## Preface: General Chair

Welcome to Jeju Island — where ACL makes a return to Asia!

As General Chair, I am indeed honored to pen the first words of ACL 2012 proceedings. In the past year, research in computational linguistics has continued to thrive across Asia and all over the world. On this occasion, I share with you the excitement of our community as we gather again at our annual meeting. On behalf of the organizing team, it is my great pleasure to welcome you to Jeju Island and ACL 2012.

In 2012, ACL turns 50. I feel privileged to chair the conference that marks such an important milestone for our community. We have prepared special programs to commemorate the 50th anniversary, including ‘Rediscovering 50 Years of Discovery’, a main conference workshop chaired by **Rafael Banchs** with a program on ‘the People, the Contents, and the Anthology’, which recollects some of the great moments in ACL history, and ‘ACL 50th Anniversary Lectures’ by **Mark Johnson**, **Aravind K. Joshi** and a Lifetime Achievement Award Recipient.

A large number of people have worked hard to bring this annual meeting to fruition. It has been an unforgettable experience for everyone involved. My deepest thanks go to the authors, reviewers, volunteers, participants, and all members and chairs of the organizing committees. It is your participation that makes a difference.

Program Chairs, **Chin-Yew Lin** and **Miles Osborne**, deserve our gratitude for putting an immense amount of work to ensure that each of the 940 submissions was taken care of. They put together a superb technical program like nobody else. Publication Chairs, **Maggie Li** and **Michael White**, extended the publishing tools to take care of every detail and compiled all the books within an impossible schedule. Tutorial Chair, **Michael Strube**, put together six tutorials that you can never miss. Workshop Chairs, **Massimo Poesio** and **Satoshi Sekine**, working with their EACL and NAACL counterparts, selected 11 quality workshops, many of which are new editions in their popular workshop series. Demo Chair, **Min Zhang**, started a novel review process and selected 29 quality system demos. Faculty Advisors, **Kentaro Inui**, **Greg Kondrak**, and **Yang Liu**, and Student Chairs, **Jackie Cheung**, **Jun Hatori**, **Carlos Henriquez** and **Ann Irvine**, assembled an excellent program for the Student Research Workshop with 12 accepted papers. Mentoring Chair, **Joyce Chai**, coordinated the mentorship of 13 papers. Publicity Chairs, **Jung-jae Kim** and **Youngjoong Ko**, developed the website, newsletters, and conference handbook that kept us updated all the time. Exhibition Chair, **Byeongchang Kim**, coordinated more than 10 exhibitors with a strong industry presence. All the events are now brought to us on Jeju Island by the Local Arrangements Chairs, **Gary Lee** and **Jong Park**, and their team. I can never thank them enough for all the preparations they have made to host us in such a spectacular place!

I would like to express my gratitude and appreciation to **Kevin Knight**, Chair of the ACL Conference Coordination Committee, **Dragomir Radev**, ACL Secretary, and **Priscilla Rasmussen**, ACL Business Manager, for their advice and guidance throughout the process.

The financial sponsors generously supported ACL 2012 in a meaningful way despite a challenging

economic outlook. We are honored to have Baidu as the Platinum Sponsor, Elsevier and Google as Gold Sponsors, Microsoft, KAIST and SK as Silver Sponsors, 7 Bronze Sponsors, and 3 Supporters. The Donald and Betty Walker Student Scholarship Fund and Asian Federation of Natural Language Processing have supported our student travel grants. The sponsorship program was made possible by the ACL sponsorship committee: **Eiichiro Sumita, Haifeng Wang, Michael Gamon, Patrick Pantel, Massimiliano Ciaramita, and Idan Szpektor.**

Finally, I do hope that you have an enjoyable and productive time on Jeju Island, and that you will leave with fond memories of ACL's 50th Anniversary. With my best wishes for a successful conference!

Haizhou Li  
ACL 2012 General Chair  
July 2012

## Preface: Programme Committee Co-Chairs

This year we received 571 valid long paper submissions and 369 short paper submissions. 19% of the long papers and 20% of the short papers were accepted. As usual, some are presented orally and some as posters. Taking unigram counts from accepted long paper titles, and ignoring function words, the most popular word were:

entity 5  
evaluation 5  
hierarchical 5  
information 5  
joint 5  
syntactic 5  
topic 5  
discriminative 6  
lexical 6  
statistical 6  
chinese 7  
dependency 7  
machine 8  
modeling 8  
models 8  
language 10  
word 10  
parsing 11  
model 12  
learning 14  
translation 15

Some areas have grown over time and some have diminished. The most popular area for submissions (as expected) was Machine Translation. We promoted Social Media as a new area.

Twenty nine Area Chairs worked with 665 reviewers, producing 1830 long paper reviews and 1187 short paper reviews. Everything ran to a tight schedule and there were no slippages. This would not have been possible without our wonderful and diligent Area Chairs and Reviewers. Thanks!

We are delighted to have two keynote speakers, both of whom are very well known to the language community: Aravind Joshi and Mark Johnson. They will give coordinated talks addressing the 50th ACL anniversary: “Remembrance of ACLs past” and “Computational linguistics: Where do we go from here?” The ACL Lifetime Achievement Award will be announced on the last day of the conference.

Of the many papers, we selected two as being outstanding:

*Bayesian Symbol-Refined Tree Substitution Grammars for Syntactic Parsing*  
Hiroyuki Shindo, Yusuke Miyao, Akinori Fujino, Masaaki Nagata

*String Re-writing Kernel*  
Fan Bu, Hang Li, Xiaoyan Zhu

They will be presented as best papers in a dedicated session.

We thank the General Conference Chair Haizhou Li, the Local Arrangements Committee headed by Gary Geunbae Lee, Michael White and Maggie Li, the Publication Co-Chairs for coordinating and putting the proceedings together and all other committee chairs for their work. MO is especially thankful to Steve Clark for helpful tips on how to manage and run the whole process.

We hope you enjoy the conference!

Chin-Yew Lin, Microsoft Research Asia  
Miles Osborne, University of Edinburgh

# Organizing Committee

## General Chair

Haizhou Li, Institute for Infocomm Research

## Program Co-Chairs

Chin-Yew Lin, Microsoft Research Asia

Miles Osborne, University of Edinburgh

## Local Arrangement Co-Chairs

Gary Geunbae Lee, Pohang University of Science and Technology (POSTECH)

Jong C. Park, Korea Advanced Institute of Science and Technology (KAIST)

## Workshop Co-Chairs

Massimo Poesio, University of Essex

Satoshi Sekine, New York University

## Publication Co-Chairs

Maggie Li, The Hong Kong Polytechnic University

Michael White, The Ohio State University

## Publicity Chairs

Jung-jae Kim, Nanyang Technological University

Youngjoong Ko, Dong-A University

## Tutorial Chair

Michael Strube, HITS gmbH

## Demo Chair

Min Zhang, Institute for Infocomm Research

## Special Session Chair

Rafael E. Banchs, Institute for Infocomm Research

## Mentoring Service Chair

Joyce Chai, Michigan State University

## Exhibit Chair

Byeongchang Kim, Catholic University of Daegu

## Faculty Advisors (Student Research Workshop)

Kentaro Inui, Tohoku University

Greg Kondrak, University of Alberta

Yang Liu, University of Texas at Dallas

### **Student Chairs (Student Research Workshop)**

Jackie Cheung, University of Toronto  
Jun Hatori, University of Tokyo  
Carlos Henriquez, Technical University of Catalonia (UPC)  
Ann Irvine, Johns Hopkins University

### **Sponsorship Chairs**

Eiichiro Sumita, NICT  
Haifeng Wang, Baidu  
Michael Gamon, Microsoft  
Patrick Pantel, Microsoft  
Massimiliano Ciaramita, Google  
Idan Szpektor, Yahoo!

### **Local Arrangements Committee**

Gary Geunbae Lee (co-chair)  
Jong C. Park (co-chair)  
Jeong-Won Cha (social activities)  
Hanmin Jung (local sponsorship)  
Seungshik Kang (local finance)  
Byeongchang Kim (local exhibit)  
Harksoo Kim (government sponsorship)  
Jung-jae Kim (conference handbook)  
Youngjoong Ko (web site and flyer)  
Heuseok Lim (student volunteer management)  
Seong-Bae Park (internet, wifi and equipments)

### **Business Manager**

Priscilla Rasmussen

# Program Committee

## Program Co-chairs

Chin-Yew Lin, Microsoft Research Asia  
Miles Osborne, University of Edinburgh

## Area Chairs

Hongyuan Zha, School of Computational Science and Engineering, College of Computing, Georgia Institute of Technology  
Hsin-Hsi Chen, Department of Computer Science and Information Engineering, National Taiwan University, Taipei, Taiwan  
Kemal Oflazer, Carnegie Mellon University - Qatar  
Mikio Nakano, Honda Research Institute, Japan  
Andrei Popescu-Belis, Idiap Research Institute, Switzerland  
Eneko Agirre, University of the Basque Country, Spain  
Jason Baldridge, The University of Texas at Austin, USA  
David Weir, University of Sussex, UK  
Trevor Cohn, University of Sheffield, UK  
Mark Dredze, Johns Hopkins University, USA  
Noah Smith, Carnegie Mellon University, USA  
Jan Wiebe, University of Pittsburgh, USA  
Daniel M. Bikel, Google Research, USA  
Mona T. Diab, Center for Computational Learning Systems, Columbia University, USA  
Fei Xia, Univ. of Washington, Seattle, USA  
Marcello Federico, Fondazione Bruno Kessler, Trento, Italy  
Adam Lopez, Human Language Technology Center of Excellence, Johns Hopkins University, USA  
David Talbot, Google Research, USA  
Hua Wu, Baidu, China  
Evgeniy Gabrilovich, Google, USA  
Naoaki Okazaki, Graduate School of Information Sciences, Tohoku University, Japan  
Stephen Clark, University of Cambridge, UK  
Liang Huang, University Southern California, USA  
Anja Belz, School of Computing, Engineering and Maths, University of Brighton, UK  
Ani Nenkova, University of Pennsylvania, USA  
Chung-Hsien Wu, Department of Computer Science and Information Engineering, National Cheng Kung University, TAIWAN  
Jian Su, Institute for Infocomm Research, Singapore  
Jianfeng Gao, Microsoft Research, Redmond, USA  
Vincent Ng, University of Texas at Dallas, USA

## Program Committee

Apoorv Agarwal, Lars Ahrenberg, Hua Ai, Cem Akkaya, Inaki Alegria, Jan Alexandersson, Enrique Alfonseca, Ben Allison, Sophia Ananiadou, Abhishek Arun, Giuseppe Attardi, Necip Fazil Ayan, Cecilia Ovesdotter Alm

Jing Bai, Collin Baker, Kirk Baker, Jason Baldrige, Breck Baldwin, Tim Baldwin, Carmen Banea, Marco Baroni, Regina Barzilay, Roberto Basili, Tilman Becker, Michael Bendersky, Taylor Berg-Kirkpatrick, Sabine Bergler, Shane Bergsma, Indrajit Bhattacharya, Pushpak Bhat-tacharyya, Archana Bhattarai, Jiang Bian, Gann Bierner, Ann Bies, Arianna Bisazza, John Blitzer, Michael Bloodgood, Phil Blunsom, Bernd Bohnet, Ondrej Bojar, Danushka Bollegala, Fran-cis Bond, Kalina Bontcheva, Stefano Borgo, Alexandre Bouchard, Jordan Boyd-Graber, Kristy Boyer, S.R.K. Branavan, Thorsten Brants, Chris Brew, Ted Briscoe, Samuel Brody, Sabine Buch-holz, Paul Buitelaar, Paula Buttery, William Byrne, Donna Byron, Olga babko-malaya, Antal van den Bosch

Aoife Cahill, Mary Elaine Califf, Chris Callison-Burch, Nicoletta Calzolari Zamorani, Nicola Cancedda, Yunbo Cao, Claire Cardie, Michael Carl, Xavier Carreras, John Carroll, Francisco Casacuberta, Vittorio Castelli, Asli Celikyilmaz, Mauro Cettolo, Joyce Chai, Nate Chambers, Yee Seng Chan, Ming-Wei Chang, Pi-Chuan Chang, Berlin Chen, Chia-Ping Chen, John Chen, Keh-Jiann Chen, Xueqi Cheng, Colin Cherry, David Chiang, Christian Chiercos, Hai Leong Chieu, Laura Chiticariu, Yejin Choi, Jennifer Chu-Carroll, Tat-Seng Chua, Ken Church, Alexan-der Clark, Shay Cohen, Trevor Cohn, Kevyn Collins-Thompson, Marta Ruiz Costa Jussa, Dan Cristea, Hang Cui, Aron Culotta, James Cussens, Chaoliu Chaoliu

Walter Daelemans, Ido Dagan, R. I. Damper, Cristian Danescu-Niculescu-Mizil, Van Dang, Lau-rence Danlos, Dipanjan Das, Hal Daume, Gerard De Melo, Guy De Pauw, Steve DeNeeffe, John DeNero, Vera Demberg, Yasuharu Den, Pascal Denis, Markus Dickinson, Mike Dillinger, Xi-aowen Ding, Kohji Dohsaka, John Dowding, Doug Downey, Markus Dreyer, Rebecca Dridan, Jinhua Du, Kevin Duh, Chris Dyer, Marc Dymetman

Judith Ecker-Kohler, Koji Eguchi, Andreas Eisele, Jacob Eisenstein, Jason Eisner, Michael El-hadad

Benoit Favre, Anna Feldman, Christiane Fellbaum, Raquel Fernandez, Margaret Fleck, Dan Flickinger, Radu Florian, Corina Forascu, Kate Forbes-Riley, George Foster, Anette Frank, Bob Frank, Dayne Freitag, Kotaro Funakoshi

Michel Galley, Michael Gamon, Kavita Ganesan, Juri Ganitkevitch, Wei Gao, Claire Gardent, Nikesh Garera, Michael Gasser, Albert Gatt, Dmitriy Genzel, Kallirroi Georgila, Sean Gerrish, Daniel Gildea, Jennifer Gillenwater, Dan Gillick, Kevin Gimpel, Roxana Girju, Claudio Giu-liano, Amir Globerson, Yoav Goldberg, Sharon Goldwater, Julio Gonzalo, Cyril Goutte, Joao Graca, Spence Green, Charlie Greenbacker, Stephan Greene, Ralph Grishman, Jiafeng Guo, Iryna Gurevych, Adria de Gispert, Josef van Genabith

Nizar Habash, Ben Hachey, Barry Haddow, Patrick Haffner, Dilek Hakkani-Tur, David Hall, Keith Hall, Xianpei Han, Jirka Hana, Sanda Harabagiu, Christian Hardmeier, Kazi Saidul Hasan, Sasa Hasan, Chikara Hashimoto, Koiti Hasida, Ahmed Hassan, Helen Hastie, Katsuhiko Hayashi, Xiaodong He, Zhongjun He, Jeffrey Heinz, John Henderson, Iris Hendrickx, Graeme Hirst, Hieu Hoang, Julia Hockenmaier, Matt Honnibal, Mark Hopkins, Veronique Hoste, Eduard Hovy, Paul Hsu, Fei Huang, Liang Huang, Minlie Huang, Ruihong Huang, Zhongqiang Huang, Mans Hulden

Nancy Ide, Gonzalo Iglesias, Ryu Iida, Nitin Indurkha, Grant Ingersoll, Diana Inkpen, Pierre Isabelle, Mitsuru Ishizuka, Tatsuya Izuha, Aranta Diaz de Ilarraza, Gary Lee

Jagadeesh Jagarlamudi, Heng Ji, Sittichai Jiampojarn, Jing Jiang, Wenbin Jiang, Richard Johansson, Howard Johnson, Mark Johnson, Rie Johnson, Doug Jones, Vanja Josifovski

Min-Yen Kan, Damianos Karakos, Daisuke Kawahara, Tatsuya Kawahara, Jun'ichi Kazama, Frank Keller, Andre Kempe, Shahram Khadivi, Emre Kiciman, Bernd Kiefer, Jungi Kim, Su Nam Kim, Katrin Kirchhoff, Ioannis Klapaftis, Thomas Kleinbauer, Alexandre Klementiev, Kevin Knight, Philipp Koehn, Rob Koeling, Oskar Kohonen, Kazunori Komatani, Greg Kondrak, Moshe Koppel, Anna Korhonen, Andras Kornai, Zornitsa Kozareva, Emiel Kraemer, Lun-Wei Ku, Sandra Kuebler, Marco Kuhlmann, Roland Kuhn, Seth Kulick, Tom Kwiatkowski, Oi Yee Kwong

Mikel L. Forcada, Wai Lam, Mathias Lambert, Felipe Langlais, Mirella Lapata, Alberto Lavelli, Alon Lavie, Yoong Keok Lee, Oliver Lemon, James Lester, Gregor Leusch, Gina-Anne Levow, Roger Levy, William Lewis, Fangtao Li, Haizhou Li, Hang Li, Shoushan Li, Xiao Li, Zhifei Li, Percy Liang, Shasha Liao, Chuan-Jie Lin, Ken Litkowski, Marina Litvak, Bing Liu, Fei Liu, Qun Liu, Yan Liu, Yang Liu, Yi Liu, Elena Lloret, Adam Lopez, Annie Louis, Xiaofei Lu, Yue Lu, Yajuan Lv, Keith vander Linden

Bin Ma, Yanjun Ma, Klaus Macherey, Wolfgang Macherey, Nitin Madnani, Suresh Manandhar, Gideon Mann, Christopher Manning, Daniel Marcu, Katja Markert, Konstantin Markov, Erwin Marsi, Andre Martins, Yuval Marton, Spyros Matsoukas, Yuichiroh Matsubayashi, Yuji Matsumoto, Takuya Matsuzaki, Evgeny Matusov, Arne Mauser, Jon May, Diana Maynard, Andrew McCallum, Diana McCarthy, David McClosky, Kathy McCoy, Ryan McDonald, Tara McIntosh, Kathy McKeown, Paul McNamee, Arul Menezes, Paola Merlo, Donald Metzler, Adam Meyers, Haitao Mi, Jeff Mielke, Rada Mihalcea, Yusuke Miyao, Saif Mohammad, Emad Mohammed, Behrang Mohit, Karo Moilanen, Dan Moldovan, Christian Monson, Christof Monz, Taesun Moon, Robert Moore, Roser Morante, Hamish Morgan, Alessandro Moschitti, Smaranda Muresan, Gabriel Murray, Markos Mylonakis

Toshiaki Nakazawa, Preslav Nakov, Tahira Nasseem, Vivi Nastase, Roberto Navigli, Mark-Jan Nederhof, Graham Neubig, Günter Neumann, Hwee Tou Ng, Vincent Ng, Jian-Yun Nie, Zaiqing Nie, Joakim Nivre, Gertjan van Noord

Stephan Oepen, Jong-Hoon Oh, Manabu Okumura, Constantin Orasan

Martha Palmer, Sinno Pan, Bo Pang, Ivandre Paraboni, Christopher Parisien, Kristen P. Parton, Becky Passonneau, Siddharth Patwardhan, Michael Paul, Matthias Paulik, Adam Pauls, Adam Pease, Fuchun Peng, Jing Peng, Gerald Penn, Marco Pennacchiotti, Slav Petrov, Sasa Petrovic, Daniele Pighin, Manfred Pinkal, Elias Ponvert, Simone Paolo Ponzetto, Hoifung Poon, Andrei Popescu-Belis, Maja Popovic, Fred Popowich, Matt Post, Christopher Potts, David Powers, Sameer Pradhan, Rashmi Prasad, Daniel Preotiuc, Adam Przepiórkowski, Matthew Purver, James Pustejovsky, Sampo Pyysalo

Ariadna Quattoni

Rob Gaizauskas, Drago Radev, Dragomir Radev, Kira Radinsky, Hema Raghavan, Altaf Rahman, Daniel Ramage, Ganesh Ramakrishnan, Owen Rambow, Delip Rao, Ari Rappoport, Antoine Raux, Sujith Ravi, Emmanuel Rayner, Roi Reichart, Ehud Reiter, Norbert Reithinger, Sebastian Riedel, Jason Riesa, Stefan Riezler, German Rigau, Laura Rimell, Eric Ringger, Alan Ritter, Brian Roark, Horacio Rodríguez, Carolyn Rose, Andrew Rosenberg, Dan Roth, Vasile Rus, Alexander Rush, Graham Russell, Anton Rytting

Soo Ngee Koh, Kenji Sagae, Hassan Sajjad, Hasim Sak, Tapio Salakoski, Murat Saraclar, Anoop Sarkar, Sudeshna Sarkar, Christina Sauper, David Schlangen, Helmut Schmid, Nathan Schneider, William Schuler, Sabine Schulte im Walde, Hinrich Schütze, Satoshi Sekine, Jean Senellart, Violeta Seretan, Hendra Setiawan, Dipti Sharma, Libin Shen, Wade Shen, Shuming Shi, Eyal Shnarch, Luo Si, Candy Sidner, Michel Simard, Khalil Sima'an, Gabriel Skantze, Otakar Smrz, Rion Snow, Ben Snyder, Stephen Soderland, Yang Song, Youngin Song, Lucia Specia, Caroline Sporleder, Rohini Srihari, Manfred Stede, Mark Steedman, Josef Steinberger, Amanda Stent, Svetlana Stoyanchev, Veselin Stoyanov, Michael Strube, Keh-Yih Su, Fabian Suchanek, Weiwei Sun, Mihai Surdeanu, Hisami Suzuki, Jun Suzuki, Stan Szpakowicz, Idan Szpektor, Sien Moens, Diarmuid ó Séaghdha

Hiroya Takamura, Koichi Takeda, David Talbot, Partha Talukdar, Kumiko Tanaka-Ishii, Stefan Thater, Mariet Theune, Joerg Tiedemann, Christoph Tillmann, Ivan Titov, Cigdem Toprak, Kristina Toutanova, Roy Tromble, Junichi Tsujii, Yoshimasa Tsuruoka, Dan Tufis

Jakob Uszkoreit, Masao Utiyama

Benjamin Van Durme, Lucy Vanderwende, Vasudeva Varma, Tony Veale, Paola Velardi, Marc Vilain, David Vilar, Aline Villavicencio, Sami Virpioja, Andreas Vlachos, Piek Vossen

Marilyn Walker, Hanna Wallach, Michael Walsh, Stephen Wan, Xiaojun Wan, Haifeng Wang, Hsin-Min Wang, Leo Wanner, Taro Watanabe, Yotaro Watanabe, Bonnie Webber, Julie Weeds, Daniel S. Weld, Ben Wellner, Ji-Rong Wen, Michael Wiegand, Jason Williams, Theresa Wilson, Shuly Wintner, John Wong, Kam-Fai Wong, Tak-Lam Wong, Kristian Woodsend, Chung-Hsien Wu, Xianchao Wu, Fei Wu

Yunqing Xia, Lei Xie, Shasha Xie, Deyi Xiong, Gu Xu, Peng Xu, Nianwen Xue, Xiaobin Xue

Charles Yang, Muyun Yang, Shuang-Hong Yang, Roman Yangarber, Tae Yano, Alexander Yates, Xing Yi, Scott Wen-Tau Yih, Anssi Yli-Jyra, Dong Yu, Kai Yu, Liang-Chih Yu, Yisong Yue, Deniz Yuret, Yichang Yichang

Fabio Zanzotto, Jakub Zavrel, Klaus Zechner, Dmitry Zelenko, Richard Zens, Torsten Zesch, Luke Zettlemoyer, ChengXiang Zhai, Bing Zhang, Duo Zhang, Hui Zhang, Joy Zhang, Min Zhang, Qi Zhang, Yi Zhang, Yue Zhang, Liu Zhanyi, Bing Zhao, Jun Zhao, Shiqi Zhao, Tiejun Zhao, Jing Zheng, Guodong Zhou, Qiang Zhou, Michael Zock, Ingrid Zukerman

## **Invited Talk**

### **Remembrance of ACLs past**

**Aravind K. Joshi**

Henry Salvatori Professor of Computer and Cognitive Science  
University of Pennsylvania

#### **Abstract**

Besides briefly covering some highlights of the past 50 years of ACL from my perspective, I will try to comment on (1) why some directions of research were pursued for a while and then dropped, sometimes for a good reason and sometimes apparently for no reason, (2) why the relationship to Linguistics, Psycholinguistics, and AI goes up and down, and (3) are there any leftovers that have the possibility of being turned into delicious contributions!

#### **Short Bio**

After completing his undergraduate work in Electrical and Communication Engineering in India, Aravind Joshi came to the University of Pennsylvania and obtained his Ph.D. in Electrical Engineering in 1960. At present, he is the Henry Salvatori Professor of Computer and Cognitive Science at the University of Pennsylvania.

Joshi has worked on several problems that overlap computer science and linguistics. More specifically, he has worked on topics in mathematical linguistics as they relate to formal and linguistic adequacy of different formalisms and their processing implications. He has also worked on several aspects of theories of representation and inference in natural language, especially as they relate to discourse.

Joshi was the President of ACL in 1975 and was appointed as a Founding Fellow of ACL in 2011. He was awarded the Lifetime Achievement Award of ACL in 2002, the David Rumelhart Prize of the Cognitive Science Society in 2003 and the Franklin Medal for Computer and Cognitive Science, Franklin Institute, Philadelphia, in 2005.

## **Invited Talk**

### **Computational linguistics: Where do we go from here?**

**Mark Johnson**

Professor of Language Sciences (CORE)  
Director, Centre for Language Sciences (CLaS)  
Department of Computing Faculty of Science  
Macquarie University  
Sydney, Australia

“Prediction is very difficult, especially about the future” —Niels Bohr

### **Abstract**

The very fact that we’re having a 50th annual meeting means that our field hasn’t been a complete failure, but will there still be computational linguistics meetings in 50 years time? How do we fit into the larger intellectual picture, and what would it take to make computational linguistics into a real engineering discipline, or, for that matter, a scientific one? Prognosticating fearlessly (or perhaps just foolishly) I’ll draw some lessons from the last 50 years about what the next few might hold.

### **Short Bio**

Mark Johnson is a Professor of Language Science (CORE) in the Department of Computing at Macquarie University. He was awarded a BSc (Hons) in 1979 from the University of Sydney, an MA in 1984 from the University of California, San Diego and a PhD in 1987 from Stanford University. He held a postdoctoral fellowship at MIT from 1987 until 1988, and has been a visiting researcher at the University of Stuttgart, the Xerox Research Centre in Grenoble, CSAIL at MIT and the Natural Language group at Microsoft Research. He has worked on a wide range of topics in computational linguistics, but his main research area is parsing and its applications to text and speech processing. He was President of the Association for Computational Linguistics in 2003, and was a professor from 1989 until 2009 in the Departments of Cognitive and Linguistic Sciences and Computer Science at Brown University.

## Table of Contents

<i>Learning to Translate with Multiple Objectives</i>	
Kevin Duh, Katsuhito Sudoh, Xianchao Wu, Hajime Tsukada and Masaaki Nagata . . . . .	1
<i>Joint Feature Selection in Distributed Stochastic Learning for Large-Scale Discriminative Training in SMT</i>	
Patrick Simianer, Stefan Riezler and Chris Dyer . . . . .	11
<i>Prediction of Learning Curves in Machine Translation</i>	
Prasanth Kolachina, Nicola Cancedda, Marc Dymetman and Sriram Venkatapathy . . . . .	22
<i>Probabilistic Integration of Partial Lexical Information for Noise Robust Haptic Voice Recognition</i>	
Khe Chai Sim . . . . .	31
<i>A Nonparametric Bayesian Approach to Acoustic Model Discovery</i>	
Chia-ying Lee and James Glass . . . . .	40
<i>Automated Essay Scoring Based on Finite State Transducer: towards ASR Transcription of Oral English Speech</i>	
Xingyuan Peng, Dengfeng Ke and Bo Xu . . . . .	50
<i>Text-level Discourse Parsing with Rich Linguistic Features</i>	
Vanessa Wei Feng and Graeme Hirst . . . . .	60
<i>PDTB-style Discourse Annotation of Chinese Text</i>	
Yuping Zhou and Nianwen Xue . . . . .	69
<i>SITS: A Hierarchical Nonparametric Model using Speaker Identity for Topic Segmentation in Multi-party Conversations</i>	
Viet-An Nguyen, Jordan Boyd-Graber and Philip Resnik . . . . .	78
<i>Extracting Narrative Timelines as Temporal Dependency Structures</i>	
Oleksandr Kolomiyets, Steven Bethard and Marie-Francine Moens . . . . .	88
<i>Labeling Documents with Timestamps: Learning from their Time Expressions</i>	
Nathanael Chambers . . . . .	98
<i>Temporally Anchored Relation Extraction</i>	
Guillermo Garrido, Anselmo Peñas, Bernardo Cabaleiro and Álvaro Rodrigo . . . . .	107
<i>Efficient Tree-based Approximation for Entailment Graph Learning</i>	
Jonathan Berant, Ido Dagan, Meni Adler and Jacob Goldberger . . . . .	117
<i>Learning High-Level Planning from Text</i>	
S.R.K. Branavan, Nate Kushman, Tao Lei and Regina Barzilay . . . . .	126

<i>Distributional Semantics in Technicolor</i>	
Elia Bruni, Gemma Boleda, Marco Baroni and Nam Khanh Tran . . . . .	136
<i>A Class-Based Agreement Model for Generating Accurately Inflected Translations</i>	
Spence Green and John DeNero . . . . .	146
<i>Deciphering Foreign Language by Combining Language Models and Context Vectors</i>	
Malte Nuhn, Arne Mauser and Hermann Ney . . . . .	156
<i>Machine Translation without Words through Substring Alignment</i>	
Graham Neubig, Taro Watanabe, Shinsuke Mori and Tatsuya Kawahara . . . . .	165
<i>Fast Syntactic Analysis for Statistical Language Modeling via Substructure Sharing and Uptraining</i>	
Ariya Rastrow, Mark Dredze and Sanjeev Khudanpur . . . . .	175
<i>Bootstrapping a Unified Model of Lexical and Phonetic Acquisition</i>	
Micha Elsner, Sharon Goldwater and Jacob Eisenstein . . . . .	184
<i>Discriminative Pronunciation Modeling: A Large-Margin, Feature-Rich Approach</i>	
Hao Tang, Joseph Keshet and Karen Livescu . . . . .	194
<i>Discriminative Strategies to Integrate Multiword Expression Recognition and Parsing</i>	
Matthieu Constant, Anthony Sigogne and Patrick Watrin . . . . .	204
<i>Utilizing Dependency Language Models for Graph-based Dependency Parsing Models</i>	
Wenliang Chen, Min Zhang and Haizhou Li . . . . .	213
<i>Spectral Learning of Latent-Variable PCFGs</i>	
Shay B. Cohen, Karl Stratos, Michael Collins, Dean P. Foster and Lyle Ungar . . . . .	223
<i>Reducing Approximation and Estimation Errors for Chinese Lexical Processing with Heterogeneous Annotations</i>	
Weiwei Sun and Xiaojun Wan . . . . .	232
<i>Capturing Paradigmatic and Syntagmatic Lexical Relations: Towards Accurate Chinese Part-of-Speech Tagging</i>	
Weiwei Sun and Hans Uszkoreit . . . . .	242
<i>Fast Online Training with Frequency-Adaptive Learning Rates for Chinese Word Segmentation and New Word Detection</i>	
Xu Sun, Houfeng Wang and Wenjie Li . . . . .	253
<i>Verb Classification using Distributional Similarity in Syntactic and Semantic Structures</i>

# Conference Program

**Monday July 9, 2012**

**(9:00 – 10:30) Invited Talk: Remembrance of ACLs past, by Aravind K. Joshi**

**Session 1a: (11:00 – 12:30) Machine Translation**

*Learning to Translate with Multiple Objectives*

Kevin Duh, Katsuhito Sudoh, Xianchao Wu, Hajime Tsukada and Masaaki Nagata

*Joint Feature Selection in Distributed Stochastic Learning for Large-Scale Discriminative Training in SMT*

Patrick Simianer, Stefan Riezler and Chris Dyer

*Prediction of Learning Curves in Machine Translation*

Prasanth Kolachina, Nicola Cancedda, Marc Dymetman and Sriram Venkatapathy

**Session 1b: (11:00 – 12:30) Speech**

*Probabilistic Integration of Partial Lexical Information for Noise Robust Haptic Voice Recognition*

Khe Chai Sim

*A Nonparametric Bayesian Approach to Acoustic Model Discovery*

Chia-ying Lee and James Glass

*Automated Essay Scoring Based on Finite State Transducer: towards ASR Transcription of Oral English Speech*

Xingyuan Peng, Dengfeng Ke and Bo Xu

**Monday July 9, 2012 (continued)**

**Session 1c: (11:00 – 12:30) Discourse**

*Text-level Discourse Parsing with Rich Linguistic Features*

Vanessa Wei Feng and Graeme Hirst

*PDTB-style Discourse Annotation of Chinese Text*

Yuping Zhou and Nianwen Xue

*SITS: A Hierarchical Nonparametric Model using Speaker Identity for Topic Segmentation in Multiparty Conversations*

Viet-An Nguyen, Jordan Boyd-Graber and Philip Resnik

**Session 1d: (11:00 – 12:30) Time**

*Extracting Narrative Timelines as Temporal Dependency Structures*

Oleksandr Kolomiyets, Steven Bethard and Marie-Francine Moens

*Labeling Documents with Timestamps: Learning from their Time Expressions*

Nathanael Chambers

*Temporally Anchored Relation Extraction*

Guillermo Garrido, Anselmo Peñas, Bernardo Cabaleiro and Álvaro Rodrigo

**Session 1e: (11:00 – 12:30) Meaning**

*Efficient Tree-based Approximation for Entailment Graph Learning*

Jonathan Berant, Ido Dagan, Meni Adler and Jacob Goldberger

*Learning High-Level Planning from Text*

S.R.K. Branavan, Nate Kushman, Tao Lei and Regina Barzilay

*Distributional Semantics in Technicolor*

Elia Bruni, Gemma Boleda, Marco Baroni and Nam Khanh Tran

**Monday July 9, 2012 (continued)**

**Session 2a: (14:00 – 15:30) Machine Translation**

*A Class-Based Agreement Model for Generating Accurately Inflected Translations*

Spence Green and John DeNero

*Deciphering Foreign Language by Combining Language Models and Context Vectors*

Malte Nuhn, Arne Mauser and Hermann Ney

*Machine Translation without Words through Substring Alignment*

Graham Neubig, Taro Watanabe, Shinsuke Mori and Tatsuya Kawahara

**Session 2b: (14:00 – 15:30) Speech**

*Fast Syntactic Analysis for Statistical Language Modeling via Substructure Sharing and Uptraining*

Ariya Rastrow, Mark Dredze and Sanjeev Khudanpur

*Bootstrapping a Unified Model of Lexical and Phonetic Acquisition*

Micha Elsner, Sharon Goldwater and Jacob Eisenstein

*Discriminative Pronunciation Modeling: A Large-Margin, Feature-Rich Approach*

Hao Tang, Joseph Keshet and Karen Livescu

**Session 2c: (14:00 – 15:30) Parsing**

*Discriminative Strategies to Integrate Multiword Expression Recognition and Parsing*

Matthieu Constant, Anthony Sigogne and Patrick Watrin

*Utilizing Dependency Language Models for Graph-based Dependency Parsing Models*

Wenliang Chen, Min Zhang and Haizhou Li

*Spectral Learning of Latent-Variable PCFGs*

Shay B. Cohen, Karl Stratos, Michael Collins, Dean P. Foster and Lyle Ungar

**Monday July 9, 2012 (continued)**

**Session 2d: (14:00 – 15:30) Chinese lexical processing**

*Reducing Approximation and Estimation Errors for Chinese Lexical Processing with Heterogeneous Annotations*

Weiwei Sun and Xiaojun Wan

*Capturing Paradigmatic and Syntagmatic Lexical Relations: Towards Accurate Chinese Part-of-Speech Tagging*

Weiwei Sun and Hans Uszkoreit

*Fast Online Training with Frequency-Adaptive Learning Rates for Chinese Word Segmentation and New Word Detection*

Xu Sun, Houfeng Wang and Wenjie Li

**Session 2e: (14:00 – 15:30) Lexical semantics**

*Verb Classification using Distributional Similarity in Syntactic and Semantic Structures*

