowd workforce refines the LR classifiers by providing feedback to the training data.

abilistic models; such models have recently been used to relax various assumptions of distant supervision (Riedel et al., 2010; Yao et al., 2010; Hoffmann et al., 2011). Specifically, they address the noisy assumption that, if two entities participate in a relation in a knowledge base, then all co-occurrences of these entities express this relation. In contrast, we explore the effectiveness of increasing the training data sizes to improve distant-supervision quality.

Sheng et al. (2008) and Gormley et al. (2010) study the quality-control issue for collecting training labels via crowdsourcing. Their focus is the collection process; in contrast, our goal is to quantify the impact of this additional data source on distant-supervision quality. Moreover, we experiment with one order of magnitude more human labels. Hoffmann et al. (2009) study how to acquire end-user feedback on relation-extraction results posted on an augmented Wikipedia site; it is interesting future work to integrate this source in our experiments. One technique for obtaining human input is active learning. We tried several active-learning techniques as described by Settles (2010), but did not observe any notable advantage over uniform sampling-based example selection.<sup>3</sup>

### 3 Distant Supervision Methodology

Relation extraction is the task of identifying relationships between mentions, in natural-language text, of entities. An example relation is that two persons are married, which for mentions of entities  $x$  and  $y$  is denoted  $R(x, y)$ . Given a corpus  $C$  con-

taining mentions of named entities, our goal is to learn a classifier for  $R(x, y)$  using linguistic features of  $x$  and  $y$ , e.g., dependency-path information. The problem is that we lack the large amount of labeled examples that are typically required to apply supervised learning techniques. We describe an overview of these techniques and the methodological choices we made to implement our study. Figure 1 illustrates the overall workflow of a distant supervision system. At each step of the distant supervision process, we closely follow the recent literature (Mintz et al., 2009; Yao et al., 2010).

#### 3.1 Distant Supervision

Distant supervision compensates for a lack of training examples by generating what are known as *silver-standard examples* (Wu and Weld, 2007). The observation is that we are often able to obtain a structured, but incomplete, database  $D$  that instantiates relations of interest and a text corpus  $C$  that contains mentions of the entities in our database. Formally, a database is a tuple  $D = (E, \bar{R})$  where  $E$  is a set of entities and  $\bar{R} = (R_1 \dots, R_N)$  is a tuple of instantiated predicates. For example,  $R_i$  may contain pairs of married people.<sup>4</sup> We use the facts in  $R_i$  combined with  $C$  to generate examples.

Following recent work (Mintz et al., 2009; Yao et al., 2010; Hoffmann et al., 2011), we use Freebase<sup>5</sup> as the knowledge base for seed facts. We use two text corpora: (1) the TAC-KBP<sup>6</sup> 2010 corpus that

<sup>3</sup>More details in our technical report (Zhang et al., 2012).

<sup>4</sup>We only consider binary predicates in this work.

<sup>5</sup><http://freebase.com>

<sup>6</sup>KBP stands for “Knowledge-Base Population.”

consists of 1.8M newswire and blog articles<sup>7</sup>, and (2) the ClueWeb09 corpus that is a 2009 snapshot of 500M webpages. We use the TAC-KBP slot filling task and select those TAC-KBP relations that are present in the Freebase schema as targets (20 relations on people and organization).

One problem is that relations in  $D$  are defined at the entity level. Thus, the pairs in such relations are not embedded in text, and so these pairs lack the linguistic context that we need to extract features, i.e., the features used to describe examples. In turn, this implies that these pairs cannot be used directly as training examples for our classifier. To generate training examples, we need to map the entities back to mentions in the corpus. We denote the relation that describes this mapping as the relation  $EL(e, m)$  where  $e \in E$  is an entity in the database  $D$  and  $m$  is a mention in the corpus  $C$ . For each relation  $R_i$ , we generate a set of (noisy) positive examples denoted  $R_i^+$  defined as  $R_i^+ =$

$$\{(m_1, m_2) \mid R(e_1, e_2) \wedge EL(e_1, m_1) \wedge EL(e_2, m_2)\}$$

As in previous work, we impose the constraint that both mentions  $(m_1, m_2) \in R_i^+$  are contained in the same sentence (Mintz et al., 2009; Yao et al., 2010; Hoffmann et al., 2011). To generate negative examples for each relation, we follow the assumption in Mintz et al. (2009) that relations are disjoint and sample from other relations, i.e.,  $R_i^- = \cup_{j \neq i} R_j^+$ .

### 3.2 Feature Extraction

Once we have constructed the set of possible mention pairs, the state-of-the-art technique to generate feature vectors uses linguistic tools such as part-of-speech taggers, named-entity recognizers, dependency parsers, and string features. Following recent work on distant supervision (Mintz et al., 2009; Yao et al., 2010; Hoffmann et al., 2011), we use both lexical and syntactic features. After this stage, we have a well-defined machine learning problem that is solvable using standard supervised techniques. We use *sparse logistic regression* ( $\ell_1$  regularized) (Tibshirani, 1996), which is used in previous studies. Our feature extraction process consists of three steps:

1. Run Stanford CoreNLP with POS tagging and named entity recognition (Finkel et al., 2005);
2. Run dependency parsing on TAC with the Ensemble parser (Surdeanu and Manning, 2010) and on ClueWeb with MaltParser (Nivre et al., 2007)<sup>8</sup>; and
3. Run a simple entity-linking system that utilizes NER results and string matching to identify mentions of Freebase entities (with types).<sup>9</sup>

The output of this processing is a repository of structured objects (with POS tags, dependency parse, and entity types and mentions) for sentences from the training corpus. Specifically, for each pair of entity mentions  $(m_1, m_2)$  in a sentence, we extract the following features  $F(m_1, m_2)$ : (1) the word sequence (including POS tags) between these mentions after normalizing entity mentions (e.g., replacing “John Nolen” with a place holder PER); if the sequence is longer than 6, we take the 3-word prefix and the 3-word suffix; (2) the dependency path between the mention pair. To normalize, in both features we use lemmas instead of surface forms. We discard features that occur in fewer than three mention pairs.

### 3.3 Crowd-Sourced Data

Crowd sourcing provides a cheap source of human labeling to improve the quality of our classifier. In this work, we specifically examine feedback on the result of distant supervision. Precisely, we construct the union of  $R_1^+ \cup \dots \cup R_N^+$  from Section 3.1. We then solicit human labeling from Mechanical Turk (MTurk) while applying state-of-the-art quality control protocols following Gormley et al. (2010) and those in the MTurk manual.<sup>10</sup>

These quality-control protocols are critical to ensure high quality: spamming is common on MTurk and some turkers may not be as proficient or careful as expected. To combat this, we replicate each question three times and, following Gormley

<sup>8</sup>We did not run Ensemble on ClueWeb because we had very few machines satisfying Ensemble’s memory requirement. In contrast, MaltParser requires less memory and we could leverage Condor (Thain et al., 2005) to parse ClueWeb with MaltParser within several days (using about 50K CPU hours).

<sup>9</sup>We experiment with a slightly more sophisticated entity-linking system as well, which resulted in higher overall quality. The results below are from the simple entity-linking system.

<sup>10</sup>[http://mturkpublic.s3.amazonaws.com/docs/MTURK\\_BP.pdf](http://mturkpublic.s3.amazonaws.com/docs/MTURK_BP.pdf)

<sup>7</sup><http://nlp.cs.qc.cuny.edu/kbp/2010/>

et al. (2010), plant gold-standard questions: each task consists of five yes/no questions, one of which comes from our gold-standard pool.<sup>11</sup> By retaining only those answers that are consistent with this protocol, we are able to filter responses that were not answered with care or competency. We only use answers from workers who display overall high consistency with the gold standard (i.e., correctly answering at least 80% of the gold-standard questions).

### 3.4 Statistical Modeling Issues

Following Mintz et al. (2009), we use logistic regression classifiers to represent relation extractors. However, while Mintz et al. use a single multi-class classifier for all relations, Hoffman et al. (2011) and use an independent binary classifier for each individual relation; the intuition is that a pair of mentions (or entities) might participate in multiple target relations. We experimented with both protocols; since relation overlapping is rare for TAC-KBP and there was little difference in result quality, we focus on the binary-classification approach using training examples constructed as described in Section 3.1.

We compensate for the different sizes of distant and human labeled examples by training an objective function that allows to tune the weight of human versus distant labeling. We separately tune this parameter for each training set (with cross validation), but found that the result quality was robust with respect to a broad range of parameter values.<sup>12</sup>

## 4 Experiments

We describe our experiments to test the hypotheses that the following two factors improve distant-supervision quality: increasing the

- (1) corpus size, and
- (2) the amount of crowd-sourced feedback.

We confirm hypothesis (1), but, surprisingly, are unable to confirm (2). Specifically, when using logistic regression to train relation extractors, increasing corpus size improves, consistently and significantly, the precision and recall produced by distant supervision, regardless of human feedback levels. Using the

<sup>11</sup>We obtain the gold standard from a separate MTurk submission by taking examples that at least 10 out of 11 turkers answered yes, and then negate half of these examples by altering the relation names (e.g., *spouse* to *sibling*).

<sup>12</sup>More details in our technical report (Zhang et al., 2012).

methodology described in Section 3, human feedback has limited impact on the precision and recall produced from distant supervision by itself.

### 4.1 Evaluation Metrics

Just as direct training data are scarce, ground truth for relation extraction is scarce as well. As a result, prior work mainly considers two types of evaluation methods: (1) randomly sample a small portion of predictions (e.g., top-k) and manually evaluate precision/recall; and (2) use a held-out portion of seed facts (usually Freebase) as a kind of “distant” ground truth. We replace manual evaluation with a standardized relation-extraction benchmark: TAC-KBP 2010. TAC-KBP asks for extractions of 46 relations on a given set of 100 entities. Interestingly, the Freebase held-out metric (Mintz et al., 2009; Yao et al., 2010; Hoffmann et al., 2011) turns out to be heavily biased toward distantly labeled data (e.g., increasing human feedback *hurts* precision; see Section 4.6).

### 4.2 Experimental Setup

Our first group of experiments use the 1.8M-doc TAC-KBP corpus for training. We exclude from it the 33K documents that contain query entities in the TAC-KBP metrics. There are two key parameters: the corpus size (#docs)  $M$  and human feedback budget (#examples)  $N$ . We perform different levels of down-sampling on the training corpus. On TAC, we use subsets with  $M = 10^3, 10^4, 10^5$ , and  $10^6$  documents respectively. For each value of  $M$ , we perform 30 independent trials of uniform sampling, with each trial resulting in a training corpus  $D_i^M$ ,  $1 \leq i \leq 30$ . For each training corpus  $D_i^M$ , we perform distant supervision to train a set of logistic regression classifiers. From the full corpus, distant supervision creates around 72K training examples.

To evaluate the impact of human feedback, we randomly sample 20K examples from the input corpus (we remove any portion of the corpus that is used in an evaluation). Then, we ask three different crowd workers to label each example as either positive or negative using the procedure described in Section 3.3. We retain only credible answers using the gold-standard method (see Section 3.3), and use them as the pool of human feedback that we run experiments with. About 46% of our human labels are negative. Denote by  $N$  the number of examples that

Figure 2: Impact of input sizes under the TAC-KBP metric, which uses documents mentioning 100 predefined entities as testing corpus with entity-level ground truth. We vary the sizes of the training corpus and human feedback while measuring the scores (F1, recall, and precision) on the TAC-KBP benchmark.

we want to incorporate human feedback for; we vary  $N$  in the range of 0, 10,  $10^2$ ,  $10^3$ ,  $10^4$ , and  $2 \times 10^4$ . For each selected corpus and value of  $N$ , we perform without-replacement sampling from examples of this corpus to select feedback for up to  $N$  examples. In our experiments, we found that on average an  $M$ -doc corpus contains about  $0.04M$  distant labels, out of which  $0.01M$  have human feedback. After incorporating human feedback, we evaluate the relation extractors on the TAC-KBP benchmark. We then compute the average F1, recall, and precision scores among all trials for each metric and each  $(M,N)$  pair. Besides the KBP metrics, we also evaluate each  $(M,N)$  pair using Freebase held-out data. Furthermore, we experiment with a much larger corpus: ClueWeb09. On ClueWeb09, we vary  $M$  over  $10^3, \dots, 10^8$ . Using the same metrics, we show at a larger scale that increasing corpus size can significantly improve both precision and recall.

### 4.3 Overall Impact of Input Sizes

We first present our experiment results on the TAC corpus. As shown in Figure 2, the F1 graph closely tracks the recall graph, which supports our earlier claim that quality is recall gated (Section 1). While increasing the corpus size improves F1 at a roughly log-linear rate, human feedback has little impact until both corpus size and human feedback size approach maximum  $M, N$  values. Table 1 shows the quality comparisons with minimum/maximum values of  $M$  and  $N$ .<sup>13</sup> We observe that increasing the corpus size significant improves per-relation recall

<sup>13</sup>When the corpus size is small, the total number of examples with feedback can be smaller than the budget size  $N$  – for example, when  $M = 10^3$  there are on average 10 examples with feedback even if  $N = 10^4$ .

	$M = 10^3$	$M = 1.8 \times 10^6$
$N = 0$	0.124	0.201
$N = 2 \times 10^4$	0.118	0.214

Table 1: TAC F1 scores with max/min values of  $M/N$ .

and F1 on 17 out of TAC-KBP’s 20 relations; in contrast, human feedback has little impact on recall, and only significantly improves the precision and F1 of 9 relations – while hurting F1 of 2 relations (i.e., `MemberOf` and `LivesInCountry`).<sup>14</sup>

(a) Impact of corpus size changes.

$M \setminus N$	0	10	$10^2$	$10^3$	$10^4$	$2e4$
$10^3 \rightarrow 10^4$	+	+	+	+	+	+
$10^4 \rightarrow 10^5$	+	+	+	+	+	+
$10^5 \rightarrow 10^6$	+	+	+	+	+	+
$10^6 \rightarrow 1.8e6$	0	0	0	+	+	+

(b) Impact of feedback size changes.

$N \setminus M$	$10^3$	$10^4$	$10^5$	$10^6$	$1.8e6$
$0 \rightarrow 10$	0	0	0	0	0
$10 \rightarrow 10^2$	0	0	0	+	+
$10^2 \rightarrow 10^3$	0	0	0	+	+
$10^3 \rightarrow 10^4$	0	0	0	0	+
$10^4 \rightarrow 2e4$	0	0	0	0	-
$0 \rightarrow 2e4$	0	0	0	+	+

Table 2: Two-tail t-test with d.f.=29 and  $p=0.05$  on the impact of corpus size and feedback size changes respectively. (We also tried  $p=0.01$ , which resulted in change of only a single cell in the two tables.) In (a), each column corresponds to a fixed human-feedback budget size  $N$ . Each row corresponds to a jump from one corpus size  $(M)$  to the immediate larger size. Each cell value indicates whether the TAC F1 metric changed significantly: + (resp. -) indicates that the quality increased (resp. decreased) significantly; 0 indicates that the quality did not change significantly. Table (b) is similar.

<sup>14</sup>We report more details on per-relation quality in our technical report (Zhang et al., 2012).

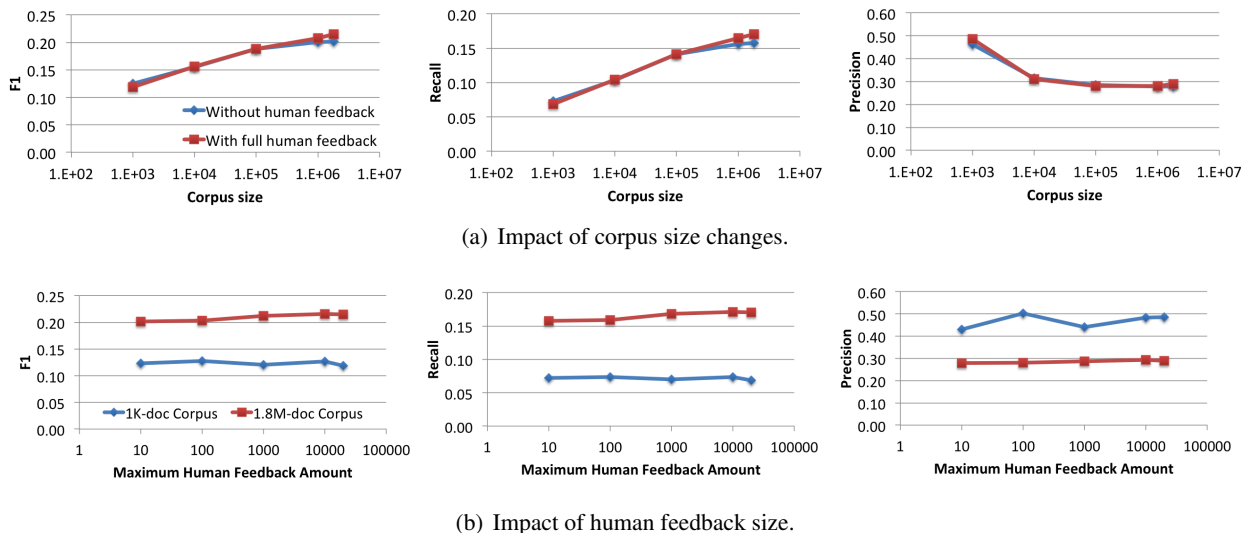

Figure 3: Projections of Figure 2 to show the impact of corpus size and human feedback amount on TAC-KBP F1, recall, and precision.

#### 4.4 Impact of Corpus Size

In Figure 3(a) we plot a projection of the graphs in Figure 2 to show the impact of corpus size on distant-supervision quality. The two curves correspond to when there is no human feedback and when we use all applicable human feedback. The fact that the two curves almost overlap indicates that human feedback had little impact on precision or recall. On the other hand, the quality improvement rate is roughly log-linear against the corpus size. Recall that each data point in Figure 2 is the average from 30 trials. To measure the statistical significance of changes in F1, we calculate t-test results to compare adjacent corpus size levels given each fixed human feedback level. As shown in Table 2(a), increasing the corpus size by a factor of 10 consistently and significantly improves F1. Although precision decreases as we use larger corpora, the decreasing trend is sub-log-linear and stops at around 100K docs. On the other hand, recall and F1 keep increasing at a log-linear rate.

#### 4.5 Impact of Human Feedback

Figure 3(b) provides another perspective on the results under the TAC metric: We fix a corpus size and plot the F1, recall, and precision as functions of human-feedback amount. Confirming the trend in Figure 2, we see that human feedback has little

Figure 4: TAC-KBP quality of relation extractors trained using different amounts of human labels. The horizontal lines are comparison points.

impact on precision or recall with both corpus sizes.

We calculate t-tests to compare adjacent human feedback levels given each fixed corpus size level. Table 2(b)'s last row reports the comparison, for various corpus sizes (and, hence, number of distant labels), of (i) using no human feedback and (ii) using *all* of the human feedback we collected. When the corpus size is small (fewer than  $10^5$  docs), human feedback has no statistically significant impact on F1. The locations of '+'s suggest that the influence of human feedback becomes notable only when the corpus is very large (say with  $10^6$  docs). However, comparing the slopes of the curves in Figure 3(b) against Figure 3(a), the impact of human feedback is substantially smaller. The precision graph in Figure 3(b) suggests that human feedback does not no-

Figure 5: Impact of input sizes under the Freebase held-out metric. Note that the human feedback axis is in the reverse order compared to Figure 2.

tably improve precision on either the full corpus or on a small 1K-doc corpus. To assess the quality of human labels, we train extraction models with human labels only (on examples obtained from distant supervision). We vary the amount of human labels and plot the F1 changes in Figure 4. Although the F1 improves as we use more human labels, the best model has roughly the same performance as those trained from distant labels (with or without human labels). This suggests that the accuracy of human labels is not substantially better than distant labels.

#### 4.6 Freebase Held-out Metric

In addition to the TAC-KBP benchmark, we also follow prior work (Mintz et al., 2009; Yao et al., 2010; Hoffmann et al., 2011) and measure the quality using held-out data from Freebase. We randomly partition both Freebase and the corpus into two halves. One database-corpus pair is used for training and the other pair for testing. We evaluate the precision over the  $10^3$  highest-probability predictions on the test set. In Figure 5, we vary the size of the corpus in the train pair and the number of human labels; the precision reaches a dramatic peak when the corpus size is above  $10^5$  and uses little human feedback. This suggests that this Freebase held-out metric is biased toward solely relying on distant labels alone.

#### 4.7 Web-scale Corpora

To study how a Web corpus impacts distant-supervision quality, we select the first 100M English webpages from the ClueWeb09 dataset and measure how distant-supervision quality changes as we vary the number of webpages used. As shown in Figure 6, increasing the corpus size improves F1 up to

Figure 6: Impact of corpus size on the TAC-KBP quality with the ClueWeb dataset.

$10^7$  docs ( $p = 0.05$ ), while at  $10^8$  the two-tailed significance test reports no significant impact on F1 ( $p = 0.05$ ). The dip in precision in Figure 6 from  $10^6$  to either  $10^7$  or  $10^8$  is significant ( $p = 0.05$ ), and it is interesting future work to perform a detailed error analysis. Recall from Section 3 that to preprocess ClueWeb we use MaltParser instead of Ensemble. Thus, the F1 scores in Figure 6 are not comparable to those from the TAC training corpus.

## 5 Discussion and Conclusion

We study how the size of two types of cheaply available resources impact the precision and recall of distant supervision: (1) an unlabeled text corpus from which distantly labeled training examples can be extracted, and (2) crowd-sourced labels on training examples. We found that text corpus size has a stronger impact on precision and recall than human feedback. We observed that distant-supervision systems are often *recall gated*; thus, to improve distant-supervision quality, one should first try to enlarge the input training corpus and then increase precision.

It was initially counter-intuitive to us that human labels did not have a large impact on precision. One reason is that human labels acquired from crowd-sourcing have comparable noise level as distant labels – as shown by Figure 4. Thus, techniques that improve the accuracy of crowd-sourced answers are an interesting direction for future work. We used a particular form of human input (yes/no votes on distant labels) and a particular statistical model to incorporate this information (logistic regression). It is interesting future work to study other types of human input (e.g., new examples or features) and more sophisticated techniques for incorporating human input, as well as machine learning methods that explicitly model feature interactions.

# Automatic Event Extraction with Structured Preference Modeling

Wei Lu and Dan Roth

University of Illinois at Urbana-Champaign

{luwei,danr}@illinois.edu

## Abstract

This paper presents a novel sequence labeling model based on the latent-variable semi-Markov conditional random fields for jointly extracting argument roles of events from texts. The model takes in coarse mention and type information and predicts argument roles for a given event template.

This paper addresses the event extraction problem in a primarily unsupervised setting, where no labeled training instances are available. Our key contribution is a novel learning framework called *structured preference modeling* (PM), that allows arbitrary preference to be assigned to certain structures during the learning procedure. We establish and discuss connections between this framework and other existing works. We show empirically that the structured preferences are crucial to the success of our task. Our model, trained without annotated data and with a small number of structured preferences, yields performance competitive to some baseline supervised approaches.

## 1 Introduction

Automatic template-filling-based event extraction is an important and challenging task. Consider the following text span that describes an “Attack” event:

... North Korea’s military may have fired a laser at a U.S. helicopter in March, a U.S. official said Tuesday, as the communist state ditched its last legal obligation to keep itself free of nuclear weapons ...

A partial event template for the “Attack” event is shown on the left of Figure 1. Each row shows an

argument for the event, together with a set of its acceptable mention types, where the type specifies a high-level semantic class a mention belongs to.

The task is to automatically fill the template entries with texts extracted from the text span above. The correct filling of the template for this particular example is shown on the right of Figure 1.

Performing such a task without any knowledge about the semantics of the texts is hard. One typical assumption is that certain coarse mention-level information, such as mention boundaries and their semantic class (a.k.a. *types*), are available. E.g.:

... [North Korea’s military]<sub>ORG</sub> may have fired [a laser]<sub>WEA</sub> at [a U.S. helicopter]<sub>VEH</sub> in [March]<sub>TME</sub>, a U.S. official said Tuesday, as the communist state ditched its last legal obligation to keep itself free of nuclear weapons ...

Such mention type information as shown on the left of Figure 1 can be obtained from various sources such as dictionaries, gazetteers, rule-based systems (Strötgen and Gertz, 2010), statistically trained classifiers (Ratinov and Roth, 2009), or some web resources such as Wikipedia (Ratinov et al., 2011).

However, in practice, outputs from existing mention identification and typing systems can be far from ideal. Instead of obtaining the above ideal annotation, one might observe the following noisy and ambiguous annotation for the given event span:

... [[North Korea’s]<sub>GPE|LOC</sub> military]<sub>ORG</sub> may have fired a laser at [a [U.S.]<sub>GPE|LOC</sub> helicopter]<sub>VEH</sub> in [March]<sub>TME</sub>, [a [U.S.]<sub>GPE|LOC</sub> official]<sub>PER</sub> said [Tuesday]<sub>TME</sub>, as [the communist state]<sub>ORG|FAC|LOC</sub> ditched its last legal obligation to keep [itself]<sub>ORG</sub> free of [nuclear weapons]<sub>WEA</sub> ...

Our task is to design a model to effectively select mentions in an event span and assign them with corresponding argument information, given such coarse

Argument	Possible Types	Extracted Text
ATTACKER	GPE, ORG, PER	<i>N. Korea's military</i>
INSTRUMENT	VEH, WEA	<i>a laser</i>
PLACE	FAC, GPE, LOC	-
TARGET	FAC, GPE, LOC ORG, PER, VEH	<i>a U.S. helicopter</i>
TIME-WITHIN	TME	<i>March</i>

Figure 1: The partial event template for the Attack event (left), and the correct event template annotation for the example event span given in Sec 1 (right). We primarily follow the ACE standard in defining arguments and types.

and often noisy mention type annotations.

This work addresses this problem by making the following contributions:

- Naturally, we are interested in identifying the active mentions (the mentions that serve as arguments) and their correct boundaries from the data. This motivates us to build a novel latent-variable semi-Markov conditional random fields model (Sarawagi and Cohen, 2004) for such an event extraction task. The learned model takes in coarse information as produced by existing mention identification and typing modules, and jointly outputs selected mentions and their corresponding argument roles.
- We address the problem in a more realistic scenario where annotated training instances are not available. We propose a novel general learning framework called *structured preference modeling* (or *preference modeling*, PM), which encompasses both the fully supervised and the latent-variable conditional models as special cases. The framework allows arbitrary declarative structured preference knowledge to be introduced to guide the learning procedure in a primarily unsupervised setting.

We present our semi-Markov model and discuss our preference modeling framework in Section 2 and 3 respectively. We then discuss the model’s relation with existing constraint-driven learning frameworks in Section 4. Finally, we demonstrate through experiments that structured preference information is crucial to model and present empirical results on a standard dataset in Section 5.

## 2 The Model

It is not hard to observe from the example presented in the previous section that dependencies between

Figure 2: A simplified graphical illustration for the semi-Markov CRF, under a specific segmentation  $S \equiv \overline{C_1 C_2 \dots C_n}$ . In a supervised setting, only correct arguments are observed but their associated correct mention types are hidden (shaded).

arguments can be important and need to be properly modeled. This motivates us to build a joint model for extracting the event structures from the text.

We show a simplified graphical representation of our model in Figure 2. In the graph,  $C_1, C_2 \dots C_n$  refer to a particular segmentation of the event span, where  $C_1, C_3 \dots$  correspond to mentions (e.g., “North Korea’s military”, “a laser”) and  $C_2, C_4 \dots$  correspond to in-between mention word sequences (we call them *gaps*) (e.g., “may have fired”). The symbols  $T_1, T_3 \dots$  refer to mention types (e.g., GPE, ORG). The symbols  $A_1, A_3 \dots$  refer to event arguments that carry specific roles (e.g., ATTACKER). We also introduce symbols  $B_2, B_4 \dots$  to refer to inter-argument gaps. The event span is split into segments, where each segment is either linked to a mention type ( $T_i$ ; these segments can be referred to as “argument segments”), or directly linked to an inter-argument gap ( $B_j$ ; they can be referred to as “gap segments”). The two types of segments appear in the sequence in a strictly alternate manner, where the gaps can be of length zero. In the figure, for example, the segments  $C_1$  and  $C_3$  are identified as two argument segments (which are mentions of types  $T_1$  and  $T_3$  respectively) and are mapped to two “nodes”, and the segment  $C_2$  is identified as a gap segment that connects the two arguments  $A_1$  and  $A_3$ . Note that no overlapping arguments are allowed in this model<sup>1</sup>.

We use  $s$  to denote an event span and  $t$  to denote a specific realization (filling) of the event template. Templates consist of a set of arguments. Denote by  $h$  a particular mention boundary and type assignment for an event span, which gives us a specific segmentation of the given span. Following the conditional

<sup>1</sup>Extending the model to support certain argument overlapping is possible – we leave it for future work.

random fields model (Lafferty et al., 2001), we parameterize the conditional probability of the  $(t, h)$  pair given an event span  $s$  as follows:

$$P_{\Theta}(t, h|s) = \frac{e^{\mathbf{f}(s, h, t) \cdot \Theta}}{\sum_{t, h} e^{\mathbf{f}(s, h, t) \cdot \Theta}} \quad (1)$$

where  $\mathbf{f}$  gives the feature functions defined on the tuple  $(s, h, t)$ , and  $\Theta$  defines the parameter vector.

Our objective function is the logarithm of the joint conditional probability of observing the template realization for the observed event span  $s$ :

$$\begin{aligned} \mathcal{L}(\Theta) &= \sum_i \log P_{\Theta}(t_i|s_i) \\ &= \sum_i \log \frac{\sum_h e^{\mathbf{f}(s_i, h, t_i) \cdot \Theta}}{\sum_{t, h} e^{\mathbf{f}(s_i, h, t) \cdot \Theta}} \end{aligned} \quad (2)$$

This function is not convex due to the summation over the hidden variable  $h$ . To optimize it, we take its partial derivative with respect to  $\theta_j$ :

$$\begin{aligned} \frac{\partial \mathcal{L}(\Theta)}{\partial \theta_j} &= \sum_i \mathbb{E}_{p_{\Theta}(h|s_i, t_i)}[f_j(s_i, h, t_i)] \\ &\quad - \sum_i \mathbb{E}_{p_{\Theta}(t, h|s_i)}[f_j(s_i, h, t)] \end{aligned} \quad (3)$$

which requires computation of expectations terms under two different distributions. Such statistics can be collected efficiently with a forward-backward style algorithm in polynomial time (Okanohara et al., 2006). We will discuss the time complexity for our case in the next section.

Given its partial derivatives in Equation 3, one could optimize the objective function of Equation 2 with stochastic gradient ascent (LeCun et al., 1998) or L-BFGS (Liu and Nocedal, 1989). We choose to use L-BFGS for all our experiments in this paper.

Inference involves computing the most probable template realization  $t$  for a given event span:

$$\arg \max_t P_{\Theta}(t|s) = \arg \max_t \sum_h P_{\Theta}(t, h|s) \quad (4)$$

where the possible hidden assignments  $h$  need to be marginalized out. In this task, a particular realization  $t$  already uniquely defines a particular segmentation (mention boundaries) of the event span, thus the  $h$  only contributes type information to  $t$ . As we will discuss in Section 2.3, only a collection of local features are defined. Thus, a Viterbi-style dynamic programming algorithm is used to efficiently compute the desired solution.

## 2.1 Possible Segmentations

According to Equation 3, summing over all possible  $h$  is required. Since one primary assumption is that we have access to the output of existing mention identification and typing systems, the set of all possible mentions defines a lattice representation containing the set of all possible segmentations that comply with such mention-level information. Assuming there are  $A$  possible arguments for the event and  $K$  annotated mentions, the complexity of the forward-backward style algorithm is in  $O(A^3 K^2)$  under the “second-order” setting that we will discuss in Section 2.2. Typically,  $K$  is smaller than the number of words in the span, and the factor  $A^3$  can be regarded as a constant. Thus, the algorithm is very efficient.

As we have mentioned earlier, such coarse information, as produced by existing resources, could be highly ambiguous and noisy. Also, the output mentions can highly overlap with each other. For example, the phrase “North Korea” as in “North Korea’s military” can be assigned both type GPE and LOC, while “North Korea’s military” can be assigned the type ORG. Our model will need to disambiguate the mention boundaries as well as their types.

## 2.2 The Gap Segments

We believe the gap segments<sup>2</sup> are important to model since they can potentially capture dependencies between two or more adjacent arguments. For example, the word sequence “may have fired” clearly indicates an Attacker-Instrument relation between the two mentions “North Korea’s military” and “a laser”. Since we are only interested in modeling dependencies between adjacent argument segments, we assign hard labels to each gap segment based on its contextual argument information. Specifically, the label of each gap segment is uniquely determined by its surrounding argument segments with a list representation. For example, in a “first-order” setting, the gap segment that appears between its previous argument segment “ATTACKER” and its next argument segment “INSTRUMENT” is annotated as the list consisting of two elements: [ATTACKER, INSTRUMENT]. To capture longer-range dependencies, in this work we use a “second-order” setting (as shown in Figure 2),

<sup>2</sup>The length of a gap segment is arbitrary (including zero), unlike the seminal semi-Markov CRF model of Sarawagi and Cohen (2004).

which means each gap segment is annotated with a list that consists of its previous two argument segments as well as its subsequent one.

### 2.3 Features

Feature functions are factorized as products of two indicator functions: one defined on the input sequence (input features) and the other on the output labels (output features). In other words, we could re-write  $f_j(s, h, t)$  as  $f_k^{in}(s) \times f_l^{out}(h, t)$ .

For gap segments, we consider the following input feature templates:

- N-GRAM: Indicator function for  $n$ -gram appeared in the segment ( $n = 1, 2$ )
- ANCHOR: Indicator function for its relative position to the event anchor words (to the left, to the right, overlaps, contains)

and the following output feature templates:

- 1STORDER: Indicator function for the combination of its immediate left argument and its immediate right argument.
- 2NDOORDER: Indicator function for the combination of its immediate two left arguments and its immediate right argument.

For argument segments, we also define the same input feature templates as above, with the following additional ones to capture contextual information:

- CWORDS: Indicator function for the previous and next  $k$  ( $= 1, 2, 3$ ) words.
- CPOS: Indicator function for the previous and next  $k$  ( $= 1, 2, 3$ ) words' POS tags.

and we define the following output feature template:

- ARGTYPE: Indicator function for the combination of the argument and its associated type.

Although the semi-Markov CRF model gives us the flexibility in introducing features that can not be exploited in a standard CRF, such as entity name similarity scores and distance measures, in practice we found the above simple and general features work well. This way, the unnormalized score assigned to each structure is essentially a linear sum of the feature weights, each corresponding to an indicator function.

## 3 Learning without Annotated Data

The supervised model presented in the previous section requires substantial human efforts to annotate the training instances. Human annotations can be very expensive and sometimes impractical. Even if annotators are available, getting annotators to agree

with each other is often a difficult task in itself. Worse still, annotations often can not be reused: experimenting on a different domain or dataset typically require annotating new training instances for that particular domain or dataset.

We investigate inexpensive methods to alleviate this issue in this section. We introduce a novel general learning framework called *structured preference modeling*, which allows arbitrary prior knowledge about structures to be introduced to the learning process in a declarative manner.

### 3.1 Structured Preference Modeling

Denote by  $\mathcal{X}_\Omega$  and  $\mathcal{Y}_\Omega$  the entire input and output space, respectively. For a particular input  $x \in \mathcal{X}_\Omega$ , the set  $x \times \mathcal{Y}_\Omega$  gives us all possible structures that contain  $x$ . However, structures are not equally good. Some structures are generally regarded as better structures while some are worse.

Let's assume there is a function  $\kappa : \{x \times \mathcal{Y}_\Omega \rightarrow [0, 1]\}$  that measures the quality of the structures. This function returns the quality of a certain structure  $(x, y)$ , where the value 1 indicates a perfect structure, and 0 an impossible structure.

Under such an assumption, it is easy to observe that for a good structure  $(x, y)$ , we have  $p_\Theta(x, y) \times \kappa(x, y) = p_\Theta(x, y)$ , while for a bad structure  $(x, y)$ , we have  $p_\Theta(x, y) \times \kappa(x, y) = 0$ .

This motivates us to optimize the following objective function:

$$\mathcal{L}_u(\Theta) = \sum_i \log \frac{\sum_y p_\Theta(x_i, y) \times \kappa(x_i, y)}{\sum_y p_\Theta(x_i, y)} \quad (5)$$

Intuitively, optimizing such an objective function is equivalent to pushing the probability mass from bad structures to good structures corresponding to the same input.

When the preference function  $\kappa$  is defined as the indicator function for the correct structure  $(x_i, y_i)$ , the numerator terms of the above formula are simply of the forms  $p_\Theta(x_i, y_i)$ , and the model corresponds to the fully supervised CRF model.

The model also contains the latent-variable CRF as a special case. In a latent-variable CRF, we have input-output pairs  $(x_i, y_i)$ , but the underlying specific structure  $h$  that contains both  $x_i$  and  $y_i$  is hidden. The objective function is:

$$\sum_i \log \frac{\sum_h p_\Theta(x_i, h, y_i)}{\sum_{h, y'} p_\Theta(x_i, h, y')} \quad (6)$$

where  $p_{\Theta}(x_i, h, y_i) = 0$  unless  $h$  contains  $(x_i, y_i)$ . We define the following two functions:

$$q_{\Theta}(x_i, h) = \sum_{y'} p_{\Theta}(x_i, h, y') \quad (7)$$

$$\kappa(x_i, h) = \begin{cases} 1 & h \text{ contains } (x_i, y_i) \\ 0 & \text{otherwise} \end{cases} \quad (8)$$

Note that this definition of  $\kappa$  models instance-specific preferences since it relies on  $y_i$ , which can be thought of as certain external prior knowledge related to  $x_i$ . It is easy to verify that  $p_{\Theta}(x_i, h, y_i) = q_{\Theta}(x_i, h) \times \kappa(x_i, h)$ , with  $q_{\Theta}$  remains a distribution. Thus, we could re-write the objective function as:

$$\sum_{i=1} \log \frac{\sum_h q_{\Theta}(x_i, h) \times \kappa(x_i, h)}{\sum_h q_{\Theta}(x_i, h)} \quad (9)$$

This shows that the latent-variable CRF is a special case of our objective function, with the above-defined  $\kappa$  function. Thus, this new objective function of Equation 5 is a generalization of both the supervised CRF and the latent-variable CRF.

The preference function  $\kappa$  serves as a source from which certain prior knowledge about the structure can be injected into our model in a principled way. Note that the function is defined at the complete structure level. This allows us to incorporate both local and arbitrary global structured information into the preference function.

Under the log-linear parameterization, we have:

$$\mathcal{L}'(\Theta) = \sum_i \log \frac{\sum_y e^{\mathbf{f}(x_i, y) \cdot \Theta} \times \kappa(x_i, y)}{\sum_y e^{\mathbf{f}(x_i, y) \cdot \Theta}} \quad (10)$$

This is again a non-convex optimization problem in general, and to solve it we take its partial derivative with respect to  $\theta_k$ :

$$\begin{aligned} \frac{\partial \mathcal{L}'(\Theta)}{\partial \theta_k} &= \sum_i \mathbb{E}_{p_{\Theta}(y|x_i; \kappa)} [f_k(x_i, y)] \\ &\quad - \sum_i \mathbb{E}_{p_{\Theta}(y|x_i)} [f_k(x_i, y)] \quad (11) \\ p_{\Theta}(y|x_i; \kappa) &\propto e^{\mathbf{f}(x_i, y) \cdot \Theta} \times \kappa(x_i, y) \\ p_{\Theta}(y|x_i) &\propto e^{\mathbf{f}(x_i, y) \cdot \Theta} \end{aligned}$$

### 3.2 Approximate Learning

Computation of the denominator terms of Equation 10 (and the second term of Equation 11) can be done

efficiently and exactly with dynamic programming. Our main concern is the computation of its numerator terms (and the first term of Equation 11).

The preference function  $\kappa$  is defined at the complete structure level. Unless the function is defined in specific forms that allow tractable dynamic programming (in the supervised case, which gives a unique term, or in the hidden variable case, which can define a packed representations of derivations), the efficient dynamic programming algorithm used by CRF is no longer generally applicable for arbitrary  $\kappa$ . In general, we resort to approximations.

In this work, we exploit a specific form of the preference function  $\kappa$ . We assume that there exists a projection from another decomposable function to  $\kappa$ . Specifically, we assume a collection of auxiliary functions, each of the form  $\kappa_p : (x, y) \rightarrow R$ , that scores a property  $p$  of the complete structure  $(x, y)$ . Each such function measures certain aspect of the quality of the structure. These functions assign positive scores to good structural properties and negative scores to bad ones. We then define  $\kappa(x, y) = 1$  for all structures that appear at the top- $n$  positions as ranked by  $\sum_p \kappa_p(x, y)$  for all possible  $y$ 's, and  $\kappa(x, y) = 0$  otherwise. We show some actual  $\kappa_p$  functions used for a particular event in Section 5.

At each iteration of the training process, to generate such a  $n$ -best list, we first use our model to produce top  $n \times b$  candidate outputs as scored by the current model parameters, and extract the top  $n$  outputs as scored by  $\sum_p \kappa_p(x, y)$ . In practice we set  $n = 10$  and  $b = 1000$ .

### 3.3 Event Extraction

Now we can obtain the objective function for our event extraction task. We replace  $x$  by  $s$  and  $y$  by  $(h, t)$  in Equation 10. This gives us the following function:

$$\mathcal{L}_u(\Theta) = \sum_i \log \frac{\sum_{t, h} e^{\mathbf{f}(s_i, h, t) \cdot \Theta} \times \kappa(s_i, h, t)}{\sum_{t, h} e^{\mathbf{f}(s_i, h, t) \cdot \Theta}} \quad (12)$$

The partial derivatives are as follows:

$$\begin{aligned} \frac{\partial \mathcal{L}_u(\Theta)}{\partial \theta_k} &= \sum_i \mathbb{E}_{p_{\Theta}(t, h|s_i; \kappa)} [f_k(s_i, h, t)] \\ &\quad - \sum_i \mathbb{E}_{p_{\Theta}(t, h|s_i)} [f_k(s_i, h, t)] \quad (13) \\ p_{\Theta}(t, h|s_i; \kappa) &\propto e^{\mathbf{f}(s_i, h, t) \cdot \Theta} \times \kappa(s_i, h, t) \\ p_{\Theta}(t, h|s_i) &\propto e^{\mathbf{f}(s_i, h, t) \cdot \Theta} \end{aligned}$$

Recall that  $s$  is an event span,  $t$  is a specific realization of the event template, and  $h$  is the hidden mention information for the event span.

#### 4 Discussion: Preferences v.s. Constraints

Note that the objective function in Equation 5, if written in the additive form, leads to a cost function reminiscent of the one used in constraint-driven learning algorithm (CoDL) (Chang et al., 2007) (and similarly, posterior regularization (Ganchev et al., 2010), which we will discuss later at Section 6). Specifically, in CoDL, the following cost function is involved in its EM-like inference procedure:

$$\arg \max_y \Theta \cdot \mathbf{f}(x, y) - \rho \sum_c d(y, \mathcal{Y}_c) \quad (14)$$

where  $\mathcal{Y}_c$  defines the set of  $y$ 's that all satisfy a certain constraint  $c$ , and  $d$  defines a distance function from  $y$  to that set. The parameter  $\rho$  controls the degree of the penalty when constraints are violated.

There are some important distinctions between structured preference modeling (PM) and CoDL. CoDL primarily concerns *constraints*, which penalizes bad structures without explicitly rewarding good ones. On the other hand, PM concerns *preferences*, which can explicitly reward good structures.

Constraints are typically useful when one works on structured prediction problems for data with certain (often rigid) regularities, such as citations, advertisements, or POS tagging for complete sentences. In such tasks, desired structures typically present certain canonical forms. This allows declarative constraints to be specified as either local structure prototypes (e.g., in citation extraction, the word *pp.* always corresponds to the PAGES field, while *proceedings* is always associated with BOOKTITLE or JOURNAL), or as certain global regulations about complete structures (e.g., at least one word should be tagged as verb when performing a sentence-level POS tagging).

Unfortunately, imposing such (hard or soft) constraints for certain tasks such as ours, where the data tends to be of arbitrary forms without many rigid regularities, can be difficult and often inappropriate. For example, there is no guarantee that a certain argument will always be present in the event span, nor should a particular mention, if appeared, always be selected and assigned to a specific argument. For example, in the example event span given

in Section 1, both “*March*” and “*Tuesday*” are valid candidate mentions for the TIME-WITHIN argument given their annotated type TME. One important clue is that *March* appears after the word *in* and is located nearer to other mentions that can be potentially useful arguments. However, encoding such information as a general constraint can be inappropriate, as potentially better structures can be found if one considers other alternatives. On the other hand, if we believe the structural pattern “*at TARGET in TIME-WITHIN*” is in general considered a better sub-structure than “*said TIME-WITHIN*” for the “Attack” event, we may want to assign structured preference to a complete structure that contains the former, unless there exist other structured evidence showing the latter turns out to be better.

In this work, our preference function is related to another function that can be decomposed into a collection of property functions  $\kappa_p$ . Each of them scores a certain aspect of the complete structure. This formulation gives us a complete flexibility to assign arbitrary structured preferences, where positive scores can be assigned to good properties, and negative scores to bad ones. Thus, in this way, the quality of a complete structure is jointly measured with multiple different property functions.

To summarize, preferences are an effective way to “define” the event structure to the learner, which is essential in an unsupervised setting, which may not be easy to do with other forms of constraints. Preferences are naturally decomposable, which allows us to extend their impact without significantly effecting the complexity of inference.

## 5 Experiments

In this section, we present our experimental results on the standard ACE05<sup>3</sup> dataset (newswire portion). We choose to perform our evaluations on 4 events (namely, “Attack”, “Meet”, “Die” and “Transport”), which are the only events in this dataset that have more than 50 instances. For each event, we randomly split the instances into two portions, where 70% are used for learning, and the remaining 30% for evaluation. We list the corpus statistics in Table 2.

To present general results while making minimal assumptions, our primary event extraction results

Table 2: Corpus statistics (#A: number of possible arguments for the event; #I: number of instances; #M: number of active/total mentions; #P: number of preference patterns used for performing our structured preference modeling.)

are independent of mention identification and typing modules, which are based on the gold mention information as given by the dataset. Additionally, we present results obtained by exploiting our in-house automatic mention identification and typing module, which is a hybrid system that combines statistical and rule-based approaches. The module’s statistical component is trained on the ACE04 dataset (newswire portion) and overall it achieves a micro-averaged F1-measure of 71.25% at our dataset.

### 5.1 With Annotated Training Data

With hand-annotated training data, we are able to train our model in a fully supervised manner. The right part of Table 1 shows the performance for the fully supervised models. For comparison, we present results from several alternative approaches based a collection of locally trained maximum entropy (MaxEnt) classifiers. In these approaches, we treat each argument of the template as one possible output class, plus a special “NONE” class for not selecting it as an argument. We train and apply the classifiers on argument segments (i.e., mentions) only. All the models are trained with the same feature set used in the semi-CRF model.

In the simplest baseline approach MaxEnt-b, type information for each mention is simply treated as one special feature. In the approach MaxEnt-t, we instead use the type information to constrain the

classifier’s predictions based on the acceptable types associated with each argument. This approach gives better performance than that of MaxEnt-b. This indicates that such locally trained classifiers are not robust enough to disambiguate arguments that take different types. As such, type information serving as additional constraints at the end does help.

To assess the importance of structured preference, we also perform experiments where structured preference information is incorporated at the inference time of the MaxEnt classifiers. Specifically, for each event, we first generate  $n$ -best lists for output structures. Next, we re-rank this list based on scores from our structured preference functions (we used the same preferences as to be discussed in the next section). The results for these approaches are given in the column of MaxEnt-p of Table 1. This simple approach gives us significant improvements, closing the gap between locally trained classifiers and the joint model (in one case the former even outperforms the latter). Note that no structured preference information is used when training and evaluating our semi-CRF model. This set of results is not surprising. In fact, similar observations are also reported in previous works when comparing joint model against local models with constraints incorporated (Roth and Yih, 2005). This clearly indicates that structured preference information is crucial to model.

### 5.2 Without Annotated Training Data

Now we turn to experiments for the more realistic scenario where human annotations are not available.

We first build our simplest baseline by randomly assigning arguments to each mention with mention type information serving as constraints. Averaged results over 1000 runs are reported in the first column of Table 1.

Since our model formulation leaves us with complete freedom in designing the preference function,

Type	Preference pattern ( $p$ )
General	$\{at in on\}$ followed by PLACE $\{during at in on\}$ followed by TIME-WITHIN
Die	AGENT (immediately) followed by $\{killed\}$ $\{killed\}$ (immediately) followed by VICTIM VICTIM (immediately) followed by $\{be\ killed\}$ AGENT followed by $\{killed\}$ (immediately) followed by VICTIM
Transport	X immediately followed by $\{, and\}$ immediately followed by X, where $X \in \{ORIGIN DESTINATION\}$ $\{from leave\}$ (immediately) followed by ORIGIN $\{at in to into\}$ immediately followed by DESTINATION PERSON followed by $\{to visit arrived\}$

Figure 3: The **complete list** of preference patterns used for the “Die” and “Transport” event. We simply set  $\kappa_p = 1.0$  for all  $p$ ’s. In other words, when a structure contains a pattern, its score is incremented by 1.0. We use  $\{ \}$  to refer to a set of possible words or arguments. For example,  $\{from|leave\}$  means a word which is either *from* or *leave*. The symbol  $()$  denotes optional. For example, “ $\{killed\}$  (immediately) followed by VICTIM” is equivalent to the following two preferences: “ $\{killed\}$  immediately followed by VICTIM”, and “ $\{killed\}$  followed by VICTIM”.

one could design arbitrarily good, domain-specific or even instance-specific preferences. However, to demonstrate its general effectiveness, in this work we only choose a minimal amount of general preference patterns for evaluations.

We make our preference patterns as general as possible. As shown in the last column (#P) of Table 2, we use only 7 preference patterns each for the “Attack” and “Meet” events, and 6 patterns each for the other two events. In Figure 3, we show the complete list of the 6 preference patterns for the “Die” and “Transport” event used for our experiments. Out of those 6 patterns, 2 are more general patterns shared across different events, and 4 are event-specific. In contrast, for example, for the “Die” event, the supervised approach requires human to select from 174 candidate mentions and annotate 89 of them.

Despite its simplicity, it works very well in practice. Results are given in the column of “PM” of Table 1. It generally gives competitive performance as compared to the supervised MaxEnt baselines.

On the other hand, a completely unsupervised approach where structured preferences are not specified, performs substantially worse. To run such completely unsupervised models, we essentially follow the same training procedure as that of the preference modeling, except that structured preference information is not in place when generating the  $n$ -best list. In the absence of proper guidances, such a procedure can easily converge to bad local minima. The results are reported in the “Unsup” column of Table 1. In practice, we found that very often, such a model would prefer short structures where many mentions are not selected as desired. As a result, the

unsupervised model without preference information can even perform worse than the random baseline<sup>4</sup>.

Finally, we also compare against an approach that regards the preferences as rules. All such rules are associated with a same weight and are used to jointly score each structure. We then output the structure that is assigned the highest total weight. Such an approach performs worse than our approach with preference modeling. The results are presented in the column of “Rule” of Table 1. This indicates that our model is able to learn to generalize with features through the guidance of our informative preferences. However, we also note that the performance of preference modeling depends on the actual quality and amount of preferences used for learning. In the extreme case, where only few preferences are used, the performance of preference modeling will be close to that of the unsupervised approach, while the rule-based approach will yield performance close to that of the random baseline.

The results with automatically predicted mention boundaries and types are given in Table 3. Similar observations can be made when comparing the performance of preference modeling with other approaches. This set of results further confirms the effectiveness of our approach using preference modeling for the event extraction task.

## 6 Related Work

Structured prediction with limited supervision is a popular topic in natural language processing.

<sup>4</sup>For each event, we only performed 1 run with all the initial feature weights set to zeros.

Event	Random	Unsup	PM	semi-CRF
Attack	14.26	26.19	32.89	<b>46.92</b>
Meet	26.65	14.08	45.28	<b>58.18</b>
Die	19.17	9.09	44.44	<b>48.57</b>
Transport	15.78	10.14	49.73	<b>52.34</b>

Table 3: Event extraction performance with automatic mention identifier and typer. We report F1 percentage scores for preference modeling (PM) as well as two baseline approaches. We also report performance of the supervised approach trained with the semi-CRF model for comparison.

Prototype driven learning (Haghighi and Klein, 2006) tackled the sequence labeling problem in a primarily unsupervised setting. In their work, a Markov random fields model was used, where some local constraints are specified via their *prototype list*.

Constraint-driven learning (CoDL) (Chang et al., 2007) and posterior regularization (PR) (Ganchev et al., 2010) are both primarily semi-supervised models. They define a constrained EM framework that regularizes posterior distribution at the E-step of each EM iteration, by pushing posterior distributions towards a constrained posterior set. We have already discussed CoDL in Section 4 and gave a comparison to our model. Unlike CoDL, in the PR framework constraints are relaxed to *expectation constraints*, in order to allow tractable dynamic programming. See also Samdani et al. (2012) for more discussions.

Contrastive estimation (CE) (Smith and Eisner, 2005a) is another log-linear framework for primarily unsupervised structured prediction. Their objective function is related to the pseudolikelihood estimator proposed by Besag (1975). One challenge is that it requires one to design a priori an effective neighborhood (which also needs to be designed in certain forms to allow efficient computation of the normalization terms) in order to obtain optimal performance. The model has been shown to work in unsupervised tasks such as POS induction (Smith and Eisner, 2005a), grammar induction (Smith and Eisner, 2005b), and morphological segmentation (Poon et al., 2009), where good neighborhoods can be identified. However, it is less intuitive what constitutes a good neighborhood in this task.

The neighborhood assumption of CE is relaxed in another latent structure approach (Chang et al., 2010a; Chang et al., 2010b) that focuses on semi-supervised learning with indirect supervisions, inspired by the CoDL model described above.

The locally normalized logistic regression (Berg-

Kirkpatrick et al., 2010) is another recently proposed framework for unsupervised structured prediction. Their model can be regarded as a generative model whose component multinomial is replaced with a miniature logistic regression where a rich set of local features can be incorporated. Empirically the model is effective in various unsupervised structured prediction tasks, and outperforms the globally normalized model. Although modeling the semi-Markov properties of our segments (especially the gap segments) in our task is potentially challenging, we plan to investigate in the future the feasibility for our task with such a framework.

## 7 Conclusions

In this paper, we present a novel model based on the semi-Markov conditional random fields for the challenging event extraction task. The model takes in coarse mention boundary and type information and predicts complete structures indicating the corresponding argument role for each mention.

To learn the model in an unsupervised manner, we further develop a novel learning approach called *structured preference modeling* that allows structured knowledge to be incorporated effectively in a declarative manner.

Empirically, we show that knowledge about structured preference is crucial to model and the preference modeling is an effective way to guide learning in this setting. Trained in a primarily unsupervised manner, our model incorporating structured preference information exhibits performance that is competitive to that of some supervised baseline approaches. Our event extraction system and code will be available for download from our group web page.

## Abstract

This paper presents a joint model for template filling, where the goal is to automatically specify the fields of target relations such as seminar announcements or corporate acquisition events. The approach models mention detection, unification and field extraction in a flexible, feature-rich model that allows for joint modeling of interdependencies at all levels and across fields. Such an approach can, for example, learn likely event durations and the fact that start times should come before end times. While the joint inference space is large, we demonstrate effective learning with a Perceptron-style approach that uses simple, greedy beam decoding. Empirical results in two benchmark domains demonstrate consistently strong performance on both mention detection and template filling tasks.

## 1 Introduction

Information extraction (IE) systems recover structured information from text. Template filling is an IE task where the goal is to populate the fields of a target relation, for example to extract the attributes of a job posting (Califf and Mooney, 2003) or to recover the details of a corporate acquisition event from a news story (Freitag and McCallum, 2000).

This task is challenging due to the wide range of cues from the input documents, as well as non-textual background knowledge, that must be considered to find the best joint assignment for the fields of the extracted relation. For example, Figure 1 shows an extraction from CMU seminar announcement corpus (Freitag and McCallum, 2000). Here, the goal is to perform mention detection and extraction, by finding all of the text spans, or *mentions*,

"Some Necessary Conditions for a Good User Interface"

For our final Human-Computer Interaction seminar of the semester,
Raj Reddy will be presenting his thoughts on what makes a good
interface good. He hopes the discussion of "necessary conditions"
can serve as a source for new HCI research ideas. Should be a
thought-provoking way to transition to the summer!
```

Title	Some Necessary Conditions for a Good User Interface
End Time	-

Figure 1: An example email and its template. Field mentions are highlighted in the text, grouped by color.

that describe field values, unify these mentions by grouping them according to target field, and normalizing the results within each group to provide the final extractions. Each of these steps requires significant knowledge about the target relation. For example, in Figure 1, the mention “3:30” appears three times and provides the only reference to a time. We must infer that this is the starting time, that the end time is never explicitly mentioned, and also that the event is in the afternoon. Such inferences may not hold in more general settings, such as extraction for medical emergencies or related events.

In this paper, we present a joint modeling and learning approach for the combined tasks of mention detection, unification, and template filling, as described above. As we will see in Section 2, previous work has mostly focused on learning tagging

models for mention detection, which can be difficult to aggregate into a full template extraction, or directly learning template field value extractors, often in isolation and with no reasoning across different fields in the same relation. We present a simple, feature-rich, discriminative model that readily incorporates a broad range of possible constraints on the mentions and joint field assignments.

Such an approach allows us to learn, for each target relation, an integrated model to weight the different extraction options, including for example the likely lengths for events, or the fact that start times should come before end times. However, there are significant computation challenges that come with this style of joint learning. We demonstrate empirically that these challenges can be solved with a combination of greedy beam decoding, performed directly in the joint space of possible mention clusters and field assignments, and structured Perceptron-style learning algorithm (Collins, 2002).

We report experimental evaluations on two benchmark datasets in different genres, the CMU seminar announcements and corporate acquisitions (Freitag and McCallum, 2000). In each case, we evaluated both template extraction and mention detection performance. Our joint learning approach provides consistently strong results across every setting, including new state-of-the-art results. We also demonstrate, through ablation studies on the feature set, the need for joint modeling and the relative importance of the different types of joint constraints.

## 2 Related Work

Research on the task of template filling has focused on the extraction of field value mentions from the underlying text. Typically, these values are extracted based on local evidence, where the most likely entity is assigned to each slot (Roth and Yih, 2001; Siefkes, 2008). There has been little effort towards a comprehensive approach that includes mention unification, as well as considers the structure of the target relational schema to create semantically valid outputs.

Recently, Haghighi and Klein (2010) presented a generative semi-supervised approach for template filling. In their model, slot-filling entities are first generated, and entity mentions are then realized in text. Thus, their approach performs coreference at

slot level. In addition to proper nouns (named entity mentions) that are considered in this work, they also account for nominal and pronominal noun mentions. This work presents a discriminative approach to this problem. An advantage of a discriminative framework is that it allows the incorporation of rich and possibly overlapping features. In addition, we enforce label consistency and semantic coherence at record level.

Other related works perform structured relation discovery for different settings of information extraction. In *open IE*, entities and relations may be inferred jointly (Roth and Yih, 2002; Yao et al., 2011). In this IE task, the target relation must agree with the entity types assigned to it; e.g., *born-in* relation requires a *place* as its argument. In addition, extracted relations may be required to be consistent with an existing ontology (Carlson et al., 2010). Compared with the extraction of tuples of entity mention pairs, template filling is associated with a more complex target relational schema.

Interestingly, several researchers have attempted to model label consistency and high-level relational constraints using state-of-the-art sequential models of named entity recognition (NER). Mainly, predetermined word-level dependencies were represented as links in the underlying graphical model (Sutton and McCallum, 2004; Finkel et al., 2005). Finkel *et al.* (2005) further modelled high-level semantic constraints; for example, using the CMU seminar announcements dataset, spans labeled as *start time* or *end time* were required to be semantically consistent. In the proposed framework we take a bottom-up approach to identifying entity mentions in text, where given a noisy set of candidate named entities, described using rich semantic and surface features, discriminative learning is applied to label these mentions. We will show that this approach yields better performance on the CMU seminar announcement dataset when evaluated in terms of NER. Our approach is complimentary to NER methods, as it can consolidate noisy overlapping predictions from multiple systems into coherent sets.

## 3 Problem Setting

In the template filling task, a target relation  $r$  is provided, comprised of attributes (also referred to as

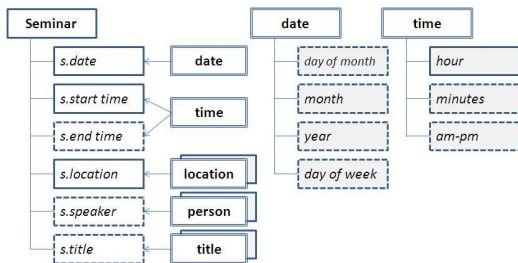

Figure 2: The relational schema for the seminars domain.

Figure 3: A record partially populated from text.

fields, or slots)  $A(r)$ . Given a document  $d$ , which is known to describe a tuple of the underlying relation, the goal is to populate the fields with values based on the text.

**The relational schema.** In this work, we describe domain knowledge through an extended relational database schema  $R$ . In this schema, every field of the target relation maps to a tuple of another relation, giving rise to a hierarchical view of template filling. Figure 2 describes a relational schema for the seminar announcement domain. As shown, each field of the *seminar* relation maps to another relation; e.g., *speaker*'s values correspond to *person* tuples. According to the outlined schema, most relations (e.g., *person*) consist of a single attribute, whereas the *date* and *time* relations are characterised with multiple attributes; for example, the *time* relation includes the fields of *hour*, *minutes* and *ampm*.

We will make use of limited domain knowledge, expressed as relation-level constraints that are typically realized in a database. Namely, the following tests are supported for each relation.

**Tuple validity.** This test reflects data integrity. The attributes of a relation may be defined as *mandatory* or *optional*. Mandatory attributes are denoted with a solid boundary in Figure 2 (e.g., *seminar.date*), and

optional attributes are denoted with a dashed boundary (e.g., *seminar.title*). Similar constraints can be posed on a set of attributes; e.g., either *day-of-month* or *day-of-week* must be populated in the *date* relation. Finally, a combination of field values may be required to be valid, e.g., the values of *day*, *month*, *year* and *day-of-week* must be consistent.

**Tuple contradiction.** This function checks whether two *valid* tuples  $v_1$  and  $v_2$  are inconsistent, implying a negation of possible unification of these tuples. In this work, we consider *date* and *time* tuples as contradictory if they contain semantically different values for some field; tuples of *location*, *person* and *title* are required to have minimal overlap in their string values to avoid contradiction.

**Template filling.** Given document  $d$ , the hierarchical schema  $R$  is populated in a bottom-up fashion. Generally, parent-free relations in the hierarchy correspond to generic entities, realized as entity mentions in the text. In Figure 2, these relations are denoted by double-line boundary, including *location*, *person*, *title*, *date* and *time*; every tuple of these relations maps to a named entity mention.<sup>1</sup>

Figure 3 demonstrates the correct mapping of named entity mentions to tuples, as well as tuple unification, for the example shown in Figure 1. For example, the mentions “Wean 5409” and “Wean Hall 5409” correspond to tuples of the *location* relation, where the two tuples are resolved into a unified set. To complete template filling, the remaining relations of the schema are populated bottom-up, where each field links to a unified set of populated tuples. For example, in Figure 3, the *seminar.location* field is linked to {“Wean Hall 5409”, “Wean 5409”}.

Value normalization of the unified tuples is another component of template filling. We partially address normalization: tuples of semantically detailed (multi-attribute) relations, e.g., *date* and *time*, are resolved into their semantic union, while textual tuples (e.g., *location*) are normalized to the longest string in the set. In this work, we assume that each template slot contains at most one value. This restriction can be removed, at the cost of increasing the size of the decoding search space.

<sup>1</sup>In the multi-attribute relations of *date* and *time*, each attribute maps to a text span, where the set of spans at tuple-level is required to be sequential (up to a small distance  $d$ ).

## 4 Structured Learning

Next, we describe how valid candidate extractions are instantiated (Sec. 4.1) and how learning is applied to assess the quality of the candidates (Sec. 4.2), where beam search is used to find the top scoring candidates efficiently (Sec. 4.3).

### 4.1 Candidate Generation

*Named entity recognition.* A set of candidate mentions  $S_d(a)$  is extracted from document  $d$  per each attribute  $a$  of a relation  $r \in L$ , where  $L$  is the set of parent-free relations in  $T$ . We aim at *high-recall* extractions; i.e.,  $S_d(a)$  is expected to contain the correct mentions with high probability. Various IE techniques, as well as an ensemble of methods, can be employed for this purpose. For each relation  $r \in L$ , *valid* candidate tuples  $E_d(r)$  are constructed from the candidate mentions that map to its attributes.

*Unification.* For every relation  $r \in L$ , we construct candidate sets of unified tuples,  $\{C_d(r) \subseteq E_d(r)\}$ . Naively, the number of candidate sets is exponential in the size of  $E_d(r)$ . Importantly, however, the tuples within a candidate unification set are required to be *non-contradictory*. In addition, the text spans that comprise the mentions within each set must not overlap. Finally, we do not split tuples with identical string values between different sets.

*Candidate tuples.* To construct the space of candidate tuples of the target relation, the remaining relations  $r \in \{T - L\}$  are visited bottom-up, where each field  $a \in A(r)$  is mapped in turn to a (possibly unified) populated tuple of its type. The valid (and non-overlapping) combinations of field mappings constitute a set of candidate tuples of  $r$ .

The candidate tuples generated using this procedure are structured entities, constructed using typed named entity recognition, unification, and hierarchical assignment of field values (Figure 3). We will derive features that describe local and global properties of the candidate tuples, encoding both surface and semantic information.

### 4.2 Learning

We employ a discriminative learning algorithm, following Collins (2002). Our goal is to find the candi-

### Algorithm 1: The beam search procedure

1. Populate every low-level relation  $r \in L$  from text  $d$ :
  - Construct a set of candidate valid tuples  $E_d(r)$  given high-recall typed candidate text spans  $S_d(a)$ ,  $a \in A(r)$ .
  - Group  $E_d(r)$  into possibly overlapping unified sets,  $\{C_d(r) \subseteq E_d(r)\}$ .
2. Iterate bottom-up through relations  $r \in \{T - L\}$ :
  - Initialize the set of candidate tuples  $E_d(r)$  to an empty set.
  - Iterate through attributes  $a \in A(r)$ :
    - Retrieve the set of candidate tuples (or unified tuple sets)  $E_d(r')$ , where  $r'$  is the relation that attribute  $a$  links to in  $T$ . Add an empty tuple to the set.
    - For every pair of candidate tuples  $e \in E_d(r)$  and  $e' \in E_d(r')$ , modify  $e$  by linking attribute  $a(e)$  to tuple  $e'$ .
    - Add the modified tuples, if valid, to  $E_d(r)$ .
    - Apply Equation 1 to rank the partially filled candidate tuples  $e \in E_d(r)$ . Keep the  $k$  top scoring candidates in  $E_d(r)$ , and discard the rest.
3. Apply Equation 1 to output a ranked list of extracted records  $E_d(r^*)$ , where  $r^*$  is the target relation.

date that maximizes:

$$F(y, \bar{\alpha}) = \sum_{j=1}^m \alpha_j f_j(y, d, T) \quad (1)$$

where  $f_j(d, y, T)$ ,  $j = 1, \dots, m$ , are pre-defined feature functions describing a candidate record  $y$  of the target relation given document  $d$  and the extended schema  $T$ . The parameter weights  $\alpha_j$  are to be learned from labeled instances. The training procedure involves initializing the weights  $\bar{\alpha}$  to zero. Given  $\bar{\alpha}$ , an inference procedure is applied to find the candidate that maximizes Equation 1. If the top-scoring candidate is different from the correct mapping known, then: (i)  $\bar{\alpha}$  is incremented with the feature vector of the correct candidate, and (ii) the feature vector of the top-scoring candidate is subtracted from  $\bar{\alpha}$ . This procedure is repeated for a fixed number of epochs. Following Collins, we employ the averaged Perceptron online algorithm (Collins, 2002; Freund and Schapire, 1999) for weight learning.

### 4.3 Beam Search

Unfortunately, optimal local decoding algorithms (such as the Viterbi algorithm in tagging problems (Collins, 2002)) can not be applied to our problem. We therefore propose using beam search to efficiently find the top scoring candidate. This means

that rather than instantiate the full space of valid candidate records (Section 4.1), we are interested in instantiating only those candidates that are likely to be assigned a high score by  $F$ . Algorithm 1 outlines the proposed beam search procedure. As detailed, only a set of top scoring tuples of size  $k$  (beam size) is maintained per relation  $r \in T$  during candidate generation. A given relation is populated incrementally, having each of its attributes  $a \in A(r)$  map in turn to populated tuples of its type, and using Equation 1 to find the  $k$  highest scoring *partially* populated tuples; this limits the number of candidate tuples evaluated to  $k^2$  per attribute, and to  $nk^2$  for a relation with  $n$  attributes. While beam search is efficient, performance may be compromised compared with an unconstrained search. The beam size  $k$  allows controlling the trade-off between performance and cost. An advantage of the proposed approach is that rather than output a single prediction, a list of coherent candidate tuples may be generated, ranked according to Equation 1.

## 5 Seminar Extraction Task

**Dataset** The CMU seminar announcement dataset (Freitag and McCallum, 2000) includes 485 emails containing seminar announcements. The dataset has been originally annotated with text spans referring to four slots: *speaker*, *location*, *stime*, and *etime*. We have annotated this dataset with two additional attributes: *date* and *title*.<sup>2</sup> We consider this corpus as an example of semi-structured text, where some of the field values appear in the email header, in a tabular structure, or using special formatting (Califf and Mooney, 1999; Minkov et al., 2005).<sup>3</sup>

We used a set of rules to extract candidate named entities per the types specified in Figure 2.<sup>4</sup> The rules encode information typically used in NER, including content and contextual patterns, as well as lookups in available dictionaries (Finkel et al., 2005; Minkov et al., 2005). The extracted candidates are high-recall and overlapping. In order to increase recall further, additional candidates were extracted based on document structure (Siefkes, 2008). The

<sup>2</sup>A modified dataset is available on the author’s homepage.

<sup>3</sup>Such structure varies across messages. Otherwise, the problem would reduce to wrapper learning (Zhu et al., 2006).

<sup>4</sup>The rule language used is based on cascaded finite state machines (Minorthird, 2008).

recall for the named entities of type *date* and *time* is near perfect, and is estimated at 96%, 91% and 90% for *location*, *speaker* and *title*, respectively.

**Features** The categories of the features used are described below. All features are binary and typed.<sup>5</sup>

*Lexical.* These features indicate the value and pattern of words within the text spans corresponding to each field. For example, lexical features per Figure 1 include *location.content.word.vean*, *location.pattern.capitalized*. Similar features are derived for a window of three words to the right and to the left of the included spans. In addition, we observe whether the words that comprise the text spans appear in relevant dictionaries: e.g., whether the spans assigned to the location field include words typical of location, such as “room” or “hall”. Lexical features of this form are commonly used in NER (Finkel et al., 2005; Minkov et al., 2005).

*Structural.* It has been previously shown that the structure available in semi-structured documents such as email messages is useful for information extraction (Minkov et al., 2005; Siefkes, 2008). As shown in Figure 1, an email message includes a header, specifying textual fields such as *topic*, *dates* and *time*. In addition, space lines and line breaks are used to emphasize blocks of important information. We propose a set of features that model correspondence between the text spans assigned to each field and document structure. Specifically, these features model whether at least one of the spans mapped to each field appears in the email header; captures a full line in the document; is indent; appears within space lines; or in a tabular format. In Figure 1, structural active features include *location.inHeader*, *location.fullLine*, *title.withinSpaceLines*, etc.

*Semantic.* These features refer to the semantic interpretation of field values. According to the relational schema (Figure 2), *date* and *time* include detailed attributes, whereas other relations are represented as strings. The semantic features encoded therefore refer to *date* and *time* only. Specifically, these features indicate whether a unified set of tuples defines a value for all attributes; for example, in Figure 1, the union of entities that map to the *date* field specify all of the attribute values of this relation, including *day-of-month*, *month*, *year*, and

<sup>5</sup>Real-value features were discretized into segments.

Table 2: Seminar extraction results (5-fold CV, trained on 50% of corpus): Field-level F1

*day-of-week*. Another feature encodes the size of the most semantically detailed named entity that maps to a field; for example, the most detailed entity mention of type *stime* in Figure 1 is “3:30”, comprising of two attribute values, namely *hour* and *minutes*. Similarly, the total number of semantic units included in a unified set is represented as a feature. These features were designed to favor semantically detailed mentions and unified sets. Finally, domain-specific semantic knowledge is encoded as features, including the *duration* of the seminar, and whether a *time* value is round (minutes divide by 5).

In addition to the features described, one may be interested in modeling cross-field information. We have experimented with features that encode the shortest distance between named entity mentions mapping to different fields (measured in terms of separating lines or sentences), based on the hypothesis that field values typically co-appear in the same segments of the document. These features were not included in the final model since their contribution was marginal. We leave further exploration of cross-field features in this domain to future work.

**Experiments** We conducted 5-fold cross validation experiments using the seminar extraction dataset. As discussed earlier, we assume that a single record is described in each document, and that each field corresponds to a single value. These assumptions are violated in a minority of cases. In evaluating the template filling task, only exact matches are accepted as true positives, where partial matches are counted as errors (Siefkes, 2008). Notably, the annotated labels as well as corpus itself are not error-free; for example, in some announcements the date and day-of-week specified are inconsistent.

Our evaluation is strict, where non-empty predicted values are counted as errors in such cases.

Table 1 shows the results of our full model using beam size  $k = 10$ , as well as model variants. In order to evaluate the contribution of the proposed features, we eliminated every feature group in turn. As shown in the table, removing the structural features hurt performance consistently across fields. In particular, structure is informative for the *title* field, which is otherwise characterised with low content and contextual regularity. Removal of the semantic features affected performance on the *stime* and *etime* fields, modeled by these features. In particular, the optional *etime* field, which has fewer occurrences in the dataset, benefits from modeling semantics.

An important question to be addressed in evaluation is to what extent the joint modeling approach contributes to performance. In another experiment we therefore mimic the typical scenario of template filling, in which the value of the highest scoring named entity is assigned to each field. In our framework, this corresponds to a setting in which a unified set includes no more than a single entity. The results are shown in Table 1 (‘no unification’). Due to reduced evidence given a single entity versus a coreferent set of entities, this results in significantly degraded performance. Finally, we experimented with populating every field of the target schema independently of the other fields. While results are overall comparable on most fields, this had negative impact on the *title* field. This is largely due to erroneous assignments of named entities of other types (mainly, *person*) as titles; such errors are avoided in the full joint model, where tuple validity is enforced.

Table 2 provides a comparison of the full model

	Date	Stime	Etime	Location	Speaker	Title

Table 3: Seminar extraction results: Token-level F1

against previous state-of-the-art results. These results were all obtained using half of the corpus for training, and its remaining half for evaluation; the reported figures were averaged over five random splits. For comparison, we used 5-fold cross validation, where only a subset of each train fold that corresponds to 50% of the corpus was used for training. Due to the reduced training data, the results are slightly lower than in Table 1. (Note that we used the same test examples in both cases.) The best results per field are marked in boldface. The proposed approach yields the best or second-best performance on all target fields, and gives the best performance overall. While a variety of methods have been applied in previous works, none has modeled template filling in a joint fashion. As argued before, joint modeling is especially important for irregular fields, such as *title*; we provide first results on this field.

Previously, Sutton and McCallum (2004) and later Finkel *et-al.* (2005), applied sequential models to perform NER on this dataset, identifying named entities that pertain to the template slots. Both of these works incorporated coreference and high-level semantic information to a limited extent. We compare our approach to their work, having obtained and used the same 5-fold cross validation splits as both works. Table 3 shows results in terms of token F1. Our results evaluated on the named mention recognition task are superior overall, giving comparable or best performance on all fields. We believe that these results demonstrate the benefit of performing mention recognition as part of a joint model that takes into account detailed semantics of the underlying relational schema, when available.

Finally, we evaluate the *global* quality of the extracted records. Rather than assess performance at field-level, this stricter evaluation mode considers a whole tuple, requiring the values assigned to all of its fields to be correct. Overall, our full model (Table 1) extracts globally correct records for 52.6% of the examples. To our knowledge, this is the first work that provides this type of evaluation on this dataset. Importantly, an advantage of the proposed approach

Figure 4: The relational schema for acquisitions.

is that it readily outputs a ranked list of coherent predictions. While the performance at the top of the output lists was roughly comparable, increasing  $k$  gives higher oracle recall: the correct record was included in the output  $k$ -top list 69.7%, 76.1% and 80.4% of the time, for  $k = 5, 10, 20$  respectively.

## 6 Corporate Acquisitions

**Dataset** The corporate acquisitions corpus contains 600 newswire articles, describing factual or potential corporate acquisition events. The corpus has been annotated with the official names of the parties to an acquisition: *acquired*, *purchaser* and *seller*, as well as their corresponding abbreviated names and company codes.<sup>6</sup> We describe the target schema using the relational structure depicted in Figure 4. The schema includes two relations: the *corp* relation describes a corporate entity, including its full name, abbreviated name and code as attributes; the target *acquisition* relation includes three role-designating attributes, each linked to a *corp* tuple.

Candidate name mentions in this strictly grammatical genre correspond to *noun phrases*. Documents were pre-processed to extract noun phrases, similarly to Haghighi and Klein (2010).

**Features** We model *syntactic* features, following Haghighi and Klein (2010). In order to compensate for parsing errors, shallow syntactic features were added, representing the values of neighboring verbs and prepositions (Cohen et al., 2005). While newswire documents are mostly unstructured, *structural* features are used to indicate whether any of the *purchaser*, *acquired* and *seller* text spans appears in

<sup>6</sup>In this work, we ignore other fields annotated, as they are inconsistently defined, have low number of occurrences in the corpus, and are loosely inter-related semantically.

the article’s header. *Semantic* features are applied to *corp* tuples: we model whether the abbreviated name is a subset of the full name; whether the corporate code forms exact initials of the full or abbreviated names; or whether it has high string similarity to any of these values. Finally, *cross-type features* encode the shortest string between spans mapping to different roles in the *acquisition* relation.

**Experiments** We applied beam search, where *corp* tuples are extracted first, and *acquisition* tuples are constructed using the top scoring *corp* entities. We used a default beam size  $k = 10$ . The dataset is split into a 300/300 train/test subsets.

Table 4 shows results of our full model in terms of field-level F1, compared against TIE, a state-of-the-art discriminative system (Siefkes, 2008). Unfortunately, we can not directly compare against a generative joint model evaluated on this dataset (Haghighi and Klein, 2010).<sup>7</sup> The best results per attribute are shown in boldface. Our full model performs better overall than TIE trained incrementally (similarly to our system), and is competitive with TIE using batch learning. Interestingly, the performance of our model on the *code* fields is high; these fields do not involve boundary prediction, and thus reflect the quality of role assignment.

Table 4 also shows the results of model variants. Removing the *inter type* and *structural* features mildly hurt performance, on average. In contrast, the *semantic* features, which account for the semantic cohesiveness of the populated *corp* tuples, are shown to be necessary. In particular, remov-

<sup>7</sup>They report average performance on a different set of fields; in addition, their results include modeling of pronouns and nominal mentions, which are not considered here.

ing them degrades the extraction of the abbreviated names; these features allow prediction of abbreviated names jointly with the full corporate names, which are more regular (e.g., include a distinctive suffix). Finally, we show results of predicting each role filler individually. Inferring the roles jointly (‘full model’) significantly improves performance.

Table 5 further shows results on NER, the task of recovering the sets of named entity mentions pertaining to each target field. As shown, the proposed joint approach performs overall significantly better than previous results reported. These results are consistent with the case study of seminar extraction.

## 7 Summary and Future Work

We presented a joint approach for template filling that models mention detection, unification, and field extraction in a flexible, feature-rich model. This approach allows for joint modeling of interdependencies at all levels and across fields. Despite the computational challenges of this joint inference space, we obtained effective learning with a Perceptron-style approach and simple beam decoding.

An interesting direction of future research is to apply reranking to the output list of candidate records using additional evidence, such as supporting evidence on the Web (Banko et al., 2008). Also, modeling additional features or feature combinations in this framework as well as effective feature selection or improved parameter estimation (Cramer et al., 2009) may boost performance. Finally, it is worth exploring scaling the approach to unrestricted event extraction, and jointly model extracting more than one relation per document.

## Abstract

We present a novel approach to the automatic acquisition of a Verbnets like classification of French verbs which involves the use (i) of a neural clustering method which associates clusters with features, (ii) of several supervised and unsupervised evaluation metrics and (iii) of various existing syntactic and semantic lexical resources. We evaluate our approach on an established test set and show that it outperforms previous related work with an F-measure of 0.70.

## 1 Introduction

Verb classifications have been shown to be useful both from a theoretical and from a practical perspective. From the theoretical viewpoint, they permit capturing syntactic and/or semantic generalisations about verbs (Levin, 1993; Kipper Schuler, 2006). From a practical perspective, they support factorisation and have been shown to be effective in various NLP (Natural language Processing) tasks such as semantic role labelling (Swier and Stevenson, 2005) or word sense disambiguation (Dang, 2004).

While there has been much work on automatically acquiring verb classes for English (Sun et al., 2010) and to a lesser extent for German (Brew and Schulte im Walde, 2002; Schulte im Walde, 2003; Schulte im Walde, 2006), Japanese (Oishi and Matsumoto, 1997) and Italian (Merlo et al., 2002), few studies have been conducted on the automatic classification of French verbs. Recently however, two proposals have been put forward.

On the one hand, (Sun et al., 2010) applied a clustering approach developed for English to French. They exploit features extracted from a large scale subcategorisation lexicon (LexSchem (Messiant, 2008)) acquired fully automatically from Le Monde newspaper corpus and show that, as for English, syntactic frames and verb selectional preferences perform better than lexical cooccurrence features. Their approach achieves a F-measure of 55.1 on 116 verbs occurring at least 150 times in LexSchem. The best performance is achieved when restricting the approach to verbs occurring at least 4000 times (43 verbs) with an F-measure of 65.4.

On the other hand, Falk and Gardent (2011) present a classification approach for French verbs based on the use of Formal Concept Analysis (FCA). FCA (Barbut and Monjardet, 1970) is a symbolic classification technique which permits creating classes associating sets of objects (eg. French verbs) with sets of features (eg. syntactic frames). Falk and Gardent (2011) provide no evaluation for their results however, only a qualitative analysis.

In this paper, we describe a novel approach to the clustering of French verbs which (i) gives good results on the established benchmark used in (Sun et al., 2010) and (ii) associates verbs with a feature profile describing their syntactic and semantic properties. The approach exploits a clustering method called IGNMF (Incremental Growing Neural Gas with Feature Maximisation, (Lamirel et al., 2011b)) which uses the features characterising each cluster both to guide the clustering process and to label the output clusters. We apply this method to the data contained in various verb lexicons and we evalu-

ate the resulting classification on a slightly modified version of the gold standard provided by (Sun et al., 2010). We show that the approach yields promising results (F-measure of 70%) and that the clustering produced systematically associates verbs with syntactic frames and thematic grids thereby providing an interesting basis for the creation and evaluation of a Verbnet-like classification.

Section 2 describes the lexical resources used for feature extraction and Section 3 the experimental setup. Sections 4 and 5 present the data used for and the results obtained. Section 6 concludes.

## 2 Lexical Resources Used

Our aim is to acquire a classification which covers the core verbs of French, could be used to support semantic role labelling and is similar in spirit to the English Verbnet. In this first experiment, we therefore favoured extracting the features used for clustering, not from a large corpus parsed automatically, but from manually validated resources<sup>1</sup>. These lexical resources are (i) a syntactic lexicon produced by merging three existing lexicons for French and (ii) the English Verbnet.

Among the many syntactic lexicons available for French (Nicolas et al., 2008; Messiant, 2008; Kupśc and Abeillé, 2008; van den Eynde and Mertens, 2003; Gross, 1975), we selected and merged three lexicons built or validated manually namely, Dicovalence, TreeLex and the LADL tables. The resulting lexicon contains 5918 verbs, 20433 lexical entries (i.e., verb/frame pairs) and 345 subcategorisation frames. It also contains more detailed syntactic and semantic features such as lexical preferences (e.g., locative argument, concrete object) or thematic role information (e.g., symmetric arguments, asset role) which we make use of for clustering.

We use the English Verbnet as a resource for associating French verbs with thematic grids as follows. We translate the verbs in the English Verbnet classes to French using English-French dictionaries<sup>2</sup>. To

<sup>1</sup>Of course, the same approach could be applied to corpus based data (as done e.g., in (Sun et al., 2010)) thus making the approach fully unsupervised and directly applicable to any language for which a parser is available.

<sup>2</sup>For the translation we use the following resources: Sci-Fran-Euradic, a French-English bilingual dictionary, built and improved by linguists (<http://catalog.elra.info/>

deal with polysemy, we train a supervised classifier as follows. We first map French verbs with English Verbnet classes: A French verb is associated with an English Verbnet class if, according to our dictionaries, it is a translation of an English verb in this class. The task of the classifier is then to produce a probability estimate for the correctness of this association, given the training data. The training set is built by stating for 1740 ⟨French verb, English Verbnet class⟩ pairs whether the verb has the thematic grid given by the pair’s Verbnet class<sup>3</sup>. This set is used to train an SVM (support vector machine) classifier<sup>4</sup>. The features we use are similar to those used in (Mouton, 2010): they are numeric and are derived for example from the number of translations an English or French verb had, the size of the Verbnet classes, the number of classes a verb is a member of etc. The resulting classifier gives for each ⟨French verb, English VN class⟩ pair the estimated probability of the pair’s verb being a member of the pair’s class<sup>5</sup>. We select 6000 pairs with highest probability estimates and obtain the translated classes by assigning each verb in a selected pair to the pair’s class. This way French verbs are effectively associated with one or more English Verbnet thematic grids.

## 3 Clustering Methods, Evaluation Metrics and Experimental Setup

### 3.1 Clustering Methods

The IGNGF clustering method is an incremental neural “winner-take-most” clustering method belonging to the family of the free topology neural clustering methods. Like other neural free topology methods such as Neural Gas (NG) (Martinetz and Schulen, 1991), Growing Neural Gas (GNG) (Fritzke, 1995), or Incremental Growing Neural Gas (IGNG) (Prudent and Ennaji, 2005), the IGNGF method makes use of Hebbian learning

[product\\_info.php?products\\_id=666](http://product_info.php?products_id=666)), Google dictionary (<http://www.google.com/dictionary>) and Dicovalence (van den Eynde and Mertens, 2003).

<sup>3</sup>The training data consists of the verbs and Verbnet classes used in the gold standard presented in (Sun et al., 2010).

<sup>4</sup>We used the libsvm (Chang and Lin, 2011) implementation of the classifier for this step.

<sup>5</sup>The accuracy of the classifier on the held out random test set of 100 pairs was of 90%.

(Hebb, 1949) for dynamically structuring the learning space. However, contrary to these methods, the use of a standard distance measure for determining a winner is replaced in IGNGF by feature maximisation. Feature maximisation is a cluster quality metric which associates each cluster with maximal features i.e., features whose Feature F-measure is maximal. Feature F-measure is the harmonic mean of Feature Recall and Feature Precision which in turn are defined as:

$$FR_c(f) = \frac{\sum_{v \in c} W_v^f}{\sum_{c' \in C} \sum_{v \in c'} W_v^f}, \quad FP_c(f) = \frac{\sum_{v \in c} W_v^f}{\sum_{f' \in F_c, v \in c} W_v^{f'}}$$

where  $W_x^f$  represents the weight of the feature  $f$  for element  $x$  and  $F_c$  designates the set of features associated with the verbs occurring in the cluster  $c$ . A feature is then said to be maximal for a given cluster iff its Feature F-measure is higher for that cluster than for any other cluster.

The IGNGF method was shown to outperform other usual neural and non neural methods for clustering tasks on relatively clean data (Lamirel et al., 2011b). Since we use features extracted from manually validated sources, this clustering technique seems a good fit for our application. In addition, the feature maximisation and cluster labeling performed by the IGNGF method has proved promising both for visualising clustering results (Lamirel et al., 2008) and for validating or optimising a clustering method (Attik et al., 2006). We make use of these processes in all our experiments and systematically compute cluster labelling and feature maximisation on the output clusterings. As we shall see, this permits distinguishing between clusterings with similar F-measure but lower “linguistic plausibility” (cf. Section 5). This facilitates clustering interpretation in that cluster labeling clearly indicates the association between clusters (verbs) and their prevalent features. And this supports the creation of a Verbnets style classification in that cluster labeling directly provides classes grouping together verbs, thematic grids and subcategorisation frames.

### 3.2 Evaluation metrics

We use several evaluation metrics which bear on different properties of the clustering.

**Modified Purity and Accuracy.** Following (Sun et al., 2010), we use modified purity (mPUR); weighted class accuracy (ACC) and F-measure to evaluate the clusterings produced. These are computed as follows. Each induced cluster is assigned the gold class (its *prevalent class*,  $\text{prev}(C)$ ) to which most of its member verbs belong. A verb is then said to be correct if the gold associates it with the prevalent class of the cluster it is in. Given this, purity is the ratio between the number of correct gold verbs in the clustering and the total number of gold verbs in the clustering<sup>6</sup>:

$$mPUR = \frac{\sum_{C \in \text{Clustering}, |\text{prev}(C)| > 1} |\text{prev}(C) \cap C|}{\text{Verbs}_{\text{Gold} \cap \text{Clustering}}},$$

where  $\text{Verbs}_{\text{Gold} \cap \text{Clustering}}$  is the total number of gold verbs in the clustering.

Accuracy represents the proportion of gold verbs in those clusters which are associated with a gold class, compared to all the gold verbs in the clustering. To compute accuracy we associate to each gold class  $C_{\text{Gold}}$  a dominant cluster, i.e. the cluster  $\text{dom}(C_{\text{Gold}})$  which has most verbs in common with the gold class. Then accuracy is given by the following formula:

$$ACC = \frac{\sum_{C \in \text{Gold}} |\text{dom}(C) \cap C|}{\text{Verbs}_{\text{Gold} \cap \text{Clustering}}}$$

Finally, F-measure is the harmonic mean of mPUR and ACC.

**Coverage.** To assess the extent to which a clustering matches the gold classification, we additionally compute the *coverage* of each clustering that is, the proportion of gold classes that are prevalent classes in the clustering.

**Cumulative Micro Precision (CMP).** As pointed out in (Lamirel et al., 2008; Attik et al., 2006), unsupervised evaluation metrics based on cluster labelling and feature maximisation can prove very useful for identifying the best clustering strategy. Following (Lamirel et al., 2011a), we use CMP to identify the best clustering. Computed on the clustering results, this metrics evaluates the quality of a clustering w.r.t. the cluster features rather than w.r.t.

<sup>6</sup>Clusters for which the prevalent class has only one element are ignored

to a gold standard. It was shown in (Ghribi et al., 2010) to be effective in detecting degenerated clustering results including a small number of large heterogeneous, “garbage” clusters and a big number of small size “chunk” clusters.

First, the *local Recall* ( $R_c^f$ ) and the *local Precision* ( $P_c^f$ ) of a feature  $f$  in a cluster  $c$  are defined as follows:

$$R_c^f = \frac{|v_c^f|}{|V^f|} \quad P_c^f = \frac{|v_c^f|}{|V_c|}$$

where  $v_c^f$  is the set of verbs having feature  $f$  in  $c$ ,  $V_c$  the set of verbs in  $c$  and  $V^f$ , the set of verbs with feature  $f$ .

Cumulative Micro-Precision (CMP) is then defined as follows:

$$CMP = \frac{\sum_{i=|C_{in f}|, |C_{sup}|} \frac{1}{|C_{i+}|^2} \sum_{c \in C_{i+}, f \in F_c} P_c^f}{\sum_{i=|C_{in f}|, |C_{sup}|} \frac{1}{C_{i+}}}$$

where  $C_{i+}$  represents the subset of clusters of  $C$  for which the number of associated verbs is greater than  $i$ , and:  $C_{in f} = \operatorname{argmin}_{c_i \in C} |c_i|$ ,  $C_{sup} = \operatorname{argmax}_{c_i \in C} |c_i|$

### 3.3 Cluster display, feature f-Measure and confidence score

To facilitate interpretation, clusters are displayed as illustrated in Table 1. Features are displayed in decreasing order of Feature F-measure (cf. Section 3.1) and features whose Feature F-measure is under the average Feature F-measure of the overall clustering are clearly delineated from others. In addition, for each verb in a cluster, a confidence score is displayed which is the ratio between the sum of the F-measures of its cluster maximised features over the sum of the F-measures of the overall cluster maximised features. Verbs whose confidence score is 0 are considered as orphan data.

### 3.4 Experimental setup

We applied an IDF-Norm weighting scheme (Robertson and Jones, 1976) to decrease the influence of the most frequent features (IDF component) and to compensate for discrepancies in feature number (normalisation).

Table 1: Sample output for a cluster produced with the **grid-scf-sem** feature set and the IGNGF clustering method.

We use K-Means as a baseline. For each clustering method (K-Means and IGNGF), we let the number of clusters vary between 1 and 30 to obtain a partition that reaches an optimum F-measure and a number of clusters that is in the same order of magnitude as the initial number of Gold classes (i.e. 11 classes).

## 4 Features and Data

**Features** In the simplest case the features are the subcategorisation frames (**scf**) associated to the verbs by our lexicon. We also experiment with different combinations of additional, syntactic (**synt**) and semantic features (**sem**) extracted from the lexicon and with the thematic grids (**grid**) extracted from the English Verbnet.

The thematic grid information is derived from the English Verbnet as explained in Section 2. The syntactic features extracted from the lexicon are listed in Table 1(a). They indicate whether a verb accepts symmetric arguments (e.g., *John met Mary/John and Mary met*); has four or more arguments; combines with a predicative phrase (e.g., *John named Mary president*); takes a sentential complement or an optional object; or accepts the passive in *se* (similar to the English middle voice *Les habits se vendent bien/ The clothes sell well*). As shown in Table 1(a), these

(a) Additional syntactic features.

Plural role	<i>amalgamate-22.2, correspond-36.1</i>

Table 2: Additional syntactic (a) and semantic (b) features extracted from the LADL and Dicovalence resources and the alternations/roles they are possibly related to.

features are meant to help identify specific Verbnet classes and thematic roles. Finally, we extract four semantic features from the lexicon. These indicate whether a verb takes a locative or an asset argument and whether it requires a concrete object (non human role) or a plural role. The potential correlation between these features and Verbnet classes is given in Table 1(b).

**French Gold Standard** To evaluate our approach, we use the gold standard proposed by Sun et al. (2010). This resource consists of 16 fine grained Levin classes with 12 verbs each whose predominant sense in English belong to that class. Since our goal is to build a Verbnet like classification for French, we mapped the 16 Levin classes of the Sun et al. (2010)’s Gold Standard to 11 Verbnet classes thereby associating each class with a thematic grid. In addition we group Verbnet semantic roles as shown in Table 4. Table 3 shows the reference we use for evaluation.

**Verbs** For our clustering experiments we use the 2183 French verbs occurring in the translations of the 11 classes in the gold standard (cf. Section 4). Since we ignore verbs with only one feature the number of verbs and ⟨verb, feature⟩ pairs considered may vary slightly across experiments.

## 5 Results

### 5.1 Quantitative Analysis

Table 4(a) includes the evaluation results for all the feature sets when using IGNMF clustering.

In terms of F-measure, the results range from 0.61 to 0.70. This generally outperforms (Sun et al., 2010) whose best F-measures vary between 0.55 for verbs occurring at least 150 times in the training data and 0.65 for verbs occurring at least 4000 times in this training data. The results are not directly comparable however since the gold data is slightly different due to the grouping of Verbnet classes through their thematic grids.

In terms of features, the best results are obtained using the **grid-scf-sem** feature set with an F-measure of 0.70. Moreover, for this data set, the unsupervised evaluation metrics (cf. Section 3) highlight strong cluster cohesion with a number of clusters close to the number of gold classes (13 clusters for 11 gold classes); a low number of orphan verbs (i.e., verbs whose confidence score is zero); and a high Cumulated Micro Precision (CMP = 0.3) indicating homogeneous clusters in terms of maximising features. The coverage of 0.72 indicates that approximately 8 out of the 11 gold classes could be matched to a prevalent label. That is, 8 clusters were labelled with a prevalent label corresponding to 8 distinct gold classes.

In contrast, the classification obtained using the **scf-synt-sem** feature set has a higher CMP for the clustering with optimal mPUR (0.57); but a lower F-measure (0.61), a larger number of classes (16)

Table 3: French gold classes and their member verbs presented in (Sun et al., 2010).

and a higher number of orphans (156). That is, this clustering has many clusters with strong feature cohesion but a class structure that markedly differs from the gold. Since there might be differences in structure between the English Verbnet and the thematic classification for French we are building, this is not necessarily incorrect however. Further investigation on a larger data set would be required to assess which clustering is in fact better given the data used and the classification searched for.

In general, data sets whose description includes semantic features (**sem** or **grid**) tend to produce better results than those that do not (**scf** or **synt**). This is in line with results from (Sun et al., 2010) which shows that semantic features help verb classification. It differs from it however in that the semantic features used by Sun et al. (2010) are selectional preferences while ours are thematic grids and a restricted set of manually encoded selectional preferences.

Noticeably, the **synt** feature degrades performance throughout: **grid,scf,synt** has lower F-measure than **grid,scf**; **scf,synt,sem** than **scf,sem**;

and **scf,synt** than **scf**. We have no clear explanation for this.

The best results are obtained with IGNGF method on most of the data sets. Table 4(b) illustrates the differences between the results obtained with IGNGF and those obtained with K-means on the **grid-sc-f-sem** data set (best data set). Although K-means and IGNGF optimal model reach similar F-measure and display a similar number of clusters, the very low CMP (0.10) of the K-means model shows that, despite a good Gold class coverage (0.81), K-means tend to produce more heterogeneous clusters in terms of features.

Table 4(b) also shows the impact of IDF feature weighting and feature vector normalisation on clustering. The benefit of preprocessing the data appears clearly. When neither IDF weighting nor vector normalisation are used, F-measure decreases from 0.70 to 0.68 and cumulative micro-precision from 0.30 to 0.21. When either normalisation or IDF weighting is left out, the cumulative micro-precision drops by up to 15 points (from 0.30 to 0.15 and 0.18) and the number of orphans increases from 67 up to 180.

(a) The impact of the feature set.

Table 5: Results. Cumulative micro precision (CMP) is given for the clustering at the mPUR optimum and in parentheses for 13 classes clustering.

That is, clusters are less coherent in terms of features.

## 5.2 Qualitative Analysis

We carried out a manual analysis of the clusters examining both the semantic coherence of each cluster (do the verbs in that cluster share a semantic component?) and the association between the thematic grids, the verbs and the syntactic frames provided by clustering.

**Semantic homogeneity:** To assess semantic homogeneity, we examined each cluster and sought to identify one or more Verbnet labels characterising the verbs contained in that cluster. From the 13 clusters produced by clustering, 11 clusters could be labelled. Table 6 shows these eleven clusters, the associated labels (abbreviated Verbnet class names), some example verbs, a sample sub-categorisation frame drawn from the cluster maximising features and an illustrating sentence. As can be seen, some clusters group together several subclasses and conversely, some Verbnet classes are spread over several clusters. This is not necessarily incorrect though. To start with, recall that we are aiming for a classification which groups together verbs with the same thematic grid. Given this, cluster C2 correctly groups together two Verbnet classes (other\_cos-45.4 and hit-18.1) which share the same thematic grid (cf. Table 3). In addition, the features

associated with this cluster indicate that verbs in these two classes are transitive, select a concrete object, and can be pronominalised which again is correct for most verbs in that cluster. Similarly, cluster C11 groups together verbs from two Verbnet classes with identical theta grid (light\_emission-43.1 and modes\_of\_being\_with\_motion-47.3) while its associated features correctly indicate that verbs from both classes accept both the intransitive form without object (*la jeune fille rayonne / the young girl glows, un cheval galope / a horse gallops*) and with a prepositional object (*la jeune fille rayonne de bonheur / the young girl glows with happiness, un cheval galope vers l’infini / a horse gallops to infinity*). The third cluster grouping together verbs from two Verbnet classes is C7 which contains mainly judgement verbs (to applaud, bless, compliment, punish) but also some verbs from the (very large) other\_cos-45.4 class. In this case, a prevalent shared feature is that both types of verbs accept a de-object that is, a prepositional object introduced by "de" (*Jean applaudit Marie d’avoir dansé / Jean applaudit Marie for having danced; Jean dégage le sable de la route / Jean clears the sand of the road*). The semantic features necessary to provide a finer grained analysis of their differences are lacking.

Interestingly, clustering also highlights classes which are semantically homogeneous but syntactically distinct. While clusters C6 and C10 both

contain mostly verbs from the amuse-31.1 class (*amuser, agacer, énerver, déprimer*), their features indicate that verbs in C10 accept the pronominal form (e.g., *Jean s’amuse*) while verbs in C6 do not (e.g., \**Jean se déprime*). In this case, clustering highlights a syntactic distinction which is present in French but not in English. In contrast, the dispersion of verbs from the other\_cos-45.4 class over clusters C2 and C7 has no obvious explanation. One reason might be that this class is rather large (361 verbs) and thus might contain French verbs that do not necessarily share properties with the original Verbnet class.

**Syntax and Semantics.** We examined whether the prevalent syntactic features labelling each cluster were compatible with the verbs and with the semantic class(es) manually assigned to the clusters. Table 6 sketches the relation between cluster, syntactic frames and Verbnet like classes. It shows for instance that the prevalent frame of the C0 class (manner\_speaking-37.3) correctly indicates that verbs in that cluster subcategorise for a sentential argument and an AOBJ (prepositional object in “à”) (e.g., *Jean bafouille à Marie qu’il est amoureux / Jean stammers to Mary that he is in love*); and that verbs in the C9 class (characterize-29.2) subcategorise for an object NP and an attribute (*Jean nomme Marie présidente / Jean appoints Marie president*). In general, we found that the prevalent frames associated with each cluster adequately characterise the syntax of that verb class.

## 6 Conclusion

We presented an approach to the automatic classification of french verbs which showed good results on an established testset and associates verb clusters with syntactic and semantic features.

Whether the features associated by the IINGF clustering with the verb clusters appropriately characterise these clusters remains an open question. We carried out a first evaluation using these features to label the syntactic arguments of verbs in a corpus with thematic roles and found that precision is high but recall low mainly because of polysemy: the frames and grids made available by the classification for a given verb are correct for that verb but not for the verb sense occurring in the corpus. This suggests that overlapping clustering techniques need to

be applied.

We are also investigating how the approach scales up to the full set of verbs present in the lexicon. Both Dicovalence and the LADL tables contain rich detailed information about the syntactic and semantic properties of French verbs. We intend to tap on that potential and explore how well the various semantic features that can be extracted from these resources support automatic verb classification for the full set of verbs present in our lexicon.

## Abstract

Sentence Similarity is the process of computing a similarity score between two sentences. Previous sentence similarity work finds that latent semantics approaches to the problem do not perform well due to insufficient information in single sentences. In this paper, we show that by carefully handling words that are **not** in the sentences (missing words), we can train a reliable latent variable model on sentences. In the process, we propose a new evaluation framework for sentence similarity: Concept Definition Retrieval. The new framework allows for large scale tuning and testing of Sentence Similarity models. Experiments on the new task and previous data sets show significant improvement of our model over baselines and other traditional latent variable models. Our results indicate comparable and even better performance than current state of the art systems addressing the problem of sentence similarity.

## 1 Introduction

Identifying the degree of semantic similarity [SS] between two sentences is at the core of many NLP applications that focus on sentence level semantics such as Machine Translation (Kauchak and Barzilay, 2006), Summarization (Zhou et al., 2006), Text Coherence Detection (Lapata and Barzilay, 2005), etc. To date, almost all Sentence Similarity [SS] approaches work in the high-dimensional word space and rely mainly on word similarity. There are two main (not unrelated) disadvantages to word similarity based approaches: 1. lexical ambiguity as the pairwise word similarity ignores the semantic interaction between the word and its sentential context;

2. word co-occurrence information is not sufficiently exploited.

Latent variable models, such as Latent Semantic Analysis [LSA] (Landauer et al., 1998), Probabilistic Latent Semantic Analysis [PLSA] (Hofmann, 1999), Latent Dirichlet Allocation [LDA] (Blei et al., 2003) can solve the two issues naturally by modeling the semantics of words and sentences simultaneously in the low-dimensional latent space. However, attempts at addressing SS using LSA perform significantly below high dimensional word similarity based models (Mihalcea et al., 2006; O’Shea et al., 2008).

We believe that the latent semantics approaches applied to date to the SS problem have not yielded positive results due to the deficient modeling of the sparsity in the semantic space. SS operates in a very limited contextual setting where the sentences are typically very short to derive robust latent semantics. Apart from the SS setting, robust modeling of the latent semantics of short sentences/texts is becoming a pressing need due to the pervasive presence of more bursty data sets such as Twitter feeds and SMS where short contexts are an inherent characteristic of the data.

In this paper, we propose to model the missing words (words that are not in the sentence), a feature that is typically overlooked in the text modeling literature, to address the sparseness issue for the SS task. We define the missing words of a sentence as the whole vocabulary in a corpus minus the observed words in the sentence. Our intuition is since observed words in a sentence are too few to tell us what the sentence is about, missing words can be used to tell us what the sentence is **not** about. We assume that the semantic space of both the observed

and missing words make up the complete semantics profile of a sentence.

After analyzing the way traditional latent variable models (LSA, PLSA/LDA) handle missing words, we decide to model sentences using a weighted matrix factorization approach (Srebro and Jaakkola, 2003), which allows us to treat observed words and missing words differently. We handle missing words using a weighting scheme that distinguishes missing words from observed words yielding robust latent vectors for sentences.

Since we use a feature that is already implied by the text itself, our approach is very general (similar to LSA/LDA) in that it can be applied to any format of short texts. In contrast, existing work on modeling short texts focuses on exploiting additional data, e.g., Ramage et al. (2010) model tweets using their metadata (author, hashtag, etc.).

Moreover in this paper, we introduce a new evaluation framework for SS: Concept Definition Retrieval (CDR). Compared to existing data sets, the CDR data set allows for large scale tuning and testing of SS modules without further human annotation.

## 2 Limitations of Topic Models and LSA for Modeling Sentences

Usually latent variable models aim to find a latent semantic profile for a sentence that is most relevant to the observed words. By explicitly modeling missing words, we set another criterion to the latent semantics profile: it should **not** be related to the missing words in the sentence. However, missing words are not as informative as observed words, hence the need for a model that does a good job of modeling missing words at the right level of **emphasis/impact** is central to completing the semantic picture for a sentence.

LSA and PLSA/LDA work on a word-sentence co-occurrence matrix. Given a corpus, the row entries of the matrix are the unique  $M$  words in the corpus, and the  $N$  columns are the sentence ids. The yielded  $M \times N$  co-occurrence matrix  $X$  comprises the TF-IDF values in each  $X_{ij}$  cell, namely that TF-IDF value of word  $w_i$  in sentence  $s_j$ . For ease of exposition, we will illustrate the problem using a special case of the SS framework where the sentences are concept definitions in a dictionary such

as WordNet (Fellbaum, 1998) (WN). Therefore, the sentence corresponding to the concept definition of *bank#n#1* is a sparse vector in  $X$  containing the following observed words where  $X_{ij} \neq 0$ :

*the* 0.1, *financial* 5.5, *institution* 4, *that* 0.2, *accept* 2.1, *deposit* 3, and 0.1, *channel* 6, *the* 0.1, *money* 5, *into* 0.3, *lend* 3.5, *activity* 3

All the other words (*girl, car, ..., check, loan, business, ...*) in matrix  $X$  that do not occur in the concept definition are considered missing words for the concept entry *bank#n#1*, thereby their  $X_{ij} = 0$ .

Topic models (PLSA/LDA) do not explicitly model missing words. PLSA assumes each document has a distribution over  $K$  topics  $P(z_k|d_j)$ , and each topic has a distribution over all vocabularies  $P(w_i|z_k)$ . Therefore, PLSA finds a topic distribution for each concept definition that maximizes the log likelihood of the corpus  $X$  (LDA has a similar form):

$$\sum_i \sum_j X_{ij} \log \sum_k P(z_k|d_j) P(w_i|z_k) \quad (1)$$

In this formulation, missing words do not contribute to the estimation of sentence semantics, i.e., excluding missing words ( $X_{ij} = 0$ ) in equation 1 does not make a difference.

However, empirical results show that given a small number of observed words, usually topic models can only find one topic (most evident topic) for a sentence, e.g., the concept definitions of *bank#n#1* and *stock#n#1* are assigned the financial topic only without any further discernability. This results in many sentences are assigned exactly the same semantics profile as long as they are pertaining/mentioned within the same domain/topic. The reason is topic models try to learn a 100-dimension latent vector (assume dimension  $K = 100$ ) from very few data points (10 observed words on average). It would be desirable if topic models can exploit missing words (a lot more data than observed words) to render more nuanced latent semantics, so that pairs of sentences in the same domain can be differentiable.

On the other hand, LSA explicitly models missing words but not at the right level of emphasis. LSA finds another matrix  $\hat{X}$  (latent vectors) with rank  $K$  to approximate  $X$  using Singular Vector Decomposition ( $X \approx \hat{X} = U_K \Sigma_K V_K^T$ ), such that the Frobe-

	financial	sport	institution	$R_o$	$R_m$	$R_o - R_m$	$R_o - 0.01R_m$
$v_1$	1	0	0	<b>20</b>	<b>600</b>	-580	14
$v_2$	0.6	0	0.1	18	300	-282	<b>15</b>
$v_3$	0.2	0.3	0.2	5	100	<b>-95</b>	4

Table 1: Three possible latent vectors hypotheses for the definition of *bank#n#1*

nius norm of difference between the two matrices is minimized:

$$\sqrt{\sum_i \sum_j (\hat{X}_{ij} - X_{ij})^2} \quad (2)$$

In effect, LSA allows missing and observed words to equally impact the objective function. Given the inherent short length of the sentences, LSA (equation 2) allows for much more potential influence from missing words rather than observed words (99.9% cells are 0 in  $X$ ). Hence the contribution of the observed words is significantly diminished. Moreover, the true semantics of the concept definitions is actually related to some missing words, but such true semantics will not be favored by the objective function, since equation 2 allows for too strong an impact by  $\hat{X}_{ij} = 0$  for **any** missing word. Therefore the LSA model, in the context of short texts, is allowing missing words to have a significant “uncontrolled” impact on the model.

## 2.1 An Example

The three latent semantics profiles in table 1 illustrate our analysis for topic models and LSA. Assume there are three dimensions: financial, sports, institution. We use  $R_o^v$  to denote the sum of relatedness between latent vector  $v$  and all observed words; similarly,  $R_m^v$  is the sum of relatedness between the vector  $v$  and all missing words. The first latent vector (generated by topic models) is chosen by maximizing  $R_{obs} = 600$ . It suggests *bank#n#1* is only related to the *financial* dimension. The second latent vector (found by LSA) has the maximum value of  $R_{obs} - R_{miss} = 95$ , but obviously the latent vector is not related to *bank#n#1* at all. This is because LSA treats observed words and missing words equally the same, and due to the large number of missing words, the information of observed words is lost:  $R_{obs} - R_{miss} \approx -R_{miss}$ . The third vector is the ideal semantics profile, since it is also related to the *institution* dimension. It has a slightly smaller  $R_{obs}$  in comparison to the first vector, yet it has a substantially smaller  $R_{miss}$ .

In order to favor the ideal vector over other vectors, we simply need to adjust the objective func-

tion by assigning a smaller weight to  $R_{miss}$  such as:  $R_{obs} - 0.01 \times R_{miss}$ . Accordingly, we use weighted matrix factorization (Srebro and Jaakkola, 2003) to model missing words.

## 3 The Proposed Approach

### 3.1 Weighted Matrix Factorization

The weighted matrix factorization [WMF] approach is very similar to SVD, except that it allows for direct control on each matrix cell  $X_{ij}$ . The model factorizes the original matrix  $X$  into two matrices such that  $X \approx P^T Q$ , where  $P$  is a  $K \times M$  matrix, and  $Q$  is a  $K \times N$  matrix (figure 1).

The model parameters (vectors in  $P$  and  $Q$ ) are optimized by minimizing the objective function:

$$\sum_i \sum_j W_{ij} (P_{\cdot,i} \cdot Q_{\cdot,j} - X_{ij})^2 + \lambda \|P\|_2^2 + \lambda \|Q\|_2^2 \quad (3)$$

where  $\lambda$  is a free regularization factor, and the weight matrix  $W$  defines a weight for each cell in  $X$ .

Accordingly,  $P_{\cdot,i}$  is a  $K$ -dimension latent semantics vector profile for word  $w_i$ ; similarly,  $Q_{\cdot,j}$  is the  $K$ -dimension vector profile that represents the sentence  $s_j$ . Operations on these  $K$ -dimensional vectors have very intuitive semantic meanings:

- (1) the inner product of  $P_{\cdot,i}$  and  $Q_{\cdot,j}$  is used to approximate semantic relatedness of word  $w_i$  and sentence  $s_j$ :  $P_{\cdot,i} \cdot Q_{\cdot,j} \approx X_{ij}$ , as the shaded parts in Figure 1;
- (2) equation 3 explicitly requires a sentence should not be related to its missing words by forcing  $P_{\cdot,i} \cdot Q_{\cdot,j} = 0$  for missing words  $X_{ij} = 0$ .
- (3) we can compute the similarity of two sentences  $s_j$  and  $s_{j'}$  using the cosine similarity between  $Q_{\cdot,j}$ ,  $Q_{\cdot,j'}$ .

The latent vectors in  $P$  and  $Q$  are first randomly initialized, then can be computed iteratively by the following equations (derivation is omitted due to limited space, which can be found in (Srebro and Jaakkola, 2003)):

$$\begin{aligned} P_{\cdot,i} &= (Q\tilde{W}^{(i)}Q^T + \lambda I)^{-1} Q\tilde{W}^{(i)}X_{i\cdot}^T \\ Q_{\cdot,j} &= (P\tilde{W}^{(j)}P^T + \lambda I)^{-1} P\tilde{W}^{(j)}X_{\cdot j} \end{aligned} \quad (4)$$

Figure 1: Matrix Factorization

where  $\tilde{W}^{(i)} = \text{diag}(W_{\cdot,i})$  is an  $M \times M$  diagonal matrix containing  $i$ th row of weight matrix  $W$ . Similarly,  $\tilde{W}^{(j)} = \text{diag}(W_{\cdot,j})$  is an  $N \times N$  diagonal matrix containing  $j$ th column of  $W$ .

### 3.2 Modeling Missing Words

It is straightforward to implement the idea in Section 2.1 (choosing a latent vector that maximizes  $R_{obs} - 0.01 \times R_{miss}$ ) in the WMF framework, by assigning a small weight for all the missing words and minimizing equation 3:

$$W_{i,j} = \begin{cases} 1, & \text{if } X_{ij} \neq 0 \\ w_m, & \text{if } X_{ij} = 0 \end{cases} \quad (5)$$

We refer to our model as Weighted Textual Matrix Factorization [WTMF].<sup>1</sup>

This solution is quite elegant: 1. it explicitly tells the model that in general all missing words should not be related to the sentence; 2. meanwhile latent semantics are mainly generalized based on observed words, and the model is not penalized too much ( $w_m$  is very small) when it is very confident that the sentence is highly related to a small subset of missing words based on their latent semantics profiles (*bank#n#1* definition sentence is related to its missing words *check loan*).

We adopt the same approach (assigning a small weight for some cells in WMF) proposed for recommender systems [RS] (Steck, 2010). In RS, an incomplete rating matrix  $R$  is proposed, where rows are users and columns are items. Typically, a user rates only some of the items, hence, the RS system needs to predict the missing ratings. Steck (2010) guesses a value for all the missing cells, and sets a small weight for those cells.

Compared to (Steck, 2010), we are facing a different problem and targeting a different goal. We have a full matrix  $X$  where missing words have a 0 value, while the missing ratings in RS are unavailable – the values are unknown, hence  $R$  is not complete. In the RS setting, they are interested in predicting individual ratings, while we are interested in the sentence

<sup>1</sup>An efficient way to compute equation 4 is proposed in (Steck, 2010).

semantics. More importantly, they do not have the sparsity issue (each user has rated over 100 items in the movie lens data<sup>2</sup>) and robust predictions can be made based on the observed ratings alone.

## 4 Evaluation for SS

We need to show the impact of our proposed model WTMF on the SS task. However we are faced with a problem, the lack of a suitable large evaluation set from which we can derive robust observations. The two data sets we know of for SS are: 1. human-rated sentence pair similarity data set (Li et al., 2006) [LI06]; 2. the Microsoft Research Paraphrase Corpus (Dolan et al., 2004) [MSR04]. The LI06 data set consists of 65 pairs of noun definitions selected from the Collin Cobuild Dictionary. A subset of 30 pairs is further selected by LI06 to render the similarity scores evenly distributed. While this is the ideal data set for SS, the small size makes it impossible for tuning SS algorithms or deriving significant performance conclusions.

On the other hand, the MSR04 data set comprises a much larger set of sentence pairs: 4,076 training and 1,725 test pairs. The ratings on the pairs are binary labels: similar/not similar. This is not a problem per se, however the issue is that it is very strict in its assignment of a positive label, for example the following sentence pair as cited in (Islam and Inkpen, 2008) is rated not semantically similar:

*Ballmer has been vocal in the past warning that Linux is a threat to Microsoft.*

*In the memo, Ballmer reiterated the open-source threat to Microsoft.*

We believe that the ratings on a data set for SS should accommodate variable degrees of similarity with various ratings, however such a large scale set does not exist yet. Therefore for purposes of evaluating our proposed approach we devise a new framework inspired by the LI06 data set in that it comprises concept definitions but on a large scale.

### 4.1 Concept Definition Retrieval

We define a new framework for evaluating SS and project it as a Concept Definition Retrieval (CDR) task where the data points are dictionary definitions. The intuition is that two definitions in different dic-

<sup>2</sup><http://www.grouplens.org/node/73>, with 1M data set being the most widely used.

tionaries referring to the same concept should be assigned large similarity. In this setting, we design the CDR task in a search engine style. The SS algorithm has access to all the definitions in WordNet (WN). Given an OntoNotes (ON) definition (Hovy et al., 2006), the SS algorithm should rank the equivalent WN definition as high as possible based on sentence similarity.

The manual mapping already exists for ON to WN. One ON definition can be mapped to several WN definitions. After preprocessing we obtain 13669 ON definitions mapped to 19655 WN definitions. The data set has the advantage of being very large and it doesn't require further human scrutiny.

After the SS model learns the co-occurrence of words from WN definitions, in the testing phase, given an ON definition  $d$ , the SS algorithm needs to identify the equivalent WN definitions by computing the similarity values between all WN definitions and the ON definition  $d$ , then sorting the values in decreasing order. Clearly, it is very difficult to rank the one correct definition as highest out of all WN definitions (110,000 in total), hence we use  $ATOP_d$ , *area under the TOPK $_d(k)$  recall curve for an ON definition  $d$* , to measure the performance. Basically, it is the ranking of the correct WN definition among all WN definitions. The higher a model is able to rank the correct WN definition, the better its performance.

Let  $N_d$  be the number of aligned WN definitions for the ON definition  $d$ , and  $N_d^k$  be the number of aligned WN definitions in the top-k list. Then with a normalized  $k \in [0,1]$ ,  $TOPK_d(k)$  and  $ATOP_d$  is defined as:

$$\begin{aligned} TOPK_d(k) &= N_d^k / N_d \\ ATOP_d &= \int_0^1 TOPK_d(k) dk \end{aligned} \quad (6)$$

$ATOP_d$  computes the normalized rank (in the range of  $[0, 1]$ ) of aligned WN definitions among all WN definitions, with value 0.5 being the random case, and 1 being ranked as most similar.

## 5 Experiments and Results

We evaluate WTMF on three data sets: 1. CDR data set using  $ATOP$  metric; 2. Human-rated Sentence Similarity data set [LI06] using Pearson and Spearman Correlation; 3. MSR Paraphrase corpus [MSR04] using accuracy.

The performance of WTMF on CDR is compared with (a) an Information Retrieval model (IR) that is based on surface word matching, (b) an n-gram model (N-gram) that captures phrase overlaps by returning the number of overlapping ngrams as the similarity score of two sentences, (c) LSA that uses `svds()` function in Matlab, and (d) LDA that uses Gibbs Sampling for inference (Griffiths and Steyvers, 2004). WTMF is also compared with all existing reported SS results on LI06 and MSR04 data sets, as well as LDA that is trained on the same data as WTMF. The similarity of two sentences is computed by cosine similarity (except N-gram). More details on each task will be explained in the subsections.

To eliminate randomness in statistical models (WTMF and LDA), all the reported results are averaged over 10 runs. We run 20 iterations for WTMF. And we run 5000 iterations for LDA; each LDA model is averaged over the last 10 Gibbs Sampling iterations to get more robust predictions.

The latent vector of a sentence is computed by: (1) using equation 4 in WTMF, or (2) summing up the latent vectors of all the constituent words weighted by  $X_{ij}$  in LSA and LDA, similar to the work reported in (Mihalcea et al., 2006). For LDA the latent vector of a word is computed by  $P(z|w)$ . It is worth noting that we could directly use the estimated topic distribution  $\theta_j$  to represent a sentence, however, as discussed the topic distribution has only non-zero values on one or two topics, leading to a low  $ATOP$  value around 0.8.

### 5.1 Corpus

The corpus we use comprises three dictionaries WN, ON, Wiktionary [Wik],<sup>3</sup> Brown corpus. For all dictionaries, we only keep the definitions without examples, and discard the mapping between sense ids and definitions. All definitions are simply treated as individual documents. We crawl Wik and remove the entries that are not tagged as noun, verb, adjective, or adverb, resulting in 220,000 entries. For the Brown corpus, each sentence is treated as a document in order to create more coherent co-occurrence values. All data is tokenized, pos-tagged<sup>4</sup>, and lem-

<sup>3</sup>[http://en.wiktionary.org/wiki/Wiktionary:Main\\_Page](http://en.wiktionary.org/wiki/Wiktionary:Main_Page)

<sup>4</sup><http://nlp.stanford.edu/software/tagger.shtml>

Models	Parameters	Dev	Test
1. IR	-	0.8578	0.8515
2. N-gram	-	0.8238	0.8171
3. LSA	-	0.8218	0.8143
4a. LDA	$\alpha = 0.1, \beta = 0.01$	$0.9466 \pm 0.0020$	$0.9427 \pm 0.0006$
4b. LDA	$\alpha = 0.05, \beta = 0.05$	$0.9506 \pm 0.0017$	$0.9470 \pm 0.0005$
5. WTMF	$w_m = 1, \lambda = 0$	$0.8273 \pm 0.0028$	$0.8273 \pm 0.0014$
6. WTMF	$w_m = 0, \lambda = 20$	$0.8745 \pm 0.0058$	$0.8645 \pm 0.0031$
7a. WTMF	$w_m = 0.01, \lambda = 20$	$0.9555 \pm 0.0015$	$0.9511 \pm 0.0003$
7b. WTMF	$w_m = 0.0005, \lambda = 20$	$0.9610 \pm 0.0011$	$0.9558 \pm 0.0004$

Table 2: ATOP Values of Models ( $K = 100$  for LSA/LDA/WTMF)

matized<sup>5</sup>. The importance of words in a sentence is estimated by the TF-IDF schema.

All the latent variable models (LSA, LDA, WTMF) are built on the same set of corpus: WN+Wik+Brown (393, 666 sentences and 4, 262, 026 words). Words that appear only once are removed. The test data is never used during training phrase.

## 5.2 Concept Definition Retrieval

Among the 13669 ON definitions, 1000 definitions are randomly selected as a development set (dev) for picking best parameters in the models, and the rest is used as a test set (test). The performance of each model is evaluated by the average  $ATOP_d$  value over the 12669 definitions (test). We use the subscript *set* in  $ATOP_{set}$  to denote the average of  $ATOP_d$  of a set of ON definitions, where  $d \in \{set\}$ . If all the words in an ON definition are not covered in the training data (WN+Wik+Br), then  $ATOP_d$  for this instance is set to 0.5.

To compute  $ATOP_d$  for an ON definition efficiently, we use the rank of the aligned WN definition among a random sample (size=1000) of WN definitions, to approximate its rank among all WN definitions. In practice, the difference between using 1000 samples and all data is tiny for  $ATOP_{test}$  ( $\pm 0.0001$ ), due to the large number of data points in CDR.

We mainly compare the performance of IR, N-gram, LSA, LDA, and WTMF models. Generally results are reported based on the last iteration. However, we observe that for model 6 in table 2, the best performance occurs at the first few iterations. Hence for that model we use the  $ATOP_{dev}$  to indicate when to stop.

<sup>5</sup><http://wn-similarity.sourceforge.net>, WordNet::QueryData

### 5.2.1 Results

Table 2 summarizes the ATOP values on the dev and test sets. All parameters are tuned based on the dev set. In LDA, we choose an optimal combination of  $\alpha$  and  $\beta$  from  $\{0.01, 0.05, 0.1, 0.5\}$ . In WTMF, we choose the best parameters of weight  $w_m$  for missing words and  $\lambda$  for regularization. We fix the dimension  $K = 100$ . Later in section 5.2.2, we will see that a larger value of  $K$  can further improve the performance.

WTMF that models missing words using a small weight (model 7b with  $w_m = 0.0005$ ) outperforms the second best model LDA by a large margin. This is because LDA only uses 10 observed words to infer a 100 dimension vector for a sentence, while WTMF takes advantage of much more missing words to learn more robust latent semantics vectors.

The IR model that works in word space achieves better ATOP scores than N-gram, although the idea of N-gram is commonly used in detecting paraphrases as well as machine translation. Applying TF-IDF for N-gram is better, but still the  $ATOP_{test}$  is not higher: 0.8467. The reason is words are enough to capture semantics for SS, while n-grams/phrases are used for a more fine-grained level of semantics.

We also present model 5 and 6 (both are WTMF), to show the impact of: 1. modeling missing words with equal weights as observed words ( $w_m = 1$ ) (LSA manner), and 2. not modeling missing words at all ( $w_m = 0$ ) (LDA manner) in the context of WTMF model. As expected, both model 5 and model 6 generate much worse results.

Both LDA and model 6 ignore missing words, with better  $ATOP_{test}$  scores achieved by LDA. This may be due to the different inference algorithms. Model 5 and LSA are comparable, where missing words are used with a large weight. Both of them yield low results. This confirms our assumption

Figure 2: missing words weight  $w_m$  in WTMF

Figure 3: dimension  $K$  in WTMF and LDA

that allowing for equal impact of both observed and missing words is not the correct characterization of the semantic space.

### 5.2.2 Analysis

In these latent variable models, there are several essential parameters: weight of missing words  $w_m$ , and dimension  $K$ . Figure 2 and 3 analyze the impact of these parameters on  $ATOP_{test}$ .

Figure 2 shows the influence of  $w_m$  on  $ATOP_{test}$  values. The peak  $ATOP_{test}$  is around  $w_m = 0.0005$ , while other values of  $w_m$  (except  $w_m = 0.05$ ) also yield high ATOP values (better than LDA).

We also measure the influence of the dimension  $K = \{50, 75, 100, 125, 150\}$  on LDA and WTMF in Figure 3, where parameters for WTMF are  $w_m = 0.0005$ ,  $\lambda = 20$ , and for LDA are  $\alpha = 0.05$ ,  $\beta = 0.05$ . We can see WTMF consistently outperforms LDA by an ATOP value of 0.01 in each dimension. Although a larger  $K$  yields a better result, we still use a 100 due to computational complexity.

### 5.3 LI06: Human-rated Sentence Similarity

We also assess WTMF and LDA model on LI06 data set. We still use  $K = 100$ . As we can see in Figure 2, choosing the appropriate parameter  $w_m$  could boost the performance significantly. Since we do not have any tuning data for this task, we present Pearson’s correlation  $r$  for different values of  $w_m$  in Table 3. In addition, to demonstrate that  $w_m$  does not overfit the 30 data points, we also evaluate on

$w_m$	30 pairs		35 pairs	
	$r$	$\rho$	$r$	$\rho$
0.0005	0.8247	0.8440	0.4200	0.6006
0.001	0.8470	0.8636	0.4308	0.5985
0.005	0.8876	0.8966	<b>0.4638</b>	<b>0.5809</b>
0.01	<b>0.8984</b>	<b>0.9091</b>	0.4564	0.5450
0.05	0.8804	0.8812	0.4087	0.4766

Table 3: Different  $w_m$  of WTMF on LI06 ( $K = 100$ )

the other 35 pairs in LI06. Same as in (Tsatsaronis et al., 2010), we also include Spearman’s rank order correlation  $\rho$ , which is correlation of ranks of similarity values. Note that  $r$  and  $\rho$  are much lower for 35 pairs set, since most of the sentence pairs have a very low similarity (the average similarity value is 0.065 in 35 pairs set and 0.367 in 30 pairs set) and SS models need to identify the tiny difference among them, thereby rendering this set much harder to predict.

Using  $w_m = 0.01$  gives the best results on 30 pairs while on 35 pairs the peak values of  $r$  and  $\rho$  happens when  $w_m = 0.005$ . In general, the correlations in 30 pairs and in 35 pairs are consistent, which indicates  $w_m = 0.01$  or  $w_m = 0.005$  does not overfit the 30 pairs set.

Compared to CDR, LI06 data set has a strong preference for a larger  $w_m$ . This could be caused by different goals of the two tasks: CDR is evaluated by the rank of the most similar ones among all candidates, while the LI06 data set treats similar pairs and dissimilar pairs as equally important. Using a smaller  $w_m$  means the similarity score is computed mainly from semantics of the observed words. This benefits CDR, since it gives more accurate similarity scores for those similar pairs, but not so accurate for dissimilar pairs. In fact, from Figure 2 and Table 2 we see that  $w_m = 0.01$  also produces a very high  $ATOP_{test}$  value in CDR.

Table 4 shows the results of all current SS models with respect to the LI06 data set (30 pairs set). We cite their best performance for all reported results.

Once the correct  $w_m = 0.01$  is chosen, WTMF results in the best Pearson’s  $r$  and best Spearman’s  $\rho$  ( $w_m = 0.005$  yields the second best  $r$  and  $\rho$ ). Same as in CDR task, WTMF outperforms LDA by a large margin in both  $r$  and  $\rho$ . It indicates that the latent vectors induced by WTMF are able to not only identify same/similar sentences, but also identify the “correct” degree of dissimilar sentences.

Model	$r$	$\rho$
STASIS (Li et al., 2006)	0.8162	0.8126
(Liu et al., 2007)	0.841	0.8538
(Feng et al., 2008)	0.756	0.608
STS (Islam and Inkpen, 2008)	0.853	0.838
LSA (O’Shea et al., 2008)	0.8384	0.8714
Omiotis (Tsatsaronis et al., 2010)	0.856	0.8905
WSD-STIS (Ho et al., 2010)	0.864	0.8341
SPD-STIS (Ho et al., 2010)	0.895	0.9034

WTMF ( $w_m = 0.01, \lambda = 20$ )	<b>0.8984</b>	<b>0.9091</b>

Table 4: Pearson’s correlation  $r$  and Spearman’s correlation  $\rho$  on LI06 30 pairs

Model	Accuracy
Random	51.3
LSA (Mihalcea et al., 2006)	68.4
full model (Mihalcea et al., 2006)	70.3
STS (Islam and Inkpen, 2008)	72.6
Omiotis (Tsatsaronis et al., 2010)	69.97
LDA ( $\alpha = 0.05, \beta = 0.05$ )	68.6
WTMF ( $w_m = 0.01, \lambda = 20$ )	71.51

Table 5: Performance on MSR04 test set

#### 5.4 MSR04: MSR Paraphrase Corpus

Finally, we briefly discuss results of applying WTMF on MSR04 data. We use the same parameter setting used for the LI06 evaluation setting since both sets are human-rated sentence pairs ( $\lambda = 20, w_m = 0.01, K = 100$ ). We use the training set of MSR04 data to select a threshold of sentence similarity for the binary label. Table 5 summarizes the accuracy of other SS models noted in the literature and evaluated on MSR04 test set.

Compared to previous SS work and LDA, WTMF has the second best accuracy. It suggests that WTMF is quite competitive in the paraphrase recognition task.

It is worth noting that the best system on MSR04, STS (Islam and Inkpen, 2008), has much lower correlations on LI06 data set. The second best system among previous work on LI06 uses Spearman correlation, Omiotis (Tsatsaronis et al., 2010), and it yields a much worse accuracy on MSR04. The other works do not evaluate on both data sets.

## 6 Related Work

Almost all current SS methods work in the high-dimensional word space, and rely heavily on word/sense similarity measures, which is knowledge based (Li et al., 2006; Feng et al., 2008; Ho et al., 2010; Tsatsaronis et al., 2010), corpus-based (Islam

and Inkpen, 2008) or hybrid (Mihalcea et al., 2006). Almost all of them are evaluated on LI06 data set. It is interesting to see that most works find word similarity measures, especially knowledge based ones, to be the most effective component, while other features do not work well (such as word order or syntactic information). Mihalcea et al. (2006) use LSA as a baseline, and O’Shea et al. (2008) train LSA on regular length documents. Both results are considerably lower than word similarity based methods. Hence, our work is the first to successfully approach SS in the latent space.

Although there has been work modeling latent semantics for short texts (tweets) in LDA, the focus has been on exploiting additional features in Twitter, hence restricted to Twitter data. Ramage et al. (2010) use tweet metadata (author, hashtag) as some supervised information to model tweets. Jin et al. (2011) use long similar documents (the article that is referred by a url in tweets) to help understand the tweet. In contrast, our approach relies solely on the information in the texts by modeling local missing words, and does not need any additional data, which renders our approach much more widely applicable.

## 7 Conclusions

We explicitly model missing words to alleviate the sparsity problem in modeling short texts. We also propose a new evaluation framework for sentence similarity that allows large scale tuning and testing. Experiment results on three data sets show that our model WTMF significantly outperforms existing methods. For future work, we would like to compare the text modeling performance of WTMF with LSA and LDA on regular length documents.

# Improving Word Representations via Global Context and Multiple Word Prototypes

Eric H. Huang, Richard Socher\*, Christopher D. Manning, Andrew Y. Ng  
Computer Science Department, Stanford University, Stanford, CA 94305, USA  
{ehhuang, manning, ang}@stanford.edu, \*richard@socher.org

## Abstract

Unsupervised word representations are very useful in NLP tasks both as inputs to learning algorithms and as extra word features in NLP systems. However, most of these models are built with only local context and one representation per word. This is problematic because words are often polysemous and global context can also provide useful information for learning word meanings. We present a new neural network architecture which 1) learns word embeddings that better capture the semantics of words by incorporating both local and global document context, and 2) accounts for homonymy and polysemy by learning multiple embeddings per word. We introduce a new dataset with human judgments on pairs of words in sentential context, and evaluate our model on it, showing that our model outperforms competitive baselines and other neural language models.<sup>1</sup>

## 1 Introduction

Vector-space models (VSM) represent word meanings with vectors that capture semantic and syntactic information of words. These representations can be used to induce similarity measures by computing distances between the vectors, leading to many useful applications, such as information retrieval (Manning et al., 2008), document classification (Sebastiani, 2002) and question answering (Tellex et al., 2003).

<sup>1</sup>The dataset and word vectors can be downloaded at <http://ai.stanford.edu/~ehhuang/>.

Despite their usefulness, most VSMS share a common problem that each word is only represented with one vector, which clearly fails to capture homonymy and polysemy. Reisinger and Mooney (2010b) introduced a multi-prototype VSM where word sense discrimination is first applied by clustering contexts, and then prototypes are built using the contexts of the sense-labeled words. However, in order to cluster accurately, it is important to capture both the syntax and semantics of words. While many approaches use local contexts to disambiguate word meaning, global contexts can also provide useful topical information (Ng and Zelle, 1997). Several studies in psychology have also shown that global context can help language comprehension (Hess et al., 1995) and acquisition (Li et al., 2000).

We introduce a new neural-network-based language model that distinguishes and uses both local and global context via a joint training objective. The model learns word representations that better capture the semantics of words, while still keeping syntactic information. These improved representations can be used to represent contexts for clustering word instances, which is used in the multi-prototype version of our model that accounts for words with multiple senses.

We evaluate our new model on the standard WordSim-353 (Finkelstein et al., 2001) dataset that includes human similarity judgments on pairs of words, showing that combining both local and global context outperforms using only local or global context alone, and is competitive with state-of-the-art methods. However, one limitation of this evaluation is that the human judgments are on pairs

Figure 1: An overview of our neural language model. The model makes use of both local and global context to compute a score that should be large for the actual next word (*bank* in the example), compared to the score for other words. When word meaning is still ambiguous given local context, information in global context can help disambiguation.

of words presented in *isolation*, ignoring meaning variations in context. Since word interpretation in context is important especially for homonymous and polysemous words, we introduce a new dataset with human judgments on similarity between pairs of words in sentential context. To capture interesting word pairs, we sample different senses of words using WordNet (Miller, 1995). The dataset includes verbs and adjectives, in addition to nouns. We show that our multi-prototype model improves upon the single-prototype version and outperforms other neural language models and baselines on this dataset.

## 2 Global Context-Aware Neural Language Model

In this section, we describe the training objective of our model, followed by a description of the neural network architecture, ending with a brief description of our model’s training method.

### 2.1 Training Objective

Our model jointly learns word representations while learning to discriminate the next word given a short word sequence (local context) and the document (global context) in which the word sequence occurs. Because our goal is to learn useful word representations and not the *probability* of the next word given previous words (which prohibits looking ahead), our model can utilize the entire document to provide

global context.

Given a word sequence  $s$  and document  $d$  in which the sequence occurs, our goal is to discriminate the correct last word in  $s$  from other random words. We compute scores  $g(s, d)$  and  $g(s^w, d)$  where  $s^w$  is  $s$  with the last word replaced by word  $w$ , and  $g(\cdot, \cdot)$  is the scoring function that represents the neural networks used. We want  $g(s, d)$  to be larger than  $g(s^w, d)$  by a margin of 1, for any other word  $w$  in the vocabulary, which corresponds to the training objective of minimizing the ranking loss for each  $(s, d)$  found in the corpus:

$$C_{s,d} = \sum_{w \in V} \max(0, 1 - g(s, d) + g(s^w, d)) \quad (1)$$

Collobert and Weston (2008) showed that this ranking approach can produce good word embeddings that are useful in several NLP tasks, and allows much faster training of the model compared to optimizing log-likelihood of the next word.

### 2.2 Neural Network Architecture

We define two scoring components that contribute to the final score of a (word sequence, document) pair. The scoring components are computed by two neural networks, one capturing local context and the other global context, as shown in Figure 1. We now describe how each scoring component is computed.

The score of local context uses the local word sequence  $s$ . We first represent the word sequence  $s$  as

an ordered list of vectors  $x = (x_1, x_2, \dots, x_m)$  where  $x_i$  is the embedding of word  $i$  in the sequence, which is a column in the embedding matrix  $L \in \mathbb{R}^{n \times |V|}$  where  $|V|$  denotes the size of the vocabulary. The columns of this embedding matrix  $L$  are the word vectors and will be learned and updated during training. To compute the score of local context,  $\text{score}_l$ , we use a neural network with one hidden layer:

$$a_1 = f(W_1[x_1; x_2; \dots; x_m] + b_1) \quad (2)$$

$$\text{score}_l = W_2 a_1 + b_2 \quad (3)$$

where  $[x_1; x_2; \dots; x_m]$  is the concatenation of the  $m$  word embeddings representing sequence  $s$ ,  $f$  is an element-wise activation function such as  $\tanh$ ,  $a_1 \in \mathbb{R}^{h \times 1}$  is the activation of the hidden layer with  $h$  hidden nodes,  $W_1 \in \mathbb{R}^{h \times (mn)}$  and  $W_2 \in \mathbb{R}^{1 \times h}$  are respectively the first and second layer weights of the neural network, and  $b_1, b_2$  are the biases of each layer.

For the score of the global context, we represent the document also as an ordered list of word embeddings,  $d = (d_1, d_2, \dots, d_k)$ . We first compute the weighted average of all word vectors in the document:

$$c = \frac{\sum_{i=1}^k w(t_i) d_i}{\sum_{i=1}^k w(t_i)} \quad (4)$$

where  $w(\cdot)$  can be any weighting function that captures the importance of word  $t_i$  in the document. We use idf-weighting as the weighting function.

We use a two-layer neural network to compute the global context score,  $\text{score}_g$ , similar to the above:

$$a_1^{(g)} = f(W_1^{(g)}[c; x_m] + b_1^{(g)}) \quad (5)$$

$$\text{score}_g = W_2^{(g)} a_1^{(g)} + b_2^{(g)} \quad (6)$$

where  $[c; x_m]$  is the concatenation of the weighted average document vector and the vector of the last word in  $s$ ,  $a_1^{(g)} \in \mathbb{R}^{h^{(g)} \times 1}$  is the activation of the hidden layer with  $h^{(g)}$  hidden nodes,  $W_1^{(g)} \in \mathbb{R}^{h^{(g)} \times (2n)}$  and  $W_2^{(g)} \in \mathbb{R}^{1 \times h^{(g)}}$  are respectively the first and second layer weights of the neural network, and  $b_1^{(g)}, b_2^{(g)}$  are the biases of each layer. Note that instead of using the document where the sequence occurs, we can also specify a fixed  $k > m$  that captures larger context.

The final score is the sum of the two scores:

$$\text{score} = \text{score}_l + \text{score}_g \quad (7)$$

The local score preserves word order and syntactic information, while the global score uses a weighted average which is similar to bag-of-words features, capturing more of the semantics and topics of the document. Note that Collobert and Weston (2008)'s language model corresponds to the network using only local context.

### 2.3 Learning

Following Collobert and Weston (2008), we sample the gradient of the objective by randomly choosing a word from the dictionary as a *corrupt* example for each sequence-document pair,  $(s, d)$ , and take the derivative of the ranking loss with respect to the parameters: weights of the neural network and the embedding matrix  $L$ . These weights are updated via backpropagation. The embedding matrix  $L$  is the word representations. We found that word embeddings move to good positions in the vector space faster when using mini-batch L-BFGS (Liu and Nocedal, 1989) with 1000 pairs of good and corrupt examples per batch for training, compared to stochastic gradient descent.

### 3 Multi-Prototype Neural Language Model

Despite distributional similarity models' successful applications in various NLP tasks, one major limitation common to most of these models is that they assume only one representation for each word. This single-prototype representation is problematic because many words have multiple meanings, which can be wildly different. Using one representation simply cannot capture the different meanings. Moreover, using all contexts of a homonymous or polysemous word to build a single prototype could hurt the representation, which cannot represent any one of the meanings well as it is influenced by all meanings of the word.