Danilo Croce, Alessandro Moschitti, Roberto Basili and Martha Palmer

*Word Sense Disambiguation Improves Information Retrieval*

Zhi Zhong and Hwee Tou Ng

*Efficient Search for Transformation-based Inference*

Asher Stern, Roni Stern, Ido Dagan and Ariel Felner

**Session 3a: (16:00 – 17:30) Machine Translation**

*Maximum Expected BLEU Training of Phrase and Lexicon Translation Models*

Xiaodong He and Li Deng

*Learning Translation Consensus with Structured Label Propagation*

Shujie Liu, Chi-Ho Li, Mu Li and Ming Zhou

*Smaller Alignment Models for Better Translations: Unsupervised Word Alignment with the  $l_0$ -norm*

Ashish Vaswani, Liang Huang and David Chiang

**Monday July 9, 2012 (continued)**

**Session 3b: (16:00 – 17:30) Aspect**

*Modeling Review Comments*

Arjun Mukherjee and Bing Liu

*A Joint Model for Discovery of Aspects in Utterances*

Asli Celikyilmaz and Dilek Hakkani-Tur

*Aspect Extraction through Semi-Supervised Modeling*

Arjun Mukherjee and Bing Liu

**Session 3c: (16:00 – 17:30) Generation and Machine Reading**

*Learning to "Read Between the Lines" using Bayesian Logic Programs*

Sindhu Raghavan, Raymond Mooney and Hyeonsoo Ku

*Collective Generation of Natural Image Descriptions*

Polina Kuznetsova, Vicente Ordonez, Alexander Berg, Tamara Berg and Yejin Choi

*Concept-to-text Generation via Discriminative Reranking*

Ioannis Konstas and Mirella Lapata

**Session 3d: (16:00 – 17:30) Dialogue and Discourse**

*A Discriminative Hierarchical Model for Fast Coreference at Large Scale*

Michael Wick, Sameer Singh and Andrew McCallum

*Coreference Semantics from Web Features*

Mohit Bansal and Dan Klein

*Subgroup Detection in Ideological Discussions*

Amjad Abu-Jbara, Pradeep Dasigi, Mona Diab and Dragomir Radev

**Monday July 9, 2012 (continued)**

**Session 3e: (16:00 – 17:30) Lexicon**

*Cross-Domain Co-Extraction of Sentiment and Topic Lexicons*

Fangtao Li, Sinno Jialin Pan, Ou Jin, Qiang Yang and Xiaoyan Zhu

*Learning Syntactic Verb Frames using Graphical Models*

Thomas Lippincott, Anna Korhonen and Diarmuid Ó Séaghdha

*Fast Online Lexicon Learning for Grounded Language Acquisition*

David Chen

**(18:00 – 20:30) Poster Session**

**Tuesday July 10, 2012**

**(9:00 – 10:30) Best Paper Session**

*Bayesian Symbol-Refined Tree Substitution Grammars for Syntactic Parsing*

Hiroyuki Shindo, Yusuke Miyao, Akinori Fujino and Masaaki Nagata

*String Re-writing Kernel*

Fan Bu, Hang Li and Xiaoyan Zhu

**Session 4b: (11:00 – 12:30) Machine Translation**

*Translation Model Adaptation for Statistical Machine Translation with Monolingual Topic Information*

Jinsong Su, Hua Wu, Haifeng Wang, Yidong Chen, Xiaodong Shi, Huailin Dong and Qun Liu

*A Statistical Model for Unsupervised and Semi-supervised Transliteration Mining*

Hassan Sajjad, Alexander Fraser and Helmut Schmid

*Modified Distortion Matrices for Phrase-Based Statistical Machine Translation*

Arianna Bisazza and Marcello Federico

**Tuesday July 10, 2012 (continued)**

**Session 4c: (11:00 – 12:30) Parsing**

*Semantic Parsing with Bayesian Tree Transducers*  
Bevan Jones, Mark Johnson and Sharon Goldwater

*Dependency Hashing for n-best CCG Parsing*  
Dominick Ng and James R. Curran

*Strong Lexicalization of Tree Adjoining Grammars*  
Andreas Maletti and Joost Engelfriet

**Session 4d: (11:00 – 12:30) Social Media**

*Tweet Recommendation with Graph Co-Ranking*  
Rui Yan, Mirella Lapata and Xiaoming Li

*Joint Inference of Named Entity Recognition and Normalization for Tweets*  
Xiaohua Liu, Ming Zhou, Xiangyang Zhou, Zhongyang Fu and Furu Wei

*Finding Bursty Topics from Microblogs*  
Qiming Diao, Jing Jiang, Feida Zhu and Ee-Peng Lim

**Session 4e: (11:00 – 12:30) User generated content**

*Spice it up? Mining Refinements to Online Instructions from User Generated Content*  
Gregory Druck and Bo Pang

*Sentence Dependency Tagging in Online Question Answering Forums*  
Zhonghua Qu and Yang Liu

*Mining Entity Types from Query Logs via User Intent Modeling*  
Patrick Pantel, Thomas Lin and Michael Gamon

**Tuesday July 10, 2012 (continued)**

**Session 5b: (14:00 – 15:30) NLP Apps**

*Cross-Lingual Mixture Model for Sentiment Classification*

Xinfan Meng, Furu Wei, Xiaohua Liu, Ming Zhou, Ge Xu and Houfeng Wang

*Community Answer Summarization for Multi-Sentence Question with Group L1 Regularization*

Wen Chan, Xiangdong Zhou, Wei Wang and Tat-Seng Chua

*Error Mining on Dependency Trees*

Claire Gardent and Shashi Narayan

**Session 5c: (14:00 – 15:30) Machine Learning**

*Computational Approaches to Sentence Completion*

Geoffrey Zweig, John C. Platt, Christopher Meek, Christopher J.C. Burges, Ainur Yesse-  
nalina and Qiang Liu

*Iterative Viterbi A\* Algorithm for K-Best Sequential Decoding*

Zhiheng Huang, Yi Chang, Bo Long, Jean-Francois Crespo, Anlei Dong, Sathiya Keerthi  
and Su-Lin Wu

*Bootstrapping via Graph Propagation*

Max Whitney and Anoop Sarkar

**Session 5d: (14:00 – 15:30) Multilinguality**

*Selective Sharing for Multilingual Dependency Parsing*

Tahira Naseem, Regina Barzilay and Amir Globerson

*The Creation of a Corpus of English Metalanguage*

Shomir Wilson

*Crosslingual Induction of Semantic Roles*

Ivan Titov and Alexandre Klementiev

**Tuesday July 10, 2012 (continued)**

**Session 5e: (14:00 – 15:30) Parsing**

*Head-driven Transition-based Parsing with Top-down Prediction*

Katsuhiko Hayashi, Taro Watanabe, Masayuki Asahara and Yuji Matsumoto

*MIX Is Not a Tree-Adjoining Language*

Makoto Kanazawa and Sylvain Salvati

*Exploiting Multiple Treebanks for Parsing with Quasi-synchronous Grammars*

Zhenghua Li, Ting Liu and Wanxiang Che

**Session 6b: (16:00 – 17:30) Names**

*A Probabilistic Model for Canonicalizing Named Entity Mentions*

Dani Yogatama, Yanchuan Sim and Noah A. Smith

*Multilingual Named Entity Recognition using Parallel Data and Metadata from Wikipedia*

Sungchul Kim, Kristina Toutanova and Hwanjo Yu

*A Computational Approach to the Automation of Creative Naming*

Gozde Ozbek and Carlo Strapparava

**Session 6c: (16:00 – 17:30) Relations**

*Unsupervised Relation Discovery with Sense Disambiguation*

Limin Yao, Sebastian Riedel and Andrew McCallum

*Reducing Wrong Labels in Distant Supervision for Relation Extraction*

Shingo Takamatsu, Issei Sato and Hiroshi Nakagawa

*Finding Salient Dates for Building Thematic Timelines*

Rémy Kessler, Xavier Tannier, Caroline Hagège, Véronique Moriceau and André Bittar

**Tuesday July 10, 2012 (continued)**

**Session 6d: (16:00 – 17:30) Topics**

*Historical Analysis of Legal Opinions with a Sparse Mixed-Effects Latent Variable Model*

William Yang Wang, Elijah Mayfield, Suresh Naidu and Jeremiah Dittmar

*A Topic Similarity Model for Hierarchical Phrase-based Translation*

Xinyan Xiao, Deyi Xiong, Min Zhang, Qun Liu and Shouxun Lin

*Modeling Topic Dependencies in Hierarchical Text Categorization*

Alessandro Moschitti, Qi Ju and Richard Johansson

**Session 6e: (16:00 – 17:30) Parsing**

*Attacking Parsing Bottlenecks with Unlabeled Data and Relevant Factorizations*

Emily Pitler

*Semi-supervised Dependency Parsing using Lexical Affinities*

Seyed Abolghasem Mirroshandel, Alexis Nasr and Joseph Le Roux

**Wednesday July 11, 2012**

**(9:00 – 10:30) Invited Talk: Computational linguistics: Where do we go from here?,  
by Mark Johnson**

**Monday July 9, 2012**

**(18:00 – 20:30) Poster Session**

*Chinese Comma Disambiguation for Discourse Analysis*

Yaqin Yang and Nianwen Xue

*Collective Classification for Fine-grained Information Status*

Katja Markert, Yufang Hou and Michael Strube

*Structuring E-Commerce Inventory*

Karin Mauge, Khash Rohanimanesh and Jean-David Ruvini

**Monday July 9, 2012 (continued)**

*Named Entity Disambiguation in Streaming Data*

Alexandre Davis, Adriano Veloso, Altigran Soares, Alberto Laender and Wagner Meira Jr.

*Big Data versus the Crowd: Looking for Relationships in All the Right Places*

Ce Zhang, Feng Niu, Christopher Ré and Jude Shavlik

*Automatic Event Extraction with Structured Preference Modeling*

Wei Lu and Dan Roth

*Discriminative Learning for Joint Template Filling*

Einat Minkov and Luke Zettlemoyer

*Classifying French Verbs Using French and English Lexical Resources*

Ingrid Falk, Claire Gardent and Jean-Charles Lamirel

*Modeling Sentences in the Latent Space*

Weiwei Guo and Mona Diab

*Improving Word Representations via Global Context and Multiple Word Prototypes*

Eric Huang, Richard Socher, Christopher Manning and Andrew Ng

*Exploiting Social Information in Grounded Language Learning via Grammatical Reduction*

Mark Johnson, Katherine Demuth and Michael Frank

*You Had Me at Hello: How Phrasing Affects Memorability*

Cristian Danescu-Niculescu-Mizil, Justin Cheng, Jon Kleinberg and Lillian Lee

*Modeling the Translation of Predicate-Argument Structure for SMT*

Deyi Xiong, Min Zhang and Haizhou Li

*A Ranking-based Approach to Word Reordering for Statistical Machine Translation*

Nan Yang, Mu Li, Dongdong Zhang and Nenghai Yu

*Character-Level Machine Translation Evaluation for Languages with Ambiguous Word Boundaries*

Chang Liu and Hwee Tou Ng

**Monday July 9, 2012 (continued)**

*PORT: a Precision-Order-Recall MT Evaluation Metric for Tuning*

Boxing Chen, Roland Kuhn and Samuel Larkin

*Mixing Multiple Translation Models in Statistical Machine Translation*

Majid Razmara, George Foster, Baskaran Sankaran and Anoop Sarkar

*Hierarchical Chunk-to-String Translation*

Yang Feng, Dongdong Zhang, Mu Li and Qun Liu

## Abstract

We introduce an approach to optimize a machine translation (MT) system on multiple metrics *simultaneously*. Different metrics (e.g. BLEU, TER) focus on different aspects of translation quality; our multi-objective approach leverages these diverse aspects to improve overall quality.

Our approach is based on the theory of Pareto Optimality. It is simple to implement on top of existing single-objective optimization methods (e.g. MERT, PRO) and outperforms ad hoc alternatives based on linear-combination of metrics. We also discuss the issue of metric tunability and show that our Pareto approach is more effective in incorporating new metrics from MT evaluation for MT optimization.

## 1 Introduction

Weight optimization is an important step in building machine translation (MT) systems. Discriminative optimization methods such as MERT (Och, 2003), MIRA (Crammer et al., 2006), PRO (Hopkins and May, 2011), and Downhill-Simplex (Nelder and Mead, 1965) have been influential in improving MT systems in recent years. These methods are effective because they tune the system to maximize an automatic evaluation metric such as BLEU, which serve as surrogate objective for translation quality.

However, we know that a single metric such as BLEU is not enough. *Ideally*, we want to tune towards an automatic metric that has *perfect* correlation with human judgments of translation quality.

While many alternatives have been proposed, such a perfect evaluation metric remains elusive.

As a result, many MT evaluation campaigns now report multiple evaluation metrics (Callison-Burch et al., 2011; Paul, 2010). Different evaluation metrics focus on different aspects of translation quality. For example, while BLEU (Papineni et al., 2002) focuses on word-based n-gram precision, METEOR (Lavie and Agarwal, 2007) allows for stem/synonym matching and incorporates recall. TER (Snover et al., 2006) allows arbitrary chunk movements, while permutation metrics like RIBES (Isozaki et al., 2010; Birch et al., 2010) measure deviation in word order. Syntax (Owczarzak et al., 2007) and semantics (Pado et al., 2009) also help. Arguably, all these metrics correspond to our intuitions on what is a good translation.

The current approach of optimizing MT towards a single metric runs the risk of sacrificing other metrics. Can we really claim that a system is good if it has high BLEU, but very low METEOR? Similarly, is a high-METEOR low-BLEU system desirable? Our goal is to propose a multi-objective optimization method that avoids “overfitting to a single metric”. We want to build a MT system that does well with respect to many aspects of translation quality.

In general, we cannot expect to improve multiple metrics jointly if there are some inherent trade-offs. We therefore need to define the notion of Pareto Optimality (Pareto, 1906), which characterizes this tradeoff in a rigorous way and distinguishes the set of equally good solutions. We will describe Pareto Optimality in detail later, but roughly speaking, a

---

\*Now at Nara Institute of Science & Technology (NAIST)

hypothesis is pareto-optimal if there exist no other hypothesis better in all metrics. The contribution of this paper is two-fold:

- We introduce **PMO** (*Pareto-based Multi-objective Optimization*), a general approach for learning with multiple metrics. Existing single-objective methods can be easily extended to multi-objective using PMO.
- We show that PMO outperforms the alternative (single-objective optimization of linearly-combined metrics) in multi-objective space, and especially obtains stronger results for metrics that may be difficult to tune individually.

In the following, we first explain the theory of Pareto Optimality (Section 2), and then use it to build up our proposed PMO approach (Section 3). Experiments on NIST Chinese-English and PubMed English-Japanese translation using BLEU, TER, and RIBES are presented in Section 4. We conclude by discussing related work (Section 5) and opportunities/limitations (Section 6).

## 2 Theory of Pareto Optimality

### 2.1 Definitions and Concepts

The idea of Pareto optimality comes originally from economics (Pareto, 1906), where the goal is to characterize situations when a change in allocation of goods does not make anybody worse off. Here, we will explain it in terms of MT:

Let  $h \in L$  be a hypothesis from an N-best list  $L$ . We have a total of  $K$  different metrics  $M_k(h)$  for evaluating the quality of  $h$ . Without loss of generality, we assume metric scores are bounded between 0 and 1, with 1 being perfect. Each hypothesis  $h$  can be mapped to a  $K$ -dimensional vector  $M(h) = [M_1(h); M_2(h); \dots; M_K(h)]$ . For example, suppose  $K = 2$ ,  $M_1(h)$  computes the BLEU score, and  $M_2(h)$  gives the METEOR score of  $h$ . Figure 1 illustrates the set of vectors  $\{M(h)\}$  in a 10-best list.

For two hypotheses  $h_1, h_2$ , we write  $M(h_1) > M(h_2)$  if  $h_1$  is *better than*  $h_2$  in all metrics, and  $M(h_1) \geq M(h_2)$  if  $h_1$  is *better than or equal to*  $h_2$  in all metrics. When  $M(h_1) \geq M(h_2)$  and  $M_k(h_1) > M_k(h_2)$  for at least one metric  $k$ , we say that  $h_1$  *dominates*  $h_2$  and write  $M(h_1) \triangleright M(h_2)$ .

Figure 1: Illustration of Pareto Frontier. Ten hypotheses are plotted by their scores in two metrics. Hypotheses indicated by a circle (o) are pareto-optimal, while those indicated by a plus (+) are not. The line shows the convex hull, which attains only a subset of pareto-optimal points. The triangle ( $\Delta$ ) is a point that is weakly pareto-optimal but not pareto-optimal.

**Definition 1.** *Pareto Optimal:* A hypothesis  $h^* \in L$  is pareto-optimal iff there does not exist another hypothesis  $h \in L$  such that  $M(h) \triangleright M(h^*)$ .

In Figure 1, the hypotheses indicated by circle (o) are pareto-optimal, while those with plus (+) are not. To visualize this, take for instance the pareto-optimal point (0.4,0.7). There is no other point with either (metric1  $>$  0.4 and metric2  $\geq$  0.7), or (metric1  $\geq$  0.4 and metric2  $>$  0.7). On the other hand, the non-pareto point (0.6,0.4) is “dominated” by another point (0.7,0.6), because for metric1:  $0.7 > 0.6$  and for metric2:  $0.6 > 0.4$ .

There is another definition of optimality, which disregards ties and may be easier to visualize:

**Definition 2.** *Weakly Pareto Optimal:* A hypothesis  $h^* \in L$  is weakly pareto-optimal iff there is no other hypothesis  $h \in L$  such that  $M(h) > M(h^*)$ .

Weakly pareto-optimal points are a superset of pareto-optimal points. A hypothesis is weakly pareto-optimal if there is no other hypothesis that improves all the metrics; a hypothesis is pareto-optimal if there is no other hypothesis that improves at least one metric without detriment to other metrics. In Figure 1, point (0.1,0.8) is weakly pareto-optimal but not pareto-optimal, because of the competing point (0.3,0.8). Here we focus on pareto-optimality, but note our algorithms can be easily

modified for weakly pareto-optimality. Finally, we can introduce the key concept used in our proposed PMO approach:

**Definition 3. Pareto Frontier:** Given an  $N$ -best list  $L$ , the set of all pareto-optimal hypotheses  $h \in L$  is called the Pareto Frontier.

The Pareto Frontier has two desirable properties from the multi-objective optimization perspective:

1. Hypotheses on the Frontier are equivalently good in the Pareto sense.
2. For each hypothesis not on the Frontier, there is always a better (pareto-optimal) hypothesis.

This provides a principled approach to optimization: i.e. optimizing towards points on the Frontier and away from those that are not, and giving no preference to different pareto-optimal hypotheses.

## 2.2 Reduction to Linear Combination

Multi-objective problems can be formulated as:

$$\arg \max_w [M_1(h); M_2(h); \dots; M_k(h)] \quad (1)$$

where  $h = \text{Decode}(w, f)$

Here, the MT system's `Decode` function, parameterized by weight vector  $w$ , takes in a foreign sentence  $f$  and returns a translated hypothesis  $h$ . The `argmax` operates in vector space and our goal is to find  $w$  leading to hypotheses on the Pareto Frontier.

In the study of Pareto Optimality, one central question is: To what extent can multi-objective problems be solved by single-objective methods? Equation 1 can be *reduced* to a single-objective problem by scalarizing the vector  $[M_1(h); \dots; M_k(h)]$  with a linear combination:

$$\arg \max_w \sum_{k=1}^K p_k M_k(h) \quad (2)$$

where  $h = \text{Decode}(w, f)$

Here,  $p_k$  are positive real numbers indicating the relative importance of each metric (without loss of generality, assume  $\sum_k p_k = 1$ ). Are the solutions to Eq. 2 also solutions to Eq. 1 (i.e. pareto-optimal) and vice-versa? The theory says:

**Theorem 1. Sufficient Condition:** If  $w^*$  is solution to Eq. 2, then it is weakly pareto-optimal. Further, if  $w^*$  is unique, then it is pareto-optimal.

**Theorem 2. No Necessary Condition:** There may exist solutions to Eq. 1 that cannot be achieved by Eq. 2, irregardless of any setting of  $\{p_k\}$ .

Theorem 1 is a positive result asserting that linear combination can give pareto-optimal solutions. However, Theorem 2 states the limits: in particular, Eq. 2 attains only pareto-optimal points that are on the convex hull. This is illustrated in Figure 1: imagine sweeping all values of  $p_1 = [0, 1]$  and  $p_2 = 1 - p_1$  and recording the set of hypotheses that maximizes  $\sum_k p_k M_k(h)$ . For  $0.6 < p_1 \leq 1$  we get  $h = (0.9, 0.1)$ , for  $p_1 = 0.6$  we get  $(0.7, 0.6)$ , and for  $0 < p_1 < 0.6$  we get  $(0.4, 0.8)$ . At no setting of  $p_1$  do we attain  $h = (0.4, 0.7)$  which is also pareto-optimal but not on the convex hull.<sup>1</sup> This may have ramifications for issues like metric tunability and local optima. To summarize, linear combination is reasonable but has limitations. Our proposed approach will instead *directly* solve Eq. 1.

Pareto Optimality and multi-objective optimization is a deep field with active inquiry in engineering, operations research, economics, etc. For the interested reader, we recommend the survey by Marler and Arora (2004) and books by (Sawaragi et al., 1985; Miettinen, 1998).

## 3 Multi-objective Algorithms

### 3.1 Computing the Pareto Frontier

Our PMO approach will need to compute the Pareto Frontier for potentially large sets of points, so we first describe how this can be done efficiently. Given a set of  $N$  vectors  $\{M(h)\}$  from an  $N$ -best list  $L$ , our goal is extract the subset that are pareto-optimal.

Here we present an algorithm based on *iterative filtering*, in our opinion the simplest algorithm to understand and implement. The strategy is to loop through the list  $L$ , keeping track of any dominant points. Given a dominant point, it is easy to filter out many points that are dominated by it. After successive rounds, any remaining points that are not fil-

<sup>1</sup>We note that scalarization by *exponentiated*-combination  $\sum_k p_k M_k(h)^q$ , for a suitable  $q > 0$ , does satisfy necessary conditions for pareto optimality. However the proper tuning of  $q$  is not known a priori. See (Miettinen, 1998) for theorem proofs.

---

**Algorithm 1** FindParetoFrontier

---

**Input:**  $\{M(h)\}, h \in L$ **Output:** All pareto-optimal points of  $\{M(h)\}$ 

```
1:  $\mathcal{F} = \emptyset$ 
2: while  $L$  is not empty do
3:    $h^* = \text{shift}(L)$ 
4:   for each  $h$  in  $L$  do
5:     if  $(M(h^*) \triangleright M(h))$ : remove  $h$  from  $L$ 
6:     else if  $(M(h) \triangleright M(h^*))$ : remove  $h$  from  $L$ ; set  $h^* = h$ 
7:   end for
8:   Add  $h^*$  to Frontier Set  $\mathcal{F}$ 
9:   for each  $h$  in  $L$  do
10:    if  $(M(h^*) \triangleright M(h))$ : remove  $h$  from  $L$ 
11:  end for
12: end while
13: Return  $\mathcal{F}$ 
```

---

tered are necessarily pareto-optimal. Algorithm 1 shows the pseudocode. In line 3, we take a point  $h^*$  and check if it is dominating or dominated in the for-loop (lines 4-8). At least one pareto-optimal point will be found by line 8. The second loop (lines 9-11) further filters the list for points that are dominated by  $h^*$  but iterated before  $h^*$  in the first for-loop.

The outer while-loop stops exactly after  $P$  iterations, where  $P$  is the actual number of pareto-optimal points in  $L$ . Each inner loop costs  $O(KN)$  so the total complexity is  $O(PKN)$ . Since  $P \leq N$  with the actual value depending on the probability distribution of  $\{M(h)\}$ , the worst-case run-time is  $O(KN^2)$ . For a survey of various Pareto algorithms, refer to (Godfrey et al., 2007). The algorithm we described here is borrowed from the database literature in what is known as skyline operators.<sup>2</sup>

### 3.2 PMO-PRO Algorithm

We are now ready to present an algorithm for multi-objective optimization. As we will see, it can be seen as a generalization of the pairwise ranking optimization (PRO) of (Hopkins and May, 2011), so we call it PMO-PRO. PMO-PRO approach works by iteratively decoding-and-optimizing on the devset, sim-

---

<sup>2</sup>The inquisitive reader may wonder how is Pareto related to databases. The motivation is to incorporate preferences into relational queries (Börzsönyi et al., 2001). For  $K = 2$  metrics, they also present an alternative faster  $O(N \log N)$  algorithm by first topologically sorting along the 2 dimensions. All dominated points can be filtered by one-pass by comparing with the most-recent dominating point.

ilar to many MT optimization methods. The main difference is that rather than trying to maximize a single metric, we maximize the number of pareto points, in order to expand the Pareto Frontier

We will explain PMO-PRO in terms of the pseudo-code shown in Algorithm 2. For each sentence pair  $(f, e)$  in the devset, we first generate an N-best list  $L \equiv \{h\}$  using the current weight vector  $w$  (line 5). In line 6, we evaluate each hypothesis  $h$  with respect to the  $K$  metrics, giving a set of  $K$ -dimensional vectors  $\{M(h)\}$ .

Lines 7-8 is the critical part: it gives a “label” to each hypothesis, based on whether it is in the Pareto Frontier. In particular, first we call FindParetoFrontier (Algorithm 1), which returns a set of pareto hypotheses; pareto-optimal hypotheses will get label 1 while non-optimal hypotheses will get label 0. This information is added to the training set  $\mathcal{T}$  (line 8), which is then optimized by any conventional subroutine in line 10. We will follow PRO in using a pairwise classifier in line 10, which finds  $w^*$  that separates hypotheses with labels 1 vs. 0. In essence, this is the trick we employ to directly optimize on the Pareto Frontier. If we had used BLEU scores rather than the  $\{0, 1\}$  labels in line 8, the entire PMO-PRO algorithm would revert to single-objective PRO.

By definition, there is no single “best” result for multi-objective optimization, so we collect all weights and return the Pareto-optimal set. In line 13 we evaluate each weight  $w$  on  $K$  metrics across the entire corpus and call FindParetoFrontier in line 14.<sup>3</sup> This choice highlights an interesting change of philosophy: While setting  $\{p_k\}$  in linear-combination forces the designer to make an *a priori* preference among metrics prior to optimization, the PMO strategy is to optimize first agnostically and *a posteriori* let the designer choose among a set of weights. Arguably it is easier to choose among solutions based on their evaluation scores rather than devising exact values for  $\{p_k\}$ .

### 3.3 Discussion

**Variants:** In practice we find that a slight modification of line 8 in Algorithm 2 leads to more sta-

---

<sup>3</sup>Note this is the same FindParetoFrontier algorithm as used in line 7. Both operate on sets of *points* in  $K$ -dimensional space, induced from either weights  $\{w\}$  or hypotheses  $\{h\}$ .

---

**Algorithm 2** Proposed PMO-PRO algorithm

---

**Input:** Devset, max number of iterations  $I$ **Output:** A set of (pareto-optimal) weight vectors

```
1: Initialize  $w$ . Let  $\mathcal{W} = \emptyset$ .
2: for  $i = 1$  to  $I$  do
3:   Let  $\mathcal{T} = \emptyset$ .
4:   for each  $(f, e)$  in devset do
5:      $\{h\} = \text{DecodeNbest}(w, f)$ 
6:      $\{M(h)\} = \text{EvalMetricsOnSentence}(\{h\}, e)$ 
7:      $\{f\} = \text{FindParetoFrontier}(\{M(h)\})$ 
8:     foreach  $h \in \{h\}$ :
9:       if  $h \in \{f\}$ , set  $l=1$ , else  $l=0$ ; Add  $(l, h)$  to  $\mathcal{T}$ 
10:    end for
11:    $w^* = \text{OptimizationSubroutine}(\mathcal{T}, w)$ 
12:   Add  $w^*$  to  $\mathcal{W}$ ; Set  $w = w^*$ .
13: end for
14: Return  $\text{FindParetoFrontier}(\{M(w)\})$ 
```

---

ble results for PMO-PRO: for non-pareto hypotheses  $h \notin \{f\}$ , we set label  $l = \sum_k M_k(h)/K$  instead of  $l=0$ , so the method not only learns to discriminate pareto vs. non-pareto but also also learns to discriminate among competing non-pareto points. Also, like other MT works, in line 5 the N-best list is concatenated to N-best lists from previous iterations, so  $\{h\}$  is a set with  $i \cdot N$  elements.

**General PMO Approach:** The strategy we outlined in Section 3.2 can be easily applied to other MT optimization techniques. For example, by replacing the optimization subroutine (line 10, Algorithm 2) with a Powell search (Och, 2003), one can get PMO-MERT<sup>4</sup>. Alternatively, by using the large-margin optimizer in (Chiang et al., 2009) and moving it into the for-each loop (lines 4-9), one can get an online algorithm such PMO-MIRA. Virtually all MT optimization algorithms have a place where metric scores feedback into the optimization procedure; the idea of PMO is to replace these raw scores with labels derived from Pareto optimality.

## 4 Experiments

### 4.1 Evaluation Methodology

We experiment with two datasets: (1) The **PubMed** task is English-to-Japanese translation of scientific

<sup>4</sup>A difference with traditional MERT is the necessity of sentence-BLEU (Liang et al., 2006) in line 6. We use sentence-BLEU for optimization but corpus-BLEU for evaluation here.

abstracts. As metrics we use BLEU and RIBES (which demonstrated good human correlation in this language pair (Goto et al., 2011)). (2) The **NIST** task is Chinese-to-English translation with OpenMT08 training data and MT06 as devset. As metrics we use BLEU and NTER.

- BLEU =  $BP \times (\prod prec_n)^{1/4}$ . BP is brevity penalty.  $prec_n$  is precision of  $n$ -gram matches.
- RIBES =  $(\tau + 1)/2 \times prec_1^{1/4}$ , with Kendall’s  $\tau$  computed by measuring permutation between matching words in reference and hypothesis<sup>5</sup>.
- NTER =  $\max(1 - \text{TER}, 0)$ , which normalizes Translation Edit Rate<sup>6</sup> so that NTER=1 is best.

We compare two multi-objective approaches:

1. Linear-Combination of metrics (Eq. 2), optimized with PRO. We search a range of combination settings:  $(p_1, p_2) = \{(0, 1), (0.3, 0.7), (0.5, 0.5), (0.7, 0.3), (1, 0)\}$ . Note (1, 0) reduces to standard single-metric optimization of e.g. BLEU.
2. Proposed Pareto approach (PMO-PRO).

Evaluation of multi-objective problems can be tricky because there is no single figure-of-merit. We thus adopted the following methodology: We run both methods 5 times (i.e. using the 5 different  $(p_1, p_2)$  setting each time) and  $I = 20$  iterations each. For each method, this generates  $5 \times 20 = 100$  results, and we plot the Pareto Frontier of these points in a 2-dimensional metric space (e.g. see Figure 2). A method is deemed better if its final Pareto Frontier curve is strictly dominating the other. We report devset results here; testset trends are similar but not included due to space constraints.<sup>7</sup>

<sup>5</sup>from [www.kecl.ntt.co.jp/icl/lirg/ribes](http://www.kecl.ntt.co.jp/icl/lirg/ribes)

<sup>6</sup>from [www.umd.edu/~snoover/tercom](http://www.umd.edu/~snoover/tercom)

<sup>7</sup>An aside: For comparing optimization methods, we believe devset comparison is preferable to testset since data mismatch may confound results. If one worries about generalization, we advocate to *re-decode* the devset with final weights and evaluate its 1-best output (which is done here). This is preferable to simply reporting the achieved scores on devset N-best (as done in some open-source scripts) since the learned weight may pick out good hypotheses in the N-best but perform poorly when re-decoding the same devset. The *re-decode devset* approach avoids being overly optimistic while accurately measuring optimization performance.

	Train	Devset	#Feat	Metrics
PubMed	0.2M	2k	14	BLEU, RIBES
NIST	7M	1.6k	8	BLEU, NTER

Table 1: Task characteristics: #sentences in Train/Dev, # of features, and metrics used. Our MT models are trained with standard phrase-based Moses software (Koehn and others, 2007), with IBM M4 alignments, 4gram SRILM, lexical ordering for PubMed and distance ordering for the NIST system. The decoder generates 50-best lists each iteration. We use SVMRank (Joachims, 2006) as optimization subroutine for PRO, which efficiently handle all pairwise samples without the need for sampling.

## 4.2 Results

Figures 2 and 3 show the results for PubMed and NIST, respectively. A method is better if its Pareto Frontier lies more towards the upper-right hand corner of the graph. Our observations are:

1. PMO-PRO generally outperforms Linear-Combination with any setting of  $(p_1, p_2)$ . The Pareto Frontier of PMO-PRO dominates that of Linear-Combination. This implies PMO is effective in optimizing towards Pareto hypotheses.
2. For both methods, trading-off between metrics is necessary. For example in PubMed, the designer would need to make a choice between picking the best weight according to BLEU (BLEU=.265,RIBES=.665) vs. another weight with higher RIBES but poorer BLEU, e.g. (.255,.675). Nevertheless, both the PMO and Linear-Combination with various  $(p_1, p_2)$  samples this joint-objective space broadly.
3. Interestingly, a multi-objective approach can sometimes outperform a single-objective optimizer in its own metric. In Figure 2, single-objective PRO focusing on optimizing RIBES only achieves 0.68, but PMO-PRO using both BLEU and RIBES outperforms with 0.685.

The third observation relates to the issue of *metric tunability* (Liu et al., 2011). We found that RIBES can be difficult to tune directly. It is an extremely non-smooth objective with many local optima—slight changes in word ordering causes large changes in RIBES. So the best way to improve RIBES is to

Figure 2: PubMed Results. The curve represents the Pareto Frontier of all results collected after multiple runs.

Figure 3: NIST Results

not to optimize it directly, but jointly with a more tunable metric BLEU. The learning curve in Figure 4 show that single-objective optimization of RIBES quickly falls into local optimum (at iteration 3) whereas PMO can zigzag and sacrifice RIBES in intermediate iterations (e.g. iteration 2, 15) leading to a stronger result ultimately. The reason is the diversity of solutions provided by the Pareto Frontier. This finding suggests that multi-objective approaches may be preferred, especially when dealing with new metrics that may be difficult to tune.

## 4.3 Additional Analysis and Discussions

**What is the training time?** The Pareto approach does not add much overhead to PMO-PRO. While FindParetoFrontier scales quadratically by size of N-best list, Figure 5 shows that the runtime is triv-

Figure 4: Learning Curve on RIBES: comparing single-objective optimization and PMO.

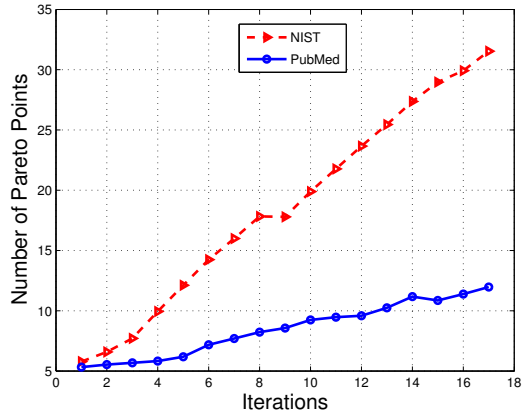

Figure 6: Average number of Pareto points

Figure 5: Avg. runtime per sentence of FindPareto

ial (0.3 seconds for 1000-best). Table 2 shows the time usage breakdown in different iterations for PubMed. We see it is mostly dominated by decoding time (constant per iteration at 40 minutes on single 3.33GHz processor). At later iterations, Opt takes more time due to larger file I/O in SVMRank. Note Decode and Pareto can be “embarrassingly parallelized.”

Iter	Time	Decode (line 5)	Pareto (line 7)	Opt (line 10)	Misc. (line 6,8)
1	47m	85%	1%	1%	13%
10	62m	67%	6%	8%	19%
20	91m	47%	15%	22%	16%

Table 2: Training time usage in PMO-PRO (Algo 2).

**How many Pareto points?** The number of pareto

hypotheses gives a rough indication of the diversity of hypotheses that can be exploited by PMO. Figure 6 shows that this number increases gradually per iteration. This perhaps gives PMO-PRO more directions for optimizing around potential local optimal. Nevertheless, we note that tens of Pareto points is far few compared to the large size of N-best lists used at later iterations of PMO-PRO. This may explain why the differences between methods in Figure 3 are not more substantial. Theoretically, the number will eventually level off as it gets increasingly harder to generate new Pareto points in a crowded space (Bentley et al., 1978).