Instead of using only one representation per word, Reisinger and Mooney (2010b) proposed the multi-prototype approach for vector-space models, which uses multiple representations to capture different senses and usages of a word. We show how our

model can readily adopt the multi-prototype approach. We present a way to use our learned single-prototype embeddings to represent each context window, which can then be used by clustering to perform word sense discrimination (Schütze, 1998).

In order to learn multiple prototypes, we first gather the fixed-sized context windows of all occurrences of a word (we use 5 words before and after the word occurrence). Each context is represented by a weighted average of the context words’ vectors, where again, we use idf-weighting as the weighting function, similar to the document context representation described in Section 2.2. We then use spherical k-means to cluster these context representations, which has been shown to model semantic relations well (Dhillon and Modha, 2001). Finally, each word occurrence in the corpus is re-labeled to its associated cluster and is used to train the word representation for that cluster.

Similarity between a pair of words  $(w, w')$  using the multi-prototype approach can be computed with or without context, as defined by Reisinger and Mooney (2010b):

$$\text{AvgSimC}(w, w') = \frac{1}{K^2} \sum_{i=1}^k \sum_{j=1}^k p(c, w, i) p(c', w', j) d(\mu_i(w), \mu_j(w')) \quad (8)$$

where  $p(c, w, i)$  is the likelihood that word  $w$  is in its cluster  $i$  given context  $c$ ,  $\mu_i(w)$  is the vector representing the  $i$ -th cluster centroid of  $w$ , and  $d(v, v')$  is a function computing similarity between two vectors, which can be any of the distance functions presented by Curran (2004). The similarity measure can be computed in absence of context by assuming uniform  $p(c, w, i)$  over  $i$ .

## 4 Experiments

In this section, we first present a qualitative analysis comparing the nearest neighbors of our model’s embeddings with those of others, showing our embeddings better capture the semantics of words, with the use of global context. Our model also improves the correlation with human judgments on a word similarity task. Because word interpretation in context is

important, we introduce a new dataset with human judgments on similarity of pairs of words in sentential context. Finally, we show that our model outperforms other methods on this dataset and also that the multi-prototype approach improves over the single-prototype approach.

We chose Wikipedia as the corpus to train all models because of its wide range of topics and word usages, and its clean organization of document by topic. We used the April 2010 snapshot of the Wikipedia corpus (Shaoul and Westbury, 2010), with a total of about 2 million articles and 990 million tokens. We use a dictionary of the 30,000 most frequent words in Wikipedia, converted to lower case. In preprocessing, we keep the frequent numbers intact and replace each digit of the uncommon numbers to “DG” so as to preserve information such as it being a year (e.g. “DGDGDGDG”). The converted numbers that are rare are mapped to a NUMBER token. Other rare words not in the dictionary are mapped to an UNKNOWN token.

For all experiments, our models use 50-dimensional embeddings. We use 10-word windows of text as the local context, 100 hidden units, and no weight regularization for both neural networks. For multi-prototype variants, we fix the number of prototypes to be 10.

### 4.1 Qualitative Evaluations

In order to show that our model learns more semantic word representations with global context, we give the nearest neighbors of our single-prototype model versus C&W’s, which only uses local context. The nearest neighbors of a word are computed by comparing the cosine similarity between the center word and all other words in the dictionary. Table 1 shows the nearest neighbors of some words. The nearest neighbors of “market” that C&W’s embeddings give are more constrained by the syntactic constraint that words in plural form are only close to other words in plural form, whereas our model captures that the singular and plural forms of a word are similar in meaning. Other examples show that our model induces nearest neighbors that better capture semantics.

Table 2 shows the nearest neighbors of our model using the multi-prototype approach. We see that the clustering is able to group contexts of different

Center Word	C&W	Our Model
markets	firms, industries, stores	market, firms, businesses
American	Australian, Indian, Italian	U.S., Canadian, African
illegal	alleged, overseas, banned	harmful, prohibited, convicted

Table 1: Nearest neighbors of words based on cosine similarity. Our model is less constrained by syntax and is more semantic.

Center Word	Nearest Neighbors
bank_1	corporation, insurance, company
bank_2	shore, coast, direction
star_1	movie, film, radio
star_2	galaxy, planet, moon
cell_1	telephone, smart, phone
cell_2	pathology, molecular, physiology
left_1	close, leave, live
left_2	top, round, right

Table 2: Nearest neighbors of word embeddings learned by our model using the multi-prototype approach based on cosine similarity. The clustering is able to find the different meanings, usages, and parts of speech of the words.

meanings of a word into separate groups, allowing our model to learn multiple meaningful representations of a word.

## 4.2 WordSim-353

A standard dataset for evaluating vector-space models is the WordSim-353 dataset (Finkelstein et al., 2001), which consists of 353 pairs of nouns. Each pair is presented without context and associated with 13 to 16 human judgments on similarity and relatedness on a scale from 0 to 10. For example, (cup,drink) received an average score of 7.25, while (cup,substance) received an average score of 1.92.

Table 3 shows our results compared to previous methods, including C&W’s language model and the hierarchical log-bilinear (HLBL) model (Mnih and Hinton, 2008), which is a probabilistic, linear neural model. We downloaded these embeddings from Turian et al. (2010). These embeddings were trained on the smaller corpus RCV1 that contains one year of Reuters English newswire, and show similar correlations on the dataset. We report the result of

Model	Corpus	$\rho \times 100$
Our Model-g	Wiki.	22.8
C&W	RCV1	29.5
HLBL	RCV1	33.2
C&W*	Wiki.	49.8
C&W	Wiki.	55.3
Our Model	Wiki.	64.2
Our Model*	Wiki.	71.3
Pruned <i>tf-idf</i>	Wiki.	73.4
ESA	Wiki.	75
Tiered Pruned <i>tf-idf</i>	Wiki.	76.9

Table 3: Spearman’s  $\rho$  correlation on WordSim-353, showing our model’s improvement over previous neural models for learning word embeddings. C&W\* is the word embeddings trained and provided by C&W. Our Model\* is trained without stop words, while Our Model-g uses only global context. Pruned *tf-idf* (Reisinger and Mooney, 2010b) and ESA (Gabrilovich and Markovitch, 2007) are also included.

our re-implementation of C&W’s model trained on Wikipedia, showing the large effect of using a different corpus.

Our model is able to learn more semantic word embeddings and noticeably improves upon C&W’s model. Note that our model achieves higher correlation (64.2) than either using local context alone (C&W: 55.3) or using global context alone (Our Model-g: 22.8). We also found that correlation can be further improved by removing stop words (71.3). Thus, each window of text (training example) contains more information but still preserves some syntactic information as the words are still ordered in the local context.

## 4.3 New Dataset: Word Similarity in Context

The many previous datasets that associate human judgments on similarity between pairs of words, such as WordSim-353, MC (Miller and Charles, 1991) and RG (Rubenstein and Goodenough, 1965), have helped to advance the development of vector-space models. However, common to all datasets is that similarity scores are given to pairs of words in *isolation*. This is problematic because the meanings of homonymous and polysemous words depend highly on the words’ contexts. For example, in the two phrases, “he swings the baseball *bat*” and “the

Word 1	Word 2

Table 4: Example pairs from our new dataset. Note that words in a pair can be the same word and have different parts of speech.

*bat* flies”, *bat* has completely different meanings. It is unclear how this variation in meaning is accounted for in human judgments of words presented without context.

One of the main contributions of this paper is the creation of a new dataset that addresses this issue. The dataset has three interesting characteristics: 1) human judgments are on pairs of words presented in sentential context, 2) word pairs and their contexts are chosen to reflect interesting variations in meanings of homonymous and polysemous words, and 3) verbs and adjectives are present in addition to nouns. We now describe our methodology in constructing the dataset.

#### 4.3.1 Dataset Construction

Our procedure of constructing the dataset consists of three steps: 1) select a list a words, 2) for each word, select another word to form a pair, 3) for each word in a pair, find a sentential context. We now describe each step in detail.

In step 1, in order to make sure we select a diverse list of words, we consider three attributes of a word: frequency in a corpus, number of parts of speech, and number of synsets according to WordNet. For frequency, we divide words into three groups, top 2,000 most frequent, between 2,000 and 5,000, and between 5,000 to 10,000 based on occurrences in Wikipedia. For number of parts of speech, we group words based on their number of possible parts of

speech (noun, verb or adjective), from 1 to 3. We also group words by their number of synsets: [0,5], [6,10], [11, 20], and [20, max]. Finally, we sample at most 15 words from each combination in the Cartesian product of the above groupings.

In step 2, for each of the words selected in step 1, we want to choose the other word so that the pair captures an interesting relationship. Similar to Manandhar et al. (2010), we use WordNet to first randomly select one synset of the first word, we then construct a set of words in various relations to the first word’s chosen synset, including hypernyms, hyponyms, holonyms, meronyms and attributes. We randomly select a word from this set of words as the second word in the pair. We try to repeat the above twice to generate two pairs for each word. In addition, for words with more than five synsets, we allow the second word to be the same as the first, but with different synsets. We end up with pairs of words as well as the one chosen synset for each word in the pairs.

In step 3, we aim to extract a sentence from Wikipedia for each word, which contains the word and corresponds to a usage of the chosen synset. We first find all sentences in which the word occurs. We then POS tag<sup>2</sup> these sentences and filter out those that do not match the chosen POS. To find the

<sup>2</sup>We used the MaxEnt Treebank POS tagger in the python nltk library.

Model	$\rho \times 100$
C&W-S	57.0
Our Model-S	58.6
Our Model-M AvgSim	62.8
Our Model-M AvgSimC	<b>65.7</b>
<i>tf-idf</i> -S	26.3
Pruned <i>tf-idf</i> -S	62.5
Pruned <i>tf-idf</i> -M AvgSim	60.4
Pruned <i>tf-idf</i> -M AvgSimC	60.5

Table 5: Spearman’s  $\rho$  correlation on our new dataset. Our Model-S uses the single-prototype approach, while Our Model-M uses the multi-prototype approach. AvgSim calculates similarity with each prototype contributing equally, while AvgSimC weighs the prototypes according to probability of the word belonging to that prototype’s cluster.

word usages that correspond to the chosen synset, we first construct a set of related words of the chosen synset, including hypernyms, hyponyms, holonyms, meronyms and attributes. Using this set of related words, we filter out a sentence if the document in which the sentence appears does not include one of the related words. Finally, we randomly select one sentence from those that are left.

Table 4 shows some examples from the dataset. Note that the dataset also includes pairs of the same word. Single-prototype models would give the max similarity score for those pairs, which can be problematic depending on the words’ contexts. This dataset requires models to examine context when determining word meaning.

Using Amazon Mechanical Turk, we collected 10 human similarity ratings for each pair, as Snow et al. (2008) found that 10 non-expert annotators can achieve very close inter-annotator agreement with expert raters. To ensure worker quality, we only allowed workers with over 95% approval rate to work on our task. Furthermore, we discarded all ratings by a worker if he/she entered scores out of the accepted range or missed a rating, signaling low-quality work.

We obtained a total of 2,003 word pairs and their sentential contexts. The word pairs consist of 1,712 unique words. Of the 2,003 word pairs, 1328 are noun-noun pairs, 399 verb-verb, 140 verb-noun, 97 adjective-adjective, 30 noun-adjective, and 9 verb-adjective. 241 pairs are same-word pairs.

### 4.3.2 Evaluations on Word Similarity in Context

For evaluation, we also compute Spearman correlation between a model’s computed similarity scores and human judgments. Table 5 compares different models’ results on this dataset. We compare against the following baselines: *tf-idf* represents words in a word-word matrix capturing co-occurrence counts in all 10-word context windows. Reisinger and Mooney (2010b) found pruning the low-value *tf-idf* features helps performance. We report the result of this pruning technique after tuning the threshold value on this dataset, removing all but the top 200 features in each word vector. We tried the same multi-prototype approach and used spherical k-means<sup>3</sup> to cluster the contexts using *tf-idf* representations, but obtained lower numbers than single-prototype (55.4 with AvgSimC). We then tried using pruned *tf-idf* representations on contexts with our clustering assignments (included in Table 5), but still got results worse than the single-prototype version of the pruned *tf-idf* model (60.5 with AvgSimC). This suggests that the pruned *tf-idf* representations might be more susceptible to noise or mistakes in context clustering.

By utilizing global context, our model outperforms C&W’s vectors and the above baselines on this dataset. With multiple representations per word, we show that the multi-prototype approach can improve over the single-prototype version without using context (62.8 vs. 58.6). Moreover, using AvgSimC<sup>4</sup> which takes contexts into account, the multi-prototype model obtains the best performance (65.7).

## 5 Related Work

Neural language models (Bengio et al., 2003; Mnih and Hinton, 2007; Collobert and Weston, 2008; Schwenk and Gauvain, 2002; Emami et al., 2003) have been shown to be very powerful at language modeling, a task where models are asked to accurately predict the next word given previously seen words. By using distributed representations of

<sup>3</sup>We first tried movMF as in Reisinger and Mooney (2010b), but were unable to get decent results (only 31.5).

<sup>4</sup>probability of being in a cluster is calculated as the inverse of the distance to the cluster centroid.

words which model words' similarity, this type of models addresses the data sparseness problem that  $n$ -gram models encounter when large contexts are used. Most of these models used relative local contexts of between 2 to 10 words. Schwenk and Gauvain (2002) tried to incorporate larger context by combining partial parses of past word sequences and a neural language model. They used up to 3 previous head words and showed increased performance on language modeling. Our model uses a similar neural network architecture as these models and uses the ranking-loss training objective proposed by Collobert and Weston (2008), but introduces a new way to combine local and global context to train word embeddings.

Besides language modeling, word embeddings induced by neural language models have been useful in chunking, NER (Turian et al., 2010), parsing (Socher et al., 2011b), sentiment analysis (Socher et al., 2011c) and paraphrase detection (Socher et al., 2011a). However, they have not been directly evaluated on word similarity tasks, which are important for tasks such as information retrieval and summarization. Our experiments show that our word embeddings are competitive in word similarity tasks.

Most of the previous vector-space models use a single vector to represent a word even though many words have multiple meanings. The multi-prototype approach has been widely studied in models of categorization in psychology (Rosseel, 2002; Griffiths et al., 2009), while Schütze (1998) used clustering of contexts to perform word sense discrimination. Reisinger and Mooney (2010b) combined the two approaches and applied them to vector-space models, which was further improved in Reisinger and Mooney (2010a). Two other recent papers (Dhillon et al., 2011; Reddy et al., 2011) present models for constructing word representations that deal with context. It would be interesting to evaluate those models on our new dataset.

Many datasets with human similarity ratings on pairs of words, such as WordSim-353 (Finkelstein et al., 2001), MC (Miller and Charles, 1991) and RG (Rubenstein and Goodenough, 1965), have been widely used to evaluate vector-space models. Motivated to evaluate composition models, Mitchell and Lapata (2008) introduced a dataset where an intransitive verb, presented with a subject noun, is com-

pared to another verb chosen to be either similar or dissimilar to the intransitive verb in context. The context is short, with only one word, and only verbs are compared. Erk and Padó (2008), Thater et al. (2011) and Dinu and Lapata (2010) evaluated word similarity in context with a modified task where systems are to rerank gold-standard paraphrase candidates given the SemEval 2007 Lexical Substitution Task dataset. This task only indirectly evaluates similarity as only reranking of already similar words are evaluated.

## 6 Conclusion

We presented a new neural network architecture that learns more semantic word representations by using both local and global context in learning. These learned word embeddings can be used to represent word contexts as low-dimensional weighted average vectors, which are then clustered to form different meaning groups and used to learn multi-prototype vectors. We introduced a new dataset with human judgments on similarity between pairs of words in context, so as to evaluate model's abilities to capture homonymy and polysemy of words in context. Our new multi-prototype neural language model outperforms previous neural models and competitive baselines on this new dataset.

## Abstract

This paper uses an unsupervised model of grounded language acquisition to study the role that social cues play in language acquisition. The input to the model consists of (orthographically transcribed) child-directed utterances accompanied by the set of objects present in the non-linguistic context. Each object is annotated by *social cues*, indicating e.g., whether the caregiver is looking at or touching the object. We show how to model the task of inferring which objects are being talked about (and which words refer to which objects) as standard grammatical inference, and describe PCFG-based *unigram* models and adaptor grammar-based *collocation* models for the task. Exploiting social cues improves the performance of all models. Our models learn the relative importance of each social cue jointly with word-object mappings and collocation structure, consistent with the idea that children could discover the importance of particular social information sources during word learning.

## 1 Introduction

From learning sounds to learning the meanings of words, social interactions are extremely important for children's early language acquisition (Baldwin, 1993; Kuhl et al., 2003). For example, children who engage in more joint attention (e.g. looking at particular objects together) with caregivers tend to learn words faster (Carpenter et al., 1998). Yet computational or formal models of social interaction are rare, and those that exist have rarely gone beyond the stage of cue-weighting models. In order to study the role that *social cues* play in language acquisition, this paper presents a structured statistical model of

grounded learning that learns a mapping between words and objects from a corpus of child-directed utterances in a completely unsupervised fashion. It exploits five different *social cues*, which indicate which object (if any) the child is looking at, which object the child is touching, etc. Our models learn the salience of each social cue in establishing reference, relative to their co-occurrence with objects that are not being referred to. Thus, this work is consistent with a view of language acquisition in which children *learn to learn*, discovering organizing principles for how language is organized and used socially (Baldwin, 1993; Hollich et al., 2000; Smith et al., 2002).

We reduce the grounded learning task to a grammatical inference problem (Johnson et al., 2010; Börschinger et al., 2011). The strings presented to our grammatical learner contain a prefix which encodes the objects and their social cues for each utterance, and the rules of the grammar encode relationships between these objects and specific words. These rules permit every object to map to every word (including function words; i.e., there is no “stop word” list), and the learning process decides which of these rules will have a non-trivial probability (these encode the object-word mappings the system has learned).

This reduction of grounded learning to grammatical inference allows us to use standard grammatical inference procedures to learn our models. Here we use the *adaptor grammar* package described in Johnson et al. (2007) and Johnson and Goldwater (2009) with “out of the box” default settings; no parameter tuning whatsoever was done. Adaptor grammars are a framework for specifying hierarchical non-parametric models that has been previously used to model language acquisition (Johnson, 2008).

Social cue	Value
<i>child.eyes</i>	objects child is looking at
<i>child.hands</i>	objects child is touching
<i>mom.eyes</i>	objects care-giver is looking at
<i>mom.hands</i>	objects care-giver is touching
<i>mom.point</i>	objects care-giver is pointing to

Figure 1: The 5 social cues in the Frank et al. (to appear) corpus. The value of a social cue for an utterance is a subset of the available topics (i.e., the objects in the non-linguistic context) of that utterance.

A semanticist might argue that our view of referential mapping is flawed: full noun phrases (e.g., *the dog*), rather than nouns, refer to specific objects, and nouns denote properties (e.g., *dog* denotes the property of being a dog). Learning that a noun, e.g., *dog*, is part of a phrase used to refer to a specific dog (say, Fido) does not suffice to determine the noun’s meaning: the noun could denote a specific breed of dog, or animals in general. But learning word-object relationships is a plausible first step for any learner: it is often only the contrast between learned relationships and novel relationships that allows children to induce super- or sub-ordinate mappings (Clark, 1987). Nevertheless, in deference to such objections, we call the object that a phrase containing a given noun refers to the *topic* of that noun. (This is also appropriate, given that our models are specialisations of topic models).

Our models are intended as an “ideal learner” approach to early social language learning, attempting to weight the importance of social and structural factors in the acquisition of word-object correspondences. From this perspective, the primary goal is to investigate the relationships between acquisition tasks (Johnson, 2008; Johnson et al., 2010), looking for synergies (areas of acquisition where attempting two learning tasks jointly can provide gains in both) as well as areas where information overlaps.

### 1.1 A training corpus for social cues

Our work here uses a corpus of child-directed speech annotated with social cues, described in Frank et al. (to appear). The corpus consists of 4,763 orthographically-transcribed utterances of caregivers to their pre-linguistic children (ages 6, 12, and 18 months) during home visits where children played with a consistent set of toys. The sessions were video-taped, and each utterance was annotated with the five social cues described in Figure 1.

Each utterance in the corpus contains the follow-

ing information:

- the sequence of orthographic words uttered by the care-giver,
- a set of *available topics* (i.e., objects in the non-linguistic objects),
- the values of the social cues, and
- a set of *intended topics*, which the care-giver refers to.

Figure 2 presents this information for an example utterance. All of these but the intended topics are provided to our learning algorithms; the intended topics are used to evaluate the output produced by our learners.

Generally the intended topics consist of zero or one elements from the available topics, but not always: it is possible for the caregiver to refer to two objects in a single utterance, or to refer to an object not in the current non-linguistic context (e.g., to a toy that has been put away). There is a considerable amount of anaphora in this corpus, which our models currently ignore.

Frank et al. (to appear) give extensive details on the corpus, including inter-annotator reliability information for all annotations, and provide detailed statistical analyses of the relationships between the various social cues, the available topics and the intended topics. That paper also gives instructions on obtaining the corpus.

### 1.2 Previous work

There is a growing body of work on the role of social cues in language acquisition. The language acquisition research community has long recognized the importance of social cues for child language acquisition (Baldwin, 1991; Carpenter et al., 1998; Kuhl et al., 2003).

Siskind (1996) describes one of the first examples of a model that learns the relationship between words and topics, albeit in a non-statistical framework. Yu and Ballard (2007) describe an associative learner that associates words with topics and that exploits prosodic as well as social cues. The relative importance of the various social cues are specified a priori in their model (rather than learned, as they are here), and unfortunately their training corpus is not available. Frank et al. (2008) describes a Bayesian model that learns the relationship between words and topics, but the version of their model that included social cues presented a number of challenges for inference. The unigram model we describe below corresponds most closely to the Frank

*.dog # .pig child.eyes mom.eyes mom.hands # ## wheres the piggie*

Figure 2: The photograph indicates non-linguistic context containing a (toy) pig and dog for the utterance *Where's the piggie?*. Below that, we show the representation of this utterance that serves as the input to our models. The prefix (the portion of the string before the “##”) lists the available topics (i.e., the objects in the non-linguistic context) and their associated social cues (the cues for the pig are *child.eyes*, *mom.eyes* and *mom.hands*, while the dog is not associated with any social cues). The intended topic is the pig. The learner's goals are to identify the utterance's intended topic, and which words in the utterance are associated with which topic.

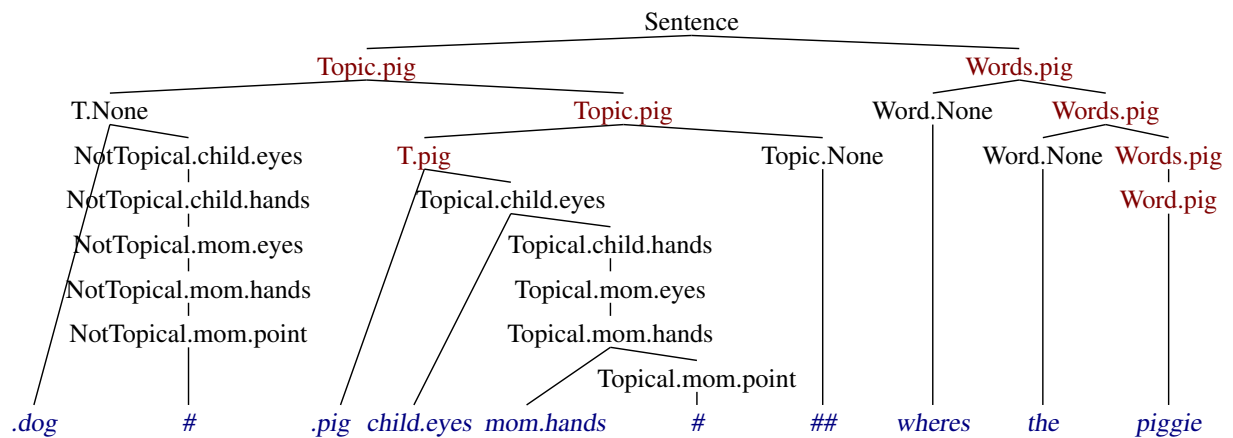

Figure 3: Sample parse generated by the Unigram PCFG. Nodes coloured red show how the “pig” topic is propagated from the prefix (before the “##” separator) into the utterance. The social cues associated with each object are generated either from a “Topical” or a “NotTopical” nonterminal, depending on whether the corresponding object is topical or not.

et al. model. Johnson et al. (2010) reduces grounded learning to grammatical inference for adaptor grammars and shows how it can be used to perform word segmentation as well as learning word-topic relationships, but their model does not take social cues into account.

## 2 Reducing grounded learning with social cues to grammatical inference

This section explains how we reduce ground learning problems with social cues to grammatical inference problems, which lets us apply a wide variety of grammatical inference algorithms to grounded learning problems. An advantage of reducing grounded learning to grammatical inference is that it suggests new ways to generalise grounded learning models; we explore three such generalisations here. The main challenge in this reduction is finding a way of expressing the non-linguistic information as part of the strings that serve as the grammatical inference procedure’s input. Here we encode the non-linguistic information in a “prefix” to each utterance as shown in Figure 2, and devise a grammar such that inference for the grammar corresponds to learning the word-topic relationships and the salience of the social cues for grounded learning.

All our models associate each utterance with zero or one topics (this means we cannot correctly analyse utterances with more than one intended topic). We analyse an utterance associated with zero topics as having the special topic None, so we can assume that every utterance has exactly one topic. All our grammars generate strings of the form shown in Figure 2, and they do so by parsing the prefix and the words of the utterance separately; the top-level rules of the grammar force the same topic to be associated with both the prefix and the words of the utterance (see Figure 3).

### 2.1 Topic models and the unigram PCFG

As Johnson et al. (2010) observe, this kind of grounded learning can be viewed as a specialised kind of topic inference in a topic model, where the utterance topic is constrained by the available objects (possible topics). We exploit this observation here using a reduction based on the reduction of LDA topic models to PCFGs proposed by Johnson (2010). This leads to our first model, the unigram grammar, which is a PCFG.<sup>1</sup>

<sup>1</sup>In fact, the unigram grammar is equivalent to a HMM, but the PCFG parameterisation makes clear the relationship

Sentence	$\rightarrow$ Topic <sub><i>t</i></sub> Words <sub><i>t</i></sub>	$\forall t \in T'$
Topic <sub>None</sub>	$\rightarrow$ ##	
Topic <sub><i>t</i></sub>	$\rightarrow$ T <sub><i>t</i></sub> Topic <sub>None</sub>	$\forall t \in T'$
Topic <sub><i>t</i></sub>	$\rightarrow$ T <sub>None</sub> Topic <sub><i>t</i></sub>	$\forall t \in T$
T <sub><i>t</i></sub>	$\rightarrow$ <i>t</i> Topical <sub><i>c</i><sub>1</sub></sub>	$\forall t \in T$
Topical <sub><i>c</i><sub><i>i</i></sub></sub>	$\rightarrow$ ( <i>c</i> <sub><i>i</i></sub> ) Topical <sub><i>c</i><sub><i>i</i>+1</sub></sub>	$i = 1, \dots, \ell - 1$
Topical <sub><i>c</i><sub><math>\ell</math></sub></sub>	$\rightarrow$ ( <i>c</i> <sub><math>\ell</math></sub> ) #	
T <sub>None</sub>	$\rightarrow$ <i>t</i> NotTopical <sub><i>c</i><sub>1</sub></sub>	$\forall t \in T$
NotTopical <sub><i>c</i><sub><i>i</i></sub></sub>	$\rightarrow$ ( <i>c</i> <sub><i>i</i></sub> ) NotTopical <sub><i>c</i><sub><i>i</i>+1</sub></sub>	$i = 1, \dots, \ell - 1$
NotTopical <sub><i>c</i><sub><math>\ell</math></sub></sub>	$\rightarrow$ ( <i>c</i> <sub><math>\ell</math></sub> ) #	
Words <sub><i>t</i></sub>	$\rightarrow$ Word <sub>None</sub> (Words <sub><i>t</i></sub> )	$\forall t \in T'$
Words <sub><i>t</i></sub>	$\rightarrow$ Word <sub><i>t</i></sub> (Words <sub><i>t</i></sub> )	$\forall t \in T$
Word <sub><i>t</i></sub>	$\rightarrow$ <i>w</i>	$\forall t \in T', w \in W$

Figure 4: The rule schema that generate the unigram PCFG. Here (*c*<sub>1</sub>, . . . , *c* <sub>$\ell$</sub> ) is an ordered list of the social cues, *T* is the set of all non-None available topics,  $T' = T \cup \{\text{None}\}$ , and *W* is the set of words appearing in the utterances. Parentheses indicate optionality.

Figure 4 presents the rules of the unigram grammar. This grammar has two major parts. The rules expanding the Topic<sub>*t*</sub> nonterminals ensure that the social cues for the available topic *t* are parsed under the Topical nonterminals. All other available topics are parsed under T<sub>None</sub> nonterminals, so their social cues are parsed under NotTopical nonterminals. The rules expanding these non-terminals are specifically designed so that the generation of the social cues corresponds to a series of binary decisions about each social cue. For example, the probability of the rule

$$\text{Topical}_{child.eyes} \rightarrow .child.eyes \text{Topical}_{child.hands}$$

is the probability of an object that is an utterance topic occurring with the *child.eyes* social cue. By estimating the probabilities of these rules, the model effectively learns the probability of each social cue being associated with a Topical or a NotTopical available topic, respectively.

The nonterminals Words<sub>*t*</sub> expand to a sequence of Word<sub>*t*</sub> and Word<sub>None</sub> nonterminals, each of which can expand to any word whatsoever. In practice Word<sub>*t*</sub> will expand to those words most strongly associated with topic *t*, while Word<sub>None</sub> will expand to those words not associated with any topic.

between grounded learning and estimation of grammar rule weights.

Sentence	$\rightarrow$ Topic <sub>t</sub> Colloc <sub>t</sub>	$\forall t \in T'$
Colloc <sub>t</sub>	$\rightarrow$ Colloc <sub>t</sub> (Colloc <sub>s</sub> <sub>t</sub> )	$\forall t \in T'$
Colloc <sub>s</sub> <sub>t</sub>	$\rightarrow$ Colloc <sub>None</sub> (Colloc <sub>s</sub> <sub>t</sub> )	$\forall t \in T$
<u>Colloc<sub>t</sub></u>	$\rightarrow$ Words <sub>t</sub>	$\forall t \in T'$
<u>Words<sub>t</sub></u>	$\rightarrow$ Word <sub>t</sub> (Words <sub>t</sub> )	$\forall t \in T'$
Words <sub>s</sub> <sub>t</sub>	$\rightarrow$ Word <sub>None</sub> (Words <sub>s</sub> <sub>t</sub> )	$\forall t \in T$
<u>Word<sub>t</sub></u>	$\rightarrow$ Word	$\forall t \in T'$
Word	$\rightarrow$ w	$\forall w \in W$

Figure 5: The rule schema that generate the collocation adaptor grammar. Adapted nonterminals are indicated via underlining. Here  $T$  is the set of all non-None available topics,  $T' = T \cup \{\text{None}\}$ , and  $W$  is the set of words appearing in the utterances. The rules expanding the Topic<sub>t</sub> nonterminals are exactly as in unigram PCFG.

## 2.2 Adaptor grammars

Our other grounded learning models are based on reductions of grounded learning to adaptor grammar inference problems. Adaptor grammars are a framework for stating a variety of Bayesian non-parametric models defined in terms of a hierarchy of Pitman-Yor Processes: see Johnson et al. (2007) for a formal description. Informally, an adaptor grammar is specified by a set of rules just as in a PCFG, plus a set of *adapted nonterminals*. The set of trees generated by an adaptor grammar is the same as the set of trees generated by a PCFG with the same rules, but the generative process differs. Non-adapted nonterminals in an adaptor grammar expand just as they do in a PCFG: the probability of choosing a rule is specified by its probability. However, the expansion of an adapted nonterminal depends on how it expanded in previous derivations. An adapted nonterminal can directly expand to a subtree with probability proportional to the number of times that subtree has been previously generated; it can also “back off” to expand using a grammar rule, just as in a PCFG, with probability proportional to a constant.<sup>2</sup>

Thus an adaptor grammar can be viewed as caching each tree generated by each adapted nonterminal, and regenerating it with probability proportional to the number of times it was previously generated (with some probability mass reserved to generate “new” trees). This enables adaptor gram-

<sup>2</sup>This is a description of Chinese Restaurant Processes, which are the predictive distributions for Dirichlet Processes. Our adaptor grammars are actually based on the more general Pitman-Yor Processes, as described in Johnson and Goldwater (2009).

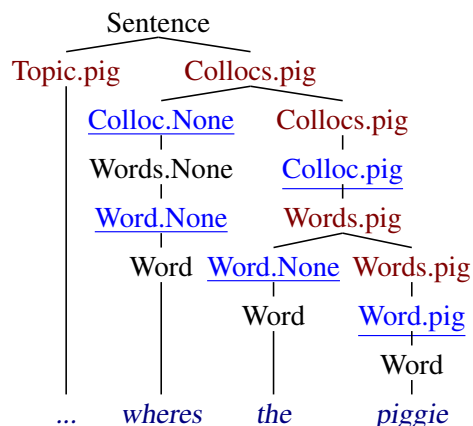

Figure 6: Sample parse generated by the collocation adaptor grammar. The adapted nonterminals Colloc<sub>t</sub> and Word<sub>t</sub> are shown underlined; the subtrees they dominate are “cached” by the adaptor grammar. The prefix (not shown here) is parsed exactly as in the Unigram PCFG.

mars to generalise over subtrees of arbitrary size. Generic software is available for adaptor grammar inference, based either on Variational Bayes (Cohen et al., 2010) or Markov Chain Monte Carlo (Johnson and Goldwater, 2009). We used the latter software because it is capable of performing hyper-parameter inference for the PCFG rule probabilities and the Pitman-Yor Process parameters. We used the “out-of-the-box” settings for this software, i.e., uniform priors on all PCFG rule parameters, a Beta(2, 1) prior on the Pitman-Yor  $a$  parameters and a “vague” Gamma(100, 0.01) prior on the Pitman-Yor  $b$  parameters. (Presumably performance could be improved if the priors were tuned, but we did not explore this here).

Here we explore a simple “collocation” extension to the unigram PCFG which associates multiword collocations, rather than individual words, with topics. Hardisty et al. (2010) showed that this significantly improved performance in a sentiment analysis task.

The collocation adaptor grammar in Figure 5 generates the words of the utterance as a sequence of collocations, each of which is a sequence of words. Each collocation is either associated with the sentence topic or with the None topic, just like words in the unigram model. Figure 6 shows a sample parse generated by the collocation adaptor grammar.

We also experimented with a variant of the unigram and collocation grammars in which the topic-specific word distributions Word<sub>t</sub> for each  $t \in T$

Model	Social cues	Utterance topic				Word topic			Lexicon

Figure 7: Utterance topic, word topic and lexicon results for all models, on data with and without social cues. The results for the variant models, in which  $\text{Word}_t$  nonterminals expand via  $\text{Word}_{\text{None}}$ , are shown under unigram' and colloc'. Utterance topic shows how well the model discovered the intended topics at the utterance level, word topic shows how well the model associates word tokens with topics, and lexicon shows how well the topic most frequently associated with a word type matches an external word-topic dictionary. In this figure and below, “colloc” abbreviates “collocation”, “acc.” abbreviates “accuracy”, “prec.” abbreviates “precision” and “rec.” abbreviates “recall”.

(the set of non-None available topics) expand via  $\text{Word}_{\text{None}}$  non-terminals. That is, in the variant grammars topical words are generated with the following rule schema:

$$\begin{aligned} \text{Word}_t &\rightarrow \text{Word}_{\text{None}} && \forall t \in T \\ \text{Word}_{\text{None}} &\rightarrow \text{Word} \\ \text{Word} &\rightarrow w && \forall w \in W \end{aligned}$$

In these variant grammars, the  $\text{Word}_{\text{None}}$  nonterminal generates all the words of the language, so it defines a generic “background” distribution over all the words, rather than just the nontopical words. An effect of this is that the variant grammars tend to identify fewer words as topical.

### 3 Experimental evaluation

We performed grammatical inference using the adaptor grammar software described in Johnson and Goldwater (2009).<sup>3</sup> All experiments involved 4 runs of 5,000 samples each, of which the first 2,500 were discarded for “burn-in”.<sup>4</sup> From these samples we extracted the modal (i.e., most frequent) analysis,

<sup>3</sup>Because adaptor grammars are a generalisation of PCFGs, we could use the adaptor grammar software to estimate the unigram model.

<sup>4</sup>We made no effort to optimise the computation, but it seems the samplers actually stabilised after around a hundred iterations, so it was probably not necessary to sample so extensively. We estimated the error in our results by running our most complex model (the colloc' model with all social cues) 20 times (i.e.,  $20 \times 8$  chains for 5,000 iterations) so we could compute the variance of each of the evaluation scores (it is reasonable to assume that the simpler models will have smaller variance). The standard deviation of all utterance topic and word topic measures is between 0.005 and 0.01; the standard deviation for lexicon f-score is 0.02, lexicon precision is 0.01 and lexicon recall is 0.03. The adaptor grammar software uses a sentence-wise

which we evaluated as described below. The results of evaluating each model on the corpus with social cues, and on another corpus identical except that the social cues have been removed, are presented in Figure 7.

Each model was evaluated on each corpus as follows. First, we extracted the utterance’s topic from the modal parse (this can be read off the  $\text{Topic}_t$  nodes), and compared this to the intended topics annotated in the corpus. The frequency with which the models’ predicted topics exactly matches the intended topics is given under “utterance topic accuracy”; the f-score, precision and recall of each model’s topic predictions are also given in the table.

Because our models all associate word tokens with topics, we can also evaluate the accuracy with which word tokens are associated with topics. We constructed a small dictionary which identifies the words that can be used as the head of a phrase to refer to the topical objects (e.g., the dictionary indicates that *dog*, *doggie* and *puppy* name the topical object DOG). Our dictionary is relatively conservative; between one and eight words are associated with each topic. We scored the topic label on each word token in our corpus as follows. A topic label is scored as correct if it is given in our dictionary and the topic is one of the intended topics for the utterance. The “word topic” entries in Figure 7 give the results of this evaluation.

blocked sampler, so it requires fewer iterations than a pointwise sampler. We used 5,000 iterations because this is the software’s default setting; evaluating the trace output suggests it only takes several hundred iterations to “burn in”. However, we ran 8 chains for 25,000 iterations of the colloc' model; as expected the results of this run are within two standard deviations of the results reported above.

Figure 8: Effect of using just one social cue on the experimental results for the unigram and collocation models. The “importance” of a social cue can be quantified by the degree to which the model’s evaluation score improves when using a corpus containing that social cue relative to its evaluation score when using a corpus without any social cues. The most important social cue is the one which causes performance to improve the most.

Finally, we extracted a lexicon from the parsed corpus produced by each model. We counted how often each word type was associated with each topic in our sampler’s output (including the None topic), and assigned the word to its most frequent topic. The “lexicon” entries in Figure 7 show how well the entries in these lexicons match the entries in the manually-constructed dictionary discussed above.

There are 10 different evaluation scores, and no model dominates in all of them. However, the top-scoring result in every evaluation is always for a model trained using social cues, demonstrating the importance of these social cues. The variant collocation model (trained on data with social cues) was the top-scoring model on four evaluation scores, which is more than any other model.

One striking thing about this evaluation is that the recall scores are all much higher than the precision scores, for each evaluation. This indicates that all of the models, especially the unigram model, are labelling too many words as topical. This is perhaps not too surprising: because our models completely lack any notion of syntactic structure and simply model the association between words and topics, they label many non-nouns with topics (e.g., *woof* is typically labelled with the topic DOG).

### 3.1 Evaluating the importance of social cues

It is scientifically interesting to be able to evaluate the importance of each of the social cues to grounded learning. One way to do this is to study the effect of adding or removing social cues from the corpus on the ability of our models to perform grounded learning. An important social cue should

have a large impact on our models’ performance; an unimportant cue should have little or no impact.

Figure 8 compares the performance of the unigram and collocation models on corpora containing a single social cue to their performance on the corpus without any social cues, while Figure 9 compares the performance of these models on corpora containing all but one social cue to the corpus containing all of the social cues. In both of these evaluations, with respect to all 10 evaluation measures, the *child.eyes* social cue had the most impact on model performance.

Why would the child’s own gaze be more important than the caregiver’s? Perhaps caregivers are *following in*, i.e., talking about objects that their children are interested in (Baldwin, 1991). However, another possible explanation is that this result is due to the general continuity of conversational topics over time. Frank et al. (to appear) show that for the current corpus, the topic of the preceding utterance is very likely to be the topic of the current one also. Thus, the child’s eyes might be a good predictor because they reflect the fact that the child’s attention has been drawn to an object by previous utterances.

Notice that these two possible explanations of the importance of the *child.eyes* cue are diametrically opposed; the first explanation claims that the cue is important because the child is driving the discourse, while the second explanation claims that the cue is important because the child’s gaze follows the topic of the caregiver’s previous utterance. This sort of question about causal relationships in conversations may be very difficult to answer using standard descriptive techniques, but it may be an interesting av-

Figure 9: Effect of using all but one social cue on the experimental results for the unigram and collocation models. The “importance” of a social cue can be quantified by the degree to which the model’s evaluation score degrades when that just social cue is removed from the corpus, relative to its evaluation score when using a corpus without all social cues. The most important social cue is the one which causes performance to degrade the most.

enue for future investigation using more structured models such as those proposed here.<sup>5</sup>

#### 4 Conclusion and future work

This paper presented four different grounded learning models that exploit social cues. These models are all expressed via reductions to grammatical inference problems, so standard “off the shelf” grammatical inference tools can be used to learn them. Here we used the same adaptor grammar software tools to learn all these models, so we can be relatively certain that any differences we observe are due to differences in the models, rather than quirks in the software.

Because the adaptor grammar software performs full Bayesian inference, including for model parameters, an unusual feature of our models is that we did not need to perform any parameter tuning whatsoever. This feature is particularly interesting with respect to the parameters on social cues. Psychological proposals have suggested that children may discover that particular social cues help in establishing reference (Baldwin, 1993; Hollich et al., 2000), but prior modeling work has often assumed that cues, cue weights, or both are prespecified. In contrast, the models described here could in principle discover a wide range of different social conventions.

<sup>5</sup>A reviewer suggested that we can test whether *child.eyes* effectively provides the same information as the previous topic by adding the previous topic as a (pseudo-) social cue. We tried this, and *child.eyes* and *previous.topic* do in fact seem to convey very similar information: e.g., the model with *previous.topic* and without *child.eyes* scores essentially the same as the model with all social cues.

Our work instantiates the strategy of investigating the structure of children’s learning environment using “ideal learner” models. We used our models to investigate scientific questions about the role of social cues in grounded language learning. Because the performance of all four models studied in this paper improve dramatically when provided with social cues in all ten evaluation metrics, this paper provides strong support for the view that social cues are a crucial information source for grounded language learning.

We also showed that the importance of the different social cues in grounded language learning can be evaluated using “add one cue” and “subtract one cue” methodologies. According to both of these, the *child.eyes* cue is the most important of the five social cues studied here. There are at least two possible reasons for this: the caregiver’s topic could be determined by the child’s gaze, or the *child.eyes* cue could be providing our models with information about the topic of the previous utterance.

Incorporating topic continuity and anaphoric dependencies into our models would be likely to improve performance. This improvement might also help us distinguish the two hypotheses about the *child.eyes* cue. If the *child.eyes* cue is just providing indirect information about topic continuity, then the importance of the *child.eyes* cue should decrease when we incorporate topic continuity into our models. But if the child’s gaze is in fact determining the care-giver’s topic, then *child.eyes* should remain a strong cue even when anaphoric dependencies and topic continuity are incorporated into our models.

## Abstract

Understanding the ways in which information achieves widespread public awareness is a research question of significant interest. We consider whether, and how, the way in which the information is phrased — the choice of words and sentence structure — can affect this process. To this end, we develop an analysis framework and build a corpus of movie quotes, annotated with memorability information, in which we are able to control for both the speaker and the setting of the quotes. We find that there are significant differences between memorable and non-memorable quotes in several key dimensions, even after controlling for situational and contextual factors. One is *lexical distinctiveness*: in aggregate, memorable quotes use less common word choices, but at the same time are built upon a scaffolding of common syntactic patterns. Another is that memorable quotes tend to be more *general* in ways that make them easy to apply in new contexts — that is, more portable. We also show how the concept of “memorable language” can be extended across domains.

## 1 Hello. My name is Inigo Montoya.

Understanding what items will be retained in the public consciousness, and why, is a question of fundamental interest in many domains, including marketing, politics, entertainment, and social media; as we all know, many items barely register, whereas others catch on and take hold in many people’s minds.

An active line of recent computational work has employed a variety of perspectives on this question.

Building on a foundation in the sociology of diffusion [27, 31], researchers have explored the ways in which network structure affects the way information spreads, with domains of interest including blogs [1, 11], email [37], on-line commerce [22], and social media [2, 28, 33, 38]. There has also been recent research addressing temporal aspects of how different media sources convey information [23, 30, 39] and ways in which people react differently to information on different topics [28, 36].

Beyond all these factors, however, one’s everyday experience with these domains suggests that the way in which a piece of information is expressed — the choice of words, the way it is phrased — might also have a fundamental effect on the extent to which it takes hold in people’s minds. Concepts that attain wide reach are often carried in messages such as political slogans, marketing phrases, or aphorisms whose language seems intuitively to be memorable, “catchy,” or otherwise compelling.

Our first challenge in exploring this hypothesis is to develop a notion of “successful” language that is precise enough to allow for quantitative evaluation. We also face the challenge of devising an evaluation setting that separates the phrasing of a message from the conditions in which it was delivered — highly-cited quotes tend to have been delivered under compelling circumstances or fit an existing cultural, political, or social narrative, and potentially what appeals to us about the quote is really just its invocation of these extra-linguistic contexts. Is the form of the language adding an effect *beyond or independent of* these (obviously very crucial) factors? To investigate the question, one needs a way of control-

ling — as much as possible — for the role that the surrounding context of the language plays.

**The present work (i): Evaluating language-based memorability** Defining what makes an utterance memorable is subtle, and scholars in several domains have written about this question. There is a rough consensus that an appropriate definition involves elements of both *recognition* — people should be able to retain the quote and recognize it when they hear it invoked — and *production* — people should be motivated to refer to it in relevant situations [15]. One suggested reason for why some memes succeed is their ability to provoke emotions [16]. Alternatively, memorable quotes can be good for expressing the feelings, mood, or situation of an individual, a group, or a culture (the *zeitgeist*): “Certain quotes exquisitely capture the mood or feeling we wish to communicate to someone. We hear them ... and store them away for future use” [10].

None of these observations, however, serve as definitions, and indeed, we believe it desirable to not pre-commit to an abstract definition, but rather to adopt an operational formulation based on external human judgments. In designing our study, we focus on a domain in which (i) there is rich use of language, some of which has achieved deep cultural penetration; (ii) there already exist a large number of external human judgments — perhaps implicit, but in a form we can extract; and (iii) we can control for the setting in which the text was used.

Specifically, we use the complete scripts of roughly 1000 movies, representing diverse genres, eras, and levels of popularity, and consider which lines are the most “memorable”. To acquire memorability labels, for each sentence in each script, we determine whether it has been listed as a “memorable quote” by users of the widely-known IMDb (the Internet Movie Database), and also estimate the number of times it appears on the Web. Both of these serve as memorability metrics for our purposes.

When we evaluate properties of memorable quotes, we compare them with quotes that are not assessed as memorable, but were spoken by the same character, at approximately the same point in the same movie. This enables us to control in a fairly fine-grained way for the confounding effects of context discussed above: we can observe differences

that persist even after taking into account both the speaker and the setting.

In a pilot validation study, we find that human subjects are effective at recognizing the more IMDb-memorable of two quotes, even for movies they have not seen. This motivates a search for features intrinsic to the text of quotes that signal memorability. In fact, comments provided by the human subjects as part of the task suggested two basic forms that such textual signals could take: subjects felt that (i) memorable quotes often involve a *distinctive* turn of phrase; and (ii) memorable quotes tend to invoke *general* themes that aren’t tied to the specific setting they came from, and hence can be more easily invoked for future (out of context) uses. We test both of these principles in our analysis of the data.

**The present work (ii): What distinguishes memorable quotes** Under the controlled-comparison setting sketched above, we find that memorable quotes exhibit significant differences from non-memorable quotes in several fundamental respects, and these differences in the data reinforce the two main principles from the human pilot study. First, we show a concrete sense in which memorable quotes are indeed *distinctive*: with respect to lexical language models trained on the newswire portions of the Brown corpus [21], memorable quotes have significantly lower likelihood than their non-memorable counterparts. Interestingly, this distinctiveness takes place at the level of words, but not at the level of other syntactic features: the part-of-speech composition of memorable quotes is in fact more likely with respect to newswire. Thus, we can think of memorable quotes as consisting, in an aggregate sense, of unusual word choices built on a scaffolding of common part-of-speech patterns.

We also identify a number of ways in which memorable quotes convey greater *generality*. In their patterns of verb tenses, personal pronouns, and determiners, memorable quotes are structured so as to be more “free-standing,” containing fewer markers that indicate references to nearby text.

Memorable quotes differ in other interesting aspects as well, such as sound distributions.

Our analysis of memorable movie quotes suggests a framework by which the memorability of text in a range of different domains could be investigated.

We provide evidence that such cross-domain properties may hold, guided by one of our motivating applications in marketing. In particular, we analyze a corpus of advertising slogans, and we show that these slogans have significantly greater likelihood at both the word level and the part-of-speech level with respect to a language model trained on memorable movie quotes, compared to a corresponding language model trained on non-memorable movie quotes. This suggests that some of the principles underlying memorable text have the potential to apply across different areas.

**Roadmap** §2 lays the empirical foundations of our work: the design and creation of our movie-quotes dataset, which we make publicly available (§2.1), a pilot study with human subjects validating IMDb-based memorability labels (§2.2), and further study of incorporating search-engine counts (§2.3). §3 details our analysis and prediction experiments, using both movie-quotes data and, as an exploration of cross-domain applicability, slogans data. §4 surveys related work across a variety of fields. §5 briefly summarizes and indicates some future directions.

## 2 I’m ready for my close-up.

### 2.1 Data

To study the properties of memorable movie quotes, we need a source of movie lines and a designation of memorability. Following [8], we constructed a corpus consisting of all lines from roughly 1000 movies, varying in genre, era, and popularity; for each movie, we then extracted the list of quotes from IMDb’s *Memorable Quotes* page corresponding to the movie.<sup>1</sup>

A memorable quote in IMDb can appear either as an individual sentence spoken by one character, or as a multi-sentence line, or as a block of dialogue involving multiple characters. In the latter two cases, it can be hard to determine which particular portion is viewed as memorable (some involve a build-up to a punch line; others involve the follow-through after a well-phrased opening sentence), and so we focus in our comparisons on those memorable quotes that

<sup>1</sup>This extraction involved some edit-distance-based alignment, since the exact form of the line in the script can exhibit minor differences from the version typed into IMDb.

Figure 1: Location of memorable quotes in each decile of movie scripts (the first 10th, the second 10th, etc.), summed over all movies. The same qualitative results hold if we discard each movie’s very first and last line, which might have privileged status.

appear as a single sentence rather than a multi-line block.<sup>2</sup>

We now formulate a task that we can use to evaluate the features of memorable quotes. Recall that our goal is to identify effects based in the language of the quotes themselves, beyond any factors arising from the speaker or context. Thus, for each (single-sentence) memorable quote  $M$ , we identify a non-memorable quote that is as similar as possible to  $M$  in all characteristics but the choice of words. This means we want it to be spoken by the same character in the same movie. It also means that we want it to have the same length: controlling for length is important because we expect that on average, shorter quotes will be easier to remember than long quotes, and that wouldn’t be an interesting textual effect to report. Moreover, we also want to control for the fact that a quote’s position in a movie can affect memorability: certain scenes produce more memorable dialogue, and as Figure 1 demonstrates, in aggregate memorable quotes also occur disproportionately near the beginnings and especially the ends of movies. In summary, then, for each  $M$ , we pick a contrasting (single-sentence) quote  $N$  from the same movie that is as close in the script as possible to  $M$  (either before or after it), subject to the conditions that (i)  $M$  and  $N$  are uttered by the same speaker, (ii)  $M$  and  $N$  have the same number of words, and (iii)  $N$  does not occur in the IMDb list of memorable

<sup>2</sup>We also ran experiments relaxing the single-sentence assumption, which allows for stricter scene control and a larger dataset but complicates comparisons involving syntax. The non-syntax results were in line with those reported here.

Movie	First Quote	Second Quote
Jackie Brown	Half a million dollars will always be missed.	I know the type, trust me on this.
Star Trek: Nemesis	I think it's time to try some unsafe velocities.	No cold feet, or any other parts of our anatomy.
Ordinary People	A little advice about feelings kiddo; don't expect it always to tickle.	I mean there's someone besides your mother you've got to forgive.

Table 1: Three example pairs of movie quotes. Each pair satisfies our criteria: the two component quotes are spoken close together in the movie by the same character, have the same length, and one is labeled memorable by the IMDb while the other is not. (Contractions such as “it’s” count as two words.)

quotes for the movie (either as a single line or as part of a larger block).

Given such pairs, we formulate a *pairwise comparison task*: given  $M$  and  $N$ , determine which is the memorable quote. Psychological research on subjective evaluation [35], as well as initial experiments using ourselves as subjects, indicated that this pairwise set-up easier to work with than simply presenting a single sentence and asking whether it is memorable or not; the latter requires agreement on an “absolute” criterion for memorability that is very hard to impose consistently, whereas the former simply requires a judgment that one quote is more memorable than another.

Our main dataset, available at <http://www.cs.cornell.edu/~cristian/memorability.html>,<sup>3</sup> thus consists of approximately 2200 such  $(M, N)$  pairs, separated by a median of 5 same-character lines in the script. The reader can get a sense for the nature of the data from the three examples in Table 1.

We now discuss two further aspects to the formulation of the experiment: a preliminary pilot study involving human subjects, and the incorporation of search engine counts into the data.

## 2.2 Pilot study: Human performance

As a preliminary consideration, we did a small pilot study to see if humans can distinguish memorable from non-memorable quotes, assuming our IMDb-induced labels as gold standard. Six subjects, all native speakers of English and none an author of this paper, were presented with 11 or 12 pairs of memorable vs. non-memorable quotes; again, we controlled for extra-textual effects by ensuring that in each pair the two quotes come from the same movie, are by the same character, have the same length, and

<sup>3</sup>Also available there: other examples and factoids.

subject	number of matches with IMDb-induced annotation
A	11/11 = 100%
B	11/12 = 92%
C	9/11 = 82%
D	8/11 = 73%
E	7/11 = 64%
F	7/12 = 58%
macro avg	— 78%

Table 2: Human pilot study: number of matches to IMDb-induced annotation, ordered by decreasing match percentage. For the null hypothesis of random guessing, these results are statistically significant,  $p < 2^{-6} \approx .016$ .

appear as nearly as possible in the same scene.<sup>4</sup> The order of quotes within pairs was randomized. Importantly, because we wanted to understand whether the language of the quotes by itself contains signals about memorability, we chose quotes from movies that the subjects said they had not seen. (This means that each subject saw a different set of quotes.) Moreover, the subjects were requested not to consult any external sources of information.<sup>5</sup> The reader is welcome to try a demo version of the task at <http://www.cs.cornell.edu/~cristian/memorability.html>.

Table 2 shows that all the subjects performed (sometimes much) better than chance, and against the null hypothesis that all subjects are guessing randomly, the results are statistically significant,  $p < 2^{-6} \approx .016$ . These preliminary findings provide evidence for the validity of our task: despite the apparent difficulty of the job, even humans who haven’t seen the movie in question can recover our IMDb-

<sup>4</sup>In this pilot study, we allowed multi-sentence quotes.

<sup>5</sup>We did not use crowd-sourcing because we saw no way to ensure that this condition would be obeyed by arbitrary subjects. We do note, though, that after our research was completed and as of Apr. 26, 2012,  $\approx 11,300$  people completed the online test: average accuracy: 72%, mode number correct: 9/12.

induced labels with some reliability.<sup>6</sup>

### 2.3 Incorporating search engine counts

Thus far we have discussed a dataset in which memorability is determined through an explicit labeling drawn from the IMDb. Given the “production” aspect of memorability discussed in §1, we should also expect that memorable quotes will tend to appear more extensively on Web pages than non-memorable quotes; note that incorporating this insight makes it possible to use the (implicit) judgments of a much larger number of people than are represented by the IMDb database. It therefore makes sense to try using search-engine result counts as a second indication of memorability.

We experimented with several ways of constructing memorability information from search-engine counts, but this proved challenging. Searching for a quote as a stand-alone phrase runs into the problem that a number of quotes are also sentences that people use without the movie in mind, and so high counts for such quotes do not testify to the phrase’s status as a memorable quote from the movie. On the other hand, searching for the quote in a Boolean conjunction with the movie’s title discards most of these uses, but also eliminates a large fraction of the appearances on the Web that we want to find: precisely because memorable quotes tend to have widespread cultural usage, people generally don’t feel the need to include the movie’s title when invoking them. Finally, since we are dealing with roughly 1000 movies, the result counts vary over an enormous range, from recent blockbusters to movies with relatively small fan bases.

In the end, we found that it was more effective to use the result counts in conjunction with the IMDb labels, so that the counts played the role of an additional filter rather than a free-standing numerical value. Thus, for each pair  $(M, N)$  produced using the IMDb methodology above, we searched for each of  $M$  and  $N$  as quoted expressions in a Boolean conjunction with the title of the movie. We then kept only those pairs for which  $M$  (i) produced more than five results in our (quoted, conjoined) search, and (ii) produced at least twice as many results as the cor-

<sup>6</sup>The average accuracy being below 100% reinforces that context is very important, too.

responding search for  $N$ . We created a version of this filtered dataset using each of Google and Bing, and all the main findings were consistent with the results on the IMDb-only dataset. Thus, in what follows, we will focus on the main IMDb-only dataset, discussing the relationship to the dataset filtered by search engine counts where relevant (in which case we will refer to the +Google dataset).

## 3 Never send a human to do a machine’s job.

We now discuss experiments that investigate the hypotheses discussed in §1. In particular, we devise methods that can assess the distinctiveness and generality hypotheses and test whether there exists a notion of “memorable language” that operates across domains. In addition, we evaluate and compare the predictive power of these hypotheses.

### 3.1 Distinctiveness

One of the hypotheses we examine is whether the use of language in memorable quotes is to some extent unusual. In order to quantify the level of distinctiveness of a quote, we take a language-model approach: we model “common language” using the newswire sections of the Brown corpus [21]<sup>7</sup>, and evaluate how distinctive a quote is by evaluating its likelihood with respect to this model — the lower the likelihood, the more distinctive. In order to assess different levels of lexical and syntactic distinctiveness, we employ a total of six Laplace-smoothed<sup>8</sup> language models: 1-gram, 2-gram, and 3-gram word LMs and 1-gram, 2-gram and 3-gram part-of-speech<sup>9</sup> LMs.

We find strong evidence that from a lexical perspective, memorable quotes are more distinctive than their non-memorable counterparts. As indicated in Table 3, for each of our lexical “common language” models, in about 60% of the quote pairs, the memorable quote is more distinctive.

Interestingly, the reverse is true when it comes to

<sup>7</sup>Results were qualitatively similar if we used the fiction portions. The age of the Brown corpus makes it less likely to contain modern movie quotes.

<sup>8</sup>We employ Laplace (additive) smoothing with a smoothing parameter of 0.2. The language models’ vocabulary was that of the entire training corpus.

<sup>9</sup>Throughout we obtain part-of-speech tags by using the NLTK maximum entropy tagger with default parameters.

“common language” model		IMDb-only	+Google
lexical	1-gram	61.13%***	59.21%***
	2-gram	59.22%***	57.03%***
	3-gram	59.81%***	58.32%***
syntactic	1-gram	43.60%***	44.77%***
	2-gram	48.31%	47.84%
	3-gram	50.91%	50.92%

Table 3: Distinctiveness: percentage of quote pairs in which the the memorable quote is more distinctive than the non-memorable one according to the respective “common language” model. Significance according to a two-tailed sign test is indicated using \*-notation (\*\*\*)=“ $p < .001$ ”.

syntax: memorable quotes appear to follow the syntactic patterns of “common language” as closely as or more closely than non-memorable quotes. Together, these results suggest that memorable quotes consist of unusual word sequences built on common syntactic scaffolding.

### 3.2 Generality

Another of our hypotheses is that memorable quotes are easier to use outside the specific context in which they were uttered — that is, more “portable” — and therefore exhibit fewer terms that refer to those settings. We use the following syntactic properties as proxies for the generality of a quote:

- **Fewer 3<sup>rd</sup>-person pronouns**, since these commonly refer to a person or object that was introduced earlier in the discourse. Utterances that employ fewer such pronouns are easier to adapt to new contexts, and so will be considered more general.
- **More indefinite articles** like *a* and *an*, since they are more likely to refer to general concepts than definite articles. Quotes with more indefinite articles will be considered more general.
- **Fewer past tense verbs and more present tense verbs**, since the former are more likely to refer to specific previous events. Therefore utterances that employ fewer past tense verbs (and more present tense verbs) will be considered more general.

Table 4 gives the results for each of these four metrics — in each case, we show the percentage of

Generality metric	IMDb-only	+Google
fewer 3 <sup>rd</sup> pers. pronouns	64.37%***	62.93%***
more indef. article	57.21%***	58.23%***
less past tense	57.91%***	59.74%***
more present tense	54.60%***	55.86%***

Table 4: Generality: percentage of quote pairs in which the memorable quote is more general than the non-memorable ones according to the respective metric. Pairs where the metric does not distinguish between the quotes are not considered.

quote pairs for which the memorable quote scores better on the generality metric.

Note that because the issue of generality is a complex one for which there is no straightforward single metric, our approach here is based on several proxies for generality, considered independently; yet, as the results show, all of these point in a consistent direction. It is an interesting open question to develop richer ways of assessing whether a quote has greater generality, in the sense that people intuitively attribute to memorable quotes.

### 3.3 “Memorable” language beyond movies

One of the motivating questions in our analysis is whether there are general principles underlying “memorable language.” The results thus far suggest potential families of such principles. A further question in this direction is whether the notion of memorability can be extended across different domains, and for this we collected (and distribute on our website) 431 phrases that were explicitly designed to be memorable: advertising slogans (e.g., “Quality never goes out of style.”). The focus on slogans is also in keeping with one of the initial motivations in studying memorability, namely, marketing applications — in other words, assessing whether a proposed slogan has features that are consistent with memorable text.

The fact that it’s not clear how to construct a collection of “non-memorable” counterparts to slogans appears to pose a technical challenge. However, we can still use a language-modeling approach to assess whether the textual properties of the slogans are closer to the memorable movie quotes (as one would conjecture) or to the non-memorable movie quotes. Specifically, we train one language model on memorable quotes and another on non-memorable quotes

(Non)memorable language models		Slogans	Newswire
lexical	1-gram	56.15%**	33.77%***
	2-gram	51.51%	25.15%***
	3-gram	52.44%	28.89%***
syntactic	1-gram	73.09%***	68.27%***
	2-gram	64.04%***	50.21%
	3-gram	62.88%***	55.09%***

Table 5: Cross-domain concept of “memorable” language: percentage of slogans that have higher likelihood under the memorable language model than under the non-memorable one (for each of the six language models considered). Rightmost column: for reference, the percentage of newswire sentences that have higher likelihood under the memorable language model than under the non-memorable one.

Generality metric	slogans	mem.	n-mem.
% 3 <sup>rd</sup> pers. pronouns	2.14%	2.16%	3.41%
% indefinite articles	2.68%	2.63%	2.06%
% past tense	14.60%	21.13%	26.69%

Table 6: Slogans are most general when compared to memorable and non-memorable quotes. (%s of 3<sup>rd</sup> pers. pronouns and indefinite articles are relative to all tokens, %s of past tense are relative to all past and present verbs.)

and compare how likely each slogan is to be produced according to these two models. As shown in the middle column of Table 5, we find that slogans are better predicted both lexically and syntactically by the former model. This result thus offers evidence for a concept of “memorable language” that can be applied beyond a single domain.

We also note that the higher likelihood of slogans under a “memorable language” model is not simply occurring for the trivial reason that this model predicts all other large bodies of text better. In particular, the newswire section of the Brown corpus is predicted better at the lexical level by the language model trained on non-memorable quotes.

Finally, Table 6 shows that slogans employ general language, in the sense that for each of our generality metrics, we see a slogans/memorable-quotes/non-memorable quotes spectrum.

### 3.4 Prediction task

We now show how the principles discussed above can provide features for a basic prediction task, corresponding to the task in our human pilot study:

given a pair of quotes, identify the memorable one.

Our first formulation of the prediction task uses a standard bag-of-words model<sup>10</sup>. If there were no information in the textual content of a quote to determine whether it were memorable, then an SVM employing bag-of-words features should perform no better than chance. Instead, though, it obtains 59.67% (10-fold cross-validation) accuracy, as shown in Table 7. We then develop models using features based on the measures formulated earlier in this section: generality measures (the four listed in Table 4); distinctiveness measures (likelihood according to 1, 2, and 3-gram “common language” models at the lexical and part-of-speech level for each quote in the pair, their differences, and pairwise comparisons between them); and similarity-to-slogans measures (likelihood according to 1, 2, and 3-gram slogan-language models at the lexical and part-of-speech level for each quote in the pair, their differences, and pairwise comparisons between them).

Even a relatively small number of distinctiveness features, on their own, improve significantly over the much larger bag-of-words model. When we include additional features based on generality and language-model features measuring similarity to slogans, the performance improves further (last line of Table 7).

Thus, the main conclusion from these prediction tasks is that abstracting notions such as distinctiveness and generality can produce relatively streamlined models that outperform much heavier-weight bag-of-words models, and can suggest steps toward approaching the performance of human judges who — very much unlike our system — have the full cultural context in which movies occur at their disposal.

### 3.5 Other characteristics

We also made some auxiliary observations that may be of interest. Specifically, we find differences in letter and sound distribution (e.g., memorable quotes — after curse-word removal — use significantly more “front sounds” (labials or front vowels such as represented by the letter *i*) and significantly fewer “back sounds” such as the one represented by *u*),<sup>11</sup>

<sup>10</sup>We discarded terms appearing fewer than 10 times.

<sup>11</sup>These findings may relate to marketing research on *sound symbolism* [7, 19, 40].

Feature set	# feats	Accuracy
bag of words	962	59.67%
distinctiveness	24	62.05%*
generality	4	56.70%
slogan sim.	24	58.30%
<i>all three types together</i>	52	64.27%**

Table 7: Prediction: SVM 10-fold cross validation results using the respective feature sets. Random baseline accuracy is 50%. Accuracies statistically significantly greater than bag-of-words according to a two-tailed t-test are indicated with \*( $p < .05$ ) and \*\*( $p < .01$ ).

word complexity (e.g., memorable quotes use words with significantly more syllables) and phrase complexity (e.g., memorable quotes use fewer coordinating conjunctions). The latter two are in line with our distinctiveness hypothesis.

#### 4 A long time ago, in a galaxy far, far away

How an item’s linguistic form affects the reaction it generates has been studied in several contexts, including evaluations of product reviews [9], political speeches [12], on-line posts [13], scientific papers [14], and retweeting of Twitter posts [36]. We use a different set of features, abstracting the notions of distinctiveness and generality, in order to focus on these higher-level aspects of phrasing rather than on particular lower-level features.

Related to our interest in distinctiveness, work in advertising research has studied the effect of syntactic complexity on recognition and recall of slogans [5, 6, 24]. There may also be connections to Von Restorff’s *isolation effect* Hunt [17], which asserts that when all but one item in a list are similar in some way, memory for the different item is enhanced.

Related to our interest in generality, Knapp et al. [20] surveyed subjects regarding memorable messages or pieces of advice they had received, finding that the ability to be applied to multiple concrete situations was an important factor.

Memorability, although distinct from “memorizability”, relates to short- and long-term recall. Thorn and Page [34] survey sub-lexical, lexical, and semantic attributes affecting short-term memorability of lexical items. Studies of verbatim recall have also considered the task of distinguishing an exact quote from close paraphrases [3]. Investigations of long-term recall have included studies of culturally signif-

icant passages of text [29] and findings regarding the effect of rhetorical devices of alliterative [4], “rhythmic, poetic, and thematic constraints” [18, 26].

Finally, there are complex connections between humor and memory [32], which may lead to interactions with computational humor recognition [25].

#### 5 I think this is the beginning of a beautiful friendship.

Motivated by the broad question of what kinds of information achieve widespread public awareness, we studied the the effect of phrasing on a quote’s memorability. A challenge is that quotes differ not only in how they are worded, but also in who said them and under what circumstances; to deal with this difficulty, we constructed a controlled corpus of movie quotes in which lines deemed memorable are paired with non-memorable lines spoken by the same character at approximately the same point in the same movie. After controlling for context and situation, memorable quotes were still found to exhibit, *on average* (there will always be individual exceptions), significant differences from non-memorable quotes in several important respects, including measures capturing distinctiveness and generality. Our experiments with slogans show how the principles we identify can extend to a different domain.

Future work may lead to applications in marketing, advertising and education [4]. Moreover, the subtle nature of memorability, and its connection to research in psychology, suggests a range of further research directions. We believe that the framework developed here can serve as the basis for further computational studies of the process by which information takes hold in the public consciousness, and the role that language effects play in this process.

## Abstract

Predicate-argument structure contains rich semantic information of which statistical machine translation hasn't taken full advantage. In this paper, we propose two discriminative, feature-based models to exploit predicate-argument structures for statistical machine translation: 1) a predicate translation model and 2) an argument reordering model. The predicate translation model explores lexical and semantic contexts surrounding a verbal predicate to select desirable translations for the predicate. The argument reordering model automatically predicts the moving direction of an argument relative to its predicate after translation using semantic features. The two models are integrated into a state-of-the-art phrase-based machine translation system and evaluated on Chinese-to-English translation tasks with large-scale training data. Experimental results demonstrate that the two models significantly improve translation accuracy.

## 1 Introduction

Recent years have witnessed increasing efforts towards integrating predicate-argument structures into statistical machine translation (SMT) (Wu and Fung, 2009b; Liu and Gildea, 2010). In this paper, we take a step forward by introducing a novel approach to incorporate such semantic structures into SMT. Given a source side predicate-argument structure, we attempt to translate each semantic frame (predicate and its associated arguments) into an appropriate target string. We believe that the translation of predicates and reordering of arguments are the two central

issues concerning the transfer of predicate-argument structure across languages.

Predicates<sup>1</sup> are essential elements in sentences. Unfortunately they are usually neither correctly translated nor translated at all in many SMT systems according to the error study by Wu and Fung (2009a). This suggests that conventional lexical and phrasal translation models adopted in those SMT systems are not sufficient to correctly translate predicates in source sentences. Thus we propose a discriminative, feature-based **predicate translation model** that captures not only lexical information (i.e., surrounding words) but also high-level semantic contexts to correctly translate predicates.

Arguments contain information for questions of *who*, *what*, *when*, *where*, *why*, and *how* in sentences (Xue, 2008). One common error in translating arguments is about their reorderings: arguments are placed at incorrect positions after translation. In order to reduce such errors, we introduce a discriminative **argument reordering model** that uses the position of a predicate as the reference axis to estimate positions of its associated arguments on the target side. In this way, the model predicts moving directions of arguments relative to their predicates with semantic features.

We integrate these two discriminative models into a state-of-the-art phrase-based system. Experimental results on large-scale Chinese-to-English translation show that both models are able to obtain significant improvements over the baseline. Our analysis on system outputs further reveals that they can indeed help reduce errors in predicate translations and argument reorderings.

\*Corresponding author

<sup>1</sup>We only consider verbal predicates in this paper.

The paper is organized as follows. In Section 2, we will introduce related work and show the significant differences between our models and previous work. In Section 3 and 4, we will elaborate the proposed predicate translation model and argument reordering model respectively, including details about modeling, features and training procedure. Section 5 will introduce how to integrate these two models into SMT. Section 6 will describe our experiments and results. Section 7 will empirically discuss how the proposed models improve translation accuracy. Finally we will conclude with future research directions in Section 8.

## 2 Related Work

Predicate-argument structures (PAS) are explored for SMT on both the source and target side in some previous work. As PAS analysis widely employs global and sentence-wide features, it is computationally expensive to integrate target side predicate-argument structures into the dynamic programming style of SMT decoding (Wu and Fung, 2009b). Therefore they either postpone the integration of target side PASs until the whole decoding procedure is completed (Wu and Fung, 2009b), or directly project semantic roles from the source side to the target side through word alignments during decoding (Liu and Gildea, 2010).

There are other previous studies that explore only source side predicate-argument structures. Komachi and Matsumoto (2006) reorder arguments in source language (Japanese) sentences using heuristic rules defined on source side predicate-argument structures in a pre-processing step. Wu et al. (2011) automate this procedure by automatically extracting reordering rules from predicate-argument structures and applying these rules to reorder source language sentences. Aziz et al. (2011) incorporate source language semantic role labels into a tree-to-string SMT system.

Although we also focus on source side predicate-argument structures, our models differ from the previous work in two main aspects: 1) we propose two separate discriminative models to exploit predicate-argument structures for predicate translation and argument reordering respectively; 2) we consider argument reordering as an argument movement (rel-

ative to its predicate) prediction problem and use a discriminatively trained classifier for such predictions.

Our predicate translation model is also related to previous discriminative lexicon translation models (Berger et al., 1996; Venkatapathy and Bangalore, 2007; Mauser et al., 2009). While previous models predict translations for all words in vocabulary, we only focus on verbal predicates. This will tremendously reduce the amount of training data required, which usually is a problem in discriminative lexicon translation models (Mauser et al., 2009). Furthermore, the proposed translation model also differs from previous lexicon translation models in that we use both lexical and semantic features. Our experimental results show that semantic features are able to further improve translation accuracy.

## 3 Predicate Translation Model

In this section, we present the features and the training process of the predicate translation model.

### 3.1 Model

Following the context-dependent word models in (Berger et al., 1996), we propose a discriminative predicate translation model. The essential component of our model is a maximum entropy classifier  $p_t(e|\mathcal{C}(v))$  that predicts the target translation  $e$  for a verbal predicate  $v$  given its surrounding context  $\mathcal{C}(v)$ . The classifier can be formulated as follows.

$$p_t(e|\mathcal{C}(v)) = \frac{\exp(\sum_i \theta_i f_i(e, \mathcal{C}(v)))}{\sum_{e'} \exp(\sum_i \theta_i f_i(e', \mathcal{C}(v)))} \quad (1)$$

where  $f_i$  are binary features,  $\theta_i$  are weights of these features. Given a source sentence which contains  $N$  verbal predicates  $\{v_i\}_1^N$ , our predicate translation model  $M_t$  can be denoted as

$$M_t = \prod_{i=1}^N p_t(e_{v_i}|\mathcal{C}(v_i)) \quad (2)$$

Note that we do not restrict the target translation  $e$  to be a single word. We allow  $e$  to be a phrase of length up to 4 words so as to capture multi-word translations for a verbal predicate. For example, a Chinese verb “发行(issue)” can be translated as “to be issued” or “have issued” with modality words.

This will increase the number of classes to be predicted by the maximum entropy classifier. But according to our observation, it is still computationally tractable (see Section 3.3). If a verbal predicate is not translated, we set  $e = \text{NULL}$  so that we can also capture null translations for verbal predicates.

### 3.2 Features

The apparent advantage of discriminative lexicon translation models over generative translation models (e.g., conventional lexical translation model as described in (Koehn et al., 2003)) is that discriminative models allow us to integrate richer contexts (lexical, syntactic or semantic) into target translation prediction. We use two kinds of features to predict translations for verbal predicates: 1) lexical features and 2) semantic features. All features are in the following binary form.

$$f(e, \mathcal{C}(v)) = \begin{cases} 1, & \text{if } e = \clubsuit \text{ and } \mathcal{C}(v). \heartsuit = \spadesuit \\ 0, & \text{else} \end{cases} \quad (3)$$

where the symbol  $\clubsuit$  is a placeholder for a possible target translation (up to 4 words), the symbol  $\heartsuit$  indicates a contextual (lexical or semantic) element for the verbal predicate  $v$ , and the symbol  $\spadesuit$  represents the value of  $\heartsuit$ .

**Lexical Features:** The lexical element  $\heartsuit$  is extracted from the surrounding words of verbal predicate  $v$ . We use the preceding 3 words and the succeeding 3 words to define the lexical context for the verbal predicate  $v$ . Therefore  $\heartsuit \in \{w_{-3}, w_{-2}, w_{-1}, v, w_1, w_2, w_3\}$ .

**Semantic Features:** The semantic element  $\heartsuit$  is extracted from the surrounding arguments of verbal predicate  $v$ . In particular, we define a semantic window centered at the verbal predicate with 6 arguments  $\{A_{-3}, A_{-2}, A_{-1}, A_1, A_2, A_3\}$  where  $A_{-3} - A_{-1}$  are arguments on the left side of  $v$  while  $A_1 - A_3$  are those on the right side. Different verbal predicates have different number of arguments in different linguistic scenarios. We observe on our training data that the number of arguments for 96.5% verbal predicates on each side (left/right) is not larger than 3. Therefore the defined 6-argument semantic window is sufficient to describe argument contexts for predicates.

For each argument  $A_i$  in the defined seman-

$f(e, \mathcal{C}(v)) = 1$  **if and only if**

---

$e = \text{adjourn}$  and  $\mathcal{C}(v).A_{-3}^h = \text{安理会}$   
 $e = \text{adjourn}$  and  $\mathcal{C}(v).A_{-1}^r = \text{ARGM-TMP}$   
 $e = \text{adjourn}$  and  $\mathcal{C}(v).A_1^h = \text{天}$   
 $e = \text{adjourn}$  and  $\mathcal{C}(v).A_2^r = \text{null}$   
 $e = \text{adjourn}$  and  $\mathcal{C}(v).A_3^h = \text{null}$

Table 1: Semantic feature examples.

tic window, we use its semantic role (i.e., ARG0, ARGM-TMP and so on)  $A_i^r$  and head word  $A_i^h$  to define semantic context elements  $\heartsuit$ . If an argument  $A_i$  does not exist for the verbal predicate  $v$ <sup>2</sup>, we set the value of both  $A_i^r$  and  $A_i^h$  to null.

Figure 1 shows a Chinese sentence with its predicate-argument structure and English translation. The verbal predicate “**休会/adjourn**” (in bold) has 4 arguments: one in an ARG0 agent role, one in an ARGM-ADV adverbial modifier role, one in an ARGM-TMP temporal modifier role and the last one in an ARG1 patient role. Table 1 shows several semantic feature examples of this verbal predicate.

### 3.3 Training

In order to train the discriminative predicate translation model, we first parse source sentences and labeled semantic roles for all verbal predicates (see details in Section 6.1) in our word-aligned bilingual training data. Then we extract all training events for verbal predicates which occur at least 10 times in the training data. A training event for a verbal predicate  $v$  consists of all contextual elements  $\mathcal{C}(v)$  (e.g.,  $w_1, A_1^h$ ) defined in the last section and the target translation  $e$ . Using these events, we train one maximum entropy classifier per verbal predicate (16,121 verbs in total) via the off-the-shelf MaxEnt toolkit<sup>3</sup>. We perform 100 iterations of the L-BFGS algorithm implemented in the training toolkit for each verbal predicate with both Gaussian prior and event cutoff set to 1 to avoid overfitting. After event cutoff, we have an average of 140 classes (target translations) per verbal predicate with the maximum number of classes being 9,226. The training takes an average of 52.6 seconds per verb. In order to expedite the train-

<sup>2</sup>For example, the verb  $v$  has only two arguments on its left side. Thus argument  $A_{-3}$  does not exist.

Figure 1: An example of predicate-argument structure in Chinese and its aligned English translation. The bold word in Chinese is the verbal predicate. The subscripts on the Chinese sentence show the indexes of words from left to right.

ing, we run the training toolkit in a parallel manner.

## 4 Argument Reordering Model

In this section we introduce the discriminative argument reordering model, features and the training procedure.

### 4.1 Model

Since the predicate determines what arguments are involved in its semantic frame and semantic frames tend to be cohesive across languages (Fung et al., 2006), the movements of predicate and its arguments across translations are like the motions of a planet and its satellites. Therefore we consider the reordering of an argument as the motion of the argument relative to its predicate. In particular, we use the position of the predicate as the reference axis. The motion of associated arguments relative to the reference axis can be roughly divided into 3 categories<sup>4</sup>: 1) no change across languages (NC); 2) moving from the left side of its predicate to the right side of the predicate after translation (L2R); and 3) moving from the right side of its predicate to the left side of the predicate after translation (R2L).

Let’s revisit Figure 1. The ARG0, ARGM-ADV and ARG1 are located at the same side of their predicate after being translated into English, therefore the reordering category of these three arguments is assigned as “NC”. The ARGM-TMP is moved from the left side of “休会/adjourn” to the right side of “adjourn” after translation, thus its reordering category is L2R.

In order to predict the reordering category for an argument, we propose a discriminative argument reordering model that uses a maximum en-

<sup>4</sup>Here we assume that the translations of arguments are not interrupted by their predicates, other arguments or any words outside the arguments in question. We leave for future research the task of determining whether arguments should be translated as a unit or not.

ropy classifier to calculate the reordering category  $m \in \{\text{NC}, \text{L2R}, \text{R2L}\}$  for an argument  $A$  as follows.

$$p_r(m|\mathcal{C}(A)) = \frac{\exp(\sum_i \theta_i f_i(m, \mathcal{C}(A)))}{\sum_{m'} \exp(\sum_i \theta_i f_i(m', \mathcal{C}(A)))} \quad (4)$$

where  $\mathcal{C}(A)$  indicates the surrounding context of  $A$ . The features  $f_i$  will be introduced in the next section. We assume that motions of arguments are independent on each other. Given a source sentence with labeled arguments  $\{A_i\}_1^N$ , our discriminative argument reordering model  $M_r$  is formulated as

$$M_r = \prod_{i=1}^N p_r(m_{A_i}|\mathcal{C}(A_i)) \quad (5)$$

### 4.2 Features

The features  $f_i$  used in the argument reordering model still takes the binary form as in Eq. (3). Table 2 shows the features that are used in the argument reordering model. We extract features from both the source and target side. On the source side, the features include the verbal predicate, the semantic role of the argument, the head word and the boundary words of the argument. On the target side, the translation of the verbal predicate, the translation of the head word of the argument, as well as the boundary words of the translation of the argument are used as features.

### 4.3 Training

To train the argument reordering model, we first extract features defined in the last section from our bilingual training data where source sentences are annotated with predicate-argument structures. We also study the distribution of argument reordering categories (i.e., NC, L2R and R2L) in the training data, which is shown in Table 3. Most arguments, accounting for 82.43%, are on the same side of their verbal predicates after translation. The remaining

	Features of an argument $A$ for reordering
<b>src</b>	its verbal predicate $A^p$
	its semantic role $A^r$
	its head word $A^h$
	the leftmost word of $A$
	the rightmost word of $A$
<b>tgt</b>	the translation of $A^p$
	the translation of $A^h$
	the leftmost word of the translation of $A$
	the rightmost word of the translation of $A$

Table 2: Features adopted in the argument reordering model.

Reordering Category	Percent
NC	82.43%
L2R	11.19%
R2L	6.38%

Table 3: Distribution of argument reordering categories in the training data.

arguments (17.57%) are moved either from the left side of their predicates to the right side after translation (accounting for 11.19%) or from the right side to the left side of their translated predicates (accounting for 6.38%).

After all features are extracted, we use the maximum entropy toolkit in Section 3.3 to train the maximum entropy classifier as formulated in Eq. (4). We perform 100 iterations of L-BFGS.

## 5 Integrating the Two Models into SMT

In this section, we elaborate how to integrate the two models into phrase-based SMT. In particular, we integrate the models into a phrase-based system which uses bracketing transduction grammars (BTG) (Wu, 1997) for phrasal translation (Xiong et al., 2006). Since the system is based on a CKY-style decoder, the integration algorithms introduced here can be easily adapted to other CKY-based decoding systems such as the hierarchical phrasal system (Chiang, 2007).

### 5.1 Integrating the Predicate Translation Model

It is straightforward to integrate the predicate translation model into phrase-based SMT (Koehn et al.,

2003; Xiong et al., 2006). We maintain word alignments for each phrase pair in the phrase table. Given a source sentence with its predicate-argument structure, we detect all verbal predicates and load trained predicate translation classifiers for these verbs. Whenever a hypothesis covers a new verbal predicate  $v$ , we find the target translation  $e$  for  $v$  through word alignments and then calculate its translation probability  $p_t(e|\mathcal{C}(v))$  according to Eq. (1).

The predicate translation model (as formulated in Eq. (2)) is integrated into the whole log-linear model just like the conventional lexical translation model in phrase-based SMT (Koehn et al., 2003). The two models are independently estimated but complementary to each other. While the lexical translation model calculates the probability of a verbal predicate being translated given its local lexical context, the discriminative predicate translation model is able to employ both lexical and semantic contexts to predict translations for verbs.

### 5.2 Integrating the Argument Reordering Model

Before we introduce the integration algorithm for the argument reordering model, we define two functions  $\mathcal{A}$  and  $\mathcal{N}$  on a source sentence and its predicate-argument structure  $\tau$  as follows.

- $\mathcal{A}(i, j, \tau)$ : from the predicate-argument structure  $\tau$ , the function finds all predicate-argument pairs which are completely located within the span from source word  $i$  to  $j$ . For example, in Figure 1,  $\mathcal{A}(3, 6, \tau) = \{(\text{休会}, \text{ARGM-TMP})\}$  while  $\mathcal{A}(2, 3, \tau) = \{\}$ ,  $\mathcal{A}(1, 5, \tau) = \{\}$  because the verbal predicate “休会” is located outside the span (2,3) and (1,5).
- $\mathcal{N}(i, k, j, \tau)$ : the function finds all predicate-argument pairs that cross the two neighboring spans  $(i, k)$  and  $(k+1, j)$ . It can be formulated as  $\mathcal{A}(i, j, \tau) - (\mathcal{A}(i, k, \tau) \cup \mathcal{A}(k+1, j, \tau))$ .

We then define another function  $\mathcal{P}_r$  to calculate the argument reordering model probability on all arguments which are found by the previous two functions  $\mathcal{A}$  and  $\mathcal{N}$  as follows.

$$\mathcal{P}_r(\mathcal{B}) = \prod_{A \in \mathcal{B}} p_r(m_A | \mathcal{C}(A)) \quad (6)$$

where  $\mathcal{B}$  denotes either  $\mathcal{A}$  or  $\mathcal{N}$ .

Following (Chiang, 2007), we describe the algorithm in a deductive system. It is shown in Figure 2. The algorithm integrates the argument reordering model into a CKY-style decoder (Xiong et al., 2006). The item  $[X, i, j]$  denotes a BTG node  $X$  spanning from  $i$  to  $j$  on the source side. For notational convenience, we only show the argument reordering model probability for each item, ignoring all other sub-model probabilities such as the language model probability. The Eq. (7) shows how we calculate the argument reordering model probability when a lexical rule is applied to translate a source phrase  $c$  to a target phrase  $e$ . The Eq. (8) shows how we compute the argument reordering model probability for a span  $(i, j)$  in a dynamic programming manner when a merging rule is applied to combine its two sub-spans in a straight ( $X \rightarrow [X_1, X_2]$ ) or inverted order ( $X \rightarrow \langle X_1, X_2 \rangle$ ). We directly use the probabilities  $\mathcal{P}_r(\mathcal{A}(i, k, \tau))$  and  $\mathcal{P}_r(\mathcal{A}(k + 1, j, \tau))$  that have been already obtained for the two sub-spans  $(i, k)$  and  $(k + 1, j)$ . In this way, we only need to calculate the probability  $\mathcal{P}_r(\mathcal{N}(i, k, j, \tau))$  for predicate-argument pairs that cross the two sub-spans.

## 6 Experiments

In this section, we present our experiments on Chinese-to-English translation tasks, which are trained with large-scale data. The experiments are aimed at measuring the effectiveness of the proposed discriminative predicate translation model and argument reordering model.

### 6.1 Setup

The baseline system is the BTG-based phrasal system (Xiong et al., 2006). Our training corpora<sup>5</sup> consist of 3.8M sentence pairs with 96.9M Chinese words and 109.5M English words. We ran GIZA++ on these corpora in both directions and then applied the “grow-diag-final” refinement rule to obtain word alignments. We then used all these word-aligned corpora to generate our phrase table. Our 5-gram language model was trained on the Xinhua section of the English Gigaword corpus (306 million words)

<sup>5</sup>The corpora include LDC2004E12, LDC2004T08, LDC2005T10, LDC2003E14, LDC2002E18, LDC2005T06, LDC2003E07 and LDC2004T07.

using the SRILM toolkit (Stolcke, 2002) with modified Kneser-Ney smoothing.

To train the proposed predicate translation model and argument reordering model, we first parsed all source sentences using the Berkeley Chinese parser (Petrov et al., 2006) and then ran the Chinese semantic role labeler<sup>6</sup> (Li et al., 2010) on all source parse trees to annotate semantic roles for all verbal predicates. After we obtained semantic roles on the source side, we extracted features as described in Section 3.2 and 4.2 and used these features to train our two models as described in Section 3.3 and 4.3.

We used the NIST MT03 evaluation test data as our development set, and the NIST MT04, MT05 as the test sets. We adopted the case-insensitive BLEU-4 (Papineni et al., 2002) as the evaluation metric. Statistical significance in BLEU differences was tested by paired bootstrap re-sampling (Koehn, 2004).

### 6.2 Results

Our first group of experiments is to investigate whether the predicate translation model is able to improve translation accuracy in terms of BLEU and whether semantic features are useful. The experimental results are shown in Table 4. From the table, we have the following two observations.

- The proposed predicate translation models achieve an average improvement of 0.57 BLEU points across the two NIST test sets when all features (lex+sem) are used. Such an improvement is statistically significant ( $p < 0.01$ ). According to our statistics, there are 5.07 verbal predicates per sentence in NIST04 and 4.76 verbs per sentence in NIST05, which account for 18.02% and 16.88% of all words in NIST04 and 05 respectively. This shows that not only verbal predicates are semantically important, they also form a major part of the sentences. Therefore, whether verbal predicates are translated correctly or not has a great impact on the translation accuracy of the whole sentence<sup>7</sup>.

<sup>6</sup>Available at: <http://nlp.suda.edu.cn/~jhli/>.

<sup>7</sup>The example in Table 6 shows that the translations of verbs even influences reorderings and translations of neighboring words.

$$\frac{X \rightarrow c/e}{[X, i, j] : \mathcal{P}_r(\mathcal{A}(i, j, \tau))} \quad (7)$$

$$\frac{X \rightarrow [X_1, X_2] \text{ or } \langle X_1, X_2 \rangle \quad [X_1, i, k] : \mathcal{P}_r(\mathcal{A}(i, k, \tau)) \quad [X_2, k+1, j] : \mathcal{P}_r(\mathcal{A}(k+1, j, \tau))}{[X, i, j] : \mathcal{P}_r(\mathcal{A}(i, k, \tau)) \cdot \mathcal{P}_r(\mathcal{A}(k+1, j, \tau)) \cdot \mathcal{P}_r(\mathcal{N}(i, k, j, \tau))} \quad (8)$$

Figure 2: Integrating the argument reordering model into a BTG-style decoder.

Model	NIST04	NIST05
Base	35.52	33.80
Base+PTM (lex)	35.71+	34.09+
Base+PTM (lex+sem)	36.10++**	34.35++*

Table 4: Effects of the proposed predicate translation model (PTM). PTM (lex): predicate translation model with lexical features; PTM (lex+sem): predicate translation model with both lexical and semantic features; +/++: better than the baseline ( $p < 0.05/0.01$ ). \*\*/\*: better than Base+PTM (lex) ( $p < 0.05/0.01$ ).

Model	NIST04	NIST05
Base	35.52	33.80
Base+ARM	35.82++	34.29++
Base+ARM+PTM	36.19++	34.72++

Table 5: Effects of the proposed argument reordering model (ARM) and the combination of ARM and PTM. ++: better than the baseline ( $p < 0.01$ ).

- When we integrate both lexical and semantic features (lex+sem) described in Section 3.2, we obtain an improvement of about 0.33 BLEU points over the system where only lexical features (lex) are used. Such a gain, which is statistically significant, confirms the effectiveness of semantic features.

Our second group of experiments is to validate whether the argument reordering model is capable of improving translation quality. Table 5 shows the results. We obtain an average improvement of 0.4 BLEU points on the two test sets over the baseline when we incorporate the proposed argument reordering model into our system. The improvements on the two test sets are both statistically significant ( $p < 0.01$ ).

Finally, we integrate both the predicate translation model and argument reordering model into the final system. The two models collectively achieve an im-

provement of up to 0.92 BLEU points over the baseline, which is shown in Table 5.

## 7 Analysis

In this section, we conduct some case studies to show how the proposed models improve translation accuracy by looking into the differences that they make on translation hypotheses.

Table 6 displays a translation example which shows the difference between the baseline and the system enhanced with the predicate translation model. There are two verbal predicates “赶往/head to” and “参加/attend” in the source sentence. In order to get the most appropriate translations for these two verbal predicates, we should adopt different ways to translate them. The former should be translated as a corresponding verb word or phrase while the latter into a preposition word “for”. Unfortunately, the baseline incorrectly translates the two verbs. Furthermore, such translation errors even result in undesirable reorderings of neighboring words “伯利恒/Bethlehem and “弥撒/mass”. This indicates that verbal predicate translation errors may lead to more errors, such as inappropriate reorderings or lexical choices for neighboring words. On the contrary, we can see that our predicate translation model is able to help select appropriate words for both verbs. The correct translations of these two verbs also avoid incorrect reorderings of neighboring words.

Table 7 shows another example to demonstrate how the argument reordering model improve reorderings. The verbal predicate “进行/carry out” has three arguments, ARG0, ARG-ADV and ARG1. The ARG1 argument should be moved from the right side of the predicate to its left side after translation. The ARG0 argument can either stay on the left side or move to right side of the predicate. Ac-

Base	[数千] 信徒 赶往 伯利恒 参加 [平安夜] 弥撒 [thousands of] followers to Mass in Bethlehem [Christmas Eve]
Base+PTM	[数千] 信徒 赶往 伯利恒 参加 [平安夜] 弥撒 [thousands of] devotees [rushed to] Bethlehem for [Christmas Eve] mass
Ref	thousands of worshippers head to Bethlehem for Christmas Midnight mass

Table 6: A translation example showing the difference between the baseline and the system with the predicate translation model (PTM). Phrase alignments in the two system outputs are shown with dashed lines. Chinese words in bold are verbal predicates.

PAS	
Base	[有关这] 套 灾难 [警告系统] 还要 [进行更多] [重要的磋商] the more [important consultations] also set disaster [warning system]
Base+ARM	有关 [这套] 灾难 [警告系统] [还要进行] [更多] [重要的磋商] more [important consultations] on [such a] disaster [warning system] [should be carried out]
Ref	more important discussions will be held on the disaster warning system

Table 7: A translation example showing the difference between the baseline and the system with the argument reordering model (ARM). The predicate-argument structure (PAS) of the source sentence is also displayed in the first row.

According to the phrase alignments of the baseline, we clearly observe three serious translation errors: 1) the ARG0 argument is translated into separate groups which are not adjacent on the target side; 2) the predicate is not translated at all; and 3) the ARG1 argument is not moved to the left side of the predicate after translation. All of these 3 errors are avoided in the Base+ARM system output as a result of the argument reordering model that correctly identifies arguments and moves them in the right directions.

## 8 Conclusions and Future Work

We have presented two discriminative models to incorporate source side predicate-argument structures into SMT. The two models have been integrated into a phrase-based SMT system and evaluated on Chinese-to-English translation tasks using large-scale training data. The first model is the predicate translation model which employs both lexical and semantic contexts to translate verbal predicates.

The second model is the argument reordering model which estimates the direction of argument movement relative to its predicate after translation. Experimental results show that both models are able to significantly improve translation accuracy in terms of BLEU score.

In the future work, we will extend our predicate translation model to translate both verbal and nominal predicates. Nominal predicates also frequently occur in Chinese sentences and thus accurate translations of them are desirable for SMT. We also want to address another translation issue of arguments as shown in Table 7: arguments are wrongly translated into separate groups instead of a cohesive unit (Wu and Fung, 2009a). We will build an argument segmentation model that follows (Xiong et al., 2011) to determine whether arguments should be translated as a unit or not.

## Abstract

Long distance word reordering is a major challenge in statistical machine translation research. Previous work has shown using source syntactic trees is an effective way to tackle this problem between two languages with substantial word order difference. In this work, we further extend this line of exploration and propose a novel but simple approach, which utilizes a ranking model based on word order precedence in the target language to reposition nodes in the syntactic parse tree of a source sentence. The ranking model is automatically derived from word aligned parallel data with a syntactic parser for source language based on both lexical and syntactical features. We evaluated our approach on large-scale Japanese-English and English-Japanese machine translation tasks, and show that it can significantly outperform the baseline phrase-based SMT system.

## 1 Introduction

Modeling word reordering between source and target sentences has been a research focus since the emerging of statistical machine translation. In phrase-based models (Och, 2002; Koehn et al., 2003), phrase is introduced to serve as the fundamental translation element and deal with local reordering, while a distance based distortion model is used to coarsely depict the exponentially decayed word movement probabilities in language translation. Further work in this direction employed lexi-

calized distortion models, including both generative (Koehn et al., 2005) and discriminative (Zens and Ney, 2006; Xiong et al., 2006) variants, to achieve finer-grained estimations, while other work took into account the hierarchical language structures in translation (Chiang, 2005; Galley and Manning, 2008).

Long-distance word reordering between language pairs with substantial word order difference, such as Japanese with Subject-Object-Verb (SOV) structure and English with Subject-Verb-Object (SVO) structure, is generally viewed beyond the scope of the phrase-based systems discussed above, because of either distortion limits or lack of discriminative features for modeling. The most notable solution to this problem is adopting syntax-based SMT models, especially methods making use of source side syntactic parse trees. There are two major categories in this line of research. One is tree-to-string model (Quirk et al., 2005; Liu et al., 2006) which directly uses source parse trees to derive a large set of translation rules and associated model parameters. The other is called *syntax pre-reordering* – an approach that re-positions source words to approximate target language word order as much as possible based on the features from source syntactic parse trees. This is usually done in a preprocessing step, and then followed by a standard phrase-based SMT system that takes the re-ordered source sentence as input to finish the translation.

In this paper, we continue this line of work and address the problem of word reordering based on source syntactic parse trees for SMT. Similar to most previous work, our approach tries to rearrange the source tree nodes sharing a common parent to mimic

\*This work has been done while the first author was visiting Microsoft Research Asia.

the word order in target language. To this end, we propose a simple but effective ranking-based approach to word reordering. The ranking model is automatically derived from the word aligned parallel data, viewing the source tree nodes to be reordered as list items to be ranked. The ranks of tree nodes are determined by their relative positions in the target language – the node in the most front gets the highest rank, while the ending word in the target sentence gets the lowest rank. The ranking model is trained to directly minimize the mis-ordering of tree nodes, which differs from the prior work based on maximum likelihood estimations of reordering patterns (Li et al., 2007; Genzel, 2010), and does not require any special tweaking in model training. The ranking model can not only be used in a pre-reordering based SMT system, but also be integrated into a phrase-based decoder serving as additional distortion features.

We evaluated our approach on large-scale Japanese-English and English-Japanese machine translation tasks, and experimental results show that our approach can bring significant improvements to the baseline phrase-based SMT system in both pre-ordering and integrated decoding settings.

In the rest of the paper, we will first formally present our ranking-based word reordering model, then followed by detailed steps of modeling training and integration into a phrase-based SMT system. Experimental results are shown in Section 5. Section 6 consists of more discussions on related work, and Section 7 concludes the paper.

## 2 Word Reordering as Syntax Tree Node Ranking

Given a source side parse tree  $T_e$ , the task of word reordering is to transform  $T_e$  to  $T'_e$ , so that  $e'$  can match the word order in target language as much as possible. In this work, we only focus on reordering that can be obtained by permuting *children* of every tree nodes in  $T_e$ . We use *children* to denote direct descendants of tree nodes for constituent trees; while for dependency trees, *children* of a node include not only all direct dependents, but also the head word itself. Figure 1 gives a simple example showing the word reordering between English and Japanese. By rearranging the position of tree nodes in the English

Figure 1: An English-to-Japanese sentence pair. By permuting tree nodes in the parse tree, the source sentence is reordered into the target language order. Constituent tree is shown above the source sentence; arrows below the source sentences show head-dependent arcs for dependency tree; word alignment links are lines without arrow between the source and target sentences.

parse tree, we can obtain the same word order of Japanese translation. It is true that tree-based reordering cannot cover all word movement operations in language translation, previous work showed that this method is still very effective in practice (Xu et al., 2009, Visweswariah et al., 2010).

Following this principle, the word reordering task can be broken into sub-tasks, in which we only need to determine the order of children nodes for all non-leaf nodes in the source parse tree. For a tree node  $t$  with children  $\{c_1, c_2, \dots, c_n\}$ , we rearrange the children to target-language-like order  $\{c_{\pi(i_1)}, c_{\pi(i_2)}, \dots, c_{\pi(i_n)}\}$ . If we treat the reordered position  $\pi(i)$  of child  $c_i$  as its “rank”, the reorder-

ing problem is naturally translated into a ranking problem: to reorder, we determine a “rank” for each child, then the children are sorted according to their “ranks”. As it is often impractical to directly assign a score for each permutation due to huge number of possible permutations, a widely used method is to use a real valued function  $f$  to assign a value to each node, which is called a ranking function (Herbrich et al., 2000). If we can guarantee  $(f(i) - f(j))$  and  $(\pi(i) - \pi(j))$  always has the same sign, we can get the same permutation as  $\pi$  because values of  $f$  are only used to sort the children. For example, consider the node rooted at *trying* in the dependency tree in Figure 1. Four children form a list  $\{I, am, trying, play\}$  to be ranked. Assuming ranking function  $f$  can assign values  $\{0.94, -1.83, -1.50, -1.20\}$  for  $\{I, am, trying, play\}$  respectively, we can get a sorted list  $\{I, play, trying, am\}$ , which is the desired permutation according to the target.

More formally, for a tree node  $t$  with children  $\{c_1, c_2, \dots, c_n\}$ , our ranking model assigns a rank  $f(c_i, t)$  for each child  $c_i$ , then the children are sorted according to the rank in a descending order. The ranking function  $f$  has the following form:

$$f(c_i, t) = \sum_j \theta_j(c_i, t) \cdot w_j \quad (1)$$

where the  $\theta_j$  is a feature representing the tree node  $t$  and its child  $c_i$ , and  $w_j$  is the corresponding feature weight.

### 3 Ranking Model Training

To learn ranking function in Equation (1), we need to determine the feature set  $\theta$  and learn weight vector  $w$  from reorder examples. In this section, we first describe how to extract reordering examples from parallel corpus; then we show our features for ranking function; finally, we discuss how to train the model from the extracted examples.

#### 3.1 Reorder Example Acquisition

For a sentence pair  $(e, f, a)$  with syntax tree  $T_e$  on the source side, we need to determine which reordered tree  $T'_e$  best represents the word order in target sentence  $f$ . For a tree node  $t$  in  $T_e$ , if its children align to disjoint target spans, we can simply arrange them in the order of their corresponding target

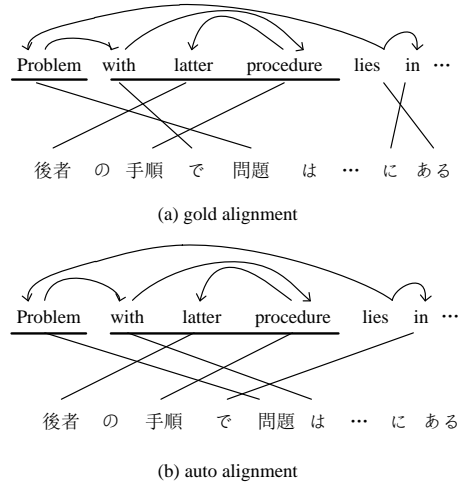

Figure 2: Fragment of a sentence pair. (a) shows gold alignment; (b) shows automatically generated alignment which contains errors.

spans. Figure 2 shows a fragment of one sentence pair in our training data. Consider the subtree rooted at word “*Problem*”. With the gold alignment, “*Problem*” is aligned to the 5th target word, and “*with latter procedure*” are aligned to target span  $[1, 3]$ , thus we can simply put “*Problem*” after “*with latter procedure*”. Recursively applying this process down the subtree, we get “*latter procedure with Problem*” which perfectly matches the target language.

As pointed out by (Li et al., 2007), in practice, nodes often have overlapping target spans due to erroneous word alignment or different syntactic structures between source and target sentences. (b) in Figure 2 shows the automatically generated alignment for the sentence pair fragment. The word “*with*” is incorrectly aligned to the 6th Japanese word “*ha*”; as a result, “*with latter procedure*” now has target span  $[1, 6]$ , while “*Problem*” aligns to  $[5, 5]$ . Due to this overlapping, it becomes unclear which permutation of “*Problem*” and “*with latter procedure*” is a better match of the target phrase; we need a better metric to measure word order similarity between reordered source and target sentences. We choose to find the tree  $T'_e$  with minimal *alignment crossing-link number (CLN)* (Genzel, 2010) to  $f$  as our golden reordered tree.<sup>1</sup> Each crossing-

<sup>1</sup>A simple solution is to exclude all trees with overlapping target spans from training. But in our experiment, this method

link  $(i_1j_1, i_2j_2)$  is a pair of alignment links crossing each other.  $CLN$  reaches zero if  $f$  is monotonically aligned to  $e'$ , and increases as there are more word reordering between  $e'$  and  $f$ . For example, in Figure 1, there are 6 crossing-links in the original tree:  $(e_1j_4, e_2j_3)$ ,  $(e_1j_4, e_4j_2)$ ,  $(e_1j_4, e_5j_1)$ ,  $(e_2j_3, e_4j_2)$ ,  $(e_2j_3, e_5j_1)$  and  $(e_4j_2, e_5j_1)$ ; thus  $CLN$  for the original tree is 6.  $CLN$  for the reordered tree is 0 as there are no crossing-links. This metric is easy to compute, and is not affected by unaligned words (Genzel, 2010).

We need to find the reordered tree with minimal  $CLN$  among all reorder candidates. As the number of candidates is in the magnitude exponential with respect to the degree of tree  $T_e$ <sup>2</sup>, it is not always computationally feasible to enumerate through all candidates. Our solution is as follows.

First, we give two definitions.

- $CLN(t)$ : the number of crossing-links  $(i_1j_1, i_2j_2)$  whose source words  $e'_{i_1}$  and  $e'_{i_2}$  both fall under sub span of the tree node  $t$ .
- $CCLN(t)$ : the number of crossing-links  $(i_1j_1, i_2j_2)$  whose source words  $e'_{i_1}$  and  $e'_{i_2}$  fall under sub span of  $t$ 's two different children nodes  $c_1$  and  $c_2$  respectively.

Apparently  $CLN$  of a tree  $T'$  equals to  $CLN(\text{root of } T')$ , and  $CLN(t)$  can be recursively expressed as:

$$CLN(t) = CCLN(t) + \sum_{\text{child } c \text{ of } t} CLN(c)$$

Take the original tree in Figure 1 for example. At the root node *trying*,  $CLN(\text{trying})$  is 6 because there are six crossing-links under its sub-span:  $(e_1j_4, e_2j_3)$ ,  $(e_1j_4, e_4j_2)$ ,  $(e_1j_4, e_5j_1)$ ,  $(e_2j_3, e_4j_2)$ ,  $(e_2j_3, e_5j_1)$  and  $(e_4j_2, e_5j_1)$ . On the other hand,  $CCLN(\text{trying})$  is 5 because  $(e_4j_2, e_5j_1)$  falls under its child node *play*, thus does not count towards  $CCLN$  of *trying*.

From the definition, we can easily see that  $CCLN(t)$  can be determined solely by the order of  $t$ 's direct children, and  $CLN(t)$  is only affected by

<sup>2</sup>discarded too many training instances and led to degraded reordering performance.

<sup>2</sup>In our experiments, there are nodes with more than 10 children for English dependency trees.

the reorder in the subtree of  $t$ . This observation enables us to divide the task of finding the reordered tree  $T'_e$  with minimal  $CLN$  into independently finding the children permutation of each node with minimal  $CCLN$ . Unfortunately, the time cost for the sub-task is still  $O(n!)$  for a node with  $n$  children. Instead of enumerating through all permutations, we only search the *Inversion Transduction Grammar neighborhood* of the initial sequence (Tromble, 2009). As pointed out by (Tromble, 2009), the ITG neighborhood is large enough for reordering task, and can be searched through efficiently using a CKY decoder.

After finding the best reordered tree  $T'_e$ , we can extract one reorder example from every node with more than one child.

### 3.2 Features

Features for the ranking model are extracted from source syntax trees. For English-to-Japanese task, we extract features from Stanford English Dependency Tree (Marneffe et al., 2006), including lexicons, Part-of-Speech tags, dependency labels, punctuations and tree distance between head and dependent. For Japanese-to-English task, we use a chunk-based Japanese dependency tree (Kudo and Matsumoto, 2002). Different from features for English, we do not use dependency labels because they are not available from the Japanese parser. Additionally, Japanese function words are also included as features because they are important grammatical clues. The detailed feature templates are shown in Table 1.

### 3.3 Learning Method

There are many well studied methods available to learn the ranking function from extracted examples., ListNet (?) etc. We choose to use RankingSVM (Herbrich et al., 2000), a pair-wised ranking method, for its simplicity and good performance.

For every reorder example  $t$  with children  $\{c_1, c_2, \dots, c_n\}$  and their desired permutation  $\{c_{\pi(i_1)}, c_{\pi(i_2)}, \dots, c_{\pi(i_n)}\}$ , we decompose it into a set of pair-wised training instances. For any two children nodes  $c_i$  and  $c_j$  with  $i < j$ , we extract a positive instance if  $\pi(i) < \pi(j)$ , otherwise we extract a negative instance. The feature vector for both positive instance and negative instance is  $(\theta_{c_i} - \theta_{c_j})$ , where  $\theta_{c_i}$  and  $\theta_{c_j}$  are feature vectors for  $c_i$  and  $c_j$

E-J		
$c_l$	$c_l \cdot dst$	$c_l \cdot pct$
$c_l \cdot dst \cdot pct$	$c_l \cdot lc_l$	$c_l \cdot rc_l$
$c_l \cdot lc_l \cdot dst$	$c_l \cdot rc_l \cdot dst$	$c_l \cdot c_{lex}$
$c_l \cdot c_{lex}$	$c_l \cdot c_{lex} \cdot dst$	$c_l \cdot c_{lex} \cdot dst$
$c_l \cdot h_{lex}$	$c_l \cdot h_{lex}$	$c_l \cdot h_{lex} \cdot dst$
$c_l \cdot h_{lex} \cdot dst$	$c_l \cdot c_{lex} \cdot pct$	$c_l \cdot c_{lex} \cdot pct$
$c_l \cdot h_{lex} \cdot pct$	$c_l \cdot h_{lex} \cdot pct$	
J-E

$c_{tf} \cdot rc_t$	$c_{tf} \cdot lc_t \cdot dst$	$c_l \cdot rc_t \cdot dst$
$c_{tf} \cdot c_{lex}$	$c_{tf} \cdot c_{lex}$	$c_{tf} \cdot c_{lex} \cdot dst$
$c_{tf} \cdot c_{lex} \cdot dst$	$c_{tf} \cdot h_f$	$c_{tf} \cdot h_f$
$c_{tf} \cdot h_f \cdot dst$	$c_{tf} \cdot h_f \cdot dst$	$c_{tf} \cdot h_{lex}$
$c_{tf} \cdot h_{lex}$	$c_{tf} \cdot h_{lex} \cdot dst$	$c_{tf} \cdot h_{lex} \cdot dst$

Table 1: Feature templates for ranking function. All templates are implicitly conjuncted with the pos tag of head node.

$c$ : child to be ranked;  $h$ : head node  
 $lc$ : left sibling of  $c$ ;  $rc$ : right sibling of  $c$   
 $l$ : dependency label;  $t$ : pos tag  
 $lex$ : top frequency lexicons  
 $f$ : Japanese function word  
 $dst$ : tree distance between  $c$  and  $h$   
 $pct$ : punctuation node between  $c$  and  $h$

respectively. In this way, ranking function learning is turned into a simple binary classification problem, which can be easily solved by a two-class linear support vector machine.

## 4 Integration into SMT system

There are two ways to integrate the ranking reordering model into a phrase-based SMT system: the pre-reorder method, and the decoding time constraint method.

For pre-reorder method, ranking reorder model is applied to reorder source sentences during both training and decoding. Reordered sentences can go through the normal pipeline of a phrase-based decoder.

The ranking reorder model can also be integrated into a phrase based decoder. Integrated method takes the original source sentence  $e$  as input, and ranking model generates a reordered  $e'$  as a word order ref-

erence for the decoder. A simple penalty scheme is utilized to penalize decoder reordering violating ranking reorder model's prediction  $e'$ . In this paper, our underlying decoder is a CKY decoder following Bracketing Transduction Grammar (Wu, 1997; Xiong et al., 2006), thus we show how the penalty is implemented in the BTG decoder as an example. Similar penalty can be designed for other decoders without much effort.

Under BTG, three rules are used to derive translations: one unary terminal rule, one *straight* rule and one *inverse* rule:

$$\begin{aligned}
 A &\rightarrow e/f \\
 A &\rightarrow [A_1, A_2] \\
 A &\rightarrow \langle A_1, A_2 \rangle
 \end{aligned}$$

We have three penalty triggers when any rules are applied during decoding:

- Discontinuous penalty  $f_{dc}$ : it fires for all rules when source span of either  $A$ ,  $A_1$  or  $A_2$  is mapped to discontinuous span in  $e'$ .
- Wrong straight rule penalty  $f_{st}$ : it fires for straight rule when source spans of  $A_1$  and  $A_2$  are not mapped to two adjacent spans in  $e'$  in straight order.
- Wrong inverse rule penalty  $f_{iv}$ : it fires for inverse rule when source spans of  $A_1$  and  $A_2$  are not mapped to two adjacent spans in  $e'$  in inverse order.

The above three penalties are added as additional features into the log-linear model of the phrase-based system. Essentially they are soft constraints to encourage the decoder to choose translations with word order similar to the prediction of ranking reorder model.

## 5 Experiments

To test our ranking reorder model, we carry out experiments on large scale English-To-Japanese, and Japanese-To-English translation tasks.

### 5.1 Data

#### 5.1.1 Evaluation Data

We collect 3,500 Japanese sentences and 3,500 English sentences from the web. They come from

a wide range of domains, such as technical documents, web forum data, travel logs etc. They are manually translated into the other language to produce 7,000 sentence pairs, which are split into two parts: 2,000 pairs as development set (*dev*) and the other 5,000 pairs as test set (*web* test).

Beside that, we collect another 999 English sentences from newswire domain which are translated into Japanese to form an out-of-domain test data set (*news* test).

### 5.1.2 Parallel Corpus

Our parallel corpus is crawled from the web, containing news articles, technical documents, blog entries etc. After removing duplicates, we have about 18 million sentence pairs, which contain about 270 millions of English tokens and 320 millions of Japanese tokens. We use Giza++ (Och and Ney, 2003) to generate the word alignment for the parallel corpus.

### 5.1.3 Monolingual Corpus

Our monolingual Corpus is also crawled from the web. After removing duplicate sentences, we have a corpus of over 10 billion tokens for both English and Japanese. This monolingual corpus is used to train a 4-gram language model for English and Japanese respectively.

## 5.2 Parsers

For English, we train a dependency parser as (Nivre and Scholz, 2004) on WSJ portion of Penn Treebank, which are converted to dependency trees using Stanford Parser (Marneffe et al., 2006). We convert the tokens in training data to lower case, and re-tokenize the sentences using the same tokenizer from our MT system.

For Japanese parser, we use CABOCHA, a chunk-based dependency parser (Kudo and Matsumoto, 2002). Some heuristics are used to adapt CABOCHA generated trees to our word segmentation.

## 5.3 Settings

### 5.3.1 Baseline System

We use a BTG phrase-based system with a Max-Ent based lexicalized reordering model (Wu, 1997; Xiong et al., 2006) as our baseline system for

both English-to-Japanese and Japanese-to-English Experiment. The distortion model is trained on the same parallel corpus as the phrase table using a home implemented maximum entropy trainer.

In addition, a pre-reorder system using manual rules as (Xu et al., 2009) is included for the English-to-Japanese experiment (ManR-PR). Manual rules are tuned by a bilingual speaker on the development set.

### 5.3.2 Ranking Reordering System

Ranking reordering model is learned from the same parallel corpus as phrase table. For efficiency reason, we only use 25% of the corpus to train our reordering model. LIBLINEAR (Fan et al., 2008) is used to do the SVM optimization for RankingSVM.

We test it on both pre-reorder setting (*Rank-PR*) and integrated setting (*Rank-IT*).

## 5.4 End-to-End Result

	system	dev	web test	news test
E-J	Baseline	21.45	21.12	14.18
	ManR-PR	23.00	22.42	15.61
	Rank-PR	22.92	22.51	<b>15.90</b>
	Rank-IT	<b>23.14</b>	<b>22.85</b>	15.72
J-E	Baseline	25.39	24.20	14.26
	Rank-PR	26.57	25.56	<b>15.42</b>
	Rank-IT	<b>26.72</b>	<b>25.87</b>	15.27

Table 2: BLEU(%) score on dev and test data for both E-J and J-E experiment. All settings significantly improve over the baseline at 95% confidence level. Baseline is the BTG phrase system system; ManR-PR is pre-reorder with manual rule; Rank-PR is pre-reorder with ranking reorder model; Rank-IT is system with integrated ranking reorder model.

From Table 2, we can see our ranking reordering model significantly improves the performance for both English-to-Japanese and Japanese-to-English experiments over the BTG baseline system. It also out-performs the manual rule set on English-to-Japanese result, but the difference is not significant.

## 5.5 Reordering Performance

In order to show whether the improved performance is really due to improved reordering, we would like to measure the reorder performance directly.

As we do not have access to a golden re-ordered sentence set, we decide to use the alignment crossing-link numbers between aligned sentence pairs as the measure for reorder performance.

We train the ranking model on 25% of our parallel corpus, and use the rest 75% as test data (*auto*). We sample a small corpus (575 sentence pairs) and do manual alignment (*man-small*). We denote the automatic alignment for these 575 sentences as (*auto-small*). From Table 3, we can see

	setting	auto	auto-small	man-small
	None	36.3	35.9	40.1
E-J	Oracle	4.3	4.1	7.4
	ManR	13.4	13.6	16.7
	Rank	12.1	12.8	17.2
J-E	Oracle	6.9	7.0	9.4
	Rank	15.7	15.3	20.5

Table 3: Reorder performance measured by crossing-link number per sentence. *None* means the original sentences without reordering; *Oracle* means the best permutation allowed by the source parse tree; *ManR* refers to manual reorder rules; *Rank* means ranking reordering model.

our ranking reordering model indeed significantly reduces the crossing-link numbers over the original sentence pairs. On the other hand, the performance of the ranking reorder model still fall far short of oracle, which is the lowest crossing-link number of all possible permutations allowed by the parse tree. By manual analysis, we find that the gap is due to both errors of the ranking reorder model and errors from word alignment and parser.

Another thing to note is that the crossing-link number of manual alignment is higher than automatic alignment. The reason is that our annotators tend to align function words which might be left unaligned by automatic word aligner.

### 5.6 Effect of Ranking Features

Here we examine the effect of features for ranking reorder model. We compare their influence on RankingSVM accuracy, alignment crossing-link number, end-to-end BLEU score, and the model size. As Table 4 shows, a major part of reduction of *CLN* comes from features such as Part-of-Speech tags,

	Features	Acc.	<i>CLN</i>	BLEU	Feat.#
E-J	<i>tag+label</i>	88.6	16.4	22.24	26k
	<i>+dst</i>	91.5	13.5	22.66	55k
	<i>+pct</i>	92.2	13.1	22.73	79k
	<i>+lex<sub>100</sub></i>	92.9	12.1	22.85	347k
	<i>+lex<sub>1000</sub></i>	94.0	11.5	22.79	2,410k
	<i>+lex<sub>2000</sub></i>	95.2	10.7	22.81	3,794k
J-E	<i>tag+fw</i>	85.0	18.6	25.43	31k
	<i>+dst</i>	90.3	16.9	25.62	65k
	<i>+lex<sub>100</sub></i>	91.6	15.7	25.87	293k
	<i>+lex<sub>1000</sub></i>	92.4	14.8	25.91	2,156k
	<i>+lex<sub>2000</sub></i>	93.0	14.3	25.84	3,297k

Table 4: Effect of ranking features. Acc. is RankingSVM accuracy in percentage on the training data; *CLN* is the crossing-link number per sentence on parallel corpus with automatically generated word alignment; BLEU is the BLEU score in percentage on **web** test set on *Rank-IT* setting (system with integrated rank reordering model); *lex<sub>n</sub>* means n most frequent lexicons in the training corpus.

dependency labels (for English), function words (for Japanese), and the distance and punctuations between child and head. These features also correspond to BLEU score improvement for End-to-End evaluations. Lexicon features generally continue to improve the RankingSVM accuracy and reduce *CLN* on training data, but they do not bring further improvement for SMT systems beyond the top 100 most frequent words. Our explanation is that less frequent lexicons tend to help local reordering only, which is already handled by the underlying phrase-based system.

### 5.7 Performance on different domains

From Table 2 we can see that pre-reorder method has higher BLEU score on **news** test, while integrated model performs better on **web** test set which contains informal texts. By error analysis, we find that the parser commits more errors on informal texts, and informal texts usually have more flexible translations. Pre-reorder method makes “hard” decision before decoding, thus is more sensitive to parser errors; on the other hand, integrated model is forced to use a longer distortion limit which leads to more search errors during decoding time. It is possible to

use system combination method to get the best of both systems, but we leave this to future work.

## 6 Discussion on Related Work

There have been several studies focusing on compiling hand-crafted syntactic reorder rules. Collins et al. (2005), Wang et al. (2007), Ramanathan et al. (2008), Lee et al. (2010) have developed rules for German-English, Chinese-English, English-Hindi and English-Japanese respectively. Xu et al. (2009) designed a clever precedence reordering rule set for translation from English to several SOV languages. The drawback for hand-crafted rules is that they depend upon expert knowledge to produce and are limited to their targeted language pairs.

Automatically learning syntactic reordering rules have also been explored in several work. Li et al. (2007) and Visweswariah et al. (2010) learned probability of reordering patterns from constituent trees using either Maximum Entropy or maximum likelihood estimation. Since reordering patterns are matched against a tree node together with all its direct children, data sparseness problem will arise when tree nodes have many children (Li et al., 2007); Visweswariah et al. (2010) also mentioned their method yielded no improvement when applied to dependency trees in their initial experiments. Genzel (2010) dealt with the data sparseness problem by using window heuristic, and learned reordering pattern sequence from dependency trees. Even with the window heuristic, they were unable to evaluate all candidates due to the huge number of possible patterns. Different from the previous approaches, we treat syntax-based reordering as a ranking problem between different source tree nodes. Our method does not require the source nodes to match some specific patterns, but encodes reordering knowledge in the form of a ranking function, which naturally handles reordering between any number of tree nodes; the ranking function is trained by well-established rank learning method to minimize the number of mis-ordered tree nodes in the training data.

Tree-to-string systems (Quirk et al., 2005; Liu et al., 2006) model syntactic reordering using minimal or composed translation rules, which may contain reordering involving tree nodes from multiple tree

levels. Our method can be naturally extended to deal with such multiple level reordering. For a tree-to-string rule with multiple tree levels, instead of ranking the direct children of the root node, we rank all leaf nodes (Most are frontier nodes (Galley et al., 2006)) in the translation rule. We need to redesign our ranking feature templates to encode the reordering information in the source part of the translation rules. We need to remember the source side context of the rules, the model size would still be much smaller than a full-fledged tree-to-string system because we do not need to explicitly store the target variants for each rule.

## 7 Conclusion and Future Work

In this paper we present a ranking based reordering method to reorder source language to match the word order of target language given the source side parse tree. Reordering is formulated as a task to rank different nodes in the source side syntax tree according to their relative position in the target language. The ranking model is automatically trained to minimize the mis-ordering of tree nodes in the training data. Large scale experiment shows improvement on both reordering metric and SMT performance, with up to 1.73 point BLEU gain in our evaluation test.

In future work, we plan to extend the ranking model to handle reordering between multiple levels of source trees. We also expect to explore better way to integrate ranking reorder model into SMT system instead of a simple penalty scheme. Along the research direction of preprocessing the source language to facilitate translation, we consider to not only change the order of the source language, but also inject syntactic structure of the target language into source language by adding pseudo words into source sentences.

## Abstract

In this work, we introduce the TESLA-CELAB metric (Translation Evaluation of Sentences with Linear-programming-based Analysis – Character-level Evaluation for Languages with Ambiguous word Boundaries) for automatic machine translation evaluation. For languages such as Chinese where words usually have meaningful internal structure and word boundaries are often fuzzy, TESLA-CELAB acknowledges the advantage of character-level evaluation over word-level evaluation. By reformulating the problem in the linear programming framework, TESLA-CELAB addresses several drawbacks of the character-level metrics, in particular the modeling of synonyms spanning multiple characters. We show empirically that TESLA-CELAB significantly outperforms character-level BLEU in the English-Chinese translation evaluation tasks.

## 1 Introduction

Since the introduction of BLEU (Papineni et al., 2002), automatic machine translation (MT) evaluation has received a lot of research interest. The Workshop on Statistical Machine Translation (WMT) hosts regular campaigns comparing different machine translation evaluation metrics (Callison-Burch et al., 2009; Callison-Burch et al., 2010; Callison-Burch et al., 2011). In the WMT shared tasks, many new generation metrics, such as METEOR (Banerjee and Lavie, 2005), TER (Snover et al., 2006), and TESLA (Liu et al., 2010) have consistently outperformed BLEU as judged by the correlations with human judgments.

The research on automatic machine translation evaluation is important for a number of reasons. Automatic translation evaluation gives machine translation researchers a cheap and reproducible way to guide their research and makes it possible to compare machine translation methods across different studies. In addition, machine translation system parameters are tuned by maximizing the automatic scores. Some recent research (Liu et al., 2011) has shown evidence that replacing BLEU by a newer metric, TESLA, can improve the human judged translation quality.

Despite the importance and the research interest on automatic MT evaluation, almost all existing work has focused on European languages, in particular on English. Although many methods aim to be language neutral, languages with very different characteristics such as Chinese do present additional challenges. The most obvious challenge for Chinese is that of word segmentation.

Unlike European languages, written Chinese is not split into words. Segmenting Chinese sentences into words is a natural language processing task in its own right (Zhao and Liu, 2010; Low et al., 2005). However, many different segmentation standards exist for different purposes, such as Microsoft Research Asia (MSRA) for Named Entity Recognition (NER), Chinese Treebank (CTB) for parsing and part-of-speech (POS) tagging, and City University of Hong Kong (CITYU) and Academia Sinica (AS) for general word segmentation and POS tagging. It is not clear which standard is the best in a given scenario.

The only prior work attempting to address the problem of word segmentation in automatic MT evaluation for Chinese that we are aware of is Li et

买	伞	
buy	umbrella	
买	雨伞	
buy	umbrella	
买	雨	伞
buy	rain	umbrella

Figure 1: Three forms of the same expression *buy umbrella* in Chinese

al. (2011). The work compared various MT evaluation metrics (BLEU, NIST, METEOR, GTM, 1 – TER) with different segmentation schemes, and found that treating every single character as a token (character-level MT evaluation) gives the best correlation with human judgments.

## 2 Motivation

Li et al. (2011) identify two reasons that character-based metrics outperform word-based metrics. For illustrative purposes, we use Figure 1 as a running example in this paper. All three expressions are semantically identical (*buy umbrella*). The first two forms are identical because 雨伞<sup>1</sup> and 伞 are synonyms. The last form is simply an (arguably wrong) alternative segmented form of the second expression.

1. Word-based metrics do not award partial matches, e.g., 买\_雨伞 and 买\_伞 would be penalized for the mismatch between 雨伞 and 伞. Character-based metrics award the match between characters 伞 and 伞.
2. Character-based metrics do not suffer from errors and differences in word segmentation, so 买\_雨伞 and 买\_雨\_伞 would be judged exactly equal.

Li et al. (2011) conduct empirical experiments to show that character-based metrics consistently outperform their word-based counterparts. Despite that, we observe two important problems for the character-based metrics:

1. Although partial matches are partially awarded, the mechanism breaks down for n-grams where

<sup>1</sup>Literally, *rain umbrella*.

$n > 1$ . For example, between 买\_雨\_伞 and 买\_伞, higher-order n-grams such as 买\_雨 and 雨\_伞 still have no match, and will be penalized accordingly, even though 买\_雨\_伞 and 买\_伞 should match exactly. N-grams such as 买\_雨 which cross natural word boundaries and are meaningless by themselves can be particularly tricky.

2. Character-level metrics can utilize only a small part of the Chinese synonym dictionary, such as 你 and 您 (*you*). The majority of Chinese synonyms involve more than one character, such as 雨伞 and 伞 (*umbrella*), and 儿童 and 小孩 (*child*).

In this work, we attempt to address both of these issues by introducing TESLA-CELAB, a character-level metric that also models word-level linguistic phenomenon. We formulate the n-gram matching process as a real-valued linear programming problem, which can be solved efficiently. The metric is based on the TESLA automatic MT evaluation framework (Liu et al., 2010; Dahlmeier et al., 2011).

## 3 The Algorithm

### 3.1 Basic Matching

We illustrate our matching algorithm using the examples in Figure 1. Let 买雨伞 be the reference, and 买伞 be the candidate translation.

We use Cilin (同义词词林)<sup>2</sup> as our synonym dictionary. The basic n-gram matching problem is shown in Figure 2. Two n-grams are connected if they are identical, or if they are identified as synonyms by Cilin. Notice that all n-grams are put in the same matching problem regardless of  $n$ , unlike in translation evaluation metrics designed for European languages. This enables us to designate n-grams with different values of  $n$  as synonyms, such as 雨伞 ( $n = 2$ ) and 伞 ( $n = 1$ ).

In this example, we are able to make a total of two successful matches. The recall is therefore 2/6 and the precision is 2/3.

<sup>2</sup>[http://ir.hit.edu.cn/phpwebsite/index.php?module=pagemaster&PAGE\\_user\\_op=view\\_page&PAGE\\_id=162](http://ir.hit.edu.cn/phpwebsite/index.php?module=pagemaster&PAGE_user_op=view_page&PAGE_id=162)

Figure 2: The basic n-gram matching problem

Figure 3: The n-gram matching problem after phrase matching

### 3.2 Phrase Matching

We note in Figure 2 that the trigram 买雨伞 and the bigram 买伞 are still unmatched, even though the match between 雨伞 and 伞 should imply the match between 买雨伞 and 买伞.

We infer the matching of such phrases using a dynamic programming algorithm. Two n-grams are considered synonyms if they can be segmented into synonyms that are aligned. With this extension, we are able to match 买雨伞 and 买伞 (since 买 matches 买 and 雨伞 matches 伞). The matching problem is now depicted by Figure 3.

The linear programming problem is mathematically described as follows. The variables  $w(\cdot, \cdot)$  are the weights assigned to the edges,

$$\begin{aligned} w(\text{买}, \text{买}) &\in [0, 1] \\ w(\text{伞}, \text{伞}) &\in [0, 1] \\ w(\text{雨伞}, \text{伞}) &\in [0, 1] \\ w(\text{买雨伞}, \text{买伞}) &\in [0, 1] \end{aligned}$$

We require that for any node  $N$ , the sum of weights assigned to edges linking  $N$  must not exceed one.

$$\begin{aligned} w_{\text{ref}}(\text{买}) &= w(\text{买}, \text{买}) \\ w_{\text{ref}}(\text{伞}) &= w(\text{伞}, \text{伞}) \\ w_{\text{ref}}(\text{雨伞}) &= w(\text{雨伞}, \text{伞}) \\ w_{\text{ref}}(\text{买雨伞}) &= w(\text{买雨伞}, \text{买伞}) \end{aligned}$$

Figure 4: A covered n-gram matching problem

$$\begin{aligned} w_{\text{cand}}(\text{买}) &= w(\text{买}, \text{买}) \\ w_{\text{cand}}(\text{伞}) &= w(\text{伞}, \text{伞}) + w(\text{雨伞}, \text{伞}) \\ w_{\text{cand}}(\text{买伞}) &= w(\text{买雨伞}, \text{买伞}) \end{aligned}$$

where

$$\begin{aligned} w_{\text{ref}}(X) &\in [0, 1] && \forall X \\ w_{\text{cand}}(X) &\in [0, 1] && \forall X \end{aligned}$$

Now we maximize the total match,

$$w(\text{买}, \text{买}) + w(\text{伞}, \text{伞}) + w(\text{雨伞}, \text{伞}) + w(\text{买雨伞}, \text{买伞})$$

In this example, the best match is 3, resulting in a recall of 3/6 and a precision of 3/3.

### 3.3 Covered Matching

In Figure 3, n-grams 雨 and 买雨 in the reference remain impossible to match, which implies misguided penalty for the candidate translation. We observe that since 买雨伞 has been matched, all its sub-n-grams should be considered matched as well, including 雨 and 买雨. We call this the covered n-gram matching rule. This relationship is implicit in the matching problem for English translation evaluation metrics where words are well delimited. But with phrase matching in Chinese, it must be modeled explicitly.

However, we cannot simply perform covered n-gram matching as a post processing step. As an example, suppose we are matching phrases 雨伞 and 伞, as shown in Figure 4. The linear programming solver may come up with any of the solutions where  $w(\text{伞}, \text{伞}) + w(\text{雨伞}, \text{伞}) = 1$ ,  $w(\text{伞}, \text{伞}) \in [0, 1]$ , and  $w(\text{雨伞}, \text{伞}) \in [0, 1]$ .

To give the maximum coverage for the node 雨, only the solution  $w(\text{伞}, \text{伞}) = 0$ ,  $w(\text{雨伞}, \text{伞}) = 1$  is accepted. This indicates the need to model covered

n-gram matching in the linear programming problem itself.

We return to the matching of the reference 买雨伞 and the candidate 买伞 in Figure 3. On top of the  $w(\cdot)$  variables already introduced, we add the variables *maximum covering weights*  $c(\cdot)$ . Each  $c(X)$  represents the maximum  $w(Y)$  variable where n-gram  $Y$  completely covers n-gram  $X$ .

$$\begin{aligned}
c_{\text{ref}}(\text{买}) &\leq \max(w_{\text{ref}}(\text{买}), w_{\text{ref}}(\text{买雨}), \\
&\quad w_{\text{ref}}(\text{买雨伞})) \\
c_{\text{ref}}(\text{雨}) &\leq \max(w_{\text{ref}}(\text{雨}), w_{\text{ref}}(\text{买雨}), \\
&\quad w_{\text{ref}}(\text{雨伞}), w_{\text{ref}}(\text{买雨伞})) \\
c_{\text{ref}}(\text{伞}) &\leq \max(w_{\text{ref}}(\text{伞}), w_{\text{ref}}(\text{雨伞}), \\
&\quad w_{\text{ref}}(\text{买雨伞})) \\
c_{\text{ref}}(\text{买雨}) &\leq \max(w_{\text{ref}}(\text{买雨}), w_{\text{ref}}(\text{买雨伞})) \\
c_{\text{ref}}(\text{雨伞}) &\leq \max(w_{\text{ref}}(\text{雨伞}), w_{\text{ref}}(\text{买雨伞})) \\
c_{\text{ref}}(\text{买雨伞}) &\leq w_{\text{ref}}(\text{买雨伞}) \\
c_{\text{cand}}(\text{买}) &\leq \max(w_{\text{cand}}(\text{买}), w_{\text{cand}}(\text{买伞})) \\
c_{\text{cand}}(\text{伞}) &\leq \max(w_{\text{cand}}(\text{伞}), w_{\text{cand}}(\text{买伞})) \\
c_{\text{cand}}(\text{买伞}) &\leq w_{\text{cand}}(\text{买伞})
\end{aligned}$$

where

$$\begin{aligned}
c_{\text{ref}}(X) &\in [0, 1] && \forall X \\
c_{\text{cand}}(X) &\in [0, 1] && \forall X
\end{aligned}$$

However, the  $\max(\cdot)$  operator is not allowed in the linear programming formulation. We get around this by approximating  $\max(\cdot)$  with the sum instead. Hence,

$$\begin{aligned}
c_{\text{ref}}(\text{买}) &\leq w_{\text{ref}}(\text{买}) + w_{\text{ref}}(\text{买雨}) + \\
&\quad w_{\text{ref}}(\text{买雨伞}) \\
c_{\text{ref}}(\text{雨}) &\leq w_{\text{ref}}(\text{雨}) + w_{\text{ref}}(\text{买雨}) + \\
&\quad w_{\text{ref}}(\text{雨伞}) + w_{\text{ref}}(\text{买雨伞}) \\
&\dots
\end{aligned}$$

We justify this approximation by the following observation. Consider the sub-problem consisting of just the  $w(\cdot, \cdot)$ ,  $w_{\text{ref}}(\cdot)$ ,  $w_{\text{cand}}(\cdot)$  variables and their associated constraints. This sub-problem can be seen as a maximum flow problem where all constants are integers, hence there exists an optimal solution where each of the  $w$  variables is assigned a value of either 0 or 1. For such a solution, the

$\max$  and the sum forms are equivalent, since the  $c_{\text{ref}}(\cdot)$  and  $c_{\text{cand}}(\cdot)$  variables are also constrained to the range  $[0, 1]$ .

The maximum flow equivalence breaks down when the  $c(\cdot)$  variables are introduced, so in the general case, replacing  $\max$  with sum is only an approximation.

Returning to our sample problem, the linear programming solver simply needs to assign:

$$\begin{aligned}
w(\text{买雨伞}, \text{买伞}) &= 1 \\
w_{\text{ref}}(\text{买雨伞}) &= 1 \\
w_{\text{cand}}(\text{买伞}) &= 1
\end{aligned}$$

Consequently, due to the maximum covering weights constraint, we can give the following value assignment, implying that all n-grams have been matched.

$$\begin{aligned}
c_{\text{ref}}(X) &= 1 && \forall X \\
c_{\text{cand}}(X) &= 1 && \forall X
\end{aligned}$$

### 3.4 The Objective Function

We now define our objective function in terms of the  $c(\cdot)$  variables. The recall is a function of  $\sum_X c_{\text{ref}}(X)$ , and the precision is a function of  $\sum_Y c_{\text{cand}}(Y)$ , where  $X$  is the set of all n-grams of the reference, and  $Y$  is the set of all n-grams of the candidate translation.

Many prior translation evaluation metrics such as MAXSIM (Chan and Ng, 2008) and TESLA (Liu et al., 2010; Dahlmeier et al., 2011) use the F-0.8 measure as the final score:

$$F_{0.8} = \frac{\text{Precision} \times \text{Recall}}{0.8 \times \text{Precision} + 0.2 \times \text{Recall}}$$

Under some simplifying assumptions — specifically, that precision = recall — basic calculus shows that  $F_{0.8}$  is four times as sensitive to recall than to precision. Following the same reasoning, we want to place more emphasis on recall than on precision. We are also constrained by the linear programming framework, hence we set the objective function as

$$\frac{1}{Z} \left( \sum_X c_{\text{ref}}(X) + f \sum_Y c_{\text{cand}}(Y) \right) \quad 0 < f < 1$$

We set  $f = 0.25$  so that our objective function is also four times as sensitive to recall than to precision.<sup>3</sup> The value of this objective function is our TESLA-CELAB score. Similar to the other TESLA metrics, when there are  $N$  multiple references, we match the candidate translation against each of them and use the average of the  $N$  objective function values as the segment level score. System level score is the average of all the segment level scores.

$Z$  is a normalizing constant to scale the metric to the range  $[0, 1]$ , chosen so that when all the  $c(\cdot)$  variables have the value of one, our metric score attains the value of one.

## 4 Experiments

In this section, we test the effectiveness of TESLA-CELAB on some real-world English-Chinese translation tasks.

### 4.1 IWSLT 2008 English-Chinese CT

The test set of the IWSLT 2008 (Paul, 2008) English-Chinese ASR challenge task (CT) consists of 300 sentences of spoken language text. The average English source sentence is 5.8 words long and the average Chinese reference translation is 9.2 characters long. The domain is travel expressions.

The test set was translated by seven MT systems, and each translation has been manually judged for adequacy and fluency. Adequacy measures whether the translation conveys the correct meaning, even if the translation is not fully fluent, whereas fluency measures whether a translation is fluent, regardless of whether the meaning is correct. Due to high evaluation costs, adequacy and fluency assessments were limited to the translation outputs of four systems. In addition, the translation outputs of the MT systems are also manually ranked according to their translation quality.

Inter-judge agreement is measured by the Kappa coefficient, defined as:

$$\text{Kappa} = \frac{P(A) - P(E)}{1 - P(E)}$$

where  $P(A)$  is the percentage of agreement, and  $P(E)$  is the percentage of agreement by pure

<sup>3</sup>Our empirical experiments suggest that the correlations do plateau near this value. For simplicity, we choose not to tune  $f$  on the training data.

Judgment Set	2	3
1	0.4406	0.4355
2	-	0.4134

Table 1: Inter-judge Kappa for the NIST 2008 English-Chinese task

chance. The inter-judge Kappa is 0.41 for fluency, 0.40 for adequacy, and 0.57 for ranking. Kappa values between 0.4 and 0.6 are considered *moderate*, and the numbers are in line with other comparable experiments.

### 4.2 NIST 2008 English-Chinese MT Task

The NIST 2008 English-Chinese MT task consists of 127 documents with 1,830 segments, each with four reference translations and eleven automatic MT system translations. The data is available as LDC2010T01 from the Linguistic Data Consortium (LDC). The domain is newswire texts. The average English source sentence is 21.5 words long and the average Chinese reference translation is 43.2 characters long.

Since no manual evaluation is given for the data set, we recruited twelve bilingual judges to evaluate the first thirty documents for adequacy and fluency (355 segments for a total of  $355 \times 11 = 3,905$  translated segments). The final score of a sentence is the average of its adequacy and fluency scores. Each judge works on one quarter of the sentences so that each translation is judged by three judges. The judgments are concatenated to form three full sets of judgments.

We ignore judgments where two sentences are equal in quality, so that there are only two possible outcomes (X is better than Y; or Y is better than X), and  $P(E) = 1/2$ . The Kappa values are shown in Table 1. The values indicate moderate agreement, and are in line with other comparable experiments.

### 4.3 Baseline Metrics

#### 4.3.1 BLEU

Although word-level BLEU has often been found inferior to the new-generation metrics when the target language is English or other European languages, prior research has shown that character-level BLEU is highly competitive when the target language is Chinese (Li et al., 2011). Therefore, we

Metric	Type	Segment consistency	Pearson correlation	Spearman rank correlation
BLEU	character-level	0.7004	0.9130	0.9643
TESLA-M	word-level	0.6771	0.9167	0.8929
TESLA-CELAB–	character-level	0.7018	0.9229	0.9643
TESLA-CELAB	hybrid	0.7281*	0.9490**	0.9643

Table 2: Correlation with human judgment on the IWSLT 2008 English-Chinese challenge task. \* denotes better than the BLEU baseline at 5% significance level. \*\* denotes better than the BLEU baseline at 1% significance level.

Metric	Type	Segment consistency	Pearson correlation	Spearman rank correlation
BLEU	character-level	0.7091	0.8429	0.7818
TESLA-M	word-level	0.6969	0.8301	0.8091
TESLA-CELAB–	character-level	0.7158	0.8514	0.8227
TESLA-CELAB	hybrid	0.7162	0.8923**	0.8909**

Table 3: Correlation with human judgment on the NIST 2008 English-Chinese MT task. \*\* denotes better than the BLEU baseline at 1% significance level.

use character-level BLEU as our main baseline.

The correlations of character-level BLEU and the average human judgments are shown in the first row of Tables 2 and 3 for the IWSLT and the NIST data set, respectively. Segment-level consistency is defined as the number of correctly predicted pairwise rankings divided by the total number of pairwise rankings. Ties are excluded from the calculation. We also report the Pearson correlation and the Spearman rank correlation of the system-level scores. Note that in the IWSLT data set, the Spearman rank correlation is highly unstable due to the small number of participating systems.

#### 4.3.2 TESLA-M

In addition to character-level BLEU, we also present the correlations for the word-level metric TESLA. Compared to BLEU, TESLA allows more sophisticated weighting of n-grams and measures of word similarity including synonym relations. It has been shown to give better correlations than BLEU for many European languages including English (Callison-Burch et al., 2011). However, its use of POS tags and synonym dictionaries prevents its use at the character-level. We use TESLA as a representative of a competitive word-level metric.

We use the Stanford Chinese word segmenter (Tseng et al., 2005) and POS tagger (Toutanova et al., 2003) for preprocessing and Cilin for synonym

definition during matching. TESLA has several variants, and the simplest and often the most robust, TESLA-M, is used in this work. The various correlations are reported in the second row of Tables 2 and 3.

The scores show that word-level TESLA-M has no clear advantage over character-level BLEU, despite its use of linguistic features. We consider this conclusion to be in line with that of Li et al. (2011).

#### 4.4 TESLA-CELAB

In all our experiments here we use TESLA-CELAB with n-grams for  $n$  up to four, since the vast majority of Chinese words, and therefore synonyms, are at most four characters long.

The correlations between the TESLA-CELAB scores and human judgments are shown in the last row of Tables 2 and 3. We conducted significance testing using the resampling method of (Koehn, 2004). Entries that outperform the BLEU baseline at 5% significance level are marked with ‘\*’, and those that outperform at the 1% significance level are marked with ‘\*\*’. The results indicate that TESLA-CELAB significantly outperforms BLEU.

For comparison, we also run TESLA-CELAB without the use of the Cilin dictionary, reported in the third row of Tables 2 and 3 and denoted as TESLA-CELAB–. This disables TESLA-

CELAB’s ability to detect word-level synonyms and turns TESLA-CELAB into a linear programming based character-level metric. The performance of TESLA-CELAB– is comparable to the character-level BLEU baseline.

Note that

- TESLA-M can process word-level synonyms, but does not award character-level matches.
- TESLA-CELAB– and character-level BLEU award character-level matches, but do not consider word-level synonyms.
- TESLA-CELAB can process word-level synonyms and can award character-level matches.

Therefore, the difference between TESLA-M and TESLA-CELAB highlights the contribution of character-level matching, and the difference between TESLA-CELAB– and TESLA-CELAB highlights the contribution of word-level synonyms.

#### 4.5 Sample Sentences

Some sample sentences taken from the IWSLT test set are shown in Table 4 (some are simplified from the original). The Cilin dictionary correctly identified the following as synonyms:

周	=	星期	<i>week</i>
女儿	=	闺女	<i>daughter</i>
你	=	您	<i>you</i>
工作	=	上班	<i>work</i>

The dictionary fails to recognize the following synonyms:

一个	=	个	<i>a</i>
这儿	=	这里	<i>here</i>

However, partial awards are still given for the matching characters 这 and 个.

Based on these synonyms, TESLA-CELAB is able to award less trivial n-gram matches, such as 下周=下星期, 个女儿=个闺女, and 工作吗=上班吗, as these pairs can all be segmented into aligned synonyms. The covered n-gram matching rule is then able to award tricky n-grams such as 下星, 个女, 个闺, 作吗 and 班吗, which are covered by 下星期, 个女儿, 个闺女, 工作吗 and 上班吗 respectively.

Note also that the word segmentations shown in these examples are for clarity only. The TESLA-CELAB algorithm does not need pre-segmented

sentences, and essentially finds multi-character synonyms opportunistically.

## 5 Discussion and Future Work

### 5.1 Other Languages with Ambiguous Word Boundaries

Although our experiments here are limited to Chinese, many other languages have similarly ambiguous word boundaries. For example, in German, the exact counterpart to our example exists, as depicted in Figure 5.

Regenschirm, literally *rain-umbrella*, is a synonym of Schirm. The first two forms in Figure 5 appear in natural text, and in standard BLEU, they would be penalized for the non-matching words *Schirm* and *Regenschirm*. Since compound nouns such as *Regenschirm* are very common in German and generate many out-of-vocabulary words, a common preprocessing step in German translation (and translation evaluation to a lesser extent) is to split compound words, and we end up with the last form *Regen schirm kaufen*. This process is analogous to

Chinese word segmentation.

We plan to conduct experiments on German and other Asian languages with the same linguistic phenomenon in future work.

## 5.2 Fractional Similarity Measures

In the current formulation of TESLA-CELAB, two n-grams  $X$  and  $Y$  are either synonyms which completely match each other, or are completely unrelated. In contrast, the linear-programming based TESLA metric allows fractional similarity measures between 0 (completely unrelated) and 1 (exact synonyms). We can then award partial scores for related words, such as those identified as such by WordNet or those with the same POS tags.

Supporting fractional similarity measures is non-trivial in the TESLA-CELAB framework. We plan to address this in future work.

## 5.3 Fractional Weights for N-grams

The TESLA-M metric allows each n-gram to have a weight, which is primarily used to discount function words. TESLA-CELAB can support fractional weights for n-grams as well by the following extension. We introduce a function  $m(X)$  that assigns a weight in  $[0, 1]$  for each n-gram  $X$ . Accordingly, our objective function is replaced by:

$$\frac{1}{Z} \left( \sum_X m(X)c_{\text{ref}}(X) + f \sum_Y m(Y)c_{\text{cand}}(Y) \right)$$

where  $Z$  is a normalizing constant so that the metric has a range of  $[0, 1]$ .

$$Z = \sum_X m(X) + f \sum_Y m(Y)$$

However, experiments with different weight functions  $m(\cdot)$  on the test data set failed to find a better weight function than the currently implied  $m(\cdot) = 1$ . This is probably due to the linguistic characteristics of Chinese, where human judges apparently give equal importance to function words and content words. In contrast, TESLA-M found discounting function words very effective for English and other European languages such as German. We plan to investigate this in the context of non-Chinese languages.

## 6 Conclusion

In this work, we devise a new MT evaluation metric in the family of TESLA (Translation Evaluation of Sentences with Linear-programming-based Analysis), called TESLA-CELAB (Character-level Evaluation for Languages with Ambiguous word Boundaries), to address the problem of fuzzy word boundaries in the Chinese language, although neither the phenomenon nor the method is unique to Chinese. Our metric combines the advantages of character-level and word-level metrics:

1. TESLA-CELAB is able to award scores for partial word-level matches.
2. TESLA-CELAB does not have a segmentation step, hence it will not introduce word segmentation errors.
3. TESLA-CELAB is able to take full advantage of the synonym dictionary, even when the synonyms differ in the number of characters.

We show empirically that TESLA-CELAB significantly outperforms the strong baseline of character-level BLEU in two well known English-Chinese MT evaluation data sets. The source code of TESLA-CELAB is available from <http://nlp.comp.nus.edu.sg/software/>.

## Abstract

Many machine translation (MT) evaluation metrics have been shown to correlate better with human judgment than BLEU. In principle, tuning on these metrics should yield better systems than tuning on BLEU. However, due to issues such as speed, requirements for linguistic resources, and optimization difficulty, they have not been widely adopted for tuning. This paper presents PORT<sup>1</sup>, a new MT evaluation metric which combines precision, recall and an ordering metric and which is primarily designed for tuning MT systems. PORT does not require external resources and is quick to compute. It has a better correlation with human judgment than BLEU. We compare PORT-tuned MT systems to BLEU-tuned baselines in five experimental conditions involving four language pairs. PORT tuning achieves consistently better performance than BLEU tuning, according to four automated metrics (including BLEU) and to human evaluation: in comparisons of outputs from 300 source sentences, human judges preferred the PORT-tuned output 45.3% of the time (*vs.* 32.7% BLEU tuning preferences and 22.0% ties).

## 1 Introduction

Automatic evaluation metrics for machine translation (MT) quality are a key part of building statistical MT (SMT) systems. They play two

roles: to allow rapid (though sometimes inaccurate) comparisons between different systems or between different versions of the same system, and to perform tuning of parameter values during system training. The latter has become important since the invention of minimum error rate training (MERT) (Och, 2003) and related tuning methods. These methods perform repeated decoding runs with different system parameter values, which are tuned to optimize the value of the evaluation metric over a development set with reference translations.

MT evaluation metrics fall into three groups:

- BLEU (Papineni *et al.*, 2002), NIST (Doddington, 2002), WER, PER, TER (Snover *et al.*, 2006), and LRscore (Birch and Osborne, 2011) do not use external linguistic information; they are fast to compute (except TER).
- METEOR (Banerjee and Lavie, 2005), METEOR-NEXT (Denkowski and Lavie 2010), TER-Plus (Snover *et al.*, 2009), MaxSim (Chan and Ng, 2008), TESLA (Liu *et al.*, 2010), AMBER (Chen and Kuhn, 2011) and MTeRater (Parton *et al.*, 2011) exploit some limited linguistic resources, such as synonym dictionaries, part-of-speech tagging, paraphrasing tables or word root lists.
- More sophisticated metrics such as RTE (Pado *et al.*, 2009), DCU-LFG (He *et al.*, 2010) and MEANT (Lo and Wu, 2011) use higher level syntactic or semantic analysis to score translations.

Among these metrics, BLEU is the most widely used for both evaluation and tuning. Many of the metrics correlate better with human judgments of translation quality than BLEU, as shown in recent WMT *Evaluation Task* reports (Callison-Burch *et*

---

<sup>1</sup> PORT: Precision-Order-Recall Tunable metric.

al., 2010; Callison-Burch *et al.*, 2011). However, BLEU remains the *de facto* standard tuning metric, for two reasons. First, there is no evidence that any other tuning metric yields better MT systems. Cer *et al.* (2010) showed that BLEU tuning is more robust than tuning with other metrics (METEOR, TER, *etc.*), as gauged by both automatic and human evaluation. Second, though a tuning metric should correlate strongly with human judgment, MERT (and similar algorithms) invoke the chosen metric so often that it must be computed quickly.

Liu *et al.* (2011) claimed that TESLA tuning performed better than BLEU tuning according to human judgment. However, in the WMT 2011 “tunable metrics” shared pilot task, this did not hold (Callison-Burch *et al.*, 2011). In (Birch and Osborne, 2011), humans preferred the output from LRscore-tuned systems 52.5% of the time, versus BLEU-tuned system outputs 43.9% of the time.

In this work, our goal is to devise a metric that, like BLEU, is computationally cheap and language-independent, but that yields better MT systems than BLEU when used for tuning. We tried out different combinations of statistics before settling on the final definition of our metric. The final version, PORT, combines precision, recall, strict brevity penalty (Chiang *et al.*, 2008) and strict redundancy penalty (Chen and Kuhn, 2011) in a quadratic mean expression. This expression is then further combined with a new measure of word ordering,  $v$ , designed to reflect long-distance as well as short-distance word reordering (BLEU only reflects short-distance reordering). In a later section, 3.3, we describe experiments that vary parts of the definition of PORT.

Results given below show that PORT correlates better with human judgments of translation quality than BLEU does, and sometimes outperforms METEOR in this respect, based on data from WMT (2008-2010). However, since PORT is designed for tuning, the most important results are those showing that PORT tuning yields systems with better translations than those produced by BLEU tuning – both as determined by automatic metrics (including BLEU), and according to human judgment, as applied to five data conditions involving four language pairs.

## 2 BLEU and PORT

First, define n-gram precision  $p(n)$  and recall  $r(n)$ :

$$p(n) = \frac{\# \text{n - grams}(T \cap R)}{\# \text{n - grams}(T)} \quad (1)$$

$$r(n) = \frac{\# \text{n - grams}(T \cap R)}{\# \text{n - grams}(R)} \quad (2)$$

where  $T$  = translation,  $R$  = reference. Both BLEU and PORT are defined on the document-level, *i.e.*  $T$  and  $R$  are whole texts. If there are multiple references, we use closest reference length for each translation hypothesis to compute the numbers of the reference n-grams.

### 2.1 BLEU

BLEU is composed of precision  $P_g(N)$  and brevity penalty  $BP$ :

$$BLEU = P_g(N) \times BP \quad (3)$$

where  $P_g(N)$  is the geometric average of n-gram precisions

$$P_g(N) = \left( \prod_{n=1}^N p(n) \right)^{\frac{1}{N}} \quad (4)$$

The BLEU brevity penalty punishes the score if the translation length  $len(T)$  is shorter than the reference length  $len(R)$ ; it is:

$$BP = \min(1.0, e^{1-len(R)/len(T)}) \quad (5)$$

### 2.2 PORT

PORT has five components: precision, recall, strict brevity penalty (Chiang *et al.*, 2008), strict redundancy penalty (Chen and Kuhn, 2011) and an ordering measure  $v$ . The design of PORT is based on exhaustive experiments on a development data set. We do not have room here to give a rationale for all the choices we made when we designed PORT. However, a later section (3.3) reconsiders some of these design decisions.

#### 2.2.1 Precision and Recall

The average precision and average recall used in PORT (unlike those used in BLEU) are the arithmetic average of n-gram precisions  $P_a(N)$  and recalls  $R_a(N)$ :

$$P_a(N) = \frac{1}{N} \sum_{n=1}^N p(n) \quad (6)$$

$$R_a(N) = \frac{1}{N} \sum_{n=1}^N r(n) \quad (7)$$

We use two penalties to avoid too long or too short MT outputs. The first, the strict brevity penalty (SBP), is proposed in (Chiang *et al.*, 2008). Let  $t_i$  be the translation of input sentence  $i$ , and let  $r_i$  be its reference. Set

$$SBP = \exp\left(1 - \frac{\sum_i |r_i|}{\sum_i \min\{|t_i|, |r_i|\}}\right) \quad (8)$$

The second is the strict redundancy penalty (SRP), proposed in (Chen and Kuhn, 2011):

$$SRP = \exp\left(1 - \frac{\sum_i \max\{|t_i|, |r_i|\}}{\sum_i |r_i|}\right) \quad (9)$$

To combine precision and recall, we tried four averaging methods: arithmetic (A), geometric (G), harmonic (H), and quadratic (Q) mean. If all of the values to be averaged are positive, the order is  $min \leq H \leq G \leq A \leq Q \leq max$ , with equality holding if and only if all the values being averaged are equal. We chose the quadratic mean to combine precision and recall, as follows:

$$Qmean(N) = \sqrt{\frac{(P_a(N) \times SBP)^2 + (R_a(N) \times SRP)^2}{2}} \quad (10)$$

### 2.2.2 Ordering Measure

Word ordering measures for MT compare two permutations of the original source-language word sequence: the permutation represented by the sequence of corresponding words in the MT output, and the permutation in the reference. Several ordering measures have been integrated into MT evaluation metrics recently. Birch and Osborne (2011) use either Hamming Distance or Kendall’s  $\tau$  Distance (Kendall, 1938) in their metric LRscore, thus obtaining two versions of LRscore. Similarly, Isozaki *et al.* (2011) adopt either Kendall’s  $\tau$  Distance or Spearman’s  $\rho$  (Spearman, 1904) distance in their metrics.

Our measure,  $v$ , is different from all of these. We use word alignment to compute the two permutations (LRscore also uses word alignment). The word alignment between the source input and reference is computed using GIZA++ (Och and Ney, 2003) beforehand with the default settings, then is refined with the heuristic *grow-diag-final-and*; the word alignment between the source input and the translation is generated by the decoder with the help of word alignment inside each phrase pair.

PORT uses permutations. These encode one-to-one relations but not one-to-many, many-to-one, many-to-many or null relations, all of which can occur in word alignments. We constrain the forbidden types of relation to become one-to-one, as in (Birch and Osborne, 2011). Thus, in a one-to-many alignment, the single source word is forced to align with the first target word; in a many-to-one alignment, monotone order is assumed for the target words; and source words originally aligned to null are aligned to the target word position just after the previous source word’s target position.

After the normalization above, suppose we have two permutations for the same source  $n$ -word input. *E.g.*, let  $P_1$  = reference,  $P_2$  = hypothesis:

$$P_1: p_1^1 \ p_1^2 \ p_1^3 \ p_1^4 \ \dots \ p_1^i \ \dots \ p_1^n$$

$$P_2: p_2^1 \ p_2^2 \ p_2^3 \ p_2^4 \ \dots \ p_2^i \ \dots \ p_2^n$$

Here, each  $p_i^j$  is an integer denoting position in the original source (*e.g.*,  $p_1^1 = 7$  means that the first word in  $P_1$  is the 7<sup>th</sup> source word).

The ordering metric  $v$  is computed from two distance measures. The first is absolute permutation distance:

$$DIST_1(P_1, P_2) = \sum_{i=1}^n |p_1^i - p_2^i| \quad (11)$$

$$\text{Let } v_1 = 1 - \frac{DIST_1(P_1, P_2)}{n(n+1)/2} \quad (12)$$

$v_1$  ranges from 0 to 1; a larger value means more similarity between the two permutations. This metric is similar to Spearman’s  $\rho$  (Spearman, 1904). However, we have found that  $\rho$  punishes long-distance reorderings too heavily. For instance,  $v_1$  is more tolerant than  $\rho$  of the movement of “recently” in this example:

Ref: *Recently, I visited Paris*

Hyp: *I visited Paris recently*

Inspired by HMM word alignment (Vogel *et al.*, 1996), our second distance measure is based on jump width. This punishes a sequence of words that moves a long distance with its internal order conserved, only once rather than on every word. In the following, only two groups of words have moved, so the jump width punishment is light:

Ref: *In the winter of 2010, I visited Paris*

Hyp: *I visited Paris in the winter of 2010*

So the second distance measure is

$$DIST_2(P_1, P_2) = \sum_{i=1}^n |(p_1^i - p_1^{i-1}) - (p_2^i - p_2^{i-1})| \quad (13)$$

where we set  $p_1^0 = 0$  and  $p_2^0 = 0$ . Let

$$v_2 = 1 - \frac{DIST_2(P_1, P_2)}{n^2 - 1} \quad (14)$$

As with  $v_1$ ,  $v_2$  is also from 0 to 1, and larger values indicate more similar permutations. The ordering measure  $v_s$  is the harmonic mean of  $v_1$  and  $v_2$ :

$$v_s = 2 / (1/v_1 + 1/v_2) \quad (15)$$

$v_s$  in (15) is computed at segment level. For multiple references, we compute  $v_s$  for each, and then choose the biggest one as the segment level ordering similarity. We compute document level ordering with a weighted arithmetic mean:

$$v = \frac{\sum_{s=1}^l v_s \times len_s(R)}{\sum_{s=1}^l len_s(R)} \quad (16)$$

where  $l$  is the number of segments of the document, and  $len(R)$  is the length of the reference.

### 2.2.3 Combined Metric

Finally,  $Qmean(N)$  (Eq. (10) and the word ordering measure  $v$  are combined in a harmonic mean:

$$PORT = \frac{2}{1/Qmean(N) + 1/v^\alpha} \quad (17)$$

Here  $\alpha$  is a free parameter that is tuned on held-out data. As it increases, the importance of the ordering measure  $v$  goes up. For our experiments, we tuned  $\alpha$  on Chinese-English data, setting it to 0.25 and keeping this value for the other language pairs. The use of  $v$  means that unlike BLEU, PORT requires word alignment information.

## 3 Experiments

### 3.1 PORT as an Evaluation Metric

We studied PORT as an evaluation metric on WMT data; test sets include WMT 2008, WMT 2009, and WMT 2010 all-to-English, plus 2009, 2010 English-to-all submissions. The languages “all” (“xx” in Table 1) include French, Spanish, German and Czech. Table 1 summarizes the test set statistics. In order to compute the  $v$  part of PORT, we require source-target word alignments for the references and MT outputs. These aren’t included in WMT data, so we compute them with GIZA++.

We used Spearman’s rank correlation coefficient  $\rho$  to measure correlation of the metric with system-level human judgments of translation. The human judgment score is based on the “Rank” only, *i.e.*, how often the translations of the system were rated as better than those from other systems (Callison-Burch *et al.*, 2008). Thus, BLEU, METEOR, and PORT were evaluated on how well their rankings correlated with the human ones. For the segment level, we follow (Callison-Burch *et al.*, 2010) in using Kendall’s rank correlation coefficient  $\tau$ .

As shown in Table 2, we compared PORT with smoothed BLEU (*mteval-v13a*), and METEOR v1.0. Both BLEU and PORT perform matching of  $n$ -grams up to  $n = 4$ .

Set	Year	Lang.	#system	#sent-pair
Test1	2008	xx-en	43	7,804
Test2	2009	xx-en	45	15,087
Test3	2009	en-xx	40	14,563
Test4	2010	xx-en	53	15,964
Test5	2010	en-xx	32	18,508

Table 1: Statistics of the WMT dev and test sets.

Metric	Into-En		Out-of-En	
	sys.	seg.	sys.	seg.
BLEU	0.792	0.215	0.777	0.240
METEOR	<b>0.834</b>	0.231	<b>0.835</b>	0.225
<b>PORT</b>	0.801	<b>0.236</b>	0.804	<b>0.242</b>

Table 2: Correlations with human judgment on WMT

PORT achieved the best segment level correlation with human judgment on both the “into English” and “out of English” tasks. At the system level, PORT is better than BLEU, but not as good as METEOR. This is because we designed PORT to carry out tuning; we did not optimize its performance as an evaluation metric, but rather, to optimize system tuning performance. There are some other possible reasons why PORT did not outperform METEOR v1.0 at system level. Most WMT submissions involve language pairs with similar word order, so the ordering factor  $v$  in PORT won’t play a big role. Also,  $v$  depends on source-target word alignments for reference and test sets. These alignments were performed by GIZA++ models trained on the test data only.

## 3.2 PORT as a Metric for Tuning

### 3.2.1 Experimental details

The first set of experiments to study PORT as a tuning metric involved Chinese-to-English (zh-en); there were two data conditions. The first is the *small data* condition where *FBIS*<sup>2</sup> is used to train the translation and reordering models. It contains 10.5M target word tokens. We trained two language models (LMs), which were combined loglinearly. The first is a 4-gram LM which is estimated on the target side of the texts used in the *large data* condition (below). The second is a 5-gram LM estimated on English *Gigaword*.

The *large data* condition uses training data from NIST<sup>3</sup> 2009 (Chinese-English track). All allowed bilingual corpora except *UN*, *Hong Kong Laws* and *Hong Kong Hansard* were used to train the translation model and reordering models. There are about 62.6M target word tokens. The same two LMs are used for *large data* as for *small data*, and the same development (“dev”) and test sets are also used. The dev set comprised mainly data from the NIST 2005 test set, and also some balanced-genre web-text from NIST. Evaluation was performed on NIST 2006 and 2008. Four references were provided for all dev and test sets.

The third data condition is a French-to-English (fr-en). The parallel training data is from Canadian Hansard data, containing 59.3M word tokens. We used two LMs in loglinear combination: a 4-gram LM trained on the target side of the parallel training data, and the English *Gigaword* 5-gram LM. The dev set has 1992 sentences; the two test sets have 2140 and 2164 sentences respectively. There is one reference for all dev and test sets.

The fourth and fifth conditions involve German-English Europarl data. This parallel corpus contains 48.5M German tokens and 50.8M English tokens. We translate both German-to-English (de-en) and English-to-German (en-de). The two conditions both use an LM trained on the target side of the parallel training data, and de-en also uses the English *Gigaword* 5-gram LM. News test 2008 set is used as dev set; News test 2009, 2010, 2011 are used as test sets. One reference is provided for all dev and test sets.

All experiments were carried out with  $\alpha$  in Eq. (17) set to 0.25, and involved only lowercase European-language text. They were performed with MOSES (Koehn *et al.*, 2007), whose decoder includes lexicalized reordering, translation models, language models, and word and phrase penalties. Tuning was done with n-best MERT, which is available in MOSES. In all tuning experiments, both BLEU and PORT performed lower case matching of  $n$ -grams up to  $n = 4$ . We also conducted experiments with tuning on a version of BLEU that incorporates SBP (Chiang *et al.*, 2008) as a baseline. The results of original IBM BLEU and BLEU with SBP were tied; to save space, we only report results for original IBM BLEU here.

### 3.2.2 Comparisons with automatic metrics

First, let us see if BLEU-tuning and PORT-tuning yield systems with different translations for the same input. The first row of Table 3 shows the percentage of identical sentence outputs for the two tuning types on test data. The second row shows the similarity of the two outputs at word-level (as measured by 1-TER): *e.g.*, for the two zh-en tasks, the two tuning types give systems whose outputs are about 25-30% different at the word level. By contrast, only about 10% of output words for fr-en differ for BLEU vs. PORT tuning.

	zh-en <i>small</i>	zh-en <i>large</i>	fr-en Hans	de-en WMT	en-de WMT
Same sent.	17.7%	13.5%	56.6%	23.7%	26.1%
1-TER	74.2	70.9	91.6	87.1	86.6

Table 3: Similarity of BLEU-tuned and PORT-tuned system outputs on test data.

Task	Tune	Evaluation metrics (%)			
		BLEU	MTR	1-TER	PORT
zh-en <i>small</i>	BLEU	26.8	55.2	38.0	49.7
	PORT	<b>27.2*</b>	<b>55.7</b>	38.0	<b>50.0</b>
zh-en <i>large</i>	BLEU	29.9	58.4	41.2	53.0
	PORT	<b>30.3*</b>	<b>59.0</b>	<b>42.0</b>	<b>53.2</b>
fr-en Hans	BLEU	38.8	<b>69.8</b>	54.2	57.1
	PORT	38.8	69.6	<b>54.6</b>	57.1

en-de WMT	BLEU	13.6	43.3	30.1	31.7
	PORT	13.6	43.3	<b>30.7</b>	31.7

Table 4: Automatic evaluation scores on test data. \* indicates the results are significantly better than the baseline ( $p < 0.05$ ).

<sup>2</sup> LDC2003E14

<sup>3</sup> <http://www.nist.gov/speech/tests/mt>

Table 4 shows translation quality for BLEU- and PORT-tuned systems, as assessed by automatic metrics. We employed BLEU4, METEOR (v1.0), TER (v0.7.25), and the new metric PORT. In the table, TER scores are presented as 1-TER to ensure that for all metrics, higher scores mean higher quality. All scores are averages over the relevant test sets. There are twenty comparisons in the table. Among these, there is one case (French-English assessed with METEOR) where BLEU outperforms PORT, there are seven ties, and there are twelve cases where PORT is better. Table 3 shows that fr-en outputs are very similar for both tuning types, so the fr-en results are perhaps less informative than the others. Overall, PORT tuning has a striking advantage over BLEU tuning.

Both (Liu *et al.*, 2011) and (Cer *et al.*, 2011) showed that with MERT, if you want the best possible score for a system’s translations according to metric M, then you should tune with M. This doesn’t appear to be true when PORT and BLEU tuning are compared in Table 4. For the two Chinese-to-English tasks in the table, PORT tuning yields a better BLEU score than BLEU tuning, with significance at  $p < 0.05$ . We are currently investigating why PORT tuning gives higher BLEU scores than BLEU tuning for Chinese-English and German-English. In internal tests we have found no systematic difference in dev-set BLEUs, so we speculate that PORT’s emphasis on reordering yields models that generalize better for these two language pairs.

### 3.2.3 Human Evaluation

We conducted a human evaluation on outputs from BLEU- and PORT-tuned systems. The examples are randomly picked from all “to-English” conditions shown in Tables 3 & 4 (*i.e.*, all conditions except English-to-German).

We performed pairwise comparison of the translations produced by the system types as in (Callison-Burch *et al.*, 2010; Callison-Burch *et al.*, 2011). First, we eliminated examples where the reference had fewer than 10 words or more than 50 words, or where outputs of the BLEU-tuned and PORT-tuned systems were identical. The evaluators (colleagues not involved with this paper) objected to comparing two bad translations, so we then selected for human evaluation only translations that had high sentence-level (1-TER) scores. To be fair to both metrics, for each

condition, we took the union of examples whose BLEU-tuned output was in the top  $n\%$  of BLEU outputs and those whose PORT-tuned output was in the top  $n\%$  of PORT outputs (based on (1-TER)). The value of  $n$  varied by condition: we chose the top 20% of zh-en *small*, top 20% of en-de, top 50% of fr-en and top 40% of zh-en *large*. We then randomly picked 450 of these examples to form the manual evaluation set. This set was split into 15 subsets, each containing 30 sentences. The first subset was used as a common set; each of the other 14 subsets was put in a separate file, to which the common set is added. Each of the 14 evaluators received one of these files, containing 60 examples (30 unique examples and 30 examples shared with the other evaluators). Within each example, BLEU-tuned and PORT-tuned outputs were presented in random order.

After receiving the 14 annotated files, we computed Fleiss’s Kappa (Fleiss, 1971) on the common set to measure inter-annotator agreement,  $\kappa_{all}$ . Then, we excluded annotators one at a time to compute  $\kappa^i$  (Kappa score without  $i$ -th annotator, *i.e.*, from the other 13). Finally, we filtered out the files from the 4 annotators whose answers were most different from everybody else’s: *i.e.*, annotators with the biggest  $\kappa_{all} - \kappa^i$  values.

This left 10 files from 10 evaluators. We threw away the common set in each file, leaving 300 pairwise comparisons. Table 5 shows that the evaluators preferred the output from the PORT-tuned system 136 times, the output from the BLEU-tuned one 98 times, and had no preference the other 66 times. This indicates that there is a human preference for outputs from the PORT-tuned system over those from the BLEU-tuned system at the  $p < 0.01$  significance level (in cases where people prefer one of them).

PORT tuning seems to have a bigger advantage over BLEU tuning when the translation task is hard. Of the Table 5 language pairs, the one where PORT tuning helps most has the lowest BLEU in Table 4 (German-English); the one where it helps least in Table 5 has the highest BLEU in Table 4 (French-English). (Table 5 does not prove BLEU is superior to PORT for French-English tuning: statistically, the difference between 14 and 17 here is a tie). Maybe by picking examples for each condition that were the easiest for the system to translate (to make human evaluation easier), we

mildly biased the results in Table 5 against PORT tuning. Another possible factor is reordering. PORT differs from BLEU partly in modeling long-distance reordering more accurately; English and French have similar word order, but the other two language pairs don't. The results in section 3.3 (below) for Qmean, a version of PORT without word ordering factor  $\nu$ , suggest  $\nu$  may be defined suboptimally for French-English.

	PORT win	BLEU win	equal	total
zh-en	<b>19</b>	18	12	49
<i>small</i>	<b>38.8%</b>	36.7%	24.5%	
zh-en	<b>69</b>	46	36	151
<i>large</i>	<b>45.7%</b>	30.5%	23.8%

Hans	32.6%	<b>39.5%</b>	27.9%	
de-en	<b>34</b>	17	6	57
WMT	<b>59.7%</b>	29.8%	10.5%	
All	<b>136</b>	98	66	300
	<b>45.3%</b>	32.7%	22.0%	

Table 5: Human preference for outputs from PORT-tuned vs. BLEU-tuned system.

### 3.2.4 Computation time

A good tuning metric should run very fast; this is one of the advantages of BLEU. Table 6 shows the time required to score the 100-best hypotheses for the dev set for each data condition during MERT for BLEU and PORT in similar implementations. The average time of each iteration, including model loading, decoding, scoring and running MERT<sup>4</sup>, is in brackets. PORT takes roughly 1.5 – 2.5 as long to compute as BLEU, which is reasonable for a tuning metric.

	zh-en	zh-en	fr-en	de-en	en-de
	<i>small</i>	<i>large</i>	Hans	WMT	WMT
BLEU	3 (13)	3 (17)	2 (19)	2 (20)	2 (11)
PORT	5 (21)	5 (24)	4 (28)	5 (28)	4 (15)

Table 6: Time to score 100-best hypotheses (average time per iteration) in minutes.

### 3.2.5 Robustness to word alignment errors

PORT, unlike BLEU, depends on word alignments. How does quality of word alignment between source and reference affect PORT tuning? We created a dev set from Chinese Tree Bank

<sup>4</sup> Our experiments are run on a cluster. The average time for an iteration includes queuing, and the speed of each node is slightly different, so bracketed times are only for reference.

(CTB) hand-aligned data. It contains 588 sentences (13K target words), with one reference. We also ran GIZA++ to obtain its automatic word alignment, computed on CTB and FBIS. The AER of the GIZA++ word alignment on CTB is 0.32.

In Table 7, CTB is the dev set. The table shows tuning with BLEU, PORT with human word alignment (PORT + HWA), and PORT with GIZA++ word alignment (PORT + GWA); the condition is zh-en *small*. Despite the AER of 0.32 for automatic word alignment, PORT tuning works about as well with this alignment as for the gold standard CTB one. (The BLEU baseline in Table 7 differs from the Table 4 BLEU baseline because the dev sets differ).

Tune	BLEU	MTR	1-TER	PORT
BLEU	25.1	53.7	36.4	47.8
PORT + HWA	<b>25.3</b>	54.4	<b>37.0</b>	<b>48.2</b>
PORT + GWA	<b>25.3</b>	<b>54.6</b>	36.4	48.1

Table 7: PORT tuning - human & GIZA++ alignment

	Qmean	13.6	<b>43.4</b>	30.3	31.7

Table 8: Impact of ordering measure  $\nu$  on PORT

## 3.3 Analysis

Now, we look at the details of PORT to see which of them are the most important. We do not have space here to describe all the details we studied, but we can describe some of them. *E.g.*, does the ordering measure  $\nu$  help tuning performance? To answer this, we introduce an intermediate metric. This is Qmean as in Eq. (10): PORT without the ordering measure. Table 8 compares tuning with BLEU, PORT, and Qmean. PORT outperforms Qmean on seven of the eight automatic scores shown for *small* and *large* Chinese-English.

However, for the European language pairs, PORT and Qmean seem to be tied. This may be because we optimized  $\alpha$  in Eq. (18) for Chinese-English, making the influence of word ordering measure  $v$  in PORT too strong for the European pairs, which have similar word order.

Measure  $v$  seems to help Chinese-English tuning. What would results be on that language pair if we were to replace  $v$  in PORT with another ordering measure? Table 9 gives a partial answer, with Spearman’s  $\rho$  and Kendall’s  $\tau$  replacing  $v$  with  $\rho$  or  $\tau$  in PORT for the zh-en *small* condition (CTB with human word alignment is the dev set). The original definition of PORT seems preferable.

Tune	BLEU	METEOR	1-TER
BLEU	25.1	53.7	36.4
PORT( $v$ )	<b>25.3</b>	<b>54.4</b>	<b>37.0</b>
PORT( $\rho$ )	25.1	54.2	36.3
PORT( $\tau$ )	25.1	54.0	36.0

Table 9: Comparison of the ordering measure: replacing  $v$  with  $\rho$  or  $\tau$  in PORT.

Task	Tune	ordering measures		
		$\rho$	$\tau$	$v$
NIST06	BLEU	0.979	0.926	0.915
	PORT	0.979	<b>0.928</b>	<b>0.917</b>
NIST08	BLEU	0.980	0.926	0.916
	PORT	<b>0.981</b>	<b>0.929</b>	<b>0.918</b>
CTB	BLEU	0.973	0.860	0.847
	PORT	<b>0.975</b>	<b>0.866</b>	<b>0.853</b>