**Practical recommendation:** We present the Pareto approach as a way to agnostically optimize multiple metrics jointly. However, in practice, one may have intuitions about metric tradeoffs even if one cannot specify  $\{p_k\}$ . For example, we might believe that approximately 1-point BLEU degradation is acceptable only if RIBES improves by at least 3-points. In this case, we recommend the following trick: Set up a multi-objective problem where one metric is BLEU and the other is  $3/4\text{BLEU} + 1/4\text{RIBES}$ . This encourages PMO to explore the joint metric space but avoid solutions that sacrifice too much BLEU, and should also outperform Linear Combination that searches only on the  $(3/4, 1/4)$  direction.

## 5 Related Work

Multi-objective optimization for MT is a relatively new area. Linear-combination of BLEU/TER is

the most common technique (Zaidan, 2009), sometimes achieving good results in evaluation campaigns (Dyer et al., 2009). As far as we know, the only work that directly proposes a multi-objective technique is (He and Way, 2009), which modifies MERT to optimize a single metric subject to the constraint that it does not degrade others. These approaches all require some setting of constraint strength or combination weights  $\{p_k\}$ . Recent work in MT evaluation has examined combining metrics using machine learning for better correlation with human judgments (Liu and Gildea, 2007; Albrecht and Hwa, 2007; Gimnez and Màrquez, 2008) and may give insights for setting  $\{p_k\}$ . We view our Pareto-based approach as orthogonal to these efforts.

The tunability of metrics is a problem that is gaining recognition (Liu et al., 2011). If a good evaluation metric could not be used for tuning, it would be a pity. The Tunable Metrics task at WMT2011 concluded that BLEU is still the easiest to tune (Callison-Burch et al., 2011). (Mauser et al., 2008; Cer et al., 2010) report similar observations, in addition citing WER being difficult and BLEU-TER being amenable. One unsolved question is whether metric tunability is a problem inherent to the metric only, or depends also on the underlying optimization algorithm. Our positive results with PMO suggest that the choice of optimization algorithm can help.

Multi-objective ideas are being explored in other NLP areas. (Spitkovsky et al., 2011) describe a technique that alternates between hard and soft EM objectives in order to achieve better local optimum in grammar induction. (Hall et al., 2011) investigates joint optimization of a supervised parsing objective and some extrinsic objectives based on downstream applications. (Agarwal et al., 2011) considers using multiple signals (of varying quality) from online users to train recommendation models. (Eisner and Daumé III, 2011) trades off speed and accuracy of a parser with reinforcement learning. None of the techniques in NLP use Pareto concepts, however.

## 6 Opportunities and Limitations

We introduce a new approach (PMO) for training MT systems on multiple metrics. Leveraging the diverse perspectives of different evaluation metrics has the potential to improve overall quality. Based

on Pareto Optimality, PMO is easy to implement and achieves better solutions compared to linear-combination baselines, for *any setting* of combination weights. Further we observe that multi-objective approaches can be helpful for optimizing difficult-to-tune metrics; this is beneficial for quickly introducing new metrics developed in MT evaluation into MT optimization, especially when good  $\{p_k\}$  are not yet known. We conclude by drawing attention to some limitations and opportunities raised by this work:

**Limitations:** (1) The performance of PMO is limited by the size of the Pareto set. Small N-best lists lead to sparsely-sampled Pareto Frontiers, and a much better approach would be to enlarge the hypothesis space using lattices (Macherey et al., 2008). How to compute Pareto points directly from lattices is an interesting open research question. (2) The binary distinction between pareto vs. non-pareto points ignores the fact that 2nd-place non-pareto points may also lead to good practical solutions. A better approach may be to adopt a *graded* definition of Pareto optimality as done in some multi-objective works (Deb et al., 2002). (3) A robust evaluation methodology that enables significance testing for multi-objective problems is sorely needed. This will make it possible to compare multi-objective methods on more than 2 metrics. We also need to follow up with human evaluation.

**Opportunities:** (1) There is still much we do not understand about metric tunability; we can learn much by looking at joint metric-spaces and examining how new metrics correlate with established ones. (2) Pareto is just one approach among many in multi-objective optimization. A wealth of methods are available (Marler and Arora, 2004) and more experimentation in this space will definitely lead to new insights. (3) Finally, it would be interesting to explore other creative uses of multiple-objectives in MT beyond multiple metrics. For example: Can we learn to translate faster while sacrificing little on accuracy? Can we learn to jointly optimize cascaded systems, such as as speech translation or pivot translation? Life is full of multiple competing objectives.

## Abstract

With a few exceptions, discriminative training in statistical machine translation (SMT) has been content with tuning weights for large feature sets on small development data. Evidence from machine learning indicates that increasing the training sample size results in better prediction. The goal of this paper is to show that this common wisdom can also be brought to bear upon SMT. We deploy local features for SCFG-based SMT that can be read off from rules at runtime, and present a learning algorithm that applies  $\ell_1/\ell_2$  regularization for joint feature selection over distributed stochastic learning processes. We present experiments on learning on 1.5 million training sentences, and show significant improvements over tuning discriminative models on small development sets.

## 1 Introduction

The standard SMT training pipeline combines scores from large count-based translation models and language models with a few other features and tunes these using the well-understood line-search technique for error minimization of Och (2003). If only a handful of dense features need to be tuned, minimum error rate training can be done on small tuning sets and is hard to beat in terms of accuracy and efficiency. In contrast, the promise of large-scale discriminative training for SMT is to scale to arbitrary types and numbers of features and to provide sufficient statistical support by parameter estimation on large sample sizes. Features may be lexicalized and sparse, non-local and overlapping, or

be designed to generalize beyond surface statistics by incorporating part-of-speech or syntactic labels. The modeler's goals might be to identify complex properties of translations, or to counter errors of pre-trained translation models and language models by explicitly down-weighting translations that exhibit certain undesired properties. Various approaches to feature engineering for discriminative models have been presented (see Section 2), however, with a few exceptions, discriminative learning in SMT has been confined to training on small tuning sets of a few thousand examples. This contradicts theoretical and practical evidence from machine learning that suggests that larger training samples should be beneficial to improve prediction also in SMT. Why is this?

One possible reason why discriminative SMT has mostly been content with small tuning sets lies in the particular design of the features themselves. For example, the features introduced by Chiang et al. (2008) and Chiang et al. (2009) for an SCFG model for Chinese/English translation are of two types: The first type explicitly counters overestimates of rule counts, or rules with bad overlap points, bad rewrites, or with undesired insertions of target-side terminals. These features are specified in hand-crafted lists based on a thorough analysis of a tuning set. Such finely hand-crafted features will find sufficient statistical support on a few thousand examples and thus do not benefit from larger training sets. The second type of features deploys external information such as syntactic parses or word alignments to penalize bad reorderings or undesired translations of phrases that cross syntactic constraints. At large scale, extraction of such features quickly becomes

- (1)  $X \rightarrow X_1 \text{ hat } X_2 \text{ versprochen, } X_1 \text{ promised } X_2$
- (2)  $X \rightarrow X_1 \text{ hat mir } X_2 \text{ versprochen, } X_1 \text{ promised me } X_2$
- (3)  $X \rightarrow X_1 \text{ versprach } X_2, X_1 \text{ promised } X_2$

Figure 1: SCFG rules for translation.

infeasible because of costly generation and storage of linguistic annotations. Another possible reason why large training data did not yet show the expected improvements in discriminative SMT is a special overfitting problem of current popular online learning techniques. This is due to stochastic learning on a per-example basis where a weight update on a misclassified example may apply only to a small fraction of data that have been seen before. Thus many features will not generalize well beyond the training examples on which they were introduced.

The goal of this paper is to investigate if and how it is possible to benefit from scaling discriminative training for SMT to large training sets. We deploy generic features for SCFG-based SMT that can efficiently be read off from rules at runtime. Such features include rule ids, rule-local n-grams, or types of rule shapes. Another crucial ingredient of our approach is a combination of parallelized stochastic learning with feature selection inspired by multi-task learning. The simple but effective idea is to randomly divide training data into evenly sized shards, use stochastic learning on each shard in parallel, while performing  $\ell_1/\ell_2$  regularization for joint feature selection on the shards after each epoch, before starting a new epoch with a reduced feature vector averaged across shards. Iterative feature selection procedure is the key to both efficiency and improved prediction: Without interleaving parallelized stochastic learning with feature selection our largest experiments would not be feasible. Selecting features jointly across shards and averaging does counter the overfitting effect that is inherent to stochastic updating. Our resulting models are learned on large data sets, but they are small and outperform models that tune feature sets of various sizes on small development sets. Our software is freely available as a part of the `cdec`<sup>1</sup> framework.

<sup>1</sup><https://github.com/redpony/cdec>

## 2 Related Work

The great promise of discriminative training for SMT is the possibility to design arbitrarily expressive, complex, or overlapping features in great numbers. The focus of many approaches thus has been on feature engineering and on adaptations of machine learning algorithms to the special case of SMT (where gold standard rankings have to be created automatically). Examples for adapted algorithms include Maximum-Entropy Models (Och and Ney, 2002; Blunsom et al., 2008), Pairwise Ranking Perceptrons (Shen et al., 2004; Watanabe et al., 2006; Hopkins and May, 2011), Structured Perceptrons (Liang et al., 2006a), Boosting (Duh and Kirchhoff, 2008; Wellington et al., 2009), Structured SVMs (Tillmann and Zhang, 2006; Hayashi et al., 2009), MIRA (Watanabe et al., 2007; Chiang et al., 2008; Chiang et al., 2009), and others. Adaptations of the loss functions underlying such algorithms to SMT have recently been described as particular forms of ramp loss optimization (McAllester and Keshet, 2011; Gimpel and Smith, 2012).

All approaches have been shown to scale to large feature sets and all include some kind of regularization method. However, most approaches have been confined to training on small tuning sets. Exceptions where discriminative SMT has been used on large training data are Liang et al. (2006a) who trained 1.5 million features on 67,000 sentences, Blunsom et al. (2008) who trained 7.8 million rules on 100,000 sentences, or Tillmann and Zhang (2006) who used 230,000 sentences for training.

Our approach is inspired by Duh et al. (2010) who applied multi-task learning for improved generalization in n-best reranking. In contrast to our work, Duh et al. (2010) did not incorporate multi-task learning into distributed learning, but defined tasks as n-best lists, nor did they develop new algorithms, but used off-the-shelf multi-task tools.

## 3 Local Features for Synchronous CFGs

The work described in this paper is based on the SMT framework of hierarchical phrase-based translation (Chiang, 2005; Chiang, 2007). Translation rules are extracted from word-aligned parallel sentences and can be seen as productions of a synchronous CFG. Examples are rules like (1)-(3)

shown in Figure 1. Local features are designed to be readable directly off the rule at decoding time. We use three rule templates in our work:

**Rule identifiers:** These features identify each rule by a unique identifier. Such features correspond to the relative frequencies of rewrites rules used in standard models.

**Rule n-grams:** These features identify n-grams of consecutive items in a rule. We use bigrams on source-sides of rules. Such features identify possible source side phrases and thus can give preference to rules including them.<sup>2</sup>

**Rule shape:** These features are indicators that abstract away from lexical items to templates that identify the location of sequences of terminal symbols in relation to non-terminal symbols, on both the source- and target-sides of each rule used. For example, both rules (1) and (2) map to the same indicator, namely that a rule is being used that consists of a (NT, term\*, NT, term\*) pattern on its source side, and an (NT, term\*, NT) pattern on its target side. Rule (3) maps to a different template, that of (NT, term\*, NT) on source and target sides.

#### 4 Joint Feature Selection in Distributed Stochastic Learning

The following discussion of learning methods is based on pairwise ranking in a Stochastic Gradient Descent (SGD) framework. The resulting algorithms can be seen as variants of the perceptron algorithm. Let each translation candidate be represented by a feature vector  $\mathbf{x} \in \mathbb{R}^D$  where preference pairs for training are prepared by sorting translations according to smoothed sentence-wise BLEU score (Liang et al., 2006a) against the reference. For a preference pair  $\mathbf{x}_j = (\mathbf{x}_j^{(1)}, \mathbf{x}_j^{(2)})$  where  $\mathbf{x}_j^{(1)}$  is preferred over  $\mathbf{x}_j^{(2)}$ , and  $\bar{\mathbf{x}}_j = \mathbf{x}_j^{(1)} - \mathbf{x}_j^{(2)}$ , we consider the following hinge loss-type objective function:

$$l_j(\mathbf{w}) = (-\langle \mathbf{w}, \bar{\mathbf{x}}_j \rangle)_+$$

where  $(a)_+ = \max(0, a)$ ,  $\mathbf{w} \in \mathbb{R}^D$  is a weight vector, and  $\langle \cdot, \cdot \rangle$  denotes the standard vector dot product. Instantiating SGD to the following stochastic

<sup>2</sup>Similar ‘‘monolingual parse features’’ have been used in Dyer et al. (2011).

subgradient leads to the perceptron algorithm for pairwise ranking<sup>3</sup> (Shen and Joshi, 2005):

$$\nabla l_j(\mathbf{w}) = \begin{cases} -\bar{\mathbf{x}}_j & \text{if } \langle \mathbf{w}, \bar{\mathbf{x}}_j \rangle \leq 0, \\ 0 & \text{else.} \end{cases}$$

Our baseline algorithm 1 (SDG) scales pairwise ranking to large scale scenarios. The algorithm takes an average over the final weight updates of each epoch instead of keeping a record of all weight updates for final averaging (Collins, 2002) or for voting (Freund and Schapire, 1999).

---

#### Algorithm 1 SGD: int $I, T$ , float $\eta$

---

```

Initialize  $\mathbf{w}_{0,0,0} \leftarrow \mathbf{0}$ .
for epochs  $t \leftarrow 0 \dots T - 1$ : do
  for all  $i \in \{0 \dots I - 1\}$ : do
    Decode  $i^{\text{th}}$  input with  $\mathbf{w}_{t,i,0}$ .
    for all pairs  $x_j, j \in \{0 \dots P - 1\}$ : do
       $\mathbf{w}_{t,i,j+1} \leftarrow \mathbf{w}_{t,i,j} - \eta \nabla l_j(\mathbf{w}_{t,i,j})$ 
    end for
     $\mathbf{w}_{t,i+1,0} \leftarrow \mathbf{w}_{t,i,P}$ 
  end for
   $\mathbf{w}_{t+1,0,0} \leftarrow \mathbf{w}_{t,I,0}$ 
end for
return  $\frac{1}{T} \sum_{t=1}^T \mathbf{w}_{t,0,0}$ 

```

---

While stochastic learning exhibits a runtime behavior that is linear in sample size (Bottou, 2004), very large datasets can make sequential processing infeasible. Algorithm 2 (MixSGD) addresses this problem by parallelization in the framework of MapReduce (Dean and Ghemawat, 2004).

---

#### Algorithm 2 MixSGD: int $I, T, Z$ , float $\eta$

---

```

Partition data into  $Z$  shards, each of size  $S \leftarrow I/Z$ ;
distribute to machines.
for all shards  $z \in \{1 \dots Z\}$ : parallel do
  Initialize  $\mathbf{w}_{z,0,0,0} \leftarrow \mathbf{0}$ .
  for epochs  $t \leftarrow 0 \dots T - 1$ : do
    for all  $i \in \{0 \dots S - 1\}$ : do
      Decode  $i^{\text{th}}$  input with  $\mathbf{w}_{z,t,i,0}$ .
      for all pairs  $x_j, j \in \{0 \dots P - 1\}$ : do
         $\mathbf{w}_{z,t,i,j+1} \leftarrow \mathbf{w}_{z,t,i,j} - \eta \nabla l_j(\mathbf{w}_{z,t,i,j})$ 
      end for
       $\mathbf{w}_{z,t,i+1,0} \leftarrow \mathbf{w}_{z,t,i,P}$ 
    end for
     $\mathbf{w}_{z,t+1,0,0} \leftarrow \mathbf{w}_{z,t,S,0}$ 
  end for
end for
Collect final weights from each machine,
return  $\frac{1}{Z} \sum_{z=1}^Z \left( \frac{1}{T} \sum_{t=1}^T \mathbf{w}_{z,t,0,0} \right)$ .

```

---

<sup>3</sup>Other loss functions lead to stochastic versions of SVMs (Collobert and Bengio, 2004; Shalev-Shwartz et al., 2007; Chapelle and Keerthi, 2010).

Algorithm 2 is a variant of the SimuParallelSGD algorithm of Zinkevich et al. (2010) or equivalently of the parameter mixing algorithm of McDonald et al. (2010). The key idea of algorithm 2 is to partition the data into disjoint shards, then train SGD on each shard in parallel, and after training mix the final parameters from each shard by averaging. The algorithm requires no communication between machines until the end.

McDonald et al. (2010) also present an iterative mixing algorithm where weights are mixed from each shard after training a single epoch of the perceptron in parallel on each shard. The mixed weight vector is re-sent to each shard to start another epoch of training in parallel on each shard. This algorithm corresponds to our algorithm 3 (IterMixSGD).

---

**Algorithm 3** IterMixSGD: int  $I, T, Z$ , float  $\eta$

---

Partition data into  $Z$  shards, each of size  $S \leftarrow I/Z$ ; distribute to machines.

Initialize  $\mathbf{v} \leftarrow \mathbf{0}$ .

```

for epochs  $t \leftarrow 0 \dots T - 1$ : do
  for all shards  $z \in \{1 \dots Z\}$ : parallel do
     $\mathbf{w}_{z,t,0,0} \leftarrow \mathbf{v}$ 
    for all  $i \in \{0 \dots S - 1\}$ : do
      Decode  $i^{\text{th}}$  input with  $\mathbf{w}_{z,t,i,0}$ .
      for all pairs  $x_j, j \in \{0 \dots P - 1\}$ : do
         $\mathbf{w}_{z,t,i,j+1} \leftarrow \mathbf{w}_{z,t,i,j} - \eta \nabla l_j(\mathbf{w}_{z,t,i,j})$ 
      end for
       $\mathbf{w}_{z,t,i+1,0} \leftarrow \mathbf{w}_{z,t,i,P}$ 
    end for
  end for
  Collect weights  $\mathbf{v} \leftarrow \frac{1}{Z} \sum_{z=1}^Z \mathbf{w}_{z,t,S,0}$ .

```

```

end for
return  $\mathbf{v}$ 

```

---

Parameter mixing by averaging will help to ease the feature sparsity problem, however, keeping feature vectors on the scale of several million features in memory can be prohibitive. If network latency is a bottleneck, the increased amount of information sent across the network after each epoch may be a further problem.

Our algorithm 4 (IterSelSGD) introduces feature selection into distributed learning for increased efficiency and as a more radical measure against overfitting. The key idea is to view shards as tasks, and to apply methods for joint feature selection from multi-task learning to achieve small sets of features that are useful across all tasks or shards. Our algorithm represents weights in a  $Z$ -by- $D$  matrix  $\mathbf{W} = [\mathbf{w}_{z_1} | \dots | \mathbf{w}_{z_Z}]^T$  of stacked  $D$ -dimensional weight

vectors across  $Z$  shards. We compute the  $\ell_2$  norm of the weights in each feature column, sort features by this value, and keep  $K$  features in the model. This feature selection procedure is done after each epoch. Reduced weight vectors are mixed and the result is re-sent to each shard to start another epoch of parallel training on each shard.

---

**Algorithm 4** IterSelSGD: int  $I, T, Z, K$ , float  $\eta$

---

Partition data into  $Z$  shards, each of size  $S = I/Z$ ; distribute to machines.

Initialize  $\mathbf{v} \leftarrow \mathbf{0}$ .

```

for epochs  $t \leftarrow 0 \dots T - 1$ : do
  for all shards  $z \in \{1 \dots Z\}$ : parallel do
     $\mathbf{w}_{z,t,0,0} \leftarrow \mathbf{v}$ 
    for all  $i \in \{0 \dots S - 1\}$ : do
      Decode  $i^{\text{th}}$  input with  $\mathbf{w}_{z,t,i,0}$ .
      for all pairs  $x_j, j \in \{0 \dots P - 1\}$ : do
         $\mathbf{w}_{z,t,i,j+1} \leftarrow \mathbf{w}_{z,t,i,j} - \eta \nabla l_j(\mathbf{w}_{z,t,i,j})$ 
      end for
       $\mathbf{w}_{z,t,i+1,0} \leftarrow \mathbf{w}_{z,t,i,P}$ 
    end for
  end for
  Collect/stack weights  $\mathbf{W} \leftarrow [\mathbf{w}_{1,t,S,0} | \dots | \mathbf{w}_{Z,t,S,0}]^T$ 
  Select top  $K$  feature columns of  $\mathbf{W}$  by  $\ell_2$  norm and
  for  $k \leftarrow 1 \dots K$  do
     $\mathbf{v}[k] = \frac{1}{Z} \sum_{z=1}^Z \mathbf{W}[z][k]$ .
  end for
end for
return  $\mathbf{v}$ 

```

---

This algorithm can be seen as an instance of  $\ell_1/\ell_2$  regularization as follows: Let  $w_d$  be the  $d$ th column vector of  $\mathbf{W}$ , representing the weights for the  $d$ th feature across tasks/shards.  $\ell_1/\ell_2$  regularization penalizes weights  $\mathbf{W}$  by the weighted  $\ell_1/\ell_2$  norm

$$\lambda \|\mathbf{W}\|_{1,2} = \lambda \sum_{d=1}^D \|w_d\|_2.$$

Each  $\ell_2$  norm of a weight column represents the relevance of the corresponding feature across tasks/shards. The  $\ell_1$  sum of the  $\ell_2$  norms enforces a selection among features based on these norms. Consider for example the two 5-feature, 3-task weight matrices in Figure 2. Assuming the same loss for both matrices, the right-hand side matrix is preferred because of a smaller  $\ell_1/\ell_2$  norm (12 instead of 18). This matrix shares features across tasks which leads to larger  $\ell_2$  norms for some columns (here  $\|w_1\|_2$  and  $\|w_2\|_2$ ) and forces other columns to zero. This results in shrinking the matrix to those features that are useful across all tasks.

		$w_1$	$w_2$	$w_3$	$w_4$	$w_5$		$w_1$	$w_2$	$w_3$	$w_4$	$w_5$
	$\mathbf{w}_{z_1}$	[	6	4	0	0		[	6	4	0	0
	$\mathbf{w}_{z_2}$	[	0	0	3	0		[	3	0	0	0
	$\mathbf{w}_{z_3}$	[	0	0	0	2		[	2	3	0	0
column $\ell_2$ norm:			6	4	3	2			7	5	0	0
$\ell_1$ sum:						$\Rightarrow$ 18						$\Rightarrow$ 12

Figure 2:  $\ell_1/\ell_2$  regularization enforcing feature selection.

Our algorithm is related to Obozinski et al. (2010)’s approach to  $\ell_1/\ell_2$  regularization where feature columns are incrementally selected based on the  $\ell_2$  norms of the gradient vectors corresponding to feature columns. Their algorithm is itself an extension of gradient-based feature selection based on the  $\ell_1$  norm, e.g., Perkins et al. (2003).<sup>4</sup> In contrast to these approaches we approximate the gradient by using the weights given by the ranking algorithm itself. This relates our work to weight-based recursive feature elimination (RFE) (Lal et al., 2006). Furthermore, algorithm 4 performs feature selection based on a choice of meta-parameter of  $K$  features instead of by thresholding a regularization meta-parameter  $\lambda$ , however, these techniques are equivalent and can be transformed into each other.

## 5 Experiments

### 5.1 Data, Systems, Experiment Settings

The datasets used in our experiments are versions of the News Commentary (*nc*), News Crawl (*crawl*) and Europarl (*ep*) corpora described in Table 1. The translation direction is German-to-English.

The SMT framework used in our experiments is hierarchical phrase-based translation (Chiang, 2007). We use the `cdec` decoder<sup>5</sup> (Dyer et al., 2010) and induce SCFG grammars from two sets of symmetrized alignments using the method described by Chiang (2007). All data was tokenized and lowercased; German compounds were split (Dyer, 2009). For word alignment of the news-commentary data, we used GIZA++ (Och and Ney, 2000); for aligning the Europarl data, we used the Berkeley aligner (Liang et al., 2006b). Before training, we collect all the grammar rules necessary to

translate each individual sentence into separate files (so-called per-sentence grammars) (Lopez, 2007). When decoding, `cdec` loads the appropriate file immediately prior to translation of the sentence. The computational overhead is minimal compared to the expense of decoding. Also, deploying disk space instead of memory fits perfectly into the MapReduce framework we are working in. Furthermore, the extraction of grammars for training is done in a leave-one-out fashion (Zollmann and Sima’an, 2005) where rules are extracted for a parallel sentence pair only if the same rules are found in other sentences of the corpus as well.

3-gram (news-commentary) and 5-gram (Europarl) language models are trained on the data described in Table 1, using the SRILM toolkit (Stolcke, 2002) and binarized for efficient querying using kenlm (Heafield, 2011). For the 5-gram language models, we replaced every word in the lm training data with `<unk>` that did not appear in the English part of the parallel training data to build an open vocabulary language model.

Figure 3: Multipartite pairwise ranking.

Training data for discriminative learning are prepared by comparing a 100-best list of translations against a single reference using smoothed per-sentence BLEU (Liang et al., 2006a). From the BLEU-reordered n-best list, translations were put into sets for the top 10% level (HI), the middle 80% level (MID), and the bottom 10% level (LOW). These level sets are used for multipartite ranking

<sup>4</sup>Note that by definition of  $\|\mathbf{W}\|_{1,2}$ , standard  $\ell_1$  regularization is a special case of  $\ell_1/\ell_2$  regularization for a single task.

<sup>5</sup>`cdec` metaparameters were set to a non-terminal span limit of 15 and standard cube pruning with a pop limit of 200.

Table 1: Overview of data used for train/dev/test. News Commentary (*nc*) and Europarl (*ep*) training data and also News Crawl (*crawl*) dev/test data were taken from the WMT11 translation task (<http://statmt.org/wmt11/translation-task.html>). The dev/test data of *nc* are the sets provided with the WMT07 shared task (<http://statmt.org/wmt07/shared-task.html>). *Ep* dev/test data is from WMT08 shared task (<http://statmt.org/wmt08/shared-task.html>). The numbers in brackets for the rule counts of *ep/nc* training data are total counts of rules in the per-sentence grammars.

where translation pairs are built between the elements in HI-MID, HI-LOW, and MID-LOW, but not between translations inside sets on the same level. This idea is depicted graphically in Figure 3. The intuition is to ensure that good translations are preferred over bad translations without teasing apart small differences.

For evaluation, we used the `mteval-v11b.pl` script to compute lowercased BLEU-4 scores (Papineni et al., 2001). Statistical significance was measured using an Approximate Randomization test (Noreen, 1989; Riezler and Maxwell, 2005).

All experiments for training on dev sets were carried out on a single computer. For grammar extraction and training of the full data set we used a 30 node hadoop Map/Reduce cluster that can handle 300 jobs at once. We split the data into 2290 shards for the *ep* runs and 141 shards for the *nc* runs, each shard holding about 1,000 sentences, which corresponds to the dev set size of the *nc* data set.

## 5.2 Experimental Results

The baseline learner in our experiments is a pairwise ranking perceptron that is used on various features and training data and plugged into various meta-

Figure 4: Boxplot of BLEU-4 results for 100 runs of MIRA on news commentary data, depicting median (M), mean ( $\bar{x}$ ), interquartile range (box), standard deviation (whiskers), outliers (end points).

algorithms for distributed processing. The perceptron algorithm itself compares favorably to related learning techniques such as the MIRA adaptation of Chiang et al. (2008). Figure 4 gives a boxplot depicting BLEU-4 results for 100 runs of the MIRA implementation of the `cdec` package, tuned on dev-*nc*, and evaluated on the respective test set test-*nc*.<sup>6</sup> We see a high variance (whiskers denote standard deviations) around a median of 27.2 BLEU and a mean of 27.1 BLEU. The fluctuation of results is due to sampling training examples from the translation hy-

<sup>6</sup>MIRA was used with default meta parameters: 250 hypothesis list to search for oracles, regularization strength  $C = 0.01$  and using 15 passes over the input. It optimized IBM BLEU-4. The initial weight vector was  $\mathbf{0}$ .

Table 2: BLEU-4 results for algorithms 1 (SGD), 2 (MixSGD), 3 (IterMixSDG), and 4 (IterSelSGD) on news-commentary (*nc*) data. Feature groups are 12 dense features (default), rule identifiers (id), rule n-gram (ng), and rule shape (shape). Statistical significance at  $p$ -level  $< 0.05$  of a result difference on the test set to a different algorithm applied to the same feature group is indicated by raised algorithm number.  $\dagger$  indicates statistically significant differences to best result across features groups for same algorithm, indicated in **bold face**. @ indicates the optimal number of epochs chosen on the devtest set.

pergraph as is done in the `cdec` implementation of MIRA. We found similar fluctuations for the `cdec` implementations of PRO (Hopkins and May, 2011) or hypergraph-MERT (Kumar et al., 2009) both of which depend on hypergraph sampling. In contrast, the perceptron is deterministic when started from a zero-vector of weights and achieves favorable 28.0 BLEU on the news-commentary test set. Since we are interested in relative improvements over a stable baseline, we restrict our attention in all following experiments to the perceptron.<sup>7</sup>

Table 2 shows the results of the experimental comparison of the 4 algorithms of Section 4. The

<sup>7</sup>Absolute improvements would be possible, e.g., by using larger language models or by adding news data to the *ep* training set when evaluating on *crawl* test sets (see, e.g., Dyer et al. (2011)), however, this is not the focus of this paper.

default features include 12 dense models defined on SCFG rules;<sup>8</sup> The sparse features are the 3 templates described in Section 3. All feature weights were tuned together using algorithms 1-4. If not indicated otherwise, the perceptron was run for 10 epochs with learning rate  $\eta = 0.0001$ , started at zero weight vector, using deduplicated 100-best lists.

The results on the news-commentary (*nc*) data show that training on the development set does not benefit from adding large feature sets – BLEU result differences between tuning 12 default features

<sup>8</sup>negative log relative frequency  $p(e|f)$ ; log count( $f$ ); log count( $e, f$ ); lexical translation probability  $p(f|e)$  and  $p(e|f)$  (Koehn et al., 2003); indicator variable on singleton phrase  $e$ ; indicator variable on singleton phrase pair  $f, e$ ; word penalty; language model weight; OOV count of language model; number of untranslated words; Hiero glue rules (Chiang, 2007).

Table 3: BLEU-4 results for algorithms 1 (SGD) and 4 (IterSelSGD) on Europarl (*ep*) and news crawl (*crawl*) test data. Feature groups are 12 dense features (default), rule identifiers (id), rule n-gram (ng), and rule shape (shape). Statistical significance at  $p$ -level  $< 0.05$  of a result difference on the test set to a different algorithm applied to the same feature group is indicated by raised algorithm number. <sup>†</sup> indicates statistically significant differences to best result across features groups for same algorithm, indicated in **bold face**. @ indicates the optimal number of epochs chosen on the devtest set.

and tuning the full set of 180,000 features are not significant. However, scaling all features to the full training set shows significant improvements for algorithm 3, and especially for algorithm 4, which gains 0.8 BLEU points over tuning 12 features on the development set. The number of features rises to 4.7 million without feature selection, which iteratively selects 100,000 features with best  $\ell_2$  norm values across shards. Feature templates such as rule n-grams and rule shapes only work if iterative mixing (algorithm 3) or feature selection (algorithm 4) are used. Adding rule id features works in combination with other sparse features.

Table 3 shows results for algorithms 1 and 4 on the Europarl data (*ep*) for different devtest and test sets. Europarl data were used in all runs for training and for setting the meta-parameter of number of epochs. Testing was done on the Europarl test set and news crawl test data from the years 2010 and 2011. Here tuning large feature sets on the respective dev sets yields significant improvements of around 2 BLEU points over tuning the 12 default features on the dev sets. Another 0.5 BLEU points (test-*crawl11*) or even 1.3 BLEU points (test-*crawl10*) are gained when scaling to the full training set using iterative features selection. Result differences on the Europarl test set were not significant for moving from dev to full train set. Algorithms 2 and 3 were infeasible to run on Europarl data beyond one epoch because features vectors grew too large to be kept in memory.

## 6 Discussion

We presented an approach to scaling discriminative learning for SMT not only to large feature

sets but also to large sets of parallel training data. Since inference for SMT (unlike many other learning problems) is very expensive, especially on large training sets, good parallelization is key. Our approach is made feasible and effective by applying joint feature selection across distributed stochastic learning processes. Furthermore, our local features are efficiently computable at runtime. Our algorithms and features are generic and can easily be re-implemented and make our results relevant across datasets and language pairs.

In future work, we would like to investigate more sophisticated features, better learners, and in general improve the components of our system that have been neglected in the current investigation of relative improvements by scaling the size of data and feature sets. Ultimately, since our algorithms are inspired by multi-task learning, we would like to apply them to scenarios where a natural definition of tasks is given. For example, patent data can be characterized along the dimensions of patent classes and patent text fields (Wäschle and Riezler, 2012) and thus are well suited for multi-task translation.

## Abstract

Parallel data in the domain of interest is the key resource when training a statistical machine translation (SMT) system for a specific purpose. Since ad-hoc manual translation can represent a significant investment in time and money, a prior assesment of the amount of training data required to achieve a satisfactory accuracy level can be very useful. In this work, we show how to *predict* what the learning curve would look like *if* we were to manually translate increasing amounts of data.

We consider two scenarios, 1) Monolingual samples in the source and target languages are available and 2) An additional small amount of parallel corpus is also available. We propose methods for predicting learning curves in both these scenarios.

## 1 Introduction

Parallel data in the domain of interest is the key resource when training a statistical machine translation (SMT) system for a specific business purpose. In many cases it is possible to allocate some budget for manually translating a limited sample of relevant documents, be it via professional translation services or through increasingly fashionable crowdsourcing. However, it is often difficult to predict how much training data will be required to achieve satisfactory translation accuracy, preventing sound provisional budgetting. This prediction, or more generally the prediction of the *learning curve* of an SMT system as a function of available in-domain parallel data, is the objective of this paper.

We consider two scenarios, representative of realistic situations.

1. In the first scenario (S1), the SMT developer is given only monolingual source and target samples from the relevant domain, and a small *test* parallel corpus.

---

\*This research was carried out during an internship at Xerox Research Centre Europe.

2. In the second scenario (S2), an additional small *seed* parallel corpus is given that can be used to train small in-domain models and measure (with some variance) the evaluation score at a few points on the initial portion of the learning curve.

In both cases, the task consists in predicting an evaluation score (BLEU, throughout this work) on the test corpus as a function of the size of a subset of the source sample, assuming that we could have it manually translated and use the resulting bilingual corpus for training.

In this paper we provide the following contributions:

1. An extensive study across six parametric function families, empirically establishing that a certain three-parameter power-law family is well suited for modeling learning curves for the Moses SMT system when the evaluation score is BLEU. Our methodology can be easily generalized to other systems and evaluation scores (Section 3);
2. A method for *inferring* learning curves based on features computed from the resources available in scenario S1, suitable for both the scenarios described above (S1) and (S2) (Section 4);
3. A method for *extrapolating* the learning curve from a few measurements, suitable for scenario S2 (Section 5);
4. A method for *combining* the two approaches above, achieving on S2 better prediction accuracy than either of the two in isolation (Section 6).

In this study we limit tuning to the mixing parameters of the Moses log-linear model through MERT, keeping all meta-parameters (e.g. maximum phrase length, maximum allowed distortion, etc.) at their default values. One can expect further tweaking to lead to performance improvements, but this was a

necessary simplification in order to execute the tests on a sufficiently large scale.

Our experiments involve 30 distinct language pair and domain combinations and 96 different learning curves. They show that without any parallel data we can predict the expected translation accuracy at 75K segments within an error of 6 BLEU points (Table 4), while using a seed training corpus of 10K segments narrows this error to within 1.5 points (Table 6).

## 2 Related Work

Learning curves are routinely used to illustrate how the performance of experimental methods depend on the amount of training data used. In the SMT area, Koehn et al. (2003) used learning curves to compare performance for various meta-parameter settings such as *maximum phrase length*, while Turchi et al. (2008) extensively studied the behaviour of learning curves under a number of test conditions on Spanish-English. In Birch et al. (2008), the authors examined corpus features that contribute most to the machine translation performance. Their results showed that the most predictive features were the morphological complexity of the languages, their linguistic relatedness and their word-order divergence; in our work, we make use of these features, among others, for predicting translation accuracy (Section 4).