Table 10: Ordering scores ( $\rho$ ,  $\tau$  and  $v$ ) for test sets NIST 2006, 2008 and CTB.

A related question is how much word ordering improvement we obtained from tuning with PORT. We evaluate Chinese-English word ordering with three measures: Spearman’s  $\rho$ , Kendall’s  $\tau$  distance as applied to two permutations (see section 2.2.2) and our own measure  $v$ . Table 10 shows the effects of BLEU and PORT tuning on these three measures, for three test sets in the zh-en *large* condition. Reference alignments for CTB were created by humans, while the NIST06 and NIST08 reference alignments were produced with GIZA++. A large value of  $\rho$ ,  $\tau$ , or  $v$  implies outputs have ordering similar to that in the reference. From the table, we see that the PORT-tuned system yielded better word order than the BLEU-tuned system in all nine combinations of test sets and ordering measures. The advantage of PORT tuning is

particularly noticeable on the most reliable test set: the hand-aligned CTB data.

What is the impact of the strict redundancy penalty on PORT? Note that in Table 8, even though Qmean has no ordering measure, it outperforms BLEU. Table 11 shows the BLEU brevity penalty (BP) and (number of matching 1- & 4- grams)/(number of total 1- & 4- grams) for the translations. The BLEU-tuned and Qmean-tuned systems generate similar numbers of matching n-grams, but Qmean-tuned systems produce fewer n-grams (thus, shorter translations). *E.g.*, for zh-en *small*, the BLEU-tuned system produced 44,677 1-grams (words), while the Qmean-trained system one produced 43,555 1-grams; both have about 32,000 1-grams matching the references. Thus, the Qmean translations have higher precision. We believe this is because of the strict redundancy penalty in Qmean. As usual, French-English is the outlier: the two outputs here are typically so similar that BLEU and Qmean tuning yield very similar n-gram statistics.

Task	Tune	1-gram	4-gram	BP
zh-en <i>small</i>	BLEU	32055/44677	4603/39716	0.967
	Qmean	31996/43555	4617/38595	0.962
zh-en <i>large</i>	BLEU	34583/45370	5954/40410	0.972
	Qmean	34369/44229	5987/39271	0.959
fr-en Hans	BLEU	28141/40525	8654/34224	0.983
	Qmean	28167/40798	8695/34495	0.990

	Qmean	42173/72403	5203/63401	0.968
en-de WMT	BLEU	30326/62367	2261/54812	1.000
	Qmean	30343/62092	2298/54537	0.997

Table 11: #matching-ngram/#total-ngram and BP score

## 4 Conclusions

In this paper, we have proposed a new tuning metric for SMT systems. PORT incorporates precision, recall, strict brevity penalty and strict redundancy penalty, plus a new word ordering measure  $v$ . As an evaluation metric, PORT performed better than BLEU at the system level and the segment level, and it was competitive with or slightly superior to METEOR at the segment level. Most important, our results show that PORT-tuned MT systems yield better translations than BLEU-tuned systems on several language pairs, according both to automatic metrics and human evaluations. In future work, we plan to tune the free parameter  $\alpha$  for each language pair.

## Abstract

Statistical machine translation is often faced with the problem of combining training data from many diverse sources into a single translation model which then has to translate sentences in a new domain. We propose a novel approach, ensemble decoding, which combines a number of translation systems dynamically at the decoding step. In this paper, we evaluate performance on a domain adaptation setting where we translate sentences from the medical domain. Our experimental results show that ensemble decoding outperforms various strong baselines including mixture models, the current state-of-the-art for domain adaptation in machine translation.

## 1 Introduction

Statistical machine translation (SMT) systems require large parallel corpora in order to be able to obtain a reasonable translation quality. In statistical learning theory, it is assumed that the training and test datasets are drawn from the same distribution, or in other words, they are from the same domain. However, bilingual corpora are only available in very limited domains and building bilingual resources in a new domain is usually very expensive. It is an interesting question whether a model that is trained on an existing large bilingual corpus in a specific domain can be adapted to another domain for which little parallel data is present. Domain adaptation techniques aim at finding ways to adjust an *out-of-domain* (OUT) model to represent a target domain (*in-domain* or IN).

Common techniques for model adaptation adapt two main components of contemporary state-of-the-art SMT systems: the language model and the translation model. However, language model adaptation is a more straight-forward problem compared to

translation model adaptation, because various measures such as perplexity of adapted language models can be easily computed on data in the target domain. As a result, language model adaptation has been well studied in various work (Clarkson and Robinson, 1997; Seymore and Rosenfeld, 1997; Bacchiani and Roark, 2003; Eck et al., 2004) both for speech recognition and for machine translation. It is also easier to obtain monolingual data in the target domain, compared to bilingual data which is required for translation model adaptation. In this paper, we focused on adapting only the translation model by fixing a language model for all the experiments. We expect domain adaptation for machine translation can be improved further by combining orthogonal techniques for translation model adaptation combined with language model adaptation.

In this paper, a new approach for adapting the translation model is proposed. We use a novel system combination approach called ensemble decoding in order to combine two or more translation models with the goal of constructing a system that outperforms all the component models. The strength of this system combination method is that the systems are combined in the decoder. This enables the decoder to pick the best hypotheses for each span of the input. The main applications of ensemble models are domain adaptation, domain mixing and system combination. We have modified *Kriya* (Sankaran et al., 2012), an in-house implementation of hierarchical phrase-based translation system (Chiang, 2005), to implement ensemble decoding using multiple translation models.

We compare the results of ensemble decoding with a number of baselines for domain adaptation. In addition to the basic approach of concatenation of in-domain and out-of-domain data, we also trained a log-linear mixture model (Foster and Kuhn, 2007)

as well as the linear mixture model of (Foster et al., 2010) for conditional phrase-pair probabilities over IN and OUT. Furthermore, within the framework of ensemble decoding, we study and evaluate various methods for combining translation tables.

## 2 Baselines

The natural baseline for model adaption is to concatenate the IN and OUT data into a single parallel corpus and train a model on it. In addition to this baseline, we have experimented with two more sophisticated baselines which are based on mixture techniques.

### 2.1 Log-Linear Mixture

Log-linear translation model (TM) mixtures are of the form:

$$p(\bar{e}|\bar{f}) \propto \exp\left(\sum_m^M \lambda_m \log p_m(\bar{e}|\bar{f})\right)$$

where  $m$  ranges over IN and OUT,  $p_m(\bar{e}|\bar{f})$  is an estimate from a component phrase table, and each  $\lambda_m$  is a weight in the top-level log-linear model, set so as to maximize dev-set BLEU using minimum error rate training (Och, 2003). We learn separate weights for relative-frequency and lexical estimates for both  $p_m(\bar{e}|\bar{f})$  and  $p_m(\bar{f}|\bar{e})$ . Thus, for 2 component models (from IN and OUT training corpora), there are  $4 * 2 = 8$  TM weights to tune. Whenever a phrase pair does not appear in a component phrase table, we set the corresponding  $p_m(\bar{e}|\bar{f})$  to a small epsilon value.

### 2.2 Linear Mixture

Linear TM mixtures are of the form:

$$p(\bar{e}|\bar{f}) = \sum_m^M \lambda_m p_m(\bar{e}|\bar{f})$$

Our technique for setting  $\lambda_m$  is similar to that outlined in Foster et al. (2010). We first extract a joint phrase-pair distribution  $\tilde{p}(\bar{e}, \bar{f})$  from the development set using standard techniques (HMM word alignment with grow-diag-and symmetrization (Koehn et al., 2003)). We then find the set of weights  $\hat{\lambda}$  that minimize the cross-entropy of the mixture  $p(\bar{e}|\bar{f})$  with respect to  $\tilde{p}(\bar{e}, \bar{f})$ :

$$\hat{\lambda} = \operatorname{argmax}_{\lambda} \sum_{\bar{e}, \bar{f}} \tilde{p}(\bar{e}, \bar{f}) \log \sum_m^M \lambda_m p_m(\bar{e}|\bar{f})$$

For efficiency and stability, we use the EM algorithm to find  $\hat{\lambda}$ , rather than L-BFGS as in (Foster et al., 2010). Whenever a phrase pair does not appear in a component phrase table, we set the corresponding  $p_m(\bar{e}|\bar{f})$  to 0; pairs in  $\tilde{p}(\bar{e}, \bar{f})$  that do not appear in at least one component table are discarded. We learn separate linear mixtures for relative-frequency and lexical estimates for both  $p(\bar{e}|\bar{f})$  and  $p(\bar{f}|\bar{e})$ . These four features then appear in the top-level model as usual – there is no runtime cost for the linear mixture.

## 3 Ensemble Decoding

Ensemble decoding is a way to combine the expertise of different models in one single model. The current implementation is able to combine hierarchical phrase-based systems (Chiang, 2005) as well as phrase-based translation systems (Koehn et al., 2003). However, the method can be easily extended to support combining a number of heterogeneous translation systems e.g. phrase-based, hierarchical phrase-based, and/or syntax-based systems. This section explains how such models can be combined during the decoding.

Given a number of translation models which are already trained and tuned, the ensemble decoder uses hypotheses constructed from all of the models in order to translate a sentence. We use the bottom-up CKY parsing algorithm for decoding. For each sentence, a CKY chart is constructed. The cells of the CKY chart are populated with appropriate rules from all the phrase tables of different components. As in the Hiero SMT system (Chiang, 2005), the cells which span up to a certain length (i.e. the maximum span length) are populated from the phrase tables and the rest of the chart uses *glue rules* as defined in (Chiang, 2005).

The rules suggested from the component models are combined in a single set. Some of the rules may be unique and others may be common with other component model rule sets, though with different scores. Therefore, we need to combine the scores of such common rules and assign a single score to

them. Depending on the mixture operation used for combining the scores, we would get different mixture scores. The choice of mixture operation will be discussed in Section 3.1.

Figure 1 illustrates how the CKY chart is filled with the rules. Each cell, covering a span, is populated with rules from all component models as well as from cells covering a sub-span of it.

In the typical log-linear model SMT, the posterior probability for each phrase pair  $(\bar{e}, \bar{f})$  is given by:

$$p(\bar{e} | \bar{f}) \propto \exp \left( \underbrace{\sum_i w_i \phi_i(\bar{e}, \bar{f})}_{\mathbf{w} \cdot \boldsymbol{\phi}} \right)$$

Ensemble decoding uses the same framework for each individual system. Therefore, the score of a phrase-pair  $(\bar{e}, \bar{f})$  in the ensemble model is:

$$p(\bar{e} | \bar{f}) \propto \exp \left( \underbrace{\mathbf{w}_1 \cdot \boldsymbol{\phi}_1}_{1^{st} \text{ model}} \oplus \underbrace{\mathbf{w}_2 \cdot \boldsymbol{\phi}_2}_{2^{nd} \text{ model}} \oplus \dots \right)$$

where  $\oplus$  denotes the mixture operation between two or more model scores.

### 3.1 Mixture Operations

Mixture operations receive two or more scores (probabilities) and return the mixture score (probability). In this section, we explore different options for mixture operation and discuss some of the characteristics of these mixture operations.

- **Weighted Sum (wsum):** in *wsum* the ensemble probability is proportional to the weighted sum of all individual model probabilities (i.e. linear mixture).

$$p(\bar{e} | \bar{f}) \propto \sum_m^M \lambda_m \exp(\mathbf{w}_m \cdot \boldsymbol{\phi}_m)$$

where  $m$  denotes the index of component models,  $M$  is the total number of them and  $\lambda_i$  is the weight for component  $i$ .

- **Weighted Max (wmax):** where the ensemble score is the weighted max of all model scores.

$$p(\bar{e} | \bar{f}) \propto \max_m (\lambda_m \exp(\mathbf{w}_m \cdot \boldsymbol{\phi}_m))$$

- **Model Switching (Switch):** in model switching, each cell in the CKY chart gets populated only by rules from one of the models and the other models' rules are discarded. This is based on the hypothesis that each component model is an expert on certain parts of sentence. In this method, we need to define a binary indicator function  $\delta(\bar{f}, m)$  for each span and component model to specify rules of which model to retain for each span.

$$\delta(\bar{f}, m) = \begin{cases} 1, & m = \operatorname{argmax}_{n \in M} \psi(\bar{f}, n) \\ 0, & \text{otherwise} \end{cases}$$

The criteria for choosing a model for each cell,  $\psi(\bar{f}, n)$ , could be based on:

- **Max:** for each cell, the model that has the highest weighted best-rule score wins:

$$\psi(\bar{f}, n) = \lambda_n \max_{\bar{e}} (\mathbf{w}_n \cdot \boldsymbol{\phi}_n(\bar{e}, \bar{f}))$$

- **Sum:** Instead of comparing only the scores of the best rules, the model with the highest weighted sum of the probabilities of the rules wins. This sum has to take into account the translation table limit (*ttl*), on the number of rules suggested by each model for each cell:

$$\psi(\bar{f}, n) = \lambda_n \sum_{\bar{e}} \exp(\mathbf{w}_n \cdot \boldsymbol{\phi}_n(\bar{e}, \bar{f}))$$

The probability of each phrase-pair  $(\bar{e}, \bar{f})$  is computed as:

$$p(\bar{e} | \bar{f}) = \sum_m^M \delta(\bar{f}, m) p_m(\bar{e} | \bar{f})$$

- **Product (prod):** in Product models or Product of Experts (Hinton, 1999), the probability of the ensemble model or a rule is computed as the product of the probabilities of all components (or equally the sum of log-probabilities, i.e. log-linear mixture). Product models can also make use of weights to control the contribution of each component. These models are

explicit gradient information for the objective function. Component weights for each mixture operation are optimized on the dev-set using CONDOR.

## 4 Experiments & Results

### 4.1 Experimental Setup

We carried out translation experiments using the European Medicines Agency (EMA) corpus (Tiedemann, 2009) as IN, and the Europarl (EP) corpus<sup>1</sup> as OUT, for French to English translation. The dev and test sets were randomly chosen from the EMA corpus.<sup>2</sup> The details of datasets used are summarized in Table 1.

Dataset	Sents	Words	
		French	English
<b>EMA</b>	11770	168K	144K
<b>Europarl</b>	1.3M	40M	37M
<b>Dev</b>	1533	29K	25K
<b>Test</b>	1522	29K	25K

Table 1: Training, dev and test sets for EMA.

For the mixture baselines, we used a standard one-pass phrase-based system (Koehn et al., 2003), Portage (Sadat et al., 2005), with the following 7 features: relative-frequency and lexical translation model (TM) probabilities in both directions; word-displacement distortion model; language model (LM) and word count. The corpus was word-aligned using both HMM and IBM2 models, and the phrase table was the union of phrases extracted from these separate alignments, with a length limit of 7. It was filtered to retain the top 20 translations for each source phrase using the TM part of the current log-linear model.

For ensemble decoding, we modified an in-house implementation of hierarchical phrase-based system, *Kriya* (Sankaran et al., 2012) which uses the same features mentioned in (Chiang, 2005): forward and backward relative-frequency and lexical TM probabilities; LM; word, phrase and glue-rules penalty. GIZA++(Och and Ney, 2000) has been used for word alignment with phrase length limit of 7.

In both systems, feature weights were optimized using MERT (Och, 2003) and with a 5-gram lan-

<sup>1</sup>[www.statmt.org/europarl](http://www.statmt.org/europarl)

<sup>2</sup>Please contact the authors to access the data-sets.

guage model and Kneser-Ney smoothing was used in all the experiments. We used SRILM (Stolcke, 2002) as the language model toolkit. Fixing the language model allows us to compare various translation model combination techniques.

### 4.2 Results

Table 2 shows the results of the baselines. The first group are the baseline results on the phrase-based system discussed in Section 2 and the second group are those of our hierarchical MT system. Since the Hiero baselines results were substantially better than those of the phrase-based model, we also implemented the best-performing baseline, linear mixture, in our Hiero-style MT system and in fact it achieves the highest BLEU score among all the baselines as shown in Table 2. This baseline is run three times the score is averaged over the BLEU scores with standard deviation of 0.34.

Baseline	PBS	Hiero
<b>IN</b>	31.84	33.69
<b>OUT</b>	24.08	25.32
<b>IN + OUT</b>	31.75	33.76
<b>LOGLIN</b>	32.21	–
<b>LINMIX</b>	33.81	<b>35.57</b>

Table 2: The results of various baselines implemented in a phrase-based (PBS) and a Hiero SMT on EMA.

Table 3 shows the results of ensemble decoding with different mixture operations and model weight settings. Each mixture operation has been evaluated on the test-set by setting the component weights uniformly (denoted by *uniform*) and by tuning the weights using CONDOR (denoted by *tuned*) on a held-out set. The tuned scores (3rd column in Table 3) are averages of three runs with different initial points as in Clark et al. (2011). We also reported the BLEU scores when we applied the span-wise normalization heuristic. All of these mixture operations were able to significantly improve over the concatenation baseline. In particular, *Switching:Max* could gain up to 2.2 BLEU points over the concatenation baseline and 0.39 BLEU points over the best performing baseline (i.e. linear mixture model implemented in Hiero) which is statistically significant based on Clark et al. (2011) ( $p = 0.02$ ).

*Prod* when using with uniform weights gets the

Mixture Operation	Uniform	Tuned	Norm.
WMAX	35.39	35.47 (s=0.03)	35.47
WSUM	35.35	35.53 (s=0.04)	35.45
SWITCHING:MAX	35.93	<b>35.96</b> (s=0.01)	32.62
SWITCHING:SUM	34.90	34.72 (s=0.23)	34.90
PROD	33.93	35.24 (s=0.05)	35.02

Table 3: The results of ensemble decoding on EMEA for Fr2En when using uniform weights, tuned weights and normalization heuristic. The tuned BLEU scores are averaged over three runs with multiple initial points, as in (Clark et al., 2011), with the standard deviations in brackets .

lowest score among the mixture operations, however after tuning, it learns to bias the weights towards one of the models and hence improves by 1.31 BLEU points. Although *Switching:Sum* outperforms the concatenation baseline, it is substantially worse than other mixture operations. One explanation that *Switching:Max* is the best performing operation and *Switching:Sum* is the worst one, despite their similarities, is that *Switching:Max* prefers more peaked distributions while *Switching:Sum* favours a model that has fewer hypotheses for each span.

An interesting observation based on the results in Table 3 is that uniform weights are doing reasonably well given that the component weights are not optimized and therefore model scores may not be in the same scope (refer to discussion in §3.2). We suspect this is because a single LM is shared between both models. This shared component controls the variance of the weights in the two models when combined with the standard L-1 normalization of each model’s weights and hence prohibits models to have too varied scores for the same input. Though, it may not be the case when multiple LMs are used which are not shared.

Two sample sentences from the EMEA test-set along with their translations by the IN, OUT and Ensemble models are shown in Figure 2. The boxes show how the Ensemble model is able to use n-grams from the IN and OUT models to construct a better translation than both of them. In the first example, there are two OOVs one for each of the IN and OUT models. Our approach is able to resolve the OOV issues by taking advantage of the other model’s presence. Similarly, the second example shows how ensemble decoding improves lexical choices as well as word re-orderings.

## 5 Related Work

### 5.1 Domain Adaptation

Early approaches to domain adaptation involved information retrieval techniques where sentence pairs related to the target domain were retrieved from the training corpus using IR methods (Eck et al., 2004; Hildebrand et al., 2005). Foster et al. (2010), however, uses a different approach to select related sentences from OUT. They use language model perplexities from IN to select relevant sentences from OUT. These sentences are used to enrich the IN training set.

Other domain adaptation methods involve techniques that distinguish between general and domain-specific examples (Daumé and Marcu, 2006). Jiang and Zhai (2007) introduce a general instance weighting framework for model adaptation. This approach tries to penalize misleading training instances from OUT and assign more weight to IN-like instances than OUT instances. Foster et al. (2010) propose a similar method for machine translation that uses features to capture degrees of generality. Particularly, they include the output from an SVM classifier that uses the intersection between IN and OUT as positive examples. Unlike previous work on instance weighting in machine translation, they use phrase-level instances instead of sentences.

A large body of work uses interpolation techniques to create a single TM/LM from interpolating a number of LMs/TMs. Two famous examples of such methods are linear mixtures and log-linear mixtures (Koehn and Schroeder, 2007; Civera and Juan, 2007; Foster and Kuhn, 2007) which were used as baselines and discussed in Section 2. Other methods include using self-training techniques to exploit monolingual in-domain data (Ueffing et al., 2007;

SOURCE	aménorrhée , menstruations irrégulières
REF	amenorrhoea , irregular menstruation
IN	amenorrhoea , menstruations irrégulières
OUT	aménorrhée , irregular menstruation

Figure 2: Examples illustrating how this method is able to use expertise of both out-of-domain and in-domain systems.

Bertoldi and Federico, 2009). In this approach, a system is trained on the parallel OUT and IN data and it is used to translate the monolingual IN data set. Iteratively, most confident sentence pairs are selected and added to the training corpus on which a new system is trained.

## 5.2 System Combination

Tackling the model adaptation problem using system combination approaches has been experimented in various work (Koehn and Schroeder, 2007; Hildebrand and Vogel, 2009). Among these approaches are sentence-based, phrase-based and word-based output combination methods. In a similar approach, Koehn and Schroeder (2007) use a feature of the factored translation model framework in Moses SMT system (Koehn and Schroeder, 2007) to use multiple alternative decoding paths. Two decoding paths, one for each translation table (IN and OUT), were used during decoding. The weights are set with minimum error rate training (Och, 2003).

Our work is closely related to Koehn and Schroeder (2007) but uses a different approach to deal with multiple translation tables. The Moses SMT system implements (Koehn and Schroeder,

2007) and can treat multiple translation tables in two different ways: *intersection* and *union*. In *intersection*, for each span only the hypotheses would be used that are present in all phrase tables. For each set of hypothesis with the same source and target phrases, a new hypothesis is created whose feature-set is the union of feature sets of all corresponding hypotheses. *Union*, on the other hand, uses hypotheses from all the phrase tables. The feature set of these hypotheses are expanded to include one feature set for each table. However, for the corresponding feature values of those phrase-tables that did not have a particular phrase-pair, a default log probability value of 0 is assumed (Bertoldi and Federico, 2009) which is counter-intuitive as it boosts the score of hypotheses with phrase-pairs that do not belong to all of the translation tables.

Our approach is different from Koehn and Schroeder (2007) in a number of ways. Firstly, unlike the multi-table support of Moses which only supports phrase-based translation table combination, our approach supports ensembles of both hierarchical and phrase-based systems. With little modification, it can also support ensemble of syntax-based systems with the other two state-of-the-art SMT sys-

tems. Secondly, our combining method uses the *union* option, but instead of preserving the features of all phrase-tables, it only combines their scores using various mixture operations. This enables us to experiment with a number of different operations as opposed to sticking to only one combination method. Finally, by avoiding increasing the number of features we can add as many translation models as we need without serious performance drop. In addition, MERT would not be an appropriate optimizer when the number of features increases a certain amount (Chiang et al., 2008).

Our approach differs from the model combination approach of DeNero et al. (2010), a generalization of consensus or minimum Bayes risk decoding where the search space consists of those of multiple systems, in that model combination uses forest of derivations of all component models to do the combination. In other words, it requires all component models to fully decode each sentence, compute n-gram expectations from each component model and calculate posterior probabilities over translation derivations. While, in our approach we only use partial hypotheses from component models and the derivation forest is constructed by the ensemble model. A major difference is that in the model combination approach the component search spaces are conjoined and they are not intermingled as opposed to our approach where these search spaces are intermixed on spans. This enables us to generate new sentences that cannot be generated by component models. Furthermore, various combination methods can be explored in our approach. Finally, main techniques used in this work are orthogonal to our approach such as Minimum Bayes Risk decoding, using n-gram features and tuning using MERT.

Finally, our work is most similar to that of Liu et al. (2009) where max-derivation and max-translation decoding have been used. Max-derivation finds a derivation with highest score and max-translation finds the highest scoring translation by summing the score of all derivations with the same yield. The combination can be done in two levels: translation-level and derivation-level. Their derivation-level max-translation decoding is similar to our ensemble decoding with *wsum* as the mixture operation. We did not restrict ourself to this particular mixture operation and experimented with a

number of different mixing techniques and as Table 3 shows we could improve over *wsum* in our experimental setup. Liu et al. (2009) used a modified version of MERT to tune max-translation decoding weights, while we use a two-step approach using MERT for tuning each component model separately and then using CONDOR to tune component weights on top of them.

## 6 Conclusion & Future Work

In this paper, we presented a new approach for domain adaptation using ensemble decoding. In this approach a number of MT systems are combined at decoding time in order to form an ensemble model. The model combination can be done using various mixture operations. We showed that this approach can gain up to 2.2 BLEU points over its concatenation baseline and 0.39 BLEU points over a powerful mixture model.

Future work includes extending this approach to use multiple translation models with multiple language models in ensemble decoding. Different mixture operations can be investigated and the behaviour of each operation can be studied in more details. We will also add capability of supporting syntax-based ensemble decoding and experiment how a phrase-based system can benefit from syntax information present in a syntax-aware MT system. Furthermore, ensemble decoding can be applied on domain mixing settings in which development sets and test sets include sentences from different domains and genres, and this is a very suitable setting for an ensemble model which can adapt to new domains at test time. In addition, we can extend our approach by applying some of the techniques used in other system combination approaches such as consensus decoding, using *n*-gram features, tuning using forest-based MERT, among other possible extensions.

## Acknowledgments

This research was partially supported by an NSERC, Canada (RGPIN: 264905) grant and a Google Faculty Award to the last author. We would like to thank Philipp Koehn and the anonymous reviewers for their valuable comments. We also thank the developers of GIZA++ and Condor which we used for our experiments.

## Abstract

We present a hierarchical chunk-to-string translation model, which can be seen as a compromise between the hierarchical phrase-based model and the tree-to-string model, to combine the merits of the two models. With the help of shallow parsing, our model learns rules consisting of words and *chunks* and meanwhile introduce syntax cohesion. Under the weighed synchronous context-free grammar defined by these rules, our model searches for the best translation derivation and yields target translation simultaneously. Our experiments show that our model significantly outperforms the hierarchical phrase-based model and the tree-to-string model on English-Chinese Translation tasks.

## 1 Introduction

The hierarchical phrase-based model (Chiang, 2007) makes an advance of statistical machine translation by employing hierarchical phrases, which not only uses phrases to learn local translations but also uses hierarchical phrases to capture reorderings of words and subphrases which can cover a large scope. Besides, this model is formal syntax-based and does not need to specify the syntactic constituents of subphrases, so it can directly learn synchronous context-free grammars (SCFG) from a parallel text without relying on any linguistic annotations or assumptions, which makes it used conveniently and widely.

---

<sup>\*</sup>This work was done when the first author visited Microsoft Research Asia as an intern.

However, it is often desirable to consider syntactic constituents of subphrases, e.g. the hierarchical phrase

$$X \rightarrow \langle X_1 \text{ for } X_2, X_2 \text{ de } X_1 \rangle$$

can be applied to both of the following strings in Figure 1

“A request for a purchase of shares”  
“filed for bankruptcy”,

and get the following translation, respectively

“goumai gufen de shenqing”  
“pochan de shenqing”.

In the former, “A request” is a NP and this rule acts correctly while in the latter “filed” is a VP and this rule gives a wrong reordering. If we specify the first  $X$  on the right-hand side to NP, this kind of errors can be avoided.

The tree-to-string model (Liu et al., 2006; Huang et al., 2006) introduces linguistic syntax via source parse to direct word reordering, especially long-distance reordering. Furthermore, this model is formalised as Tree Substitution Grammars, so it observes syntactic cohesion. Syntactic cohesion means that the translation of a string covered by a subtree in a source parse tends to be continuous. Fox (2002) shows that translation between English and French satisfies cohesion in the majority cases. Many previous works show promising results with an assumption that syntactic cohesion explains almost all translation movement for some language pairs (Wu, 1997; Yamada and Knight, 2001; Eisner, 2003; Graehl and Knight, 2004; Quirk et al., 2005; Cherry, 2008; Feng et al., 2010).

But unfortunately, the tree-to-string model requires each node must be strictly matched during rule matching, which makes it strongly dependent on the relationship of tree nodes and their roles in the whole sentence. This will lead to data sparseness and being vulnerable to parse errors.

In this paper, we present a hierarchical chunk-to-string translation model to combine the merits of the two models. Instead of parse trees, our model introduces linguistic information in the form of *chunks*, so it does not need to care the internal structures and the roles in the main sentence of chunks. Based on shallow parsing results, it learns rules consisting of either words (terminals) or chunks (nonterminals), where adjacent chunks are packed into one nonterminal. It searches for the best derivation through the SCFG-motivated space defined by these rules and get target translation simultaneously. In some sense, our model can be seen as a compromise between the hierarchical phrase-based model and the tree-to-string model, specifically

- Compared with the hierarchical phrase-based model, it integrates linguistic syntax and satisfies syntactic cohesion.
- Compared with the tree-to-string model, it only needs to perform shallow parsing which introduces less parsing errors. Besides, our model allows a nonterminal in a rule to cover several chunks, which can alleviate data sparseness and the influence of parsing errors.
- we refine our hierarchical chunk-to-string model into two models: a loose model (Section 2.1) which is more similar to the hierarchical phrase-based model and a tight model (Section 2.2) which is more similar to the tree-to-string model.

The experiments show that on the 2008 NIST English-Chinese MT translation test set, both the loose model and the tight model outperform the hierarchical phrase-based model and the tree-to-string model, where the loose model has a better performance. While in terms of speed, the tight model runs faster and its speed ranking is between the tree-to-string model and the hierarchical phrase-based model.

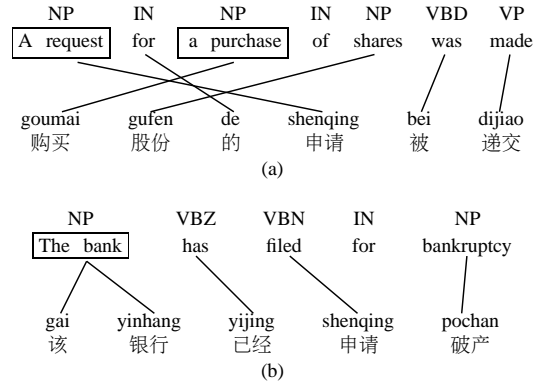

Figure 1: A running example of two sentences. For each sentence, the first row gives the chunk sequence.

(a) A parse tree

B-NP I-NP B-VBZ B-VBN B-IN B-NP  
The bank has filed for bankruptcy

(b) A chunk sequence got from the parse tree

Figure 2: An example of shallow parsing.

## 2 Modeling

**Shallow parsing** (also **chunking**) is an analysis of a sentence which identifies the constituents (noun groups, verbs, verb groups, etc), but neither specifies their internal structures, nor their roles in the main sentence. In Figure 1, we give the chunk sequence in the first row for each sentence. We treat shallow parsing as a sequence label task, and a sentence  $f$  can have many possible different chunk label sequences. Therefore, in theory, the conditional probability of a target translation  $e$  conditioned on the source sentence  $f$  is given by taking the chunk label sequences as a latent variable  $c$ :

$$p(e|f) = \sum_c p(c|f)p(e|f, c) \quad (1)$$

In practice, we only take the best chunk label sequence  $\hat{c}$  got by

$$\hat{c} = \operatorname{argmax}_c p(c|\mathbf{f}) \quad (2)$$

Then we can ignore the conditional probability  $p(\hat{c}|\mathbf{f})$  as it holds the same value for each translation, and get:

$$\begin{aligned} p(e|\mathbf{f}) &= p(\hat{c}|\mathbf{f})p(e|\mathbf{f}, \hat{c}) \\ &= p(e|\mathbf{f}, \hat{c}) \end{aligned} \quad (3)$$

We formalize our model as a weighted SCFG. In a SCFG, each rule (usually called production in SCFGs) has an aligned pair of right-hand sides — the source side and the target side, just as follows:

$$X \rightarrow \langle \alpha, \beta, \sim \rangle$$

where  $X$  is a nonterminal,  $\alpha$  and  $\beta$  are both strings of terminals and nonterminals, and  $\sim$  denotes one-to-one links between nonterminal occurrences in  $\alpha$  and nonterminal occurrences in  $\beta$ . A SCFG produces a derivation by starting with a pair of start symbols and recursively rewrites every two coindexed nonterminals with the corresponding components of a matched rule. A derivation yields a pair of strings on the right-hand side which are translation of each other.

In a weighted SCFG, each rule has a weight and the total weight of a derivation is the production of the weights of the rules used by the derivation. A translation may be produced by many different derivations and we only use the best derivation to evaluate its probability. With  $d$  denoting a derivation and  $r$  denoting a rule, we have

$$\begin{aligned} p(e|\mathbf{f}) &= \max_d p(d, e|\mathbf{f}, \hat{c}) \\ &= \max_d \prod_{r \in d} p(r, e|\mathbf{f}, \hat{c}) \end{aligned} \quad (4)$$

Following Och and Ney (2002), we frame our model as a log-linear model:

$$p(e|\mathbf{f}) = \frac{\exp \sum_k \lambda_k H_k(d, e, \hat{c}, \mathbf{f})}{\exp \sum_{d', e', k} \lambda_k H_k(d', e', \hat{c}, \mathbf{f})} \quad (5)$$

$$\text{where } H_k(d, e, \hat{c}, \mathbf{f}) = \sum_r h_k(\mathbf{f}, \hat{c}, r)$$

So the best translation is given by

$$\hat{e} = \operatorname{argmax}_e \sum_k \lambda_k H_k(d, e, \hat{c}, \mathbf{f}) \quad (6)$$

We employ the same set of features for the log-linear model as the hierarchical phrase-based model does (Chiang, 2005).

We further refine our hierarchical chunk-to-string model into two models: a loose model which is more similar to the hierarchical phrase-based model and a tight model which is more similar to the tree-to-string model. The two models differ in the form of rules and the way of estimating rule probabilities. While for decoding, we employ the same decoding algorithm for the two models: given a test sentence, the decoders first perform shallow parsing to get the best chunk sequence, then apply a CYK parsing algorithm with beam search.

## 2.1 A Loose Model

In our model, we employ rules containing nonterminals to handle long-distance reordering where boundary words play an important role. So for the subphrases which cover more than one chunk, we just maintain boundary chunks: we bundle adjacent chunks into one nonterminal and denote it as the first chunk tag immediately followed by “-” and next followed by the last chunk tag. Then, for the string pair  $\langle \text{filed for bankruptcy, shenqing pochan} \rangle$ , we can get the rule

$$r_1 : X \rightarrow \langle \text{VBN}_{\boxed{1}} \text{ for NP}_{\boxed{2}}, \text{VBN}_{\boxed{1}} \text{ NP}_{\boxed{2}} \rangle$$

while for the string pair  $\langle \text{A request for a purchase of shares, goumai gufen de shenqing} \rangle$ , we can get

$$r_2 : X \rightarrow \langle \text{NP}_{\boxed{1}} \text{ for NP-NP}_{\boxed{2}}, \text{NP-NP}_{\boxed{2}} \text{ de NP}_{\boxed{1}} \rangle.$$

The rule matching “A request for a purchase of shares was” will be

$$r_3 : X \rightarrow \langle \text{NP-NP}_{\boxed{1}} \text{ VBD}_{\boxed{2}}, \text{NP-NP}_{\boxed{1}} \text{ VBD}_{\boxed{2}} \rangle.$$

We can see that in contrast to the method of representing each chunk separately, this representation form can alleviate data sparseness and the influence of parsing errors.

$\langle S_{[1]}, S_{[1]} \rangle \Rightarrow \langle S_{[1]} X_{[1]}, S_{[1]} X_{[1]} \rangle$   
 $\Rightarrow \langle X_{[1]} X_{[1]}, X_{[1]} X_{[1]} \rangle$   
 $\Rightarrow \langle NP-NP_{[1]} VBD_{[1]} X_{[1]}, NP-NP_{[1]} VBD_{[1]} X_{[1]} \rangle$   
 $\Rightarrow \langle NP_{[1]} \text{ for } NP-NP_{[1]} VBD_{[1]} X_{[1]}, NP-NP_{[1]} \text{ de } NP_{[1]} VBD_{[1]} X_{[1]} \rangle$   
 $\Rightarrow \langle \text{A request for } NP-NP_{[1]} VBD_{[1]} X_{[1]}, NP-NP_{[1]} \text{ de shenqing } VBD_{[1]} X_{[1]} \rangle$   
 $\Rightarrow \langle \text{A request for a purchase of shares } VBD_{[1]} X_{[1]}, \text{ goumai gufen de shenqing } VBD_{[1]} X_{[1]} \rangle$   
 $\Rightarrow \langle \text{A request for a purchase of shares was } X_{[1]}, \text{ goumai gufen de shenqing bei } X_{[1]} \rangle$   
 $\Rightarrow \langle \text{A request for a purchase of shares was made, goumai gufen de shenqing bei dijiao} \rangle$

(a) The loose model

$\langle NP-VP_{[1]}, NP-VP_{[1]} \rangle \Rightarrow \langle NP-VBD_{[1]} VP_{[1]}, NP-VBD_{[1]} VP_{[1]} \rangle$   
 $\Rightarrow \langle NP-NP_{[1]} VBD_{[1]} VP_{[1]}, NP-NP_{[1]} VBD_{[1]} VP_{[1]} \rangle$   
 $\Rightarrow \langle NP_{[1]} \text{ for } NP-NP_{[1]} VBD_{[1]} VP_{[1]}, NP-NP_{[1]} \text{ de } NP_{[1]} VBD_{[1]} VP_{[1]} \rangle$   
 $\Rightarrow \langle \text{A request for } NP-NP_{[1]} VBD_{[1]} VP_{[1]}, NP-NP_{[1]} \text{ de shenqing } VBD_{[1]} VP_{[1]} \rangle$   
 $\Rightarrow \langle \text{A request for a purchase of shares } VBD_{[1]} VP_{[1]}, \text{ goumai gufen de shenqing } VBD_{[1]} VP_{[1]} \rangle$   
 $\Rightarrow \langle \text{A request for a purchase of shares was } VP_{[1]}, \text{ goumai gufen de shenqing bei } VP_{[1]} \rangle$   
 $\Rightarrow \langle \text{A request for a purchase of shares was made, goumai gufen de shenqing bei dijiao} \rangle$

(b) The tight model

Figure 3: The derivations of the sentence in Figure 1(a).

In these rules, the left-hand nonterminal symbol  $X$  can not match any nonterminal symbol on the right-hand side. So we need a set of rules such as

$$\begin{aligned}
 NP &\rightarrow \langle X_{[1]}, X_{[1]} \rangle \\
 NP-NP &\rightarrow \langle X_{[1]}, X_{[1]} \rangle
 \end{aligned}$$

and so on, and set the probabilities of these rules to 1. To simplify the derivation, we discard this kind of rules and assume that  $X$  can match any nonterminal on the right-hand side.

Only with  $r_2$  and  $r_3$ , we cannot produce any derivation of the whole sentence in Figure 1 (a). In this case we need two special *glue rules*:

$$\begin{aligned}
 r_4 : \quad S &\rightarrow \langle S_{[1]} X_{[2]}, S_{[1]} X_{[2]} \rangle \\
 r_5 : \quad S &\rightarrow \langle X_{[1]}, X_{[1]} \rangle
 \end{aligned}$$

Together with the following four lexical rules,

$$\begin{aligned}
 r_6 : \quad X &\rightarrow \langle \text{a request, shenqing} \rangle \\
 r_7 : \quad X &\rightarrow \langle \text{a purchase of shares, goumai gufen} \rangle \\
 r_8 : \quad X &\rightarrow \langle \text{was, bei} \rangle \\
 r_9 : \quad X &\rightarrow \langle \text{made, dijiao} \rangle
 \end{aligned}$$

Figure 3(a) shows the derivation of the sentence in Figure 1(a).

## 2.2 A Tight Model

In the tight model, the right-hand side of each rule remains the same as the loose model, but the left-hand side nonterminal is not  $X$  but the corresponding chunk labels. If a rule covers more than one chunk, we just use the first and the last chunk labels to denote the left-hand side nonterminal. The rule set used in the tight model for the example in Figure 1(a) corresponding to that in the loose model becomes:

$$\begin{aligned}
 r_2 : \quad NP-NP &\rightarrow \langle NP_{[1]} \text{ for } NP-NP_{[2]}, NP-NP_{[2]} \text{ de } NP_{[1]} \rangle \\
 r_3 : \quad NP-VBD &\rightarrow \langle NP-NP_{[1]} VBD_{[2]}, NP-NP_{[1]} VBD_{[2]} \rangle.
 \end{aligned}$$

$$\begin{aligned}
 r_6 : \quad NP &\rightarrow \langle \text{a request, shenqing} \rangle \\
 r_7 : \quad NP-NP &\rightarrow \langle \text{a purchase of shares, goumai gufen} \rangle \\
 r_8 : \quad VBD &\rightarrow \langle \text{was, bei} \rangle \\
 r_9 : \quad VP &\rightarrow \langle \text{made, dijiao} \rangle
 \end{aligned}$$

During decoding, we first collect rules for each span. For a span which does not have any matching rule, if we do not construct default rules for it, there will be no derivation for the whole sentence, then we need to construct default rules for this kind of span by enumerating all possible binary segmentation of the chunks in this span. For the example in Figure 1(a), there is no rule matching the whole sentence,

so we need to construct default rules for it, which should be

$$\text{NP-VP} \rightarrow \langle \text{NP-VBD}_{\square} \text{VP}_{\square}, \text{NP-VBD}_{\square} \text{VP}_{\square} \rangle.$$

$$\text{NP-VP} \rightarrow \langle \text{NP-NP}_{\square} \text{VBD-VP}_{\square}, \text{NP-NP}_{\square} \text{VBD-VP}_{\square} \rangle.$$

and so on.

Figure 3(b) shows the derivation of the sentence in Figure 1(a).

### 3 Shallow Parsing

In a parse tree, a chunk is defined by a leaf node or an inner node whose children are all leaf nodes (See Figure 2 (a)). In our model, we identify chunks by traversing a parse tree in a breadth-first order. Once a node is recognized as a chunk, we skip its children. In this way, we can get a sole chunk sequence given a parse tree. Then we label each word with a label indicating whether the word starts a chunk (B-) or continues a chunk (I-). Figure 2(a) gives an example. In this method, we get the training data for shallow parsing from Penn Tree Bank.

We take shallow Parsing (chunking) as a sequence label task and employ Conditional Random Field (CRF)<sup>1</sup> to train a chunker. CRF is a good choice for label tasks as it can avoid label bias and use more statistical correlated features. We employ the features described in Sha and Pereira (2003) for CRF. We do not introduce CRF-based chunkier in this paper and more details can be got from Hammersley and Clifford (1971), Lafferty et al. (2001), Taskar et al. (2002), Sha and Pereira (2003).

### 4 Rule Extraction

In what follows, we introduce how to get the rule set. We learn rules from a corpus that first is bi-directionally word-aligned by the GIZA++ toolkit (Och and Ney, 2000) and then is refined using a “final-and” strategy. We generate the rule set in two steps: first, we extract two sets of phrases, *basic phrases* and *chunk-based phrases*. Basic phrases are defined using the same heuristic as previous systems (Koehn et al., 2003; Och and Ney, 2004; Chiang, 2005). A chunk-based phrase is such a basic phrase that covers one or more chunks on the source side.

<sup>1</sup>We use the open source toolkit CRF++ got in <http://code.google.com/p/crfpp/>.

We identify chunk-based phrases  $\langle c_{j_1}^{j_2}, f_{j_1}^{j_2}, e_{i_1}^{i_2} \rangle$  as follows:

1. A chunk-based phrase is a basic phrase;
2.  $c_{j_1}$  begins with “B-”;
3.  $f_{j_2}$  is the end word on the source side or  $c_{j_2+1}$  does not begins with “I-”.

Given a sentence pair  $\langle f, e, \sim \rangle$ , we extract rules for the loose model as follows

1. If  $\langle f_{j_1}^{j_2}, e_{i_1}^{i_2} \rangle$  is a basic phrase, then we can have a rule

$$X \rightarrow \langle f_{j_1}^{j_2}, e_{i_1}^{i_2} \rangle$$

2. Assume  $X \rightarrow \langle \alpha, \beta \rangle$  is a rule with  $\alpha = \alpha_1 f_{j_1}^{j_2} \alpha_2$  and  $\beta = \beta_1 e_{i_1}^{i_2} \beta_2$ , and  $\langle f_{j_1}^{j_2}, e_{i_1}^{i_2} \rangle$  is a chunk-based phrase with a chunk sequence  $Y_u \cdots Y_v$ , then we have the following rule

$$X \rightarrow \langle \alpha_1 Y_u - Y_{v[\square]} \alpha_2, \beta_1 Y_u - Y_{v[\square]} \beta_2 \rangle.$$

We evaluate the distribution of these rules in the same way as Chiang (2007).

We extract rules for the tight model as follows

1. If  $\langle f_{j_1}^{j_2}, e_{i_1}^{i_2} \rangle$  is a chunk-based phrase with a chunk sequence  $Y_s \cdots Y_t$ , then we can have a rule

$$Y_s - Y_t \rightarrow \langle f_{j_1}^{j_2}, e_{i_1}^{i_2} \rangle$$

2. Assume  $Y_s - Y_t \rightarrow \langle \alpha, \beta \rangle$  is a rule with  $\alpha = \alpha_1 f_{j_1}^{j_2} \alpha_2$  and  $\beta = \beta_1 e_{i_1}^{i_2} \beta_2$ , and  $\langle f_{j_1}^{j_2}, e_{i_1}^{i_2} \rangle$  is a chunk-based phrase with a chunk sequence  $Y_u \cdots Y_v$ , then we have the following rule

$$Y_s - Y_t \rightarrow \langle \alpha_1 Y_u - Y_{v[\square]} \alpha_2, \beta_1 Y_u - Y_{v[\square]} \beta_2 \rangle.$$

We evaluate the distribution of rules in the same way as Liu et al. (2006).

For the loose model, the nonterminals must be cohesive, while the whole rule can be noncohesive: if both ends of a rule are nonterminals, the whole rule is cohesive, otherwise, it may be noncohesive. In contrast, for the tight model, both the whole rule and the nonterminal are cohesive.

Even with the cohesion constraints, our model still generates a large number of rules, but not all

of the rules are useful for translation. So we follow the method described in Chiang (2007) to filter the rule set except that we allow two nonterminals to be adjacent.

## 5 Related Works

Watanabe et al. (2003) presented a chunk-to-string translation model where the decoder generates a translation by first translating the words in each chunk, then reordering the translation of chunks. Our model distinguishes from their model mainly in reordering model. Their model reorders chunks resorting to a distortion model while our model reorders chunks according to SCFG rules which retain the relative positions of chunks.

Nguyen et al. (2008) presented a tree-to-string phrase-based method which is based on SCFGs. This method generates SCFGs through syntactic transformation including a word-to-phrase tree transformation model and a phrase reordering model while our model learns SCFG-based rules from word-aligned bilingual corpus directly

There are also some works aiming to introduce linguistic knowledge into the hierarchical phrase-based model. Marton and Resnik (2008) took the source parse tree into account and added soft constraints to hierarchical phrase-based model. Cherry (2008) used dependency tree to add syntactic cohesion. These methods work with the original SCFG defined by hierarchical phrase-based model and use linguistic knowledge to assist translation. Instead, our model works under the new defined SCFG with chunks.

Besides, some other researchers make efforts on the tree-to-string model by employing exponentially alternative parses to alleviate the drawback of 1-best parse. Mi et al. (2008) presented forest-based translation where the decoder translates a packed forest of exponentially many parses instead of i-best parse. Liu and Liu (2010) proposed to parse and to translate jointly by taking tree-based translation as parsing. Given a source sentence, this decoder produces a parse tree on the source side and a translation on the target side simultaneously. Both the models perform in the unit of tree nodes rather than chunks.

## 6 Experiments

### 6.1 Data Preparation

**Data for shallow parsing** We got training data and test data for shallow parsing from the standard Penn Tree Bank (PTB) English parsing task by splitting the sections 02-21 on the Wall Street Journal Portion (Marcus et al., 1993) into two sets: the last 1000 sentences as the test set and the rest as the training set. We filtered the features whose frequency was lower than 3 and substituted `` and '' with ~ to keep consistent with translation data. We used  $L2$  algorithm to train CRF.

**Data for Translation** We used the NIST training set for Chinese-English translation tasks excluding the Hong Kong Law and Hong Kong Hansard<sup>2</sup> as the training data, which contains 470K sentence pairs. For the training data set, we first performed word alignment in both directions using GIZA++ toolkit (Och and Ney, 2000) then refined the alignments using “final-and”. We trained a 5-gram language model with modified Kneser-Ney smoothing on the Xinhua portion of LDC Chinese Gigaword corpus. For the tree-to-string model, we parsed English sentences using Stanford parser and extracted rules using the GHKM algorithm (Galley et al., 2004).

We used our in-house English-Chinese data set as the development set and used the 2008 NIST English-Chinese MT test set (1859 sentences) as the test set. Our evaluation metric was BLEU-4 (Papineni et al., 2002) based on characters (as the target language is Chinese), which performed case-insensitive matching of n-grams up to  $n = 4$  and used the shortest reference for the brevity penalty. We used the standard minimum error-rate training (Och, 2003) to tune the feature weights to maximize the BLEU score on the development set.

### 6.2 Shallow Parsing

The standard evaluation metrics for shallow parsing are precision P, recall R, and their harmonic mean F1 score, given by:

$$P = \frac{\text{number of exactly recognized chunks}}{\text{number of output chunks}}$$
$$R = \frac{\text{number of exactly recognized chunks}}{\text{number of reference chunks}}$$

<sup>2</sup>The source side and target side are reversed.

Word number	Chunk number	Accuracy %
23861	12258	94.48

Chunk type	P %	R %	F <sub>1</sub> %	Found
All	91.14	91.35	91.25	12286
One	90.32	90.99	90.65	5236
NP	93.97	94.47	94.22	5523
ADVP	82.53	84.30	83.40	475
VP	93.66	92.04	92.84	284
ADJP	65.68	69.20	67.39	236
WHNP	96.30	95.79	96.04	189
QP	83.06	80.00	81.50	183

Table 1: Shallow parsing result. The column *Found* gives the number of chunks recognized by CRF, the row *All* represents all types of chunks, and the row *One* represents the chunks that consist of one word.

$$F_1 = \frac{2 \cdot P \cdot R}{P + R}$$

Besides, we need another metric, accuracy *A*, to evaluate the accurate rate of individual labeling decisions of every word as

$$A = \frac{\text{number of exactly labeled words}}{\text{number of words}}$$

For example, given a reference sequence B-NP I-NP I-NP B-VP I-VP B-VP, CRF outputs a sequence O-NP I-NP I-NP B-VP I-VP I-NP, then  $P = 33.33\%$ ,  $A = 66.67\%$ .

Table 1 summarizes the results of shallow parsing. For ‘‘ and ‘’ were substituted with ‘’, the performance was slightly influenced.

The F1 score of all chunks is 91.25% and the F1 score of *One* and NP, which in number account for about 90% of chunks, is 90.65% and 94.22% respectively. F score of NP chunking approaches 94.38% given in Sha and Pereira (2003).

### 6.3 Performance Comparison

We compared our loose decoder and tight decoder with our in-house hierarchical phrase-based decoder (Chiang, 2007) and the tree-to-string decoder (Liu et al., 2006). We set the same configuration for all the decoders as follows: stack size = 30, nbest size = 30. For the hierarchical chunk-based and phrase-based decoders, we set max rule length to 5. For the tree-to-string decoder, we set the configuration of rule

System	Dev	NIST08	Speed
phrase	0.2843	0.3921	1.163
tree	0.2786	0.3817	1.107
tight	0.2914	0.3987	1.208
loose	0.2936	0.4023	1.429

Table 2: Performance comparison. *Phrase* represents the hierarchical phrase-based decoder, *tree* represents the tree-to-string decoder, *tight* represents our tight decoder and *loose* represents our loose decoder. The speed is reported by seconds per sentence. The speed for the tree-to-string decoder includes the parsing time (0.23s) and the speed for the tight and loose models includes the shallow parsing time, too.

extraction as: the height up to 3 and the number of leaf nodes up to 5.

We give the results in Table 2. From the results, we can see that both the loose and tight decoders outperform the baseline decoders and the improvement is significant using the *sign-test* of Collins et al. (2005) ( $p < 0.01$ ). Specifically, the loose model has a better performance while the tight model has a faster speed.

Compared with the hierarchical phrase-based model, the loose model only imposes syntactic cohesion to nonterminals while the tight model imposes syntax cohesion to both rules and nonterminals which reduces search space, so it decodes faster. We can conclude that linguistic syntax can indeed improve the translation performance; syntactic cohesion for nonterminals can explain linguistic phenomena well; noncohesive rules are useful, too. The extra time consumption against hierarchical phrase-based system comes from shallow parsing.

By investigating the translation result, we find that our decoder does well in rule selection. For example, in the hierarchical phrase-based model, this kind of rules, such as

$$X \rightarrow \langle X \text{ of } X, * \rangle, X \rightarrow \langle X \text{ for } X, * \rangle$$

and so on, where  $*$  stands for the target component, are used with a loose restriction as long as the terminals are matched, while our models employ more stringent constraints on these rules by specifying the syntactic constituent of ‘‘X’’. With chunk labels, our models can make different treatment for different situations.

System	Dev	NIST08	Speed
cohesive	0.2936	0.4023	1.429
noncohesive	0.2937	0.3964	1.734

Table 3: Influence of cohesion. The row *cohesive* represents the loose system where nonterminals satisfy cohesion, and the row *noncohesive* represents the modified version of the loose system where nonterminals can be noncohesive.

Compared with the tree-to-string model, the result indicates that the change of the source-side linguistic syntax from parses to chunks can improve translation performance. The reasons should be our model can reduce parse errors and it is enough to use chunks as the basic unit for machine translation. Although our decoders and tree-to-string decoder all run in linear-time with beam search, tree-to-string model runs faster for it searches through a smaller SCFG-motivated space.

#### 6.4 Influence of Cohesion

We verify the influence of syntax cohesion via the loose model. The cohesive model imposes syntax cohesion on nonterminals to ensure the chunk is reordered as a whole. In this experiment, we introduce a noncohesive model by allowing a nonterminal to match part of a chunk. For example, in the noncohesive model, it is legal for a rule with the source side

“NP for NP-NP”

to match

“request for a purchase of shares”

in Figure 1 (a), where “request” is part of NP. As well, the rule with the source side

“NP for a NP-NP”

can match

“request for a purchase of shares”.

In this way, we can ensure all the rules used in the cohesive system can be used in the noncohesive system. Besides cohesive rules, the noncohesive system can use noncohesive rules, too.

We give the results in Table 3. From the results, we can see that cohesion helps to reduce search space, so the cohesive system decodes faster. The noncohesive system decoder slower, as it employs

System	Number	Dev	NIST08	Speed
loose	two	0.2936	0.4023	1.429
loose	three	0.2978	0.4037	2.056
tight	two	0.2914	0.3987	1.208
tight	three	0.2954	0.4026	1.780

Table 4: The influence of the number of nonterminals. The column *number* lists the number of nonterminals used at most in a rule.

more rules, but this does not bring any improvement of translation performance. As other researches said in their papers, syntax cohesion can explain linguistic phenomena well.

#### 6.5 Influence of the number of nonterminals

We also tried to allow a rule to hold three nonterminals at most. We give the result in Table 4. The result shows that using three nonterminals does not bring a significant improvement of translation performance but quite more time consumption. So we only retain two nonterminals at most in a rule.

### 7 Conclusion

In this paper, we present a hierarchical chunk-to-string model for statistical machine translation which can be seen as a compromise of the hierarchical phrase-based model and the tree-to-string model. With the help of shallow parsing, our model learns rules consisting of either words or chunks and compresses adjacent chunks in a rule to a nonterminal, then it searches for the best derivation under the SCFG defined by these rules. Our model can combine the merits of both the models: employing linguistic syntax to direct decoding, being syntax cohesive and robust to parsing errors. We refine the hierarchical chunk-to-string model into two models: a loose model (more similar to the hierarchical phrase-based model) and a tight model (more similar to the tree-to-string model).

Our experiments show that our decoder can improve translation performance significantly over the hierarchical phrase-based decoder and the tree-to-string decoder. Besides, the loose model gives a better performance while the tight model gives a faster speed.

## Abstract

We propose a simple generative, syntactic language model that conditions on overlapping windows of tree context (or *treelets*) in the same way that  $n$ -gram language models condition on overlapping windows of linear context. We estimate the parameters of our model by collecting counts from automatically parsed text using standard  $n$ -gram language model estimation techniques, allowing us to train a model on over one billion tokens of data using a single machine in a matter of hours. We evaluate on perplexity and a range of grammaticality tasks, and find that we perform as well or better than  $n$ -gram models and other generative baselines. Our model even competes with state-of-the-art discriminative models hand-designed for the grammaticality tasks, despite training on positive data alone. We also show fluency improvements in a preliminary machine translation experiment.

## 1 Introduction

$N$ -gram language models are a central component of all speech recognition and machine translation systems, and a great deal of research centers around refining models (Chen and Goodman, 1998), efficient storage (Pauls and Klein, 2011; Heafield, 2011), and integration into decoders (Koehn, 2004; Chiang, 2005). At the same time, because  $n$ -gram language models only condition on a local window of linear word-level context, they are poor models of long-range syntactic dependencies. Although several lines of work have proposed generative syntactic language models that improve on  $n$ -gram models for moderate amounts of data (Chelba, 1997; Xu et al., 2002; Charniak, 2001; Hall, 2004; Roark,

2004), these models have only recently been scaled to the impressive amounts of data routinely used by  $n$ -gram language models (Tan et al., 2011).

In this paper, we describe a generative, syntactic language model that conditions on local context *treelets*<sup>1</sup> in a parse tree, backing off to smaller *treelets* as necessary. Our model can be trained simply by collecting counts and using the same smoothing techniques normally applied to  $n$ -gram models (Kneser and Ney, 1995), enabling us to apply techniques developed for scaling  $n$ -gram models out of the box (Brants et al., 2007; Pauls and Klein, 2011). The simplicity of our training procedure allows us to train a model on a billion tokens of data in a matter of hours on a single machine, which compares favorably to the more involved training algorithm of Tan et al. (2011), who use a two-pass EM training algorithm that takes several days on several hundred CPUs using similar amounts of data.

The simplicity of our approach also contrasts with recent work on language modeling with tree substitution grammars (Post and Gildea, 2009), where larger *treelet* contexts are incorporated by using sophisticated priors to learn a segmentation of parse trees. Such an approach implicitly assumes that a “correct” segmentation exists, but it is not clear that this is true in practice. Instead, we build upon the success of  $n$ -gram language models, which do not assume a segmentation and instead score all overlapping contexts.

We evaluate our model in terms of perplexity, and show that we achieve the same performance as a state-of-the-art  $n$ -gram model. We also evaluate our model on several grammaticality tasks proposed in

---

<sup>1</sup>We borrow the term *treelet* from Quirk et al. (2005), who use it to refer to an arbitrary connected subgraph of a tree.

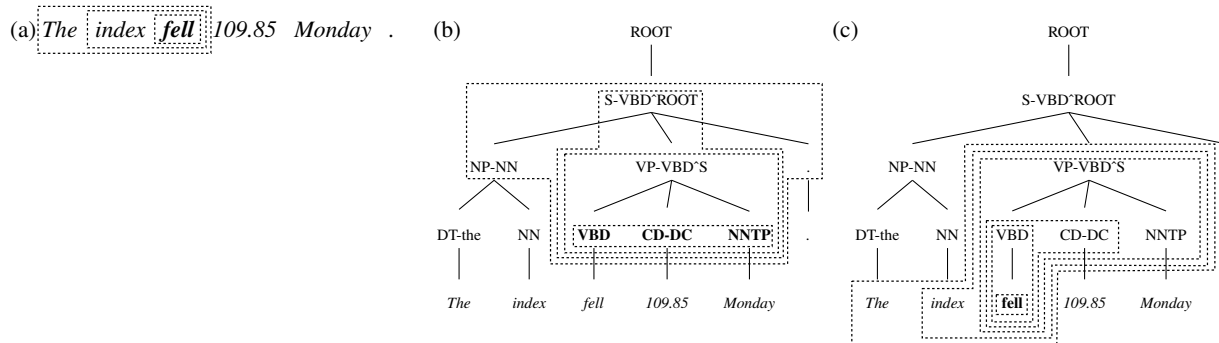

Figure 1: Conditioning contexts and back-off strategies for Markov models. The bolded symbol indicates the part of the tree/sentence being generated, and the dotted lines represent the conditioning contexts; back-off proceeds from the largest to the smallest context. (a) A trigram model. (b) The context used for non-terminal productions in our treelet model. For this context,  $P=VP-VBD^{\wedge}S$ ,  $P'=S-VBD^{\wedge}ROOT$ , and  $r'=S-VBD^{\wedge}ROOT \rightarrow NP-NN VP-VBD^{\wedge}S$ . (c) The context used for terminal productions in our treelet model. Here,  $P=VBD$ ,  $R=CD-DC$ ,  $r'=VP-VBD^{\wedge}S \rightarrow VBD CD-DC NNTP$ ,  $w_{-1}=index$ , and  $w_{-2}=The$ . Note that the tree is a modified version of a standard Penn Treebank parse – see Section 3 for details.

the literature (Okanojima and Tsujii, 2007; Foster et al., 2008; Cherry and Quirk, 2008) and show that it consistently outperforms an  $n$ -gram model as well as other head-driven and tree-driven generative baselines. Our model even competes with state-of-the-art discriminative classifiers specifically designed for each task, despite being estimated on positive data alone. We also show fluency improvements in a preliminary machine translation reranking experiment.

## 2 Treelet Language Modeling

The common denominator of most  $n$ -gram language models is that they assign probabilities roughly according to empirical frequencies for observed  $n$ -grams, but fall back to distributions conditioned on smaller contexts for unobserved  $n$ -grams, as shown in Figure 1(a). This type of smoothing is both highly robust and easy to implement, requiring only the collection of counts from data.

We would like to apply the same smoothing techniques to distributions over rule yields in a constituency tree, conditioned on contexts consisting of previously generated treelets (rules, nodes, etc.). Formally, let  $T$  be a constituency tree consisting of context-free rules of the form  $r = P \rightarrow C_1 \cdots C_d$ , where  $P$  is the parent symbol of rule  $r$  and  $C_1^d = C_1 \cdots C_d$  are its children. We wish to assign probabilities to trees<sup>2</sup>

<sup>2</sup>A distribution over trees also induces a distribution over sentences  $w_1^t$  given by  $p(w_1^t) = \sum_{T:s(T)=w_1^t} p(T)$ , where

$$p(T) = \prod_{r \in T} p(C_1^d | h)$$

where the conditioning context  $h$  is some portion of the already-generated parts of the tree. In this paper, we assume that the children of a rule are expanded from left to right, so that when generating the yield  $C_1^d$ , all treelets above and left of the parent  $P$  are available. Note that a raw PCFG would condition only on  $P$ , i.e.  $h = P$ .

As in the  $n$ -gram case, we would like to pick  $h$  to be large enough to capture relevant dependencies, but small enough that we can obtain meaningful estimates from data. We start with a straightforward choice of context: we condition on  $P$ , as well as the rule  $r'$  that generated  $P$ , as shown in in Figure 1(b).

Conditioning on the parent rule  $r'$  allows us to capture several important dependencies. First, it captures both  $P$  and its parent  $P'$ , which predicts the distribution over child symbols far better than just  $P$  (Johnson, 1998). Second, it captures positional effects. For example, subject and object noun phrases (NPs) have different distributions (Klein and Manning, 2003), and the position of an NP relative to a verb is a good indicator of this distinction. Finally, the generation of words at preterminals can condition on siblings, allowing the model to capture, for example, verb subcategorization frames.

We should be clear that we are not the first  $s(T)$  is the terminal yield of  $T$ .

to use back-off-based smoothing for syntactic language modeling – such techniques have been applied to models that condition on head-word contexts (Charniak, 2001; Roark, 2004; Zhang, 2009). Parent rule context has also been employed in translation (Vaswani et al., 2011). However, to our knowledge, we are the first to apply these techniques for language modeling on large amounts of data.

## 2.1 Lexical context

Although it is tempting to think that we can replace the left-to-right generation of  $n$ -gram models with the purely top-down generation of typical PCFGs, in practice, words are often highly predictive of the words that follow them – indeed,  $n$ -gram models would be terrible language models if this were not the case. To capture linear effects, we extend the context for terminal (lexical) productions to include the previous two words  $w_{-2}$  and  $w_{-1}$  in the sentence in addition to  $r'$ ; see Figure 1(c) for a depiction. This allows us to capture collocations and other lexical correlations.

## 2.2 Backing off

As with  $n$ -gram models, counts for rule yields conditioned on  $r'$  are sparse, and we must choose an appropriate back-off strategy. We handle terminal and non-terminal productions slightly differently.

For non-terminal productions, we back off from  $r'$  to  $P$  and its parent  $P'$ , and then to just  $P$ . That is, we back off from a rule-annotated grammar  $p(C_1^d|P, P', r')$  to a parent-annotated grammar (Johnson, 1998)  $p(C_1^d|P, P')$ , then to a raw PCFG  $p(C_1^d|P)$ . In order to generalize to unseen rule yields  $C_1^d$ , we further back off from the basic PCFG probability  $p(C_1^d|P)$  to  $p(C_i|C_{i-3}^{i-1}, P)$ , a 4-gram model over symbols  $C$  conditioned on  $P$ , interpolated with an unconditional 4-gram model  $p(C_i|C_{i-3}^{i-1})$ . In other words, we back off from a raw PCFG to

$$\lambda \prod_{i=1}^d p(C_i|C_{i-3}^{i-1}, P) + (1 - \lambda) \prod_{i=1}^d p(C_i|C_{i-3}^{i-1})$$

where  $\lambda = 0.9$  is an interpolation constant.

For terminal (i.e. lexical) productions, we first remove lexical context, backing off from

$p(w|P, R, r', w_{-1}, w_{-2})$  to  $p(w|P, R, r', w_{-1})$  and then  $p(w|P, R, r')$ . From there, we back off to  $p(w|P, R)$  where  $R$  is the sibling immediately to the right of  $P$ , then to a raw PCFG  $p(w|P)$ , and finally to a unigram distribution. We chose this scheme because  $p(w|P, R)$  allows, for example, a verb to be generated conditioned on the non-terminal category of the argument it takes (since arguments usually immediately follow verbs). We depict these two back-off schemes pictorially in Figure 1(b) and (c).

## 2.3 Estimation

Estimating the probabilities in our model can be done very simply using the same techniques (in fact, the same code) used to estimate  $n$ -gram language models. Our model requires estimates of four distributions:  $p(C_1^d|P, P', r')$ ,  $p(w|P, R, r', w_{-1}, w_{-2})$ ,  $p(C_i|C_{i-n+1}^{i-1}, P)$ , and  $p(C_i|C_{i-n+1}^{i-1})$ . In each case, we require empirical counts of treelet tuples in the same way that we require counts of word tuples for estimating  $n$ -gram language models.

There is one additional hurdle in the estimation of our model: while there exist corpora with human-annotated constituency parses like the Penn Treebank (Marcus et al., 1993), these corpora are quite small – on the order of millions of tokens – and we cannot gather nearly as many counts as we can for  $n$ -grams, for which billions or even trillions (Brants et al., 2007) of tokens are available on the Web. However, we can use one of several high-quality constituency parsers (Collins, 1997; Charniak, 2000; Petrov et al., 2006) to automatically generate parses. These parses may contain errors, but not all parsing errors are problematic for our model, since we only care about the sentences generated by our model and not the parses themselves. We show in our experiments that the addition of data with automatic parses does improve the performance of our language models across a range of tasks.

## 3 Tree Transformations

In the previous section, we described how to condition on rich parse context to better capture the distribution of English trees. While such context allows our model to capture many interesting dependencies, several important dependencies require additional attention. In this section, we describe a

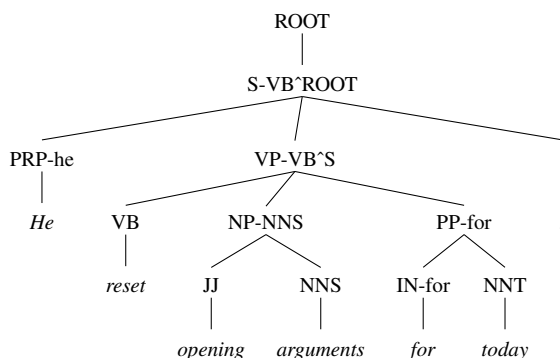

Figure 2: A sample parse from the Penn Treebank after the tree transformations described in Section 3. Note that we have not shown head tag annotations on preterminals because in that case, the head tag is the preterminal itself.

number of transformations of Treebank constituency parses that allow us to capture such dependencies. We list the annotations and deletions in the order in which they are performed. A sample transformed tree is shown in Figure 2.

**Temporal NPs** Following Klein and Manning (2003), we attempt to annotate temporal noun phrases. Although the Penn Treebank annotates temporal NPs, most off-the-shelf parsers do not retain these tags, and we do not assume their presence. Instead, we mark any noun that is the head of a NP-TMP constituent at least once in the Treebank as a temporal noun, so for example *today* would be tagged as NNT and *months* would be tagged as NNTS.

**Head Annotations** We annotate every non-terminal or preterminal with its head word if the head is a closed-class word<sup>3</sup> and with its head tag otherwise. Klein and Manning (2003) used head tag annotation extensively, though they applied their splits much more selectively.

**NP Flattening** We delete NPs dominated by other NPs, unless the child NPs are in coordination or apposition. These NPs typically occur when nouns are modified by PPs, as in (NP (NP (NN stock) (NNS sales)) (PP (IN by) (NNS traders))). By removing the dominated NP, we allow the production  $NNS \rightarrow sales$  to condition on the presence of a modifying PP (here a PP head-annotated with *by*).

**Number Annotations** Numbers are divided into five classes: CD-YR for numbers that consist of four digits (which are usually years); CD-NM for entirely numeric numbers; CD-DC for numbers that have a decimal; CD-

<sup>3</sup>We define the following to be closed class words: any punctuation; all inflections of the verbs *do*, *be*, and *have*; and any word tagged with IN, WDT, PDT, WP, WP\$, TO, WRB, RP, DT, SYM, EX, POS, PRP, AUX, or CC.

MX for numbers that mix letters and digits; and CD-AL for numbers that are entirely alphabetic.

**SBAR Flattening** We remove any sentential (S) nodes immediately dominated by an SBAR. S nodes under SBAR have very distinct distributions from other sentential nodes, mostly due to empty subjects and/or objects.

**VP Flattening** We remove any VPs immediately dominating a VP, unless it is conjoined with another VP. In the Treebank, chains of verbs (e.g. *will be going*) have a separate VP for each verb. By flattening such structures, we allow the main verb and its arguments to condition on the whole chain of verbs. This effect is particularly important for passive constructions.

**Gapped Sentence Annotation** Collins (1999) and Klein and Manning (2003) annotate nodes which have empty subjects. Because we only assume the presence of automatically derived parses, which do not produce the empty elements in the original Treebank, we must identify such elements on our own. We use a very simple procedure: we annotate all S or SBAR nodes that have a VP before any NPs.

**Parent Annotation** We annotate all VPs with their parent symbol. Because our treelet model already conditions on the parent, this has the effect of allowing verbs to condition on their grandparents. This was important for VPs under SBAR nodes, which often have empty objects. We also parent-annotated any child of the ROOT.

**Unary Deletion** We remove all unary productions except the root and preterminal productions, keeping only the bottom-most symbol. Because we are not interested in the internal labels of the trees, unaries are largely a nuisance, and their removal brings many symbols into the context of others.

## 4 Scoring a Sentence

Computing the probability of a sentence  $w_1^\ell$  under our model requires summing over all possible parses of  $w_1^\ell$ . Although our model can be formulated as a straightforward PCFG, allowing  $O(\ell^3)$  computation of this sum, the grammar constant for this PCFG would be unmanageably large (since every parent rule context would need its own state in the grammar), and extensive pruning would be in order.

In practice, however, language models are normally integrated into a decoder, a non-trivial task that is highly problem-dependent and beyond the scope of this paper. For machine translation, a model that builds target-side constituency parses, such as that of Galley et al. (2006), combined with an efficient pruning strategy like cube pruning (Chiang,

Table 1: The first four samples of length between 15 and 20 generated from the 5-GRAM and TREELET models.

2005), should be able to integrate our model without much difficulty.

That said, for evaluation purposes, whenever we need to query our model, we use the simple strategy of parsing a sentence using a black box parser, and summing over our model’s probabilities of the 1000-best parses.<sup>4</sup> Note that the bottleneck in this case is the parser, so our model can essentially score a sentence at the speed of a parser.

## 5 Experiments

We evaluate our model along several dimensions. We first show some sample generated sentences in Section 5.1. We report perplexity results in Section 5.2. In Section 5.3, we measure its ability to distinguish between grammatical English and various types of automatically generated, or *pseudo-negative*,<sup>5</sup> English. We report machine translation reranking results in Section 5.4.

### 5.1 Generating Samples

Because our model is generative, we can qualitatively assess it by generating samples and verifying that they are more syntactically coherent than other approaches. In Table 1, we show the first four samples of length between 15 and 20 generated from our model and a 5-gram model trained on the Penn Treebank.

<sup>4</sup>We found that using the 1-best worked just as well as the 1000-best on our grammaticality tasks, but significantly overestimated our model’s perplexities.

<sup>5</sup>We follow Okanojima and Tsujii (2007) in using the term pseudo-negative to highlight the fact that automatically generated negative examples might not actually be ungrammatical.

### 5.2 Perplexity

Perplexity is the standard intrinsic evaluation metric for language models. It measures the inverse of the per-word probability a model assigns to some held-out set of grammatical English (so lower is better). For training data, we constructed a large treebank by concatenating the WSJ and Brown portions of the Penn Treebank, the 50K BLLIP training sentences from Post (2011), and the AFP and APW portions of English Gigaword version 3 (Graff, 2003), totaling about 1.3 billion tokens. We used the human-annotated parses for the sentences in the Penn Treebank, but parsed the Gigaword and BLLIP sentences with the Berkeley Parser. Hereafter, we refer to this training data as our 1B corpus. We used Section 0 of the WSJ as our test corpus. Results are shown in Table 2. In addition to our TREELET model, we also show results for the following baselines:

**5-GRAM** A 5-gram interpolated Kneser-Ney model.

**PCFG-LA** The Berkeley Parser in language model mode.

**HEADLEX** A head-lexicalized model similar to, but more powerful<sup>6</sup> than, Collins Model 1 (Collins, 1999).

**PCFG** A raw PCFG.

**TREELET-TRANS** A PCFG estimated on the trees after the transformations of Section 3.

**TREELET-RULE** The TREELET-TRANS model with the parent rule context described in Section 2. This is equivalent to the full TREELET model without the lexical context described in Section 2.1.

<sup>6</sup>Specifically, like Collins Model 1, we generate a rule yield conditioned on parent symbol  $P$  and head word  $h$  by first generating its head symbol  $C_h$ , then generating the head words and symbols for left and right modifiers outwards from  $C_h$ . Unlike Model 1, which generates each modifier head and symbol conditioned only on  $C_h$ ,  $h$ , and  $P$ , we additionally condition on the previously generated modifier’s head and symbol and back off to Model 1.

Model	Perplexity
PCFG	1772
TREELET-TRANS	722
TREELET-RULE	329
TREELET	<b>198<sup>†</sup></b>
PCFG-LA	330**
HEADLEX	299
5-GRAM	207 <sup>†</sup>

Table 2: Perplexity of several generative models on Section 0 of the WSJ. The differences between scores marked with <sup>†</sup> are not statistically significant. PCFG-LA (marked with \*\*) was only trained on the WSJ and Brown corpora because it does not scale to large amounts of data.

We used the Berkeley LM toolkit (Pauls and Klein, 2011), which implements Kneser-Ney smoothing, to estimate all back-off models for both  $n$ -gram and treelet models. To deal with unknown words, we use the following strategy: after the first 10000 sentences, whenever we see a new word in our training data, we replace it with a signature<sup>7</sup> 10% of the time.

Our model outperforms all other generative models, though the improvement over the  $n$ -gram model is not statistically significant. Note that because we use a  $k$ -best approximation for the sum over trees, all perplexities (except for PCFG-LA and 5-GRAM) are pessimistic bounds.

### 5.3 Classification of Pseudo-Negative Sentences

We make use of three kinds of automatically generated pseudo-negative sentences previously proposed in the literature: Okanohara and Tsujii (2007) proposed generating pseudo-negative examples from a trigram language model; Foster et al. (2008) create “noisy” sentences by automatically inserting a single error into grammatical sentences with a script that randomly deletes, inserts, or misspells a word; and Och et al. (2004) and Cherry and Quirk (2008) both use the 1-best output of a machine translation system. Examples of these three types of pseudo-negative data are shown in Table 3. We evaluate our model’s ability to distinguish positive from pseudo-negative data, and compare against generative baselines and state-of-the-art discriminative methods.

<sup>7</sup>We use signatures generated by the Berkeley Parser. These signatures capture surface features such as capitalization, presents of digits, and common suffixes. For example, the word *vexing* would be replaced with the signature UNK-ing.

<b>Noisy</b>	<i>There was were many contributors.</i>
<b>Trigram</b>	<i>For years in dealer immediately .</i>
<b>MT</b>	<i>we must further steps .</i>

Table 3: Sample pseudo-negative sentences.

We would like to use our model to make grammaticality judgements, but as a generative model it can only provide us with probabilities. Simply thresholding generative probabilities, even with a separate threshold for each length, has been shown to be very ineffective for grammaticality judgements, both for  $n$ -gram and syntactic language models (Cherry and Quirk, 2008; Post, 2011). We used a simple measure for isolating the syntactic likelihood of a sentence: we take the log-probability under our model and subtract the log-probability under a unigram model, then normalize by the length of the sentence.<sup>8</sup> This measure, which we call the *syntactic log-odds ratio* (SLR), is a crude way of “subtracting out” the semantic component of the generative probability, so that sentences that use rare words are not penalized for doing so.

#### 5.3.1 Trigram Classification

To facilitate comparison with previous work, we used the same negative corpora as Post (2011) for trigram classification. They randomly selected 50K train, 3K development, and 3K positive test sentences from the BLLIP corpus, then trained a trigram model on 450K BLLIP sentences and generated 50K train, 3K development, and 3K negative sentences. We parsed the 50K positive training examples of Post (2011) with the Berkeley Parser and used the resulting treebank to train a treelet language model. We set an SLR threshold for each model on the 6K positive and negative development sentences.

Results are shown in Table 4. In addition to our generative baselines, we show results for the discriminative models reported in Cherry and Quirk (2008) and Post (2011). The former train a latent PCFG support vector machine for binary classification (LSVM). The latter report results for two binary classifiers: RERANK uses the reranking features of Charniak and Johnson (2005), and TSG uses

<sup>8</sup>Och et al. (2004) also report using a parser probability normalized by the unigram probability (but not length), and did not find it effective. We assume this is either because the length-normalization is important, or because their choice of syntactic language model was poor.

Generative

TSG	89.9	–
RERANK	<b>93.0</b>	–

Table 4: Classification accuracy for trigram pseudo-negative sentences on the BLLIP corpus. The number reported for PCFG-LA is marked with a \* to indicate that this model was trained on the training section of the WSJ, not the BLLIP corpus. The number reported for LSVM (marked with \*\*) was evaluated on a different random split of the BLLIP corpus, and so is not directly comparable.

indicator features extracted from a tree substitution grammar derivation of each sentence.

Our TREELET model performs nearly as well as the TSG method, and substantially outperforms the LSVM method, though the latter was not tested on the same random split. Interestingly, the TREELET-RULE baseline, which removes lexical context from our model, outperforms the full model. This is likely because the negative data is largely coherent at the trigram level (because it was generated from a trigram model), and the full model is much more sensitive to trigram coherence than the TREELET-RULE model. This also explains the poor performance of the 5-GRAM model.

We emphasize that the discriminative baselines are *specifically* trained to separate trigram text from natural English, while our model is trained on positive examples alone. Indeed, the methods in Post (2011) are simple binary classifiers, and it is not clear that these models would be properly calibrated for any other task, such as integration in a decoder.

One of the design goals of our system was that it be scalable. Unlike some of the discriminative baselines, which require expensive operations<sup>9</sup> on

<sup>9</sup>It is true that in order to train our system, one must parse large amounts of training data, which can be costly, though it only needs to be done once. In contrast, even with observed training trees, the discriminative algorithms must still iteratively perform expensive operations (like parsing) for each sentence, and a new model must be trained for new types of negative data.

Model	Pairwise		Independent	
	WSJ	1B	WSJ	1B
PCFG	79.1	77.0	58.9	58.6
TREELET-RULE	90.3	94.4	63.8	<b>66.2</b>

Foster et al. (2008)	–	–	<b>65.9</b>	–

Table 5: Classification accuracies on the noisy WSJ for models trained on WSJ Sections 2-21 and our 1B token corpus. “Pairwise” accuracy is the fraction of correct sentences whose SLR score was higher than its noisy version, and “independent” refers to standard binary classification accuracy.

each training sentence, we can very easily scale our model to much larger amounts of data. In Table 4, we also show the performance of the generative models trained on our 1B corpus. All generative models improve, but TREELET-RULE remains the best, now outperforming the RERANK system, though of course it is likely that RERANK would improve if it could be scaled up to more training data.

### 5.3.2 “Noisy” Classification

We also evaluate the performance of our model on the task of distinguishing the noisy WSJ sentences of Foster et al. (2008) from their original versions. We use the noisy versions of Section 0 and 23 produced by their error-generating procedure. Because they only report classification results on Section 0, we used Section 23 to tune an SLR threshold, and tested our model on Section 0. We show the results of both independent and pairwise classification for the WSJ and 1B training sets in Table 5. Note that independent classification is much more difficult than for the trigram data, because sentences contain at most one change, which may not even result in an ungrammaticality. Again, our model outperforms the  $n$ -gram model for both types of classification, and achieves the same performance as the discriminative system of Foster et al. (2008), which is state-of-the-art for this data set. The TREELET-RULE system again slightly outperforms the full TREELET model at independent classification, though not at pairwise classification. This probably reflects the fact that semantic coherence can still influence the SLR score, despite our efforts to subtract it out. Because the TREELET model includes lexical context, it is more sensitive to seman-

	French	German	Chinese
5-GRAM	44.8	37.8	60.0
TREELET	<b>57.9</b>	<b>66.0</b>	<b>83.8</b>

Table 6: Pairwise comparison accuracy of MT output against a reference translation for French, German, and Chinese. The BLEU scores for these outputs are 32.7, 27.8, and 20.8. This task becomes easier, at least for our TREELET model, as translation quality drops. Cherry and Quirk (2008) report an accuracy of 71.9% on a similar experiment with German a source language, though the translation system and training data were different so the numbers are not comparable. In particular, their translations had a lower BLEU score, making their task easier.

tic coherence and thus more likely to misclassify semantically coherent but ungrammatical sentences. For pairwise comparisons, where semantic coherence is effectively held constant, such sentences are not problematic.

### 5.3.3 Machine Translation Classification

We follow Och et al. (2004) and Cherry and Quirk (2008) in evaluating our language models on their ability to distinguish the 1-best output of a machine translation system from a reference translation in a pairwise fashion. Unfortunately, we do not have access to the data used in those papers, so a direct comparison is not possible. Instead, we collected the English output of Moses (Hoang et al., 2007), using both French and German as source language, trained on the Europarl corpus used by WMT 2009.<sup>10</sup> We also collected the output of Joshua (Li et al., 2009) trained on 500K sentences of GALE Chinese-English parallel newswire. We trained both our TREELET model and a 5-GRAM model on the union of our 1B corpus and the English sides of our parallel corpora.

In Table 6, we show the pairwise comparison accuracy (using SLR) on these three corpora. We see that our system prefers the reference much more often than the 5-GRAM language model.<sup>11</sup> However, we also note that the easiness of the task is correlated with the quality of translations (as measured in BLEU score). This is not surprising – high-quality translations are often grammatical and even a per-

<sup>10</sup><http://www.statmt.org/wmt09>

<sup>11</sup>We note that the  $n$ -gram language model used by the MT system was much smaller than the 5-GRAM model, as they were only trained on the English sides of their parallel data.

fect language model might not be able to differentiate such translations from their references.

### 5.4 Machine Translation Fluency

We also carried out reranking experiments on 1000-best lists from Moses using our syntactic language model as a feature. We did not find that the use of our syntactic language model made any statistically significant increases in BLEU score. However, we noticed in general that the translations favored by our model were more fluent, a useful improvement to which BLEU is often insensitive. To confirm this, we carried out an Amazon Mechanical Turk experiment where users from the United States were asked to compare translations using our TREELET language model as the language model feature to those using the 5-GRAM model.<sup>12</sup> We had 1000 such translation pairs rated by 4 separate Turkers each. Although these two hypothesis sets had the same BLEU score (up to statistical significance), the Turkers preferred the output obtained using our syntactic language model 59% of the time, indicating that our model had managed to pick out more fluent hypotheses that nonetheless were of the same BLEU score. This result was statistically significant with  $p < 0.001$  using bootstrap resampling.

## 6 Conclusion

We have presented a simple syntactic language model that can be estimated using standard  $n$ -gram smoothing techniques on large amounts of data. Our model outperforms generative baselines on several evaluation metrics and achieves the same performance as state-of-the-art discriminative classifiers specifically trained on several types of negative data.

### Acknowledgments

We would like to thank David Hall for some modeling suggestions and the anonymous reviewers for their comments. We thank both Matt Post and Jennifer Foster for providing us with their corpora. This work was partially supported by a Google Fellowship to the first author and by BBN under DARPA contract HR0011-12-C-0014.

<sup>12</sup>We used translations from the baseline Moses system of Section 5.3.3 with German as the input language. For each language model, we took  $k$ -best lists from the baseline system and replaced the baseline LM score with the new model’s score. We then retrained all feature weights with MERT on the tune set, and selected the 1-best output on the test set.

## Abstract

The problem addressed in this paper is to segment a given multilingual document into segments for each language and then identify the language of each segment. The problem was motivated by an attempt to collect a large amount of linguistic data for non-major languages from the web. The problem is formulated in terms of obtaining the minimum description length of a text, and the proposed solution finds the segments and their languages through dynamic programming. Empirical results demonstrating the potential of this approach are presented for experiments using texts taken from the Universal Declaration of Human Rights and Wikipedia, covering more than 200 languages.

## 1 Introduction

For the purposes of this paper, a multilingual text means one containing text segments, limited to those longer than a clause, written in different languages. We can often find such texts in linguistic resources collected from the World Wide Web for many non-major languages, which tend to also contain portions of text in a major language. In automatic processing of such multilingual texts, they must first be segmented by language, and the language of each segment must be identified, since many state-of-the-art NLP applications are built by learning a gold standard for one specific language. Moreover, segmentation is useful for other objectives such as collecting linguistic resources for non-major languages and automatically removing portions written in major languages, as noted above. The study reported here was motivated by this objective. The problem addressed in this article is thus to segment a multilingual text by language and identify the language of each segment. In addition, for our objective, the set of target languages consists of not only major languages but also many non-major languages: more than 200 languages in total.

Previous work that directly concerns the problem

addressed in this paper is rare. The most similar previous work that we know of comes from two sources and can be summarized as follows. First, (Teahan, 2000) attempted to segment multilingual texts by using text segmentation methods used for non-segmented languages. For this purpose, he used a gold standard of multilingual texts annotated by borders and languages. This segmentation approach is similar to that of word segmentation for non-segmented texts, and he tested it on six different European languages. Although the problem setting is similar to ours, the formulation and solution are different, particularly in that our method uses only a monolingual gold standard, not a multilingual one as in Teahan's study. Second, (Alex, 2005) (Alex et al., 2007) solved the problem of detecting words and phrases in languages other than the principal language of a given text. They used statistical language modeling and heuristics to detect foreign words and tested the case of English embedded in German texts. They also reported that such processing would raise the performance of German parsers. Here again, the problem setting is similar to ours but not exactly the same, since the embedded text portions were assumed to be words. Moreover, the authors only tested for the specific language pair of English embedded in German texts. In contrast, our work considers more than 200 languages, and the portions of embedded text are larger: up to the paragraph level to accommodate the reality of multilingual texts. The extension of our work to address the foreign word detection problem would be an interesting future work.

From a broader view, the problem addressed in this paper is further related to two genres of previous work. The first genre is text segmentation. Our problem can be situated as a sub-problem from the viewpoint of language change. A more common setting in the NLP context is segmentation into semantically coherent text portions, of which a representative method is *text tiling* as reported by (Hearst, 1997). There could be other possible bases for text

segmentation, and our study, in a way, could lead to generalizing the problem. The second genre is classification, and the specific problem of text classification by language has drawn substantial attention (Grefenstette, 1995) (Kruengkrai et al., 2005) (Kikui, 1996). Current state-of-the-art solutions use machine learning methods for languages with abundant supervision, and the performance is usually high enough for practical use. This article concerns that problem together with segmentation but has another particularity in aiming at classification into a substantial number of categories, i.e., more than 200 languages. This means that the amount of training data has to remain small, so the methods to be adopted must take this point into consideration. Among works on text classification into languages, our proposal is based on previous studies using cross-entropy such as (Teahan, 2000) and (Juola, 1997). We explain these works in further detail in §3.

This article presents one way to formulate the segmentation and identification problem as a combinatorial optimization problem; specifically, to find the set of segments and their languages that minimizes the description length of a given multilingual text. In the following, we describe the problem formulation and a solution to the problem, and then discuss the performance of our method.

## 2 Problem Formulation

In our setting, we assume that a small amount (up to kilobytes) of monolingual plain text sample data is available for every language, e.g., the Universal Declaration of Human Rights, which serves to generate the language model used for language identification. This entails two sub-assumptions.

First, we assume that for all multilingual text, every text portion is written in one of the given languages; there is no input text of an unknown language without learning data. In other words, we use supervised learning. In line with recent trends in unsupervised segmentation, the problem of finding segments without supervision could be solved through approaches such as Bayesian methods; however, we report our result for the supervised setting since we believe that every segment must be labeled by language to undergo further processing.

Second, we cannot assume a large amount of

learning data, since our objective requires us to consider segmentation by both major and non-major languages. For most non-major languages, only a limited amount of corpus data is available.<sup>1</sup>

This constraint suggests the difficulty of applying certain state-of-the-art machine learning methods requiring a large learning corpus. Hence, our formulation is based on the minimum description length (MDL), which works with relatively small amounts of learning data.

In this article, we use the following terms and notations. A multilingual text to be segmented is denoted as  $X = x_1, \dots, x_{|X|}$ , where  $x_i$  denotes the  $i$ -th character of  $X$  and  $|X|$  denotes the text's length. *Text segmentation by language* refers here to the process of segmenting  $X$  by a set of borders  $\mathbb{B} = [B_1, \dots, B_{|\mathbb{B}|}]$ , where  $|\mathbb{B}|$  denotes the number of borders, and each  $B_i$  indicates the location of a language border as an offset number of characters from the beginning. Note that a pair of square brackets indicates a list. Segmentation in this paper is character-based, i.e., a  $B_i$  may refer to a position inside a word. The list of *segments* obtained from  $\mathbb{B}$  is denoted as  $\mathbb{X} = [X_0, \dots, X_{|\mathbb{B}|}]$ , where the concatenation of the segments equals  $X$ . The language of each segment  $X_i$  is denoted as  $L_i$ , where  $L_i \in \mathcal{L}$ , the set of languages. Finally,  $\mathbb{L} = [L_0, \dots, L_{|\mathbb{B}|}]$  denotes the sequence of languages corresponding to each segment  $X_i$ . The elements in each adjacent pair in  $\mathbb{L}$  must be different.

We formulate the problem of segmenting a multilingual text by language as follows. Given a multilingual text  $X$ , the segments  $\mathbb{X}$  for a list of borders  $\mathbb{B}$  are obtained with the corresponding languages  $\mathbb{L}$ . Then, the total description length is obtained by calculating each description length of a segment  $X_i$  for the language  $L_i$ :

$$(\hat{\mathbb{X}}, \hat{\mathbb{L}}) = \arg \min_{\mathbb{X}, \mathbb{L}} \sum_{i=0}^{|\mathbb{B}|} dl_{L_i}(X_i). \quad (1)$$

The function  $dl_{L_i}(X_i)$  calculates the description length of a text segment  $X_i$  through the use of a language model for  $L_i$ . Note that the actual total description length must also include an additional term,  $\log_2 |X|$ , giving information on the number of segments (with the maximum to be segmented

<sup>1</sup>In fact, our first motivation was to collect a certain amount of corpus data for non-major languages from Wikipedia.

by each character). Since this term is a common constant for all possible segmentations and the minimization of formula (1) is not affected by this term, we will ignore it.

The model defined by (1) is additive for  $X_i$ , so the following formula can be applied to search for language  $L_i$  given a segment  $X_i$ :

$$\hat{L}_i = \arg \min_{L_i \in \mathcal{L}} dl_{L_i}(X_i), \quad (2)$$

under the constraint that  $L_i \neq L_{i-1}$  for  $i \in \{1, \dots, |\mathbb{B}|\}$ . The function  $dl$  can be further decomposed as follows to give the description length in an information-theoretic manner:

$$dl_{L_i}(X_i) = -\log_2 P_{L_i}(X_i) + \log_2 |X| + \log_2 |\mathcal{L}| + \gamma. \quad (3)$$

Here, the first term corresponds to the code length of the text chunk  $X_i$  given a language model for  $L_i$ , which in fact corresponds to the cross-entropy of  $X_i$  for  $L_i$  multiplied by  $|X_i|$ . The remaining terms give the code lengths of the parameters used to describe the length of the first term: the second term corresponds to the segment location; the third term, to the identified language; and the fourth term, to the language model of language  $L_i$ . This fourth term will differ according to the language model type; moreover, its value can be further minimized through formula (2). Nevertheless, since we use a uniform amount of training data for every language, and since varying  $\gamma$  would prevent us from improving the efficiency of dynamic programming, as explained in §4, in this article we set  $\gamma$  to a constant obtained empirically.

Under this formulation, therefore, when detecting the language of a segment as in formula (2), the terms of formula (3) other than the first term will be constant: what counts is only the first term, similarly to much of the previous work explained in the following section. We thus perform language detection itself by minimizing the cross-entropy rather than the MDL. For segmentation, however, the constant terms function as overhead and also serve to prohibit excessive decomposition.

Next, after briefly introducing methods to calculate the first term of formula (3), we explain the solution to optimize the combinatorial problem of formula (1).

### 3 Calculation of Cross-Entropy

The first term of (3),  $-\log_2 P_{L_i}(X_i)$ , is the cross-entropy of  $X_i$  for  $L_i$  multiplied by  $|X_i|$ . Various methods for computing cross-entropy have been proposed, and these can be roughly classified into two types based on different methods of universal coding and the language model. For example, (Benedetto et al., 2002) and (Cilibrasi and Vitányi, 2005) used the universal coding approach, whereas (Teahan and Harper, 2001) and (Sibun and Reynar, 1996) were based on language modeling using PPM and Kullback-Leibler divergence, respectively.

In this section, we briefly introduce two methods previously studied by (Juola, 1997) and (Teahan, 2000) as representative of the two types, and we further explain a modification that we integrate into the final optimization problem. We tested several other coding methods, but they did not perform as well as these two methods.

#### 3.1 Mean of Matching Statistics

(Farach et al., 1994) proposed a method to estimate the entropy, through a simplified version of the LZ algorithm (Ziv and Lempel, 1977), as follows. Given a text  $X = x_1x_2 \dots x_ix_{i+1} \dots$ ,  $Len_i$  is defined as the longest match length for two substrings  $x_1x_2 \dots x_i$  and  $x_{i+1}x_{i+2} \dots$ . In this article, we define the longest match for two strings A and B as the shortest prefix of string B that is not a substring of A. Letting the average of  $Len_i$  be  $E[Len]$ , Farach proved that  $|E[Len] - \frac{\log_2 i}{H(X)}|$  probabilistically converges to zero as  $i \rightarrow \infty$ , where  $H(X)$  indicates the entropy of  $X$ . Then,  $H(X)$  is estimated as

$$\hat{H}(X) = \frac{\log_2 i}{E[Len]}.$$

(Juola, 1997) applied this method to estimate the cross-entropy of two given texts. For two strings  $Y = y_1y_2 \dots y_{|Y|}$  and  $X = x_1x_2 \dots x_{|X|}$ , let  $Len_i(Y)$  be the match length starting from  $x_i$  of  $X$  for  $Y^2$ . Based on this formulation, the cross-entropy is approximately estimated as

$$\hat{J}_Y(X) = \frac{\log_2 |Y|}{E[Len_i(Y)]}.$$

<sup>2</sup>This is called a *matching statistics* value, which explains the subsection title.

Since formula (1) of §2 is based on adding the description length, it is important that the whole value be additive to enable efficient optimization (as will be explained in §4). We thus modified Juola’s method as follows to make the length additive:

$$\hat{J}'_Y(X) = E \left[ \frac{\log_2 |Y|}{Len_i(Y)} \right].$$

Although there is no mathematical guarantee that  $\hat{J}_Y(X)$  or  $\hat{J}'_Y(X)$  actually converges to the cross-entropy, our empirical tests showed a good estimate for both cases<sup>3</sup>. In this article, we use  $\hat{J}'_Y(X)$  as a function to obtain the cross-entropy and for multiplication by  $|X|$  in formula (3).

### 3.2 PPM

As a representative method for calculating the cross-entropy through statistical language modeling, we adopt prediction by partial matching (PPM), a language-based encoding method devised by (Cleary and Witten, 1984). It has the particular characteristic of using a variable  $n$ -gram length, unlike ordinary  $n$ -gram models<sup>4</sup>. It models the probability of a text  $X$  with a learning corpus  $Y$  as follows:

$$\begin{aligned} P_Y(X) &= P_Y(x_1 \dots x_{|X|}) \\ &= \prod_{t=1}^{|X|} P_Y(x_t | x_{t-1} \dots x_{\max(1, t-n)}), \end{aligned}$$

where  $n$  is a parameter of PPM, denoting the maximum length of the  $n$ -grams considered in the model<sup>5</sup>. The probability  $P_Y(X)$  is estimated by *escape probabilities* favoring the longer sequences appearing in the learning corpus (Bell et al., 1990). The total code length of  $X$  is then estimated as  $-\log P_Y(X)$ . Since this value is additive and gives the total code length of  $X$  for language  $Y$ , we adopt this value in our approach.

## 4 Segmentation by Dynamic Programming

By applying the above methods, we propose a solution to formula (1) through dynamic programming.

<sup>3</sup>This modification means that the original  $\hat{J}_Y(X)$  is obtained through the harmonic mean, with  $Len$  obtained through the arithmetic mean, whereas  $\hat{J}'_Y(X)$  is obtained through the arithmetic mean with  $Len$  as the harmonic mean.

<sup>4</sup>In the context of NLP, this is known as Witten-Bell smoothing.

<sup>5</sup>In the experiments reported here,  $n$  is set to 5 throughout.

Considering the additive characteristic of the description length formulated previously as formula (1), we denote the minimized description length for a given text  $X$  simply as  $DP(X)$ , which can be decomposed recursively as follows<sup>6</sup>:

$$\begin{aligned} DP(X) &= \min_{t \in \{0, \dots, |X|\}, L \in \mathcal{L}} \{ DP(x_0 \dots x_{t-1}) \\ &\quad + dl_L(x_t \dots x_{|X|}) \}, \end{aligned} \quad (4)$$

In other words, the computation of  $DP(X)$  is decomposed into obtaining the addition of two terms by searching through  $t \in \{0, \dots, |X|\}$  and  $L \in \mathcal{L}$ . The first term gives the MDL for the first  $t$  characters of text  $X$ , while the second term,  $dl_L(x_{t+1} \dots x_{|X|})$ , gives the description length of the remaining characters under the language model for  $L$ .

We can straightforwardly implement this recursive computation through dynamic programming, by managing a table of size  $|X| \times |\mathcal{L}|$ . To fill a cell of this table, formula (4) suggests referring to  $t \times |\mathcal{L}|$  cells and calculating the description length of the rest of the text for  $O(|X| - t)$  cells for each language. Since  $t$  ranges up to  $|X|$ , the brute-force computational complexity is  $O(|X|^3 \times |\mathcal{L}|^2)$ .

The complexity can be greatly reduced, however, when the function  $dl$  is additive. First, the description length can be calculated from the previous result, decreasing  $O(|X| - t)$  to  $O(1)$  (to obtain the code length of an additional character). Second, the referred number of cells  $t \times |\mathcal{L}|$  is in fact  $U \times |\mathcal{L}|$ , with  $U \ll |X|$ : for MMS,  $U$  can be proven to be  $O(\log |Y|)$ , where  $|Y|$  is the maximum length among the learning corpora; and for PPM,  $U$  corresponds to the maximum length of an  $n$ -gram. Third, this factor  $U \times |\mathcal{L}|$  can be further decreased to  $U \times 2$ , since it suffices to possess the results for the two<sup>7</sup> best languages in computing the first term of (4). Consequently, the complexity decreases to  $O(U \times |X| \times |\mathcal{L}|)$ .

<sup>6</sup>This formula can be used directly to generate a set  $\mathbb{L}$  in which all adjacent elements differ. The formula can also be used to generate segments for which some adjacent languages coincide and then further to generate  $\mathbb{L}$  through post-processing by concatenating segments of the same language.

<sup>7</sup>This number means the two best scores for different languages, which is required to obtain  $\mathbb{L}$  directly: in addition to the best score, if the language of the best coincides with  $L$  in formula (4), then the second best is also needed. If segments are subjected to post-processing, this value can be one.

## 5 Experimental Setting

### 5.1 Monolingual Texts (Training / Test Data)

In this work, monolingual texts were used both for training the cross-entropy computation and as test data for cross-validation: the training data does not contain any test data at all. Monolingual texts were also used to build multilingual texts, as explained in the following subsection.

Texts were collected from the World Wide Web and consisted of two sets. The first data set consisted of texts from the Universal Declaration of Human Rights (UDHR)<sup>8</sup>. We consider UDHR the most suitable text source for our purpose, since the content of every monolingual text in the declaration is unique. Moreover, each text has the tendency to maximally use its own language and avoid vocabulary from other languages. Therefore, UDHR-derived results can be considered to provide an empirical upper bound on our formulation. The set  $\mathcal{L}$  consists of 277 languages, and the texts consist of around 10,000 characters on average.

The second data set was Wikipedia data from Wikipedia Downloads<sup>9</sup>, denoted as “Wiki” in the following discussion. We automatically assembled the data through the following steps. First, tags in the Wikipedia texts were removed. Second, short lines were removed since they typically are not sentences. Third, the amount of data was set to 10,000 characters for every language, in correspondence with the size of the UDHR texts. Note that there is a limit to the complete cleansing of data. After these steps, the set  $\mathcal{L}$  contained 222 languages with sufficient data for the experiments.

Many languages adopt writing systems other than the Latin alphabet. The numbers of languages for various representative writing systems are listed in Table 1 for both UDHR and Wiki, while the Ap-

pendix at the end of the article lists the actual languages. Note that in this article, a character means a Unicode character throughout, which differs from a character rendered in block form for some writing systems.

To evaluate language identification for monolingual texts, as will be reported in §6.1, we conducted five-times cross-validation separately for both data sets. We present the results in terms of the average accuracy  $A_{\mathbb{L}}$ , the ratio of the number of texts with a correctly identified language to  $|\mathcal{L}|$ .

### 5.2 Multilingual Texts (Test Data)

Multilingual texts were needed only to test the performance of the proposed method. In other words, we trained the model only through monolingual data, as mentioned above. This differs from the most similar previous study (Teahan, 2000), which required multilingual learning data.

The multilingual texts were generated artificially, since multilingual texts taken directly from the web have other issues besides segmentation. First, proper nouns in multilingual texts complicate the final judgment of language and segment borders. In practical application, therefore, texts for segmentation must be preprocessed by named entity recognition, which is beyond the scope of this work. Second, the sizes of text portions in multilingual web texts differ greatly, which would make it difficult to evaluate the overall performance of the proposed method in a uniform manner.

Consequently, we artificially generated two kinds of test sets from a monolingual corpus. The first is a set of multilingual texts, denoted as  $Test_1$ , such that each text is the conjunction of two portions in different languages. Here, the experiment is focused on segment border detection, which must segment the text into two parts, provided that there are two languages.  $Test_1$  includes test data for all language pairs, obtained by five-times cross-validation, giving  $25 \times |\mathcal{L}| \times (|\mathcal{L}| - 1)$  multilingual texts. Each portion of text for a single language consists of 100 characters taken from a random location within the test data.

The second kind of test set is a set of multilingual texts, denoted as  $Test_2$ , each consisting of  $k$  segments in different languages. For the experiment,  $k$  is not given to the procedure, and the task is to obtain  $k$  as well as  $\mathbb{B}$  and  $\mathbb{L}$  through recursion.  $Test_2$

<sup>8</sup><http://www.ohchr.org/EN/UDHR/Pages/Introduction.aspx>

<sup>9</sup><http://download.wikimedia.org/>

was generated through the following steps:

1. Choose  $k$  from among  $1, \dots, 5$ .
2. Choose  $k$  languages randomly from  $\mathcal{L}$ , where some of the  $k$  languages can overlap.
3. Perform five-times cross-validation on the texts of all languages. Choose a text length randomly from  $\{40, 80, 120, 160\}$ , and randomly select this many characters from the test data.
4. Shuffle the  $k$  languages and concatenate the text portions in the resultant order.

For this  $Test_2$  data set, every plot in the graphs shown in §6.2 was obtained by randomly averaging 1,000 tests.

By default, the possibility of segmentation is considered at every character offset in a text, which provides a *lower bound* for the proposed method. Although language change within the middle of a word does occur in real multilingual documents, it might seem more realistic to consider language change at word borders. Therefore, in addition to choosing  $\mathbb{B}$  from  $\{1, \dots, |X|\}$ , we also tested our approach under the constraint of choosing borders from *bordering locations*, which are the locations of spaces. In this case,  $\mathbb{B}$  is chosen from this subset of  $\{1, \dots, |X|\}$ , and, in step 3 above, text portions are generated so as to end at these bordering locations.

Given a multilingual text, we evaluate the outputs  $\mathbb{B}$  and  $\mathbb{L}$  through the following scores:

$P_{\mathbb{B}}/R_{\mathbb{B}}$ : Precision/recall of the borders detected (i.e., the correct borders detected, divided by the detected/correct border).

$P_{\mathbb{L}}/R_{\mathbb{L}}$ : Precision/recall of the languages detected (i.e., the correct languages detected, divided by the detected/correct language).

$P_s$  and  $R_s$  are obtained by changing the parameter  $\gamma$  given in formula (3), which ranges over  $1, 2, 4, \dots, 256$  bits. In addition, we verify the speed, i.e., the average time required for processing a text.

Although there are web pages consisting of texts in more than 2 languages, we rarely see a web page containing 5 languages at the same time. Therefore,  $Test_1$  reflects the most important case of 2 languages only, whereas  $Test_2$  reflects the case of multiple languages to demonstrate the general potential of the proposed approach.

The experiment reported here might seem like a case of over-specification, since all languages are considered equally likely to appear. Since our motivation has been to eliminate a portion in a major

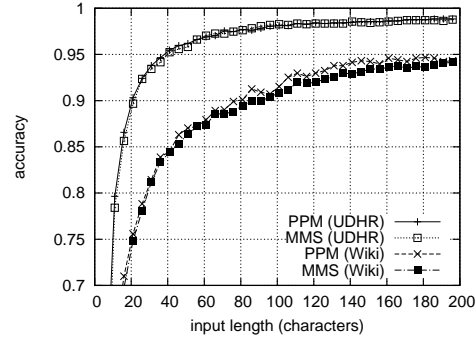

Figure 1: Accuracy of language identification for monolingual texts

language from the text, there could be a formulation specific to the problem. We consider it trivial, however, to specify such a narrow problem within our formulation, and it will lead to higher performance than that of the reported results, in any case. Therefore, we believe that our general formulation and experiment show the broadest potential of our approach to solving this problem.

## 6 Experimental Results

### 6.1 Language Identification Performance

We first show the performance of language identification using formula (2), which is used as the component of the text segmentation by language. Figure 1 shows the results for language identification of monolingual texts with the UDHR and Wiki test data. The horizontal axis indicates the size of the input text in characters, the vertical axis indicates the accuracy  $A_{\mathbb{L}}$ , and the graph contains four plots<sup>10</sup> for MMS and PPM for each set of data.

Overall, all plots rise quickly despite the severe conditions of a large number of languages (over 200), a small amount of input data, and a small amount of learning data. The results show that language identification through cross-entropy is promising.

Two further global tendencies can be seen. First, the performance was higher for UDHR than for Wiki. This is natural, since the content of Wikipedia is far broader than that of UDHR. In the case of UDHR, when the test data had a length of 40 characters, the accuracy was over 95% for both the PPM and the MMS methods. Second, PPM achieved

<sup>10</sup>The results for PPM and MMS for UDHR are almost the same, so the graph appears to contain only three plots.

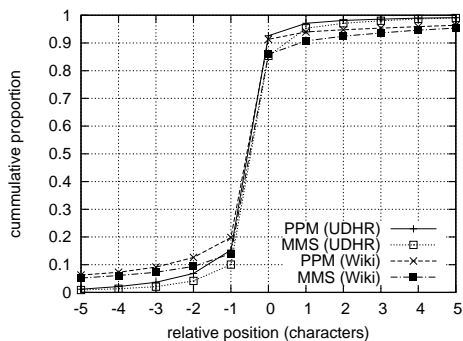

Figure 2: Cumulative distribution of segment borders

slightly better performance than did MMS. When the test data amounted to 100 characters, PPM achieved language identification with accuracy of about 91.4%. For MMS, the identification accuracy was a little less significant and was about 90.9% even with 100 characters of test data.

The amount of learning data seemed sufficient for both cases, with around 8,000 characters. In fact, we conducted tests with larger amounts of learning data and found a faster rise with respect to the input length, but the maximum possible accuracy did not show any significant increase.

Errors resulted from either noise or mistakes due to the language family. The Wikipedia test data was noisy, as mentioned in §5.1. As for language family errors, the test data includes many similar languages that are difficult even for humans to correctly judge. For example, Indonesian and Malay, Picard and Walloon, and Norwegian Bokmål and Nynorsk are all pairs representative of such confusion.

Overall, the language identification performance seems sufficient to justify its application to our main problem of text segmentation by language.

## 6.2 Text Segmentation by Language

First, we report the results obtained using the  $Test_1$  data set. Figure 2 shows the cumulative distribution obtained for segment border detection. The horizontal axis indicates the relative location by character with respect to the correct border at zero, and the vertical axis indicates the cumulative proportion of texts whose border is detected at that relative point. The figure shows four plots for all combinations of the two data sets and the two methods. Note that segment borders are judged by characters and *not* by bordering locations, as explained in §5.2.

Figure 3:  $P_L/R_L$  (language, upper graph) and  $P_B/R_B$  (border, lower graph) results, where borders were taken from *any* character offset

Since the plots rise sharply at the middle of the horizontal axis, the borders were detected at or very near the correct place in many cases.

Next, we examine the results for  $Test_2$ . Figure 3 shows the two precision/recall graphs for language identification (upper graph) and segment border detection (lower graph), where borders were taken from any character offset. In each graph, the horizontal axis indicates precision and the vertical axis indicates recall. The numbers appearing in each figure are the maximum F-score values for each method and data set combination. As can be seen from these numbers, the language identification performance was high. Since the text portion size was chosen from among the values 40, 80, 120, or 160, the performance is comprehensible from the results shown in §6.1. Note also that PPM performed slightly better than did MMS.

For segment border performance (lower graph), however, the results were limited. The main reason for this is that both MMS and PPM tend to detect a border one character earlier than the correct location, as was seen in Figure 2. At the same time, much of the test data contains unrealistic borders

Figure 4:  $P_{\mathbb{B}}/R_{\mathbb{B}}$ , where borders were limited to spaces

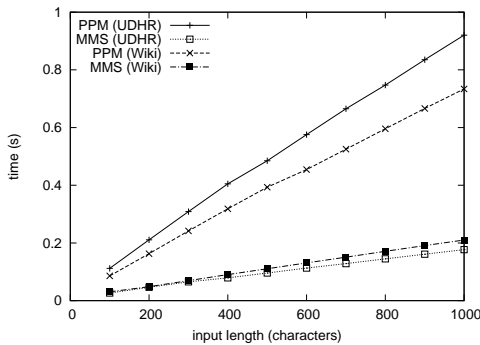

Figure 5: Average processing speed for a text

within a word, since the data was generated by concatenating two text portions with random borders. Therefore, we repeated the experiment with  $Test_2$  under the constraint that a segment border could occur only at a bordering location, as explained in §5.2. The results with this constraint were significantly better, as shown in Figure 4. The best result was for UDHR with PPM at 0.94<sup>11</sup>. We could also observe how PPM performed better at detecting borders in this case. In actual application, it would be possible to improve performance by relaxing the procedural conditions, such as by decreasing the number of language possibilities.

In this experiment for  $Test_2$ ,  $k$  ranged from 1 to 5, but the performance was not affected by the size of  $k$ . When the F-score was examined with respect to  $k$ , it remained almost equal to  $k$  in all cases. This shows how each recursion of formula (4) works almost independently, having segmentation and language identification functions that are both robust.

Lastly, we examine the speed of our method. Since  $|\mathcal{L}|$  is constant throughout the comparison,

<sup>11</sup>The language identification accuracy slightly increased as well, by 0.002.

the time should increase linearly with respect to the input length  $|X|$ , with increasing  $k$  having no effect. Figure 5 shows the speed for  $Test_2$  processing, with the horizontal axis indicating the input length and the vertical axis indicating the processing time. Here, all character offsets were taken into consideration, and the processing was done on a machine with a Xeon5650 2.66-GHz CPU. The results confirm that the complexity increased linearly with respect to the input length. When the text size became as large as several thousand characters, the processing time became as long as a second. This time could be significantly decreased by introducing constraints on the bordering locations and languages.

## 7 Conclusion

This article has presented a method for segmenting a multilingual text into segments, each in a different language. This task could serve for preprocessing of multilingual texts before applying language-specific analysis to each text. Moreover, the proposed method could be used to generate corpora in a variety of languages, since many texts in minor languages tend to contain chunks in a major language.

The segmentation task was modeled as an optimization problem of finding the best segment and language sequences to minimize the description length of a given text. An actual procedure for obtaining an optimal result through dynamic programming was proposed. Furthermore, we showed a way to decrease the computational complexity substantially, with each of our two methods having linear complexity in the input length.

Various empirical results were shown for language identification and segmentation. Overall, when segmenting a text with up to five random portions of different languages, where each portion consisted of 40 to 120 characters, the best F-scores for language identification and segmentation were 0.98 and 0.94, respectively.

For our future work, details of the methods must be worked out. In general, the proposed approach could be further applied to the actual needs of preprocessing and to generating corpora of minor languages.

## Abstract

We propose a novel approach to improve SMT via paraphrase rules which are automatically extracted from the bilingual training data. Without using extra paraphrase resources, we acquire the rules by comparing the source side of the parallel corpus with the target-to-source translations of the target side. Besides the word and phrase paraphrases, the acquired paraphrase rules mainly cover the structured paraphrases on the sentence level. These rules are employed to enrich the SMT inputs for translation quality improvement. The experimental results show that our proposed approach achieves significant improvements of 1.6~3.6 points of BLEU in the oral domain and 0.5~1 points in the news domain.

## 1 Introduction

The translation quality of the SMT system is highly related to the coverage of translation models. However, no matter how much data is used for training, it is still impossible to completely cover the unlimited input sentences. This problem is more serious for online SMT systems in real-world applications. Naturally, a solution to the coverage problem is to bridge the gaps between the input sentences and the translation models, either from the input side, which targets on rewriting the input sentences to the MT-favored expressions, or from

the side of translation models, which tries to enrich the translation models to cover more expressions.

In recent years, paraphrasing has been proven useful for improving SMT quality. The proposed methods can be classified into two categories according to the paraphrase targets: (1) enrich translation models to cover more bilingual expressions; (2) paraphrase the input sentences to reduce OOVs or generate multiple inputs. In the first category, He et al. (2011), Bond et al. (2008) and Nakov (2008) enriched the SMT models via paraphrasing the training corpora. Kuhn et al. (2010) and Max (2010) used paraphrases to smooth translation models. For the second category, previous studies mainly focus on finding translations for unknown terms using phrasal paraphrases. Callison-Burch et al. (2006) and Marton et al. (2009) paraphrase unknown terms in the input sentences using phrasal paraphrases extracted from bilingual and monolingual corpora. Mirkin et al. (2009) rewrite OOVs with entailments and paraphrases acquired from WordNet. Onishi et al. (2010) and Du et al. (2010) use phrasal paraphrases to build a word lattice to get multiple input candidates. In the above methods, only word or phrasal paraphrases are used for input sentence rewriting. No structured paraphrases on the sentence level have been investigated. However, the information in the sentence level is very important for disambiguation. For example, we can only substitute *play* with *drama* in a context related to *stage* or *theatre*. Phrasal paraphrase substitutions can hardly solve such kind of problems.

In this paper, we propose a method that rewrites

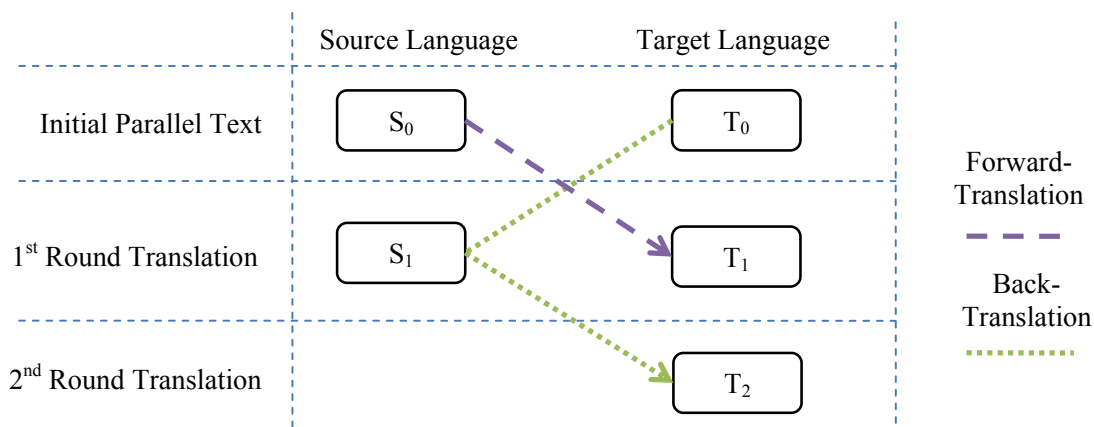

Figure 1: Procedure of Forward-Translation and Back-Translation.

the input sentences of the SMT system using automatically extracted paraphrase rules which can capture structures on sentence level in addition to paraphrases on the word or phrase level. Without extra paraphrase resources, a novel approach is proposed to acquire paraphrase rules from the bilingual training corpus based on the results of Forward-Translation and Back-Translation. The rules target on rewriting the input sentences to an MT-favored expression to ensure a better translation. The paraphrase rules cover all kinds of paraphrases on the word, phrase and sentence levels, enabling structure reordering, word or phrase insertion, deletion and substitution. The experimental results show that our proposed approach achieves significant improvements of 1.6~3.6 points of BLEU in the oral domain and 0.5~1 points in the news domain.

The remainder of the paper is organized as follows: Section 2 makes a comparison between the Forward-Translation and Back-Translation. Section 3 introduces our methods that extract paraphrase rules from the bilingual corpus of SMT. Section 4 describes the strategies for constructing word lattice with paraphrase rules. The experimental results and some discussions are presented in Section 5 and Section 6. Section 7 compares our work to the previous researches. Finally, Section 8 concludes the paper and suggests directions for future work.

## 2 Forward-Translation vs. Back-Translation

The Back-Translation method is mainly used for automatic MT evaluation (Rapp 2009). This

approach is very helpful when no target language reference is available. The only requirement is that the MT system needs to be bidirectional. The procedure includes translating a text into certain foreign language with the MT system (Forward-Translation), and translating it back into the original language with the same system (Back-Translation). Finally the translation quality of Back-Translation is evaluated by using the original source texts as references.

Sun et al. (2010) reported an interesting phenomenon: given a bilingual text, the Back-Translation results of the target sentences is better than the Forward-Translation results of the source sentences. Clearly, let  $(S_0, T_0)$  be the initial pair of bilingual text. A source-to-target translation system  $SYS\_ST$  and a target-to-source translation system  $SYS\_TS$  are trained using the bilingual corpus.  $FT(\cdot)$  is a Forward-Translation function, and  $BT(\cdot)$  is a function of Back-Translation which can be deduced with two rounds of translations:  $BT(s) = SYS\_TS(SYS\_ST(S))$ . In the first round of translation,  $S_0$  and  $T_0$  are fed into  $SYS\_ST$  and  $SYS\_TS$ , and we get  $T_1$  and  $S_1$  as translation results. In the second round, we translate  $S_1$  back into the target side with  $SYS\_ST$ , and get the translation  $T_2$ . The procedure is illustrated in Figure 1, which can also formally be described as:

1.  $T_1 = FT(S_0) = SYS\_ST(S_0)$ .
2.  $T_2 = BT(T_0)$ , which can be decomposed into two steps:  $S_1 = SYS\_TS(T_0)$ ,  $T_2 = SYS\_ST(S_1)$ .

Using  $T_0$  as reference, an interesting result is reported in Sun et al. (2010) that  $T_2$  achieves a higher score than  $T_1$  in automatic MT evaluation. This outcome is important because  $T_2$  is translated

No.	LHS	RHS
1	乘坐/ride X <sub>1</sub> 公共汽车/bus	乘坐/ride X <sub>1</sub> 巴士/bus
2	在/at X <sub>1</sub> 处/location 向左拐/turn left	向左拐/turn left 在/at X <sub>1</sub> 处/location
3	把/NULL X <sub>1</sub> 给/give 我/me	给/give 我/me X <sub>1</sub>
4	从/from X <sub>1</sub> 到/to X <sub>2</sub> 要/need 多长/how long 时间/time	要/need 花/spend 多长/how long 时间/time 从/from X <sub>1</sub> 到/to X <sub>2</sub>

Table 1: Examples of Chinese Paraphrase rules, together with English translations for every word

from a machine-generated text  $S_1$ , but  $T_1$  is translated from a human-write text  $S_0$ . Why the machine-generated text results in a better translation than the human-write text? Two possible reasons may explain this phenomenon: (1) in the first round of translation  $T_0 \rightarrow S_1$ , some target word orders are reserved due to the reordering failure, and these reserved orders lead to a better result in the second round of translation; (2) the text generated by an MT system is more likely to be matched by the reversed but homologous MT system.

Note that all the texts of  $S_0, S_1, S_2, T_0$  and  $T_1$  are sentence aligned because the initial parallel corpus  $(S_0, T_0)$  is aligned in the sentence level. The aligned sentence pairs in  $(S_0, S_1)$  can be considered as paraphrases. Since  $S_1$  has some MT-favored structures which may result in a better translation, an intuitive idea is whether we can learn these structures by comparing  $S_1$  with  $S_0$ . This is the main assumption of this paper. Taking  $(S_0, S_1)$  as paraphrase resource, we propose a method that automatically extracts paraphrase rules to capture the MT-favored structures.

### 3 Extraction of Paraphrase Rules

#### 3.1 Definition of Paraphrase Rules

We define a paraphrase rule as follows:

1. A paraphrase rule consists of two parts, left-hand-side (LHS) and right-hand-side (RHS). Both of LHS and RHS consist of non-terminals (slot) and terminals (words).
2. LHS must start/end with a terminal.
3. There must be at least one terminal between two non-terminals in LHS.

A paraphrase rule in the format of:

$$\text{LHS} \rightarrow \text{RHS}$$

which means the words matched by LHS can be paraphrased to RHS. Taking Chinese as a case

study, some examples of paraphrase rules are shown in Table 1.

#### 3.2 Selecting Paraphrase Sentence Pairs

Following the methods in Section 2, the initial bilingual corpus is  $(S_0, T_0)$ . We train a source-to-target PBMT system ( $SYS\_ST$ ) and a target-to-source PBMT system ( $SYS\_TS$ ) on the parallel corpus. Then a Forward-Translation is performed on  $S_0$  using  $SYS\_ST$ , and a Back-Translation is performed on  $T_0$  using  $SYS\_TS$  and  $SYS\_ST$ . As mentioned above, the detailed procedure is:  $T_1 = SYS\_ST(S_0)$ ,  $S_1 = SYS\_TS(T_0)$ ,  $T_2 = SYS\_ST(S_1)$ . Finally we compute BLEU (Papineni et al. 2002) score for every sentence in  $T_2$  and  $T_1$ , using the corresponding sentence in  $T_0$  as reference. If the sentence in  $T_2$  has a higher BLEU score than the aligned sentence in  $T_1$ , the corresponding sentences in  $S_0$  and  $S_1$  are selected as candidate paraphrase sentence pairs, which are used in the following steps of paraphrase extractions.

#### 3.3 Word Alignments Filtering

We can construct word alignment between  $S_0$  and  $S_1$  through  $T_0$ . On the initial corpus of  $(S_0, T_0)$ , we conduct word alignment with Giza++ (Och and Ney, 2000) in both directions and then apply the grow-diag-final heuristic (Koehn et al., 2005) for symmetrization. Because  $S_1$  is generated by feeding  $T_0$  into the PBMT system  $SYS\_TS$ , the word alignment between  $T_0$  and  $S_1$  can be acquired from the verbose information of the decoder.

The word alignments of  $S_0$  and  $S_1$  contain noises which are produced by either wrong alignment of GIZA++ or translation errors of  $SYS\_TS$ . To ensure the alignment quality, we use some heuristics to filter the alignment between  $S_0$  and  $S_1$ :

1. If two identical words are aligned in  $S_0$  and  $S_1$ , then remove all the other links to the two words.

Figure 2: Example for Word Alignment Filtration

2. Stop words (including some function words and punctuations) can only be aligned to either stop words or null.

Figure 2 illustrates an example of using the heuristics to filter alignment.

### 3.4 Extracting Paraphrase Rules

From the word-aligned sentence pairs, we then extract a set of rules that are consistent with the word alignments. We use the rule extracting methods of Chiang (2005). Take the sentence pair in Figure 2 as an example, two initial phrase pairs  $PP_1 = \text{“那只蓝色手提包 ||| 那个蓝色手提包”}$  and  $PP_2 = \text{“对那只蓝色手提包有兴趣 ||| 我很感兴趣那个蓝色手提包”}$  are identified, and  $PP_1$  is contained by  $PP_2$ , then we could form the rule:

对  $X_1$  有兴趣  $\rightarrow$  很感兴趣  $X_1$   
to have interest very feel interest

## 4 Paraphrasing the Input Sentences

The extracted paraphrase rules aim to rewrite the input sentences to an MT-favored form which may lead to a better translation. However, it is risky to directly replace the input sentence with a paraphrased sentence, since the errors in automatic paraphrase substitution may jeopardize the translation result seriously. To avoid such damage, for a given input sentence, we first transform all paraphrase rules that match the input sentences to phrasal paraphrases, and then build a word lattice

Figure 3: Example for Applying Paraphrase Rules for SMT decoder using the phrasal paraphrases. In this case, the decoder can search for the best result among all the possible paths.

The input sentences are first segmented into sub-sentences by punctuations. Then for each sub-sentence, the matched paraphrase rules are ranked according to: (1) the number of matched words; (2) the frequency of the paraphrase rule in the training data. Actually, the ranking strategy tends to select paraphrase rules that have more matched words (therefore less ambiguity) and higher frequency (therefore more reliable).

### 4.1 Applying Paraphrase Rules

Given an input sentence  $S$  and a paraphrase rule  $R \langle R_{LHS}, R_{RHS} \rangle$ , if  $S$  matches  $R_{LHS}$ , then the matched part can be replaced by  $R_{RHS}$ . An example for applying the paraphrase rules is illustrated in Figure 3.

From Figure 3, we can see that the words of position 1~3 are replaced to “乘坐 10 路 巴士”. Actually, only the words at position 3 and 4 are paraphrased to the word “巴士”, other words are left unchanged. Therefore, we can use a triple,  $\langle MIN\_RP\_TEXT, COVER\_START, COVER\_LEN \rangle$  ( $\langle \text{巴士}, 3, 1 \rangle$  in this example) to denote the paraphrase rule, which means the minimal text to replace is “巴士”, and the paraphrasing starts at position 3 and covers 1 words.

In this manner, all the paraphrase rules matched for a certain sentence can be converted to the format of  $\langle MIN\_RP\_TEXT, COVER\_START, COVER\_LEN \rangle$ , which can also be considered as phrasal paraphrases. Then the methods of building phrasal paraphrases into word lattice for SMT inputs can be used in our approaches.

Figure 4: An example of lattice-based paraphrases for an input sentence.

#### 4.2 Construction of Paraphrase Lattice

Given an input sentence, all the matched paraphrase rules are converted to phrasal paraphrases first. Then we build the phrasal paraphrases into word lattices using the methods proposed by Du et al. (2010). The construction process takes advantage of the correspondence between detected phrasal paraphrases and positions of the original words in the input sentence, and then creates extra edges in the lattices to allow the decoder to consider paths involving the paraphrase words. An example is illustrated in Figure 4: given a sequence of words  $\{w_1, \dots, w_N\}$  as the input, two phrases  $\alpha = \{\alpha_1, \dots, \alpha_p\}$  and  $\beta = \{\beta_1, \dots, \beta_q\}$  are detected as paraphrases for  $P_1 = \{w_x, \dots, w_y\}$  ( $1 \leq x \leq y \leq N$ ) and  $P_2 = \{w_m, \dots, w_n\}$  ( $1 \leq m \leq n \leq N$ ) respectively. The following steps are taken to transform them into word lattices:

1. Transform the original source sentence into word lattice.  $N + 1$  nodes ( $\theta_k, 0 \leq k \leq N$ ) are created, and  $N$  edges labeled with  $w_i$  ( $1 \leq i \leq N$ ) are generated to connect them sequentially.
2. Generate extra nodes and edges for each of the paraphrases. Taking  $\alpha$  as an example, firstly,  $p - 1$  nodes are created, and then  $p$  edges labeled with  $\alpha_j$  ( $1 \leq j \leq p$ ) are generated to connect node  $\theta_{x-1}$ ,  $p-1$  nodes and  $\theta_{y-1}$ .

Via step 2, word lattices are generated by adding new nodes and edges coming from paraphrases.

#### 4.3 Weight Estimation

The weights of new edges in the lattices are estimated by an empirical method base on ranking positions. Following Du et al. (2010), supposing that  $E = \{e_1, \dots, e_k\}$  are a set of new edges constructed from  $k$  paraphrase rules, which are sorted in a descending order. Then the weight for an edge  $e_i$  is calculated as:

$$w(e_i) = \frac{1}{k + i} \quad (1 \leq i \leq k)$$

where  $k$  is a predefined tradeoff parameter between decoding speed and the number of potential paraphrases being considered.

### 5 Experiments

#### 5.1 Experimental Data

In our experiments, we used Moses (Koehn et al., 2007) as the baseline system which can support lattice decoding. The alignment was obtained using GIZA++ (Och and Ney, 2003) and then we symmetrized the word alignment using the grow-diag-final heuristic. Parameters were tuned using Minimum Error Rate Training (Och, 2003). To comprehensively evaluate the proposed methods in different domains, two groups of experiments were carried out, namely, the oral group ( $G_{\text{oral}}$ ) and the news group ( $G_{\text{news}}$ ). The experiments were conducted in both Chinese-English and English-Chinese directions for the oral group, and Chinese-English direction for the news group. The English sentences were all tokenized and lowercased, and the Chinese sentences were segmented into words by Language Technology Platform (LTP)<sup>1</sup>. We used SRILM<sup>2</sup> for the training of language models (5-gram in all the experiments). The metrics for automatic evaluation were BLEU<sup>3</sup> and TER<sup>4</sup> (Snover et al., 2005).

The detailed statistics of the training data in  $G_{\text{oral}}$  are showed in Table 2. For the bilingual corpus, we used the BTEC and PIVOT data of IWSLT 2008, HIT corpus<sup>5</sup> and other Chinese LDC (CLDC)

<sup>1</sup> <http://ir.hit.edu.cn/ltp/>

<sup>2</sup> <http://www.speech.sri.com/projects/srilm/>

<sup>3</sup> <http://jaguar.ncsl.nist.gov/mt/resources/mteval-v13a.pl>

<sup>4</sup> <http://www.umiacs.umd.edu/~snover/terp/>

<sup>5</sup> The HIT corpus contains the CLDC Olympic corpus (2004-863-008) and the other HIT corpora available at <http://mitlab.hit.edu.cn/index.php/resources/29-the-resource/111-share-bilingual-corpus.html>.

test	NIST 2004	1,788	5
	NIST 2006	1,664	4
	NIST 2008	1,357	4

Table 4: Statistics of test/develop sets in  $G_{\text{news}}$

corpora, including the Chinese-English Sentence Aligned Bilingual Corpus (CLDC-LAC-2003-004) and the Chinese-English Parallel Corpora (CLDC-LAC-2003-006). We trained a Chinese language model for the E-C translation on the Chinese part of the bi-text. For the English language model of C-E translation, an extra corpus named Tanaka was used besides the English part of the bilingual corpora. For testing and developing, we used six Chinese-English development corpora of IWSLT 2008. The statistics are shown in Table 3.

In detail, we chose CSTAR03-test and IWSLT06-dev as the development set; and used IWSLT04-test, IWSLT05-test, IWSLT06-dev and IWSLT07-test for testing. For English-Chinese evaluation, we used IWSLT English-Chinese MT evaluation 2005 as the test set. Due to the lacking of development set, we did not tune parameters on English-Chinese side, instead, we just used the default parameters of Moses.

In the experiments of the news group, we used the Sinorama and FBIS corpora (LDC2005T10 and LDC2003E14) for bilingual corpus. After tokenization and filtering, this bilingual corpus contained 319,694 sentence pairs (7.9M tokens on

Chinese side and 9.2M tokens on English side). We trained a 5-gram language model on the English side of the bi-text. The system was tested using the Chinese-English MT evaluation sets of NIST 2004, NIST 2006 and NIST 2008. For development, we used the Chinese-English MT evaluation sets of NIST 2002 and NIST 2005. Table 4 shows the statistics of test/development sets used in the news group.

## 5.2 Results

We extract both Chinese and English rules in  $G_{\text{oral}}$ , and Chinese paraphrase rules in  $G_{\text{news}}$  by comparing the results of Forward-Translation and Back-Translation as described in Section 3. During the extraction, some heuristics are used to ensure the quality of paraphrase rules. Take the extraction of Chinese paraphrase rules in  $G_{\text{oral}}$  as a case study. Suppose  $(C_0, E_0)$  are the initial bilingual corpus of  $G_{\text{oral}}$ . A Chinese-English and an English-Chinese MT system are trained on  $(C_0, E_0)$ . We perform Back-Translation on  $E_0$  ( $E_0 \xrightarrow{E \text{ to } C} C_1 \xrightarrow{C \text{ to } E} E_2$ ), and Forward-Translation on  $C_0$  ( $C_0 \xrightarrow{C \text{ to } E} E_1$ ). Suppose  $e_{1i}$  and  $e_{2i}$  are two aligned sentences in  $E_1$  and  $E_2$ ,  $c_{0i}$  and  $c_{1i}$  are the corresponding sentences in  $C_0$  and  $C_1$ .  $(c_{0i}, c_{1i})$  are selected for the extraction of paraphrase rules if two conditions are satisfied: (1)  $\text{BLEU}(e_{2i}) - \text{BLEU}(e_{1i}) > \theta_1$ , and (2)  $\text{BLEU}(e_{2i}) > \theta_2$ , where  $\text{BLEU}(\cdot)$  is a function for computing BLEU score;  $\theta_1$  and  $\theta_2$  are thresholds for balancing the rules number and the quality of paraphrase rules. In our experiment,  $\theta_1$  and  $\theta_2$  are empirically set to 0.1 and 0.3.

As a result, we extract 912,625 Chinese and 1,116,375 English paraphrase rules for  $G_{\text{oral}}$ , and for  $G_{\text{news}}$  the number of Chinese paraphrase rules is 2,877,960. Then we use the extracted paraphrase rules to improve SMT by building word lattices for the input sentences.

The Chinese-English experimental results of  $G_{\text{oral}}$  and  $G_{\text{news}}$  are shown in Table 5 and Table 6, respectively. It can be seen that our method outperforms the baselines in both oral and news domains. Our system gains significant improvements of 1.6~3.6 points of BLEU in the oral domain, and 0.5~1 points of BLEU in the news domain. Figure 5 shows the effect of considered paraphrases (k) in the step of building

## 6 Discussion

We make a detailed analysis on the Chinese-English translation results that are affected by our paraphrase rules. The aim is to investigate what kinds of paraphrases have been captured in the rules. Firstly the input path is recovered from the translation results according to the tracing information of the decoder, and therefore we can examine which path is selected by the SMT decoder from the paraphrase lattice. A human annotator is asked to judge whether the recovered paraphrase sentence keeps the same meaning as the original input. Then the annotator compares the baseline translation with the translations proposed by our approach. The analysis is carried out on the IWSLT 2007 Chinese-English test set, 84 out of 489 input sentences have been affected by paraphrases, and the statistic of human evaluation is shown in Table 8.

It can be seen in Table 8 that the paraphrases achieve a relatively high accuracy, 60 (71.4%)

Figure 5: Effect of considered paraphrases (k) on BLEU score

paraphrased sentences retain the same meaning, and the other 24 (28.6%) are incorrect. Among the 60 correct paraphrases, 36 sentences finally result in an improved translation. We further analyze these paraphrases and the translation results to investigate what kinds of transformation finally lead to the translation quality improvement. The paraphrase variations can be classified into four categories:

- (1) Reordering: The original source sentences are reordered to be similar to the order of the target language.
- (2) Word substitution: A phrase with multi-word translations is replaced by a phrase with a single-word translation.
- (3) Recovering omitted words: Ellipsis occurs frequently in spoken language. Recovering the omitted words often leads to a better translation.
- (4) Removing redundant words: Mostly, translating redundant words may confuse the SMT system and would be unnecessary. Removing redundant words can mitigate this problem.

Cate.	Num	Original Sentence/Translation	Paraphrased Sentence/Translation
(1)	11	香烟/cigarette 可以/can 免税/duty-free 带/take 多少/how much 支/N/A ? what a cigarette can i take duty-free ?	多少/how much 香烟/cigarettes 可以/can 免税/duty-free 带/take 支/N/A ? how many cigarettes can i take duty-free one ?
(2)	18	你/you 有/have 多久/how long 的/N/A 教学/teaching 经验/experience ? you have how long teaching experience ?	你/you 有/have 多少/how much 教学/teaching 经验/experience ? how much teaching experience you have ?
(3)	10	需要/need 押金/deposit 吗/N/A ? you need a deposit ?	你/you 需要/need 押金/deposit 吗/N/A ? do you need a deposit ?
(4)	4	戒指/ring 掉/fall 进/into 洗脸池/washbasin 里/in 了/N/A 。 ring off into the washbasin is in .	戒指/ring 掉/fall 进/into 洗脸池/washbasin 了/N/A 。 ring off into the washbasin .

Table 9: Examples for classification of paraphrase rules

Four examples for category (1), (2), (3) and (4) are shown in Table 9, respectively. The numbers in the second column indicates the number of the sentences affected by the rules, among the 36 sentences with improved paraphrasing and translation. A sentence can be classified into multiple categories. Except category (2), the other three categories cannot be detected by the previous approaches, which verify our statement that our rules can capture structured paraphrases on the sentence level in addition to the paraphrases on the word or phrase level.

Not all the paraphrased results are correct. Sometimes an ill paraphrased sentence can produce better translations. Take the first line of Table 9 as an example, the paraphrased sentence “多少/How many 香烟/cigarettes 可以/can 免税/duty-free 带/take 支/NULL” is not a fluent Chinese sentence, however, the rearranged word order is closer to English, which finally results in a much better translation.

## 7 Related Work

Previous studies on improving SMT using paraphrase rules focus on hand-crafted rules. Nakov (2008) employs six rules for paraphrasing the training corpus. Bond et al. (2008) use grammars to paraphrase the source side of training data, covering aspects like word order and minor lexical variations (tenses etc.) but not content words. The paraphrases are added to the source side of the corpus and the corresponding target sentences are duplicated.

A disadvantage for hand-crafted paraphrase rules is that it is language dependent. In contrast, our method that automatically extracted paraphrase

rules from bilingual corpus is flexible and suitable for any language pairs.

Our work is similar to Sun et al. (2010). Both tried to capture the MT-favored structures from bilingual corpus. However, a clear difference is that Sun et al. (2010) captures the structures implicitly by training an MT system on ( $S_0$ ,  $S_1$ ) and “translates” the SMT input to an MT-favored expression. Actually, the rewriting process is considered as a black box in Sun et al. (2010). In this paper, the MT-favored expressions are captured explicitly by automatically extracted paraphrase rules. The advantages of the paraphrase rules are: (1) Our method can explicitly capture the structure information in the sentence level, enabling global reordering, which is impossible in Sun et al. (2010). (2) For each rule, we can control its quality automatically or manually.

## 8 Conclusion

In this paper, we propose a novel method for extracting paraphrase rules by comparing the source side of bilingual corpus to the target-to-source translation of the target side. The acquired paraphrase rules are employed to enrich the SMT inputs, which target on rewriting the input sentences to an MT-favored form. The paraphrase rules cover all kinds of paraphrases on the word, phrase and sentence levels, enabling structure reordering, word or phrase insertion, deletion and substitution. Experimental results show that the paraphrase rules can improve SMT quality in both the oral and news domains. The manual investigation on oral translation results indicate that the paraphrase rules capture four kinds of MT-favored transformation to ensure translation quality improvement.

## Abstract

In recent years there has been a growing interest in crowdsourcing methodologies to be used in experimental research for NLP tasks. In particular, evaluation of systems and theories about persuasion is difficult to accommodate within existing frameworks. In this paper we present a new cheap and fast methodology that allows fast experiment building and evaluation with fully-automated analysis at a low cost. The central idea is exploiting existing commercial tools for advertising on the web, such as Google AdWords, to measure message impact in an ecological setting. The paper includes a description of the approach, tips for how to use AdWords for scientific research, and results of pilot experiments on the impact of affective text variations which confirm the effectiveness of the approach.

## 1 Introduction

In recent years there has been a growing interest in finding new cheap and fast methodologies to be used in experimental research, for, but not limited to, NLP tasks. In particular, approaches to NLP that rely on the use of web tools - for crowdsourcing long and tedious tasks - have emerged. Amazon Mechanical Turk, for example, has been used for collecting annotated data (Snow et al., 2008). However approaches *a la* Mechanical Turk might not be suitable for all tasks.

In this paper we focus on evaluating systems and theories about persuasion, see for example (Fogg, 2009) or the survey on persuasive NL generation studies in (Guerini et al., 2011a). Measuring the

impact of a message is of paramount importance in this context, for example how affective text variations can alter the persuasive impact of a message.

The problem is that evaluation experiments represent a bottleneck: they are expensive and time consuming, and recruiting a high number of human participants is usually very difficult.

To overcome this bottleneck, we present a specific cheap and fast methodology to automatize large-scale evaluation campaigns. This methodology allows us to crowdsource experiments with thousands of subjects for a few euros in a few hours, by tweaking and using existing commercial tools for advertising on the web. In particular we make reference to the AdWords Campaign Experiment (ACE) tool provided within the Google AdWords suite. One important aspect of this tool is that it allows for real-time fully-automated data analysis to discover statistically significant phenomena. It is worth noting that this work originated in the need to evaluate the impact of short persuasive messages, so as to assess the effectiveness of different linguistic choices. Still, we believe that there is further potential for opening an interesting avenue for experimentally exploring other aspects of the wide field of pragmatics.

The paper is structured as follows: Section 2 discusses the main advantages of ecological approaches using Google ACE over traditional lab settings and state-of-the-art crowdsourcing methodologies. Section 3 presents the main AdWords features. Section 4 describes how AdWords features can be used for defining message persuasiveness metrics and what kind of stimulus characteristics can be evaluated. Finally Sections 5 and 6 describe how to build up an

experimental scenario and some pilot studies to test the feasibility of our approach.

## 2 Advantages of Ecological Approaches

Evaluation of the effectiveness of persuasive systems is very expensive and time consuming, as the STOP experience showed (Reiter et al., 2003): designing the experiment, recruiting subjects, making them take part in the experiment, dispensing questionnaires, gathering and analyzing data.

Existing methodologies for evaluating persuasion are usually split in two main sets, depending on the setup and domain: (i) long-term, in the field evaluation of behavioral change (as the STOP example mentioned before), and (ii) lab settings for evaluating short-term effects, as in (Andrews et al., 2008). While in the first approach it is difficult to take into account the role of external events that can occur over long time spans, in the second there are still problems of recruiting subjects and of time consuming activities such as questionnaire gathering and processing.

In addition, sometimes carefully designed experiments can fail because: (i) effects are too subtle to be measured with a limited number of subjects or (ii) participants are not engaged enough by the task to provoke usable reactions, see for example what reported in (Van Der Sluis and Mellish, 2010). Especially the second point is awkward: in fact, subjects can actually be convinced by the message to which they are exposed, but if they feel they do not care, they may not “react” at all, which is the case in many artificial settings. To sum up, the main problems are:

1. Time consuming activities
2. Subject recruitment
3. Subject motivation
4. Subtle effects measurements

### 2.1 Partial Solution - Mechanical Turk

A recent trend for behavioral studies that is emerging is the use of Mechanical Turk (Mason and Suri, 2010) or similar tools to overcome part of these limitations - such as subject recruitment. Still we believe that this poses other problems in assessing behavioral changes, and, more generally, persuasion effects. In fact:

1. Studies must be as ecological as possible, i.e. conducted in real, even if controlled, scenarios.
2. Subjects should be neither aware of being observed, nor biased by external rewards.

In the case of Mechanical Turk for example, subjects are willingly undergoing a process of being tested on their skills (e.g. by performing annotation tasks). Cover stories can be used to soften this awareness effect, nonetheless the fact that subjects are being paid for performing the task renders the approach unfeasible for behavioral change studies. It is necessary that the only reason for behavior induction taking place during the experiment (filling a form, responding to a questionnaire, clicking on an item, etc.) is the exposition to the experimental stimuli, not the external reward. Moreover, Mechanical Turk is based on the notion of a “gold standard” to assess contributors reliability, but for studies concerned with persuasion it is almost impossible to define such a reference: there is no “right” action the contributor can perform, so there is no way to assess whether the subject is performing the action because induced to do so by the persuasive strategy, or just in order to receive money. On the aspect of how to handle subject reliability in coding tasks, see for example the method proposed in (Negri et al., 2010).

### 2.2 Proposed Solution - Targeted Ads on the Web

Ecological studies (e.g. using Google AdWords) offer a possible solution to the following problems:

1. Time consuming activities: apart from experimental design and setup, all the rest is automatically performed by the system. Experiments can yield results in a few hours as compared to several days/weeks.
2. Subject recruitment: the potential pool of subjects is the entire population of the web.
3. Subject motivation: ads can be targeted exactly to those persons that are, in that precise moment throughout the world, most interested in the topic of the experiment, and so potentially more prone to react.
4. Subject unaware, unbiased: subjects are totally unaware of being tested, testing is performed during their “natural” activity on the web.

5. Subtle effects measurements: if there are not enough subjects, just wait for more ads to be displayed, or focus on a subset of even more interested people.

Note that similar ecological approaches are beginning to be investigated: for example in (Aral and Walker, 2010) an approach to assessing the social effects of content features on an on-line community is presented. A previous approach that uses AdWords was presented in (Guerini et al., 2010), but it crowd-sourced only the running of the experiment, not data manipulation and analysis, and was not totally controlled for subject randomness.

### 3 AdWords Features

Google AdWords is Google's advertising program. The central idea is to let advertisers display their messages only to relevant audiences. This is done by means of keyword-based contextualization on the Google network, divided into:

- Search network: includes Google search pages, search sites and properties that display search results pages (SERPs), such as Froogle and Earthlink.
- Display network: includes news pages, topic-specific websites, blogs and other properties - such as Google Mail and The New York Times.

When a user enters a query like "cruise" in the Google search network, Google displays a variety of relevant pages, along with ads that link to cruise trip businesses. To be displayed, these ads must be associated with relevant keywords selected by the advertiser.

Every advertiser has an AdWords account that is structured like a pyramid: (i) account, (ii) campaign and (iii) ad group. In this paper we focus on ad groups. Each grouping gathers similar keywords together - for instance by a common theme - around an ad group. For each ad group, the advertiser sets a cost-per-click (CPC) bid. The CPC bid refers to the amount the advertiser is willing to pay for a click on his ad; the cost of the actual click instead is based on its quality score (a complex measure out of the scope of the present paper).

For every ad group there could be multiple ads to be served, and there are many AdWords measure-

ments for identifying the performance of each single ad (its persuasiveness, from our point of view):

- CTR, Click Through Rate: measures the number of clicks divided by the number of impressions (i.e. the number of times an ad has been displayed in the Google Network).
- Conversion Rate: if someone clicks on an ad, and buys something on your site, that click is a conversion from a site visit to a sale. Conversion rate equals the number of conversions divided by the number of ad clicks.
- ROI: Other conversions can be page views or signups. By assigning a value to a conversion the resulting conversions represents a return on investment, or ROI.
- Google Analytics Tool: Google Analytics is a web analytics tool that gives insights into website traffic, like number of visited pages, time spent on the site, location of visitors, etc.

So far, we have been talking about text ads, - Google's most traditional and popular ad format - because they are the most useful for NLP analysis. In addition there is also the possibility of creating the following types of ads:

- Image (and animated) ads
- Video ads
- Local business ads
- Mobile ads

The above formats allow for a greater potential to investigate persuasive impact of messages (other than text-based) but their use is beyond the scope of the present paper<sup>1</sup>.

### 4 The ACE Tool

AdWords can be used to design and develop various metrics for fast and *fully-automated* evaluation experiments, in particular using the ACE tool.

This tool - released in late 2010 - allows testing, from a marketing perspective, if any change made to a promotion campaign (e.g. a keyword bid) had a statistically measurable impact on the campaign itself. Our primary aim is slightly different: we are

---

<sup>1</sup>For a thorough description of the AdWords tool see: <https://support.google.com/adwords/>

interested in testing how different messages impact (possibly different) audiences. Still the ACE tool goes exactly in the direction we aim at, since it incorporates *statistically significant testing* and allows avoiding many of the tweaking and tuning actions which were necessary before its release.

The ACE tool also introduces an option that was not possible before, that of *real-time testing* of statistical significance. This means that it is no longer necessary to define a-priori the sample size for the experiment: as soon as a meaningful statistically significant difference emerges, the experiment can be stopped.

Another advantage is that the statistical knowledge to evaluate the experiment is no longer necessary: the researcher can focus only on setting up proper experimental designs<sup>2</sup>.

The limit of the ACE tool is that it only allows A/B testing (single split with one control and one experimental condition) so for experiments with more than two conditions or for particular experimental settings that do not fit with ACE testing boundaries (e.g. cross campaign comparisons) we suggest taking (Guerini et al., 2010) as a reference model, even if the experimental setting is less controlled (e.g. subject randomness is not equally guaranteed as with ACE).

Finally it should be noted that even if ACE allows only A/B testing, it permits the decomposition of almost any variable affecting a campaign experiment in its basic dimensions, and then to segment such dimensions according to control and experimental conditions. As an example of this powerful option, consider Tables 3 and 6 where control and experimental conditions are compared against every single keyword and every search network/ad position used for the experiments.

## 5 Evaluation and Targeting with ACE

Let us consider the design of an experiment with 2 conditions. First we create an ad Group with 2 competing messages (one message for each condition). Then we choose the serving method (in our opinion the *rotate* option is better than *optimize*, since it

---

<sup>2</sup>Additional details about ACE features and statistics can be found at <http://www.google.com/ads/innovations/ace.html>

guarantees subject randomness and is more transparent) and the context (language, network, etc.). Then we activate the ads and wait. As soon as data begins to be collected we can monitor the two conditions according to:

- **Basic Metrics:** the highest CTR measure indicates which message is best performing. It indicates which message has the highest initial impact.
- **Google Analytics Metrics:** measures how much the messages kept subjects on the site and how many pages have been viewed. Indicates interest/attitude generated in the subjects.
- **Conversion Metrics:** measures how much the messages converted subjects to the final goal. Indicates complete success of the persuasive message.
- **ROI Metrics:** by creating specific ROI values for every action the user performs on the landing page. The more relevant (from a persuasive point of view) the action the user performs, the higher the value we must assign to that action. In our view combined measurements are better: for example, there could be cases of messages with a lower CTR but a higher conversion rate.

Furthermore, AdWords allows very complex targeting options that can help in many different evaluation scenarios:

- **Language** (see how message impact can vary in different languages).
- **Location** (see how message impact can vary in different cultures sharing the same language).
- **Keyword matching** (see how message impact can vary with users having different interests).
- **Placements** (see how message impact can vary among people having different values - e.g. the same message displayed on Democrat or Republican web sites).
- **Demographics** (see how message impact can vary according to user gender and age).

### 5.1 Setting up an Experiment

To test the extent to which AdWords can be exploited, we focused on how to evaluate lexical variations of a message. In particular we were interested

in gaining insights about a system for *affective* variations of existing commentaries on medieval frescoes for a mobile museum guide that attracts the attention of visitors towards specific paintings (Guerini et al., 2008; Guerini et al., 2011b). The various steps for setting up an experiment (or a series of experiments) are as follows:

**Choose a Partner.** If you have the opportunity to have a commercial partner that already has the infrastructure for experiments (website, products, etc.) many of the following steps can be skipped. We assume that this is not the case.

**Choose a scenario.** Since you may not be equipped with a VAT code (or with the commercial partner that furnishes the AdWords account and infrastructure), you may need to “invent something to promote” without any commercial aim. If a “social marketing” scenario is chosen you can select “personal” as a “tax status”, that do not require a VAT code. In our case we selected cultural heritage promotion, in particular the frescoes of Torre Aquila (“Eagle Tower”) in Trento. The tower contains a group of 11 frescoes named “Ciclo dei Mesi” (cycle of the months) that represent a unique example of non-religious medieval frescoes in Europe.

**Choose an appropriate keyword** on which to advertise, “medieval art” in our case. It is better to choose keywords with enough web traffic in order to speed up the experimental process. In our case the search volume for “medieval art” (in phrase match) was around 22.000 hits per month. Another suggestion is to restrict the matching modality on Keywords in order to have more control over the situations in which ads are displayed and to avoid possible extraneous effects (the order of control for matching modality is: *[exact match]*, *[phrase match]* and *[broad match]*).

Note that such a technical decision - which keyword to use - is better taken at an early stage of development because it affects the following steps.

**Write messages** optimized for that keyword (e.g. including it in the title or the body of the ad). Such optimization must be the same for control and experimental condition. The rest of the ad can be designed in such a way to meet control and experimental condition design (in our case a message with slightly affective terms and a similar message with more affectively loaded variations)

**Build an appropriate landing page**, according to the keyword and populate the website pages with relevant material. This is necessary to create a “credible environment” for users to interact with.

**Incorporate meaningful actions in the website.** Users can perform various actions on a site, and they can be monitored. The design should include actions that are meaningful indicators of persuasive effect/success of the message. In our case we decided to include some outbound links, representing:

- general interest: “Buonconsiglio Castle site”
- specific interest: “Eagle Tower history”
- activated action: “Timetable and venue”
- complete success: “Book a visit”

Furthermore, through new Google Analytics features, we set up a series of *time\_spent\_on\_site* and *number\_of\_visited\_pages* thresholds to be monitored in the ACE tool.

## 5.2 Tips for Planning an Experiment

There are variables, inherent in the Google AdWords mechanism, that from a research point of view we shall consider “extraneous”. We now propose tips for controlling such extraneous variables.

**Add negative matching Keywords:** To add more control, if in doubt, put the words/expressions of the control and experimental conditions as negative keywords. This will prevent different highlighting between the two conditions that can bias the results. It is not strictly necessary since one can always control which queries triggered a click through the report menu. An example: if the only difference between control and experimental condition is the use of the adjectives “*gentle* knights” vs. “*valorous* knights”, one can use two negative keyword matches: *-gentle* and *-valorous*. Obviously if you are using a keyword in exact matching to trigger your ads, such as *[knight]*, this is not necessary.

**Frequency capping for the display network:** if you are running ads on the display network, you can use the “frequency capping” option set to 1 to add more control to the experiment. In this way it is assured that ads are displayed only one time per user on the display network.

**Placement bids for the search network:** unfortunately this option is no longer available. Basically the option allowed to bid only for certain positions

on the SERPs to avoid possible “extraneous variables effect” given by the position. This is best explained via an example: if, for whatever reason, one of the two ads gets repeatedly promoted to the premium position on the SERPs, then the CTR difference between ads would be strongly biased. From a research point of view “premium position” would then be an extraneous variable to be controlled (i.e. either both ads get an equal amount of premium position impressions, or both ads get no premium position at all). Otherwise the difference in CTR is determined by the “premium position” rather than by the independent variable under investigation (presence/absence of particular affective terms in the text ad). However even if it is not possible to rule out this “position effect” it is possible to monitor it by using the report (*Segment > Top vs. other + Experiment*) and checking how many times each ad appeared in a given position on the SERPs, and see if the ACE tool reports any statistical difference in the frequencies of ads positions.

**Extra experimental time:** While planning an experiment, you should also take into account the ads reviewing time that can take up to several days, in worst case scenarios. Note that when ads are in *eligible* status, they begin to show on the Google Network, but they are not approved yet. This means that the ads can only run on Google search pages and can only show for users who have turned off SafeSearch filtering, until they are approved. Eligible ads cannot run on the Display Network. This status will provide much less impressions than the final “approved” status.

**Avoid seasonal periods:** for the above reason, and to avoid extra costs due to high competition, avoid seasonal periods (e.g. Christmas time).

**Delivery method:** if you are planning to use the Accelerated Delivery method in order to get the results as quick as possible (in the case of “quick and dirty” experiments or “fast prototyping-evaluation cycles”) you should consider monitoring your experiment more often (even several times per day) to avoid running out of budget during the day.

## 6 Experiments

We ran two pilot experiments to test how affective variations of existing texts alter their persuasive im-

pact. In particular we were interested in gaining initial insights about an intelligent system for affective variations of existing commentaries on medieval frescoes.

We focused on adjective variations, using a slightly biased adjective for the control conditions and a strongly biased variation for the experimental condition. In these experiments we took it for granted that affective variations of a message work better than a neutral version (Van Der Sluis and Mellish, 2010), and we wanted to explore more finely grained tactics that involve the *grade of the variation* (i.e. a moderately positive variation vs. an extremely positive variation). Note that this is a more difficult task than the one proposed in (Van Der Sluis and Mellish, 2010), where they were testing long messages with lots of variations and with polarized conditions, neutral vs. biased. In addition we wanted to test how quickly experiments could be performed (two days versus the two week suggestion of Google).

Adjectives were chosen according to MAX bigram frequencies with the modified noun, using the Web 1T 5-gram corpus (Brants and Franz, 2006). Deciding whether this is the best metric for choosing adjectives to modify a noun or not (e.g. also pointwise mutual-information score can be used with a different rationale) is out of the scope of the present paper, but previous work has already used this approach (Whitehead and Cavedon, 2010). Top ranked adjectives were then manually ordered - according to affective weight - to choose the best one (we used a standard procedure using 3 annotators and a reconciliation phase for the final decision).

### 6.1 First Experiment

The first experiment lasted 48 hour with a total of 38 thousand subjects and a cost of 30 euros (see Table 1 for the complete description of the experimental setup). It was meant to test *broadly* how affective variations in the body of the ads performed. The two variations contained a fragment of a commentary of the museum guide; the control condition contained “*gentle knight*” and “*African lion*”, while in the experimental condition the affective loaded variations were “*valorous knight*” and “*indomitable lion*” (see Figure 1, for the complete ads). As can be seen from Table 2, the experiment did not yield any significant

result, if one looks at the overall analysis. But segmenting the results according to the keyword that triggered the ads (see Table 3) we discovered that on the “medieval art” keyword, the control condition performed better than the experimental one.

---

<b>Starting Date:</b> 1/2/2012
<b>Ending Date:</b> 1/4/2012
<b>Total Time:</b> 48 hours
<b>Total Cost:</b> 30 euros
<b>Subjects:</b> 38,082
<b>Network:</b> Search and Display
<b>Language:</b> English
<b>Locations:</b> Australia; Canada; UK; US
<b>KeyWords:</b> “medieval art”, pictures middle ages

---

Table 1: First Experiment Setup

ACE split	Clicks	Impr.	CTR
Control	31	18,463	0.17%

**Discussion.** As already discussed, user motivation is a key element for success in such fine-grained experiments: while less focused keywords did not yield any statistically significant differences, the most specialized keyword “medieval art” was the one that yielded results (i.e. if we display messages like those in Figure 1, that are concerned with medieval art frescoes, only those users really interested in the topic show different reaction patterns to the affective variations, while those generically interested in medieval times behave similarly in the two conditions). In the following experiment we tried to see

whether such variations have different effects when modifying a different element in the text.

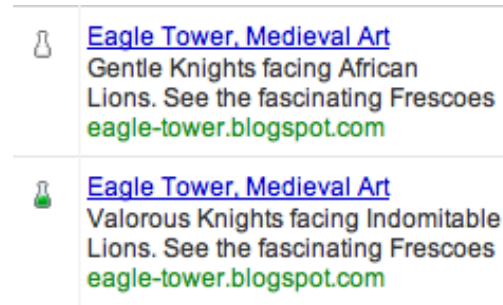

Figure 1: Ads used in the first experiment

## 6.2 Second Experiment

The second experiment lasted 48 hours with a total of one thousand subjects and a cost of 17 euros (see Table 4 for the description of the experimental setup). It was meant to test *broadly* how affective variations introduced in the title of the text Ads performed. The two variations were the same as in the first experiment for the control condition “gentle knight”, and for the experimental condition “valorous knight” (see Figure 2 for the complete ads). As can be seen from Table 5, also in this case the experiment did not yield any significant result, if one looks at the overall analysis. But segmenting the results according to the search network that triggered the ads (see Table 6) we discovered that on the search partners at the “other” position, the control condition performed better than the experimental one. Unlike the first experiment, in this case we segmented according to the ad position and search network typology since we were running our experiment only on one keyword in exact match.

Total - Search	-	986	1.82%

Table 6: Second Experiment Results Detail. <sup>†</sup> indicates a statistical significance with  $\alpha < 0.05$ , \* indicates a statistical significance with  $\alpha < 0.01$

**Discussion.** From this experiment we can confirm that at least under some circumstances a mild affective variation performs better than a strong variation. This mild variations seems to work better when user attention is high (the difference emerged when ads are displayed in a non-prominent position). Furthermore it seems that modifying the title of the ad rather than the content yields better results: 0.9% vs. 1.83% CTR ( $\chi^2 = 6.24$ ; 1 degree of freedom;  $\alpha < 0,01$ ) even if these results require further assessment with dedicated experiments.

As a side note, in this experiment we can see the problem of extraneous variables: according to AdWords' internal mechanisms, the experimental condition was displayed more often in the Google

search Network on the “other” position (277 vs. 219 impressions - and overall 524 vs. 462), still from a research perspective this is not a interesting statistical difference, and ideally should not be present (i.e. ads should get an equal amount of impressions for each position).

## Conclusions and future work

AdWords gives us an appropriate context for evaluating persuasive messages. The advantages are fast experiment building and evaluation, fully-automated analysis, and low cost. By using keywords with a low CPC it is possible to run large-scale experiments for just a few euros. AdWords proved to be very accurate, flexible and fast, far beyond our expectations. We believe careful design of experiments will yield important results, which was unthinkable before this opportunity for studies on persuasion appeared.

The motivation for this work was exploration of the impact of short persuasive messages, so to assess the effectiveness of different linguistic choices. The experiments reported in this paper are illustrative examples of the method proposed and are concerned with the evaluation of the role of minimal affective variations of short expressions. But there is enormous further potential in the proposed approach to ecological crowdsourcing for NLP: for instance, different rhetorical techniques can be checked in practice with large audiences and fast feedback. The assessment of the effectiveness of a change in the title as opposed to the initial portion of the text body provides a useful indication: one can investigate if variations inside the *given* or the *new* part of an expression or in the *topic* vs. *comment* (Levinson, 1983) have different effects. We believe there is potential for a concrete extensive exploration of different linguistic theories in a way that was simply not realistic before.

## Acknowledgments

We would like to thank Enrique Alfonseca and Steve Barrett, from Google Labs, for valuable hints and discussion on AdWords features. The present work was partially supported by a Google Research Award.

## Abstract

Polarity classification of words is important for applications such as Opinion Mining and Sentiment Analysis. A number of sentiment word/sense dictionaries have been manually or (semi)automatically constructed. The dictionaries have substantial inaccuracies. Besides obvious instances, where the same word appears with different polarities in different dictionaries, the dictionaries exhibit complex cases, which cannot be detected by mere manual inspection. We introduce the concept of polarity consistency of words/senses in sentiment dictionaries in this paper. We show that the consistency problem is NP-complete. We reduce the polarity consistency problem to the satisfiability problem and utilize a fast SAT solver to detect inconsistencies in a sentiment dictionary. We perform experiments on four sentiment dictionaries and WordNet.

## 1 Introduction

The opinions expressed in various Web and media outlets (e.g., blogs, newspapers) are an important yardstick for the success of a product or a government policy. For instance, a product with consistently good reviews is likely to sell well. The general approach is to summarize the *semantic polarity* (i.e., positive or negative) of sentences/documents by analysis of the orientations of the individual words (Pang and Lee, 2004; Danescu-N.-M. et al., 2009; Kim and Hovy, 2004; Takamura et al., 2005). Sentiment dictionaries are utilized to facilitate the summarization. There are numerous works that, given a sentiment lexicon, analyze the structure of

a sentence/document to infer its orientation, the holder of an opinion, the sentiment of the opinion, etc. (Breck et al., 2007; Ding and Liu, 2010; Kim and Hovy, 2004). Several domain independent sentiment dictionaries have been manually or (semi)-automatically created, e.g., General Inquirer (GI) (Stone et al., 1996), Opinion Finder (OF) (Wilson et al., 2005), Appraisal Lexicon (AL) (Taboada and Grieve, 2004), SentiWordNet (Baccianella et al., 2010) and Q-WordNet (Agerri and García-Serrano, 2010). Q-WordNet and SentiWordNet are lexical resources which classify the synsets(senses) in WordNet according to their polarities. We call them *sentiment sense dictionaries* (SSD). OF, GI and AL are called *sentiment word dictionaries* (SWD). They consist of words manually annotated with their corresponding polarities. The sentiment dictionaries have the following problems:

- They exhibit substantial (intra-dictionary) inaccuracies. For example, the synset  $\{\textit{Indo-European}, \textit{Indo-Aryan}, \textit{Aryan}\}$  (*of or relating to the former Indo-European people*), has a negative polarity in Q-WordNet, while most people would agree that this synset has a neutral polarity instead.
- They have (inter-dictionary) inconsistencies. For example, the adjective `cheap` is positive in AL and negative in OF.
- These dictionaries do not address the concept of polarity (in)consistency of words/synsets.

We concentrate on the concept of (in)consistency in this paper. We define consistency among the polarities of words/synsets in a dictionary and give methods to check it. A couple of examples help illustrate the problem we attempt to address.

The first example is the verbs `confute` and `disprove`, which have positive and negative polarities, respectively, in OF. According to WordNet, both words have a unique sense, which they share: *disprove, confute (prove to be false) "The physicist disproved his colleagues' theories"*

Assuming that WordNet has complete information about the two words, it is rather strange that the words have distinct polarities. By manually checking two other authoritative English dictionaries, Oxford<sup>1</sup> and Cambridge<sup>2</sup>, we note that the information about `confute` and `disprove` in WordNet is the same as that in these dictionaries. So, the problem seems to originate in OF.

The second example is the verbs `tantalize` and `taunt`, which have positive and negative polarities, respectively, in OF. They also have a unique sense in WordNet, which they share. Again, there is a contradiction. In this case Oxford dictionary mentions a sense of `tantalize` that is missing from WordNet: *"excite the senses or desires of (someone)"*. This sense conveys a positive polarity. Hence, `tantalize` conveys a positive sentiment when used with this sense.

In summary, these dictionaries have conflicting information. Manual checking of sentiment dictionaries for inconsistency is a difficult endeavor. We deem words such as `confute` and `disprove` inconsistent. We aim to unearth these inconsistencies in sentiment dictionaries. The presence of inconsistencies found via polarity analysis is not exclusively attributed to one party, i.e., either the sentiment dictionary or WordNet. Instead, as emphasized by the above examples, some of them lie in the sentiment dictionaries, while others lie in WordNet. Therefore, a by-product of our polarity consistency analysis is that it can also locate some of the likely places where WordNet needs linguists' attention.

We show that the problem of checking whether the polarities of a set of words is consistent is NP-complete. Fortunately, the consistency problem can be reduced to the satisfiability problem (SAT). A fast SAT solver is utilized to detect inconsistencies and it is known such solvers can in practice determine consistency or detect inconsistencies. Experimental results show that substantial inconsistencies

are discovered among words with polarities within and across sentiment dictionaries. This suggests that some remedial work needs to be performed on these sentiment dictionaries as well as on WordNet. The contributions of this paper are:

- address the consistency of polarities of words/senses. The problem has not been addressed before;
- show that the consistency problem is NP-complete;
- reduce the polarity consistency problem to the satisfiability problem and utilize a fast SAT solver to detect inconsistencies;
- give experimental results to demonstrate that our technique identifies considerable inconsistencies in various sentiment lexicons as well as discrepancies between these lexicons and WordNet.

## 2 Problem Definition

The polarities of the words in a sentiment dictionary may not necessarily be consistent (or correct). In this paper, we focus on the detection of polarity assignment inconsistencies for the words and synsets within and across dictionaries (e.g., OF vs. GI). We attempt to pinpoint the words with polarity inconsistencies and classify them (Section 3).

### 2.1 WordNet

We give a formal characterization of WordNet. This consists of words, synsets and frequency counts. A **word-synset network**  $\mathcal{N}$  is quadruple  $(\mathcal{W}, \mathcal{S}, \mathcal{E}, f)$  where  $\mathcal{W}$  is a finite set of words,  $\mathcal{S}$  is a finite set of synsets,  $\mathcal{E}$  is a set of undirected edges between elements in  $\mathcal{W}$  and  $\mathcal{S}$ , i.e.,  $\mathcal{E} \subseteq \mathcal{W} \times \mathcal{S}$  and  $f$  is a function assigning a positive integer to each element in  $\mathcal{E}$ . For an edge  $(w, s)$ ,  $f(w, s)$  is called the **frequency of use** of  $w$  in the sense given by  $s$ . For any word  $w$  and synset  $s$ , we say that  $s$  is a synset of  $w$  if  $(w, s) \in \mathcal{E}$ . Also, for any word  $w$ , we let  $freq(w)$  denote the sum of all  $f(w, s)$  such that  $(w, s) \in \mathcal{E}$ . If a synset has a 0 frequency of use we replace it with 0.1, which is a standard smoothing technique (Han, 2005). For instance, the word `cheap` has four senses. The frequencies of occurrence of the word in the four senses are  $f_1 = 9$ ,  $f_2 = 1$ ,  $f_3 = 1$  and  $f_4 = 0$ , respectively. By smoothing,  $f_4 = 0.1$ . Hence,  $freq(cheap) = f_1 + f_2 + f_3 + f_4 = 11.1$ . The **relative frequency** of the synset in the first sense of `cheap`, which denotes the probability that the word is used in the first sense, is  $\frac{f_1}{freq(cheap)} = \frac{9}{11.1} = 0.81$ .

<sup>1</sup><http://oxforddictionaries.com/>

<sup>2</sup><http://dictionary.cambridge.org/>

## 2.2 Consistent Polarity Assignment

We assume that each synset has a *unique* polarity. We define the polarity of a word to be a discrete probability distribution:  $P_+, P_-, P_0$  with  $P_+ + P_- + P_0 = 1$ , where they represent the “likelihoods” that the word is positive, negative or neutral, respectively. We call this distribution a **polarity distribution**. For instance, the word `cheap` has the polarity distribution  $P_+ = 0.81, P_- = 0.19$  and  $P_0 = 0$ . The polarity distribution of a word is estimated using the polarities of its underlying synsets. For instance `cheap` has four senses, with the first sense being positive and the last three senses being negative. The probability that the word expresses a negative sentiment is  $P_- = \frac{f_2 + f_3 + f_4}{\text{freq}(\text{cheap})} = 0.19$ , while the probability that the word expresses a positive sentiment is  $P_+ = \frac{f_1}{\text{freq}(\text{cheap})} = 0.81$ .  $P_0 = 1 - P_+ - P_- = 0$ .

Our view of characterizing the polarity of a word using a polarity distribution is shared with other previous works (Kim and Hovy, 2006; Andreevskaja and Bergler, 2006). Nonetheless, we depart from these works in the following key aspect. We say that a word has a (mostly) positive (negative) polarity if the **majority sense of the word** is positive (negative). That is, a word has a mostly positive polarity if  $P_+ > P_- + P_0$  and it has a mostly negative polarity if  $P_- > P_+ + P_0$ . Or, equivalently, if  $P_+ > \frac{1}{2}$  or  $P_- > \frac{1}{2}$ , respectively. For example, on majority, `cheap` conveys positive polarity since  $P_+ = .081 > \frac{1}{2}$ , i.e., the majority sense of the word `cheap` has positive connotation.

Based on this study, we contend that GI, OF and AL tacitly assume this property. For example, the verb `steal` is assigned only negative polarity in GI. This word has two other less frequently occurring senses, which have positive polarities. The polarity of `steal` according to these two senses is not mentioned in GI. This is the case for the overwhelming majority of the entries in the three dictionaries: only 112 out of a total of 14,105 entries in the three dictionaries regard words with multiple polarities. For example, the verb `arrest` is mentioned with both negative and positive polarities in GI. We regard an entry in an SWD as the majority sense of the word has the specified polarity, although the word may carry other polarities. For instance, the adjective `cheap` has positive polarity in GI. The only assumption we make about the word is that it has a po-

larity distribution such that  $P_+ > P_- + P_0$ . This interpretation is consistent with the senses of the word. In this work we show that this property allows the polarities of words in input sentiment dictionaries to be checked. We formally state this property.

**Definition 1.** *Let  $w$  be a word and  $S_w$  its set of synsets. Each synset in  $S_w$  has an associated polarity and a relative frequency with respect to  $w$ .  $w$  has polarity  $p$ ,  $p \in \{\text{positive, negative}\}$  if there is a subset of synsets  $S' \subseteq S_w$  such that each synset  $s \in S'$  has polarity  $p$  and  $\sum_{s \in S'} \frac{f(w,s)}{\text{freq}(w)} > 0.5$ .  $S'$  is called a **polarity dominant subset**. If there is no such subset then  $w$  has a neutral polarity.*

*$S' \subseteq S_w$  is a **minimally dominant subset of synsets (MDSs)** if the sum of the relative frequencies of the synsets in  $S'$  is larger than 0.5 and the removal of any synset  $s$  from  $S'$  will make the sum of the relative frequencies of the synsets in  $S' - \{s\}$  smaller than or equal to 0.5.*

The definition does not preclude a word from having a polarity with a *majority* sense and a different polarity with a *minority* sense. For example, the definition does not prevent a word from having both positive and negative senses, but it prevents a word from concomitantly having a majority sense of being positive and a majority sense of being negative.

Despite using a “hard-coded” constant in the definition, our approach is generic and does not depend on the constant 0.5. This constant is just a lower bound for deciding whether a word has a majority sense with a certain polarity. It also is intuitively appealing. The constant can be replaced with an arbitrary threshold  $\tau$  between 0.5 and 1.

We need a formal description of polarity assignments to the words and synsets in WordNet. We assign polarities from the set  $\mathcal{P} = \{\text{positive, negative, neutral}\}$  to elements in  $\mathcal{W} \cup \mathcal{S}$ . Formally, a polarity assignment  $\gamma$  for a network  $\mathcal{N}$  is a function from  $\mathcal{W} \cup \mathcal{S}$  to the set  $\mathcal{P}$ . Let  $\gamma$  be a polarity assignment for  $\mathcal{N}$ . We say that  $\gamma$  is **consistent** if it satisfies the following condition for each  $w \in \mathcal{W}$ :

For  $p \in \{\text{positive, negative}\}$ ,  $\gamma(w) = p$  iff the sum of all  $f(w, s)$  such that  $(w, s) \in \mathcal{E}$  and  $\gamma(s) = p$ , is greater than  $\frac{\text{freq}(w)}{2}$ . Note that, for any  $w \in \mathcal{W}$ ,  $\gamma(w) = \text{neutral}$  iff the above inequality is not satisfied for both values of  $p$  in  $\{\text{positive, negative}\}$ .

We contend that our approach is applicable to do-

Table 1: Disagreement between dictionaries.

Pairs of Dictionaries	Word Polarity Disagreement	
	Inconsistency	Overlap
OF & GI	90	2,924
OF & AL	73	1,150
GI & AL	18	712

main dependent sentiment dictionaries, too. We can employ WordNet Domains (Bentivogli et al., 2004). WordNet Domains augments WordNet with domain labels. Hence, we can project the words/synsets in WordNet according to a domain label and then apply our methodology to the projection.

### 3 Inconsistency Classification

Polarity inconsistencies are of two types: input and complex. We discuss them in this section.

#### 3.1 Input Dictionaries Polarity Inconsistency

Input polarity inconsistencies are of two types: intra-dictionary and inter-dictionary inconsistencies. The latter are obtained by comparing (1) two SWDs, (2) an SWD with an SSD and (3) two SSDs.

##### 3.1.1 Intra-dictionary inconsistency

An SWD may have triplets of the form  $(w, pos, p)$  and  $(w, pos, p')$ , where  $p \neq p'$ . For instance, the verb `brag` has both positive and negative polarities in OF. For these cases, we look up WordNet and apply Definition 1 to determine the polarity of word  $w$  with part of speech  $pos$ . The verb `brag` has negative polarity according to Definition 1. Such cases simply say that the team who constructs the dictionary believes the word has multiple polarities as they do not adopt our dominant sense principle. There are 58 occurrences of this type of inconsistency in GI, OF and AL. Q-WordNet, a sentiment sense dictionary, does not have intra-inconsistencies as it does not have a synset with multiple polarities.

##### 3.1.2 Inter-dictionary inconsistency

A word belongs to this category if it appears with different polarities in different SWDs. For instance, the adjective `joyless` has positive polarity in OF and negative polarity in GI. Table 1 depicts the overlapping relationships between the three SWDs: e.g., OF has 2,933 words in common with GI. The three dictionaries largely agree on the polarities of the words they pairwise share. For instance, out of 2,924 words shared by OF and GI, 2,834 have the same polarities. However, there are also a significant number

of words which have different polarities across dictionaries. Case in point, OF and GI disagree on the polarities of 90 words. Among the three dictionaries there are 181 polarity inconsistent words. These words are manually corrected using Definition 1 before the polarity consistency checking is applied to the union of the three dictionaries. This union is called *disagreement-free union*.

#### 3.2 Complex Polarity Inconsistency

This kind of inconsistency is more subtle and cannot be detected by direct comparison of words/synsets. They consist of *sets* of words and/or synsets whose polarities cannot concomitantly be satisfied. Recall the example of the verbs `confute` and `disprove` in OF given in Section 1. Recall our argument that by assuming that WordNet is correct, it is not possible for the two words to have different polarities: the sole synset, which they share, would have two different polarities, which is a contradiction.

The occurrence of an inconsistency points out the presence of incorrect input data:

- the information given in WordNet is incorrect, or
- the information in the given sentiment dictionary is incorrect, or both.

Regarding WordNet, the errors may be due to (1) a word has senses that are missing from WordNet or (2) the frequency count of a synset is inaccurate. A comprehensive analysis of every synset/word with inconsistency is a tantalizing endeavor requiring not only a careful study of multiple sources (e.g., dictionaries such as Oxford and Cambridge) but also linguistic expertise. It is beyond the scope of this paper to enlist all potentially inconsistent words/synsets and the possible remedies. Instead, we limit ourselves to drawing attention to the occurrence of these issues through examples, welcoming experts in the area to join the corrective efforts. We give more examples of inconsistencies in order to illustrate additional discrepancies between input dictionaries.