In a Machine Learning context, Perlich et al. (2003) used learning curves for predicting *maximum performance* bounds of learning algorithms and to compare them. In Gu et al. (2001), the learning curves of two classification algorithms were modelled for eight different large data sets. This work uses similar *a priori* knowledge for restricting the form of learning curves as ours (see Section 3), and also similar empirical evaluation criteria for comparing curve families with one another. While both application and performance metric in our work are different, we arrive at a similar conclusion that a power law family of the form  $y = c - a x^{-\alpha}$  is a good model of the learning curves.

Learning curves are also frequently used for determining empirically the number of iterations for an incremental learning procedure.

The crucial difference in our work is that in the previous cases, learning curves are plotted *a posteriori* i.e. once the labelled data has become available and the training has been performed, whereas

in our work the learning curve itself is the object of the prediction. Our goal is to learn to *predict* what the learning curve will be *a priori* without having to label the data at all (S1), or through labelling only a very small amount of it (S2).

In this respect, the academic field of Computational Learning Theory has a similar goal, since it strives to identify bounds to performance measures<sup>1</sup>, typically including a dependency on the training sample size. We take a purely empirical approach in this work, and obtain useful estimations for a case like SMT, where the complexity of the mapping between the input and the output prevents tight theoretical analysis.

## 3 Selecting a parametric family of curves

The first step in our approach consists in selecting a suitable family of shapes for the learning curves that we want to produce in the two scenarios being considered.

We formulate the problem as follows. For a certain bilingual test dataset  $d$ , we consider a set of observations  $O_d = \{(x_1, y_1), (x_2, y_2) \dots (x_n, y_n)\}$ , where  $y_i$  is the performance on  $d$  (measured using BLEU (Papineni et al., 2002)) of a translation model trained on a parallel corpus of size  $x_i$ . The corpus size  $x_i$  is measured in terms of the number of segments (sentences) present in the parallel corpus.

We consider such observations to be generated by a regression model of the form:

$$y_i = F(x_i; \theta) + \epsilon_i \quad 1 \leq i \leq n \quad (1)$$

where  $F$  is a function depending on a vector parameter  $\theta$  which depends on  $d$ , and  $\epsilon_i$  is Gaussian noise of constant variance.

Based on our prior knowledge of the problem, we limit the search for a suitable  $F$  to families that satisfies the following conditions- monotonically increasing, concave and bounded. The first condition just says that more training data is better. The second condition expresses a notion of “diminishing returns”, namely that a given amount of additional training data is more advantageous when added to a small rather than to a big amount of initial data. The last condition is related to our use of BLEU — which is bounded by 1 — as a performance measure; It should be noted that some growth patterns which are sometimes proposed, such as a logarithmic regime of the form  $y \simeq a + b \log x$ , are not

<sup>1</sup>More often to a *loss*, which is equivalent.

compatible with this constraint.

We consider six possible families of functions satisfying these conditions, which are listed in Table 1. Preliminary experiments indicated that curves from

Model	Formula
Exp <sub>3</sub>	$y = c - e^{-ax+b}$
Exp <sub>4</sub>	$y = c - e^{-ax^\alpha+b}$
ExpP <sub>3</sub>	$y = c - e^{(x-b)^\alpha}$
Pow <sub>3</sub>	$y = c - ax^{-\alpha}$

Table 1: Curve families.

the ‘‘Power’’ and ‘‘Exp’’ family with only two parameters underfitted, while those with five or more parameters led to overfitting and solution instability. We decided to only select families with three or four parameters.

**Curve fitting technique** Given a set of observations  $\{(x_1, y_1), (x_2, y_2) \dots (x_n, y_n)\}$  and a curve family  $F(x; \theta)$  from Table 1, we compute a best fit  $\hat{\theta}$  where:

$$\hat{\theta} = \arg \min_{\theta} \sum_{i=1}^n [y_i - F(x_i; \theta)]^2, \quad (2)$$

through use of the *Levenberg-Marquardt* method (Moré, 1978) for non-linear regression.

For selecting a learning curve family, and for all other experiments in this paper, we trained a large number of systems on multiple *configurations* of training sets and sample sizes, and tested each on multiple *test* sets; these are listed in Table 2. All experiments use Moses (Koehn et al., 2007).<sup>2</sup>

Domain	Source Language	Target Language	# Test sets
Europarl (Koehn, 2005)	Fr, De, Es En	En Fr, De, Es	4

Table 2: The translation systems used for the curve fitting experiments, comprising 30 language-pair and domain combinations for a total of 96 learning curves. Language codes: Cz=Czech, Da=Danish, En=English, De=German, Fr=French, Jp=Japanese, Es=Spanish

The goodness of fit for each of the families is eval-

<sup>2</sup>The settings used in training the systems are those described in <http://www.statmt.org/wmt11/baseline.html>

uated based on their ability to *i)* fit over the entire set of observations, *ii)* extrapolate to points beyond the observed portion of the curve and *iii)* generalize well over different datasets.

We use a recursive fitting procedure where the curve obtained from fitting the first  $i$  points is used to predict the observations at two points:  $x_{i+1}$ , i.e. the point to the immediate right of the currently observed  $x_i$  and  $x_n$ , i.e. the largest point that has been observed.

The following error measures quantify the goodness of fit of the curve families:

1. Average root mean-squared error (RMSE):

$$\frac{1}{N} \sum_{c \in S} \sum_{t \in T_c} \left\{ \frac{1}{n} \sum_{i=1}^n [y_i - F(x_i; \hat{\theta})]^2 \right\}_{ct}^{1/2}$$

where  $S$  is the set of training datasets,  $T_c$  is the set of test datasets for training configuration  $c$ ,  $\hat{\theta}$  is as defined in Eq. 2,  $N$  is the total number of combinations of training configurations and test datasets, and  $i$  ranges on a grid of training subset sizes. The expressions  $n, x_i, y_i, \hat{\theta}$  are all local to the combination  $ct$ .

2. Average root mean squared residual at next point  $X = x_{i+1}$  (NPR):

$$\frac{1}{N} \sum_{c \in S} \sum_{t \in T_c} \left\{ \frac{1}{n-k-1} \sum_{i=k}^{n-1} [y_{i+1} - F(x_{i+1}; \hat{\theta}^i)]^2 \right\}_{ct}^{1/2}$$

where  $\hat{\theta}^i$  is obtained using only observations up to  $x_i$  in Eq. 2 and where  $k$  is the number of parameters of the family.<sup>3</sup>

3. Average root mean squared residual at the last point  $X = x_n$  (LPR):

$$\frac{1}{N} \sum_{c \in S} \sum_{t \in T_c} \left\{ \frac{1}{n-k-1} \sum_{i=k}^{n-1} [y_n - F(x_n; \hat{\theta}^i)]^2 \right\}_{ct}^{1/2}$$

**Curve fitting evaluation** The evaluation of the goodness of fit for the curve families is presented in Table 3. The average values of the root mean-squared error and the average residuals across all the learning curves used in our experiments are shown in this table. The values are on the same scale as the BLEU scores. Figure 1 shows the curve fits obtained

<sup>3</sup>We start the summation from  $i = k$ , because at least  $k$  points are required for computing  $\hat{\theta}^i$ .

Figure 1: Curve fits using different curve families on a test dataset

for all the six families on a test dataset for English-German language pair.

Curve Family	RMSE	NPR	LPR
Exp <sub>3</sub>	0.0063	0.0094	0.0694
Exp <sub>4</sub>	0.0030	<i>0.0036</i>	<i>0.0072</i>
ExpP <sub>3</sub>	0.0040	0.0049	0.0145
<b>Pow<sub>3</sub></b>	<b>0.0029</b>	<b>0.0037</b>	<b>0.0091</b>
Pow <sub>4</sub>	<i>0.0026</i>	0.0042	0.0102
ILog <sub>2</sub>	0.0050	0.0067	0.0146

Table 3: Evaluation of the goodness of fit for the six families.

Looking at the values in Table 3, we decided to use the Pow<sub>3</sub> family as the best overall compromise. While it is not systematically better than Exp<sub>4</sub> and Pow<sub>4</sub>, it is good overall and has the advantage of requiring only 3 parameters.

#### 4 Inferring a learning curve from mostly monolingual data

In this section we address scenario S1: we have access to a source-language monolingual collection (from which portions to be manually translated could be sampled) and a target-language in-domain monolingual corpus, to supplement the target side of a parallel corpus while training a language model. The only available parallel resource is a very small test corpus. Our objective is to predict the evolution of the BLEU score on the given test set as a function of the size of a random subset of the training data

that we manually translate<sup>4</sup>. The intuition behind this is that the source-side and target-side monolingual data already convey significant information about the difficulty of the translation task.

We proceed in the following way. We first train models to predict the BLEU score at  $m$  anchor sizes  $s_1, \dots, s_m$ , based on a set of features globally characterizing the configuration of interest. We restrict our attention to linear models:

$$\mu_j = \mathbf{w}_j^\top \boldsymbol{\phi}, j \in \{1 \dots m\}$$

where  $\mathbf{w}_j$  is a vector of feature weights specific to predicting at anchor size  $j$ , and  $\boldsymbol{\phi}$  is a vector of size-independent configuration features, detailed below. We then perform inference using these models to predict the BLEU score at each anchor, for the test case of interest. We finally estimate the parameters of the learning curve by weighted least squares regression using the anchor predictions.

Anchor sizes can be chosen rather arbitrarily, but must satisfy the following two constraints:

1. They must be three or more in number in order to allow fitting the tri-parameter curve.
2. They should be spread as much as possible along the range of sample size.

For our experiments, we take  $m = 3$ , with anchors at 10K, 75K and 500K segments.

The feature vector  $\boldsymbol{\phi}$  consists of the following features:

1. General properties: number and average length of sentences in the (source) test set.
2. Average length of tokens in the (source) test set and in the monolingual source language corpus.
3. Lexical diversity features:
  - (a) type-token ratios for n-grams of order 1 to 5 in the monolingual corpus of both source and target languages
  - (b) perplexity of language models of order 2 to 5 derived from the monolingual source corpus computed on the source side of the test corpus.

<sup>4</sup>We specify that it is a random sample as opposed to a subset deliberately chosen to maximize learning effectiveness. While there are clear ties between our present work and active learning, we prefer to keep these two aspects distinct at this stage, and intend to explore this connection in future work.

4. Features capturing divergence between languages in the pair:
  - (a) average ratio of source/target sentence lengths in the test set.
  - (b) ratio of type-token ratios of orders 1 to 5 in the monolingual corpus of both source and target languages.
5. Word-order divergence: The divergence in the word-order between the source and the target languages can be captured using the part-of-speech (pos) tag sequences across languages. We use cross-entropy measure to capture similarity between the n-gram distributions of the pos tags in the monolingual corpora of the two languages. The order of the n-grams ranges between  $n = 2, 4 \dots 12$  in order to account for long distance reordering between languages. The pos tags for the languages are mapped to a reduced set of twelve pos tags (Petrov et al., 2012) in order to account for differences in tagsets used across languages.

These features capture our intuition that translation is going to be harder if the language in the domain is highly variable and if the source and target languages diverge more in terms of morphology and word-order.

The weights  $w_j$  are estimated from data. The training data for fitting these linear models is obtained in the following way. For each configuration (combination of language pair and domain)  $c$  and test set  $t$  in Table 2, a *gold curve* is fitted using the selected tri-parameter power-law family using a fine grid of corpus sizes. This is available as a byproduct of the experiments for comparing different parametric families described in Section 3. We then compute the value of the gold curves at the  $m$  anchor sizes: we thus have  $m$  “gold” vectors  $\mu_1, \dots, \mu_m$  with accurate estimates of BLEU at the anchor sizes<sup>5</sup>. We construct the design matrix  $\Phi$  with one column for each feature vector  $\phi_{ct}$  corresponding to each combination of training configuration  $c$  and test set  $t$ .

We then estimate weights  $w_j$  using Ridge regression ( $L^2$  regularization):

$$w_j = \arg \min_w \|\Phi^\top w - \mu_j\|^2 + C\|w\|^2 \quad (3)$$

<sup>5</sup>Computing these values from the gold curve rather than directly from the observations has the advantage of smoothing the observed values and also does not assume that observations at the anchor sizes are always directly available.

where the regularization parameter  $C$  is chosen by cross-validation. We also run experiments using Lasso ( $L^1$ ) regularization (Tibshirani, 1994) instead of Ridge. As baseline, we take a *constant mean* model predicting, for each anchor size  $s_j$ , the average of all the  $\mu_{jct}$ .

We do not assume the difficulty of predicting BLEU at all anchor points to be the same. To allow for this, we use (non-regularized) *weighted* least-squares to fit a curve from our parametric family through the  $m$  anchor points<sup>6</sup>. Following (Croarkin and Tobias, 2006, Section 4.4.5.2), the *anchor confidence* is set to be the inverse of the cross-validated mean square residuals:

$$\omega_j = \left( \frac{1}{N} \sum_{c \in S} \sum_{t \in T_c} (\phi_{ct}^\top w_j^c - \mu_{jct})^2 \right)^{-1} \quad (4)$$

where  $w_j^c$  are the feature weights obtained by the regression above on all training configurations except  $c$ ,  $\mu_{jct}$  is the gold value at anchor  $j$  for training/test combination  $c, t$ , and  $N$  is the total number of such combinations<sup>7</sup>. In other words, we assign to each anchor point a confidence inverse to the cross-validated mean squared error of the model used to predict it.

For a new unseen configuration with feature vector  $\phi_u$ , we determine the parameters  $\theta_u$  of the corresponding learning curve as:

$$\theta_u = \arg \min_{\theta} \sum_j \omega_j (F(s_j; \theta) - \phi_u^\top w_j)^2 \quad (5)$$

## 5 Extrapolating a learning curve fitted on a small parallel corpus

Given a small “seed” parallel corpus, the translation system can be used to train small in-domain models and the evaluation score can be measured at a few initial sample sizes  $\{(x_1, y_1), (x_2, y_2) \dots (x_p, y_p)\}$ . The performance of the system for these initial points provides evidence for predicting its performance for larger sample sizes.

In order to do so, a learning curve from the family  $\text{Pow}_3$  is first fit through these initial points. We

<sup>6</sup>When the number of anchor points is the same as the number of parameters in the parametric family, the curve can be fit exactly through all anchor points. However the general discussion is relevant in case there are more anchor points than parameters, and also in view of the combination of inference and extrapolation in Section 6.

<sup>7</sup>Curves on different test data for the same training configuration are highly correlated and are therefore left out.

assume that  $p \geq 3$  for this operation to be well-defined. The best fit  $\hat{\eta}$  is computed using the same curve fitting as in Eq. 2.

At each individual anchor size  $s_j$ , the accuracy of prediction is measured using the root mean-squared error between the prediction of extrapolated curves and the gold values:

$$\left( \frac{1}{N} \sum_{c \in S} \sum_{t \in T_c} [F(s_j; \hat{\eta}_{ct}) - \mu_{ctj}]^2 \right)^{1/2} \quad (6)$$

where  $\hat{\eta}_{ct}$  are the parameters of the curve fit using the initial points for the combination  $ct$ .

In general, we observed that the extrapolated curve tends to over-estimate BLEU for large samples.

## 6 Combining inference and extrapolation

In scenario S2, the models trained from the seed parallel corpus and the features used for inference (Section 4) provide complementary information. In this section we combine the two to see if this yields more accurate learning curves.

For the inference method of Section 4, predictions of models at anchor points are weighted by the inverse of the model empirical squared error ( $\omega_j$ ). We extend this approach to the extrapolated curves. Let  $u$  be a new configuration with seed parallel corpus of size  $x_u$ , and let  $x_l$  be the largest point in our grid for which  $x_l \leq x_u$ . We first train translation models and evaluate scores on samples of size  $x_1, \dots, x_l$ , fit parameters  $\hat{\eta}_u$  through the scores, and then extrapolate BLEU at the anchors  $s_j$ :  $F(s_j; \hat{\eta}_u)$ ,  $j \in \{1, \dots, m\}$ . Using the models trained for the experiments in Section 3, we estimate the squared extrapolation error at the anchors  $s_j$  when using models trained on size up to  $x_l$ , and set the confidence in the extrapolations<sup>8</sup> for  $u$  to its inverse:

$$\xi_j^{<l} = \left( \frac{1}{N} \sum_{c \in S} \sum_{t \in T_c} (F(s_j; \eta_{ct}^{<l}) - \mu_{ctj})^2 \right)^{-1} \quad (7)$$

where  $N$ ,  $S$ ,  $T_c$  and  $\mu_{ctj}$  have the same meaning as in Eq. 4, and  $\eta_{ct}^{<l}$  are parameters fitted for configuration  $c$  and test  $t$  using only scores measured at  $x_1, \dots, x_l$ . We finally estimate the parameters  $\theta_u$  of

the combined curve as:

$$\theta_u = \arg \min_{\theta} \sum_j \omega_j (F(s_j; \theta) - \phi_u^\top \mathbf{w}_j)^2 + \xi_j^{<l} (F(s_j; \theta) - F(s_j; \hat{\eta}_u))^2$$

where  $\phi_u$  is the feature vector for  $u$ , and  $w_j$  are the weights we obtained from the regression in Eq. 3.

## 7 Experiments

In this section, we report the results of our experiments on predicting the learning curves.

### 7.1 Inferred Learning Curves

Regression model	10K	75K	500K
Ridge	0.063	<b>0.060</b>	<b>0.053</b>
Lasso	<b>0.054</b>	<b>0.060</b>	0.062
Baseline	0.112	0.121	0.121

Table 4: Root mean squared error of the linear regression models for each anchor size

In the case of inference from mostly monolingual data, the accuracy of the predictions at each of the anchor sizes is evaluated using root mean-squared error over the predictions obtained in a *leave-one-out* manner over the set of configurations from Table 2. Table 4 shows these results for Ridge and Lasso regression models at the three anchor sizes. As an example, the model estimated using Lasso for the 75K anchor size exhibits a root mean squared error of 6 BLEU points. The errors we obtain are lower than the error of the baseline consisting in taking, for each anchor size  $s_j$ , the average of all the  $\mu_{ctj}$ . The Lasso regression model selected four features from the entire feature set: *i*) Size of the test set (sentences & tokens) *ii*) Perplexity of language model (order 5) on the test set *iii*) Type-token ratio of the target monolingual corpus. Feature correlation measures such as Pearsons R showed that the features corresponding to type-token ratios of both source and target languages and size of test set have a high correlation with the BLEU scores at the three anchor sizes.

Figure 2 shows an instance of the inferred learning curves obtained using a weighted least squares method on the predictions at the anchor sizes. Table 7 presents the cumulative error of the inferred learning curves with respect to the gold curves, measured as the average distance between the curves in the range  $x \in [0.1K, 100K]$ .

<sup>8</sup>In some cases these can actually be interpolations.

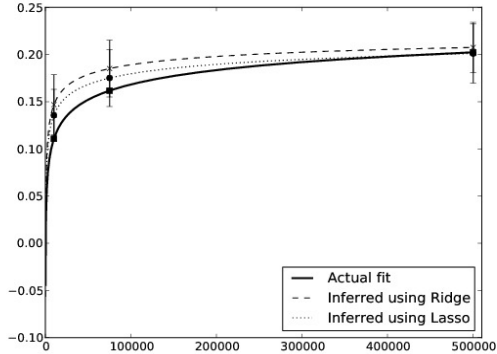

Figure 2: Inferred learning curve for English-Japanese test set. The error-bars show the *anchor confidence* for the predictions.

## 7.2 Extrapolated Learning Curves

As explained in Section 5, we evaluate the accuracy of predictions from the *extrapolated* curve using the root mean squared error (see Eq. 6) between the predictions of this curve and the gold values at the anchor points.

We conducted experiments for three sets of initial points, 1) 1K-5K-10K, 2) 5K-10K-20K, and 3) 1K-5K-10K-20K. For each of these sets, we show the prediction accuracy at the anchor sizes, 10K<sup>9</sup>, 75K, and 500K in Table 5.

Initial Points	10K	75K	500K
1K-5K-10K	0.005	0.017	0.042
5K-10K-20K	0.002	0.015	0.034
1K-5K-10K-20K	<b>0.002</b>	<b>0.008</b>	<b>0.019</b>

Table 5: Root mean squared error of the extrapolated curves at the three anchor sizes

The root mean squared errors obtained by extrapolating the learning curve are much lower than those obtained by prediction of translation accuracy using the monolingual corpus only (see Table 4), which is expected given that more direct evidence is available in the former case. In Table 5, one can also see that the root mean squared error for the sets 1K-5K-10K and 5K-10K-20K are quite close for anchor

<sup>9</sup>The 10K point is not an extrapolation point but lies within the range of the set of initial points. However, it does give a measure of the closeness of the curve fit using only the initial points with the gold fit using all the points; the value of this gold fit at 10K is not necessarily equal to the observation at 10K.

sizes 75K and 500K. However, when a configuration of four initial points is used for the same amount of “seed” parallel data, it outperforms both the configurations with three initial points.

## 7.3 Combined Learning Curves and Overall Comparison

In Section 6, we presented a method for combining the predicted learning curves from inference and extrapolation by using a weighted least squares approach. Table 6 reports the root mean squared error at the three anchor sizes from the combined curves.

Initial Points	Model	10K	75K	500K
1K-5K-10K	Ridge	0.005	0.015	0.038
	Lasso	0.005	0.014	0.038
5K-10K-20K	Ridge	0.001	0.006	0.018
	Lasso	0.001	0.006	0.018
1K-5K-10K-20K	Ridge	<b>0.001</b>	<b>0.005</b>	<b>0.014</b>
	Lasso	<b>0.001</b>	<b>0.005</b>	<b>0.014</b>

Table 6: Root mean squared error of the combined curves at the three anchor sizes

We also present an overall evaluation of all the predicted learning curves. The evaluation metric is the average distance between the predicted curves and the gold curves, within the range of sample sizes  $x_{min}=0.1K$  to  $x_{max}=500K$  segments; this metric is defined as:

$$\frac{1}{N} \sum_{c \in S} \sum_{t \in T_c} \frac{\sum_{x=x_{min}}^{x_{max}} |F(x; \hat{\eta}_{ct}) - F(x; \hat{\theta}_{ct})|}{x_{max} - x_{min}}$$

where  $\hat{\eta}_{ct}$  is the curve of interest,  $\hat{\theta}_{ct}$  is the gold curve, and  $x$  is in the range  $[x_{min}, x_{max}]$ , with a step size of 1. Table 7 presents the final evaluation.

Initial Points	IR	IL	EC	CR	CL
1K-5K-10K	0.034	0.050	0.018	0.015	<b>0.014</b>
5K-10K-20K	0.036	0.048	0.011	0.010	<b>0.009</b>
1K-5K-10K-20K	0.032	0.049	0.008	<b>0.007</b>	<b>0.007</b>

Table 7: Average distance of different predicted learning curves relative to the gold curve. Columns: IR=“Inference using Ridge model”, IL=“Inference using Lasso model”, EC=“Extrapolated curve”, CR=“Combined curve using Ridge”, CL=“Combined curve using Lasso”

We see that the combined curves (CR and CL) perform slightly better than the inferred curves (IR

and IL) and the extrapolated curves (EC). The average distance is on the same scale as the BLEU score, which suggests that our best curves can predict the gold curve within 1.5 BLEU points on average (the best result being 0.7 BLEU points when the initial points are 1K-5K-10K-20K) which is a telling result. The distances between the predicted and the gold curves for all the learning curves in our experiments are shown in Figure 3.

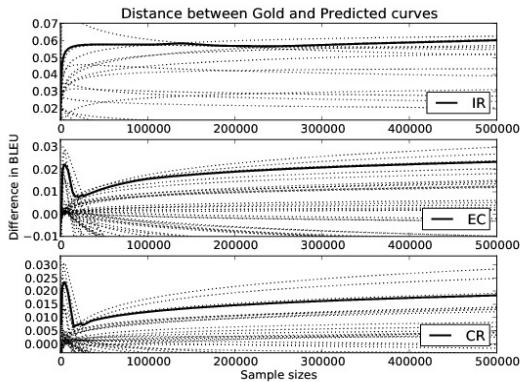

Figure 3: Distances between the predicted and the gold learning curves in our experiments across the range of sample sizes. The dotted lines indicate the distance from gold curve for each instance, while the bold line indicates the 95<sup>th</sup> quantile of the distance between the curves. IR=“Inference using Ridge model”, EC=“Extrapolated curve”, CR=“Combined curve using Ridge”.

We also provide a comparison of the different predicted curves with respect to the gold curve as shown in Figure 4.

Figure 4: Predicted curves in the three scenarios for Czech-English test set using the Lasso model

## 8 Conclusion

The ability to predict the amount of parallel data required to achieve a given level of quality is very valuable in planning business deployments of statistical machine translation; yet, we are not aware of any rigorous proposal for addressing this need.

Here, we proposed methods that can be directly applied to predicting learning curves in realistic scenarios. We identified a suitable parametric family for modeling learning curves via an extensive empirical comparison. We described an *inference* method that requires a minimal initial investment in the form of only a small parallel *test* dataset. For the cases where a slightly larger in-domain “seed” parallel corpus is available, we introduced an *extrapolation* method and a *combined* method yielding high-precision predictions: using models trained on up to 20K sentence pairs we can predict performance on a given test set with a root mean squared error in the order of 1 BLEU point at 75K sentence pairs, and in the order of 2-4 BLEU points at 500K. Considering that variations in the order of 1 BLEU point on a same test dataset can be observed simply due to the instability of the standard MERT parameter tuning algorithm (Foster and Kuhn, 2009; Clark et al., 2011), we believe our results to be close to what can be achieved in principle. Note that by using gold curves as labels instead of actual measures we implicitly average across many rounds of MERT (14 for each curve), greatly attenuating the impact of the instability in the optimization procedure due to randomness.

For enabling this work we trained a multitude of instances of the same phrase-based SMT system on 30 distinct combinations of language-pair and domain, each with fourteen distinct training sets of increasing size and tested these instances on multiple in-domain datasets, generating 96 learning curves. BLEU measurements for all 96 learning curves along with the gold curves and feature values used for inferring the learning curves are available as additional material to this submission.

We believe that it should be possible to use insights from this paper in an active learning setting, to select, from an available monolingual source, a subset of a given size for manual translation, in such a way as to yield the highest performance, and we plan to extend our work in this direction.

## Abstract

This paper presents a probabilistic framework that combines multiple knowledge sources for Haptic Voice Recognition (HVR), a multimodal input method designed to provide efficient text entry on modern mobile devices. HVR extends the conventional voice input by allowing users to provide complementary partial lexical information via touch input to improve the efficiency and accuracy of voice recognition. This paper investigates the use of the initial letter of the words in the utterance as the partial lexical information. In addition to the acoustic and language models used in automatic speech recognition systems, HVR uses the haptic and partial lexical models as additional knowledge sources to reduce the recognition search space and suppress confusions. Experimental results show that both the word error rate and runtime factor can be reduced by a factor of two using HVR.

## 1 Introduction

Nowadays, modern portable devices, such as the smartphones and tablets, are equipped with microphone and touchscreen display. With these devices becoming increasingly popular, there is an urgent need for an efficient and reliable text entry method on these small devices. Currently, text entry using an onscreen virtual keyboard is the most widely adopted input method on these modern mobile devices. Unfortunately, typing with a small virtual keyboard can sometimes be cumbersome and frustratingly slow for many people. Instead of using

a virtual keyboard, it is also possible to use handwriting gestures to input text. Handwriting input offers a more convenient input method for writing systems with complex orthography, including many Asian languages such as Chinese, Japanese and Korean. However, handwriting input is not necessarily more efficient compared to keyboard input for English. Moreover, handwriting recognition is susceptible to recognition errors, too.

Voice input offers a hands-free solution for text entry. This is an attractive alternative for text entry because it completely eliminates the need for typing. Voice input is also more natural and faster for human to convey messages. Normally, the average human speaking rate is approximately 100 words per minute (WPM). Clarkson et al. (2005) showed that the typing speed for regular users reaches only 86.79 – 98.31 using a full-size keyboard and 58.61 – 61.44 WPM using a mini-QWERTY keyboard. Evidently, speech input is the preferred text entry method, provided that speech signals can be reliably and efficiently converted into texts. Unfortunately, voice input relies on automatic speech recognition (ASR) (Rabiner, 1989) technology, which requires high computational resources and is susceptible to performance degradation due to acoustic interference, such as the presence of noise.

In order to improve the reliability and efficiency of ASR, Haptic Voice Recognition (HVR) was proposed by Sim (2010) as a novel multimodal input method combining both speech and touch inputs. Touch inputs are used to generate *haptic events*, which correspond to the initial letters of the words in the spoken utterance. In addition to the regular beam

pruning used in traditional ASR (Ortmanns et al., 1997), search paths which are inconsistent with the haptic events are also pruned away to achieve further reduction in the recognition search space. As a result, the runtime of HVR is generally more efficient than ASR. Furthermore, haptic events are not susceptible to acoustic distortion, making HVR more robust to noise.

This paper proposes a probabilistic framework that encompasses multiple knowledge sources for combining the speech and touch inputs. This framework allows coherent probabilistic models of different knowledge sources to be tightly integrated. In addition to the acoustic model and language model used in ASR, *haptic model* and *partial lexical model* are also introduced to facilitate the integration of more sophisticated haptic events, such as the keystrokes, into HVR.

The remaining of this paper is organised as follows. Section 2 gives an overview of existing techniques in the literature that aim at improving noise robustness for automatic speech recognition. Section 3 gives a brief introduction to HVR. Section 4 proposes a probabilistic framework for HVR that unifies multiple knowledge sources as an integrated probabilistic generative model. Next, Section 5 describes how multiple knowledge sources can be integrated using Weighted Finite State Transducer (WFST) operations. Experimental results are presented in Section 6. Finally, conclusions are given in Section 7.

## 2 Noise Robust ASR

As previously mentioned, the process of converting speech into text using ASR is error-prone, where significant performance degradation is often due to the presence of noise or other acoustic interference. Therefore, it is crucial to improve the robustness of voice input in noisy environment. There are many techniques reported in the literature which aim at improving the robustness of ASR in noisy environment. These techniques can be largely divided into two groups: 1) using speech enhancement techniques to increase the signal-to-noise ratio of the noisy speech (Ortega-Garcia and Gonzalez-Rodriguez, 1996); and 2) using model-based compensation schemes to *adapt* the acoustic models to

noisy environment (Gales and Young, 1996; Acero et al., 2000).

From the information-theoretic point of view, in order to achieve reliable information transmission, *redundancies* are introduced so that information lost due to channel distortion or noise corruption can be recovered. Similar concept can also be applied to improve the robustness of voice input in noisy environment. Additional complementary information can be provided using other input modalities to provide *cues* (redundancies) to boost the recognition performance. The next section will introduce a multimodal interface that combines speech and touch inputs to improve the efficiency and noise robustness for text entry using a technique known as Haptic Voice Recognition (Sim, 2010).

## 3 Haptic Voice Recognition (HVR)

For many voice-enabled applications, users often find voice input to be a *black box* that captures the users' voice and automatically converts it into texts using ASR. It does not provide much flexibility for human intervention through other modalities in case of errors. Certain applications may return multiple hypotheses, from which users can choose the most appropriate output. Any remaining errors are typically corrected manually. However, it may be more useful to give users more control during the input stage, instead of having a post-processing step for error correction. This motivates the investigation of multimodal interface that tightly integrates speech input with other modalities.

Haptic Voice Recognition (HVR) is a multimodal interface designed to offer users the opportunity to add his or her '*magic touch*' in order to improve the accuracy, efficiency and robustness of voice input. HVR is designed for modern mobile devices equipped with an embedded microphone to capture speech signals and a touchscreen display to receive touch events. The HVR interface aims to combine both speech and touch modalities to enhance speech recognition. When using an HVR interface, users will input text verbally, at the same time provide additional cues in the form of *Partial Lexical Information* (PLI) to guide the recognition search. PLIs are simplified lexical representation of words that should be easy to enter whilst speaking (*e.g.* the

prefix and/or suffix letters). Preliminary simulated experiments conducted by Sim (2010) show that potential performance improvements both in terms of recognition speed and noise robustness can be achieved using the initial letters as PLIs. For example, to enter the text “*Henry will be in Boston next Friday*”, the user will speak the sentence and enter the following letter sequence: ‘H’, ‘W’, ‘B’, ‘I’, ‘B’, ‘N’ and ‘F’. These additional letter sequence is simple enough to be entered whilst speaking; and yet they provide crucial information that can significantly improve the efficiency and robustness of speech recognition. For instance, the number of letters entered can be used to constrain the number of words in the recognition output, thereby suppressing spurious insertion and deletion errors, which are commonly observed in noisy environment. Furthermore, the identity of the letters themselves can be used to guide the search process so that partial word sequences in the search graph that do not conform to the PLIs provided by the users can be pruned away.

PLI provides additional complementary information that can be used to eliminate confusions caused by poor speech signal. In conventional ASR, acoustically similar word sequences are typically resolved implicitly using a language model where contexts of neighboring words are used for disambiguation. On the other hand, PLI can also be very effective in disambiguating homophones<sup>1</sup> and similar sounding words and phrases that have distinct initial letters. For example, ‘*hour*’ versus ‘*our*’, ‘*vary*’ versus ‘*marry*’ and ‘*great wine*’ versus ‘*grey twine*’.

This paper considers two methods of generating the initial letter sequence using a touchscreen. The first method requires the user to tap on the appropriate keys on an onscreen virtual keyboard to generate the desired letter sequence. This method is similar to that proposed in Sim (2010). However, typing on small devices like smartphones may require a great deal of concentration and precision from the users. Alternatively, the initial letters can be entered using handwriting gestures. A gesture recognizer can be used to determine the letters entered by the users. In order to achieve high recognition accuracy, each letter is represented by a single-stroke gesture, so that isolated letter recognition can be performed. Fig-

<sup>1</sup>Words with the same pronunciation

ure 1 shows the single-stroke gestures that are used in this work.

#### 4 A Probabilistic Formulation for HVR

Let  $\mathcal{O} = \{\mathbf{o}_1, \mathbf{o}_2, \dots, \mathbf{o}_T\}$  denote a sequence of  $T$  observed acoustic features such as MFCC (Davis and Mermelstein, 1980) or PLP (Hermansky, 1990) and  $\mathcal{H} = \{\mathbf{h}_1, \mathbf{h}_2, \dots, \mathbf{h}_N\}$  denote a sequence of  $N$  haptic features. For the case of keyboard input, each  $\mathbf{h}_i$  is a discrete symbol representing one of the 26 letters. On the other hand, for handwriting input, each  $\mathbf{h}_i$  represents a sequence of 2-dimensional vectors that corresponds to the coordinates of the points of the keystroke. Therefore, the haptic voice recognition problem can be defined as finding the *joint* optimal solution for both the word sequence,  $\hat{\mathcal{W}}$  and the PLI sequence,  $\hat{\mathcal{L}}$ , given  $\mathcal{O}$  and  $\mathcal{H}$ . This can be expressed using the following formulation:

$$(\hat{\mathcal{W}}, \hat{\mathcal{L}}) = \arg \max_{\mathcal{W}, \mathcal{L}} P(\mathcal{W}, \mathcal{L} | \mathcal{O}, \mathcal{H}) \quad (1)$$

where according to the Bayes’ theorem:

$$\begin{aligned} P(\mathcal{W}, \mathcal{L} | \mathcal{O}, \mathcal{H}) &= \frac{p(\mathcal{O}, \mathcal{H} | \mathcal{W}, \mathcal{L}) P(\mathcal{W}, \mathcal{L})}{p(\mathcal{O}, \mathcal{H})} \\ &= \frac{p(\mathcal{O} | \mathcal{W}) p(\mathcal{H} | \mathcal{L}) P(\mathcal{W}, \mathcal{L})}{p(\mathcal{O}, \mathcal{H})} \end{aligned} \quad (2)$$

The joint prior probability of the observed inputs,  $p(\mathcal{O}, \mathcal{H})$ , can be discarded during the maximisation of Eq. 1 since it is independent of  $\mathcal{W}$  and  $\mathcal{L}$ .  $p(\mathcal{O} | \mathcal{W})$  is the acoustic likelihood of the word sequence,  $\mathcal{W}$ , generating the acoustic feature sequence,  $\mathcal{O}$ . Similarly,  $P(\mathcal{H} | \mathcal{L})$  is the *haptic likelihood* of the lexical sequence,  $\mathcal{L}$ , generating the observed haptic inputs,  $\mathcal{H}$ . The *joint* prior probability,  $P(\mathcal{W}, \mathcal{L})$ , can be decomposed into:

$$P(\mathcal{W}, \mathcal{L}) = P(\mathcal{L} | \mathcal{W}) P(\mathcal{W}) \quad (3)$$

where  $P(\mathcal{W})$  can be modelled by the word-based  $n$ -gram language model (Chen and Goodman, 1996) commonly used in automatic speech recognition. Combining Eq. 2 and Eq. 3 yields:

$$\begin{aligned} P(\mathcal{W}, \mathcal{L} | \mathcal{O}, \mathcal{H}) &\propto \\ &p(\mathcal{O} | \mathcal{W}) \times p(\mathcal{H} | \mathcal{L}) \times P(\mathcal{L} | \mathcal{W}) \times P(\mathcal{W}) \end{aligned} \quad (4)$$

It is evident from the above equation that the probabilistic formulation of HVR combines four knowledge sources:

Figure 1: Examples of single-stroke handwriting gestures for the 26 English letters

- Acoustic model score:  $p(\mathcal{O}|\mathcal{W})$
- Haptic model score:  $p(\mathcal{H}|\mathcal{L})$
- PLI model score:  $P(\mathcal{L}|\mathcal{W})$
- Language model score:  $P(\mathcal{W})$

Note that the acoustic model and language model scores are already used in the conventional ASR. The probabilistic formulation of HVR incorporated two additional probabilities: *haptic model score*,  $p(\mathcal{H}|\mathcal{L})$  and *PLI model score*,  $P(\mathcal{L}|\mathcal{W})$ . The role of the haptic model and PLI model will be described in the following sub-sections.