##### 3.2.1 WordNet vs. Sentiment Dictionaries

The adjective `bully` is an example of a discrepancy between WordNet and a sentiment dictionary. The word has negative polarity in OF and has a single sense in WordNet. The sense is shared with the word `nifty`, which has positive polarity in OF. By applying Definition 1 to `nifty` we obtain that the sense is positive, which in turn, by Definition 1, implies that `bully` is positive. This contradicts the

input polarity of `bully`. According to the Webster dictionary, the word has a sense (i.e., *resembling or characteristic of a bully*) which has a negative polarity, but it is not present in WordNet. The example shows the presence of a discrepancy between WordNet and OF, namely, OF seems to assign polarity to a word according to a sense that is not in WordNet.

### 3.2.2 Across Sentiment Dictionaries

We provide examples of inconsistencies across sentiment dictionaries here. Our first example is obtained by comparing SWDs. The adjective `comic` has negative polarity in AL and the adjective `laughable` has positive polarity in OF. Through deduction (i.e., by successive applications of Definition 1), the word `risible`, which is not present in either of the dictionaries, is assigned negative polarity because of `comic` and is assigned positive polarity because of `laughable`.

The second example illustrates that an SWD and an SSD may have contradicting information. The verb `intoxicate` has three synsets in WordNet, each with the same frequency. Hence, their relative frequencies with respect to `intoxicate` are  $\frac{1}{3}$ . On one hand, `intoxicate` has a negative polarity in GI. This means that  $P_- > \frac{1}{2}$ . On the other hand, two of its three synsets have positive polarity in Q-WordNet. So,  $P_+ = \frac{2}{3} > \frac{1}{2}$ , which means that  $P_- < \frac{1}{2}$ . This is a contradiction. This example can also be used to illustrate the presence of a discrepancy between WordNet and sentiment dictionaries. Note that all the frequencies of use of the senses of `intoxicate` in WordNet are 0. The problem is that when all the senses of a word have a 0 frequency of use, wrong polarity inference may be produced.

### 3.3 Consistent Polarity Assignment

Given the discussion above, it clearly is important to find all occurrences of inconsistent words. This in turn boils down to finding those words with the property that there does not exist any polarity assignment to the synsets, which is consistent with their polarities. It turns out that the complexity of the problem of assigning polarities to the synsets such that the assignment is consistent with the polarities of the input words, called `Consistent Polarity Assignment` problem, is a “hard” problem, as described below. The problem is stated as follows:

Consider two sets of nodes of type synsets and type words, in which each synset of a word has a

relative frequency with respect to the word. Each synset can be assigned a positive, negative or neutral polarity. A word has polarity  $p$  if it satisfies the hypothesis of Definition 1. The question to be answered is: Given an assignment of polarities to the words, does there exist an assignment of polarities to the synsets that agrees with that of the words?

In other words, given the polarities of a subset of words (e.g., that given by one of the three SWDs) the problem of finding the polarities of the synsets that agree with this assignment is a “hard” problem.

**Theorem 1.** *The Consistent Polarity Assignment problem is NP-complete.*

## 4 Polarity Consistency Checking

To “exhaustively” solve the problem of finding the polarity inconsistencies in an SWD, we propose a solution that reduces an instance of the problem to an instance of CNF-SAT. We can then employ a fast SAT solver (e.g., (Xu et al., 2008; Babic et al., 2006)) to solve our problem. CNF-SAT is a decision problem of determining if there is an assignment of True and False to the variables of a Boolean formula  $\Phi$  in conjunctive normal form (CNF) such that  $\Phi$  evaluates to True. A formula is in CNF if it is a conjunction of one or more clauses, each of which is a disjunction of literals. CNF-SAT is a classic NP-complete problem, but, modern SAT solvers are capable of solving many practical instances of the problem. Since, in general, there is no easy way to tell the difficulty of a problem without trying it, SAT solvers include time-outs, so they will terminate even if they cannot find a solution.

We developed a method of converting an instance of the polarity consistency checking problem into an instance of CNF-SAT, which we will describe next.

### 4.1 Conversion to CNF-SAT

The input consists of an SWD  $D$  and the word-synset network  $\mathcal{N}$ . We partition  $\mathcal{N}$  into connected components. For each synset  $s$  we define three Boolean variables  $s_-$ ,  $s_+$  and  $s_0$ , corresponding to the negative, positive and neutral polarities, respectively. In this section we use  $-$ ,  $+$ ,  $0$  to denote negative, positive and neutral polarities, respectively.

Let  $\Phi$  be the Boolean formula for a connected component  $M$  of the word-synset network  $\mathcal{N}$ . We introduce its clauses. First, for each synset  $s$  we need a clause  $C(s)$  that expresses that the synset can have

only one of the three polarities:  $C(s) = (s_+ \wedge \neg s_- \wedge \neg s_0) \vee (s_- \wedge \neg s_+ \wedge \neg s_0) \vee (s_0 \wedge \neg s_- \wedge \neg s_+)$ .

Since a word has a neutral polarity if it has neither positive nor negative polarities, we have that  $s_0 = \neg s_+ \wedge \neg s_-$ . Replacing this expression in the equation above and applying standard Boolean logic formulas, we can reduce it to

$$C(s) = \neg s_+ \vee \neg s_- \quad (1)$$

For each word  $w$  with polarity  $p \in \{-, +, 0\}$  in  $D$  we need a clause  $C(w, p)$  that states that  $w$  has polarity  $p$ . So, the Boolean formula for a connected component  $M$  of the word-synset network  $\mathcal{N}$  is:

$$\Phi = \bigwedge_{s \in M} C(s) \wedge \bigwedge_{(w,p) \in D} C(w,p). \quad (2)$$

From Definition 1,  $w$  is neutral if it is neither positive nor negative. Hence,  $C(w, 0) = \neg C(w, -) \wedge \neg C(w, +)$ . So, we need to define only the clauses  $C(w, -)$  and  $C(w, +)$ , which correspond to  $w$  having polarity negative and positive, respectively. So, herein  $p \in \{-, +\}$ , unless otherwise specified.

Our method is based on the following statement in Definition 1:  $w$  has polarity  $p$  if there exists a polarity dominant subset among its synsets. Thus,  $C(w, p)$  is defined by enumerating all the MDSs of  $w$ . If at least one of them is a polarity dominant subset then  $C(w, p)$  evaluates to True.

**Exhaustive Enumeration of MDSs Method (EEM)** We now elaborate the construction of  $C(w, p)$ . We enumerate all the MDSs of  $w$  and for each of them we introduce a clause. The clauses are then concatenated by OR in the Boolean formula. Let  $C(w, p, T)$  denote the clause for an MDS  $T$  of  $w$ , when  $w$  has polarity  $p \in \{-, +\}$ . Hence,

$$C(w, p) = \bigvee_{T \in MDS(w)} C(w, p, T), \quad (3)$$

where  $MDS(w)$  is the set of all MDSs of  $w$ .

For each MDS  $T$  of  $w$ , the clause  $C(w, p, T)$  is the AND of the variables corresponding to polarity  $p$  of the synsets in  $T$ . That is,

$$C(w, p, T) = \bigwedge_{s \in T} s_p, \quad p \in \{-, +\}. \quad (4)$$

The formula  $\Phi$  is not in CNF after this construction and it needs to be converted. The conversion to CNF is a standard procedure and we omit it in this paper.  $\Phi$  in CNF is input to a SAT solver.

**Example 1.** Consider a connected component consisting of the words  $w = \text{cheap}$ ,  $v = \text{inexpensive}$  and  $u = \text{sleazy}$ . *cheap* has a positive polarity, whereas *inexpensive* and *sleazy* have negative polarities. The synsets of these words are:  $\{s^1, s^2, s^3, s^4\}$ ,  $\{s^1\}$  and  $\{s^3, s^4, s^5\}$ , respectively (refer to WordNet). The relative frequencies of  $s^3$ ,  $s^4$  and  $s^5$  w.r.t. *sleazy* are all equal to 1/3. We have 15 binary variables, 3 per synset,  $s_-^i, s_+^i, s_0^i, 1 \leq i \leq 5$ . The only MDS of *cheap* is  $\{s^1\}$ , which coincides with that of *inexpensive*. Those of *sleazy* are  $\{s^3, s^4\}$ ,  $\{s^3, s^5\}$  and  $\{s^4, s^5\}$ . For each  $s^i$  we need a clause  $C(s^i)$ . Hence,  $C(w, +) = s_+^1$ ,  $C(v, -) = s_-^1$  and  $C(u, -) = (s_-^3 \wedge s_-^4) \vee (s_-^3 \wedge s_-^5) \vee (s_-^4 \wedge s_-^5)$ . Thus,  $\Phi = \bigwedge C(s^i) \wedge [s_+^1 \wedge s_-^1 \wedge ((s_-^3 \wedge s_-^4) \vee (s_-^3 \wedge s_-^5) \vee (s_-^4 \wedge s_-^5))]$ .  $\Phi$  is not in CNF and needs to be converted. For  $\Phi$  to be True, the clauses  $C(w, +) = s_+^1$  and  $C(v, -) = s_-^1$  must be True. But, this makes  $C(s^1)$  False. Hence,  $\Phi$  is not satisfiable. The clauses  $C(w, +) = s_+^1$  and  $C(v, -) = s_-^1$  are unsatisfiable and thus the polarities of *cheap* and *inexpensive* are inconsistent.

## 4.2 Implementation Issues

The above reduction is exponential in the number of clauses (see, Equation 3) in the worst case. A polynomial reduction is possible, but it is significantly more complicated to implement. We choose to present the exponential reduction in this paper because it can handle over 97% of the words in WordNet and it is better suited to explain one of the main contributions of paper: the translation from the polarity consistency problem to SAT.

WordNet possesses nice properties, which allows the exponential reduction to run efficiently in practice. First, 97.2% of its (word, part-of-speech) pairs have 4 or fewer synsets. Thus, these words add very few clauses to a CNF formula (Equation 3). Second, WordNet can be partitioned into 33,015 *non-trivial* connected components, each of which corresponds to a Boolean formula and they all are independently handled. A non-trivial connected component has at least two words. Finally, in practice, not all connected components need to be considered for an input sentiment dictionary  $D$ , but only those having at least two words in  $D$ . In our experiments the largest number of components that need to be processed is

Table 2: Distribution of words and synsets

POS	Words	Synsets	OF	GI	AL	QWN

1,581, for the disagreement-free union dictionary.

## 5 Detecting Inconsistencies

In this section we describe how we detect the words with polarity inconsistencies using the output of a SAT solver. For an unsatisfiable formula, a modern SAT solver returns a *minimal unsatisfiable core* (MUC) from the original formula. An *unsatisfiable core* is minimal if it becomes satisfiable whenever any one of its clauses is removed. There are no known practical algorithms for computing the *minimum core* (Dershowitz et al., 2006). In our problem a MUC corresponds to a set of polarity inconsistent words. The argument is as follows. Consider  $W$  the set of words in a connected component and  $\Phi$  the CNF formula generated with the above method. During the transformation we keep track of the clauses introduced in  $\Phi$  by each word. Suppose  $\Phi$  is inconsistent. Then, the SAT solver returns a MUC. Each clause in a MUC is mapped back to its corresponding word(s). We obtain the corresponding subset of words  $W'$ ,  $W' \subseteq W$ . Suppose that  $\Phi'$  is the Boolean CNF formula for the words in  $W'$ . The set of clauses in  $\Phi'$  is a subset of those in  $\Phi$ . Also, the clauses in the MUC appear in  $\Phi'$ . Thus,  $\Phi'$  is unsatisfiable and the words in  $W'$  are inconsistent.

To find *all* inconsistent words we ought to generate all MUCs. Unfortunately, this is a “hard” problem (Dershowitz et al., 2006) and no open source SAT solver possesses this functionality. We however observe that the two SAT solvers we use for our experiments (SAT4j and PicoSAT (Biere, 2008)) return different MUCs for the same formula and we use them to find as many inconsistencies as possible.

## 6 Experiments

The goal of the experimental study is to show that our techniques can identify considerable inconsistencies in various sentiment dictionaries.

Table 3: Intra- and inter-dictionaries inconsistency

POS	OF	QW	GI	QW	AL	QW	UF	QW
<b>Noun</b>	23	119	4	61	0	42	90	140
<b>Verb</b>	66	113	2	67	0	0	63	137
<b>Adj.</b>	90	170	8	48	0	0	27	177
<b>Adv.</b>	61	1	0	0	2	0	69	1
<b>Total</b>	<b>240</b>	<b>403</b>	<b>14</b>	<b>176</b>	<b>2</b>	<b>42</b>	<b>249</b>	<b>455</b>

**Data sets** In our experiments, we use WordNet 3.0, GI, OF, AL and Q-WordNet. Their statistics are given in Table 2. The table shows the distribution of the words and synsets per part of speech. Columns 2 and 3 pertain to WordNet. There are 3,961 entries in GI, 1,759 entries in AL and 6,791 entries in OF which appear in WordNet. Q-WordNet has 15,499 entries, i.e., synsets with polarities.

**Inconsistency Detection** We applied our method to (1) each of AL, GI and OF; (2) the disagreement-free union (UF); (3) each of AL, GI and OF together with Q-WordNet and (4) UF and Q-WordNet. Table 3 summarizes the outcome of the experimental study. EEM finds 240, 14 and 2 polarity inconsistent words in OF, GI and AL, respectively. The ratio between the number of inconsistent words and the number of input words is the highest for OF and the lowest for AL. The union dictionary has 7,794 words and 249 out of them are found to be polarity inconsistent words. Recall that we manually corrected the polarities of 181 words, to the best of our understanding. So, in effect the three dictionaries have  $249 + 181 = 430$  polarity inconsistent words. As discussed in the previous section, these may not be all the polarity inconsistencies in UF. In general, to find all inconsistencies we need to generate all MUCs. Generating all MUCs is an “overkill” and the SAT solvers we use do not implement such a functionality. In addition, the intention of SAT solver designers is to use MUCs in an interactive manner. That is, the errors pointed out by a MUC are corrected and then the new improved formula is re-evaluated by the SAT solver. If an error is still present a new MUC is reported, and the process repeats until the formula has no errors. Or, in our problem, until a dictionary is consistent.

We also paired Q-WordNet with each of the SWDs. Table 3 presents the results. Observe that polarities assigned to the words in AL and GI largely agree with the polarities assigned to the synsets in

Q-WordNet. This is expected for AL because it has only two nouns and no verb, while Q-WordNet has only 40 adverbs. Consequently, these two dictionaries have limited “overlay”. The union dictionary and Q-WordNet have substantial inconsistencies: the polarity of 455 words in the union dictionary disagrees with the polarities assigned to their underlying synsets in Q-WordNet.

**Sentence Level Evaluation** We took 10 pairs of inconsistent words per part of speech; in total, we collected a set  $IW$  of 80 inconsistent words. Let  $\langle w, pos, p \rangle \in IW$ ,  $p$  is the polarity of  $w$ . We collected 5 sentences for  $\langle w, pos \rangle$  from the set of snippets returned by Google for query  $w$ . We parsed the snippets and identified the first 5 occurrences of  $w$  with the part of speech  $pos$ . Then two graduate students with English background analyzed the polarities of  $\langle w, pos \rangle$  in the 5 sentences. We counted the number of times  $\langle w, pos \rangle$  appears with polarity  $p$  and polarities different from  $p$ . We defined an agreement scale: total agreement (5/5), most agreement (4/5), majority agreement (3/5), majority disagreement (2/5), most disagreement (1/5), total disagreement (0/5). We computed the percentage of words per agreement category. We repeated the experiment for 40 randomly drawn words (10 per part of speech) from the set of consistent words. In total 600 sentences were manually analyzed. Figure 1 shows the distribution of the (in)consistent words. For example, the annotators totally agree with the polarities of 55% of the consistent words, whereas they only totally agree with 16% of the polarities of the inconsistent words. The graph suggests that the annotators disagree to some extent (total disagreement + most disagreement + major disagreement) with 40% of the polarities of the inconsistent words, whereas they disagree to some extent with only 5% of the consistent words. We also manually investigated the senses of these words in WordNet. We noted that 36 of the 80 inconsistent words (45%) have missing senses according to one of these English dictionaries: Oxford and Cambridge.

**Computational Issues** We used a 4-core CPU computer with 12GB of memory. EEM requires 10GB of memory and cannot handle words with more than 200,000 MDSs: for UF we left the SAT solver running for a week without ever terminating. In contrast, it takes about 4 hours if we limit the set

Figure 1: Human classification of (in)consistent words.

of words to those that have up to 200,000 MDSs. EEM could not handle words such as *make*, *give* and *break*. Recall however that we did not generate all MUCs. We do not know how long would that might have taken. (The polynomial method handles all the words in WordNet and it takes 5GB of memory and about 2 hours to finish.)

## 7 Related Work

Several researchers have studied the problem of finding opinion words (Liu, 2010). There are two lines of work on sentiment polarity lexicon induction: corpora-based (Hatzivassiloglou and McKeown, 1997; Kanayama and Nasukawa, 2006; Qiu et al., 2009; Wiebe, 2000) and dictionary-based (Andreevskaia and Bergler, 2006; Agerri and García-Serrano, 2010; Dragut et al., 2010; Esuli and Sebastiani, 2005; Baccianella et al., 2010; Hu and Liu, 2004; Kamps et al., 2004; Kim and Hovy, 2006; Rao and Ravichandran, 2009; Takamura et al., 2005). Our work falls into the latter. Most of these works use the lexical relations defined in WordNet (e.g., synonym, antonym) to derive sentiment lexicons. To our knowledge, none of the earlier works studied the problem of polarity consistency checking for a sentiment dictionary. Our techniques can pinpoint the inconsistencies within individual dictionaries and across dictionaries.

## 8 Conclusion

We studied the problem of checking polarity consistency for sentiment word dictionaries. We proved that this problem is NP-complete. We showed that in practice polarity inconsistencies of words both within a dictionary and across dictionaries can be obtained using an SAT solver. The inconsistencies are pinpointed and this allows the dictionaries to be improved. We reported experiments on four sentiment dictionaries and their union dictionary.

## Abstract

An ideal summarization system should produce summaries that have high content coverage and linguistic quality. Many state-of-the-art summarization systems focus on content coverage by extracting content-dense sentences from source articles. A current research focus is to process these sentences so that they read fluently as a whole. The current AESOP task encourages research on evaluating summaries on content, readability, and overall responsiveness. In this work, we adapt a machine translation metric to measure content coverage, apply an enhanced discourse coherence model to evaluate summary readability, and combine both in a trained regression model to evaluate overall responsiveness. The results show significantly improved performance over AESOP 2011 submitted metrics.

## 1 Introduction

Research and development on automatic and manual evaluation of summarization systems have been mainly focused on content coverage (Lin and Hovy, 2003; Nenkova and Passonneau, 2004; Hovy et al., 2006; Zhou et al., 2006). However, users may still find it difficult to read such high-content coverage summaries as they lack fluency. To promote research on automatic evaluation of summary readability, the Text Analysis Conference (TAC) (Owczarzak and Dang, 2011) introduced a new subtask on readability to its Automatically Evaluating Summaries of Peers (AESOP) task.

Most of the state-of-the-art summarization systems (Ng et al., 2011; Zhang et al., 2011; Conroy et al., 2011) are extraction-based. They extract the most content-dense sentences from source articles. If no post-processing is performed to the generated summaries, the presentation of the extracted sentences may confuse readers. Knott (1996) argued that when the sentences of a text are randomly ordered, the text becomes difficult to understand, as its discourse structure is disturbed. Lin et al. (2011) validated this argument by using a trained model to differentiate an original text from a randomly-ordered permutation of its sentences by looking at their discourse structures. This prior work leads us to believe that we can apply such discourse models to evaluate the readability of extract-based summaries. We will discuss the application of Lin et al.'s discourse coherence model to evaluate readability of machine generated summaries. We also introduce two new feature sources to enhance the model with hierarchical and Explicit/Non-Explicit information, and demonstrate that they improve the original model.

There are parallels between evaluations of machine translation (MT) and summarization with respect to textual content. For instance, the widely used ROUGE (Lin and Hovy, 2003) metrics are influenced by BLEU (Papineni et al., 2002): both look at surface n-gram overlap for content coverage. Motivated by this, we will adapt a state-of-the-art, linear programming-based MT evaluation metric, TESLA (Liu et al., 2010), to evaluate the content coverage of summaries.

TAC's overall responsiveness metric evaluates the

quality of a summary with regard to both its content and readability. Given this, we combine our two component coherence and content models into an SVM-trained regression model as our surrogate to overall responsiveness. Our experiments show that the coherence model significantly outperforms all AESOP 2011 submissions on both initial and update tasks, while the adapted MT evaluation metric and the combined model significantly outperform all submissions on the initial task. To the best of our knowledge, this is the first work that applies a discourse coherence model to measure the readability of summaries in the AESOP task.

## 2 Related Work

Nenkova and Passonneau (2004) proposed a manual evaluation method that was based on the idea that there is no single best model summary for a collection of documents. Human annotators construct a *pyramid* to capture important Summarization Content Units (SCUs) and their weights, which is used to evaluate machine generated summaries.

Lin and Hovy (2003) introduced an automatic summarization evaluation metric, called ROUGE, which was motivated by the MT evaluation metric, BLEU (Papineni et al., 2002). It automatically determines the content quality of a summary by comparing it to the model summaries and counting the overlapping n-gram units. Two configurations – ROUGE-2, which counts bigram overlaps, and ROUGE-SU4, which counts unigram and bigram overlaps in a word window of four – have been found to correlate well with human evaluations.

Hovy et al. (2006) pointed out that automated methods such as ROUGE, which match fixed length n-grams, face two problems of tuning the appropriate fragment lengths and matching them properly. They introduced an evaluation method that makes use of small units of content, called Basic Elements (BEs). Their method automatically segments a text into BEs, matches similar BEs, and finally scores them.

Both ROUGE and BE have been implemented and included in the ROUGE/BE evaluation toolkit<sup>1</sup>, which has been used as the default evaluation tool in the summarization track in the Document Un-

derstanding Conference (DUC) and Text Analysis Conference (TAC). DUC and TAC also manually evaluated machine generated summaries by adopting the Pyramid method. Besides evaluating with ROUGE/BE and Pyramid, DUC and TAC also asked human judges to score every candidate summary with regard to its content, readability, and overall responsiveness.

DUC and TAC defined linguistic quality to cover several aspects: grammaticality, non-redundancy, referential clarity, focus, and structure/coherence. Recently, Pitler et al. (2010) conducted experiments on various metrics designed to capture these aspects. Their experimental results on DUC 2006 and 2007 show that grammaticality can be measured by a set of syntactic features, while the last three aspects are best evaluated by local coherence. Conroy and Dang (2008) combined two manual linguistic scores – grammaticality and focus – with various ROUGE/BE metrics, and showed this helps better predict the responsiveness of the summarizers.

Since 2009, TAC introduced the task of Automatically Evaluating Summaries of Peers (AESOP). AESOP 2009 and 2010 focused on two summary qualities: content and overall responsiveness. Summary content is measured by comparing the output of an automatic metric with the manual Pyramid score. Overall responsiveness measures a combination of content and linguistic quality. In AESOP 2011 (Owczarzak and Dang, 2011), automatic metrics are also evaluated for their ability to assess summary readability, *i.e.*, to measure how linguistically readable a machine generated summary is. Submitted metrics that perform consistently well on the three aspects include Giannakopoulos and Karkaletsis (2011), Conroy et al. (2011), and de Oliveira (2011). Giannakopoulos and Karkaletsis (2011) created two character-based n-gram graph representations for both the model and candidate summaries, and applied graph matching algorithm to assess their similarity. Conroy et al. (2011) extended the model in (Conroy and Dang, 2008) to include shallow linguistic features such as term overlap, redundancy, and term and sentence entropy. de Oliveira (2011) modeled the similarity between the model and candidate summaries as a maximum bipartite matching problem, where the two summaries are represented as two sets of nodes and precision and recall are cal-

<sup>1</sup><http://berouge.com/default.aspx>

Figure 1: A BNG matching problem. Top and bottom rows of each figure represent BNG from the model and candidate summaries, respectively. Links are similarities. Both n-grams and links are weighted.

culated from the matched edges. However, none of the AESOP metrics currently apply deep linguistic analysis, which includes discourse analysis.

Motivated by the parallels between summarization and MT evaluation, we will adapt a state-of-the-art MT evaluation metric to measure summary content quality. To apply deep linguistic analysis, we also enhance an existing discourse coherence model to evaluate summary readability. We focus on metrics that measure the average quality of machine summarizers, *i.e.*, metrics that can rank a set of machine summarizers correctly (human summarizers are not included in the list).

### 3 TESLA-S: Evaluating Summary Content

TESLA (Liu et al., 2010) is an MT evaluation metric which extends BLEU by introducing a linear programming-based framework for improved matching. It also makes use of linguistic resources and considers both precision and recall.

#### 3.1 The Linear Programming Matching Framework

Figure 1 shows the matching of bags of n-grams (BNGs) that forms the core of the TESLA metric. The top row in Figure 1a represents the bag of n-grams (BNG) from the model summary, and the

bottom row represents the BNG from the candidate summary. Each n-gram has a weight. The links between the n-grams represent the similarity score, which are constrained to be between 0 and 1. Mathematically, TESLA takes as input the following:

1. The BNG of the model summary,  $X$ , and the BNG of the candidate summary,  $Y$ . The  $i$ th entry in  $X$  is  $x_i$  and has weight  $x_i^W$  (analogously for  $y_i$  and  $y_i^W$ ).
2. A similarity score  $s(x_i, y_j)$  between all n-grams  $x_i$  and  $y_j$ .

The goal of the matching process is to align the two BNGs so as to maximize the overall similarity. The variables of the problem are the allocated weights for the edges,

$$w(x_i, y_j) \quad \forall i, j$$

TESLA maximizes

$$\sum_{i,j} s(x_i, y_j) w(x_i, y_j)$$

subject to

$$\begin{aligned} w(x_i, y_j) &\geq 0 \quad \forall i, j \\ \sum_j w(x_i, y_j) &\leq x_i^W \quad \forall i \\ \sum_i w(x_i, y_j) &\leq y_j^W \quad \forall j \end{aligned}$$

This real-valued linear programming problem can be solved efficiently. The overall similarity  $S$  is the value of the objective function. Thus,

$$\begin{aligned} \text{Precision} &= \frac{S}{\sum_j y_j^W} \\ \text{Recall} &= \frac{S}{\sum_i x_i^W} \end{aligned}$$

The final TESLA score is given by the F-measure:

$$F = \frac{\text{Precision} \times \text{Recall}}{\alpha \times \text{Precision} + (1 - \alpha) \times \text{Recall}}$$

In this work, we set  $\alpha = 0.8$ , following (Liu et al., 2010). The score places more importance on recall than precision. When multiple model summaries are provided, TESLA matches the candidate BNG with each of the model BNGs. The maximum score is taken as the combined score.

### 3.2 TESLA-S: TESLA for Summarization

We adapted TESLA for the nuances of summarization. Mimicking ROUGE-SU4, we construct one matching problem between the unigrams and one between skip bigrams with a window size of four. The two F scores are averaged to give the final score.

The similarity score  $s(x_i, y_j)$  is 1 if the word surface forms of  $x_i$  and  $y_j$  are identical, and 0 otherwise. TESLA has a more sophisticated similarity measure that focuses on awarding partial scores for synonyms and parts of speech (POS) matches. However, the majority of current state-of-the-art summarization systems are extraction-based systems, which do not generate new words. Although our simplistic similarity score may be problematic when evaluating abstract-based systems, the experimental results support our choice of the similarity function. This reflects a major difference between MT and summarization evaluation: while MT systems always generate new sentences, most summarization systems focus on locating existing salient sentences.

Like in TESLA, function words (words in closed POS categories, such as prepositions and articles) have their weights reduced by a factor of 0.1, thus placing more emphasis on the content words. We found this useful empirically.

### 3.3 Significance Test

Koehn (2004) introduced a bootstrap resampling method to compute statistical significance of the difference between two machine translation systems with regard to the BLEU score. We adapt this method to compute the difference between two evaluation metrics in summarization:

1. Randomly choose  $n$  topics from the  $n$  given topics with replacement.
2. Summarize the topics with the list of machine summarizers.
3. Evaluate the list of summaries from Step 2 with the two evaluation metrics under comparison.
4. Determine which metric gives a higher correlation score.
5. Repeat Step 1 – 4 for 1,000 times.

As we have 44 topics in TAC 2011 summarization track,  $n = 44$ . The percentage of times metric  $a$  gives higher correlation than metric  $b$  is said to be the significance level at which  $a$  outperforms  $b$ .

TESLA-S	<b>0.9807</b>	<b>0.9173</b>	<b>0.7734</b>	0.9072	<b>0.8457</b>	0.6811

Table 1: Content correlation with human judgment on summarizer level. Top three scores among AESOP metrics are underlined. The TESLA-S score is bolded when it outperforms all others. ROUGE-2 is shortened to R-2 and ROUGE-SU4 to R-SU4.

### 3.4 Experiments

We test TESLA-S on the AESOP 2011 content evaluation task, judging the metric fitness by comparing its correlations with human judgments for content. The results for the initial and update tasks are reported in Table 1. We show the three baselines (ROUGE-2, ROUGE-SU4, and BE) and submitted metrics with correlations among the top three scores, which are underlined. This setting remains the same for the rest of the experiments. We use three correlation measures: Pearson’s  $r$ , Spearman’s  $\rho$ , and Kendall’s  $\tau$ , represented by P, S, and K, respectively. The ROUGE scores are the recall scores, as per convention. On the initial task, TESLA-S outperforms all metrics on all three correlation measures. On the update task, TESLA-S ranks second, first, and second on Pearson’s  $r$ , Spearman’s  $\rho$ , and Kendall’s  $\tau$ , respectively.

To test how significant the differences are, we perform significance testing using Koehn’s resampling method between TESLA-S and ROUGE-2/ROUGE-SU4, on which TESLA-S is based. The findings are:

- Initial task: TESLA-S is better than ROUGE-2 at 99% significance level as measured by Pearson’s  $r$ .
- Update task: TESLA-S is better than ROUGE-SU4 at 95% significance level as measured by Pearson’s  $r$ .
- All other differences are statistically insignificant, including all correlations on Spearman’s

$\rho$  and Kendall’s  $\tau$ .

The last point can be explained by the fact that Spearman’s  $\rho$  and Kendall’s  $\tau$  are sensitive to only the system rankings, whereas Pearson’s  $r$  is sensitive to the magnitude of the differences as well, hence Pearson’s  $r$  is in general a more sensitive measure.

#### 4 DICOMER: Evaluating Summary Readability

Intuitively, a readable text should also be coherent, and an incoherent text will result in low readability. Both readability and coherence indicate how fluent a text is. We thus hypothesize that a model that measures how coherent a text is can also measure its readability. Lin et al. (2011) introduced discourse role matrix to represent discourse coherence of a text. We first illustrate their model with an example, and then introduce two new feature sources. We then apply the models and evaluate summary readability.

##### 4.1 Lin et al.’s Discourse Coherence Model

First, a free text in Figure 2 is parsed by a discourse parser to derive its discourse relations, which are shown in Figure 3. Lin et al. observed that coherent texts preferentially follow certain relation patterns. However, simply using such patterns to measure the coherence of a text can result in feature sparseness. To solve this problem, they expand the relation sequence into a discourse role matrix, as shown in Table 2. The matrix essentially captures term occurrences in the sentence-to-sentence relation sequences. This model is motivated by the entity-based model (Barzilay and Lapata, 2008) which captures sentence-to-sentence entity transitions. Next, the discourse role transition probabilities of lengths 2 and 3 (e.g., Temp.Arg1→Exp.Arg2 and Comp.Arg1→nil→Temp.Arg1) are calculated with respect to the matrix. For example, the probability of Comp.Arg2→Exp.Arg2 is  $2/25 = 0.08$  in Table 2.

Lin et al. applied their model on the task of discerning an original text from a permuted ordering of its sentences. They modeled it as a pairwise ranking model (i.e., original vs. permuted), and trained a SVM preference ranking model with discourse role

- $S_1$  Japan normally depends heavily on the Highland Valley and Cananea mines as well as the Bougainville mine in Papua New Guinea.
- $S_2$  Recently, Japan has been buying copper elsewhere.
- $S_{3.1}$  But as Highland Valley and Cananea begin operating,
- $S_{3.2}$  they are expected to resume their roles as Japan’s suppliers.
- $S_{4.1}$  According to Fred Demler, metals economist for Drexel Burnham Lambert, New York,
- $S_{4.2}$  “Highland Valley has already started operating
- $S_{4.3}$  and Cananea is expected to do so soon.”

Figure 2: A text with four sentences.  $S_{i,j}$  means the  $j$ th clause in the  $i$ th sentence.

Figure 3: The discourse relations for Figure 2. Arrows are pointing from Arg2 to Arg1.

S#	Terms				
	copper	cananea	operat	depend	...
$S_1$	nil	Comp.Arg1	nil	Comp.Arg1	
$S_2$	Comp.Arg2 Comp.Arg1	nil	nil	nil	
$S_3$	nil	Comp.Arg2 Temp.Arg1 Exp.Arg1	Comp.Arg2 Temp.Arg1 Exp.Arg1	nil	
$S_4$	nil	Exp.Arg2	Exp.Arg1 Exp.Arg2	nil	

Table 2: Discourse role matrix fragment extracted from Figure 2 and 3. Rows correspond to sentences, columns to stemmed terms, and cells contain extracted discourse roles. Temporal, Contingency, Comparison, and Expansion are shortened to Temp, Cont, Comp, and Exp, respectively.

transitions as features and their probabilities as values.

##### 4.2 Two New Feature Sources

We observe that there are two kinds of information in Figure 3 that are not captured by Lin et al.’s

model. The first one is whether a relation is Explicit or Non-Explicit (Lin et al. (2010) termed Non-Explicit to include Implicit, AltLex, EntRel, and NoRel). Explicit relation and Non-Explicit relation have different distributions on each discourse relation (PDTB-Group, 2007). Thus, adding this information may further improve the model. In addition to the set of the discourse roles of “Relation type . Argument tag”, we introduce another set of “Explicit/Non-Explicit . Relation type . Argument tag”. The cell  $C_{cananea,S_3}$  now contains Comp.Arg2, Temp.Arg1, Exp.Arg1, E.Comp.Arg2, E.Temp.Arg1, and N.Exp.Arg1 (E for Explicit and N for Non-Explicit).

The other information that is not in the discourse role matrix is the discourse hierarchy structure, *i.e.*, whether one relation is embedded within another relation. In Figure 3,  $S_{3.1}$  is Arg1 of Explicit Temporal, which is Arg2 of the higher relation Explicit Comparison as well as Arg1 of another higher relation Implicit Expansion. These dependencies are important for us to know how well-structured a summary is. It is represented by the multiple discourse roles in each cell of the matrix. For example, the multiple discourse roles in the cell  $C_{cananea,S_3}$  capture the three dependencies just mentioned. We introduce intra-cell bigrams as a new set of features to the original model: for a cell with multiple discourse roles, we sort them by their surface strings and multiply to obtain the bigrams. For instance,  $C_{cananea,S_3}$  will produce bigrams such as Comp.Arg2 $\leftrightarrow$ Exp.Arg1 and Comp.Arg2 $\leftrightarrow$ Temp.Arg1. When both the Explicit/Non-Explicit feature source and the intra-cell feature source are joined together, it also produces bigram features such as E.Comp.Arg2 $\leftrightarrow$ Temp.Arg1.

### 4.3 Predicting Readability Scores

Lin et al. (2011) used the SVM<sup>light</sup> (Joachims, 1999) package with the preference ranking configuration. To train the model, each source text and one of its permutations form a training pair, where the source text is given a rank of 1 and the permutation is given 0. In testing, the trained model predicts a real number score for each instance, and the instance with the higher score in a pair is said to be the source text.

In the TAC summarization track, human judges scored each model and candidate summary with a readability score from 1 to 5 (5 means most readable). Thus in our setting, instead of a pair of texts, the training input consists of a list of model and candidate summaries from each topic, with their annotated scores as the rankings. Given an unseen test summary, the trained model predicts a real number score. This score essentially is the readability ranking of the test summary. Such ranking can be evaluated by the ranking-based correlations of Spearman’s  $\rho$  and Kendall’s  $\tau$ . As Pearson’s  $r$  measures linear correlation and we do not know whether the real number score follows a linear function, we take the logarithm of this score as the readability score for this instance.

We use the data from AESOP 2009 and 2010 as the training data, and test our metrics on AESOP 2011 data. To obtain the discourse relations of a summary, we use the discourse parser<sup>2</sup> developed in Lin et al. (2010).

### 4.4 Experiments

Table 3 shows the resulting readability correlations. The last four rows show the correlation scores for our coherence model: LIN is the default model by (Lin et al., 2011), LIN+C is LIN with the intra-cell feature class, LIN+E is enhanced with the Explicit/Non-Explicit feature class. We name the LIN model with both new feature sources (*i.e.*, LIN+C+E) DICOMER – a DIScourse COherence Model for Evaluating Readability.

LIN outperforms all metrics on all correlations on both tasks. On the initial task, it outperforms the best scores by 3.62%, 16.20%, and 12.95% on Pearson, Spearman, and Kendall, respectively. Similar gaps (4.27%, 18.52%, and 13.96%) are observed on the update task. The results are much better on Spearman and Kendall. This is because LIN is trained with a ranking model, and both Spearman and Kendall are ranking-based correlations.

Adding either intra-cell or Explicit/Non-Explicit features improves all correlation scores, with Explicit/Non-Explicit giving more pronounced improvements. When both new feature sources are in-

incorporated into the metric, we obtain the best results for all correlation scores: DICOMER outperforms LIN by 1.10%, 5.29%, and 3.95% on the initial task, and 2.50%, 4.74%, and 4.27% on the update task.

Table 3 shows that summarization evaluation Metric 4 tops all other AESOP metrics, except in the case of Spearman’s  $\rho$  on the initial task. We compare our four models to this metric. The results of Koehn’s significance test are reported in Table 4, which demonstrates that all four models outperform Metric 4 significantly. In the last row, we see that when comparing DICOMER to LIN, DICOMER is significantly better on three correlation measures.

## 5 CREMER: Evaluating Overall Responsiveness

With TESLA-S measuring content coverage and DICOMER measuring readability, it is feasible to combine them to predict the overall responsiveness of a summary. There exist many ways to combine two variables mathematically: we can combine them in a linear function or polynomial function, or in a way

similar to how precision and recall are combined in  $F$  measure. We applied a machine learning approach to train a regression model for measuring responsiveness. The scores predicted by TESLA-S and DICOMER are used as two features. We use SVM<sup>light</sup> with the regression configuration, testing three kernels: linear function, polynomial function, and radial basis function. We called this model CREMER – a Combined REgression Model for Evaluating Responsiveness.

We train the regression model on AESOP 2009 and 2010 data sets, and test it on AESOP 2011. The DICOMER model that is trained in Section 4 is used to predict the readability scores on all AESOP 2009, 2010, and 2011 summaries. We apply TESLA-S to predict content scores on all AESOP 2009, 2010, and 2011 summaries.

### 5.1 Experiments

The last three rows in Table 5 show the correlation scores of our regression model trained with SVM linear function (LF), polynomial function (PF), and radial basis function (RBF). PF performs better than LF, suggesting that content and readability scores should not be linearly combined. RBF gives better performances than both LF and PF, suggesting that RBF better models the way humans combine content and readability. On the initial task, the model trained with RBF outperforms all submitted metrics. It outperforms the best correlation scores

by 1.71%, 3.86%, and 4.60% on Pearson, Spearman, and Kendall, respectively. All three regression models do not perform as well on the update task. Koehn’s significance test shows that when trained with RBF, CREMER outperforms ROUGE-2 and ROUGE-SU4 on the initial task at a significance level of 99% for all three correlation measures.

## 6 Discussion

The intuition behind the combined regression model is that combining the readability and content scores will give an overall good responsiveness score. The function to combine them and their weights can be obtained by training. While the results showed that SVM radial basis kernel gave the best performances, this function may not truly mimic how human evaluates responsiveness. Human judges were told to rate summaries by their overall qualities. They may take into account other aspects besides content and readability. Given CREMER did not perform well on the update task, we hypothesize that human judgment of update summaries may involve more complicated rankings or factor in additional input that CREMER currently does not model. We plan to devise a better responsiveness metric in our future work, beyond using a simple combination.

Figure 4 shows a complete picture of Pearson’s  $r$  for all AESOP 2011 metrics and our three metrics on both initial and update tasks. We highlight our metrics with a circle on these curves. On the initial task, correlation scores for content are consistently higher than those for responsiveness with small gaps, whereas on the update task, they are almost overlapping. On the other hand, correlation scores for readability are much lower than those for content and responsiveness, with a gap of about 0.2. Comparing Figure 4a and 4b, evaluation metrics always correlate better on the initial task than on the update task. This suggests that there is much room for improvement for readability metrics, and metrics need to consider update information when evaluating update summarizers.

## 7 Conclusion

We proposed TESLA-S by adapting an MT evaluation metric to measure summary content coverage, and introduced DICOMER by applying a dis-

(a) Evaluation metric values on the initial task.

(b) Evaluation metric values on the update task.

Figure 4: Pearson’s  $r$  for all AESOP 2011 submitted metrics and our proposed metrics. Our metrics are circled. Higher  $r$  value is better.

course coherence model with newly introduced features to evaluate summary readability. We combined these two metrics in the CREMER metric – an SVM-trained regression model – for automatic summarization overall responsiveness evaluation. Experimental results on AESOP 2011 show that DICOMER significantly outperforms all submitted metrics on both initial and update tasks with large gaps, while TESLA-S and CREMER significantly outperform all metrics on the initial task.<sup>3</sup>

## Abstract

In this paper we describe a method for simplifying sentences using Phrase Based Machine Translation, augmented with a re-ranking heuristic based on dissimilarity, and trained on a monolingual parallel corpus. We compare our system to a word-substitution baseline and two state-of-the-art systems, all trained and tested on paired sentences from the English part of Wikipedia and Simple Wikipedia. Human test subjects judge the output of the different systems. Analysing the judgements shows that by relatively careful phrase-based paraphrasing our model achieves similar simplification results to state-of-the-art systems, while generating better formed output. We also argue that text readability metrics such as the Flesch-Kincaid grade level should be used with caution when evaluating the output of simplification systems.

## 1 Introduction

Sentence simplification can be defined as the process of producing a simplified version of a sentence by changing some of the lexical material and grammatical structure of that sentence, while still preserving the semantic content of the original sentence, in order to ease its understanding. Particularly language learners (Siddharthan, 2002), people with reading disabilities (Inui et al., 2003) such as aphasia (Carroll et al., 1999), and low-literacy readers (Watanabe et al., 2009) can benefit from this application. It can serve to generate output in a specific limited format, such as subtitles (Daelemans et al., 2004). Sentence simplification can also serve to preprocess the input

of other tasks, such as summarization (Knight and Marcu, 2000), parsing, machine translation (Chandrasekar et al., 1996), semantic role labeling (Vickrey and Koller, 2008) or sentence fusion (Filippova and Strube, 2008).

The goal of simplification is to achieve an improvement in readability, defined as the ease with which a text can be understood. Some of the factors that are known to help increase the readability of text are the vocabulary used, the length of the sentences, the syntactic structures present in the text, and the usage of discourse markers. One effort to create a simple version of English at the vocabulary level has been the creation of Basic English by Charles Kay Ogden. Basic English is a controlled language with a basic vocabulary consisting of 850 words. According to Ogden, 90 percent of all dictionary entries can be paraphrased using these 850 words. An example of a resource that is written using mainly Basic English is the English Simple Wikipedia. Articles on English Simple Wikipedia are similar to articles found in the traditional English Wikipedia, but written using a limited vocabulary (using Basic English where possible). Generally the structure of the sentences in English Simple Wikipedia is less complicated and the sentences are somewhat shorter than those found in English Wikipedia; we offer more detailed statistics below.

### 1.1 Related work

Most earlier work on sentence simplification adopted rule-based approaches. A frequently applied type of rule, aimed to reduce overall sentence length, splits long sentences on the basis of syntactic

information (Chandrasekar and Srinivas, 1997; Carroll et al., 1998; Canning et al., 2000; Vickrey and Koller, 2008). There has also been work on lexical substitution for simplification, where the aim is to substitute difficult words with simpler synonyms, derived from WordNet or dictionaries (Inui et al., 2003).

Zhu et al. (2010) examine the use of paired documents in English Wikipedia and Simple Wikipedia for a data-driven approach to the sentence simplification task. They propose a probabilistic, syntax-based machine translation approach to the problem and compare against a baseline of no simplification and a phrase-based machine translation approach. In a similar vein, Coster and Kauchak (2011) use a parallel corpus of paired documents from Simple Wikipedia and Wikipedia to train a phrase-based machine translation model coupled with a deletion model. Another useful resource is the edit history of Simple Wikipedia, from which simplifications can be learned (Yatskar et al., 2010). Woodsend and Lapata (2011) investigate the use of Simple Wikipedia edit histories and an aligned Wikipedia–Simple Wikipedia corpus to induce a model based on quasi-synchronous grammar. They select the most appropriate simplification by using integer linear programming.

We follow Zhu et al. (2010) and Coster and Kauchak (2011) in proposing that sentence simplification can be approached as a monolingual machine translation task, where the source and target languages are the same and where the output should be simpler in form from the input but similar in meaning. We differ from the approach of Zhu et al. (2010) in the sense that we do not take syntactic information into account; we rely on PBMT to do its work and implicitly learn simplifying paraphrasings of phrases. Our approach differs from Coster and Kauchak (2011) in the sense that instead of focusing on deletion in the PBMT decoding stage, we focus on dissimilarity, as simplification does not necessarily imply shortening (Woodsend and Lapata, 2011), or as the Simple Wikipedia guidelines state, “simpler does not mean short”<sup>1</sup>. Table 1.1 shows the average sentence length and the average

<sup>1</sup>[http://simple.wikipedia.org/wiki/Main\\_Page/Introduction](http://simple.wikipedia.org/wiki/Main_Page/Introduction)

word length for Wikipedia and Simple Wikipedia sentences in the PWKP dataset used in this study (Zhu et al., 2010). These numbers suggest that, although the selection criteria for sentences to be included in this dataset are biased (see Section 2.2), Simple Wikipedia sentences are about 17% shorter, while the average word length is virtually equal.

	Sent. length	Token length
Simple Wikipedia	20.87	4.89
Wikipedia	25.01	5.06

Table 1: Sentence and token length statistics for the PWKP dataset (Zhu et al., 2010).

Statistical machine translation (SMT) has already been successfully applied to the related task of paraphrasing (Quirk et al., 2004; Bannard and Callison-Burch, 2005; Madnani et al., 2007; Callison-Burch, 2008; Zhao et al., 2009; Wubben et al., 2010). SMT typically makes use of large parallel corpora to train a model on. These corpora need to be aligned at the sentence level. Large parallel corpora, such as the multilingual proceedings of the European Parliament (Europarl), are readily available for many languages. Phrase-Based Machine Translation (PBMT) is a form of SMT where the translation model aims to translate longer sequences of words (“phrases”) in one go, solving part of the word ordering problem along the way that would be left to the target language model in a word-based SMT system. PBMT operates purely on statistics and no linguistic knowledge is involved in the process: the phrases that are aligned are motivated statistically, rather than linguistically. This makes PBMT adaptable to any language pair for which there is a parallel corpus available. The PBMT model makes use of a translation model, derived from the parallel corpus, and a language model, derived from a monolingual corpus in the target language. The language model is typically an  $n$ -gram model with smoothing. For any given input sentence, a search is carried out producing an  $n$ -best list of candidate translations, ranked by the decoder score, a complex scoring function including likelihood scores from the translation model, and the target language model. In principle, all of this should be transportable to a data-driven machine translation account of sentence simplification, pro-

vided that a parallel corpus is available that pairs text to simplified versions of that text.

## 1.2 This study

In this work we aim to investigate the use of phrase-based machine translation modified with a dissimilarity component for the task of sentence simplification. While Zhu et al. (2010) have demonstrated that their approach outperforms a PBMT approach in terms of Flesch Reading Ease test scores, we are not aware of any studies that evaluate PBMT for sentence simplification with human judgements. In this study we evaluate the output of Zhu et al. (2010) (henceforth referred to as ‘Zhu’), Woodsend and Lapata (2011) (henceforth referred to as ‘RevILP’), our PBMT based system with dissimilarity-based re-ranking (henceforth referred to as ‘PBMT-R’), a word-substitution baseline, and, as a gold standard, the original Simple Wikipedia sentences. We will first discuss the baseline, followed by the Zhu system, the RevILP system, and our PBMT-R system in Section 2. We then describe the experiment with human judges in Section 3, and its results in Section 4. We close this paper by critically discussing our results in Section 5.

## 2 Sentence Simplification Models

### 2.1 Word-Substitution Baseline

The word substitution baseline replaces words in the source sentence with (near-)synonyms that are more likely according to a language model. For each noun, adjective and verb in the sentence this model takes that word and its part-of-speech tag and retrieves from WordNet all synonyms from all synsets the word occurs in. The word is then replaced by all of its synset words, and each replacement is scored by a SRILM language model (Stolcke, 2002) with probabilities that are obtained from training on the Simple Wikipedia data. The alternative that has the highest probability according to the language model is kept. If no relevant alternative is found, the word is left unchanged. We use the Memory-Based Tagger (Daelemans et al., 1996) trained on the Brown corpus to compute the part-of-speech tags. The WordNet::QueryData<sup>2</sup> Perl mod-

<sup>2</sup><http://search.cpan.org/dist/WordNet-QueryData/QueryData.pm>

ule is used to query WordNet (Fellbaum, 1998).

### 2.2 Zhu et al.

Zhu et al. (2010) learn a sentence simplification model which is able to perform four rewrite operations on the parse trees of the input sentences, namely substitution, reordering, splitting, and deletion. Their model is inspired by syntax-based SMT (Yamada and Knight, 2001) and consists of a language model, a translation model and a decoder. The four mentioned simplification operations together form the translation model. Their model is trained on a corpus containing aligned sentences from English Wikipedia and English Simple Wikipedia called PWKP. The PWKP dataset consists of 108,016 pairs of aligned lines from 65,133 Wikipedia and Simple Wikipedia articles. These articles were paired by following the “interlanguage link”<sup>3</sup>. TF\*IDF at the sentence level was used to align the sentences in the different articles (Nelken and Shieber, 2006).

Zhu et al. (2010) evaluate their system using BLEU and NIST scores, as well as various readability scores that only take into account the output sentence, such as the Flesch Reading Ease test and  $n$ -gram language model perplexity. Although their system outperforms several baselines at the level of these readability metrics, they do not achieve better when evaluated with BLEU or NIST.

### 2.3 RevILP

Woodsend and Lapata’s (2011) model is based on quasi-synchronous grammar (Smith and Eisner, 2006). Quasi-synchronous grammar generates a loose alignment between parse trees. It operates on individual sentences annotated with syntactic information in the form of phrase structure trees. Quasi-synchronous grammar is used to generate all possible rewrite operations, after which integer linear programming is employed to select the most appropriate simplification. Their model is trained on two different datasets: one containing alignments between Wikipedia and English Simple Wikipedia (AlignILP), and one containing alignments between edits in the revision history of Simple Wikipedia (RevILP). RevILP performs best according to the

<sup>3</sup>[http://en.wikipedia.org/wiki/Help:Interlanguage\\_links](http://en.wikipedia.org/wiki/Help:Interlanguage_links)

human judgements conducted in their study. They show that it achieves better scores than Zhu et al. (2010)’s system and is not scored significantly differently from English Simple Wikipedia. In this study we compare against their best performing system, the RevILP system.

Figure 1: Levenshtein distance and Flesch-Kincaid score of output when varying the  $n$  of the  $n$ -best output of Moses.

## 2.4 PBMT-R

We use the Moses software to train a PBMT model (Koehn et al., 2007). The data we use is the PWKP dataset created by Zhu et al. (2010). In general, a statistical machine translation model finds a best translation  $\tilde{e}$  of a text in language  $f$  to a text in language  $e$  by combining a translation model that

finds the most likely translation  $p(f|e)$  with a language model that outputs the most likely sentence  $p(e)$ :

$$\tilde{e} = \arg \max_{e \in e^*} p(f|e)p(e)$$

The GIZA++ statistical alignment package is used to perform the word alignments, which are later combined into phrase alignments in the Moses pipeline (Och and Ney, 2003) to build the sentence simplification model. GIZA++ utilizes IBM Models 1 to 5 and an HMM word alignment model to find statistically motivated alignments between words. We first tokenize and lowercase all data and use all unique sentences from the Simple Wikipedia part of the PWKP training set to train an  $n$ -gram language model with the SRILM toolkit to learn the probabilities of different  $n$ -grams. Then we invoke the GIZA++ aligner using the training simplification pairs. We run GIZA++ with standard settings and we perform no optimization. This results in a phrase table containing phrase pairs from Wikipedia and Simple Wikipedia and their conditional probabilities as assigned by Moses. Finally, we use the Moses decoder to generate simplifications for the sentences in the test set. For each sentence we let the system generate the ten best distinct solutions (or less, if fewer than ten solutions are generated) as ranked by Moses.

Arguably, dissimilarity is a key factor in simplification (and in paraphrasing in general). As output we would like to be able to select fluent sentences that adequately convey the meaning of the original input, yet that contain differences that operationalize the intended simplification. When training our PBMT system on the PWKP data we may assume that the system learns to simplify automatically, yet there is no aspect of the decoder function in Moses that is sensitive to the fact that it should try to be different from the input – Moses may well translate input to unchanged output, as much of our training data consists of partially equal input and output strings.

To expand the functionality of Moses in the intended direction we perform post-hoc re-ranking on the output based on dissimilarity to the input. We do this to select output that is as different as possible from the source sentence, so that it ideally con-

tains multiple simplifications; at the same time, we base our re-ranking on a top- $n$  of output candidates according to Moses, with a small  $n$ , to ensure that the quality of the output in terms of fluency and adequacy is also controlled for. Setting  $n = 10$ , for each source sentence we re-rank the ten best sentences as scored by the decoder according to the Levenshtein Distance (or edit distance) measure (Levenshtein, 1966) at the word level between the input and output sentence, counting the minimum number of edits needed to transform the source string into the target string, where the allowable edit operations are insertion, deletion, and substitution of a single word. In case of a tie in Levenshtein Distance, we select the sequence with the better decoder score. When Moses is unable to generate ten different sentences, we select from the lower number of outputs. Figure 1 displays Levenshtein Distance and Flesch-Kincaid grade level scores for different values of  $n$ . We use the `Lingua::EN::Fathom` module<sup>4</sup> to calculate Flesch-Kincaid grade level scores. The readability score stays more or less the same, indicating no relation between  $n$  and readability. The average edit distance starts out at just above 2 when selecting the 1-best output string, and increases roughly until  $n = 10$ .

## 2.5 Descriptive statistics

Table 2 displays the average edit distance and the percentage of cases in which no edits were performed for each of the systems and for Simple Wikipedia. We see that the Levenshtein distance between Wikipedia and Simple Wikipedia is the most substantial with an average of 12.3 edits. Given that the average number of tokens is about 25 for Wikipedia and 21 for Simple Wikipedia (cf. Table 1.1), these numbers indicate that the changes in Simple Wikipedia go substantially beyond the average four-word length difference. On average, eight more words are interchanged for other words. About half of the original tokens in the source sentence do not return in the output. Of the three simplification systems, the Zhu system (7.95) and the RevILP (7.18) attain similar edit distances, less substantial than the edits in Simple Wikipedia, but still consid-

<sup>4</sup><http://search.cpan.org/~kimryan/Lingua-EN-Fathom-1.15/lib/Lingua/EN/Fathom.pm>

erable compared to the baseline word-substitution system (4.26) and PBMT-R (3.08). Our system is clearly conservative in its edits.

System	LD	Perc. no edits
Simple Wikipedia	12.30	3
Word Sub	4.26	0
Zhu	7.95	2
RevILP	7.18	22
PBMT-R	3.08	5

Table 2: Levenshtein Distance and percentage of unaltered output sentences.

On the other hand, we observe some differences in the percentage of cases in which the systems decide to produce a sentence identical to the input. In 22 percent of the cases the RevILP system does not alter the sentence. The other systems make this decision about as often as the gold standard, Simple Wikipedia, where only 3% of sentences remain unchanged. The word-substitution baseline always manages to make at least one change.

## 3 Evaluation

### 3.1 Participants

Participants were 46 students of Tilburg University, who participated for partial course credits. All were native speakers of Dutch, and all were proficient in English, having taken a course on Academic English at University level.

### 3.2 Materials

We use the test set used by Zhu et al. (2010) and Woodsend and Lapata (2011). This test set consists of 100 sentences from articles on English Wikipedia, paired with sentences from corresponding articles in English Simple Wikipedia. We selected only those sentences where every system would perform minimally one edit, because we only want to compare the different systems when they actually generate altered, assumedly simplified output. From this subset we randomly pick 20 source sentences, resulting in 20 clusters of one source sentence and 5 simplified sentences, as generated by humans (Simple Wikipedia) and the four systems.

### 3.3 Procedure

The participants were told that they participated in the evaluation of a system that could simplify sentences, and that they would see one source sentence and five automatically simplified versions of that sentence. They were not informed of the fact that we evaluated in fact four different systems and the original Simple Wikipedia sentence. Following earlier evaluation studies (Dodding, 2002; Woodsend and Lapata, 2011), we asked participants to evaluate Simplicity, Fluency and Adequacy of the target headlines on a five point Likert scale. Fluency was defined in the instructions as the extent to which a sentence is proper, grammatical English. Adequacy was defined as the extent to which the sentence has the same meaning as the source sentence. Simplicity was defined as the extent to which the sentence was simpler than the original and thus easier to understand. The order in which the clusters had to be judged was randomized and the order of the output of the various systems was randomized as well.

## 4 Results

### 4.1 Automatic measures

The results of the automatic measures are displayed in Table 3. In terms of the Flesch-Kincaid grade level score, where lower scores are better, the Zhu system scores best, with 7.86 even lower than Simple Wikipedia (8.57). Increasingly worse Flesch-Kincaid scores are produced by RevILP (8.61) and PBMT-R (13.38), while the word substitution baseline scores worst (14.64). With regard to the BLEU score, where Simple Wikipedia is the reference, the PBMT-R system scores highest with 0.43, followed by the RevILP system (0.42) and the Zhu system (0.38). The word substitution baseline scores lowest with a BLEU score of 0.34.

System	Flesch-Kincaid	BLEU
Simple Wikipedia	8.57	1
Word Sub	14.64	0.34
Zhu	7.86	0.38
RevILP	8.61	0.42
PBMT-R	13.38	0.43

Table 3: Flesch-Kincaid grade level and BLEU scores

### 4.2 Human judgements

To test for significance we ran repeated measures analyses of variance with system (Simple Wikipedia, PBMT-R, Zhu, RevILP, word-substitution baseline) as the independent variable, and the three individual metrics as well as their combined mean as the dependent variables. Mauchly’s test for sphericity was used to test for homogeneity of variance, and when this test was significant we applied a Greenhouse-Geisser correction on the degrees of freedom (for the purpose of readability we report the normal degrees of freedom in these cases). Planned pairwise comparisons were made with the Bonferroni method. Table 4 displays these results.

First, we consider the 3 metrics in isolation, beginning with Fluency. We find that participants rated the Fluency of the simplified sentences from the four systems and Simple Wikipedia differently,  $F(4, 180) = 178.436, p < .001, \eta_p^2 = .799$ . The word-substitution baseline, Simple Wikipedia and PBMT-R receive the highest scores (3.86, 3.84 and 3.83 respectively) and don’t achieve significantly different scores on this dimension. All other pairwise comparisons are significant at  $p < .001$ . RevILP attains a score of 3.18, while the Zhu system achieves the lowest mean judgement score of 2.59.

Participants also rated the systems significantly differently on the Adequacy scale,  $F(4, 180) = 116.509, p < .001, \eta_p^2 = .721$ . PBMT-R scores highest (3.71), followed by the word-substitution baseline (3.58), RevILP (3.28), and then by Simple Wikipedia (2.91) and the Zhu system (2.82). Simple Wikipedia and the Zhu system do not differ significantly, and all other pairwise comparisons are significant at  $p < .001$ . The low score of Simple Wikipedia indicates indirectly that the human editors of Simple Wikipedia texts often choose to deviate quite markedly from the meaning of the original text.

Key to the task of simplification are the human judgements of Simplicity. Participants rated the Simplicity of the output from the four systems and Simple Wikipedia differently,  $F(4, 180) = 74.959, p < .001, \eta_p^2 = .625$ . Simple Wikipedia scores highest (3.68) and the word substitution baseline scores lowest (2.42). Between them are the RevILP (2.96), Zhu (2.93) and PBMT-R (2.88) sys-

System	Overall	Fluency	Adequacy	Simplicity
Simple Wikipedia	3.46 (0.39)	3.84 (0.46)	2.91 (0.32)	3.68 (0.39)
Word Sub	3.39 (0.43)	3.86 (0.49)	3.58 (0.35)	2.42 (0.48)
Zhu	2.78 (0.45)	2.59 (0.48)	2.82 (0.37)	2.93 (0.50)
RevILP	3.13 (0.36)	3.18 (0.45)	3.28 (0.32)	2.96 (0.39)
PBMT-R	3.47 (0.46)	3.83 (0.49)	3.71 (0.44)	2.88 (0.46)

Table 4: Mean scores assigned by human subjects, with the standard deviation between brackets

	Adequacy	Simplicity	Flesch-Kincaid	BLEU
Fluency	0.45**	0.24*	0.42**	0.26**
Adequacy		-0.19	0.40**	-0.14
Simplicity			-0.45**	0.42**
Flesch-Kincaid				-0.11

Table 5: Pearson correlation between the different dimensions as assigned by humans and the automatic metrics. Scores marked \* are significant at  $p < .05$  and scores marked \*\* are significant at  $p < .01$

tems, which do not score significantly differently from each other. All other pairwise comparisons are significant at  $p < .001$ .

Finally we report on a combined score created by averaging over the Fluency, Adequacy and Simplicity scores. Inspection of this score, displayed in the leftmost column of Table 4, reveals that the PBMT-R system and Simple Wikipedia score best (3.47 and 3.46 respectively), followed by the word substitution baseline (3.39), which in turn scores higher than RevILP (3.13) and the Zhu system (2.78). We find that participants rated the systems significantly differently overall,  $F(4, 180) = 98.880, p < .001, \eta_p^2 = .687$ . All pairwise comparisons were statistically significant ( $p < .01$ ), except the one between the PBMT-R system and Simple Wikipedia.

### 4.3 Correlations

Table 5 displays the correlations between the scores assigned by humans (Fluency, Adequacy and Simplicity) and the automatic metrics (Flesch-Kincaid and BLEU). We see a significant correlation between Fluency and Adequacy (0.45), as well as between Fluency and Simplicity (0.24). There is a negative significant correlation between Flesch-Kincaid scores and Simplicity (-0.45) while there is a positive significant correlation between Flesch-Kincaid and Adequacy and Fluency. The significant correlations between BLEU and Simplicity (0.42) and Fluency (0.26) are both in the positive direction. There is no significant correlation between BLEU and Ad-

equacy, indicating BLEU’s relative weakness in assessing the semantic overlap between input and output. BLEU and Flesch-Kincaid do not show a significant correlation.

## 5 Discussion

We conclude that a phrase-based machine translation system with added dissimilarity-based re-ranking of the best ten output sentences can successfully be used to perform sentence simplification. Even though the system merely performs phrase-based machine translation and is not specifically geared towards simplification were it not for the dissimilarity-based re-ranking of the output, it performs not significantly differently from state-of-the-art sentence simplification systems in terms of human-judged Simplification. In terms of Fluency and Adequacy our system is judged to perform significantly better. From the relatively low average numbers of edits made by our system we can conclude that our system performs relatively small numbers of changes to the input, that still constitute as sensible simplifications. It does not split sentences (which the Zhu and RevILP systems regularly do); it only rephrases phrases. Yet, it does this better than a word-substitution baseline, which can also be considered a conservative approach; this is reflected in the baseline’s high Fluency score (roughly equal to PBMT-R and Simple Wikipedia) and Adequacy score (only slightly worse than PBMT-R).

Wikipedia	the judge ordered that chapman should receive psychiatric treatment in prison and sentenced him to twenty years to life , slightly less than the maximum possible of twenty-five years to life .
Simple Wikipedia	he was sentenced to twenty-five years to life in prison in 1981 .
Word-substitution baseline	the judge ordered that chapman should have psychiatric treatment in prison and sentenced him to twenty years to life , slightly less than the maximum possible of twenty-five years to life .
Zhu	the judge ordered that chapman should get psychiatric treatment . in prison and sentenced him to twenty years to life , less maximum possible of twenty-five years to life .
RevILP	the judge ordered that chapman should will get psychiatric treatment in prison . he sentenced him to twenty years to life to life .
PBMT-R	the judge ordered that chapman should get psychiatric treatment in prison and sentenced him to twenty years to life , a little bit less than the highest possible to twenty-five years to life .

Table 6: Example output

The output of all systems, the original and the simplified version of an example sentence from the PWKP dataset is displayed in Table 6. The Simple Wikipedia sentences illustrate that significant portions of the original sentences may be dropped, and parts of the semantics of the original sentence discarded. We also see the Zhu and RevILP systems resorting to splitting the original sentence in two, leading to better Flesch-Kincaid scores. The word-substitution baseline changes ‘receive’ in ‘have’, while the PBMT-R system changes the same ‘receive’ in ‘get’, ‘slightly’ to ‘a little bit’, and ‘maximum’ to ‘highest’.

In terms of automatic measures we see that the Zhu system scores particularly well on the Flesch-Kincaid metric, while the RevILP system and our PBMT-R system achieve the highest BLEU scores. We believe that for the evaluation of sentence simplification, BLEU is a more appropriate metric than Flesch-Kincaid or a similar readability metric, although it should be noted that BLEU was found only to correlate significantly with Fluency, not with Adequacy. While BLEU and NIST may be used with this in mind, readability metrics should be avoided altogether in our view. Where machine translation evaluation metrics such as BLEU take into account gold references, readability metrics only take into account characteristics of the sentence such as word length and sentence length, and ignore grammaticality or the semantic adequacy of the content of the output sentence, which BLEU is aimed to implicitly approximate by measuring overlap in  $n$ -grams.

Arguably, readability metrics are best suited to be applied to texts that can be considered grammatical and meaningful, which is not necessarily true for the output of simplification algorithms. A disruptive example that would illustrate this point would be a system that would randomly split original sentences in two or more sequences, achieving considerably lower Flesch-Kincaid scores, yet damaging the grammaticality and semantic coherence of the original text, as is evidenced by the negative correlation for Simplicity and positive correlations for Fluency and Adequacy in Table 5.

In the future we would like to investigate how we can boost the number of edits the system performs, while still producing grammatical and meaning-preserving output. Although the comparison against the Zhu system, which uses syntax-driven machine translation, shows no clear benefit for syntax-based machine translation, it may still be the case that approaches such as Hiero (Chiang et al., 2005) and Joshua (Li et al., 2009), enhanced by dissimilarity-based re-ranking, would improve over our current system. Furthermore, typical simplification operations such as sentence splitting and more radical syntax alterations or even document-level operations such as manipulations of the co-reference structure would be interesting to implement and test

## Abstract

All types of part-of-speech (POS) tagging errors have been equally treated by existing taggers. However, the errors are not equally important, since some errors affect the performance of subsequent natural language processing (NLP) tasks seriously while others do not. This paper aims to minimize these serious errors while retaining the overall performance of POS tagging. Two gradient loss functions are proposed to reflect the different types of errors. They are designed to assign a larger cost to serious errors and a smaller one to minor errors. Through a set of POS tagging experiments, it is shown that the classifier trained with the proposed loss functions reduces serious errors compared to state-of-the-art POS taggers. In addition, the experimental result on text chunking shows that fewer serious errors help to improve the performance of subsequent NLP tasks.

## 1 Introduction

Part-of-speech (POS) tagging is needed as a pre-processor for various natural language processing (NLP) tasks such as parsing, named entity recognition (NER), and text chunking. Since POS tagging is normally performed in the early step of NLP tasks, the errors in POS tagging are critical in that they affect subsequent steps and often lower the overall performance of NLP tasks.

Previous studies on POS tagging have shown high performance with machine learning techniques (Ratnaparkhi, 1996; Brants, 2000; Lafferty et al.,

2001). Among the types of machine learning approaches, supervised machine learning techniques were commonly used in early studies on POS tagging. With the characteristics of a language (Ratnaparkhi, 1996; Kudo et al., 2004) and informative features for POS tagging (Toutanova and Manning, 2000), the state-of-the-art supervised POS tagging achieves over 97% of accuracy (Shen et al., 2007; Manning, 2011). This performance is generally regarded as the maximum performance that can be achieved by supervised machine learning techniques. There have also been many studies on POS tagging with semi-supervised (Subramanya et al., 2010; Sogaard, 2011) or unsupervised machine learning methods (Berg-Kirkpatrick et al., 2010; Das and Petrov, 2011) recently. However, there still exists room to improve supervised POS tagging in terms of error differentiation.

It should be noted that not all errors are equally important in POS tagging. Let us consider the parse trees in Figure 1 as an example. In Figure 1(a), the word “plans” is mistagged as a noun where it should be a verb. This error results in a wrong parse tree that is severely different from the correct tree shown in Figure 1(b). The verb phrase of the verb “plans” in Figure 1(b) is discarded in Figure 1(a) and the whole sentence is analyzed as a single noun phrase. Figure 1(c) and (d) show another tagging error and its effect. In Figure 1(c), a noun is tagged as a NNS (plural noun) where its correct tag is NN (singular or mass noun). However, the error in Figure 1(c) affects only locally the noun phrase to which “physics” belongs. As a result, the general structure of the parse tree in Figure 1(c) is nearly the same as

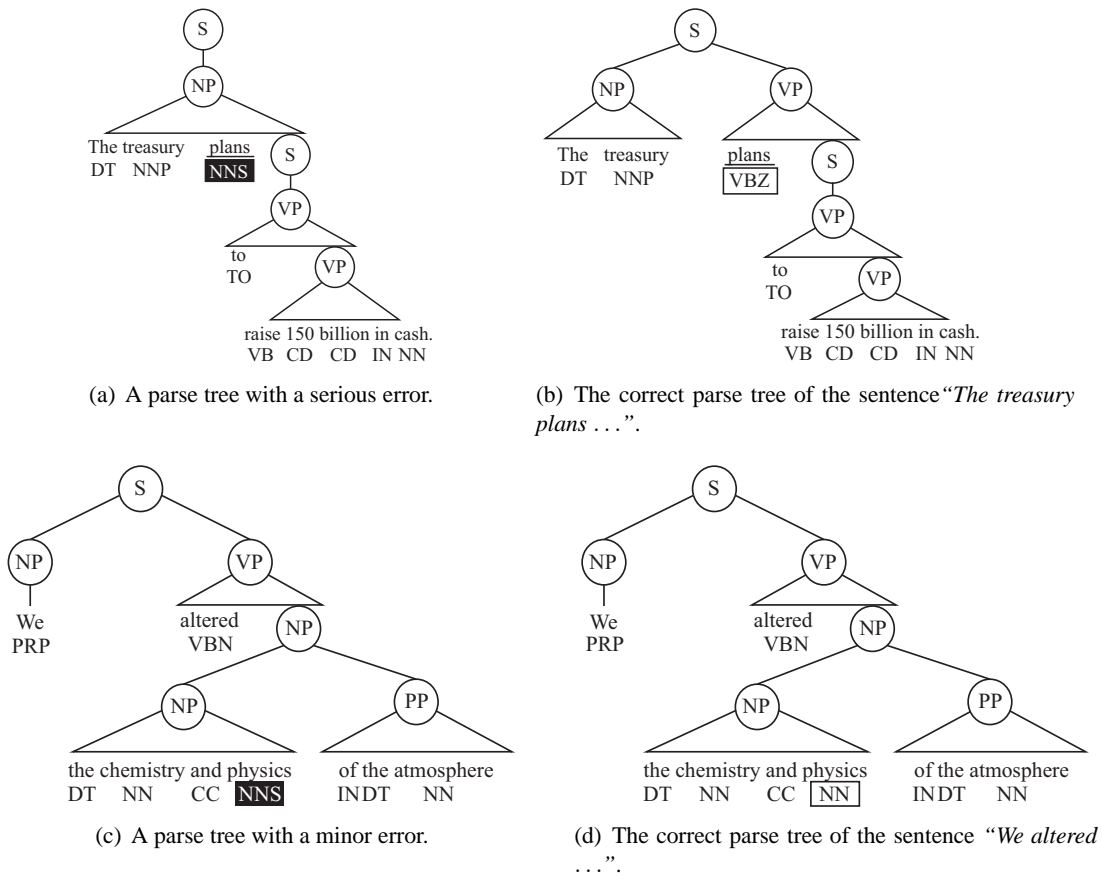

Figure 1: An example of POS tagging errors

the correct one in Figure 1(d). That is, a sentence analyzed with this type of error would yield a correct or near-correct result in many NLP tasks such as machine translation and text chunking.

The goal of this paper is to differentiate the serious POS tagging errors from the minor errors. POS tagging is generally regarded as a classification task, and zero-one loss is commonly used in learning classifiers (Altun et al., 2003). Since zero-one loss considers all errors equally, it can not distinguish error types. Therefore, a new loss is required to incorporate different error types into the learning machines.

This paper proposes two gradient loss functions to reflect differences among POS tagging errors. The functions assign relatively small cost to minor errors, while larger cost is given to serious errors. They are applied to learning multiclass support vector machines (Tsochantaridis et al., 2004) which is trained to minimize the serious errors. Overall accuracy of this SVM is not improved against the state-

of-the-art POS tagger, but the serious errors are significantly reduced with the proposed method. The effect of the fewer serious errors is shown by applying it to the well-known NLP task of text chunking. Experimental results show that the proposed method achieves a higher F1-score compared to other POS taggers.

The rest of the paper is organized as follows. Section 2 reviews the related studies on POS tagging. In Section 3, serious and minor errors are defined, and it is shown that both errors are observable in a general corpus. Section 4 proposes two new loss functions for discriminating the error types in POS tagging. Experimental results are presented in Section 5. Finally, Section 6 draws some conclusions.

## 2 Related Work

The POS tagging problem has generally been solved by machine learning methods for sequential label-

Tag category	POS tags
Substantive	NN, NNS, NNP, NNPS, CD, PRP, PRP\$
Predicate	VB, VBD, VBG, VBN, VBP, VBZ, MD, JJ, JJR, JJS
Adverbial	RB, RBR, RBS, RP, UH, EX, WP, WP\$, WRB, CC, IN, TO
Determiner	DT, PDT, WDT
Etc	FW, SYM, POS, LS

Table 1: Tag categories and POS tags in Penn Tree Bank tag set

ing. In early studies, rich linguistic features and supervised machine learning techniques are applied by using annotated corpora like the Wall Street Journal corpus (Marcus et al., 1994). For instance, Ratnaparkhi (1996) used a maximum entropy model for POS tagging. In this study, the features for rarely appearing words in a corpus are expanded to improve the overall performance. Following this direction, various studies have been proposed to extend informative features for POS tagging (Toutanova and Manning, 2000; Toutanova et al., 2003; Manning, 2011). In addition, various supervised methods such as HMMs and CRFs are widely applied to POS tagging. Lafferty et al. (2001) adopted CRFs to predict POS tags. The methods based on CRFs not only have all the advantages of the maximum entropy markov models but also resolve the well-known problem of label bias. Kudo et al. (2004) modified CRFs for non-segmented languages like Japanese which have the problem of word boundary ambiguity.

As a result of these efforts, the performance of state-of-the-art supervised POS tagging shows over 97% of accuracy (Toutanova et al., 2003; Giménez and Márquez, 2004; Tsuruoka and Tsujii, 2005; Shen et al., 2007; Manning, 2011). Due to the high accuracy of supervised approaches for POS tagging, it has been deemed that there is no room to improve the performance on POS tagging in supervised manner. Thus, recent studies on POS tagging focus on semi-supervised (Spoustová et al., 2009; Subramanya et al., 2010; Søgaard, 2011) or unsupervised approaches (Haghighi and Klein, 2006; Goldwater and Griffiths, 2007; Johnson, 2007; Graca et al., 2009; Berg-Kirkpatrick et al., 2010; Das and Petrov, 2011). Most previous studies on POS tagging have focused on how to extract more linguistic features or how to adopt supervised or unsupervised

approaches based on a single evaluation measure, *accuracy*. However, with a different viewpoint for errors on POS tagging, there is still some room to improve the performance of POS tagging for subsequent NLP tasks, even though the overall accuracy can not be much improved.

In ordinary studies on POS tagging, costs of errors are equally assigned. However, with respect to the performance of NLP tasks relying on the result of POS tagging, errors should be treated differently. In the machine learning community, cost sensitive learning has been studied to differentiate costs among errors. By adopting different misclassification costs for each type of errors, a classifier is optimized to achieve the lowest expected cost (Elkan, 2001; Cai and Hofmann, 2004; Zhou and Liu, 2006).

### 3 Error Analysis of Existing POS Tagger

The effects of POS tagging errors to subsequent NLP tasks vary according to their type. Some errors are serious, while others are not. In this paper, the seriousness of tagging errors is determined by categorical structures of POS tags. Table 1 shows the Penn tree bank POS tags and their categories. There are five categories in this table: *substantive*, *predicate*, *adverbial*, *determiner*, and *etc*. Serious tagging errors are defined as misclassifications among the categories, while minor errors are defined as misclassifications within a category. This definition follows the fact that POS tags in the same category form similar syntax structures in a sentence (Zhao and Marcus, 2009). That is, inter-category errors are treated as serious errors, while intra-category errors are treated as minor errors.

Table 2 shows the distribution of inter-category and intra-category errors observed in section 22–24 of the WSJ corpus (Marcus et al., 1994) that is tagged by the Stanford Log-linear Part-Of-Speech

		Predicted category				
		Substantive	Predicate	Adverbial	Determiner	Etc
True category	Substantive	614	<b>479</b>	<b>32</b>	<b>10</b>	<b>15</b>
	Predicate	<b>585</b>	743	<b>107</b>	<b>2</b>	<b>14</b>
	Adverbial	<b>41</b>	<b>156</b>	500	<b>42</b>	<b>2</b>
	Determiner	<b>13</b>	<b>7</b>	<b>47</b>	24	<b>0</b>
	Etc	<b>23</b>	<b>11</b>	<b>3</b>	<b>1</b>	<b>0</b>

Table 2: The distribution of tagging errors on WSJ corpus by Stanford Part-Of-Speech Tagger.

Tagger (Manning, 2011) (trained with WSJ sections 00–18). In this table, bold numbers denote inter-category errors while all other numbers show intra-category errors. The number of total errors is 3,471 out of 129,654 words. Among them, 1,881 errors (54.19%) are intra-category, while 1,590 of the errors (45.81%) are inter-category. If we can reduce these inter-category errors under the cost of minimally increasing intra-category errors, the tagging results would improve in quality.

Generally in POS tagging, all tagging errors are regarded equally in importance. However, inter-category and intra-category errors should be distinguished. Since a machine learning method is optimized by a loss function, inter-category errors can be efficiently reduced if a loss function is designed to handle both types of errors with different cost. We propose two loss functions for POS tagging and they are applied to multiclass Support Vector Machines.

## 4 Learning SVMs with Class Similarity

POS tagging has been solved as a sequential labeling problem which assumes dependency among words. However, by adopting sequential features such as POS tags of previous words, the dependency can be partially resolved. If it is assumed that words are independent of one another, POS tagging can be regarded as a multiclass classification problem. One of the best solutions for this problem is by using an SVM.

### 4.1 Training SVMs with Loss Function

Assume that a training data set  $D = \{(x_1, y_1), (x_2, y_2), \dots, (x_l, y_l)\}$  is given where  $x_i \in \mathbf{R}^d$  is an instance vector and  $y_i \in \{+1, -1\}$  is its class label. SVM finds an optimal hyperplane

satisfying

$$\begin{aligned} x_i \cdot w + b &\geq +1 & \text{for } y_i = +1, \\ x_i \cdot w + b &\leq -1 & \text{for } y_i = -1, \end{aligned}$$

where  $w$  and  $b$  are parameters to be estimated from training data  $D$ . To estimate the parameters, SVMs minimize a hinge loss defined as

$$\begin{aligned} \xi_i &= L_{\text{hinge}}(y_i, w \cdot x_i + b) \\ &= \max\{0, 1 - y_i \cdot (w \cdot x_i + b)\}. \end{aligned}$$

With regularizer  $\|w\|^2$  to control model complexity, the optimization problem of SVMs is defined as

$$\min_{w, \xi} \frac{1}{2} \|w\|^2 + C \sum_{i=1}^l \xi_i,$$

subject to

$$y_i(x_i \cdot w + b) \geq 1 - \xi_i, \text{ and } \xi_i \geq 0 \quad \forall i,$$

where  $C$  is a user parameter to penalize errors.

Crammer et al. (2002) expanded the binary-class SVM for multiclass classifications. In multiclass SVMs, by considering all classes the optimization of SVM is generalized as

$$\min_{w, \xi} \frac{1}{2} \sum_{k \in K} \|w_k\|^2 + C \sum_{i=1}^l \xi_i,$$

with constraints

$$\begin{aligned} (w_{y_i} \cdot \phi(x_i, y_i)) - (w_k \cdot \phi(x_i, k)) &\geq 1 - \xi_i, \\ \xi_i &\geq 0 \quad \forall i, \quad \forall k \in K \setminus y_i, \end{aligned}$$

where  $\phi(x_i, y_i)$  is a combined feature representation of  $x_i$  and  $y_i$ , and  $K$  is the set of classes.

Figure 2: A tree structure of POS tags.

Since both binary and multiclass SVMs adopt a hinge loss, the errors between classes have the same cost. To assign different cost to different errors, Tsochantaridis et al. (2004) proposed an efficient way to adopt arbitrary loss function,  $L(y_i, y_j)$  which returns zero if  $y_i = y_j$ , otherwise  $L(y_i, y_j) > 0$ . Then, the hinge loss  $\xi_i$  is re-scaled with the inverse of the additional loss between two classes. By scaling slack variables with the inverse loss, margin violation with high loss  $L(y_i, y_j)$  is more severely restricted than that with low loss. Thus, the optimization problem with  $L(y_i, y_j)$  is given as

$$\min_{w, \xi} \frac{1}{2} \sum_{k \in K} \|w_k\|^2 + C \sum_{i=1}^l \xi_i, \quad (1)$$

with constraints

$$(w_{y_i} \cdot \phi(x_i, y_i)) - (w_k \cdot \phi(x_i, k)) \geq 1 - \frac{\xi_i}{L(y_i, k)},$$

$$\xi_i \geq 0 \quad \forall i, \quad \forall k \in K \setminus y_i,$$

With the Lagrange multiplier  $\alpha$ , the optimization problem in Equation (1) is easily converted to the following dual quadratic problem.

$$\min_{\alpha} \frac{1}{2} \sum_{i,j} \sum_{k_i \in K \setminus y_i} \sum_{k_j \in K \setminus y_j} \alpha_{i,k_i} \alpha_{j,k_j} \times$$

$$J(x_i, y_i, k_i) J(x_j, y_j, k_j) - \sum_i \sum_{k_i \in K \setminus y_i} \alpha_{i,k_i},$$

with constraints

$$\alpha \geq 0 \quad \text{and} \quad \sum_{k_i \in K \setminus y_i} \frac{\alpha_{i,k_i}}{L(y_i, k_i)} \leq C, \quad \forall i = 1, \dots, l,$$

where  $J(x_i, y_i, k_i)$  is defined as

$$J(x_i, y_i, k_i) = \phi(x_i, y_i) - \phi(x_i, k_i).$$

## 4.2 Loss Functions for POS tagging

To design a loss function for POS tagging, this paper adopts categorical structures of POS tags. The simplest way to reflect the structure of POS tags shown in Table 1 is to assign larger cost to inter-category errors than to intra-category errors. Thus, the loss function with the categorical structure in Table 1 is defined as

$$L_c(y_i, y_j) = \begin{cases} 0 & \text{if } y_i = y_j, \\ \delta & \text{if } y_i \neq y_j \text{ but they belong} \\ & \text{to the same POS category,} \\ 1 & \text{otherwise,} \end{cases} \quad (2)$$

where  $0 < \delta < 1$  is a constant to reduce the value of  $L_c(y_i, y_j)$  when  $y_i$  and  $y_j$  are similar. As shown in this equation, inter-category errors have larger cost than intra-category errors. This loss  $L_c(y_i, y_j)$  is named as *category loss*.

The loss function  $L_c(y_i, y_j)$  is designed to reflect the categories in Table 1. However, the structure of POS tags can be represented as a more complex structure. Let us consider the category, **predicate**.

Figure 3: Effect of the proposed loss function in multiclass SVMs

This category has ten POS tags, and can be further categorized into two sub-categories: **verb** and **ad-ject**. Figure 2 represents a categorical structure of POS tags as a tree with five categories of POS tags and their seven sub-categories.

To express the tree structure of Figure 2 as a loss, another loss function  $L_t(y_i, y_j)$  is defined as

$$L_t(y_i, y_j) = \frac{1}{2} [Dist(P_{i,j}, y_i) + Dist(P_{i,j}, y_j)] \times \gamma, \quad (3)$$

where  $P_{i,j}$  denotes the nearest common parent of both  $y_i$  and  $y_j$ , and the function  $Dist(P_{i,j}, y_i)$  returns the number of steps from  $P_{i,j}$  to  $y_i$ . The user parameter  $\gamma$  is a scaling factor of a unit loss for a single step. This loss  $L_t(y_i, y_j)$  returns large value if the distance between  $y_i$  and  $y_j$  is far in the tree structure, and it is named as *tree loss*.

As shown in Equation (1), two proposed loss functions adjust margin violation between classes. They basically assign less value for intra-category errors than inter-category errors. Thus, a classifier is optimized to strictly keep inter-category errors within a smaller boundary. Figure 3 shows a simple example. In this figure, there are three POS tags and two categories. NN (singular or mass noun) and NNS (plural noun) belong to the same category, while VB (verb, base form) is in another category. Figure 3(a) shows the decision boundary of NN based on hinge loss. As shown in this figure, a

single  $\xi$  is applied for the margin violation among all classes. Figure 3(b) also presents the decision boundary of NN, but it is determined with the proposed loss function. In this figure, the margin violation is applied differently to inter-category (NN to VB) and intra-category (NN to NNS) errors. It results in reducing errors between NN and VB even if the errors between NN and NNS could be slightly increased.

## 5 Experiments

### 5.1 Experimental Setting

Experiments are performed with a well-known standard data set, the Wall Street Journal (WSJ) corpus. The data is divided into training, development and test sets as in (Toutanova et al., 2003; Tsuruoka and Tsujii, 2005; Shen et al., 2007). Table 3 shows some simple statistics of these data sets. As shown in this table, training data contains 38,219 sentences with 912,344 words. In the development data set, there are 5,527 sentences with about 131,768 words, those in the test set are 5,462 sentences and 129,654 words. The development data set is used only to select  $\delta$  in Equation (2) and  $\gamma$  in Equation (3).

Table 4 shows the feature set for our experiments. In this table,  $w_i$  and  $t_i$  denote the lexicon and POS tag for the  $i$ -th word in a sentence respectively. We use almost the same feature set as used in (Tsuruoka and Tsujii, 2005) including word features, tag fea-

	Training	Develop	Test
Section	0–18	19–21	22–24
# of sentences	38,219	5,527	5,462
# of terms	912,344	131,768	129,654

Table 3: Simple statistics of experimental data

Feature Name	Description
Word features	$w_{i-2}, w_{i-1}, w_i, w_{i+1}, w_{i+2}$ $w_{i-1} \cdot w_i, w_i \cdot w_{i+1}$
Tag features	$t_{i-2}, t_{i-1}, t_{i+1}, t_{i+2}$ $t_{i-2} \cdot t_{i-1}, t_{i+1} \cdot t_{i+2}$ $t_{i-2} \cdot t_{i-1} \cdot t_{i+1}, t_{i-1} \cdot t_{i+1} \cdot t_{i+2}$ $t_{i-2} \cdot t_{i-1} \cdot t_{i+1} \cdot t_{i+2}$
Tag/Word combination	$t_{i-2} \cdot w_i, t_{i-1} \cdot w_i, t_{i+1} \cdot w_i, t_{i+2} \cdot w_i$ $t_{i-1} \cdot t_{i+1} \cdot w_i$
Prefix features	prefixes of $w_i$ (up to length 9)
Suffix features	suffixes of $w_i$ (up to length 9)
Lexical features	whether $w_i$ contains capitals whether $w_i$ has a number whether $w_i$ has a hyphen whether $w_i$ is all capital whether $w_i$ starts with capital and locates at the middle of sentence

Table 4: Feature template for experiments

tures, word/tag combination features, prefix and suffix features as well as lexical features. The POS tags for words are obtained from a two-pass approach proposed by Nakagawa et al. (2001).

In the experiments, two multiclass SVMs with the proposed loss functions are used. One is CL-MSVM with category loss and the other is TL-MSVM with tree loss. A linear kernel is used for both SVMs.

## 5.2 Experimental Results

CL-MSVM with  $\delta = 0.4$  shows the best overall performance on the development data where its error rate is as low as 2.71%.  $\delta = 0.4$  implies that the cost of intra-category errors is set to 40% of that of inter-category errors. The error rate of TL-MSVM is 2.69% when  $\gamma$  is 0.6.  $\delta = 0.4$  and  $\gamma = 0.6$  are set in the all experiments below.

Table 5 gives the comparison with the previous work and proposed methods on the test data. As can be seen from this table, the best performing algorithms achieve near 2.67% error rate (Shen et al., 2007; Manning, 2011). CL-MSVM and TL-MSVM

	Error (%)	# of Intra error	# of Inter error
(Giménez and Màrquez, 2004)	2.84	1,995 (54.11%)	1,692 (45.89%)
(Tsuruoka and Tsujii, 2005)	2.85	-	-
(Shen et al., 2007)	<b>2.67</b>	<b>1,856 (53.52%)</b>	1,612 (46.48%)
(Manning, 2011)	2.68	1,881 (54.19%)	1,590 (45.81%)
CL-MSVM ( $\delta = 0.4$ )	2.69	1,916 (55.01%)	<b>1,567 (44.99%)</b>
TL-MSVM ( $\gamma = 0.6$ )	2.68	1,904 (54.74%)	<b>1,574 (45.26%)</b>

Table 5: Comparison with the previous works

achieve an error rate of 2.69% and 2.68% respectively. Although overall error rates of CL-MSVM and TL-MSVM are not improved compared to the previous state-of-the-art methods, they show reasonable performance.

For inter-category error, CL-MSVM achieves the best performance. The number of inter-category error is 1,567, which shows 23 errors reduction compared to previous best inter-category result by (Manning, 2011). TL-MSVM also makes 16 less inter-category errors than Manning’s tagger. When compared with Shen’s tagger, both CL-MSVM and TL-MSVM make far less inter-category errors even if their overall performance is slightly lower than that of Shen’s tagger. However, the intra-category error rate of the proposed methods has some slight increases. The purpose of proposed methods is to minimize inter-category errors but preserving overall performance. From these results, it can be found that the proposed methods which are trained with the proposed loss functions do differentiate serious and minor POS tagging errors.

## 5.3 Chunking Experiments

The task of chunking is to identify the non-recursive cores for various types of phrases. In chunking, the POS information is one of the most crucial aspects in identifying chunks. Especially inter-category POS errors seriously affect the performance of chunking because they are more likely to mislead the chunk compared to intra-category errors.

Here, chunking experiments are performed with

POS tagger	Accuracy (%)	Precision	Recall	F1-score
(Shen et al., 2007)	96.08	94.03	93.75	93.89
(Manning, 2011)	96.08	94	93.8	93.9
CL-MSVM ( $\delta = 0.4$ )	<b>96.13</b>	<b>94.1</b>	<b>93.9</b>	<b>94.00</b>
TL-MSVM ( $\gamma = 0.6$ )	96.12	<b>94.1</b>	<b>93.9</b>	<b>94.00</b>

Table 6: The experimental results for chunking

a data set provided for the CoNLL-2000 shared task. The training data contains 8,936 sentences with 211,727 words obtained from sections 15–18 of the WSJ. The test data consists of 2,012 sentences and 47,377 words in section 20 of the WSJ. In order to represent chunks, an IOB model is used, where every word is tagged with a chunk label extended with B (the beginning of a chunk), I (inside a chunk), and O (outside a chunk). First, the POS information in test data are replaced to the result of our POS tagger. Then it is evaluated using trained chunking model. Since CRFs (Conditional Random Fields) has been shown near state-of-the-art performance in text chunking (Fei Sha and Fernando Pereira, 2003; Sun et al., 2008), we use CRF++, an open source CRF implementation by Kudo (2005), with default feature template and parameter settings of the package. For simplicity in the experiments, the values of  $\delta$  in Equation (2) and  $\gamma$  in Equation (3) are set to be 0.4 and 0.6 respectively which are same as the previous section.

Table 6 gives the experimental results of text chunking according to the kinds of POS taggers including two previous works, CL-MSVM, and TL-MSVM. Shen’s tagger and Manning’s tagger show nearly the same performance. They achieve an accuracy of 96.08% and around 93.9 F1-score. On the other hand, CL-MSVM achieves 96.13% accuracy and 94.00 F1-score. The accuracy and F1-score of TL-MSVM are 96.12% and 94.00. Both CL-MSVM and TL-MSVM show slightly better performances than other POS taggers. As shown in Table 5, both CL-MSVM and TL-MSVM achieve lower accuracies than other methods, while their inter-category errors are less than that of other experimental methods. Thus, the improvement of CL-MSVM and TL-MSVM implies that, for the subsequent natural language processing, a POS tagger should consider different cost of tagging errors.