#### 4.1 Haptic Model

Similar to having an acoustic model as a statistical representation of the phoneme sequence generating the observed acoustic features, a haptic model is used to model the PLI sequence generating the observed haptic inputs,  $\mathcal{H}$ . The haptic likelihood can be factorised as

$$p(\mathcal{H}|\mathcal{L}) = \prod_{i=1}^N p(\mathbf{h}_i|l_i) \quad (5)$$

where  $\mathcal{L} = \{l_i : 1 \leq i \leq N\}$ .  $l_i$  is the  $i$ th PLI in  $\mathcal{L}$  and  $\mathbf{h}_i$  is the  $i$ th haptic input feature. In this work, each PLI represent the initial letter of a word. Therefore,  $l_i$  represents one of the 26 letters. As previously mentioned, for keyboard input,  $\mathbf{h}_i$  are discrete features whose values are also one of the 26 letters. Therefore,  $p(\mathbf{h}_i|l_i)$  forms a  $26 \times 26$  matrix. A simple model can be derived by making  $p(\mathbf{h}_i|l_i)$  an identity matrix. Therefore,  $p(\mathbf{h}_i|l_i) = 1$  if  $\mathbf{h}_i = l_i$ ; otherwise,  $p(\mathbf{h}_i|l_i) = 0$ . However, it is also possible to have a non-diagonal matrix for  $p(\mathbf{h}_i|l_i)$  in order to accommodate typing errors, so that non-zero probabilities are assigned to cases where  $\mathbf{h}_i \neq l_i$ .

For handwriting input,  $\mathbf{h}_i$  denote a sequence of 2-dimensional feature vectors, which can be modelled using Hidden Markov Models (HMMs) (Rabiner, 1989). Therefore,  $(\mathbf{h}_i|l_i)$  is simply given by the HMM likelihood. In this work, each of the 26 letters is represented by a left-to-right HMM with 3 emitting states.

#### 4.2 Partial Lexical Information (PLI) Model

Finally, a PLI model is used to impose the compatibility constraint between the PLI sequence,  $\mathcal{L}$ , and the word sequence,  $\mathcal{W}$ . Let  $\mathcal{W} = \{\mathbf{w}_i : 1 \leq i \leq M\}$  denote a word sequence of length  $M$ . If  $M = N$ , the PLI model likelihood,  $P(\mathcal{L}|\mathcal{W})$ , can be expressed in the following form:

$$P(\mathcal{L}|\mathcal{W}) = \prod_{i=1}^N P(l_i|\mathbf{w}_i) \quad (6)$$

where  $P(l_i|\mathbf{w}_i)$  is the likelihood of the  $i$ th word,  $\mathbf{w}_i$ , generating the  $i$ th PLI,  $l_i$ . Since each word is represented by a unique PLI (the initial letter) in this work, the PLI model score is given by

$$P(l_i|\mathbf{w}_i) = C_{\text{sub}} = \begin{cases} 1 & \text{if } l_i = \text{initial letter of } \mathbf{w}_i \\ 0 & \text{otherwise} \end{cases}$$

On the other hand, if  $N \neq M$ , *insertions* and *deletions* have to be taken into consideration:

$$P(l_i = \epsilon|\mathbf{w}_i) = C_{\text{del}} \quad \text{and} \quad P(l_i|\mathbf{w}_i = \epsilon) = C_{\text{ins}}$$

where  $\epsilon$  represents an empty token.  $C_{\text{del}}$  and  $C_{\text{ins}}$  denote the deletion and insertion penalties respectively. This work assumes  $C_{\text{del}} = C_{\text{ins}} = 0$ . This means that the word count of the HVR output matches the length of the initial letter sequence entered by the user. Assigning a non-zero value to  $C_{\text{del}}$  gives the users option to skip entering letters for certain words (*e.g.* short words).

Figure 2: WSFT representation of PLI model,  $\bar{\mathcal{P}}$

## 5 Integration of Knowledge Sources

As previously mentioned, the HVR recognition process involves maximising the posterior probability in Eq. 4, which can be expressed in terms of four knowledge sources. It turns out that these knowledge sources can be represented as Weighted Finite State Transducers (WFSTs) (Mohri et al., 2002) and the *composition* operation ( $\circ$ ) can be used to integrate these knowledge sources into a single WFST:

$$\bar{\mathcal{F}}_{\text{integrated}} = \bar{\mathcal{A}} \circ \bar{\mathcal{L}} \circ \bar{\mathcal{P}} \circ \bar{\mathcal{H}} \quad (7)$$

where  $\bar{\mathcal{A}}$ ,  $\bar{\mathcal{L}}$ ,  $\bar{\mathcal{P}}$  and  $\bar{\mathcal{H}}$  denote the WFST representation of the acoustic model, language model, PLI model and haptic model respectively. Mohri et al. (2002) has shown that Hidden Markov Models (HMMs) and  $n$ -gram language models can be viewed as WFSTs. Furthermore, HMM-based haptic models are also used in this work to represent the single-stroke letters shown in Fig. 1. Therefore,  $\bar{\mathcal{A}}$ ,  $\bar{\mathcal{L}}$ , and  $\bar{\mathcal{H}}$  can be obtained from the respective probabilistic models. Finally, the PLI model described in Section 4.2 can also be represented using the WFST as shown in Fig. 2. The transition weights of these WFSTs are given by the negative log probability of the respective models.  $\bar{\mathcal{P}}$  can be viewed as a merger that defines the possible alignments between the speech and haptic inputs. Each complete path in  $\bar{\mathcal{F}}$  represents a valid pair of  $\mathcal{W}$  and  $\mathcal{L}$  such that the weight of the path is given by the *negative log*  $P(\mathcal{L}, \mathcal{W} | \mathcal{O}, \mathcal{H})$ . Therefore, finding the shortest path in  $\bar{\mathcal{F}}$  is equivalent to solving Eq. 1.

Direct decoding from the overall composed WFST,  $\bar{\mathcal{F}}_{\text{integrated}}$ , is referred to as *integrated decoding*. Alternatively, HVR can also operate in a *lattice rescoring* manner. Speech input and haptic input are processed separately by the ASR system and the haptic model respectively. The ASR system may

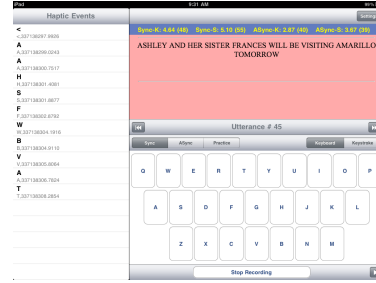

Figure 3: Screenshot depicting the HVR prototype operating with keyboard input

Figure 4: Screenshot depicting the HVR prototype operating with keystroke input

generate multiple hypotheses of word sequences in the form of a lattice. Similarly, the haptic model may also generate a lattice containing the most probably letter sequences. Let  $\hat{\mathcal{L}}$  and  $\hat{\mathcal{H}}$  represent the word and letter lattices respectively. Then, the final HVR output can be obtained by searching for the shortest path of the following merged WFST:

$$\bar{\mathcal{F}}_{\text{rescore}} = \hat{\mathcal{L}} \circ \bar{\mathcal{P}} \circ \hat{\mathcal{H}} \quad (8)$$

Note that the above composition may yield an empty WFST. This may happen if the lattices generated by the ASR system or the haptic model are not large enough to produce any valid pair of  $\mathcal{W}$  and  $\mathcal{L}$ .

## 6 Experimental Results

In this section, experimental results are reported based on the data collected using a prototype HVR interface implemented on an iPad. This prototype HVR interface allows both speech and haptic input data to be captured either synchronously or asynchronously and the partial lexical information can be entered using either a soft keyboard or handwriting gestures. Figures 3 and 4 shows the screenshot of the HVR prototype iPad app using the key-

Donna was in Cincinnati last Thursday.
Adam will be visiting Charlotte tomorrow
Janice will be in Chattanooga next month.
Christine will be visiting Corpus Christi next Tuesday.

Table 1: Example sentences used for data collection.

board and keystroke inputs respectively. Therefore, there are altogether four input configurations. For each configuration, 250 sentences were collected from a non-native fluent English speaker. 200 sentences were used as test data while the remaining 50 sentences were used for acoustic model adaptation. These sentences contain a variety of given names, surnames and city names so that confusions cannot be easily resolved using a language model. Example sentences used for data collection are shown in Table 1. In order to investigate the robustness of HVR in noisy environment, the collected speech data were also artificially corrupted with additive babble noise from the NOISEX database (Varga and Steeneken, 1993) to synthesise noisy speech signal-to-noise (SNR) levels of 20 and 10 decibels<sup>2</sup>.

The ASR system used in all the experiments reported in this paper consists of a set of HMM-based triphone acoustic models and an  $n$ -gram language model. The HMM models were trained using 39-dimensional MFCC features. Each HMM has a left-to-right topology and three emitting states. The emission probability for each state is represented by a single Gaussian component<sup>3</sup>. A bigram language model with a vocabulary size of 200 words was used for testing. The acoustic models were also noise-compensated using VTS (Acero et al., 2000) in order to achieve a better baseline performance.

### 6.1 Comparison of Input Speed

Table 2 shows the speech, letter and total input speed using different input configurations. For synchronous HVR, the total input speed is the same as the speech and letter input speed since both the speech and haptic inputs are provided concurrently. According to this study, synchronous keyboard input speed is 86 words per minutes (WPM). This is

<sup>2</sup>Higher SNR indicates a better speech quality

<sup>3</sup>A single Gaussian component system was used as a compromise between speed and accuracy for mobile apps.

Haptic Input	HVR Mode	Input Speed (WPM)		
		Speech	Letter	Total
Keyboard	Sync	86	86	86
	ASync	100	105	51
Keystroke	Sync	78	78	78
	ASync	97	83	45

Table 2: Comparison of the speech and letter input speed, measured in Words-Per-Minute (WPM), for different HVR input configurations

slightly faster than keystroke input using handwriting gestures, where the input speed is 78 WPM. This is not surprising since key taps are much quicker to generate compared to handwriting gestures. On the other hand, the individual speech and letter input speed are faster for asynchronous mode because users do not need to multi-task. However, since the speech and haptic inputs are provided concurrently, the resulting total input speed for asynchronous HVR is much slower compared to synchronous HVR. Therefore, synchronous HVR is potentially more efficient than asynchronous HVR.

### 6.2 Performance of ASR

HVR Mode	SNR	WER (%)	LER (%)
ASync	Clean	22.2	17.0
	20 dB	30.2	24.2
	10 dB	33.3	28.5
Sync (Keyboard)	Clean	25.9	20.2
	20 dB	34.6	28.8
	10 dB	35.5	29.9
Sync (Keystroke)	Clean	29.0	22.5
	20 dB	40.1	32.0
	10 dB	37.9	31.3

Table 3: WER and LER performance of ASR in different noise conditions

First of all, the Word Error Rate (WER) and Letter Error Rate (LER) performances for standard ASR systems in different noise conditions are summarized in Table 3. These are results using pure ASR, without adding the haptic inputs. Speech recorded using asynchronous HVR is considered normal speech. The ASR system achieved 22.2%, 30.2% and 33.3% WER in clean, 20dB and 10dB

conditions respectively. Note that the acoustic models have been compensated using VTS (Acero et al., 2000) for noisy conditions. Table 3 also shows the system performance considering on the initial letter sequence of the recognition output. This indicates the potential improvements that can be obtained with the additional first letter information. Note that the pure ASR system output contains substantial initial letter errors.

For synchronous HVR, the recorded speech is expected to exhibit different characteristics since it may be influenced by concurrent haptic input. Table 3 shows that there are performance degradations, both in terms of WER and LER, when performing ASR on these speech utterances. Also, the degradations caused by simultaneous keystroke input are greater. The degradation may be caused by phenomena such as the presence of *filled pauses* and the *lengthening* of phoneme duration. Other forms of disfluencies may have also been introduced to the realized speech utterances. Nevertheless, the additional information provided by the PLIs will outweigh these degradations.

### 6.3 Performance of Synchronous HVR

Haptic Input	SNR	WER (%)	LER (%)
Keyboard	Clean	11.8	1.1
	20 dB	12.7	1.0
	10 dB	15.0	1.0
Keystroke	Clean	11.4	0.3
	20 dB	13.1	0.9
	10 dB	14.0	1.0

Table 4: WER and LER performance of synchronous HVR in different noise conditions

The performance of synchronous HVR is shown in Table 4. Compared to the results shown in Table 3, the WER performance of synchronous HVR improved by approximately a factor of two. Furthermore, the LER performance improved significantly. For keyboard input, the LER reduced to about 1.0% for all noise conditions. Note that the tradeoffs between the WER and LER performance can be adjusted by applying appropriately weights to different knowledge sources during integration. For keystroke input, top five letter candidates returned

by the handwriting recognizer were used. Therefore, in clean condition, the acoustic models are able to recover some of the errors introduced by the handwriting recognizer, bringing the LER down to as low as 0.3%. However, in noisy conditions, the LER performance is similar to those using keyboard input. Overall, synchronous and asynchronous HVR achieved WER comparable performance.

### 6.4 Performance of Asynchronous HVR

Haptic Input	SNR	WER (%)	LER (%)
Keyboard	Clean	10.2	0.6
	20 dB	11.2	0.6
	10 dB	13.0	0.6
Keystroke	Clean	10.7	0.4
	20 dB	11.4	1.0
	10 dB	13.4	1.1

Table 5: WER and LER performance of asynchronous HVR in different noise conditions

Similar to synchronous HVR, asynchronous HVR also achieved significant performance improvements over the pure ASR systems. Table 5 shows the WER and LER performance of asynchronous HVR in different noise conditions. The WER performance of asynchronous HVR is consistently better than that of synchronous HVR (comparing Tables 4 and 5). This is expected since the speech quality for asynchronous HVR is higher. However, considering the much slower input speed (*c.f.* Table 2) and the marginal WER improvements for asynchronous HVR, synchronous HVR appears to be a better configuration.

### 6.5 Integrated Decoding vs. Lattice Rescoring

SNR	WER (%)		
	Clean	20dB	10dB
Integrated	11.8	12.7	15.0
Lat-rescore	11.2	18.6	18.1

Table 6: WER performance of keyboard synchronous HVR using integrated decoding and lattice rescoring

As previously mentioned in Section 5, HVR can also be performed in two stages using lattice rescoring technique. Table 6 shows the performance

comparison between integrated decoding and lattice rescoring for HVR. Both methods gave similar performance in clean condition. However, lattice rescoring yielded significantly worse performance in noisy environment. Therefore, it is important to tightly integrate the PLI into the decoding process to avoid premature pruning away optimal paths.

## 6.6 Runtime Performance

ASR system searches for the best word sequence using a dynamic programming paradigm (Ney and Ortmanns, 1999). The complexity of the search increases with the vocabulary size as well as the length of the input speech. A well-known concept of *Token Passing* (Young et al., 1989) can be used to describe the recognition search process. A set of active tokens are being propagated upon observing an acoustic feature frame. The best token that survived to the end of the utterance represents the best output. Typically, beam pruning technique (Ortmanns et al., 1997) is applied to improve the recognition efficiency. Tokens which are unlikely to yield the optimal solution will be pruned away. HVR performs a more stringent pruning, where paths that do not conform to the PLI sequence are also be pruned away.

System	SNR	RT	Active Tokens Per Frame
ASR	Clean	1.9	6260
	20 dB	2.0	6450
	10 dB	2.4	7168
Keyboard	Clean	0.9	3490
	20 dB	0.9	3764
	10 dB	1.0	4442
Keystroke	Clean	1.1	4059
	20 dB	1.2	4190
	10 dB	1.5	4969

Table 7: WER and LER performance of integrated and rescoring synchronous HVR in different noise conditions

Table 7 shows the comparison of the runtime factors and the average number of active tokens per frame for ASR and HVR systems. The standard ASR system runs at 1.9, 2.0 and 2.4 times real-time (xRT)<sup>4</sup>. The runtime factor increases with de-

<sup>4</sup>Runtime factor is computed as the ratio between the recognition duration and the input speech duration

creasing SNR because the presence of noise introduces more confusions, which renders beam pruning (Ortmanns et al., 1997) less effective. The number of active tokens per frame also increases from 6260 to 7168 as the SNR drops from the clean condition to 10dB. On the other hand, there are significant speedup in the runtime of HVR systems. In particular, synchronous HVR achieved the best runtime performance, which is roughly consistent across different noise conditions (approximately 1.0 xRT). The average number of active tokens also reduces to the range of 3490 – 4442. Therefore, the synchronous HVR using keyboard input is robust to noisy environment, both in terms of WER and runtime performance. The runtime performance using keystroke input is also comparable to that using keyboard input (only slightly worse). Therefore, both keyboard and keystroke inputs are effective ways for entering the initial letters for HVR. However, it is worth noting that the iPad was used for the studies conducted in this work. The size of the iPad screen is sufficiently large to allow efficient keyboard entry. However, for devices with smaller screen, keystroke inputs may be easier to use and less error-prone.

## 7 Conclusions

This paper has presented a unifying probabilistic framework for the multimodal Haptic Voice Recognition (HVR) interface. HVR offers users the option to interact with the system using touchscreen during voice input so that additional *cues* can be provided to improve the efficiency and robustness of voice recognition. Partial Lexical Information (PLI), such as the initial letter of the words, are used as cues to guide the recognition search process. Therefore, apart from the acoustic and language models used in conventional ASR, HVR also combines the haptic model as well as the PLI model to yield an integrated probabilistic model. This probabilistic framework integrates multiple knowledge sources using the weighted finite state transducer operation. Such integration is achieved using the composition operation which can be applied on-the-fly to yield efficient implementation. Experimental results show that this framework can be used to achieve a more efficient and robust multimodal interface for text entry on modern portable devices.

## Abstract

We investigate the problem of acoustic modeling in which prior language-specific knowledge and transcribed data are unavailable. We present an unsupervised model that simultaneously segments the speech, discovers a proper set of sub-word units (e.g., phones) and learns a Hidden Markov Model (HMM) for each induced acoustic unit. Our approach is formulated as a Dirichlet process mixture model in which each mixture is an HMM that represents a sub-word unit. We apply our model to the TIMIT corpus, and the results demonstrate that our model discovers sub-word units that are highly correlated with English phones and also produces better segmentation than the state-of-the-art unsupervised baseline. We test the quality of the learned acoustic models on a spoken term detection task. Compared to the baselines, our model improves the relative precision of top hits by at least 22.1% and outperforms a language-mismatched acoustic model.

## 1 Introduction

Acoustic models are an indispensable component of speech recognizers. However, the standard process of training acoustic models is expensive, and requires not only language-specific knowledge, e.g., the phone set of the language, a pronunciation dictionary, but also a large amount of transcribed data. Unfortunately, these necessary data are only available for a very small number of languages in the world. Therefore, a procedure for training acoustic models without annotated data would not only be a breakthrough from the traditional approach, but

would also allow us to build speech recognizers for any language efficiently.

In this paper, we investigate the problem of unsupervised acoustic modeling with only spoken utterances as training data. As suggested in Garcia and Gish (2006), unsupervised acoustic modeling can be broken down to three sub-tasks: segmentation, clustering segments, and modeling the sound pattern of each cluster. In previous work, the three sub-problems were often approached sequentially and independently in which initial steps are not related to later ones (Lee et al., 1988; Garcia and Gish, 2006; Chan and Lee, 2011). For example, the speech data was usually segmented regardless of the clustering results and the learned acoustic models.

In contrast to the previous methods, we approach the problem by modeling the three sub-problems as well as the unknown set of sub-word units as latent variables in one nonparametric Bayesian model. More specifically, we formulate a Dirichlet process mixture model where each mixture is a Hidden Markov Model (HMM) used to model a sub-word unit and to generate observed segments of that unit. Our model seeks the set of sub-word units, segmentation, clustering and HMMs that best represent the observed data through an iterative inference process. We implement the inference process using Gibbs sampling.

We test the effectiveness of our model on the TIMIT database (Garofolo et al., 1993). Our model shows its ability to discover sub-word units that are highly correlated with standard English phones and to capture acoustic context information. For the segmentation task, our model outperforms the state-of-

the-art unsupervised method and improves the relative F-score by 18.8 points (Dusan and Rabiner, 2006). Finally, we test the quality of the learned acoustic models through a keyword spotting task. Compared to the state-of-the-art unsupervised methods (Zhang and Glass, 2009; Zhang et al., 2012), our model yields a relative improvement in precision of top hits by at least 22.1% with only some degradation in equal error rate (EER), and outperforms a language-mismatched acoustic model trained with supervised data.

## 2 Related Work

**Unsupervised Sub-word Modeling** We follow the general guideline used in (Lee et al., 1988; Garcia and Gish, 2006; Chan and Lee, 2011) and approach the problem of unsupervised acoustic modeling by solving three sub-problems of the task: segmentation, clustering and modeling each cluster. The key difference, however, is that our model does not assume independence among the three aspects of the problem, which allows our model to refine its solution to one sub-problem by exploiting what it has learned about other parts of the problem. Second, unlike (Lee et al., 1988; Garcia and Gish, 2006) in which the number of sub-word units to be learned is assumed to be known, our model learns the proper size from the training data directly.

Instead of segmenting utterances, the authors of (Varadarajan et al., 2008) trained a single state HMM using all data at first, and then iteratively split the HMM states based on objective functions. This method achieved high performance in a phone recognition task using a label-to-phone transducer trained from some transcriptions. However, the performance seemed to rely on the quality of the transducer. For our work, we assume no transcriptions are available and measure the quality of the learned acoustic units via a spoken query detection task as in Jansen and Church (2011).

Jansen and Church (2011) approached the task of unsupervised acoustic modeling by first discovering repetitive patterns in the data, and then learned a whole-word HMM for each found pattern, where the state number of each HMM depends on the average length of the pattern. The states of the whole-word HMMs were then collapsed and used to represent

acoustic units. Instead of discovering repetitive patterns first, our model is able to learn from any given data.

**Unsupervised Speech Segmentation** One goal of our model is to segment speech data into small sub-word (e.g., phone) segments. Most unsupervised speech segmentation methods rely on acoustic change for hypothesizing phone boundaries (Scharenborg et al., 2010; Qiao et al., 2008; Dusan and Rabiner, 2006; Estevan et al., 2007). Even though the overall approaches differ, these algorithms are all one-stage and bottom-up segmentation methods (Scharenborg et al., 2010). Our model does not make a single one-stage decision; instead, it infers the segmentation through an iterative process and exploits the learned sub-word models to guide its hypotheses on phone boundaries.

**Bayesian Model for Segmentation** Our model is inspired by previous applications of nonparametric Bayesian models to segmentation problems in NLP and speaker diarization (Goldwater, 2009; Fox et al., 2011); particularly, we adapt the inference method used in (Goldwater, 2009) to our segmentation task. Our problem is, in principle, similar to the word segmentation problem discussed in (Goldwater, 2009). The main difference, however, is that our model is under the continuous real value domain, and the problem of (Goldwater, 2009) is under the discrete symbolic domain. For the domain our problem is applied to, our model has to include more latent variables and is more complex.

## 3 Problem Formulation

The goal of our model, given a set of spoken utterances, is to jointly learn the following:

- Segmentation: To find the phonetic boundaries within each utterance.
- Nonparametric clustering: To find a proper set of clusters and group acoustically similar segments into the same cluster.
- Sub-word modeling: To learn a HMM to model each sub-word acoustic unit.

We model the three sub-tasks as latent variables in our approach. In this section, we describe the observed data, latent variables, and auxiliary variables

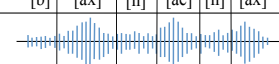

Pronunciation	b		a		n		a		n		a

Mixture ID	1	1	6	8	3	7	5	2	8	2	8	

Figure 1: An example of the observed data and hidden variables of the problem for the word *banana*. See Section 3 for a detailed explanation.

of the problem and show an example in Fig. 1. In the next section, we show the generative process our model uses to generate the observed data.

**Speech Feature ( $x_t^i$ )** The only observed data for our problem are a set of spoken utterances, which are converted to a series of 25 ms 13-dimensional Mel-Frequency Cepstral Coefficients (MFCCs) (Davis and Mermelstein, 1980) and their first- and second-order time derivatives at a 10 ms analysis rate. We use  $x_t^i \in \mathbb{R}^{39}$  to denote the  $t^{\text{th}}$  feature frame of the  $i^{\text{th}}$  utterance. Fig. 1 illustrates how the speech signal of a single word utterance *banana* is converted to a sequence of feature vectors  $x_1^i$  to  $x_{11}^i$ .

**Boundary ( $b_t^i$ )** We use a binary variable  $b_t^i$  to indicate whether a phone boundary exists between  $x_t^i$  and  $x_{t+1}^i$ . If our model hypothesizes  $x_t^i$  to be the last frame of a sub-word unit, which is called a *boundary frame* in this paper,  $b_t^i$  is assigned with value 1; or 0 otherwise. Fig. 1 shows an example of the boundary variables where the values correspond to the true answers. We use an auxiliary variable  $g_q^i$  to denote the index of the  $q^{\text{th}}$  boundary frame in utterance  $i$ . To make the derivation of posterior distributions easier in Section 5, we define  $g_0^i$  to be the beginning of an utterance, and  $L_i$  to be the number of boundary frames in an utterance. For the example shown in Fig. 1,  $L_i$  is equal to 6.

**Segment ( $p_{j,k}^i$ )** We define a segment to be composed of feature vectors between two boundary frames. We use  $p_{j,k}^i$  to denote a segment that consists of  $x_j^i, x_{j+1}^i \dots x_k^i$  and  $d_{j,k}^i$  to denote the length of  $p_{j,k}^i$ . See Fig. 1 for more examples.

**Cluster Label ( $c_{j,k}^i$ )** We use  $c_{j,k}^i$  to specify the cluster label of  $p_{j,k}^i$ . We assume segment  $p_{j,k}^i$  is generated by the sub-word HMM with label  $c_{j,k}^i$ .

**HMM ( $\theta_c$ )** In our model, each HMM has three emission states, which correspond to the beginning, middle and end of a sub-word unit (Jelinek, 1976). A traversal of each HMM must start from the first state, and only left-to-right transitions are allowed even though we allow skipping of the middle and the last state for segments shorter than three frames. The emission probability of each state is modeled by a diagonal Gaussian Mixture Model (GMM) with 8 mixtures. We use  $\theta_c$  to represent the set of parameters that define the  $c^{\text{th}}$  HMM, which includes state transition probability  $a_c^{j,k}$ , and the GMM parameters of each state emission probability. We use  $w_{c,s}^m \in \mathbb{R}$ ,  $\mu_{c,s}^m \in \mathbb{R}^{39}$  and  $\lambda_{c,s}^m \in \mathbb{R}^{39}$  to denote the weight, mean vector and the diagonal of the inverse covariance matrix of the  $m^{\text{th}}$  mixture in the GMM for the  $s^{\text{th}}$  state in the  $c^{\text{th}}$  HMM.

**Hidden State ( $s_t^i$ )** Since we assume the observed data are generated by HMMs, each feature vector,  $x_t^i$ , has an associated hidden state index. We denote the hidden state of  $x_t^i$  as  $s_t^i$ .

**Mixture ID ( $m_t^i$ )** Similarly, each feature vector is assumed to be emitted by the state GMM it belongs to. We use  $m_t^i$  to identify the Gaussian mixture that generates  $x_t^i$ .

## 4 Model

We aim to discover and model a set of sub-word units that represent the spoken data. If we think of utterances as sequences of repeated sub-word units, then in order to find the sub-words, we need a model that concentrates probability on highly frequent patterns while still preserving probability for previously unseen ones. Dirichlet processes are particularly suitable for our goal. Therefore, we construct our model as a Dirichlet Process (DP) mixture model, of which the components are HMMs that are used

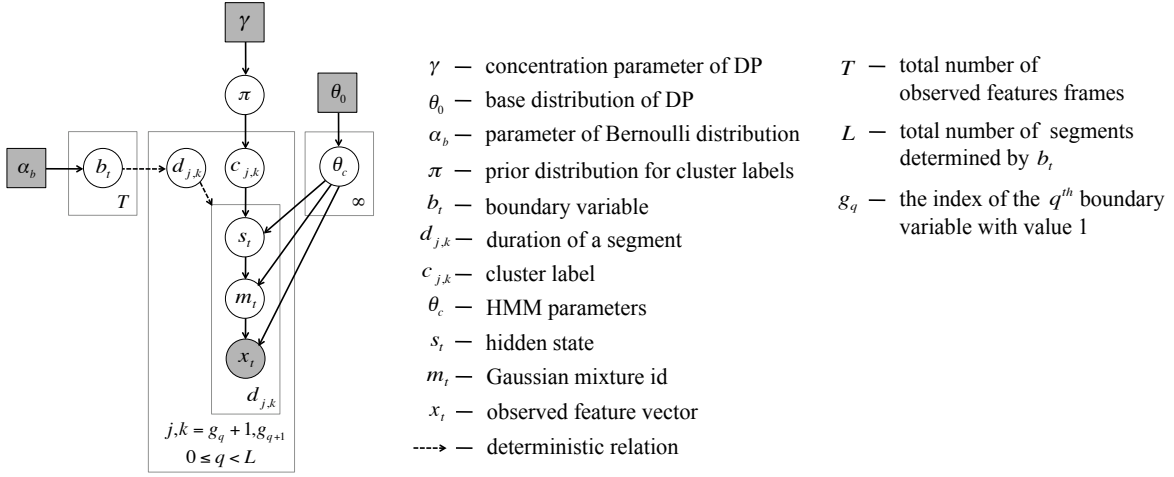

Figure 2: The graphical model for our approach. The shaded circle denotes the observed feature vectors, and the squares denote the hyperparameters of the priors used in our model. The dotted arrows indicate deterministic relations. Note that the Markov chain structure over the  $s_t$  variables is not shown here due to limited space.

to model sub-word units. We assume each spoken segment is generated by one of the clusters in this DP mixture model. Here, we describe the generative process our model uses to generate the observed utterances and present the corresponding graphical model. For clarity, we assume that the values of the boundary variables  $b_t^i$  are given in the generative process. In the next section, we explain how to infer their values.

Let  $p_{g_q^i+1, g_{q+1}^i}$  for  $0 \leq q \leq L_i - 1$  be the segments of the  $i^{th}$  utterance. Our model assumes each segment is generated as follows:

1. Choose a cluster label  $c_{g_q^i+1, g_{q+1}^i}^i$  for  $p_{g_q^i+1, g_{q+1}^i}^i$ . This cluster label can be either an existing label or a new one. Note that the cluster label determines which HMM is used to generate the segment.
2. Given the cluster label, choose a hidden state for each feature vector  $x_t^i$  in the segment.
3. For each  $x_t^i$ , based on its hidden state, choose a mixture from the GMM of the chosen state.
4. Use the chosen Gaussian mixture to generate the observed feature vector  $x_t^i$ .

The generative process indicates that our model ignores utterance boundaries and views the entire data as concatenated spoken segments. Given this

viewpoint, we discard the utterance index,  $i$ , of all variables in the rest of the paper.

The graphical model representing this generative process is shown in Fig. 2, where the shaded circle denotes the observed feature vectors, and the squares denote the hyperparameters of the priors used in our model. Specifically, we use a Bernoulli distribution as the prior of the boundary variables and impose a Dirichlet process prior on the cluster labels and the HMM parameters. The dotted arrows represent deterministic relations. For example, the boundary variables deterministically construct the duration of each segment,  $d$ , which in turn sets the number of feature vectors that should be generated for a segment. In the next section, we show how to infer the value of each of the latent variables in Fig. 2<sup>1</sup>.

## 5 Inference

We employ Gibbs sampling (Gelman et al., 2004) to approximate the posterior distribution of the hidden variables in our model. To apply Gibbs sampling to our problem, we need to derive the conditional posterior distributions of each hidden variable of the model. In the following sections, we first derive the sampling equations for each hidden variable and then describe how we incorporate acoustic cues to reduce the sampling load at the end.

<sup>1</sup>Note that the value of  $\pi$  is irrelevant to our problem; therefore, it is integrated out in the inference process

## 5.1 Sampling Equations

Here we present the sampling equations for each hidden variable defined in Section 3. We use  $P(\cdot|\dots)$  to denote a conditional posterior probability given observed data, all the other variables, and hyperparameters for the model.

**Cluster Label ( $c_{j,k}$ )** Let  $C$  be the set of distinctive label values in  $c_{-j,k}$ , which represents all the cluster labels except  $c_{j,k}$ . The conditional posterior probability of  $c_{j,k}$  for  $c \in C$  is:

$$P(c_{j,k} = c|\dots) \propto P(c_{j,k} = c|c_{-j,k}; \gamma)P(p_{j,k}|\theta_c) \\ = \frac{n^{(c)}}{N - 1 + \gamma}P(p_{j,k}|\theta_c) \quad (1)$$

where  $\gamma$  is a parameter of the DP prior. The first line of Eq. 1 follows Bayes' rule. The first term is the conditional prior, which is a result of the DP prior imposed on the cluster labels<sup>2</sup>. The second term is the conditional likelihood, which reflects how likely the segment  $p_{j,k}$  is generated by  $\text{HMM}_c$ . We use  $n^{(c)}$  to represent the number of cluster labels in  $c_{-j,k}$  taking the value  $c$  and  $N$  to represent the total number of segments in current segmentation.

In addition to existing cluster labels,  $c_{j,k}$  can also take a new cluster label, which corresponds to a new sub-word unit. The corresponding conditional posterior probability is:

$$P(c_{j,k} \neq c, c \in C|\dots) \propto \frac{\gamma}{N - 1 + \gamma} \int_{\theta} P(p_{j,k}|\theta) d\theta \quad (2)$$

To deal with the integral in Eq. 2, we follow the suggestions in (Rasmussen, 2000; Neal, 2000). We sample an HMM from the prior and compute the likelihood of the segment given the new HMM to approximate the integral.

Finally, by normalizing Eq. 1 and Eq. 2, the Gibbs sampler can draw a new value for  $c_{j,k}$  by sampling from the normalized distribution.

**Hidden State ( $s_t$ )** To enforce the assumption that a traversal of an HMM must start from the first state and end at the last state<sup>3</sup>, we do not sample hidden state indices for the first and the last frame of a segment. For each of the remaining feature vectors in

<sup>2</sup>See (Neal, 2000) for an overview on Dirichlet process mixture models and the inference methods.

<sup>3</sup>If a segment has only 1 frame, we assign the first state to it.

a segment  $p_{j,k}$ , we sample a hidden state index according to the conditional posterior probability:

$$P(s_t = s|\dots) \propto \\ P(s_t = s|s_{t-1})P(x_t|\theta_{c_{j,k}}, s_t = s)P(s_{t+1}|s_t = s) \\ = a_{c_{j,k}}^{s_{t-1}, s}P(x_t|\theta_{c_{j,k}}, s_t = s)a_{c_{j,k}}^{s, s_{t+1}} \quad (3)$$

where the first term and the third term are the conditional prior – the transition probability of the HMM that  $p_{j,k}$  belongs to. The second term is the likelihood of  $x_t$  being emitted by state  $s$  of  $\text{HMM}_{c_{j,k}}$ . Note for initialization,  $s_t$  is sampled from the first prior term in Eq. 3.

**Mixture ID ( $m_t$ )** For each feature vector in a segment, given the cluster label  $c_{j,k}$  and the hidden state index  $s_t$ , the derivation of the conditional posterior probability of its mixture ID is straightforward:

$$P(m_t = m|\dots) \\ \propto P(m_t = m|\theta_{c_{j,k}}, s_t)P(x_t|\theta_{c_{j,k}}, s_t, m_t = m) \\ = w_{c_{j,k}, s_t}^m P(x_t|\mu_{c_{j,k}, s_t}^m, \lambda_{c_{j,k}, s_t}^m) \quad (4)$$

where  $1 \leq m \leq 8$ . The conditional posterior consists of two terms: 1) the mixing weight of the  $m^{\text{th}}$  Gaussian in the state GMM indexed by  $c_{j,k}$  and  $s_t$  and 2) the likelihood of  $x_t$  given the Gaussian mixture. The sampler draws a value for  $m_t$  from the normalized distribution of Eq. 4.

**HMM Parameters ( $\theta_c$ )** Each  $\theta_c$  consists of two sets of variables that define an HMM: the state emission probabilities  $w_{c,s}^m, \mu_{c,s}^m, \lambda_{c,s}^m$  and the state transition probabilities  $a_c^{j,k}$ . In the following, we derive the conditional posteriors of these variables.

**Mixture Weight  $w_{c,s}^m$ :** We use  $\underline{w}_{c,s} = \{w_{c,s}^m | 1 \leq m \leq 8\}$  to denote the mixing weights of the Gaussian mixtures of state  $s$  of HMM  $c$ . We choose a symmetric Dirichlet distribution with a positive hyperparameter  $\beta$  as its prior. The conditional posterior probability of  $\underline{w}_{c,s}$  is:

$$P(\underline{w}_{c,s}|\dots) \propto P(\underline{w}_{c,s}; \beta)P(\mathbf{m}_{c,s}|\underline{w}_{c,s}) \\ \propto \text{Dir}(\underline{w}_{c,s}; \beta)\text{Mul}(\mathbf{m}_{c,s}; \underline{w}_{c,s}) \\ \propto \text{Dir}(\underline{w}_{c,s}; \beta') \quad (5)$$

where  $\mathbf{m}_{c,s}$  is the set of mixture IDs of feature vectors that belong to state  $s$  of HMM  $c$ . The  $m^{\text{th}}$  entry of  $\beta'$  is  $\beta + \sum_{m_t \in \mathbf{m}_{c,s}} \delta(m_t, m)$ , where we use  $\delta(\cdot)$

$$\begin{aligned}
P(p_{l,t}, p_{t+1,r} | \mathbf{c}^-, \boldsymbol{\theta}) &= P(p_{l,t} | \mathbf{c}^-, \boldsymbol{\theta}) P(p_{t+1,r} | \mathbf{c}^-, c_{l,t}, \boldsymbol{\theta}) \\
&= \left[ \sum_{c \in \mathcal{C}} \frac{n^{(c)}}{N^- + \gamma} P(p_{l,t} | \theta_c) + \frac{\gamma}{N^- + \gamma} \int_{\theta} P(p_{l,t} | \theta) d\theta \right] \\
&\quad \times \left[ \sum_{c \in \mathcal{C}} \frac{n^{(c)} + \delta(c_{l,t}, c)}{N^- + 1 + \gamma} P(p_{t+1,r} | \theta_c) + \frac{\gamma}{N^- + 1 + \gamma} \int_{\theta} P(p_{t+1,r} | \theta) d\theta \right] \\
P(p_{l,r} | \mathbf{c}^-, \boldsymbol{\theta}) &= \sum_{c \in \mathcal{C}} \frac{n^{(c)}}{N^- + \gamma} P(p_{l,r} | \theta_c) + \frac{\gamma}{N^- + \gamma} \int_{\theta} P(p_{l,r} | \theta) d\theta
\end{aligned}$$

Figure 3: The full derivation of the relative conditional posterior probabilities of a boundary variable.

to denote the discrete Kronecker delta. The last line of Eq. 5 comes from the fact that Dirichlet distributions are a conjugate prior for multinomial distributions. This property allows us to derive the update rule analytically.

**Gaussian Mixture**  $\mu_{c,s}^m, \lambda_{c,s}^m$ : We assume the dimensions in the feature space are independent. This assumption allows us to derive the conditional posterior probability for a single-dimensional Gaussian and generalize the results to other dimensions.

Let the  $d^{\text{th}}$  entry of  $\mu_{c,s}^m$  and  $\lambda_{c,s}^m$  be  $\mu_{c,s}^{m,d}$  and  $\lambda_{c,s}^{m,d}$ . The conjugate prior we use for the two variables is a normal-Gamma distribution with hyperparameters  $\mu_0, \kappa_0, \alpha_0$  and  $\beta_0$  (Murphy, 2007).

$$\begin{aligned}
&P(\mu_{c,s}^{m,d}, \lambda_{c,s}^{m,d} | \mu_0, \kappa_0, \alpha_0, \beta_0) \\
&= N(\mu_{c,s}^{m,d} | \mu_0, (\kappa_0 \lambda_{c,s}^{m,d})^{-1}) Ga(\lambda_{c,s}^{m,d} | \alpha_0, \beta_0)
\end{aligned}$$

By tracking the  $d^{\text{th}}$  dimension of feature vectors  $x \in \{x_t | m_t = m, s_t = s, c_{j,k} = c, x_t \in p_{j,k}\}$ , we can derive the conditional posterior distribution of  $\mu_{c,s}^{m,d}$  and  $\lambda_{c,s}^{m,d}$  analytically following the procedures shown in (Murphy, 2007). Due to limited space, we encourage interested readers to find more details in (Murphy, 2007).

**Transition Probabilities**  $a_c^{j,k}$ : We represent the transition probabilities at state  $j$  in HMM  $c$  using  $\underline{a}_c^j$ . If we view  $\underline{a}_c^j$  as mixing weights for states reachable from state  $j$ , we can simply apply the update rule derived for the mixing weights of Gaussian mixtures shown in Eq. 5 to  $\underline{a}_c^j$ . Assume we use a symmetric Dirichlet distribution with a positive hyperparameter  $\eta$  as the prior, the conditional posterior for  $\underline{a}_c^j$  is:

$$P(\underline{a}_c^j | \dots) \propto Dir(\underline{a}_c^j; \eta')$$

where the  $k^{\text{th}}$  entry of  $\eta'$  is  $\eta + n_c^{j,k}$ , the number of occurrences of the state transition pair  $(j, k)$  in segments that belong to HMM  $c$ .

**Boundary Variable** ( $b_t$ ) To derive the conditional posterior probability for  $b_t$ , we introduce two variables:

$$\begin{aligned}
l &= (\arg \max_{g_q} g_q < t) + 1 \\
r &= \arg \min_{g_q} t < g_q
\end{aligned}$$

where  $l$  is the index of the closest turned-on boundary variable that precedes  $b_t$  plus 1, while  $r$  is the index of the closest turned-on boundary variable that follows  $b_t$ . Note that because  $g_0$  and  $g_L$  are defined,  $l$  and  $r$  always exist for any  $b_t$ .

Note that the value of  $b_t$  only affects segmentation between  $x_l$  and  $x_r$ . If  $b_t$  is turned on, the sampler hypothesizes two segments  $p_{l,t}$  and  $p_{t+1,r}$  between  $x_l$  and  $x_r$ . Otherwise, only one segment  $p_{l,r}$  is hypothesized. Since the segmentation on the rest of the data remains the same no matter what value  $b_t$  takes, the conditional posterior probability of  $b_t$  is:

$$P(b_t = 1 | \dots) \propto P(p_{l,t}, p_{t+1,r} | \mathbf{c}^-, \boldsymbol{\theta}) \quad (6)$$

$$P(b_t = 0 | \dots) \propto P(p_{l,r} | \mathbf{c}^-, \boldsymbol{\theta}) \quad (7)$$

where we assume that the prior probabilities for  $b_t = 1$  and  $b_t = 0$  are equal;  $\mathbf{c}^-$  is the set of cluster labels of all segments except those between  $x_l$  and  $x_r$ ; and  $\boldsymbol{\theta}$  indicates the set of HMMs that have associated segments. Our Gibbs sampler hypothesizes  $b_t$ 's value by sampling from the normalized distribution of Eq. 6 and Eq. 7. The full derivations of Eq. 6 and Eq. 7 are shown in Fig. 3.

Note that in Fig. 3,  $N^-$  is the total number of segments in the data except those between  $x_l$  and  $x_r$ .

For  $b_t = 1$ , to account the fact that when the model generates  $p_{t+1,r}$ ,  $p_{l,t}$  is already generated and owns a cluster label, we sample a cluster label for  $p_{l,t}$  that is reflected in the Kronecker delta function. To handle the integral in Fig. 3, we sample one HMM from the prior and compute the likelihood using the new HMM to approximate the integral as suggested in (Rasmussen, 2000; Neal, 2000).

## 5.2 Heuristic Boundary Elimination

To reduce the inference load on the boundary variables  $b_t$ , we exploit acoustic cues in the feature space to eliminate  $b_t$ 's that are unlikely to be phonetic boundaries. We follow the pre-segmentation method described in Glass (2003) to achieve the goal. For the rest of the boundary variables that are proposed by the heuristic algorithm, we randomly initialize their values and proceed with the sampling process described above.

## 6 Experimental Setup

To the best of our knowledge, there are no standard corpora for evaluating unsupervised methods for acoustic modeling. However, numerous related studies have reported performance on the TIMIT corpus (Dusan and Rabiner, 2006; Estevan et al., 2007; Qiao et al., 2008; Zhang and Glass, 2009; Zhang et al., 2012), which creates a set of strong baselines for us to compare against. Therefore, the TIMIT corpus is chosen as the evaluation set for our model. In this section, we describe the methods used to measure the performance of our model on the following three tasks: sub-word acoustic modeling, segmentation and nonparametric clustering.

**Unsupervised Segmentation** We compare the phonetic boundaries proposed by our model to the manual labels provided in the TIMIT dataset. We follow the suggestion of (Scharenborg et al., 2010) and use a 20-ms tolerance window to compute recall, precision rates and F-score of the segmentation our model proposed for TIMIT's training set. We compare our model against the state-of-the-art unsupervised and semi-supervised segmentation methods that were also evaluated on the TIMIT training set (Dusan and Rabiner, 2006; Qiao et al., 2008).

**Nonparametric Clustering** Our model automatically groups speech segments into different clus-

ters. One question we are interested in answering is whether these learned clusters correlate to English phones. To answer the question, we develop a method to map cluster labels to the phone set in a dataset. We align each cluster label in an utterance to the phone(s) it overlaps with in time by using the boundaries proposed by our model and the manually-labeled ones. When a cluster label overlaps with more than one phone, we align it to the phone with the largest overlap.<sup>4</sup> We compile the alignment results for 3696 training utterances<sup>5</sup> and present a confusion matrix between the learned cluster labels and the 48 phonetic units used in TIMIT (Lee and Hon, 1989).

**Sub-word Acoustic Modeling** Finally, and most importantly, we need to gauge the quality of the learned sub-word acoustic models. In previous work, Varadarajan et al. (2008) and Garcia and Gish (2006) tested their models on a phone recognition task and a term detection task respectively. These two tasks are fair measuring methods, but performance on these tasks depends not only on the learned acoustic models, but also other components such as the label-to-phone transducer in (Varadarajan et al., 2008) and the grapheme model in (Garcia and Gish, 2006). To reduce performance dependencies on components other than the acoustic model, we turn to the task of spoken term detection, which is also the measuring method used in (Jansen and Church, 2011).

We compare our unsupervised acoustic model with three supervised ones: 1) an English triphone model, 2) an English monophone model and 3) a Thai monophone model. The first two were trained on TIMIT, while the Thai monophone model was trained with 32 hour clean read Thai speech from the LOTUS corpus (Kasuriya et al., 2003). All of the three models, as well as ours, used three-state HMMs to model phonetic units. To conduct spoken term detection experiments on the TIMIT dataset, we computed a posteriorigram representation for both training and test feature frames over the

<sup>4</sup>Except when a cluster label is mapped to /vcl/ /b/, /vcl/ /g/ and /vcl/ /d/, where the duration of the release /b/, /g/, /d/ is almost always shorter than the closure /vcl/. In this case, we align the cluster label to both the closure and the release.

<sup>5</sup>The TIMIT training set excluding the sa-type subset.

$\gamma$	$\alpha_b$	$\beta$	$\eta$	$\mu_0$	$\kappa_0$	$\alpha_0$	$\beta_0$
1	0.5	3	3	$\mu^d$	5	3	$3/\lambda^d$

Table 1: The values of the hyperparameters of our model, where  $\mu^d$  and  $\lambda^d$  are the  $d^{\text{th}}$  entry of the mean and the diagonal of the inverse covariance matrix of training data.

HMM states for each of the four models. Ten keywords were randomly selected for the task. For every keyword, spoken examples were extracted from the training set and were searched for in the test set using segmental dynamic time warping (Zhang and Glass, 2009).

In addition to the supervised acoustic models, we also compare our model against the state-of-the-art unsupervised methods for this task (Zhang and Glass, 2009; Zhang et al., 2012). Zhang and Glass (2009) trained a GMM with 50 components to decode posteriorgrams for the feature frames, and Zhang et al. (2012) used a deep Boltzmann machine (DBM) trained with pseudo phone labels generated from an unsupervised GMM to produce a posteriorgram representation. The evaluation metrics they used were: 1) P@N, the average precision of the top N hits, where N is the number of occurrences of each keyword in the test set; 2) EER: the average equal error rate at which the false acceptance rate is equal to the false rejection rate. We also report experimental results using the P@N and EER metrics.

**Hyperparameters and Training Iterations** The values of the hyperparameters of our model are shown in Table 1, where  $\mu^d$  and  $\lambda^d$  are the  $d^{\text{th}}$  entry of the mean and the diagonal of the inverse covariance matrix computed from training data. We pick these values to impose weak priors on our model.<sup>6</sup> We run our sampler for 20,000 iterations, after which the evaluation metrics for our model all converged. In Section 7, we report the performance of our model using the sample from the last iteration.

## 7 Results

Fig. 4 shows a confusion matrix of the 48 phones used in TIMIT and the sub-word units learned from 3696 TIMIT utterances. Each circle represents a mapping pair for a cluster label and an English phone. The confusion matrix demonstrates a strong

<sup>6</sup>In the future, we plan to extend the model and infer the values of these hyperparameters from data directly.

Figure 4: A confusion matrix of the learned cluster labels from the TIMIT training set excluding the sa type utterances and the 48 phones used in TIMIT. Note that for clarity, we show only pairs that occurred more than 200 times in the alignment results. The average co-occurrence frequency of the mapping pairs in this figure is 431.

correlation between the cluster labels and individual English phones. For example, clusters 19, 20 and 21 are mapped exclusively to the vowel /ae/. A more careful examination on the alignment results shows that the three clusters are mapped to the same vowel in a different acoustic context. For example, cluster 19 is mapped to /ae/ followed by stop consonants, while cluster 20 corresponds to /ae/ followed by nasal consonants. This context-dependent relationship is also observed in other English phones and their corresponding sets of clusters. Fig. 4 also shows that a cluster may be mapped to multiple English phones. For instance, clusters 85 and 89 are mapped to more than one phone; nevertheless, a closer look reveals that these clusters are mapped to /n/, /d/ and /b/, which are sounds with a similar place of articulation (i.e. labial and dental). These correlations indicate that our model is able to discover the phonetic composition of a set of speech data without any language-specific knowledge.

The performance of the four acoustic models on the spoken term detection task is presented in Table 2. The English triphone model achieves the best P@N and EER results and performs slightly better than the English monophone model, which indicates a correlation between the quality of an acoustic model and its performance on the spoken term detection task. Although our unsupervised model does not perform as well as the supervised English

unit(%)	P@N	EER
English triphone	75.9	11.7
English monophone	74.0	11.8
Thai monophone	56.6	14.9
Our model	63.0	16.9

Table 2: The performance of our model and three supervised acoustic models on the spoken term detection task.

acoustic models, it generates a comparable EER and a more accurate detection performance for top hits than the Thai monophone model. This indicates that even without supervision, our model captures and learns the acoustic characteristics of a language automatically and is able to produce an acoustic model that outperforms a language-mismatched acoustic model trained with high supervision.

Table 3 shows that our model improves P@N by a large margin and generates only a slightly worse EER than the GMM baseline on the spoken term detection task. At the end of the training process, our model induced 169 HMMs, which were used to compute posteriorgrams. This seems unfair at first glance because Zhang and Glass (2009) only used 50 Gaussians for decoding, and the better result of our model could be a natural outcome of the higher complexity of our model. However, Zhang and Glass (2009) pointed out that using more Gaussian mixtures for their model did not improve their model performance. This indicates that the key reason for the improvement is our joint modeling method instead of simply the higher complexity of our model.

Compared to the DBM baseline, our model produces a higher EER; however, it improves the relative detection precision of top hits by 24.3%. As indicated in (Zhang et al., 2012), the hierarchical structure of DBM allows the model to provide a descent posterior representation of phonetic units. Even though our model only contains simple HMMs and Gaussians, it still achieves a comparable, if not better, performance as the DBM baseline. This demonstrates that even with just a simple model structure, the proposed learning algorithm is able to acquire rich phonetic knowledge from data and generate a fine posterior representation for phonetic units.

Table 4 summarizes the segmentation performance of the baselines, our model and the heuristic

unit(%)	P@N	EER
GMM (Zhang and Glass, 2009)	52.5	16.4
DBM (Zhang et al., 2012)	51.1	14.7
Our model	63.0	16.9

Table 3: The performance of our model and the GMM and DBM baselines on the spoken term detection task.

unit(%)	Recall	Precision	F-score
Dusan (2006)	75.2	66.8	70.8
Qiao et al. (2008)*	77.5	76.3	76.9
Our model	76.2	76.4	76.3
Pre-seg	87.0	50.6	64.0

Table 4: The segmentation performance of the baselines, our model and the heuristic pre-segmentation on TIMIT training set. \*The number of phone boundaries in each utterance was assumed to be known in this model.

pre-segmentation (pre-seg) method. The language-independent pre-seg method is suitable for seeding our model. It eliminates most unlikely boundaries while retaining about 87% true boundaries. Even though this indicates that at best our model only recalls 87% of the true boundaries, the pre-seg reduces the search space significantly. In addition, it also allows the model to capture proper phone durations, which compensates the fact that we do not include any explicit duration modeling mechanisms in our approach. In the best semi-supervised baseline model (Qiao et al., 2008), the number of phone boundaries in an utterance was assumed to be known. Although our model does not incorporate this information, it still achieves a very close F-score. When compared to the baseline in which the number of phone boundaries in each utterance was also unknown (Dusan and Rabiner, 2006), our model outperforms in both recall and precision, improving the relative F-score by 18.8%. The key difference between the two baselines and our method is that our model does not treat segmentation as a stand-alone problem; instead, it jointly learns segmentation, clustering and acoustic units from data. The improvement on the segmentation task shown by our model further supports the strength of the joint learning scheme proposed in this paper.

## 8 Conclusion

We present a Bayesian unsupervised approach to the problem of acoustic modeling. Without any prior

knowledge, this method is able to discover phonetic units that are closely related to English phones, improve upon state-of-the-art unsupervised segmentation method and generate more precise spoken term detection performance on the TIMIT dataset. In the future, we plan to explore phonological context and use more flexible topological structures to model acoustic units within our framework.

## Acknowledgements

The authors would like to thank Hung-an Chang and Ekapol Chuangsuwanich for training the English and Thai acoustic models. Thanks to Matthew Johnson, Ramesh Sridharan, Finale Doshi, S.R.K. Branavan, the MIT Spoken Language Systems group and the anonymous reviewers for helpful comments.

## Abstract

Conventional Automated Essay Scoring (AES) measures may cause severe problems when directly applied in scoring Automatic Speech Recognition (ASR) transcription as they are error sensitive and unsuitable for the characteristic of ASR transcription. Therefore, we introduce a framework of Finite State Transducer (FST) to avoid the shortcomings. Compared with the Latent Semantic Analysis with Support Vector Regression (LSA-SVR) method (stands for the conventional measures), our FST method shows better performance especially towards the ASR transcription. In addition, we apply the synonyms similarity to expand the FST model. The final scoring performance reaches an acceptable level of 0.80 which is only 0.07 lower than the correlation (0.87) between human raters.

## 1 Introduction

The assessment of learners' language abilities is a significant part in language learning. In conventional assessment, the problem of limited teacher availability has become increasingly serious with the population increase of language learners. Fortunately, with the development of computer techniques and machine learning techniques (natural language processing and automatic speech recognition), Computer-Assisted Language Learning (CALL) systems help people to learn language by themselves.

One form of CALL is evaluating the speech of the learner. Efforts in speech assessment usually fo-

cus on the integrality, fluency, pronunciation, and prosody (Cucchiari et al., 2000; Neumeyer et al., 2000; Maier et al., 2009; Huang et al., 2010) of the speech, which are highly predictable like the exam form of the read-aloud text passage. Another form of CALL is textual assessment. This work is also named AES. Efforts in this area usually focus on the content, arrangement and language usage (Landauer et al., 2003; Ishioka and Kameda, 2004; Kakkonen et al., 2005; Attali and Burstein, 2006; Burstein et al., 2010; Persing et al., 2010; Peng et al., 2010; Attali, 2011; Yannakoudakis et al., 2011) of the text written by the learner under a certain form of examination.

In this paper, our evaluation objects are the oral English picture compositions in English as a Second Language (ESL) examination. This examination requires students to talk about four successive pictures with at least five sentences in one minute, and the beginning sentence is given. This examination form combines both of the two forms described above. Therefore, we need two steps in the scoring task. The first step is Automatic Speech Recognition (ASR), in which we get the speech scoring features as well as the textual transcriptions of the speeches. Then, the second step could grade the text-free transcription in an (conventional) AES system. The present work is mainly about the AES system under the certain situation as the examination grading criterion is more concerned about the integrated content of the speech (the reason will be given in subsection 3.1).

There are many features and techniques which are very powerful in conventional AES systems, but

applying them in this task will cause two different problems as the scoring objects are the ASR output results. The first problem is that the inevitable recognition errors of the ASR will affect the performance of the feature extractions and scoring system. The second problem is caused by the special characteristic of the ASR result. As all these methods are designed under the normal AES situation that they are not suitable for the characteristic.

The impact of the first problem can be reduced by either perfecting the results of the ASR system or building the AES system which is not sensitive to the ASR errors. Improving the performance of the ASR is not what we concern about, so building an error insensitive AES system is what we care about in this paper. This makes many conventional features no longer useful in the AES system, such as spelling errors, punctuation errors and even grammar errors.

The second problem is caused by applying the bag-of-words (BOW) techniques to score the ASR transcription. The BOW are very useful in measuring the content features and are usually robust even if there are some errors in the scoring transcription. However, the robustness would not exist anymore because of the characteristic of the ASR result. It is known that better performance of ASR (reduce the word error rate in ASR) usually requires a strong constrain Language Model (LM). It means that more meaningless parts of the oral speeches would be recognized as the words quite related to the topic content. These words will usually be the key words in the BOW methods, which will lead to a great disturbance for the methods. Therefore, the conventional BOW methods are no longer appropriate because of the characteristic of the ASR result.

To tackle the two problems described above, we apply the FST (Mohri, 2004). As the evaluating objects are from an oral English picture composition examination, it has two important features that make the FST algorithm quite suitable.

- Picture composition examinations require students to speak according to the sequence of the pictures, so there is strong sequentiality in the speech.
- The sentences for describing the same picture are very identical in expression, so there is a hierarchy between the word sequences in the

sentences (the expression) and the sense for the same picture.

FST is designed to describe a structure mapping two different types of information sequences. It is very useful in expressing the sequences and the hierarchy in picture composition. Therefore, we build a FST-based model to extract features related to the transcription assessment in this paper. As the FST-based model is similar to the BOW metrics, it is also an error insensitive model. In this way, the impact of the first problem could be reduced. The FST model is very powerful in delivering the sequence information that a meaningless sequence of words related to the topic content will get low score under the model. Therefore, it works well concerning the second problem. In a word, the FST model can not only be insensitive to the recognition error in the ASR system, but also remedy the weakness of BOW methods in ASR result scoring.

In the remainder of the paper, the related work of conventional AES methods is addressed in section 2. The details of the speech corpus and the examination grading criterion are introduced in section 3. The FST model and its improved method are proposed in section 4. The experiments and the results are presented in section 5. The final section presents the conclusion and future work.

## 2 Related Work

Conventional AES systems usually exploit textual features to assess the quality of writing mainly in three different facets: the content facet, the arrangement facet and the language usage facet. In the content facet, many existing BOW techniques have been applied, such as the content vector analysis (Attali and Burstein, 2006; Attali, 2011) and the LSA to reduce the dimension of content vector (Landauer et al., 2003; Ishioka and Kameda, 2004; Kakkonen et al., 2005; Peng et al., 2010). In arrangement facet, Burstein et al. (2010) modeled the coherence in student essays, while Persing et al. (2010) modeled the organization. In language usage facet, grammar, spelling and punctuation are common features in assessment of the writing competence (Landauer et al., 2003; Attali and Burstein, 2006), and so does the diversity of words and clauses (Lonsdale and Strong-Krause, 2003; Ishioka and Kameda, 2004). Besides

Grading levels		Content Integrity	Acoustic
(18-20)	passed	Describe the information in the four pictures with proper elaboration	Perfect
(15-17)		Describe all the information in all of the four pictures	Good
(12-14)		Describe most of the information in all of the four pictures	Allow errors
(9-11)	failed	Describe most of the information in the pictures, but lose about 1 or 2 pictures	--
(6-8)		Describe some of the information in the pictures, but lose about 2 or 3 pictures	
(3-5)		Describe little information in the four pictures	
(0-2)		Describe some words related to the four pictures	

Table 1: Criterion of Grading

the textual features, many methods are also proposed to evaluate the quality. The cosine similarity is one of the most common used similarity measures (Laudauer et al., 2003; Ishioka and Kameda, 2004; Attali and Burstein, 2006; Attali, 2011). Also, the regression or the classification method is a good choice for scoring (Rudner and Liang, 2002; Peng et al., 2010). The rank preference techniques show excellent performance in grading essays (Yannakoudakis et al., 2011). Chen et al. (2010) proposed an unsupervised approach to AES.

As our work concerns more about the content integrity, we applied the LSA-SVR approach (Peng et al., 2010) as the contrast experiment, which is very effective and robust. In the LSA-SVR method, each essay transcription is represented by a latent semantic space vector, which is regarded as the features in the SVR model. The LSA (Deerwester et al., 1990) considers the relations between the dimensions in conventional vector space model (VSM) (Salton et al., 1975), and it can order the importance of each dimension in the Latent Semantic Space (LSS). Therefore, it is useful in reducing the dimensions of the vector by truncate the high dimensions. The support vector machine can be performed for the function estimation (Smola and Schölkopf, 2004). The LSA-SVR method takes the LSS vector as the feature vector, and applies the SVR for the training data to obtain the SVR model. Each test transcription represented by the LSS vector can be scored by the model.

### 3 Data

As characteristics of the data determine the effectiveness of our methods, the details of it will be introduced first. Our experimental data is acquired in an oral English examination for ESL students. Three

score	> 0	> 12	> 15	> 18
<b>WER(%)</b>	58.86	50.58	45.56	36.36
<b>MR(%)</b>	72.88	74.03	75.70	78.45

Table 2: WER and MR of ASR result

classes of students participated in the exam and 417 valid speeches are obtained in the examination. As the paper mainly focuses on scoring the text transcriptions, we have two ways to obtain them. One is manually typing the text transcriptions which we regarded as the Correct Recognition Result (CRR) transcription, and another is the ASR result which we named ASR transcription. We use the HTK (Young et al., 2006), which stands for the state of art in speech recognition, to build the ASR system.

To better reveal the differences of the methods' performance, all the experiments will be done in both transcriptions. A better understanding of the difference in the CRR transcription and the ASR transcription from the low score to the high score is shown in Table 2, where WER is the word error rate and MR is the match rate which is the words' correct rate.

#### 3.1 Criterion of Grading

According to the Grading Criterion of the examination, the score of the examination ranges from 0 to 20, and the grading score is divided into 7 levels with 3 points' interval for each level. The criterion mainly concerns about two facets of the speech: the acoustic level and the content integrity. The details of the criterion are shown in Table 1. The criterion indicates that the integrity is the most important part in rating the speech. The acoustic level only works well in excellent speeches (Huang et al., 2010). Therefore, this paper mainly focuses on the integrity

Correlation	R1	R2	R3	ES	OC
<b>R1</b>	-	0.8966	0.8557	0.9620	0.9116
<b>R2</b>	-	-	0.8461	0.9569	0.9048
<b>R3</b>	-	-	-	0.9441	0.8739
<b>Average</b>		0.8661		0.9543	0.8968

Table 3: Correlations of Human Scores

Figure 1: Distribution of Final Expert Scores

of content. The acoustic level as well as other levels such as grammar errors is ignored. Because the criterion is almost based on the content, our methods obtain good performance although we ignore some features.

### 3.2 Human Score Correlation and Distribution

Each speech in our experiments was scored by three raters. Therefore, we have three scores for each speech. The final expert score is the average of these three scores. The correlations between human scores are shown in Table 3.

R1, R2, and R3 stand for the three raters, and ES is the final expert score. The Open Correlation (OC) is the correlation between human rater scores and the final scores, which are not related to the human scores themselves (average of the other two scores).

As most students are supposed to pass the examination, the expert scores are mostly distributed above 12 points, as shown in Figure 1. In the range of the pass score, the distribution is close to normal distribution, while in the range of failed score except 0, the distribution is close to uniform distribution.

## 4 Approach

The approach used in this paper is to build a standard FST for the current examination topic. However, the annotation of the corpus is necessary before the

Figure 2: Distribution of Sentence Labels

building. After the annotation and the building, the features are extracted based on the FST. The automated machine score is computed from the features at last. Therefore, subsection 4.1 will show the corpus annotation, subsection 4.2 will introduce how to build the standard FST of the current topic, and subsections 4.3 and 4.4 will discuss how to extract the features, at last, an improved method is proposed in subsection 4.5.

### 4.1 Corpus Annotation

The definitions of the sequences and hierarchy in the corpus will be given before we apply the FST algorithm. According to the characteristics of the picture composition examination, each composition can be held as an orderly combination of the senses of pictures. The senses of pictures are called sense-groups here. We define a sense-group as one sentence either describing the same one or two pictures or elaborating on the same pictures. The description sentence is labeled with a tag 'm'(main sense of the picture) and the elaboration one is labeled with 's'(subordinate sense of the picture). The first given sentence in the examination is labeled with 0m and the other describing sentences for the 1 to 4 pictures are labeled with 1m to 4m, while the elaboration ones for the 4 pictures are labeled with 1s to 4s. Therefore, each sentence in the composition is labeled as a sense-group. For the entire 417 CRR transcriptions, we manually labeled 274 transcriptions whose scores are higher than 15 points. We gained 8 types of labels from the manually labeled results. They are 0m, 1m, 2m, 3m, 34m (one sentence describes both of the third and the fourth pictures), 4m, 2s and 4s. Other labels were discarded for the number of their appearance is very low. The distribution of sentences with each label is shown in Figure 2. There are 1679 sentences in the 274 CRR

Figure 3: FST Building

transcriptions and 1667 are labeled in the eight symbols.

## 4.2 FST Building

In this paper, we build three types of FST to extract scoring features with the help of openFST tool (Al-lauzen et al., 2007). The first is the sense-group FST, the second is the words to each sense-group FST and the last is the words to all the sense-groups FST. They are shown in Figure 3.

The definition of the sense-group has been given in subsection 4.1. The sense-group FST can describe all the possible proper sense-group sequences of the current picture composition topic. It is also an acceptor trained from the labeled corpus. We use manually labeled corpus, which are the sequences of sense-groups of the CRR transcriptions with expert scores higher than 15 points, to build the sense-group FST. In the process, each CRR transcription sense-group sequence is a simple sense-group FST. Later, we unite these sense-group FSTs to get the final FST which considers every situation of sense-group sequences in the train corpus. Also, we use the operation of "determinize" and "minimize" in openFST to optimize the final sense-group FST that its states have no same input label and is a smallest FST.

The second type is the words to sense-group FST. It determines what word sequence input will result in what sense-group output. With the help of these FSTs, we can find out how students use language to describe a certain sense-group, or in other words, a certain sense-group is usually constructed with what kind of word sequence. All the different sentences with their sense-group labels are tak-

en from the train corpus. We regard each sentence as a simple words to sense-group FST, and then unite these FSTs which have the same sense-group label. The final union FSTs can transform proper word sequence into the right sense-group. Like building the sense-group FST, the optimization operations of "determinize" and "minimize" are also done for the FSTs.

The last type of FST is a words to sense-groups FST. We can also treat it as a words FSA, because any word sequence accepted by the words to sense-groups FST is considered to be an integrated composition. Meanwhile, it can transform the word sequence into the sense-group label sequence which is very useful in extracting the scoring features (details will be presented in subsection 4.4). The FST is built from the other two types of FST that we made before. We compute the composition of all the words to each sense-group FSTs (the second type) and the sense-group FST (the first type) with the operations of "compose" in openFST. Then, the composition result is the words to sense-groups FST, the third type of FST in this paper.

## 4.3 Search for the Best Path in FST

Now we have successfully built the words to sense-groups FST, the third type described above. Just like the similarity methods mentioned in section 2 can score essays from a have-been-scored similar essay, we need to find the best path, which is closest to the to-be-scored transcription, in the FST. Here, we apply the edit distance to measure how best the path is. This means the best path is the word sequence path in the FST which has the smallest edit distance compared with the to-be-scored transcription's word sequences.

Here, we modify the Wagner-Fischer algorithm (Wagner and Fischer, 1974), which is a Dynamic Programming (DP) algorithm, to quest the best path in the FST. A simple example is illustrated in Figure 4. The best path can be described as

$$path = \arg \min_{\substack{path \in \\ allpath}} EDcost(path, transcription) \quad (1)$$

$$EDcost = ins + del + sub \quad (2)$$

EDcost is the edit distance from the transcription to the paths which start at state 0 and end at the end

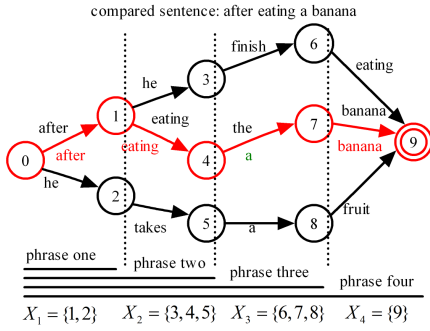

Figure 4: Search the Best Path in the FST by DP

state. The DP process can be described by equation (3):

$$\min EDcost(i) = \arg \min_{j \in X_1, \dots, X_{p-1}} (\min EDcost(j) + cost(j, i)) \quad (3)$$

The  $\min EDcost(j)$  is the accumulated minimum edit distance from state 0 to state  $j$ , and the  $cost(i, j)$  is the cost of insertion, deletion or substitution from state  $j$  to state  $i$ . The equation means the  $\min ED$  of state  $i$  can be computed by the accumulated  $\min ED$ -cost of state  $j$  in the phase  $p$ . The state  $j$  belongs to the have-been-calculated state set  $\{X_0, \dots, X_{p-1}\}$  in phase  $p$ . In phrase  $p$ , we compute the best path and its edit distance from the transcription for all the to-be-calculated states which is the  $X_p$  shown in Figure 4. After computing all the phrases, the best path and its edit distances of the end states are obtained. Then the final best path is the one with the smallest edit distance.

#### 4.4 Feature Extraction

After building the FST and finding the best path for the to-be-scored transcription, we can extract some effective features from the path information and the transcription. Inspired by the similarity scoring measures, our proposed features represent the similarity between the best path's word sequence and the to-be-scored transcription.

The features used for the scoring model are as follows:

- **The Edit Distance (ED):**

The edit distance is the linear combination of the weights of insertion, deletion and substitution. The relation is shown in equation (2), where  $ins$ ,  $del$  and  $sub$  are the appearance times

of insertions, deletions and substitutions, respectively. Normally, we set the cost of each to be 1.