## 6 Conclusion

In this paper, we have shown that supervised POS tagging can be improved by discriminating inter-category errors from intra-category ones. An inter-category error occurs by mislabeling a word with a totally different tag, while an intra-category error is caused by a similar POS tag. Therefore, inter-category errors affect the performances of subsequent NLP tasks far more than intra-category errors. This implies that different costs should be considered in training POS tagger according to error types.

As a solution to this problem, we have proposed two gradient loss functions which reflect different costs for two error types. The cost of an error type is set according to (i) categorical difference or (ii) distance in the tree structure of POS tags. Our POS experiment has shown that if these loss functions are applied to multiclass SVMs, they could significantly reduce inter-category errors. Through the text chunking experiment, it is shown that the multiclass SVMs trained with the proposed loss functions which generate fewer inter-category errors achieve higher performance than existing POS taggers.

We have shown that cost sensitive learning can be applied to POS tagging only with multiclass SVMs. However, the proposed loss functions are general enough to be applied to other existing POS taggers. Most supervised machine learning techniques are optimized on their loss functions. Therefore, the performance of POS taggers based on supervised machine learning techniques can be improved by applying the proposed loss functions to learn their classifiers.

{fixed-term.xiao.jiang}@us.bosch.com

## Abstract

Social media language contains huge amount and wide variety of nonstandard tokens, created both intentionally and unintentionally by the users. It is of crucial importance to normalize the noisy nonstandard tokens before applying other NLP techniques. A major challenge facing this task is the system coverage, i.e., for *any* user-created nonstandard term, the system should be able to restore the correct word within its top  $n$  output candidates. In this paper, we propose a cognitively-driven normalization system that integrates different *human* perspectives in normalizing the nonstandard tokens, including the enhanced letter transformation, visual priming, and string/phonetic similarity. The system was evaluated on both word- and message-level using four SMS and Twitter data sets. Results show that our system achieves over 90% word-coverage across all data sets (a 10% absolute increase compared to state-of-the-art); the broad word-coverage can also successfully translate into message-level performance gain, yielding 6% absolute increase compared to the best prior approach.

## 1 Introduction

The amount of user generated content has increased drastically in the past few years, driven by the prosperous development of the social media websites such as Twitter, Facebook, and Google+. As of June 2011, Twitter has attracted over 300 million users and produces more than 2 billion tweets per week (Twitter, 2011). In a broader sense, Twitter messages, SMS messages, Facebook updates, chat logs, Emails, etc. can all be considered as “social text”,

which is significantly different from the traditional news text due to the informal writing style and the conversational nature. The social text serves as a very valuable information source for many NLP applications, such as the information extraction (Ritter et al., 2011), retrieval (Subramaniam et al., 2009), summarization (Liu et al., 2011a), sentiment analysis (Celikyilmaz et al., 2010), etc. Yet existing systems often perform poorly in this domain due to the extensive use of the nonstandard tokens, emoticons, incomplete and ungrammatical sentences, etc. It is reported that the Stanford named entity recognizer (NER) experienced a performance drop from 90.8% to 45.8% on tweets (Liu et al., 2011c); the part-of-speech (POS) tagger and dependency parser degraded 12.2% and 20.65% respectively on tweets (Foster et al., 2011). It is therefore of great importance to normalize the social text before applying the standard NLP techniques. Text normalization is also crucial for building robust text-to-speech (TTS) systems, which need to determine the pronunciations for nonstandard words in the social text.

The goal of this work is to automatically convert the noisy nonstandard tokens observed in the social text into standard English words. We aim for a robust text normalization system with “broad coverage”, i.e., for *any* user-created nonstandard token, the system should be able to restore the correct word within its top  $n$  candidates ( $n = 1, 3, 10\dots$ ). This is a very challenging task due to two facts: first, there exists huge amount and a wide variety of nonstandard tokens. (Liu et al., 2011b) found more than 4 million distinct out-of-vocabulary tokens in the Edinburgh Twitter corpus (Petrovic et al., 2010); second, the nonstandard tokens consist

2gether (6326)	togetha (919)	tgthr (250)	togeda (20)
2getha (1266)	together (207)	t0gether (57)	togethaa (10)
2gthr (178)	together (94)	together (49)	2getter (10)
u (3240535)	ya (460963)	yo (252274)	yaa (17015)
yaaa (7740)	yew (7591)	yuo (467)	youz (426)
yooooou (186)	youy (105)	yoiu (128)	yoooouuu (82)

Table 1: Nonstandard tokens and their frequencies in the Edinburgh Twitter corpus. The corresponding standard words are “**together**” and “**you**”, respectively.

of a mixture of both unintentional misspellings and intentionally-created tokens for various reasons<sup>1</sup>, including the needs for speed, ease of typing (Crystal, 2009), sentiment expressing (e.g., “coool” (Brody and Diakopoulos, 2011)), intimacy and social purpose (Thurlow, 2003), etc., making it even harder to decipher the social messages. Table 1 shows some example nonstandard tokens.

Existing spell checkers and normalization systems rely heavily on lexical/phonetic similarity to select the correct candidate words. This may not work well since a good portion of the correct words lie outside the specified similarity threshold (e.g., (tomorrow, “tmrw”)<sup>2</sup>), yet the number of candidates increases dramatically as the system strives to increase the coverage by enlarging the threshold. (Han and Baldwin, 2011) reported an average of 127 candidates per nonstandard token with the correct-word coverage of 84%. The low coverage score also enforces an undesirable performance ceiling for the candidate reranking approaches. Different from previous work, we tackle the text normalization problem from a cognitive-sensitive perspective and investigate the human rationales for normalizing the nonstandard tokens. We argue that there exists a set of letter transformation patterns that humans use to decipher the nonstandard tokens. Moreover, the “visual priming” effect may play an important role in human comprehension of the noisy tokens. “Priming” represents an implicit memory effect. For example, if a person reads a list of words including the word *table*, and is later asked to complete a word starting with *tab-*, it is very likely that he answers *table* since the person is *primed*.

In this paper, we propose a broad-coverage normalization system by integrating three human per-

<sup>1</sup>For this reason, we will use the term “nonstandard tokens” instead of “ill-formed tokens” throughout the paper.

<sup>2</sup>We use the form (standard word, “nonstandard token”) to denote an example nonstandard token and its corresponding standard word.

spectives, including the enhanced letter transformation, visual priming, and the string and phonetic similarity. For an arbitrary nonstandard token, the three subnormalizers each suggest their most confident candidates from a different perspective. The candidates can then be heuristically combined or reranked using a message-level decoding process. We evaluate the system on both word- and message-level using four SMS and Twitter data sets. Results show that our system can achieve over 90% word-coverage with limited number of candidates and the broad word-coverage can be successfully translated into message-level performance gain. In addition, our system requires no human annotations, therefore can be easily adapted to different domains.

## 2 Related work

Text normalization, in its traditional sense, is the first step of a speech synthesis system, where the numbers, dates, acronyms, etc. found in the real-world text were converted into standard dictionary words, so that the system can pronounce them correctly. Spell checking plays an important role in this process. (Church and Gale, 1991; Mays et al., 1991; Brill and Moore, 2000) proposed to use the noisy channel framework to generate a list of corrections for any misspelled word, ranked by the corresponding posterior probabilities. (Sproat et al., 2001) enhanced this framework by calculating the likelihood probability as the chance of a noisy token and its associated tag being generated by a specific word.

With the rapid growth of SMS and social media content, text normalization system has drawn increasing attention in the recent decade, where the focus is on converting the noisy nonstandard tokens in the informal text into standard dictionary words. (Choudhury et al., 2007) modeled each standard English word as a hidden Markov model (HMM) and calculated the probability of observing the noisy-token under each of the HMM models; (Cook and Stevenson, 2009) calculated the sum of the probabilities of a noisy token being generated by a specific word and a word formation process; (Beaufort et al., 2010) employed the weighted finite-state machines (FSMs) and rewriting rules for normalizing French SMS; (Pennell and Liu, 2010) focused on tweets created by handsets and developed a CRF tagger for deletion-based abbreviation. The text normalization problem was also tackled under the machine transla-

tion (MT) or speech recognition (ASR) framework. (Aw et al., 2006) adapted a phrase-based MT model for normalizing SMS and achieved satisfying performance. (Kobus et al., 2008) showed that using a statistical MT system in combination with an analogy of the ASR system improved performance in French SMS normalization. (Pennell and Liu, 2011) proposed a two-phase character-level MT system for expanding the abbreviations into standard text.

Recent work also focuses on normalizing the Twitter messages, which is generally considered a more challenging task. (Han and Baldwin, 2011) developed classifiers for detecting the ill-formed words and generated corrections based on the morpho-phonemic similarity. (Liu et al., 2011b) proposed to normalize the nonstandard tokens without explicitly categorizing them. (Xue et al., 2011) adopted the noisy-channel framework and incorporated orthographic, phonetic, contextual, and acronym expansion factors in calculating the likelihood probabilities. (Gouws et al., 2011) revealed that different populations exhibit different shortening styles.

Most of the above systems limit their processing scope to certain categories (e.g., deletion-based abbreviations, misspellings) or require large-scale human annotated corpus for training, which greatly hinders the scalability of the system. In this paper, we propose a novel cognitively-driven text normalization system that robustly tackle both the unintentional misspellings and the intentionally-created noisy tokens. We propose a global context-based approach to purify the automatically collected training data and learn the letter transformation patterns without human supervision. We also propose a cognitively-grounded “visual priming” approach that leverages the “priming” effect to suggest the candidate words. By integrating different perspectives, our system can successfully mimic the human rationales and yield broad word-coverage on both SMS and Twitter messages. To the best of our knowledge, we are the first to integrate these human perspectives in the text normalization system.

### 3 Broad-Coverage Normalization System

In this section, we describe our broad-coverage normalization system, which consists of four key components. For a standard/nonstandard token, three subnormalizers each suggest their most confident

Figure 1: Examples of nonstandard tokens generated by performing letter transformation on the dictionary words.

candidates from a different perspective<sup>3</sup>: “Enhanced Letter Transformation” automatically learns a set of letter transformation patterns and is most effective in normalizing the intentionally created nonstandard tokens through letter insertion, repetition, deletion, and substitution (Section 3.1); “Visual Priming” proposes candidates based on the visual cues and a *primed* perspective (Section 3.2); “Spell Checker” corrects the misspellings (Section 3.3). The fourth component, “Candidate Combination” introduces various strategies to combine the candidates with or without the local context (Section 3.4). Note that it is crucial to integrate different human perspectives so that the system is flexible in processing both unintentional misspellings and various intentionally-created noisy tokens.

#### 3.1 Enhanced Letter Transformation

Given a noisy token  $t_i$  seen in the text, the letter transformation subnormalizer produces a list of correction candidates  $s_i$  under the noisy channel model:

$$\hat{s} = \arg \max_{s_i} p(s_i|t_i) = \arg \max_{s_i} p(t_i|s_i)p(s_i)$$

where we assume each nonstandard token  $t_i$  is dependent on only one English word  $s_i$ , that is, we are not considering acronyms (e.g., “bbl” for “be back later”) in this study.  $p(s_i)$  can be calculated as the unigram count from a background corpus. We formulate the process of generating a nonstandard token  $t_i$  from the dictionary word  $s_i$  using a letter transformation model, and use the model confidence as the probability  $p(t_i|s_i)$ . Figure 1 shows several example (word, token) pairs.

To form a nonstandard token, each letter in the dictionary word can be labeled with: (a) one of the 0-9 digits; (b) one of the 26 characters including itself; (c) the null character “-”; (d) a letter combination<sup>4</sup>. This transformation process from dictio-

<sup>3</sup>For the dictionary word, we allow the subnormalizers to either return the word itself or candidates that are the possibly intended words in the given context (e.g., (with, “wit”).

<sup>4</sup>The set of letter combinations used in this work are {ah, ai, aw, ay, ck, ea, ey, ie, ou, te, wh}

nary words to nonstandard tokens will be learned by a character-level sequence labeling system using the automatically collected (word, token) pairs. Next, we create a large lookup table by applying the character-level labeling system to the standard dictionary words and generate multiple variations for each word using the n-best labeling output, the labeling confidence is used as  $p(t_i|s_i)$ . During testing, we search this lookup table to find the best candidate words for the nonstandard tokens. For tokens with letter repetition, we first generate a set of variants by varying the repetitive letters (e.g.  $C_i = \{\text{“pleas”}, \text{“pleeas”}, \text{“pleaas”}, \text{“pleeaaas”}, \text{“pleeeaaas”}\}$  for  $t_i = \{\text{“pleeeaaas”}\}$ ), then select the maximum posterior probability among all the variants:

$$p(t_i|s_i) = \max_{\tilde{t}_i \in C_i} p(\tilde{t}_i|s_i)$$

Different from the work in (Liu et al., 2011b), we enhanced the letter transformation process with two novel aspects: first, we devise a set of phoneme-, syllable-, morpheme- and word-boundary based features that effectively characterize the formation process of the nonstandard tokens; second, we propose a global context-aware approach to purify the automatically collected training (word, token) pairs, resulting system yielded similar performance but with only one ninth of the original data. We name this subnormalizer “Enhanced Letter Transformation”.

### 3.1.1 Context-Aware Training Pair Selection

Manual annotation of the noisy nonstandard tokens takes a lot of time and effort. (Liu et al., 2011b) proposed to use Google search engine to automatically collect large amount of training pairs. Yet the resulting (work, token) pairs are often noisy, containing pairs such as (events, “ents”), (downtown, “downto”), etc. The ideal training data should consist of the most frequent nonstandard tokens paired with the corresponding corrections, so that the system can learn from the most representative letter transformation patterns.

Motivated by research on word sense disambiguation (WSD) (Mihalcea, 2007), we hypothesize the nonstandard token and the standard word share a lot of common terms in their global context. For example, “luv” and “love” share “i”, “you”, “u”, “it”, etc. among their top context words. Based on this finding, we propose to filter out the low-quality train-

ing pairs by evaluating the global contextual similarity between the word and token. To the best of our knowledge, we are the first to explore this global contextual similarity for the text normalization task.

Given a noisy (word, token) pair, we construct two context vectors  $v_i$  and  $v_j$  by collecting the most frequent terms appearing before or after the work/token. We consider two terms on each side of the word/token as context and restrict the vector length to the top 100 terms. The frequency information were calculated using a large background corpus; stopwords were not excluded from the context vector. The contextual similarity of the (word, token) pair is defined as the cosine similarity between the context vectors  $v_i$  and  $v_j$ :

$$ContextSim(v_i, v_j) = \frac{\sum_{k=1}^n w_{i,k} \times w_{j,k}}{\sqrt{\sum_{k=1}^n w_{i,k}^2} \times \sqrt{\sum_{k=1}^n w_{j,k}^2}}$$

where  $w_{i,k}$  is the weight of term  $t_k$  within the context of term  $t_i$ . The term weights are defined using a normalized TF-IDF method:

$$w_{i,k} = \frac{TF_{i,k}}{TF_i} \times \log\left(\frac{N}{DF_k}\right)$$

where  $TF_{i,k}$  is the count of term  $t_k$  appearing within the context of term  $t_i$ ;  $TF_i$  is the total count of  $t_i$  in the corpus.  $\frac{TF_{i,k}}{TF_i}$  is therefore the relative frequency of  $t_k$  appearing in the context of  $t_i$ ;  $\log\left(\frac{N}{DF_k}\right)$  denotes the inverse document frequency of  $t_k$ , calculated as the logarithm of total tweets ( $N$ ) divided by the number of tweets containing  $t_k$ .

To select the most representative (word, token) pairs for training, we rank the automatically collected 46,288 pairs by the token frequency, filter out pairs whose contextual similarity lower than a threshold  $\theta$  (set empirically at 0.0003), and retain only the top portion (5,000 pairs) for experiments.

### 3.1.2 Character-level Sequence Labeling

For a dictionary word  $s_i$ , we use the conditional random fields (CRF) model to perform character-level labeling to generate its variant  $t_i$ . In the training stage, we align the collected (word, token) pairs at the character level (Liu et al., 2011b), then construct a feature vector for each letter of the dictionary word, using its mapped character as the reference label. This aligned data set is used to train a CRF model (Lafferty et al., 2001; Kudo, 2005)

Character	a	d	v	e	r	t	i	s	e	m	e	n	t	s
Phoneme	AE	D	V	ER	ER	T	AY	Z	_	M	AH	N	T	S
Phoneme boundary	O	O	O	B1	L1	O	O	O	O	O	O	O	O	O
Syllable boundary	B	L	B	I	L	B	I	I	L	B	I	I	I	L
Morpheme boundary	B	I	I	I	I	I	I	L	B	I	I	L	U	
Word boundary	B	I	I	I	I	I	I	I	I	I	I	I	L	

Table 2: Example boundary tags for word “**advertisements**” on the phoneme-, syllable-, morpheme-, and word-level, labeled with the “BILOU” encoding scheme.

with L-BFGS optimization. We use the character/phoneme n-gram and binary vowel features as in (Liu et al., 2011b), but develop a set of boundary features to effectively characterize the letter transformation process.

We notice that in creating the nonstandard tokens, humans tend to drop certain letter units from the word or replace them with other letters. For example, in abbreviating “advertisements” to “ads”, humans may first break the word into smaller units “ad-ver-tise-ment-s”, then drop the middle parts. This also conforms with the word construction theory where a word is composed of smaller units and construction rules. Based on this assumption, we decompose the dictionary words on the phoneme-, syllable-, morpheme-, and word-level<sup>5</sup> and use the “BILOU” tagging scheme (Ratinov and Roth, 2009) to represent the unit boundary, where “BILOU” stands for B(egin), I(nside), L(ast), O(utside), and U(nit-length) of the corresponding unit<sup>6</sup>. Example “BILOU” boundary tags were shown in Table 2.

On top of the boundary tags, we develop a set of conjunction features to accurately pinpoint the current character position. We consider conjunction features formed by concatenating character position in syllable and current syllable position in the word (e.g., conjunction feature “L\_B” for the letter “d” in Table 2). A similar set of features are also developed on morpheme level. We consider conjunction of character/vowel feature and their boundary tags on the syllable/morpheme/word level; conjunction of phoneme and phoneme boundary tags, and absolute position of current character within the corre-

<sup>5</sup>Phoneme decomposition is generated using the (Jiampongamarn et al., 2007) algorithm to map up to two letters to phonemes (2-to-2 alignment); syllable boundary acquired by the hyphenation algorithm (Liang, 1983); morpheme boundary determined by toolkit Morfessor 1.0 (Creutz and Lagus, 2005).

<sup>6</sup>For phoneme boundary, we use “B1” and “L1” to represent two different characters aligned to one phoneme and “B2”, “L2” represent same characters aligned to one phoneme.

sponding syllable/morpheme/word.

We use the aforementioned features to train the CRF model, then apply the model on dictionary words  $s_i$  to generate multiple variations  $t_i$  for each word. When a nonstandard token is seen during testing, we apply the noisy channel to generate a list of best candidate words:  $\hat{s} = \arg \max_{s_i} p(t_i|s_i)p(s_i)$ .

### 3.2 Visual Priming Approach

A second key component of the broad-coverage normalization system is a novel “Visual Priming” subnormalizer. It is built on a cognitively-driven “priming” effect, which has not been explored by other studies yet was shown to be effective across all our data sets.

“Priming”<sup>7</sup> is an implicit memory effect caused by spreading neural networks (Tulving and Stark, 1982). As an example, in the word-stem completion task, participants are given a list of study words, and then asked to complete word “stems” consisting of first 3 letters. A priming effect is observed when participants complete stems with words on the study list more often than with the novel words. The study list activates parts of the human brain right before the stem completion task, later when a word stem is seen, less additional activation is needed for one to choose a word from the study list.

We argue that the “priming” effect may play an important role in human comprehension of the noisy tokens. A person familiarized with the “social talk” is highly *primed* with the most commonly used words; later when a nonstandard token shows only minor visual cues or visual stimulus, it can still be quickly recognized by the person. In this process, the first letter or first few letters of the word serve as a very important visual stimulus. Based on this assumption, we introduce the “priming” subnormalizer based only on the word frequency and the minor visual stimulus. Concretely, this approach proposes candidate words based on the following equation:

$$VisualPrim(s_i|t_i) = \frac{len(LCS(t_i, s_i))}{len(t_i)} \times \log(TF(s_i))$$

Where  $TF(s_i)$  is the term frequency of  $s_i$  as in the background social text corpus;  $\log(TF(s_i))$  *primes* the system with the most common words in the social text;  $LCS(\cdot)$  means the longest common character subsequence;  $len(\cdot)$  denotes the length of the

<sup>7</sup>[http://en.wikipedia.org/wiki/Priming\\_\(psychology\)](http://en.wikipedia.org/wiki/Priming_(psychology))

character sequence. Together  $\frac{\text{len}(LCS(t_i, s_i))}{\text{len}(t_i)}$  provides the minor visual stimulus from  $t_i$ . Note that the first character has been shown to be a crucial visual cue for the brain to understand jumbled words (Davis, ), we therefore consider as candidates only those words  $s_i$  that start with the same character as  $t_i$ . In the case that the nonstandard token  $t_i$  starts with a digit (e.g., “2moro”), we use the mostly likely corresponding letter to search the candidates (those starting with letter “t”). This setting also effectively reduces the candidate search space.

The “visual priming” subnormalizer promotes the candidate words that are frequently used in the social talk and also bear visual similarity with the given noisy token. It slightly deviates from the traditional “priming” notion in that the frequency information were acquired from the global corpus rather than from the prior context. This approach also inherently follows the noisy channel framework, with  $p(t_i|s_i)$  represents the visual stimulus and  $p(s_i)$  being the logarithm of frequency. The candidate words are ranked by  $\hat{s} = \arg \max_{s_i} \text{VisualPrim}(s_i|t_i)$ . We show that the “priming” subnormalizer is robust across data sets abide its simplistic representation.

### 3.3 Spell Checker

The third subnormalizer is the spell checker, which combines the string and phonetic similarity algorithms and is most effective in normalizing the misspellings. We use the Jazzy spell checker (Idzels, 2005) that integrates the DoubleMetaphone phonetic matching algorithm and the Levenshtein distance using the near-miss strategy, which enables the interchange of two adjacent letters, and the replacing/deleting/adding of letters.

### 3.4 Candidate Combination

Each of the three subnormalizers is a stand-alone system and can suggest corrections for the nonstandard tokens. Yet we show that each subnormalizer mimics a different perspective that humans use to decode the nonstandard tokens, as a result, our broad-coverage normalization system is built by integrating candidates from the three subnormalizers using various strategies.

For a noisy token seen in the informal text, the most convenient way of system combination is to harvest up to  $n$  candidates from each of the subnormalizers, and use the pool of candidates (up to

$3n$ ) as the system output. This sets an upper bound for other candidate combination strategies, and we name this approach “**Oracle**”.

A second combination strategy is to give higher priority to candidates from high-precision subsystems. Both “Letter Transformation” and “Spell Checker” have been shown to have high precision in suggesting corrections (Liu et al., 2011b), while “Visual Priming” may not yield high precision due to its definition. We therefore take the top-3 candidates from each of the “Letter Tran.” and “Spell Checker” subsystems, but put candidates from “Letter Tran.” ahead of “Spell Checker” if the confidence of the best candidate is greater than a threshold  $\lambda$  and vice versa. The list of candidates is then compensated using the “Visual Priming” output until the total number reaches  $n$ . We name this approach “**Word-level**” combination since no message-level context information is involved.

Based on the “Word-level” combination output, we can further rerank all the candidates using a message-level Viterbi decoding process (Pennell and Liu, 2011) where the local context information is used to select the best candidate. This approach is named “**Message-level**” combination.

## 4 Experiments

### 4.1 Experimental Setup

We use four SMS and Twitter data sets to evaluate the system effectiveness. Statistics of these data sets are summarized in Table 3. Data set (1) to (3) are used for word-level evaluation; data set (4) for both word- and message-level evaluation. In Table 3, we also present the number of distinct nonstandard tokens found in each data set, and notice that only a small portion of the nonstandard tokens correspond to multiple standard words. We calculate the dictionary coverage of the manually annotated words since this sets an upper bound for any normalization system. We use the Edinburgh Twitter corpus (Petrovic et al., 2010) as the background corpus for frequency calculation, and a dictionary containing 82,324 words.<sup>8</sup> The nonstandard tokens may consist of both numbers/characters and apostrophe.

<sup>8</sup>The dictionary is created by combining the CMU (CMU, 2007) and Aspell (Atkinson, 2006) dictionaries and dropping words with frequency  $< 20$  in the background corpus. “rt” and all single characters except “a” and “i” are excluded.

Index	Domain	Time Period	#Msgs	#Uniq Nonstan. Tokens	%Nonstan. Tkns w/ Multi-cands	%Dict cov. of cands	Reference
(1)	SMS	Around 2007	n/a	303	1.32%	100%	(Choudhury et al., 2007)
(2)	Twitter	Nov 2009 – Feb 2010	6150	3802	3.87%	99.34%	(Liu et al., 2011)
(3)	SMS/Twitter	Aug 2009	4660	2040	2.41%	96.84%	(Pennell and Liu, 2011)
(4)	Twitter	Aug 2010 – Oct 2010	549	558	2.87%	99.10%	(Han and Baldwin, 2011)

Table 3: Statistics of different SMS and Twitter data sets.

The goal of word-level normalization is to convert the list of distinct nonstandard tokens into standard words. For each nonstandard token, the system is considered correct if any of the corresponding standard words is among the  $n$ -best output from the system. We adopt this word-level  $n$ -best accuracy to make our results comparable to other state-of-the-art systems. On message-level, we evaluate the 1-best system output using precision, recall, and  $f$ -score, calculated respective to the nonstandard tokens.

## 4.2 Word-level Results

The word-level results are presented in Table 4, 5, and 6, evaluated on data set (1), (2), (3) respectively. We present the  $n$ -best accuracy ( $n = 1, 3, 10, 20$ ) of the system as well as the ‘‘Oracle’’ results generated by pooling the top-20 candidates from each of the three subnormalizers. The best prior results on the data sets are also included in the tables.

We notice that the broad-coverage system outperforms all other systems on the reported data sets. It achieves about 90% word-level accuracy on data set (1) and (2) with the top-10 candidates (an average 10% performance gain compared to (Liu et al., 2011b)). This is of crucial importance to a normalization system, since the high accuracy and limited number of candidates will enable more sophisticated reranking or supervised learning techniques to select the best candidate. We also observe the ‘‘Oracle’’ system has averagely only 5% gap to the dictionary coverage. A detailed analysis shows that the human annotators perform many semantic/grammar corrections as well as inconsistent annotations, e.g., (sleepy, ‘‘zzz’’), (disliked, ‘‘unliked’’). These are out of the capabilities of the current text normalization system and partly explains the remaining 5% gap.

Regarding the subnormalizer performance, the spell checker yields only 50% to 60% accuracy on all data sets, indicating that the vast amount of the intentionally created nonstandard tokens can hardly be tackled by a system relies solely on the lexical/phonetic similarity. The ‘‘Visual Priming’’ sub-

Table 5: Word-level results on data set (2).

normalizer performs surprisingly well and shows robust performance across all data sets. A minor side-effect is that the candidates were restricted to have the same first letter with the noisy token, this sets the upper bound of the approach to 89.77%, 92.45%, and 93.51%, respectively on data set (1), (2), and (3). Compared to other subnormalizers, the ‘‘Enhanced Letter Tran.’’ is effective at normalizing intentionally created tokens and has better precision regarding its top candidate ( $n = 1$ ). We demonstrate the context-aware training pair selection results in Figure 2, by plotting the learning curve using different amounts of training data, ranging from 1,000 (word, token) pairs to the total 46,288 pairs. We notice that the system can effectively learn the letter transformation patterns from a small number of high quality training pairs. The final system was trained using the top 5,000 pairs and the lookup table was created by generating 50 variations for each dictionary word.

## 4.3 Message-level Results

The goal of message-level normalization is to replace each occurrence of the nonstandard token with the candidate word that best fits the local context.

SMS/Twitter Dataset (2404 pairs)	Word Level Accuracy (%)				
	1-best	3-best	10-best	20-best	Oracle
Jazzy Spell Checker	39.89	46.51	48.54	48.67	n/a

Table 6: Word-level results on data set (3). \* denotes system requires human annotations for training.

Figure 2: Learning curve of the enhanced letter transformation system using random training pair selection or the context-aware approach. Evaluated on data set (2).

We use the word-level “Broad-Cov. System” for candidate suggestion and the Viterbi algorithm for message-level decoding. The system is evaluated on data set (4) and results shown in Table 7. Following research in (Han and Baldwin, 2011), we focus on the the normalization task and assume perfect non-standard token detection.

The “Word-level w/o Context” results are generated by replacing each nonstandard token using the 1-best word-level candidate. Although the replacement process is static, it results in 70.97% f-score due to the high performance of the word-level system. We explore two language models (LM) for the Viterbi decoding process. First, a bigram LM is trained using the Edinburgh Twitter corpus (53,794,549 English tweets) with the SRILM toolkit (Stolcke, 2002) and Kneser-Ney smoothing; second, we retrieve the bigram probabilities from the Microsoft Web N-gram API (Wang et al., 2010) since this represents a more comprehensive web-based corpus. During decoding, we use the “VisualPrim” score as the emission probability, since this score best fits the log scale and applies to all candidates. For the Twitter LM, we apply a scaling factor of 0.5 to the “VisualPrim” score to make it comparable in scale to the LM probabilities. We use the 3-best word-level candidates for Viterbi decoding. In addition, we add the commonly used corrections for

	Twitter LM	<b>84.13</b>	<b>78.38</b>	<b>81.15</b>
(Han and Baldwin, 2011)*		75.30	75.30	75.30

Table 7: Message-level results on data set (4). \* denotes system requires human annotations for training.

16 single-characters, e.g., for “r”, “c”, we add “are”, “see” to the candidate list if they are not already presented. A default “VisualPrim” score ( $\eta = 25$ ) is used for these candidates. As seen from Table 7, both Web LM and Twitter LM achieve better performance than the best prior results, with Twitter LM outperforms the Web LM, yielding a f-score of 81%. This shows that a vanilla Viterbi decoding process is able to outperform the fine-tuned supervised system given competitive word-level candidates. In future, we will investigate other comprehensive message-level candidate reranking process.

## 5 Conclusion

In this paper, we propose a broad-coverage normalization system for the social media language without using the human annotations. It integrates three key components: the enhanced letter transformation, visual priming, and string/phonetic similarity. The system was evaluated on both word- and message-level using four SMS and Twitter data sets. We show that our system achieves over 90% word-coverage across all data sets and the broad word-coverage can be successfully translated into message-level performance gain. We observe that the social media is an emotion-rich language, therefore future normalization system will need to address various sentiment-related expressions, such as emoticons (“:d”, “X-8”), interjections (“bwahaha”, “brrrr”), acronyms (“lol”, “lmao”), etc., whether and how these expressions should be normalized is an unaddressed issue and worths future investigation.

## Acknowledgments

We thank the three anonymous reviewers for their insightful comments and valuable input. We thank Prof. Yang Liu, Deana Pennell, Bo Han, and Prof. Tim Baldwin for sharing the annotated data and the useful discussions. Part of this work was done while Xiao Jiang was a research intern in Bosch Research.

## Abstract

We propose the first joint model for word segmentation, POS tagging, and dependency parsing for Chinese. Based on an extension of the incremental joint model for POS tagging and dependency parsing (Hatori et al., 2011), we propose an efficient character-based decoding method that can combine features from state-of-the-art segmentation, POS tagging, and dependency parsing models. We also describe our method to align comparable states in the beam, and how we can combine features of different characteristics in our incremental framework. In experiments using the Chinese Treebank (CTB), we show that the accuracies of the three tasks can be improved significantly over the baseline models, particularly by 0.6% for POS tagging and 2.4% for dependency parsing. We also perform comparison experiments with the partially joint models.

## 1 Introduction

In processing natural languages that do not include delimiters (e.g. spaces) between words, word segmentation is the crucial first step that is necessary to perform virtually all NLP tasks. Furthermore, the word-level information is often augmented with the POS tags, which, along with segmentation, form the basic foundation of statistical NLP.

Because the tasks of word segmentation and POS tagging have strong interactions, many studies have been devoted to the task of joint word segmentation and POS tagging for languages such as Chinese (e.g. Kruengkrai et al. (2009)). This is because some of the segmentation ambiguities cannot be resolved without considering the surrounding grammatical constructions encoded in a sequence of POS tags. The joint approach to word segmentation and POS tagging has been reported to improve word segmentation and POS tagging accuracies by more than

1% in Chinese (Zhang and Clark, 2008). In addition, some researchers recently proposed a joint approach to Chinese POS tagging and dependency parsing (Li et al., 2011; Hatori et al., 2011); particularly, Hatori et al. (2011) proposed an incremental approach to this joint task, and showed that the joint approach improves the accuracies of these two tasks.

In this context, it is natural to consider further a question regarding the joint framework: how strongly do the tasks of word segmentation and dependency parsing interact? In the following Chinese sentences:

当今 和平奖 与 和平 事业 相关  
current peace-prize and peace operation related  
*The current peace prize and peace operations are related.*

当今 和平 奖与 和平 事业 相关 团体  
current peace award peace operation related group  
*The current peace is awarded to peace-operation-related groups.*

the only difference is the existence of the last word 团体; however, whether or not this word exists changes the whole syntactic structure and segmentation of the sentence. This is an example in which word segmentation cannot be handled properly without considering long-range syntactic information.

Syntactic information is also considered beneficial to improve the segmentation of out-of-vocabulary (OOV) words. Unlike languages such as Japanese that use a distinct character set (i.e. *katakana*) for foreign words, the transliterated words in Chinese, many of which are OOV words, frequently include characters that are also used as common or function words. In the current systems, the existence of these characters causes numerous over-segmentation errors for OOV words.

Based on these observations, we aim at building a joint model that simultaneously processes word segmentation, POS tagging, and dependency parsing, trying to capture global interaction among

these three tasks. To handle the increased computational complexity, we adopt the incremental parsing framework with dynamic programming (Huang and Sagae, 2010), and propose an efficient method of character-based decoding over candidate structures.

Two major challenges exist in formalizing the joint segmentation and dependency parsing task in the character-based incremental framework. First, we must address the problem of how to align comparable states effectively in the beam. Because the number of dependency arcs varies depending on how words are segmented, we devise a step alignment scheme using the number of character-based arcs, which enables effective joint decoding for the three tasks.

Second, although the feature set is fundamentally a combination of those used in previous works (Zhang and Clark, 2010; Huang and Sagae, 2010), to integrate them in a single incremental framework is not straightforward. Because we must perform decisions of three kinds (segmentation, tagging, and parsing) in an incremental framework, we must adjust which features are to be activated when, and how they are combined with which action labels. We have also found that we must balance the learning rate between features for segmentation and tagging decisions, and those for dependency parsing.

We perform experiments using the Chinese Treebank (CTB) corpora, demonstrating that the accuracies of the three tasks can be improved significantly over the pipeline combination of the state-of-the-art joint segmentation and POS tagging model, and the dependency parser. We also perform comparison experiments with partially joint models, and investigate the tradeoff between the running speed and the model performance.

## 2 Related Works

In Chinese, Luo (2003) proposed a joint constituency parser that performs segmentation, POS tagging, and parsing within a single character-based framework. They reported that the POS tags contribute to segmentation accuracies by more than 1%, but the syntactic information has no substantial effect on the segmentation accuracies. In contrast, we built a joint model based on a dependency-based framework, with a rich set of structural features. Using it, we show the first positive result in Chinese that the segmentation accuracies can be improved using the syntactic information.

Another line of work exists on lattice-based parsing for Semitic languages (Cohen and Smith, 2007; Goldberg and Tsarfaty, 2008). These methods first convert an input sentence into a lattice encoding the morphological ambiguities, and then conduct joint morphological segmentation and PCFG parsing. However, the segmentation possibilities considered in those studies are limited to those output by an existing morphological analyzer. In addition, the lattice does not include word segmentation ambiguities crossing boundaries of space-delimited tokens. In contrast, because the Chinese language does not have spaces between words, we fundamentally need to consider the lattice structure of the whole sentence. Therefore, we place no restriction on the segmentation possibilities to consider, and we assess the full potential of the joint segmentation and dependency parsing model.

Among the many recent works on joint segmentation and POS tagging for Chinese, the linear-time incremental models by Zhang and Clark (2008) and Zhang and Clark (2010) largely inspired our model. Zhang and Clark (2008) proposed an incremental joint segmentation and POS tagging model, with an effective feature set for Chinese. However, it requires to computationally expensive multiple beams to compare words of different lengths using beam search. More recently, Zhang and Clark (2010) proposed an efficient character-based decoder for their word-based model. In their new model, a single beam suffices for decoding; hence, they reported that their model is practically ten times as fast as their original model. To incorporate the word-level features into the character-based decoder, the features are decomposed into substring-level features, which are effective for incomplete words to have comparable scores to complete words in the beam. Because we found that even an incremental approach with beam search is intractable if we perform the word-based decoding, we take a character-based approach to produce our joint model.

The incremental framework of our model is based on the joint POS tagging and dependency parsing model for Chinese (Hatori et al., 2011), which is an extension of the shift-reduce dependency parser with dynamic programming (Huang and Sagae, 2010). They specifically modified the shift action so that it assigns the POS tag when a word is shifted onto the stack. However, because they regarded word segmentation as given, their model did not consider the

interaction between segmentation and POS tagging.

### 3 Model

#### 3.1 Incremental Joint Segmentation, POS Tagging, and Dependency Parsing

Based on the joint POS tagging and dependency parsing model by Hatori et al. (2011), we build our joint model to solve word segmentation, POS tagging, and dependency parsing within a single framework. Particularly, we change the role of the shift action and additionally use the append action, inspired by the character-based actions used in the joint segmentation and POS tagging model by Zhang and Clark (2010).

The list of actions used is the following:

- A: *append* the first character in the queue to the word on top of the stack.
- SH( $t$ ): *shift* the first character in the input queue as a new word onto the stack, with POS tag  $t$ .
- RL/RR: *reduce* the top two trees on the stack,  $(s_0, s_1)$ , into a subtree  $s_0 \hat{\ } s_1 / s_0 \hat{\ } s_1$ , respectively.

Although SH( $t$ ) is similar to the one used in Hatori et al. (2011), now it shifts the first character in the queue as a new word, instead of shifting a word. Following Zhang and Clark (2010), the POS tag is assigned to the word when its first character is shifted, and the word–tag pairs observed in the training data and the closed-set tags (Xia, 2000) are used to prune unlikely derivations. Because 33 tags are defined in the CTB tag set (Xia, 2000), our model exploits a total of 36 actions.

To train the model, we use the averaged perceptron with the early update (Collins and Roark, 2004). In our joint model, the early update is invoked by mistakes in any of word segmentation, POS tagging, or dependency parsing.

#### 3.2 Alignment of States

When dependency parsing is integrated into the task of joint word segmentation and POS tagging, it is not straightforward to define a scheme to *align (synchronize)* the states in the beam. In beam search, we use the *step index* that is associated with each state: the parser states in process are aligned according to the index, and the beam search pruning is applied to those states with the same index. Consequently, for the beam search to function effectively, all states with the same index must be *comparable*, and all terminal states should have the same step index.

We can first think of using the number of shifted characters as the step index, as Zhang and Clark (2010) does. However, because RL/RR actions can be performed without incrementing the step index, the decoder tends to prefer states with more dependency arcs, resulting more likely in premature choice of ‘reduce’ actions or oversegmentation of words. Alternatively, we can consider using the number of actions that have been applied as the step index, as Hatori et al. (2011) does. However, this results in inconsistent numbers of actions to reach the terminal states: some states that segment words into larger chunks reach a terminal state earlier than other states with smaller chunks. For these reasons, we have found that both approaches yield poor models that are not at all competitive with the baseline (pipeline) models<sup>1</sup>.

To address this issue, we propose an indexing scheme using the number of character-based arcs. We presume that in addition to the word-to-word dependency arcs, each word (of length  $M$ ) implicitly has  $M - 1$  inter-character arcs, as in:  $\boxed{A \hat{\ } B \hat{\ } C}$ ,  $\boxed{A \hat{\ } B} \hat{\ } \boxed{C}$ , and  $\boxed{A} \hat{\ } \boxed{B} \hat{\ } \boxed{C}$  (each rectangle denotes a word). Then we can define the step index as the sum of the number of shifted characters and the total number of (inter-word and intra-word) dependency arcs, which thereby meets all the following conditions:

- (1) All subtrees spanning  $M$  consecutive characters have the same index  $2M - 1$ .
- (2) All terminal states have the same step index  $2N$  (including the root arc), where  $N$  is the number of characters in the sentence.
- (3) Every action increases the index.

Note that the number of shifted characters is also necessary to meet condition (3). Otherwise, it allows an unlimited number of SH( $t$ ) actions without incrementing the step index. Figure 1 portrays how the states are aligned using the proposed scheme, where a subtree is denoted as a rectangle with its partial index shown inside it.

In our framework, because an action increases the step index by 1 (for SH( $t$ ) or RL/RR) or 2 (for A), we need to use two beams to store new states at each step. The computational complexity of the entire process is  $O(B(T + 3) \cdot 2N)$ , where  $B$  is the beam

<sup>1</sup>For example, in our preliminary experiment on CTB-5, the step indexing according to the number of actions underperforms the baseline model by 0.2–0.3% in segmentation accuracy.

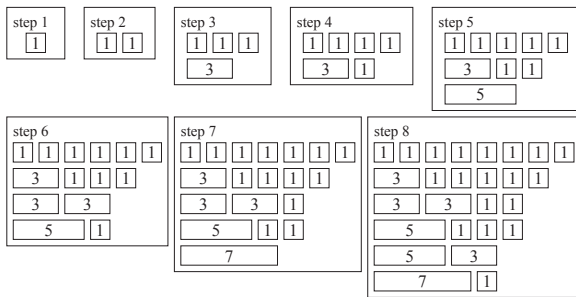

Figure 1: Illustration of the alignment of steps.

size,  $T$  is the number of POS tags ( $= 33$ ), and  $N$  is the number of characters in the sentence. Theoretically, the computational time is greater than that with the character-based joint segmentation and tagging model by Zhang and Clark (2010) by a factor of  $\frac{T+3}{T+1} \cdot \frac{2N}{N} \simeq 2.1$ , when the same beam size is used.

### 3.3 Features

The feature set of our model is fundamentally a combination of the features used in the state-of-the-art joint segmentation and POS tagging model (Zhang and Clark, 2010) and dependency parser (Huang and Sagae, 2010), both of which are used as baseline models in our experiment. However, we must carefully adjust which features are to be activated and when, and how they are combined with which action labels, depending on the type of the features because we intend to perform three tasks in a single incremental framework.

The list of the features used in our joint model is presented in Table 1, where S01–S05, W01–W21, and T01–05 are taken from Zhang and Clark (2010), and P01–P28 are taken from Huang and Sagae (2010). Note that not all features are always considered: each feature is only considered if the action to be performed is included in the list of actions in the “When to apply” column. Because S01–S05 are used to represent the likelihood score of substring sequences, they are only used for A and SH( $t$ ) without being combined with any action label. Because T01–T05 are used to determine the POS tag of the word being shifted, they are only applied for SH( $t$ ). Because W01–W21 are used to determine whether to segment at the current position or not, they are only used for those actions involved in boundary determination decisions (A, SH( $t$ ), RL<sub>0</sub>, and RR<sub>0</sub>). The action labels RL<sub>0</sub>/RR<sub>0</sub> are used to

denote the ‘reduce’ actions that determine the word boundary<sup>2</sup>, whereas RL<sub>1</sub>/RR<sub>1</sub> denote those ‘reduce’ actions that are applied when the word boundary has already been fixed. In addition, to capture the shared nature of boundary determination actions (SH( $t$ ), RL<sub>0</sub>/RR<sub>0</sub>), we use a generalized action label SH’ to represent any of them when combined with W01–W21. We also propose to use the features U01–U03, which we found are effective to adjust the character-level and substring-level scores.

Regarding the parsing features P01–P28, because we found that P01–P17 are also useful for segmentation decisions, these features are applied to all actions including A, with an explicit distinction of action labels RL<sub>0</sub>/RR<sub>0</sub> from RL<sub>1</sub>/RR<sub>1</sub>. On the other hand, P18–P28 are only used when one of the parser actions (SH( $t$ ), RL, or RR) is applied. Note that P07–P09 and P18–P21 (*look-ahead features*) require the look-ahead information of the next word form and POS tags, which cannot be incorporated straightforwardly in an incremental framework. Although we have found that these features can be incorporated using the *delayed features* proposed by Hatori et al. (2011), we did not use them in our current model because it results in the significant increase of computational time.

#### 3.3.1 Dictionary features

Because segmentation using a dictionary alone can serve as a strong baseline in Chinese word segmentation (Sproat et al., 1996), the use of dictionaries is expected to make our joint model more robust and enables us to investigate the contribution of the syntactic dependency in a more realistic setting. Therefore, we optionally use four features D01–D04 associated with external dictionaries. These features distinguish each dictionary source, reflecting the fact that different dictionaries have different characteristics. These features will also be used in our reimplementation of the model by Zhang and Clark (2010).

### 3.4 Adjusting the Learning Rate of Features

In formulating the three tasks in the incremental framework, we found that adjusting the update rate depending on the type of the features (segmentation/tagging vs. parsing) crucially impacts the final performance of the model. To investigate this point, we define the feature vector  $\vec{\phi}$  and score  $\Phi$  of the

<sup>2</sup>A reduce action has an additional effect of fixing the boundary of the top word on the stack if the last action was A or SH( $t$ ).

Table 2: Statistics of datasets.

action  $a$  being applied to the state  $\psi$  as

$$\Phi(\psi, a) = \vec{\lambda} \cdot \vec{\phi}(\psi, a) = \vec{\lambda} \cdot \left\{ \vec{\phi}_{st}(\psi, a) + \sigma_p \vec{\phi}_p(\psi, a) \right\},$$

where  $\vec{\phi}_{st}$  corresponds to the segmentation and tagging features (those starting with ‘U’, ‘S’, ‘T’, or ‘D’), and  $\vec{\phi}_p$  is the set of the parsing features (starting with ‘P’). Then, if we set  $\sigma_p$  to a number smaller than 1, perceptron updates for the parsing features will be kept small at the early stage of training because the update is proportional to the values of the feature vector. However, even if  $\sigma_p$  is initially small, the global weights for the parsing features will increase as needed and compensate for the small  $\sigma_p$  as the training proceeds. In this way, we can control the contribution of syntactic dependencies at the early stage of training. Section 4.3 shows that the best setting we found is  $\sigma_p = 0.5$ : this result suggests that we probably should resolve remaining errors by preferentially using the local  $n$ -gram based features at the early stage of training. Otherwise, the premature incorporation of the non-local syntactic dependencies might engender overfitting to the training data.

## 4 Experiment

### 4.1 Experimental Settings

We use the Chinese Penn Treebank ver. 5.1, 6.0, and 7.0 (hereinafter CTB-5, CTB-6, and CTB-7) for evaluation. These corpora are split into training, development, and test sets, according to previous works. For CTB-5, we refer to the split by Duan et al. (2007) as CTB-5d, and to the split by Jiang et al. (2008) as CTB-5j. We also prepare a dataset for cross validation: the dataset CTB-5c consists of sentences from CTB-5 excluding the development and test sets of CTB-5d and CTB-5j. We split CTB-5c into five sets (CTB-5c- $n$ ), and alternatively use four of these as the training set and the rest as the test set. CTB-6 is split according to the official split

described in the documentation, and CTB-7 is split according to Wang et al. (2011). The statistics of these splits are shown in Table 2. As external dictionaries, we use the HowNet Word List<sup>3</sup>, consisting of 91,015 words, and page names from the Chinese Wikipedia<sup>4</sup> as of Oct 26, 2011, consisting of 709,352 words. These dictionaries only consist of word forms with no frequency or POS information.

We use standard measures of word-level precision, recall, and F1 score, for evaluating each task. The output of dependencies cannot be correct unless the syntactic head and dependent of the dependency relation are both segmented correctly. Following the standard setting in dependency parsing works, we evaluate the task of dependency parsing with the unlabeled attachment scores excluding punctuations. Statistical significance is tested by McNemar’s test ( $\dagger : p < 0.05$ ,  $\ddagger : p < 0.01$ ).

## 4.2 Baseline and Proposed Models

We use the following baseline and proposed models for evaluation.

- **SegTag**: our reimplementation of the joint segmentation and POS tagging model by Zhang and Clark (2010). Table 5 shows that this reimplementation almost reproduces the accuracy of their implementation. We used the beam of 16, which they reported to achieve the best accuracies.
- **Dep’**: the state-of-the-art dependency parser by Huang and Sagae (2010). We used our reimplementation, which is used in Hatori et al. (2011).
- **Dep**: Dep’ without look-ahead features.
- **TagDep**: the joint POS tagging and dependency parsing model (Hatori et al., 2011), where the look-ahead features are omitted.<sup>5</sup>
- **SegTag+Dep/SegTag+Dep’**: a pipeline combination of SegTag and Dep or Dep’.
- **SegTag+TagDep**: a pipeline combination of SegTag and TagDep, where only the segmentation output of SegTag is used as input to TagDep; the output tags of TagDep are used for evaluation.
- **SegTagDep**: the proposed full joint model.

All of the models described above except Dep’ are based on the same feature sets for segmentation and

<sup>3</sup>[http://www.keenage.com/html/e\\_index.html](http://www.keenage.com/html/e_index.html)

<sup>4</sup><http://zh.wikipedia.org/wiki>

<sup>5</sup>We used the original implementation used in Hatori et al. (2011). In Hatori et al. (2011), we confirmed that omission of the look-ahead features results in a 0.26% decrease in the parsing accuracy on CTB-5d (dev).

Figure 2: F1 scores (in %) of SegTagDep on CTB-5c-1 w.r.t. the training epoch (x-axis) and parsing feature weights (in legend).

tagging (Zhang and Clark, 2008; Zhang and Clark, 2010) and dependency parsing (Huang and Sagae, 2010). Therefore, we can investigate the contribution of the joint approach through comparison with the pipeline and joint models.

## 4.3 Development Results

We have some parameters to tune: parsing feature weight  $\sigma_p$ , beam size, and training epoch. All these parameters are set based on experiments on CTB-5c. For experiments on CTB-5j, CTB-6, and CTB-7, the training epoch is set using the development set.

Figure 2 shows the F1 scores of the proposed model (SegTagDep) on CTB-5c-1 with respect to the training epoch and different parsing feature weights, where “Seg”, “Tag”, and “Dep” respectively denote the F1 scores of word segmentation, POS tagging, and dependency parsing. In this experiment, the external dictionaries are not used, and the beam size of 32 is used. Interestingly, if we simply set  $\sigma_p$  to 1, the accuracies seem to converge at lower levels. The  $\sigma_p = 0.2$  setting seems to reach almost identical segmentation and tagging accuracies as the best setting  $\sigma_p = 0.5$ , but the convergence occurs more slowly. Based on this experiment, we set  $\sigma_p$  to 0.5 throughout the experiments in this paper.

Table 3 shows the performance and speed of the full joint model (with no dictionaries) on CTB-5c-1 with respect to the beam size. Although even the beam size of 32 results in competitive accuracies for word segmentation and POS tagging, the dependency accuracy is affected most by the increase of the beam size. Based on this experiment, we set the beam size of SegTagDep to 64 throughout the exper-

iments in this paper, unless otherwise noted.

#### 4.4 Main Results

In this section, we present experimentally obtained results using the proposed and baseline models. Table 4 shows the segmentation, POS tagging, and dependency parsing F1 scores of these models on CTB-5c. Irrespective of the existence of the dictionary features, the joint model SegTagDep largely increases the POS tagging and dependency parsing accuracies (by 0.56–0.63% and 2.34–2.44%); the improvements in parsing accuracies are still significant even compared with SegTag+Dep<sup>7</sup> (the pipeline model with the look-ahead features). However, when the external dictionaries are not used (“wo/dict”), no substantial improvements for segmentation accuracies were observed. In contrast, when the dictionaries are used (“w/dict”), the segmentation accuracies are now improved over the baseline model SegTag consistently (on every trial). Although the overall improvement in segmentation is only around 0.1%, more than 1% improvement is observed if we specifically examine OOV<sup>6</sup> words. The difference between “wo/dict” and “w/dict” results suggests that the syntactic dependencies might work as a noise when the segmentation model is insufficiently stable, but the model does improve when it is stable, not receiving negative effects from the syntactic dependencies.

The partially joint model SegTag+TagDep is shown to perform reasonably well in dependency parsing: with dictionaries, it achieved the 2.02% improvement over SegTag+Dep, which is only 0.32% lower than SegTagDep. However, whereas SegTag+TagDep showed no substantial improvement in tagging accuracies over SegTag (when the dictionaries are used), SegTagDep achieved consistent improvements of 0.46% and 0.58% (without/with dic-

tionaries); these differences can be attributed to the combination of the relieved error propagation and the incorporation of the syntactic dependencies. In addition, SegTag+TagDep has OOV tagging accuracies consistently lower than SegTag, suggesting that the syntactic dependency has a negative effect on the POS tagging accuracy of OOV words<sup>7</sup>. In contrast, this negative effect is not observed for SegTagDep: both the overall tagging accuracy and the OOV accuracy are improved, demonstrating the effectiveness of the proposed model.

Figure 3 shows the performance and processing time comparison of various models and their combinations. Although SegTagDep takes a few times longer to achieve accuracies comparable to those of SegTag+Dep/TagDep, it seems to present potential

<sup>7</sup>This is consistent with Hatori et al. (2011)’s observation that although the joint POS tagging and dependency parsing improves the accuracy of syntactically influential POS tags, it has a slight side effect of increasing the confusion between general and proper nouns (NN vs. NR).

for greater improvement, especially for tagging and parsing accuracies, when a larger beam can be used.

#### 4.5 Comparison with Other Systems

Table 5 and Table 6 show a comparison of the segmentation and POS tagging accuracies with other state-of-the-art models. “Kruengkrai+ ’09” is a lattice-based model by Kruengkrai et al. (2009). “Zhang ’10” is the incremental model by Zhang and Clark (2010). These two systems use no external resources other than the CTB corpora. “Sun+ ’11” is a CRF-based model (Sun, 2011) that uses a combination of several models, with a dictionary of idioms. “Wang+ ’11” is a semi-supervised model by Wang et al. (2011), which additionally uses the Chinese Gigaword Corpus.

Our models with dictionaries (those marked with ‘(d)’) have competitive accuracies to other state-of-the-art systems, and SegTagDep(d) achieved the best reported segmentation and POS tagging accuracies, using no additional corpora other than the dictionaries. Particularly, the POS tagging accuracy is more than 0.4% higher than the previous best system thanks to the contribution of syntactic dependencies. These results also suggest that the use of readily available dictionaries can be more effective than semi-supervised approaches.

## 5 Conclusion

In this paper, we proposed the first joint model for word segmentation, POS tagging, and dependency parsing in Chinese. The model demonstrated substantial improvements on the three tasks over the pipeline combination of the state-of-the-art joint segmentation and POS tagging model, and dependency parser. Particularly, results showed that the

Model	CTB-6 Test			CTB-7 Test		
	Seg	Tag	Dep	Seg	Tag	Dep
Kruengkrai ’09	95.50	90.50	-	95.40	89.86	-
Wang ’11	95.79	91.12	-	95.65	90.46	-
SegTag+Dep	95.46	90.64	72.57	95.49	90.11	71.25
SegTagDep	95.45	91.27	74.88	95.42	90.62	73.58
(diff.)	-0.01	+0.63 <sup>‡</sup>	+2.31 <sup>‡</sup>	-0.07	+0.51 <sup>‡</sup>	+2.33 <sup>‡</sup>

SegTagDep(d)	<b>96.18</b>	<b>91.95</b>	<b>75.76</b>	<b>96.07</b>	<b>91.28</b>	<b>74.58</b>
(diff.)	+0.05	+0.57 <sup>‡</sup>	+2.14 <sup>‡</sup>	+0.09 <sup>‡</sup>	+0.60 <sup>‡</sup>	+2.52 <sup>‡</sup>

Table 6: Final results on CTB-6 and CTB-7

accuracies of POS tagging and dependency parsing were remarkably improved by 0.6% and 2.4%, respectively corresponding to 8.3% and 10.2% error reduction. For word segmentation, although the overall improvement was only around 0.1%, greater than 1% improvements was observed for OOV words. We conducted some comparison experiments of the partially joint and full joint models. Compared to SegTagDep, SegTag+TagDep performs reasonably well in terms of dependency parsing accuracy, whereas the POS tagging accuracies are more than 0.5% lower.

In future work, probabilistic pruning techniques such as the one based on a maximum entropy model are expected to improve the efficiency of the joint model further because the accuracies are apparently still improved if a larger beam can be used. More efficient decoding would also allow the use of the look-ahead features (Hatori et al., 2011) and richer parsing features (Zhang and Nivre, 2011).

# Exploring Deterministic Constraints: From a Constrained English POS Tagger to an Efficient ILP Solution to Chinese Word Segmentation

Qiuye Zhao     Mitch Marcus

Dept. of Computer & Information Science  
University of Pennsylvania  
qiuye, mitch@cis.upenn.edu

## Abstract

We show for both English POS tagging and Chinese word segmentation that with proper representation, large number of deterministic constraints can be learned from training examples, and these are useful in constraining probabilistic inference. For tagging, learned constraints are directly used to constrain Viterbi decoding. For segmentation, character-based tagging constraints can be learned with the same templates. However, they are better applied to a word-based model, thus an integer linear programming (ILP) formulation is proposed. For both problems, the corresponding constrained solutions have advantages in both efficiency and accuracy.

## 1 introduction

In recent work, interesting results are reported for applications of integer linear programming (ILP) such as semantic role labeling (SRL) (Roth and Yih, 2005), dependency parsing (Martins et al., 2009) and so on. In an ILP formulation, 'non-local' deterministic constraints on output structures can be naturally incorporated, such as "*a verb cannot take two subject arguments*" for SRL, and the projectivity constraint for dependency parsing. In contrast to probabilistic constraints that are estimated from training examples, this type of constraint is usually hand-written reflecting one's linguistic knowledge.

Dynamic programming techniques based on Markov assumptions, such as Viterbi decoding, cannot handle those 'non-local' constraints as discussed above. However, it is possible to constrain Viterbi

decoding by 'local' constraints, e.g. "*assign label t to word w*" for POS tagging. This type of constraint may come from human input solicited in interactive inference procedure (Kristjansson et al., 2004).

In this work, we explore deterministic constraints for two fundamental NLP problems, English POS tagging and Chinese word segmentation. We show by experiments that, with proper representation, large number of deterministic constraints can be learned automatically from training data, which can then be used to constrain probabilistic inference.

For POS tagging, the learned constraints are directly used to constrain Viterbi decoding. The corresponding constrained tagger is 10 times faster than searching in a raw space pruned with beam-width 5. Tagging accuracy is moderately improved as well.

For Chinese word segmentation (CWS), which can be formulated as character tagging, analogous constraints can be learned with the same templates as English POS tagging. High-quality constraints can be learned with respect to a special tagset, however, with this tagset, the best segmentation accuracy is hard to achieve. Therefore, these character-based constraints are not directly used for determining predictions as in English POS tagging. We propose an ILP formulation of the CWS problem. By adopting this ILP formulation, segmentation F-measure is increased from 0.968 to 0.974, as compared to Viterbi decoding with the same feature set. Moreover, the learned constraints can be applied to reduce the number of possible words over a character sequence, i.e. to reduce the number of variables to set. This reduction of problem size immediately speeds up an ILP solver by more than 100 times.

## 2 English POS tagging

### 2.1 Explore deterministic constraints

Suppose that, following (Chomsky, 1970), we distinguish major lexical categories (Noun, Verb, Adjective and Preposition) by two binary features:  $+|-$  N and  $+|-$  V. Let  $(+N, -V)$ =Noun,  $(-N, +V)$ =Verb,  $(+N, +V)$ =Adjective, and  $(-N, -V)$ =preposition. A word occurring in between a preceding word *the* and a following word *of* always bears the feature  $+N$ . On the other hand, consider the annotation guideline of English Treebank (Marcus et al., 1993) instead. Part-of-speech (POS) tags are used to categorize words, for example, the POS tag VBG tags verbal gerunds, NNS tags nominal plurals, DT tags determiners and so on. Following this POS representation, there are as many as 10 possible POS tags that may occur in between *the-of*, as estimated from the WSJ corpus of Penn Treebank.

#### 2.1.1 Templates of deterministic constraints

To explore determinacy in the distribution of POS tags in Penn Treebank, we need to consider that a POS tag marks the basic syntactic category of a word as well as its morphological inflection. A constraint that may determine the POS category should reflect both the context and the morphological feature of the corresponding word.

The practical difficulty in representing such deterministic constraints is that we do not have a perfect mechanism to analyze morphological features of a word. Endings or prefixes of English words do not deterministically mark their morphological inflections. We propose to compute the morph feature of a word as the set of all of its possible tags, i.e. all tag types that are assigned to the word in training data. Furthermore, we approximate unknown words in testing data by rare words in training data. For a word that occurs less than 5 times in the training corpus, we compute its morph feature as its last two characters, which is also conjoined with binary features indicating whether the rare word contains digits, hyphens or upper-case characters respectively. See examples of morph features in Table 1.

We consider *bigram* and *trigram* templates for generating potentially deterministic constraints. Let  $w_i$  denote the  $i_{th}$  word relative to the current word  $w_0$ ; and  $m_i$  denote the morph feature of  $w_i$ . A

(frequent) $w_0=trades$	(set of possible tags of the word) $m_0=\{NNS, VBZ\}$
(rare) $w_0=time-shares$	(the last two characters...) $m_0=\{-es, HYPHEN\}$

Table 1: Morph features of frequent words and rare words as computed from the WSJ Corpus of Penn Treebank.

bi- -gram	$w_{-1}w_0, w_0w_1, m_{-1}w_0, w_0m_1$ $w_{-1}m_0, m_0w_1, m_{-1}m_0, m_0m_1$
tri- -gram	$w_{-1}w_0w_1, m_{-1}w_0w_1, w_{-1}m_0w_1, m_{-1}m_0w_1$ $w_{-1}w_0m_1, m_{-1}w_0m_1, w_{-1}m_0m_1, m_{-1}m_0m_1$

Table 2: The templates for generating potentially deterministic constraints of English POS tagging.

*bigram* constraint includes one contextual word ( $w_{-1}|w_1$ ) or the corresponding morph feature; and a *trigram* constraint includes both contextual words or their morph features. Each constraint is also conjoined with  $w_0$  or  $m_0$ , as described in Table 2.

#### 2.1.2 Learning of deterministic constraints

In the above section, we explore templates for potentially deterministic constraints that may determine POS category. With respect to a training corpus, if a constraint  $C$  relative to  $w_0$  'always' assigns a certain POS category  $t^*$  to  $w_0$  in its context, i.e.  $\frac{\text{count}(C \wedge t_0=t^*)}{\text{count}(C)} > \text{thr}$ , and this constraint occurs more than a cutoff number, we consider it as a deterministic constraint. The threshold  $\text{thr}$  is a real number just under 1.0 and the cutoff number is empirically set to 5 in our experiments.

#### 2.1.3 Decoding of deterministic constraints

By the above definition, the constraint of  $w_{-1} = \textit{the}$ ,  $m_0 = \{NNS, VBZ\}$  and  $w_1 = \textit{of}$  is deterministic. It determines the POS category of  $w_0$  to be NNS. There are at least two ways of decoding these constraints during POS tagging. Take the word *trades* for example, whose morph feature is  $\{NNS, VBZ\}$ . One alternative is that as long as *trades* occurs between *the-of*, it is tagged with NNS. The second alternative is that the tag decision is made only if all deterministic constraints relative to this occurrence of *trades* agree on the same tag. Both ways of decoding are purely rule-based and involve no probabilistic inference. In favor of a higher precision, we adopt the latter one in our experiments.

raw input	$O(nT^2)$	$n = 23$

The/DT <b>complex</b> /- <b>financing</b> /- plan/NN in/IN the/DT <b>S&amp;L</b> /- bailout/NN law/NN includes/VBZ ...		

Table 3: Comparison of raw input and constrained input.

## 2.2 Search in a constrained space

Following most previous work, we consider POS tagging as a sequence classification problem and decompose the overall sequence score over the linear structure, i.e.  $\hat{\mathbf{t}} = \arg \max_{\mathbf{t} \in \text{tagGEN}(\mathbf{w})} \sum_{i=1}^n \text{score}(t_i)$  where function **tagGEN** maps input sentence  $\mathbf{w} = w_1 \dots w_n$  to the set of all tag sequences that are of length  $n$ .

If a POS tagger takes raw input only, i.e. for every word, the number of possible tags is a constant  $T$ , the space of **tagGEN** is as large as  $T^n$ . On the other hand, if we decode deterministic constraints first before a probabilistic search, i.e. for some words, the number of possible tags is reduced to 1, the search space is reduced to  $T^m$ , where  $m$  is the number of (unconstrained) words that are not subject to any deterministic constraints.

Viterbi algorithm is widely used for tagging, and runs in  $O(nT^2)$  when searching in an unconstrained space. On the other hand, consider searching in a constrained space. Suppose that among the  $m$  unconstrained words,  $m_1$  of them follow a word that has been tagged by deterministic constraints and  $m_2 (=m-m_1)$  of them follow another unconstrained word. Viterbi decoder runs in  $O(m_1T + m_2T^2)$  while searching in such a constrained space. The example in Table 3 shows raw and constrained input with respect to a typical input sentence.

## Lookahead features

The score of tag predictions are usually computed in a high-dimensional feature space. We adopt the basic feature set used in (Ratnaparkhi, 1996) and (Collins, 2002). Moreover, when deterministic constraints have applied to contextual words of  $w_0$ , it is also possible to include some lookahead feature templates, such as:

$$t_0 \& t_1, t_0 \& t_1 \& t_2, \text{ and } t_{-1} \& t_0 \& t_1$$

where  $t_i$  represents the tag of the  $i_{th}$  word relative

to the current word  $w_0$ . As discussed in (Shen et al., 2007), categorical information of neighbouring words on both sides of  $w_0$  help resolve POS ambiguity of  $w_0$ . In (Shen et al., 2007), lookahead features may be available for use during decoding since searching is bidirectional instead of left-to-right as in Viterbi decoding. In this work, deterministic constraints are decoded before the application of probabilistic models, therefore lookahead features are made available during Viterbi decoding.

## 3 Chinese Word Segmentation (CWS)

### 3.1 Word segmentation as character tagging

Considering the ambiguity problem that a Chinese character may appear in any relative position in a word and the out-of-vocabulary (OOV) problem that it is impossible to observe all words in training data, CWS is widely formulated as a character tagging problem (Xue, 2003). A character-based CWS decoder is to find the highest scoring tag sequence  $\hat{\mathbf{t}}$  over the input character sequence  $\mathbf{c}$ , i.e.

$$\hat{\mathbf{t}} = \arg \max_{\mathbf{t} \in \text{tagGEN}(\mathbf{c})} \sum_{i=1}^n \text{score}(t_i).$$

This is the same formulation as POS tagging. The Viterbi algorithm is also widely used for decoding.

The tag of each character represents its relative position in a word. Two popular tagsets include 1) IB: where B tags the beginning of a word and I all other positions; and 2) BMES: where B, M and E represent the beginning, middle and end of a multi-character word respectively, and S tags a single-character word. For example, after decoding with BMES, 4 consecutive characters associated with the tag sequence BMME compose a word. However, after decoding with IB, characters associated with BIII may compose a word if the following tag is B or only form part of a word if the following tag is I. Even though character tagging accuracy is higher with tagset IB, tagset BMES is more popular in use since better performance of the original problem CWS can be achieved by this tagset.

### Character-based feature templates

We adopt the 'non-lexical-target' feature templates in (Jiang et al., 2008a). Let  $c_i$  denote the  $i_{th}$  character relative to the current character  $c_0$  and  $t_0$

denote the tag assigned to  $c_0$ . The following templates are used:

$c_i \& t_0$  ( $i=-2\dots 2$ ),  $c_i c_{i+1} \& t_0$  ( $i=-2\dots 1$ ) and  $c_{-1} c_1 \& t_0$ .

### Character-based deterministic constraints

We can use the same templates as described in Table 2 to generate potentially deterministic constraints for CWS character tagging, except that there are no morph features computed for Chinese characters. As we will show with experimental results in Section 5.2, useful deterministic constraints for CWS can be learned with tagset IB but not with tagset BMES. It is interesting but not surprising to notice, again, that the determinacy of a problem is sensitive to its representation. Since it is hard to achieve the best segmentations with tagset IB, we propose an indirect way to use these constraints in the following section, instead of applying these constraints as straightforwardly as in English POS tagging.

### 3.2 Word-based word segmentation

A word-based CWS decoder finds the highest scoring segmentation sequence  $\hat{\mathbf{w}}$  that is composed by the input character sequence  $\mathbf{c}$ , i.e.

$$\hat{\mathbf{w}} = \arg \max_{\mathbf{w} \in \text{segGEN}(\mathbf{c})} \sum_{i=1}^{|\mathbf{w}|} \text{score}(w_i).$$

where function **segGEN** maps character sequence  $\mathbf{c}$  to the set of all possible segmentations of  $\mathbf{c}$ . For example,  $\mathbf{w} = (c_1 \dots c_{l_1}) \dots (c_{n-l_k+1} \dots c_n)$  represents a segmentation of  $k$  words and the lengths of the first and last word are  $l_1$  and  $l_k$  respectively.

In early work, rule-based models find words one by one based on heuristics such as forward maximum match (Sproat et al., 1996). Exact search is possible with a Viterbi-style algorithm, but beam-search decoding is more popular as used in (Zhang and Clark, 2007) and (Jiang et al., 2008a).

We propose an Integer Linear Programming (ILP) formulation of word segmentation, which is naturally viewed as a word-based model for CWS. Character-based deterministic constraints, as discussed in Section 3.1, can be easily applied.

### 3.3 ILP formulation of CWS

Given a character sequence  $\mathbf{c} = c_1 \dots c_n$ , there are  $s(=n(n+1)/2)$  possible words that are contiguous subsets of  $\mathbf{c}$ , i.e.  $w_1, \dots, w_s \subseteq \mathbf{c}$ . Our goal is to find

n=11	\mathbf{x}	input
raw	55	法正研究从波黑撤军计划
constrained	18	法正研/B究从波/B黑撤/B军计/B划

Table 4: Comparison of raw input and constrained input.

an optimal solution  $\mathbf{x} = x_1 \dots x_s$  that maximizes

$\sum_{i=1}^s \text{score}(w_i) \cdot x_i$ , subject to

$$(1) \sum_{i:c \in w_i} x_i = 1, \forall c \in \mathbf{c};$$

$$(2) x_i \in \{0, 1\}, 1 \leq i \leq s$$

The boolean value of  $x_i$ , as guaranteed by constraint (2), indicates whether  $w_i$  is selected in the segmentation solution or not. Constraint (1) requires every character to be included in exactly one selected word, thus guarantees a proper segmentation of the whole sequence. This resembles the ILP formulation of the set cover problem, though the first constraint is different. Take  $n = 2$  for example, i.e.  $\mathbf{c} = c_1 c_2$ , the set of possible words is  $\{c_1, c_2, c_1 c_2\}$ , i.e.  $s = |\mathbf{x}| = 3$ . There are only two possible solutions subject to constraints (1) and (2),  $\mathbf{x} = 110$  giving an output set  $\{c_1, c_2\}$ , or  $\mathbf{x} = 001$  giving an output set  $\{c_1 c_2\}$ .

The efficiency of solving this problem depends on the number of possible words (contiguous subsets) over a character sequence, i.e. the number of variables in  $\mathbf{x}$ . So as to reduce  $|\mathbf{x}|$ , we apply deterministic constraints predicting IB tags first, which are learned as described in Section 3.1. Possible words are generated with respect to the partially tagged character sequence. A character tagged with  $B$  always occurs at the beginning of a possible word. Table 4 illustrates the constrained and raw input with respect to a typical character sequence.

### 3.4 Character- and word-based features

As studied in previous work, word-based feature templates usually include the word itself, sub-words contained in the word, contextual characters/words and so on. It has been shown that combining the use of character- and word-based features helps improve performance. However, in the character tagging formulation, word-based features are non-local.

To incorporate these non-local features and make the search tractable, various efforts have been made. For example, Jiang et al. (2008a) combine different levels of knowledge in an outside linear model of a two-layer cascaded model; Jiang et al. (2008b) uses the forest re-ranking technique (Huang, 2008); and in (Kruengkrai et al., 2009), only known words in vocabulary are included in the hybrid lattice consisting of both character- and word-level nodes.

We propose to incorporate character-based features in word-based models. Consider a character-based feature function  $\phi(c, t, \mathbf{c})$  that maps a character-tag pair to a high-dimensional feature space, with respect to an input character sequence  $\mathbf{c}$ . For a possible word over  $\mathbf{c}$  of length  $l$ ,  $w_i = c_{i_0} \dots c_{i_0+l-1}$ , tag each character  $c_{i_j}$  in this word with a character-based tag  $t_{i_j}$ . Character-based features of  $w_i$  can be computed as  $\{\phi(c_{i_j}, t_{i_j}, \mathbf{c}) | 0 \leq j < l\}$ . The first row of Table 5 illustrates character-based features of a word of length 3, which is tagged with tagset BMES. From this view, the character-based feature templates defined in Section 3.1 are naturally used in a word-based model.

When character-based features are incorporated into word-based CWS models, some word-based features are no longer of interest, such as the starting character of a word, sub-words contained in the word, contextual characters and so on. We consider word counting features as a complementary to character-based features, following the idea of using web-scale features in previous work, e.g. (Bansal and Klein, 2011). For a possible word  $w$ , let  $count(w)$  return the count of times that  $w$  occurs as a legal word in training data. The word count number is further processed following (Bansal and Klein, 2011),  $wc(w) = \text{floor}(\log(count(w)) * 5) / 5$ . In addition to  $wc(w_i)$ , we also use corresponding word count features of possible words that are composed of the boundary and contextual characters of  $w_i$ . The specific word-based feature templates are illustrated in the second row of Table 5.

## 4 Training

We use the following linear model for scoring predictions:  $score(\mathbf{y}) = \theta^T \phi(\mathbf{x}, \mathbf{y})$ , where  $\phi(\mathbf{y})$  is a high-dimensional binary feature representation of  $\mathbf{y}$  over input  $\mathbf{x}$  and  $\theta$  contains weights of these features. For

character-based	$\phi(c_{i_0}, \mathbf{B}, \mathbf{c}), \phi(c_{i_1}, \mathbf{M}, \mathbf{c}), \phi(c_{i_2}, \mathbf{E}, \mathbf{c})$
word-based	$wc(c_{i_0}c_{i_1}c_{i_2}), wc(c_l c_{i_0}), wc(c_{i_2} c_r)$

Table 5: Character- and word-based features of a possible word  $w_i$  over the input character sequence  $\mathbf{c}$ . Suppose that  $w_i = c_{i_0}c_{i_1}c_{i_2}$ , and its preceding and following characters are  $c_l$  and  $c_r$  respectively.

parameter estimation of  $\theta$ , we use the averaged perceptron as described in (Collins, 2002). This training algorithm relies on the choice of decoding algorithm. When we experiment with different decoders, by default, the parameter weights in use are trained with the corresponding decoding algorithm.

Especially, for experiments with lookahead features of English POS tagging, we prepare training data with the stacked learning technique, in order to alleviate overfitting. More specifically, we divide the training data into  $k$  folds, and tag each fold with the deterministic model learned over the other  $k-1$  folds. The predicted tags of all folds are then merged into the gold training data and used (only) as lookahead features. Sun (2011) uses this technique to merge different levels of predictors for word segmentation.

## 5 Experiments

### 5.1 Data set

We run experiments on English POS tagging on the WSJ corpus in the Penn Treebank. Following most previous work, e.g. (Collins, 2002) and (Shen et al., 2007), we divide this corpus into training set (sections 0-18), development set (sections 19-21) and the final test set (sections 22-24).

We run experiments on Chinese word segmentation on the Penn Chinese Treebank 5.0. Following (Jiang et al., 2008a), we divide this corpus into training set (chapters 1-260), development set (chapters 271-300) and the final test set (chapters 301-325).

### 5.2 Deterministic constraints

Experiments in this section are carried out on the development set. The cutoff number and threshold as defined in 2.1.2, are fixed as 5 and 0.99 respectively.

	precision	recall	$F_1$
<i>bigram</i>	0.993	0.841	0.911
<i>trigram</i>	<b>0.996</b>	0.608	0.755
<i>bi+trigram</i>	0.992	<b>0.857</b>	<b>0.920</b>

Table 6: POS tagging with deterministic constraints. The maximum in each column is bold.

$m_0=\{\text{VBN, VBZ}\}$ & $m_1=\{\text{JJ, VBD, VBN}\}$ $\rightarrow$ VBN
$w_0=\text{also}$ & $m_1=\{\text{VBD, VBN}\}$ $\rightarrow$ RB
$m_0=-\text{es}$ & $m_{-1}=\{\text{IN, RB, RP}\}$ $\rightarrow$ NNS
$w_0=\text{last}$ & $w_{-1}=\text{the}$ $\rightarrow$ JJ

Table 7: Deterministic constraints for POS tagging.

### Deterministic constraints for POS tagging

For English POS tagging, we evaluate the deterministic constraints generated by the templates described in Section 2.1.1. Since these deterministic constraints are only applied to words that occur in a constrained context, we report F-measure as the accuracy measure. Precision  $p$  is defined as the percentage of correct predictions out of all predictions, and recall  $r$  is defined as the percentage of gold predictions that are correctly predicted. F-measure  $F_1$  is computed by  $2pr/(p+r)$ .

As shown in Table 6, deterministic constraints learned with both *bigram* and *trigram* templates are all very accurate in predicting POS tags of words in their context. Constraints generated by *bigram* template alone can already cover 84.1% of the input words with a high precision of 0.993. By adding the constraints generated by *trigram* template, recall is increased to 0.857 with little loss in precision. Since these deterministic constraints are applied before the decoding of probabilistic models, reliably high precision of their predictions is crucial.

There are 114589 *bigram* deterministic constraints and 130647 *trigram* constraints learned from the training data. We show a couple of examples of *bigram* deterministic constraints in Table 7. As defined in Section 2.2, we use the set of all possible POS tags for a word, e.g.  $\{\text{VBN, VBZ}\}$ , as its morph feature if the word is frequent (occurring more than 5 times in training data). For a rare word, the last two characters are used as its morph feature, e.g.  $-\text{es}$ . A constraint is composed of  $w_{-1}$ ,  $w_0$  and  $w_1$ , as well as the morph features  $m_{-1}$ ,  $m_0$  and  $m_1$ . For ex-

tagset	precision	recall	$F_1$
BMES	0.989	0.566	0.720
IB	<b>0.996</b>	<b>0.686</b>	<b>0.812</b>

Table 8: Character tagging with deterministic constraints.

ample, the first constraint in Table 7 determines the tag VBN of  $w_0$ . A deterministic constraint is aware of neither the likelihood of each possible tag or the relative rank of their likelihoods.

### Deterministic constraints for character tagging

For the character tagging formulation of Chinese word segmentation, we discussed two tagsets IB and BMES in Section 3.1. With respect to either tagset, we use both *bigram* and *trigram* templates to generate deterministic constraints for the corresponding tagging problem. These constraints are also evaluated by F-measure as defined above. As shown in Table 8, when tagset IB is used for character tagging, high precision predictions can be made by the deterministic constraints that are learned with respect to this tagset. However, when tagset BMES is used, the learned constraints don't always make reliable predictions, and the overall precision is not high enough to constrain a probabilistic model. Therefore, we will only use the deterministic constraints that predict IB tags in following CWS experiments.

### 5.3 English POS tagging

For English POS tagging, as well as the CWS problem that will be discussed in the next section, we use the development set to choose training iterations (= 5), set beam width etc. The following experiments are done on the final test set.

As introduced in Section 2.2, we adopt a very compact feature set used in (Ratnaparkhi, 1996)<sup>1</sup>. While searching in a constrained space, we can also extend this feature set with some basic lookahead features as defined in Section 2.2. This replicates the feature set B used in (Shen et al., 2007).

In this work, our main interest in the POS tagging problem is on its efficiency. A well-known technique to speed up Viterbi decoding is to conduct beam search. Based on experiments carried out

<sup>1</sup>Our implementation of this feature set is basically the same as the version used in (Collins, 2002).

Ratnaparkhi (1996)’s feature		
	Beam=1	Beam=5
raw	96.46%/3×	97.16/1×
constrained	96.80%/14×	<b>97.20/10×</b>
Feature B in (Shen et al., 2007)		
(Shen et al., 2007)	97.15% (Beam=3)	
constrained	<b>97.03%</b> /11×	<b>97.20/8×</b>

Table 9: POS tagging accuracy and speed. The maximum in each column is bold. The baseline for speed in all cases is the unconstrained tagger using (Ratnaparkhi, 1996)’s feature and conducting a beam (=5) search.

on the development set, we set beam-width of our baseline model as 5. Our baseline model, which uses Ratnaparkhi (1996)’s feature set and conducts a beam (=5) search in the unconstrained space, achieves a tagging accuracy of 97.16%. Tagging accuracy is measured by the percentage of correct predictions out of all gold predictions. We consider the speed of our baseline model as 1×, and compare other taggers with this one. The speed of a POS tagger is measured by the number of input words processed per second.

As shown in Table 9, when the beam-width is reduced from 5 to 1, the tagger (beam=1) is 3 times faster but tagging accuracy is badly hurt. In contrast, when searching in a constrained space rather than the raw space, the constrained tagger (beam=5) is 10 times fast as the baseline and the tagging accuracy is even moderately improved, increasing to 97.20%. When we evaluate the speed of a constrained tagger, the time of decoding deterministic constraints is included. These constraints make more accurate predictions than probabilistic models, thus besides improving the overall tagging speed as we expect, tagging accuracy also improves by a little.

In Viterbi decoding, all possible transitions between two neighbour states are evaluated, so the addition of locally lookahead features may have NO impact on performance. When beam-width is set to 5, tagging accuracy is not improved by the use of Feature B in (Shen et al., 2007); and because the size of the feature model grows, efficiency is hurt. On the other hand, when lookahead features are used, Viterbi-style decoding is less affected by the reduction of beam-width. As compared to the con-

strained greedy tagger using Ratnaparkhi (1996)’s feature set, with the additional use of three locally lookahead feature templates, tagging accuracy is increased from 96.80% to 97.02%.

When no further data is used other than training data, the bidirectional tagger described in (Shen et al., 2007) achieves an accuracy of 97.33%, using a much richer feature set (E) than feature set B, the one we compare with here. As noted above, the addition of three feature templates already has a notable negative impact on efficiency, thus the use of feature set E will hurt tagging efficiency much worse. Rich feature sets are also widely used in other work that pursue state-of-art tagging accuracy, e.g. (Toutanova et al., 2003). In this work, we focus on the most compact feature sets, since tagging efficiency is our main consideration in our work on POS tagging. The proposed constrained taggers as described above can achieve near state-of-art POS tagging accuracy in a much more efficient manner.

#### 5.4 Chinese word segmentation

Like other tagging problems, Viterbi-style decoding is widely used for character tagging for CWS. We transform tagged character sequences to word segmentations first, and then evaluate word segmentations by F-measure, as defined in Section 5.2.

We proposed an ILP formulation of the CWS problem in Section 3.3, where we present a word-based model. In Section 3.4, we describe a way of mapping words to a character-based feature space. From this view, the highest scoring tagging sequence is computed subject to structural constraints, giving us an inference alternative to Viterbi decoding. For example, recall the example of input character sequence  $\mathbf{c} = c_1c_2$  discussed in Section 3.3. The two possible ILP solutions give two possible segmentations  $\{c_1, c_2\}$  and  $\{c_1c_2\}$ , thus there are 2 tag sequences evaluated by ILP, BB and BI. On the other hand, there are 4 tag sequences evaluated by Viterbi decoding: BI, BB, IB and II.

With the same feature templates as described in Section 3.1, we now compare these two decoding methods. Tagset BMES is used for character tagging as well as for mapping words to character-based feature space. We use the same Viterbi decoder as implemented for English POS tagging and use a non-commercial ILP solver included in GNU Linear Pro-

	precision	recall	F-measure
Viterbi	0.971	0.966	0.968
ILP	0.970	0.977	<b>0.974</b>
(Jiang et al., 2008a), POS-			0.971
(Jiang et al., 2008a), POS+			0.973

Table 10: F-measure on Chinese word segmentation. Only character-based features are used. POS-/+ : perceptron trained without/with POS.

gramming Kit (GLPK), version 4.3.<sup>2</sup> As shown in Table 10, optimal solutions returned by an ILP solver are more accurate than optimal solutions returned by a Viterbi decoder. The F-measure is improved by a relative error reduction of 18.8%, from 0.968 to 0.974. These results are compared to the core perceptron trained without POS in (Jiang et al., 2008a). They only report results with ‘lexical-target’ features, a richer feature set than the one we use here. As shown in Table 10, we achieve higher performance even with more compact features.

Joint inference of CWS and Chinese POS tagging is popularly studied in recent work, e.g. (Ng and Low, 2004), (Jiang et al., 2008a), and (Kruengkrai et al., 2009). It has been shown that better performance can be achieved with joint inference, e.g. F-measure 0.978 by the cascaded model in (Jiang et al., 2008a). We focus on the task of word segmentation only in this work and show that a comparable F-measure is achievable in a much more efficient manner. Sun (2011) uses the stacked learning technique to merge different levels of predictors, obtaining a combined system that beats individual ones.

Word-based features can be easily incorporated, since the ILP formulation is more naturally viewed as a word-based model. We extend character-based features with the word count features as described in Section 3.4. Currently, we only use word counts computed from training data, i.e. still a closed test. The addition of these features makes a moderate improvement on the F-measure, from 0.974 to 0.975.

As discussed in Section 3.3, if we are able to determine that some characters always start new words, the number of possible words is reduced, i.e. the number of variables in an ILP solution is reduced. As shown in Table 11, when character se-

<sup>2</sup><http://www.gnu.org/software/glpk>

	F-measure	avg. $ x $	#char per sec.
raw	0.974	1290.4	113 (1 $\times$ )
constrained	0.974	83.75	<b>12190 (107<math>\times</math>)</b>

Table 11: ILP problem size and segmentation speed.

quences are partially tagged by deterministic constraints, the number of possible words per sentence, i.e. avg.  $|x|$ , is reduced from 1290.4 to 83.7. This reduction of ILP problem size has a very important impact on the efficiency. As shown in Table 11, when taking constrained input, the segmentation speed is increased by **107** times over taking raw input, from 113 characters per second to 12,190 characters per second on a dual-core 3.0HZ CPU.

Deterministic constraints predicting IB tags are only used here for constraining possible words. They are very accurate as shown in Section 5.2. Few gold predictions are missed from the constrained set of possible words. As shown in Table 11, F-measure is not affected by applying these constraints, while the efficiency is significantly improved.

## 6 Conclusion and future work

We have shown by experiments that large number of deterministic constraints can be learned from training examples, as long as the proper representation is used. These deterministic constraints are very useful in constraining probabilistic search, for example, they may be directly used for determining predictions as in English POS tagging, or used for reducing the number of variables in an ILP solution as in Chinese word segmentation. The most notable advantage in using these constraints is the increased efficiency. The two applications are both well-studied; there isn’t much space for improving accuracy. Even so, we have shown that as tested with the same feature set for CWS, the proposed ILP formulation significantly improves the F-measure as compared to Viterbi decoding.

These two simple applications suggest that it is of interest to explore data-driven deterministic constraints learnt from training examples. There are more interesting ways in applying these constraints, which we are going to study in future work.