- **The Normalized Edit Distance(NED):**

The NED is the ED normalized with the transcription's length.

$$NEDcost = EDcost/length \quad (4)$$

- **The Match Number(MN):**

The match number is the number of words matched between the best path and the transcription.

- **The Match Rate(MR):**

The match rate is the match number normalized with the transcription's length.

$$MR = MN/length \quad (5)$$

- **The Continuous Match Value(CMV):**

Continuous match should be better than the fragmentary match, so a higher value is given for the continuous situation.

$$CMV = \sum OM + 2\sum SM + 3\sum LM \quad (6)$$

where OM (One Match) is the fragmentary match number, SM (Short Match) is the continuous match number which is no more than 4, and LM (Long Match) is the continuous match number which is more than 4.

- **The Length(L):**

The length of transcription. Length is always a very effective feature in essay scoring (Attali and Burstein, 2006).

- **The Sense-group Scoring Feature(SSF):**

For each best path, we can transform the transcription's word sequence into the sense-group label sequence with the FST. Then, the words match rate of each sense-group can be computed. The match rate of each sense-group can be regarded as one feature so that all the sense-group match rate in the transcription will be combined to a feature vector (called the Sense-group Match Rate vector (SMRv)), which is an 8-dimensional vector in the present experiments. After that, we applied the SVR algorithm to train a sense-group scoring model with the vectors and scores, and the transcription gets its SSF from the model.

#### 4.5 Extend the FST model with the similarity of synonym

Because the FST is trained from the limited corpus, it does not contain all the possible situations proper for the current composition topic. To complete the current FST model, we add the similarity of synonym to extend the FST model so that it can handle more situations.

The extension of the FST model is mainly reflected in calculation of the edit distance of the best path. The previous edit distance, in equation (2), refers to the Levenshtein distance in which the insertions, deletions and substitutions have equal cost, but in the edit distance in this section, the cost of substitutions is less than that of insertions and deletions. Here, we assume that the cost of substitutions is based on the similarity of the two words. Then with the help of different cost of substitutions, each word edge is extended to some of its synonym word edges under the cost of similarity. The new edit distance is calculated by equation (7) as follows:

$$ED_{cost} = ins + del + sub \times (1 - sim) \quad (7)$$

where,  $sim$  is the similarity of two words.

We used the Wordnet::Similarity software package (Pedersen et al., 2004) to calculate the similarity between every two words at first. However, the performance's reduction of the AES system indicates that the similarity is not good enough to extend the FST model. Therefore, we seek for human help to accurate the similarity calculation. We manually checked the similarity, and deleted some improper similarity. Thus the final similarity applied in our experiment is the Wordnet::Similarity software computing result after the manual check.

## 5 Experiments

In this section, the proposed features and our FST methods will be evaluated on the corpus we mentioned above. The contrasting approach, the LSA-SVR approach, will also be presented.

### 5.1 Data Setup

The experiment corpus consists of 417 speeches. With the help of manual typing and the ASR system, 417 CRR transcriptions and 417 ASR transcriptions are obtained from the speeches after preprocessing

FST build	SVR train	SVR test	CRR transcription	ASR transcription
Set2	Set3	Set1	0.7999	0.7505
Set3	Set2		0.8185	0.7401
Set1	Set3	Set2	0.8557	0.7372
Set3	Set1		0.8111	0.7257
Set1	Set2	Set3	0.9085	0.8086
Set2	Set1		0.8860	0.8086

Table 4: Correlation Between the SSF and the Expert Scores

which includes the capitalization processing and the stemming processing. We divide them into 3 sets by the same distribution of their scores. Therefore, there are totally 6 sets, and each of them has 139 of the transcriptions. The FST building only uses the CRR transcriptions whose expert scores are higher than 15 points. While treating one set (one CRR set) as the FST building train set, we get the ED, NED, MN, MR, CMV features and the SMR vectors for the other two sets (could be either CRR sets or ASR sets). Then, the SSF is obtained by another set as the SVR train set and the last set as the test set. The parameters of the SVR are trained through the grid search from the whole data sets (ASR or CRR sets) by cross-validation. Therefore, except the length feature, the other six features of each set can be extracted from the FST model.

Also, we presented the result of using LSA-SVR approach as a contrast experiment to show the improvement of our FST model in scoring oral English picture composition.

To quantitatively assess the effectiveness of the methods, the Pearson correlation between the expert scores and the automated results is adopted as the performance measure.

### 5.2 Correlation of Features

The correlations between the seven features and the final expert scores are shown in Tables 4 and 5 on the three sets.

The MN and CMV are very good features, while the NED is not. This is mainly due to the nature of the examination. When scoring the speech, human raters concern more about how much valid information it contains and irrelevant contents are not taken for penalty. Therefore, the match features are more reasonable than the edit distance features. This im-

Script	Train	Test	L	ED	NED	MN	MR	CMV

ASR LSA-SVR	0.5975	0.5643	0.5907	0.5842
FST	0.7992	0.7678	0.8452	<b>0.8041</b>

Table 6: Performance of the FST Method, the LSA-SVR Approach and the Length Feature

fact is similar to the result displayed by the ASR output performance in Table 2 in section 3, where the WER has significant difference from the low score speeches to the high score ones while the MR does not, and the MR is much better than the WER.

As the length feature is a strong correlation feature in CRR transcription, the MR feature, which is normalized by the length, is strongly affected. However, with the impact declining in the ASR transcription, the MR feature performs very well. This also explains the reason of different correlations of ED and NED in CRR transcription.

The SSF is entirely based on the FST model, so the impact of the length feature is very low. The decline of it in different transcriptions is mainly because of the ASR error.

### 5.3 Performance of the FST Model

For each test transcription, it has 12 dimensions of FST features. The ED, NED, MN, MR and CMV features have two dimensions of each as trained from

two different FST building sets. The SSF needs two train sets as there are two train models: one is for the FST building model and another is for the SVR model. As different sets for different models, it also has two dimension features. We use the linear regression to combine these 12 features to the final automated score. The linear regression parameters were trained from all the data by cross-validation. After the weight of each feature and the linear bias are gained, we calculate the automated score of each transcription by the FST features. The performance of our FST model is shown in Table 6. Compared with it, the performance of the LSA-SVR algorithm, the baseline in our paper, is also shown. As a usual best feature for AES, the length shows its outstanding performance in CRR transcription. However, it fails in the ASR transcription.

As we have predicted above, the BOW algorithm (the LSA-SVR) performance declines drastically in the ASR transcription, which also happens to the length feature. By contrast, the decline of the performance of our FST method is acceptable considering the impact of recognition errors in the ASR system. This means the FST model is an error insensitive model that is very appropriate for the task.

### 5.4 Improvement of FST by Adding the Similarity

The improved FST extends the original FST model by considering the word similarity in substitutions. In the extension, the similarities of the synonyms

Script	Method	Set1	Set2	Set3	Average
CRR	FST	0.8702	0.8852	0.9386	0.8980
	IFST	0.8788	0.8983	0.9418	0.9063
ASR	FST	0.7992	0.7678	0.8452	0.8041
	IFST	0.8351	0.7617	0.8168	0.8045

Table 7: Performance of the FST Method and the Improved FST Method

describe the invisible (extended) part of the FST, so it should be very accurate for the substitutions cost. Therefore, we added manual intervention to the similarity result calculated by the wordnet::similarity software packet.

After we added the similarity of synonym to extend the FST model, the performance of the new model increased stably in the CRR transcription. However, the increase is not significant in the ASR transcription (shown in Table 7). We believe it is because the superiority of the improved model is disguised by the ASR error. In other words, the impact of ASR error under the FST model is more significant than the improvement of the FST model. The performance correlation of our FST model in the CRR transcription is about 0.9 which is very close to the human raters' (shown in Table 3). Even though the performance correlation in the ASR transcription declines compared with that in the CRR transcription, the FST methods still perform very well under the current recognition errors of the ARS system.

## 6 Conclusion and Future work

The aforementioned experiments indicate three points. First, the BOW algorithm has its own weakness. In regular text essay scoring, the BOW algorithm can have excellent performance. However, in certain situations, such as towards ASR transcription of oral English speech, its weakness of sequence neglect will be magnified, leading to drastic decline of performance. Second, the introduced FST model is suitable in our task. It is an error insensitive model under the task of automated oral English picture composition scoring. Also, it considers the sequence and the hierarchy information. As we expected, the performance of the FST model is more outstanding than that of the BOW metrics in CRR transcription, and the decline of performance is acceptable in ASR transcription scoring. Third, adding the similarity

of synonyms to extend the FST model improves the system performance. The extension can complete the FST model, and achieve better performance in the CRR transcription.

The future work may focus on three facets. First, as the extension of the FST model is a preliminary study, there is much work that can be done, such as calculating the similarity more accurately without manual intervention, or finding a balance between the original FST model and the extended one to improve the performance in ASR transcription. Second, as the task is speech evaluation, considering the acoustic features may give more information to the automated scoring system. Therefore, the features at the acoustic level could be introduced to complete the scoring model. Third, the decline of the performance in ASR transcription is derived from the recognition error of ASR system. Therefore, improving the performance of the ASR system or making full use of the N-best lists may give more accurate transcription for the AES system.

## Abstract

In this paper, we develop an RST-style text-level discourse parser, based on the HILDA discourse parser (Hernault et al., 2010b). We significantly improve its tree-building step by incorporating our own rich linguistic features. We also analyze the difficulty of extending traditional sentence-level discourse parsing to text-level parsing by comparing discourse-parsing performance under different discourse conditions.

## 1 Introduction

In a well-written text, no unit of the text is completely isolated; interpretation requires understanding the unit’s relation with the context. Research in discourse parsing aims to unmask such relations in text, which is helpful for many downstream applications such as summarization, information retrieval, and question answering.

However, most existing discourse parsers operate on individual sentences alone, whereas discourse parsing is more powerful for text-level analysis. Therefore, in this work, we aim to develop a text-level discourse parser. We follow the framework of Rhetorical Structure Theory (Mann and Thompson, 1988) and we take the HILDA discourse parser (Hernault et al., 2010b) as the basis of our work, because it is the first fully implemented text-level discourse parser with state-of-the-art performance. We significantly improve the performance of HILDA’s tree-building step (introduced in Section 5.1 below) by incorporating rich linguistic features (Section 5.3). In our experiments (Section 6), we also analyze the

difficulty with extending traditional sentence-level discourse parsing to text-level parsing, by comparing discourse parsing performance under different discourse conditions.

## 2 Discourse-annotated corpora

### 2.1 The RST Discourse Treebank

Rhetorical Structure Theory (Mann and Thompson, 1988) is one of the most widely accepted frameworks for discourse analysis. In the framework of RST, a coherent text can be represented as a discourse tree whose leaves are non-overlapping text spans called *elementary discourse units* (EDUs); these are the minimal text units of discourse trees. Adjacent nodes can be related through particular discourse relations to form a discourse subtree, which can then be related to other adjacent nodes in the tree structure. According to RST, there are two types of discourse relations, hypotactic (“mononuclear”) and paratactic (“multi-nuclear”). In mononuclear relations, one of the text spans, the *nucleus*, is more salient than the other, the *satellite*, while in multi-nuclear relations, all text spans are equally important for interpretation.

The example text fragment shown in Figure 1 consists of four EDUs ( $e_1$ - $e_4$ ), segmented by square brackets. Its discourse tree representation is shown below in the figure, following the notational convention of RST. The two EDUs  $e_1$  and  $e_2$  are related by a mononuclear relation *ATTRIBUTION*, where  $e_1$  is the more salient span; the span ( $e_1$ - $e_2$ ) and the EDU  $e_3$  are related by a multi-nuclear relation *SAME-UNIT*, where they are equally salient.

[Catching up with commercial competitors in retail banking and financial services,] $e_1$  [they argue,] $e_2$  [will be difficult,] $e_3$  [particularly if market conditions turn sour.] $e_4$

Figure 1: An example text fragment (wsj\_0616) composed of four EDUs, and its RST discourse tree representation.

The RST Discourse Treebank (RST-DT) (Carlson et al., 2001), is a corpus annotated in the framework of RST. It consists of 385 documents (347 for training and 38 for testing) from the *Wall Street Journal*. In RST-DT, the original 24 discourse relations defined by Mann and Thompson (1988) are further divided into a set of 18 relation classes with 78 finer-grained rhetorical relations in total, which provides a high level of expressivity.

## 2.2 The Penn Discourse Treebank

The Penn Discourse Treebank (PDTB) (Prasad et al., 2008) is another annotated discourse corpus. Its text is a superset of that of RST-DT (2159 *Wall Street Journal* articles). Unlike RST-DT, PDTB does not follow the framework of RST; rather, it follows a lexically grounded, predicate-argument approach with a different set of predefined discourse relations, as proposed by Webber (2004). In this framework, a discourse connective (e.g., *because*) is considered to be a predicate that takes two text spans as its arguments. The argument that the discourse connective structurally attaches to is called **Arg2**, and the other argument is called **Arg1** — unlike in RST, the two arguments are not distinguished by their saliency for interpretation. Another important difference between PDTB and RST-DT is that in PDTB, there does not necessarily exist a tree structure covering the full text, i.e., PDTB-styled discourse relations exist only in a very local contextual window. In PDTB, relation types are organized hierarchically: there are 4 *classes*, which can be further divided into 16 *types* and 23 *subtypes*.

## 3 Related work

Discourse parsing was first brought to prominence by Marcu (1997). Since then, many different algorithms and systems (Soricut and Marcu, 2003; Reitter, 2003; LeThanh et al., 2004; Baldrige and Lascarides, 2005; Subba and Di Eugenio, 2009; Sagae, 2009; Hernault et al., 2010b) have been proposed, which extracted different textual information and adopted various approaches for discourse tree building. Here we briefly review two fully implemented text-level discourse parsers with the state-of-the-art performance.

The HILDA discourse parser of Hernault and his colleagues (duVerle and Prendinger, 2009; Hernault et al., 2010b) is the first fully-implemented feature-based discourse parser that works at the full text level. Hernault et al. extracted a variety of lexical and syntactic features from the input text, and trained their system on RST-DT. While some of their features were inspired by the previous work of others, e.g., lexico-syntactic features borrowed from Soricut and Marcu (2003), Hernault et al. also proposed the novel idea of discourse tree building by using two classifiers in cascade — a binary structure classifier to determine whether two adjacent text units should be merged to form a new subtree, and a multi-class classifier to determine which discourse relation label should be assigned to the new subtree — instead of the more-usual single multi-class classifier with the additional label NO-REL. Hernault et al. obtained 93.8% *F*-score for EDU segmentation, 85.0% accuracy for structure classification, and 66.8% accuracy for 18-class relation classification.

Lin et al. (2009) attempted to recognize implicit discourse relations (discourse relations which are not signaled by explicit connectives) in PDTB by using four classes of features — contextual features, constituent parse features, dependency parse features, and lexical features — and explored their individual influence on performance. They showed that the production rules extracted from constituent parse trees are the most effective features, while contextual features are the weakest. Subsequently, they fully implemented an end-to-end PDTB-style discourse parser (Lin et al., 2010).

Recently, Hernault et al. (2010a) argued that more effort should be focused on improving performance

on certain infrequent relations presented in the discourse corpora, since due to the imbalanced distribution of different discourse relations in both RST-DT and PDTB, the overall accuracy score can be overwhelmed by good performance on the small subset of frequent relations, even though the algorithms perform poorly on all other relations. However, because of infrequent relations for which we do not have sufficient instances for training, many unseen features occur in the test data, resulting in poor test performance. Therefore, Hernault et al. proposed a semi-supervised method that exploits abundant, freely-available unlabeled data as a basis for feature vector extension to alleviate such issues.

#### 4 Text-level discourse parsing

Not until recently has discourse parsing for full texts been a research focus — previously, discourse parsing was only performed on the sentence level<sup>1</sup>. In this section, we explain why we believe text-level discourse parsing is crucial.

Unlike syntactic parsing, where we are almost never interested in parsing above sentence level, sentence-level parsing is not sufficient for discourse parsing. While a sequence of local (sentence-level) grammaticality can be considered to be global grammaticality, a sequence of local discourse coherence does not necessarily form a globally coherent text. For example, the text shown in Figure 2 contains two sentences, each of which is coherent and sensible itself. However, there is no reasonable content transition between these two sentences, so the combination of the two sentences does not make much sense. If we attempt to represent the text as an RST discourse tree like the one shown in Figure 1, we find that no discourse relation can be assigned to relate the spans  $(e_1-e_2)$  and  $(e_3-e_4)$  and the text cannot be represented by a valid discourse tree structure.

In order to rule out such unreasonable transitions between sentences, we have to expand the text units upon which discourse parsing is performed: from sentences to paragraphs, and finally paragraphs to

<sup>1</sup>Strictly speaking, for PDTB-style discourse parsing (e.g., Lin et al. (2009; 2010)), there is no absolute distinction between sentence-level and text-level parsing, since in PDTB, discourse relations are annotated at a level no higher than that of adjacent sentences. Here we are concerned with RST-style discourse parsing.

[No wonder he got an A for his English class,] $e_1$  [he was studying so hard.] $e_2$  [He avoids eating chocolates,] $e_3$  [since he is really worried about gaining weight.] $e_4$

Figure 2: An example of incoherent text fragment composed of two sentences. The two EDUs associated with each sentence are coherent themselves, whereas the combination of the two sentences is not coherent at the sentence boundary. No discourse relation can be associated with the spans  $(e_1-e_2)$  and  $(e_3-e_4)$ .

the full text.

Text-level discourse parsing imposes more constraints on the global coherence than sentence-level discourse parsing. However, if, technically speaking, text-level discourse parsing were no more difficult than sentence-level parsing, any sentence-level discourse parser could be easily upgraded to a text-level discourse parser just by applying it to full texts. In our experiments (Section 6), we show that when applied above the sentence level, the performance of discourse parsing is consistently inferior to that within individual sentences, and we will briefly discuss what the key difficulties with extending sentence-level to text-level discourse parsing are.

#### 5 Method

We use the HILDA discourse parser of Hernault et al. (2010b) as the basis of our work. We refine Hernault et al.’s original feature set by incorporating our own features as well as some adapted from Lin et al. (2009). We choose HILDA because it is a fully implemented text-level discourse parser with the best reported performance up to now. On the other hand, we also follow the work of Lin et al. (2009), because their features can be good supplements to those used by HILDA, even though Lin et al.’s work was based on PDTB. More importantly, Lin et al.’s strategy of performing feature selection prior to classification proves to be effective in reducing the total feature dimensions, which is favorable since we wish to incorporate rich linguistic features into our discourse parser.

### 5.1 Bottom-up approach and two-stage labeling step

Following the methodology of HILDA, an input text is first segmented into EDUs. Then, from the EDUs, a bottom-up approach is applied to build a discourse tree for the full text. Initially, a binary *Structure* classifier evaluates whether a discourse relation is likely to hold between consecutive EDUs. The two EDUs which are most probably connected by a discourse relation are merged into a discourse subtree of two EDUs. A multi-class *Relation* classifier evaluates which discourse relation label should be assigned to this new subtree. Next, the *Structure* classifier and the *Relation* classifier are employed in cascade to re-evaluate which relations are the most likely to hold between adjacent spans (discourse subtrees of any size, including atomic EDUs). This procedure is repeated until all spans are merged, and a discourse tree covering the full text is therefore produced.

Since EDU boundaries are highly correlated with the syntactic structures embedded in the sentences, EDU segmentation is a relatively trivial step — using machine-generated syntactic parse trees, HILDA achieves an *F*-score of 93.8% for EDU segmentation. Therefore, our work is focused on the tree-building step, i.e., the *Structure* and the *Relation* classifiers. In our experiments, we improve the overall performance of these two classifiers by incorporating rich linguistic features, together with appropriate feature selection. We also explore how these two classifiers perform differently under different discourse conditions.

### 5.2 Instance extraction

Because HILDA adopts a bottom-up approach for discourse tree building, errors produced on lower levels will certainly propagate to upper levels, usually causing the final discourse tree to be very dissimilar to the gold standard. While appropriate post-processing may be employed to fix these errors and help global discourse tree recovery, we feel that it might be more effective to directly improve the raw instance performance of the *Structure* and *Relation* classifiers. Therefore, in our experiments, all classifications are conducted and evaluated on the basis of individual instances.

Each instance is of the form  $(S_L, S_R)$ , which is a

pair of adjacent text spans  $S_L$  (left span) and  $S_R$  (right span), extracted from the discourse tree representation in RST-DT. From each discourse tree, we extract positive instances as those pairs of text spans that are siblings of the same parent node, and negative examples as those pairs of adjacent text spans that are not siblings in the tree structure. In all instances, both  $S_L$  and  $S_R$  must correspond to a constituent in the discourse tree, which can be either an atomic EDU or a concatenation of multiple consecutive EDUs.

### 5.3 Feature extraction

Given a pair of text spans  $(S_L, S_R)$ , we extract the following seven types of features.

**HILDA’s features:** We incorporate the original features used in the HILDA discourse parser with slight modification, which include the following four types of features occurring in  $S_L$ ,  $S_R$ , or both: (1) N-gram prefixes and suffixes; (2) syntactic tag prefixes and suffixes; (3) lexical heads in the constituent parse tree; and (4) POS tag of the dominating nodes.

**Lin et al.’s features:** Following Lin et al. (2009), we extract the following three types of features: (1) pairs of words, one from  $S_L$  and one from  $S_R$ , as originally proposed by Marcu and Echihabi (2002); (2) dependency parse features in  $S_L$ ,  $S_R$ , or both; and (3) syntactic production rules in  $S_L$ ,  $S_R$ , or both.

**Contextual features:** For a globally coherent text, there exist particular sequential patterns in the local usage of different discourse relations. Given  $(S_L, S_R)$ , the pair of text spans of interest, contextual features attempt to encode the discourse relations assigned to the preceding and the following text span pairs. Lin et al. (2009) also incorporated contextual features in their feature set. However, their work was based on PDTB, which has a very different annotation framework from RST-DT (see Section 2): in PDTB, annotated discourse relations can form a chain-like structure such that contextual features can be more readily extracted. However, in RST-DT, a full text is represented as a discourse tree structure, so the *previous* and the *next* discourse relations are not well-defined.

We resolve this problem as follows. Suppose  $S_L = (e_i - e_j)$  and  $S_R = (e_{j+1} - e_k)$ , where  $i \leq j < k$ . To find the previous discourse relation  $REL_{prev}$  that immedi-

ately precedes  $(S_L, S_R)$ , we look for the largest span  $S_{prev} = (e_h - e_{i-1}), h < i$ , such that it ends right before  $S_L$  and all its leaves belong to a single subtree which neither  $S_L$  nor  $S_R$  is a part of. If  $S_L$  and  $S_R$  belong to the same sentence,  $S_{prev}$  must also be a *within-sentence* span, and it must be a *cross-sentence* span if  $S_L$  and  $S_R$  are a cross-sentence span pair.  $REL_{prev}$  is then the discourse relation which covers  $S_{prev}$ . The next discourse relation  $REL_{next}$  that immediately follows  $(S_L, S_R)$  is found in the analogous way.

However, when building a discourse tree using a greedy bottom-up approach, as adopted by the HILDA discourse parser,  $REL_{prev}$  and  $REL_{next}$  are not always available; therefore these contextual features represent an idealized situation. In our experiments we wish to explore whether incorporating perfect contextual features can help better recognize discourse relations, and if so, set an upper bound of performance in more realistic situations.

**Discourse production rules:** Inspired by Lin et al. (2009)’s syntactic production rules as features, we develop another set of production rules, namely discourse production rules, derived directly from the tree structure representation in RST-DT.

For example, with respect to the RST discourse tree shown in Figure 1, we extract the following discourse production rules:  $ATTRIBUTION \rightarrow NO-REL\ NO-REL$ ,  $SAME-UNIT \rightarrow ATTRIBUTION\ NO-REL$ ,  $CONDITION \rightarrow SAME-UNIT\ NO-REL$ , where  $NO-REL$  denotes a leaf node in the discourse subtree.

The intuition behind using discourse production rules is that the discourse tree structure is able to reflect the relatedness of different discourse relations — discourse relations on the lower level of the tree can determine the relation of their direct parent to some degree. Hernault et al. (2010b) attempt to capture such relatedness by traversing a discourse subtree and encoding its traversal path as features, but since they used a depth-first traversal order, the information encoded in a node’s direct children is too distant; whereas most useful information can be gained from the relations covering these direct children.

**Semantic similarities:** Semantic similarities are useful for recognizing relations such as  $COMPARISON$ , when there are no explicit syntactic structures or lexical features signaling such relations.

We use two subsets of similarity features for verbs

and nouns separately. For each verb in either  $S_L$  or  $S_R$ , we look up its most frequent verb class ID in VerbNet<sup>2</sup>, and specify whether that verb class ID appears in  $S_L$ ,  $S_R$ , or both. For nouns, we extract all pairs of nouns from  $(S_L, S_R)$ , and compute the average similarity among these pairs. In particular, we use *path\_similarity*, *lch\_similarity*, *wup\_similarity*, *res\_similarity*, *jcn\_similarity*, and *lin\_similarity* provided in the *nlk.wordnet.similarity* package (Bird et al., 2009) for computing WordNet-based similarity, and always choose the most frequent sense for each noun.

**Cue phrases:** We compile a list of cue phrases, the majority of which are connectives collected by Knott and Dale (1994). For each cue phrase in this list, we determine whether it appears in  $S_L$  or  $S_R$ . If a cue phrase appears in a span, we also determine whether its appearance is in the beginning, the end, or the middle of that span.

## 5.4 Feature selection

If we consider all possible combinations of the features listed in Section 5.3, the resulting data space can be horribly high dimensional and extremely sparse. Therefore, prior to training, we first conduct feature selection to effectively reduce the dimension of the data space.

We employ the same feature selection method as Lin et al. (2009). Feature selection is done for each feature type separately. Among all features belonging to the feature type to be selected, we first extract all possible features that have been seen in the training data, e.g., when applying feature selection for *word pairs*, we find all word pairs that appear in some text span pair that have a discourse relation between them. Then for each extracted feature, we compute its mutual information with all 18 discourse relation classes defined in RST-DT, and use the highest mutual information to evaluate the effectiveness of that feature. All extracted features are sorted to form a ranked list by effectiveness. After that, we use a threshold to select the top features from that ranked list. The total number of selected features used in our experiments is 21,410.

## 6 Experiments

As discussed in Section 5.1, our research focus in this paper is the tree-building step of the HILDA discourse parser, which consists of two classifications: *Structure* and *Relation* classification. The binary *Structure* classifier decides whether a discourse relation is likely to hold between consecutive text spans, and the multi-class *Relation* classifier decides which discourse relation label holds between these two text spans if the *Structure* classifier predicts the existence of such a relation.

Although HILDA’s bottom-up approach is aimed at building a discourse tree for the full text, it does not explicitly employ different strategies for *within-sentence* text spans and *cross-sentence* text spans. However, we believe that discourse parsing is significantly more difficult for text spans at higher levels of the discourse tree structure. Therefore, we conduct the following three sub-experiments to explore whether the two classifiers behave differently under different discourse conditions.

**Within-sentence:** Trained and tested on text span pairs belonging to the same sentence.

**Cross-sentence:** Trained and tested on text span pairs belonging to different sentences.

**Hybrid:** Trained and tested on all text span pairs.

In particular, we split the training set and the testing set following the convention of RST-DT, and conduct *Structure* and *Relation* classification by incorporating our rich linguistic features, as listed in Section 5.3 above. To rule out all confounding factors, all classifiers are trained and tested on the basis of individual text span pairs, by assuming the discourse subtree structure (if any) covering each individual text span has been already correctly identified (no error propagation).

### 6.1 Structure classification

The number of training and testing instances used in this experiment for different discourse conditions is listed in Table 1. Instances are extracted in the manner described in Section 5.2. We observe that the distribution of positive and negative instances is extremely skewed for cross-sentence instances, while for all conditions, the distribution is similar in the training and the testing set.

In this experiment, classifiers are trained using

	Dataset	Pos #	Neg #	Total #
<i>Within</i>	Training	11,087	10,188	21,275
	Testing	1,340	1,181	2,521
<i>Cross</i>	Training	6,646	49,467	56,113
	Testing	882	6,357	7,239
<i>Hybrid</i>	Training	17,733	59,655	77,388
	Testing	2,222	7,539	9,761

Table 1: Number of training and testing instances used in *Structure* classification.

the  $SVM^{perf}$  classifier (Joachims, 2005) with a linear kernel.

*Structure* classification performance for all three discourse conditions is shown in Table 2. The columns **Full** and **NC** (No Context) denote the performance of using all features listed in Section 5.3 and all features except for *contextual features* respectively. As discussed in Section 5.3, contextual features represent an ideal situation which is not always available in real applications; therefore, we wish to see how they affect the overall performance by comparing the performance obtained with them and without them as features. The column **HILDA** lists the performance of using Hernault et al. (2010b)’s original features, and **Baseline** denotes the performance obtained by always picking the more frequent class. Performance is measured by four metrics: accuracy, precision, recall, and  $F_1$  score on the test set, shown in the first section in each sub-table.

Under the within-sentence condition, we observe that, surprisingly, incorporating contextual features boosts the overall performance by a large margin, even though it requires only 38 additional features. Under the cross-sentence condition, our features result in lower accuracy and precision than HILDA’s features. However, under this discourse condition, the distribution of positive and negative instances in both training and test sets is extremely skewed, which makes it more sensible to compare the recall and  $F_1$  scores for evaluation. In fact, our features achieve much higher recall and  $F_1$  score despite a much lower precision and a slightly lower accuracy.

In the second section of each sub-table, we also list the  $F_1$  score on the training data. This allows

us to compare the model-fitting capacity of different feature sets from another perspective, especially when the training data is not sufficiently well fitted by the model. For example, looking at the training  $F_1$  score under the cross-sentence condition, we can see that classification using full features and classification without contextual features both perform significantly better on the training data than HILDA does. At the same time, such superior performance is not due to possible over-fitting on the training data, because we are using significantly fewer features (21,410 for **Full** and 21,372 for **NC**) than Hernault et al. (2010b)’s 136,987; rather, it suggests that using carefully selected rich linguistic features is able to better model the problem itself.

Comparing the results obtained under the first two conditions, we see that the binary classification problem of whether a discourse relation is likely to hold between two adjacent text spans is much more difficult under the cross-sentence condition. One major reason is that many features that are predictive for within-sentence instances are no longer applicable (e.g., *Dependency parse features*). In addition, given the extremely imbalanced nature of the dataset under this discourse condition, we might need to employ special approaches to deal with this needle-in-a-haystack problem. This difficulty can also be perceived from the training performance. Compared to the within-sentence condition, all features fit the training data much more poorly under the cross-sentence condition. This suggests that sophisticated features or models in addition to our rich linguistic features must be incorporated in order to fit the problem sufficiently well. Unfortunately, this underfitting issue cannot be resolved by exploiting any abundant linguistic resources for feature vector extension (e.g., Hernault et al. (2010a)), because the poor training performance is no longer caused by the unknown features found in test vectors.

Turning to the hybrid condition, the performance of **Full** features is surprisingly good, probably because we have more available training data than the other two conditions. However, with contextual features removed, our features perform quite similarly to those of Hernault et al. (2010b), but still with a marginal, but nonetheless statistically significant, improvement on recall and  $F_1$  score.

	<b>Full</b>	<b>NC</b>	<b>HILDA</b>	<b>Baseline</b>

Table 2: *Structure* classification performance (in percentage) on text spans of *within-sentence*, *cross-sentence*, and *all* level. Performance that is significantly superior to that of HILDA ( $p < .01$ , using the Wilcoxon sign-rank test for significance) is denoted by \*.

## 6.2 Relation classification

The *Relation* classifier has 18 possible output labels, which are the coarse-grained relation classes defined in RST-DT. We do not consider nuclearity when classifying different discourse relations, i.e., `ATtribution[N][S]` and `ATtribution[S][N]` are treated as the same label. The training and test instances in this experiment are from the positive subset used in *Structure* classification.

In this experiment, classifiers are trained using LibSVM classifier (Chang and Lin, 2011) with a linear kernel and probability estimation.

*Relation* classification performance under three discourse conditions is shown in Table 3. We list the performance achieved by **Full**, **NC**, and **HILDA** features, as well as the majority baseline, which is obtained by always picking the most frequent class label (`ELABORATION` in all cases).

	Full	NC	HILDA	Baseline
<i>Within-sentence</i>				
MAFS	<b>0.490</b>	0.485	0.446	—
WAFS	<b>0.763</b>	0.762	0.740	—
Acc (%)	78.06	<b>78.13</b>	76.42	31.42
TAcc (%)	99.90	<b>99.93</b>	99.26	33.38
<i>Cross-sentence</i>				
MAFS	<b>0.194</b>	0.184	0.127	—
WAFS	<b>0.334</b>	0.329	0.316	—
Acc (%)	<b>46.83</b>	46.71	45.69	42.52

WAFS	<b>0.607</b>	0.604	0.588	—
Acc (%)	<b>65.30</b>	65.12	64.18	35.82
TAcc (%)	<b>99.96</b>	99.95	90.11	38.78

Table 3: *Relation* classification performance on text spans of *within-sentence*, *cross-sentence*, and *all* levels.

Following Hernault et al. (2010a), we use Macro-averaged  $F$ -scores (MAFS) to evaluate the performance of each classifier. Macro-averaged  $F$ -score is not influenced by the number of instances that exist in each relation class, by equally weighting the performance of each relation class<sup>3</sup>. Therefore, the evaluation is not biased by the performance on those prevalent classes such as *ATTRIBUTION* and *ELABORATION*. For reasons of space, we do not show the class-wise  $F$ -scores, but in our results, we find that using our features consistently provides superior performance for most class relations over HILDA’s features, and therefore results in higher overall MAFS under all conditions. We also list two other metrics for performance on the test data — Weight-averaged  $F$ -score (WAFS), which weights the performance of each relation class by the number of its existing instances, and the testing accuracy (Acc) — but these metrics are relatively more bi-

<sup>3</sup>No significance test is reported for relation classification, because we are comparing MAFS, which equally weights the performance of each relation. Therefore, traditional significance tests which operate on individual instances rather than individual relation classes are not applicable.

ased evaluation metrics in this task. Similar to *Structure* classification, the accuracy on the training data (TAcc)<sup>4</sup> is listed in the second section of each sub-table. It demonstrates that our carefully selected rich linguistic features are able to better fit the classification problem, especially under the *cross-sentence* condition.

Similar to our observation in *Structure* classification, the performance of *Relation* classification for cross-sentence instances is also much poorer than that on within-sentence instances, which again reveals the difficulty of text-level discourse parsing.

## 7 Conclusions

In this paper, we aimed to develop an RST-style text-level discourse parser. We chose the HILDA discourse parser (Hernault et al., 2010b) as the basis of our work, and significantly improved its tree-building step by incorporating our own rich linguistic features, together with features suggested by Lin et al. (2009). We analyzed the difficulty of extending traditional sentence-level discourse parsing to text-level parsing by showing that using exactly the same set of features, the performance of *Structure* and *Relation* classification on cross-sentence instances is consistently inferior to that on within-sentence instances. We also explored the effect of contextual features on the overall performance. We showed that contextual features are highly effective for both *Structure* and *Relation* classification under all discourse conditions. Although perfect contextual features are available only in idealized situations, when they are correct, together with other features, they can almost correctly predict the tree structure and better predict the relation labels. Therefore, an iterative updating approach, which progressively updates the tree structure and the labeling based on the current estimation, may push the final results toward this idealized end.

Our future work will be to fully implement an end-to-end discourse parser using our rich linguistic features, and focus on improving performance on cross-sentence instances.

<sup>4</sup>We use accuracy instead of MAFS as the evaluation metric on the training data because it is the metric that the training procedure is optimized toward.

## Abstract

We describe a discourse annotation scheme for Chinese and report on the preliminary results. Our scheme, inspired by the Penn Discourse TreeBank (PDTB), adopts the lexically grounded approach; at the same time, it makes adaptations based on the linguistic and statistical characteristics of Chinese text. Annotation results show that these adaptations work well in practice. Our scheme, taken together with other PDTB-style schemes (e.g. for English, Turkish, Hindi, and Czech), affords a broader perspective on how the generalized lexically grounded approach can flesh itself out in the context of cross-linguistic annotation of discourse relations.

## 1 Introduction

In the realm of discourse annotation, the Penn Discourse TreeBank (PDTB) (Prasad et al., 2008) separates itself by adopting a lexically grounded approach: Discourse relations are lexically anchored by discourse connectives (e.g., *because*, *but*, *therefore*), which are viewed as predicates that take abstract objects such as propositions, events and states as their arguments. In the absence of explicit discourse connectives, the PDTB asks the annotator to fill in a discourse connective that best describes the discourse relation between these two sentences, instead of selecting from an inventory of predefined discourse relations. By keeping the discourse annotation lexically grounded even in the case of implicit discourse relations, the PDTB appeals to the annotator’s judgment at an intuitive level. This is in

contrast with an approach in which the set of discourse relations are pre-determined by linguistic experts and the role of the annotator is just to select from those choices (Mann and Thompson, 1988; Carlson et al., 2003). This lexically grounded approach led to consistent and reliable discourse annotation, a feat that is generally hard to achieve for discourse annotation. The PDTB team reported inter-annotator agreement in the lower 90% for explicit discourse relations (Miltasakaki et al., 2004).

In this paper we describe a discourse annotation scheme for Chinese that adopts this lexically grounded approach while making adaptations when warranted by the linguistic and statistical properties of Chinese text. This scheme is shown to be practical and effective in the annotation experiment.

The rest of the paper is organized as follows: In Section 2, we review the key aspects of the PDTB annotation scheme under discussion in this paper. In Section 3, we first show that some key features of Chinese make adaptations necessary in Section 3.1, and then in Section 3.2, we present our systematic adaptations that follow from the differences outlined in Section 3.1. In Section 4, we present the preliminary annotation results we have so far. And finally in Section 5, we conclude the paper.

## 2 The PDTB annotation scheme

As mentioned in the introduction, discourse relation is viewed as a predication with two arguments in the framework of the PDTB. To characterize the predication, the PDTB annotates its argument structure and sense. Two types of discourse relation are distinguished in the annotation: explicit and implicit.

Although their annotation is carried out separately, it conforms to the same paradigm of a discourse connective with two arguments. In what follows, we highlight the key points that will be under discussion in the following sections. To get a more comprehensive and detailed picture of the PDTB scheme, see the PDTB 2.0 annotation manual (Prasad et al., 2007).

## 2.1 Annotation of explicit discourse relations

Explicit discourse relations are those anchored by explicit discourse connectives in text. Explicit connectives are drawn from three grammatical classes:

- **Subordinating conjunctions:** e.g., *because, when, since, although*;
- **Coordinating conjunctions:** e.g., *and, or, nor*;
- **Discourse adverbials:** e.g., *however, otherwise, then, as a result, for example*.

Not all uses of these lexical items are considered to function as a discourse connective. For example, coordinating conjunctions appearing in VP coordinations, such as “*and*” in (1), are not annotated as discourse connectives.

- (1) More common chrysotile fibers are curly and are more easily rejected by the body, Dr. Mossman explained.

The text spans of the two arguments of a discourse connective are marked up. The two arguments, *Arg1* and *Arg2*, are defined based on the physical location of the connective: *Arg2* is the argument expressed by the clause syntactically bound to the connective, and *Arg1* is the other argument. There are no restrictions on how many clauses can be included in the text span for an argument other than the *Minimality Principle*: Only as many clauses and/or sentences should be included in an argument selection as are minimally required and sufficient for the interpretation of the relation.

## 2.2 Annotation of implicit discourse relations

In the case of implicit discourse relations, annotators are asked to insert a discourse connective that best conveys the implicit relation; when no such connective expression is appropriate, the implicit relation is further distinguished as the following three subtypes:

- **AltLex:** when insertion of a connective leads to redundancy due to the presence of an alternatively lexicalized expression, as in (2).
- **EntRel:** when the only relation between the two arguments is that they describe different aspects of the same entity, as in (3).
- **NoRel:** when neither a lexicalized discourse relation nor entity-based coherence is present. It is to be noted that at least some of the “NoRel” cases are due to the *adjacency constraint* (see below for more detail).

- (2) And she further stunned her listeners by revealing her secret garden design method: [*Arg1* Commissioning a friend to spend five or six thousand dollars . . . on books that I ultimately cut up.] [*Arg2* AltLex After that, the layout had been easy.
- (3) [*Arg1* Hale Milgrim, 41 years old, senior vice president, marketing at Elecktra Entertainment Inc., was named president of Capitol Records Inc., a unit of this entertainment concern]. [*Arg2* EntRel Mr. Milgrim succeeds David Berman, who resigned last month].

There are restrictions on what kinds of implicit relations are subjected to annotation, presented below. These restrictions do not have counterparts in explicit relation annotation.

- Implicit relations between adjacent clauses in the same sentence not separated by a semicolon are not annotated, even though the relation may very well be definable. A case in point is presented in (4) below, involving an intra-sentential comma-separated relation between a main clause and a free adjunct.
  - Implicit relations between adjacent sentences across a paragraph boundary are not annotated.
  - The *adjacency constraint*: At least some part of the spans selected for *Arg1* and *Arg2* must belong to the pair of adjacent sentences initially identified for annotation.
- (4) [*MC* The market for export financing was liberalized in the mid-1980s], [*FA* forcing the bank to face competition].

## 2.3 Annotation of senses

Discourse connectives, whether originally present in the data in the case of explicit relations, or filled in by annotators in the case of implicit relations, along with text spans marked as “AltLex”, are annotated with respect to their senses. There are three levels in the sense hierarchy:

- **Class:** There are four major semantic classes: TEMPORAL, CONTINGENCY, COMPARISON, and EXPANSION;
- **Type:** A second level of *types* is further defined for each semantic class. For example, under the class CONTINGENCY, there are two types: “Cause” (relating two situations in a direct cause-effect relation) and “Condition” (relating a hypothetical situation with its (possible) consequences);<sup>1</sup>
- **Subtype:** A third level of *subtypes* is defined for some, but not all, types. For instance, under the type “CONTINGENCY:Cause”, there are two subtypes: “reason” (for cases like *because* and *since*) and “result” (for cases like *so* and *as a result*).

It is worth noting that a type of implicit relation, namely those labeled as “EntRel”, is not part of the sense hierarchy since it has no explicit counterpart.

## 3 Adapted scheme for Chinese

### 3.1 Key characteristics of Chinese text

Despite similarities in discourse features between Chinese and English (Xue, 2005), there are differences that have a significant impact on how discourse relations could be best annotated. These differences can be illustrated with (5):

- (5) 据悉 , [AO1 东莞 海关  
according to reports , Dongguan Customs  
共 接受 企业 合同 备案  
in total accept company contract record  
八千四百多 份] , [AO2 比 试点  
8400 plus CLASS , compare pilot  
前 略 有 上升] , [AO3 企业  
before slight EXIST increase , company

<sup>1</sup>There is another dimension to this level, i.e. literal or pragmatic use. If this dimension is taken into account, there could be said to be *four* types: “Cause”, “Pragmatic Cause”, “Condition”, and “Pragmatic Condition”. For details, see Prasad et al. (2007).

反应 良好] , [AO4 普遍  
respond/response well/good , generally  
表示 接受] 。  
acknowledge accept/acceptance .

“According to reports, [AO1 Dongguan District Customs accepted more than 8400 records of company contracts], [AO2 a slight increase from before the pilot]. [AO3 Companies responded well], [AO4 generally acknowledging acceptance].”

This sentence reports on how a pilot program worked in Dongguan City. Because all that is said is about the pilot program, it is perfectly natural to include it all in a single sentence in Chinese. Intuitively though, there are two different aspects of how the pilot program worked: the number of records and the response from the affected companies. To report the same facts in English, it is more natural to break them down into two sentences or two semi-colon-separated clauses, but in Chinese, *not only are they merely separated by comma, but also there is no connective relating them.*

This difference in writing style necessitates rethinking of the annotation scheme. If we apply the PDTB scheme to the English translation, regardless of whether the two pieces of facts are expressed in two sentences or two semi-colon-separated clauses, at least one discourse relation will be annotated, relating these two text units. In contrast, if we apply the same scheme to the Chinese sentence, no discourse relation will be picked out because this is just one comma-separated sentence with no explicit discourse connectives in it. In other words, the discourse relation within the Chinese sentence, which would be captured in its English counterpart following the PDTB procedure, would be lost when annotating Chinese. Such loss is not a sporadic occurrence but rather a very prevalent one since it is associated with the customary writing style of Chinese. To ensure a reasonable level of coverage, we need to consider comma-delimited intra-sentential implicit relations when annotating Chinese text.

There are some complications associated with this move. One of them is that it introduces into discourse annotation considerable ambiguity associated with the comma. For example, the first instance of comma in (5), immediately following “据悉” (“according to reports”), clearly does not indicate a discourse relation, so it needs to be spelt out in

the guidelines how to exclude such cases of comma as discourse relation indicators. We think, however, that disambiguating the commas in Chinese text is valuable in its own right and is a necessary step in annotating discourse relations.

Another complication is that some comma-separated chunks are ambiguous as to whether they should be considered potential arguments in a discourse relation. The chunks marked AO2 and AO4 in (5) are examples of such cases. They, judging from their English translation, may seem clear cases of *free adjuncts* in PDTB terms (Prasad et al., 2007), but there is no justification for treating them as such in Chinese. The lack of justification comes from at least three features of Chinese:

- Certain words, for instance, “反应” (“respond/response”), “良好” (“well/good”) and “接受” (“accept/acceptance”), are ambiguous with respect to their POS, and when they combine, the resulting sentence may have more than one syntactic analysis. For example, AO3 may be literally translated as “Companies responded well” or “Companies’ response was good”.
- There are no inflectional clues to differentiate free adjuncts and main clauses. For example, one can be reasonably certain that “表示” (“acknowledge”) functions as a verb in (5), however, there is no indication whether it is in the form corresponding to “acknowledging” or “acknowledged” in English. Or putting it differently, whether one wants to express in Chinese the meaning corresponding to the *-ing* form or the tensed form in English, the same form “表示” could apply.
- Both subject and object can be dropped in Chinese, and they often are when they are inferable from the context. For example, in the two-sentence sequence below, the subject of (7) is dropped since it is clearly the same as the subject of the previous sentence in (6).

(6) [S<sub>1</sub> 近五年来, 上海  
recent five years since, Shanghai through  
通过积极从外省市  
actively from other province city procure  
收购出口货源、举办中国  
export supply, organize China East

华东出口商品交易会等  
Export Commodity Fair etc. event,  
活动, 增强口岸对 全国  
strengthen port to whole country DE  
的辐射能力。]  
connection capability .

“[S<sub>1</sub> In the past five years, Shanghai strengthened the connection of its port to other areas of the country through actively procuring export supplies from other provinces and cities, and through organizing events such as the East China Export Commodities Fair.]”

(7) [S<sub>2</sub> 同时, 发展  
At the same time, develop  
跨国经营, 大力开拓  
transnational operation, vigorously open up  
多元化市场。]  
diversified market

“[S<sub>2</sub> At the same time, (it) developed transnational operations (and) vigorously opened up diversified markets.]”

Since the subject can be omitted from the entire sentence, absence or presence of subject in a clause is not an indication whether the clause is a main clause or a free adjunct, or whether it is part of a VP coordination without a connective. So if we take into account both the lack of differentiating inflectional clues and the possibility of omitting the subject, AO4 in (5) may be literally translated as “generally acknowledging acceptance”, or “(and) generally acknowledged acceptance”, or “(companies) generally acknowledged acceptance”, or “(companies) generally acknowledged (they) accepted (it)”.

Since in Chinese, there is no reliable indicator distinguishing between main clauses and free adjuncts, or distinguishing between coordination on the clause level without the subject and coordination on the VP level, *we will not rely on these distinctions in annotation*, as the PDTB team does in their annotation.

These basic decisions directly based on linguistic characteristics of Chinese lead to more systematic adaptations to the annotation scheme, to which we will turn in the next subsection.

### 3.2 Systematic adaptations

The main consequence of the basic decisions described in Section 3.1 is that we have a whole lot

more tokens of implicit relation than explicit relation to deal with. According to a rough count on 20 randomly selected files from Chinese Treebank (Xue et al., 2005), 82% are tokens of implicit relation, compared to 54.5% in the PDTB 2.0. Given the overwhelming number of implicit relations, we re-examine where it could make an impact in the annotation scheme. There are three such areas.

### 3.2.1 Procedural division between explicit and implicit discourse relation

In the PDTB, explicit and implicit relations are annotated separately. This is probably partly because explicit connectives are quite abundant in English, and partly because the project evolved in stages, expanding from the more canonical case of explicit relation to implicit relation for greater coverage. When annotating Chinese text, maintaining this procedural division makes much less sense: the landscape of discourse relation (or at least the key elements of it) has already been mapped out by the PDTB work and to set up a separate task to cover 18% of the data does not seem like a worthwhile bother without additional benefits for doing so.

So the question now is *how to annotate explicit and implicit relations in one fell swoop?* In Chinese text, the use of a discourse connective is almost always accompanied by a punctuation or two (usually period and/or comma), preceding or flanking it. So a sensible solution is to rely on punctuations as the denominator between explicit and implicit relations; and in the case of explicit relation, the connective will be marked up as an attribute of the discourse relation. This unified approach simplifies the annotation procedure while preserving the explicit/implicit distinction in the process.

One might question, at this point, whether such an approach can still call itself “lexically grounded”. Certainly not if one interprets the term literally; but in a broader sense, our approach can be seen as an instantiation of a generalized version of it, much the same way that the PDTB is an, albeit different, instantiation of it for English. The thrust of the lexically grounded approach is that discourse annotation should be a data-driven, bottom-up process, rather than a top-down one, trying to fit data into a prescriptive system. Once the insight that a discourse connective functions like a predicate with two ar-

guments is generalized to cover *all* discourse relations, there is no fundamental difference between explicit and implicit discourse relations: both work like a predicate whether or not there is a lexicalization of it. As to what role this distinction plays in the annotation procedure, it is an engineering issue, depending on a slew of factors, among which are cross-linguistic variations. In the case of Chinese, we think it is more economical to treat explicit and implicit relations alike in the annotation process.

To treat explicit and implicit relations alike actually goes beyond annotating them in one pass; it also involves how they are annotated, which we discuss next.

### 3.2.2 Annotation of implicit discourse relations

In the PDTB, treatment of implicit discourse relations is modeled after that of explicit relations, and at the same time, some restrictions are put on implicit, but not explicit, relations. This is quite understandable: implicit discourse relations tend to be vague and elusive, so making use of explicit relations as a prototype helps pin them down, and restrictions are put in place to strike a balance between high reliability and good coverage. When implicit relations constitute a vast majority of the data as is the case with Chinese, both aspects need to be re-examined to strike a new balance.

In the PDTB, annotators are asked to insert a discourse connective that best conveys the implicit discourse relation between two adjacent discourse units; when no such connective expression is appropriate, the implicit discourse relation is further distinguished as “AltLex”, “EntRel”, and “NoRel”. The inserted connectives and those marked as “AltLex”, along with explicit discourse connectives, are further annotated with respect to their senses.

When a connective needs to be inserted in a majority of cases, the difficulty of the task really stands out. In many cases, it seems, there is a good reason for not having a connective present and because of it, the wording rejects insertion of a connective even if it expresses the underlying discourse relation exactly (or sometimes, maybe the wording itself is the reason for not having a connective). So to try to insert a connective expression may very well be too hard a task for annotators, with little to show for their effort in the end.

Furthermore, the inter-annotator agreement for providing an explicit connective in place of an implicit one is computed based on the *type* of explicit connectives (e.g. cause-effect relations, temporal relations, contrastive relations, etc.), rather than based on their identity (Miltsakaki et al., 2004). This suggests that a reasonable degree of agreement for such a task may only be reached with a coarse classification scheme.

Given the above two considerations, our solution is to annotate implicit discourse relations with their senses directly, bypassing the step of inserting a connective expression. It has been pointed out that to train annotators to reason about pre-defined abstract relations with high reliability might be too hard a task (Prasad et al., 2007). This difficulty can be overcome by associating each semantic type with one or two prototypical explicit connectives and asking annotators to consider each to see if it expresses the implicit discourse relation. This way, annotators have a concrete aid to reason about abstract relations without having to choose one connective from a set expressing roughly the same relation or having to worry about whether insertion of the connective is somehow awkward.

It should be noted that annotating implicit relations directly with their senses means that sense annotation is no longer restricted to those that can be lexically expressed, but also includes those that cannot, notably those labeled “EntRel/NoRel” in the PDTB.<sup>2</sup> In other words, we annotate senses of *discourse relations*, not just connectives and their lexical alternatives (in the case of AltLex). This expansion is consistent with the generalized view of the lexically grounded approach discussed in Section 3.2.1.

With respect to restrictions on implicit relation, we will adopt them as they prove to be necessary in the annotation process, with one exception. The exception is the restriction that implicit relations between adjacent clauses in the same sentence not separated by a semi-colon are not annotated. This restriction seems to apply mainly to a main clause and any free adjunct attached to it in English; in Chinese, however, the distinction between a main clause and a

free adjunct is not as clear-cut for reasons explained in Section 3.1. So this restriction is not applicable for Chinese annotation.

### 3.2.3 Definition of Arg1 and Arg2

The third area that an overwhelming number of implicit relation in the data affects is how *Arg1* and *Arg2* are defined. As mentioned in the introduction, discourse relations are viewed as a predication with two arguments. These two arguments are defined based on the physical location of the connective in the PDTB: *Arg2* is the argument expressed by the clause syntactically bound to the connective and *Arg1* is the other argument. In the case of implicit relations, the label is assigned according to the text order.

In an annotation task where implicit relations constitute an overwhelming majority, the distinction of *Arg1* and *Arg2* is meaningless in most cases. In addition, the phenomenon of parallel connectives is predominant in Chinese. Parallel connectives are pairs of connectives that take the same arguments, examples of which in English are “*if..then*”, “*either..or*”, and “*on the one hand..on the other hand*”. In Chinese, most connectives are part of a pair; though some can be dropped from their pair, it is considered “proper” or formal to use both. (8) below presents two such examples, for which parallel connectives are not possible in English.

- (8) a. 伦敦 股市 因 适逢  
London stock market because coincide  
银行节 , 故 没有 开市。  
Bank Holiday , therefore NEG open market  
“London Stock Market did not open because it was Bank Holiday.”
- b. 虽然 他们 不 离 土 、不 离  
Although they NEG leave land , NEG leave  
乡 , 但 严格 来 讲 已  
home village , but strict PART speak already  
不再 是 传统 意义 上 的 农民。  
no longer be tradition sense PREP DE peasant  
“Although they do not leave land or their home village, strictly speaking, they are no longer peasants in the traditional sense.”

In the PDTB, parallel connectives are annotated discontinuously; but given the prevalence of such phenomenon in Chinese, such practice would generate

<sup>2</sup>Thus “EntRel” and “NoRel” are treated as relation senses, rather than relation types, in our scheme.

a considerably high percentage of essentially repetitive annotation among explicit relations.

So the situation with Chinese is that distinguishing *Arg1* and *Arg2* the PDTB way is meaningless in most cases, and in the remaining cases, it often results in duplication. Rather than abandoning the distinction altogether, we think it makes more sense to define *Arg1* and *Arg2* semantically. It will not create too much additional work beyond distinction of different senses of discourse relation in the PDTB. For example, in the semantic type CONTINGENCY:Cause, we can define “reason” as *Arg1* and “result” as *Arg2*. In this scheme, no matter which one of 因 (“because”) and 故 (“therefore”) appears without the other, or if they appear as a pair in a sentence, or if the relation is implicit, the *Arg1* and *Arg2* labels will be consistently assigned to the same clauses.

This approach is consistent with the move from annotating senses of *connectives* to annotating senses of *discourse relations*, pointed out in Section 3.2.2. For example, in the PDTB’s sense hierarchy, “reason” and “result” are subtypes under type CONTINGENCY:Cause: “reason” applies to connectives like “because” and “since” while “result” applies to connectives like “so” and “as a result”. When we move to annotating senses of discourse relations, since both types of connectives express the same underlying discourse relation, there will not be further division under CONTINGENCY:Cause, and the “reason”/“result” distinction is an intrinsic property of the semantic type. We think this level of generality makes sense semantically.

## 4 Annotation experiment

To test our adapted annotation scheme, we have conducted annotation experiments on a modest, yet significant, amount of data and computed agreement statistics.

### 4.1 Set-up

The agreement statistics come from annotation conducted by two annotators in training so far. The data set consists of 98 files taken from the Chinese Treebank (Xue et al., 2005). The source of these files is Xinhua newswire. The annotation is carried out on

the PDTB annotation tool<sup>3</sup>.

### 4.2 Inter-annotator agreement

To evaluate our proposed scheme, we measure agreement on each adaption proposed in Section 3, as well as agreement on argument span determination. Whenever applicable, we also present (roughly) comparable statistics of the PDTB (Mitsakaki et al., 2004). The results are summarized in Table 1.

	Chinese		PDTB (%)
	tkn no.	F(p/r) (%)	
<i>rel-ident</i>	3951*	95.4 (96.0/94.7)	N/A
<i>rel-type</i>	3951	95.1	N/A
<i>imp-sns-type</i>	2967	87.4	72
<i>arg-order</i>	3059	99.8	N/A
<b>argument span</b>			
<i>exp-span-xm</i>	1580	84.2	90.2
<i>exp-span-pm</i>	1580	99.6	94.5
<i>imp-span-xm</i>	5934	76.9	85.1
<i>overall-bnd-</i>	14039*	87.7 (87.5/87.9)	N/A

Table 1: Inter-annotator agreement in various aspects of Chinese discourse annotation: *rel-ident*, discourse relation identification; *rel-type*, relation type classification; *imp-sns-type*, classification of sense type of implicit relations; *arg-order*, order determination of *Arg1* and *Arg2*. For agreement on argument spans, the naming convention is <type-of-relation>-<element-as-independent-token>-<matching-method>. *exp*: explicit relations; *imp*: implicit relations; *span*: argument span; *xm*: exact match; *pm*: partial match; *bnd*: boundary. \*: number of tokens agreed on by both annotators.

The first adaption we proposed is to annotate explicit and implicit discourse relations in one pass. This introduces two steps, at which agreement can each be measured: First, the annotator needs to make the judgment, at each instance of the punctuations, whether there is a discourse relation (a step we call “relation identification”); second, once a discourse relation is identified, the annotator needs to classify the type as one of “Explicit”, “Implicit”, or “AltLex” (a step we call “relation type classification”). The agreement at these two steps is 95.4%

<sup>3</sup><http://www.seas.upenn.edu/~pdtb/tools.shtml#annotator>

and 95.1% respectively.

The second adaption is to bypass the step of inserting a connective when annotating an implicit discourse relation and classify the sense directly. The third adaptation is to define Arg1 and Arg2 semantically for each sense. To help annotators think about relation sense abstractly and determine the order of the arguments, we put a helper item alongside each sense label, like “Causation: 因为arg1所以arg2” (“Causation: *because arg1 therefore arg2*”). This approach works well, as evidenced by 87.4%<sup>4</sup> and 99.8% agreement for the two processes respectively.

To evaluate agreement on determining argument span, we adopt four measures. In the first three, explicit and implicit relations are calculated separately (although they are actually annotated in the same process) to make our results comparable to the published PDTB results. Each argument span is treated as an independent token and either exact or partial match (i.e. if two spans share one boundary) counts as 1. The fourth measure is less stringent than exact match and more stringent than partial match: It groups explicit and implicit relation together and treats each boundary as an independent token. Typically, an argument span has two boundaries, but it can have four (or more) boundaries when an argument span is interrupted by a connective and/or an AltLex item.

Evidently, determining argument span is the most challenging aspect of discourse annotation. However, it should be pointed out that agreement was on an overall upward trend, which became especially prominent after we instituted a restriction on implicit relations across a paragraph boundary towards the end of the training period. It restricts full anno-

<sup>4</sup>Two more points should be made about this number. First, it may be partially attributed to our differently structured sense hierarchy. It is a flat structure containing the following 12 values: ALTERNATIVE, CAUSATION, CONDITIONAL, CONJUNCTION, CONTRAST, EXPANSION, PROGRESSION, PURPOSE, RESTATEMENT, TEMPORAL, EntRel, and NoRel. Aside from including EntRel and NoRel (the reason and significance of which have been discussed in Section 3.2.2), the revision was by and large not motivated by Chinese-specific features, so we do not address it in detail in this paper. Second, in making the comparison with the PDTB result, the 12-value structure is collapsed into 5 values: TEMPORAL, CONTINGENCY, COMPARISON, EXPANSION, and EntRel/NoRel, which must be different from the 5 values in Miltsakaki et al. (2004), judging from the descriptions.

tation to only three specific situations so that most loose and/or hard-to-delimit relations across paragraph boundaries are excluded. This restriction appears to be quite effective, as shown in Table 2.

	num of rel.'s	Overall Arg Span	
		boundary F(p/r) (%)	span-em (%)
last 5 wks	1103	90.0 (90.0/89.9)	80.8
last 3 wks	677	91.0 (91.0/91.0)	82.5
last 2 wks	499	91.8 (91.8/91.8)	84.2

Table 2: Inter-annotator agreement on argument span during the last 5 weeks of training.

## 5 Conclusions

We have presented a discourse annotation scheme for Chinese that adopts the lexically ground approach of the PDTB while making systematic adaptations motivated by characteristics of Chinese text. These adaptations not only work well in practice, as evidenced by the results from our annotation experiment, but also embody a more generalized view of the lexically ground approach to discourse annotation: Discourse relations are predication involving two arguments; the predicate can be either covert (i.e. Implicit) or overt, lexicalized as discourse connectives (i.e. Explicit) or their more polymorphous counterparts (i.e. AltLex). Consistent with this generalized view is a more semantically motivated sense annotation scheme: Senses of *discourse relations* (as opposed to just connectives) are annotated; and the two arguments of the discourse relation are semantically defined, allowing the sense structure to be more general and less connective-dependent. These framework-level generalizations can be applied to discourse annotation of other languages.

## Abstract

One of the key tasks for analyzing conversational data is segmenting it into coherent topic segments. However, most models of topic segmentation ignore the *social* aspect of conversations, focusing only on the words used. We introduce a hierarchical Bayesian nonparametric model, Speaker Identity for Topic Segmentation (SITS), that discovers (1) the topics used in a conversation, (2) how these topics are shared across conversations, (3) when these topics shift, and (4) a person-specific tendency to introduce new topics. We evaluate against current unsupervised segmentation models to show that including person-specific information improves segmentation performance on meeting corpora and on political debates. Moreover, we provide evidence that SITS captures an individual's tendency to introduce new topics in political contexts, via analysis of the 2008 US presidential debates and the television program Crossfire.

## 1 Topic Segmentation as a Social Process

Conversation, interactive discussion between two or more people, is one of the most essential and common forms of communication. Whether in an informal situation or in more formal settings such as a political debate or business meeting, a conversation is often not about just one thing: topics evolve and are replaced as the conversation unfolds. Discovering this hidden structure in conversations is a key problem for conversational assistants (Tur et al., 2010) and tools that summarize (Murray et al., 2005) and display (Ehlen et al., 2007) conversational data. Topic segmentation also can illuminate individuals' agendas (Boydston et al., 2011), patterns of agreement and disagreement (Hawes et al., 2009; Abbott

et al., 2011), and relationships among conversational participants (Ireland et al., 2011).

One of the most natural ways to capture conversational structure is topic segmentation (Reynar, 1998; Purver, 2011). Topic segmentation approaches range from simple heuristic methods based on lexical similarity (Morris and Hirst, 1991; Hearst, 1997) to more intricate generative models and supervised methods (Georgescu et al., 2006; Purver et al., 2006; Gruber et al., 2007; Eisenstein and Barzilay, 2008), which have been shown to outperform the established heuristics.

However, previous computational work on conversational structure, particularly in topic discovery and topic segmentation, focuses primarily on content, ignoring the speakers. We argue that, because conversation is a *social* process, we can understand conversational phenomena better by explicitly modeling behaviors of conversational participants. In Section 2, we incorporate participant identity in a new model we call Speaker Identity for Topic Segmentation (SITS), which discovers topical structure in conversation while jointly incorporating a participant-level social component. Specifically, we explicitly model an individual's tendency to introduce a topic. After outlining inference in Section 3 and introducing data in Section 4, we use SITS to improve state-of-the-art-topic segmentation and topic identification models in Section 5. In addition, in Section 6, we also show that the per-speaker model is able to discover individuals who shape and influence the course of a conversation. Finally, we discuss related work and conclude the paper in Section 7.

## 2 Modeling Multiparty Discussions

**Data Properties** We are interested in turn-taking, multiparty discussion. This is a broad category, in-

cluding political debates, business meetings, and on-line chats. More formally, such datasets contain  $C$  conversations. A conversation  $c$  has  $T_c$  turns, each of which is a maximal uninterrupted utterance by one speaker.<sup>1</sup> In each turn  $t \in [1, T_c]$ , a speaker  $a_{c,t}$  utters  $N$  words  $\{w_{c,t,n}\}$ . Each word is from a vocabulary of size  $V$ , and there are  $M$  distinct speakers.

**Modeling Approaches** The key insight of topic segmentation is that segments evince lexical cohesion (Galley et al., 2003; Olney and Cai, 2005). Words within a segment will look more like their neighbors than other words. This insight has been used to tune supervised methods (Hsueh et al., 2006) and inspire unsupervised models of lexical cohesion using bags of words (Purver et al., 2006) and language models (Eisenstein and Barzilay, 2008).

We too take the unsupervised statistical approach. It requires few resources and is applicable in many domains without extensive training. Like previous approaches, we consider each turn to be a bag of words generated from an admixture of topics. Topics—after the topic modeling literature (Blei and Lafferty, 2009)—are multinomial distributions over terms. These topics are part of a generative model posited to have produced a corpus.

However, topic models alone cannot model the dynamics of a conversation. Topic models typically do not model the temporal dynamics of individual documents, and those that do (Wang et al., 2008; Gerrish and Blei, 2010) are designed for larger documents and are not applicable here because they assume that most topics appear in every time slice.

Instead, we endow each turn with a binary latent variable  $l_{c,t}$ , called the *topic shift*. This latent variable signifies whether the speaker changed the topic of the conversation. To capture the topic-controlling behavior of the speakers across different conversations, we further associate each speaker  $m$  with a latent *topic shift tendency*,  $\pi_m$ . Informally, this variable is intended to capture the propensity of a speaker to effect a topic shift. Formally, it represents the probability that the speaker  $m$  will change the topic (distribution) of a conversation.

We take a Bayesian nonparametric approach (Müller and Quintana, 2004). Unlike

<sup>1</sup>Note the distinction with phonetic utterances, which by definition are bounded by silence.

parametric models, which *a priori* fix the number of topics, nonparametric models use a flexible number of topics to better represent data. Nonparametric distributions such as the Dirichlet process (Ferguson, 1973) share statistical strength among conversations using a hierarchical model, such as the hierarchical Dirichlet process (HDP) (Teh et al., 2006).

## 2.1 Generative Process

In this section, we develop SITS, a generative model of multiparty discourse that jointly discovers topics and speaker-specific topic shifts from an unannotated corpus (Figure 1a). As in the hierarchical Dirichlet process (Teh et al., 2006), we allow an unbounded number of topics to be shared among the turns of the corpus. Topics are drawn from a base distribution  $H$  over multinomial distributions over the vocabulary, a finite Dirichlet with symmetric prior  $\lambda$ . Unlike the HDP, where every document (here, every turn) draws a new multinomial distribution from a Dirichlet process, the social and temporal dynamics of a conversation, as specified by the binary topic shift indicator  $l_{c,t}$ , determine when new draws happen.

The full generative process is as follows:

1. For speaker  $m \in [1, M]$ , draw speaker shift probability  $\pi_m \sim \text{Beta}(\gamma)$
2. Draw global probability measure  $G_0 \sim \text{DP}(\alpha, H)$
3. For each conversation  $c \in [1, C]$ 
  - (a) Draw conversation distribution  $G_c \sim \text{DP}(\alpha_0, G_0)$
  - (b) For each turn  $t \in [1, T_c]$  with speaker  $a_{c,t}$ 
    - i. If  $t = 1$ , set the topic shift  $l_{c,t} = 1$ . Otherwise, draw  $l_{c,t} \sim \text{Bernoulli}(\pi_{a_{c,t}})$ .
    - ii. If  $l_{c,t} = 1$ , draw  $G_{c,t} \sim \text{DP}(\alpha_c, G_c)$ . Otherwise, set  $G_{c,t} \equiv G_{c,t-1}$ .
    - iii. For each word index  $n \in [1, N_{c,t}]$ 
      - Draw  $\psi_{c,t,n} \sim G_{c,t}$
      - Draw  $w_{c,t,n} \sim \text{Multinomial}(\psi_{c,t,n})$

The hierarchy of Dirichlet processes allows statistical strength to be shared across contexts; within a conversation and across conversations. The per-speaker topic shift tendency  $\pi_m$  allows speaker *identity* to influence the evolution of topics.

To make notation concrete and aligned with the topic segmentation, we introduce notation for *segments* in a conversation. A segment  $s$  of conversation  $c$  is a sequence of turns  $[\tau, \tau']$  such that  $l_{c,\tau} = l_{c,\tau'+1} = 1$  and  $l_{c,t} = 0, \forall t \in (\tau, \tau']$ . When  $l_{c,t} = 0$ ,  $G_{c,t}$  is the same as  $G_{c,t-1}$  and all topics (i.e. multinomial distributions over words)  $\{\psi_{c,t,n}\}$  that generate words in turn  $t$  and the topics  $\{\psi_{c,t-1,n}\}$  that generate words in turn  $t - 1$  come from the same

Figure 1: Graphical model representations of our proposed models: (a) the nonparametric version; (b) the parametric version. Nodes represent random variables (shaded ones are observed), lines are probabilistic dependencies. Plates represent repetition. The innermost plates are turns, grouped in conversations.

distribution. Thus all topics used in a segment  $s$  are drawn from a single distribution,  $G_{C,s}$ ,

$$G_{c,s} \mid l_{c,1}, l_{c,2}, \dots, l_{c,T_c}, \alpha_c, G_c \sim \text{DP}(\alpha_c, G_c) \quad (1)$$

For notational convenience,  $S_c$  denotes the number of segments in conversation  $c$ , and  $s_t$  denotes the segment index of turn  $t$ . We emphasize that all segment-related notations are derived from the posterior over the topic shifts  $l$  and not part of the model itself.

**Parametric Version** SITS is a generalization of a parametric model (Figure 1b) where each turn has a multinomial distribution over  $K$  topics. In the parametric case, the number of topics  $K$  is fixed. Each topic, as before, is a multinomial distribution  $\phi_1 \dots \phi_K$ . In the parametric case, each turn  $t$  in conversation  $c$  has an explicit multinomial distribution over  $K$  topics  $\theta_{c,t}$ , identical for turns within a segment. A new topic distribution  $\theta$  is drawn from a Dirichlet distribution parameterized by  $\alpha$  when the topic shift indicator  $l$  is 1.

The parametric version does not share strength within or across conversations, unlike SITS. When applied on a single conversation without speaker identity (all speakers are identical) it is equivalent to (Purver et al., 2006). In our experiments (Section 5), we compare against both.

### 3 Inference

To find the latent variables that best explain observed data, we use Gibbs sampling, a widely used Markov chain Monte Carlo inference technique (Neal, 2000; Resnik and Hardisty, 2010). The state space is latent variables for topic indices assigned to all tokens  $\mathbf{z} = \{z_{c,t,n}\}$  and topic shifts assigned to turns  $\mathbf{l} = \{l_{c,t}\}$ . We marginalize over all other latent variables. Here, we only present the conditional sampling equations; for more details, see our supplement.<sup>2</sup>

#### 3.1 Sampling Topic Assignments

To sample  $z_{c,t,n}$ , the index of the shared topic assigned to token  $n$  of turn  $t$  in conversation  $c$ , we need to sample the *path* assigning each word token to a segment-specific topic, each segment-specific topic to a conversational topic and each conversational topic to a shared topic. For efficiency, we make use of the *minimal path assumption* (Wallach, 2008) to generate these assignments.<sup>3</sup> Under the minimal path assumption, an observation is assumed to have been generated by using a new distribution if and only if there is no existing distribution with the same value.

<sup>2</sup> <http://www.cs.umd.edu/~vietan/topicshift/appendix.pdf>

<sup>3</sup> We also investigated using the maximal assumption and fully sampling assignments. We found the minimal path assumption worked as well as explicitly sampling seating assignments and that the maximal path assumption worked less well.

We use  $N_{c,s,k}$  to denote the number of tokens in segment  $s$  in conversation  $c$  assigned topic  $k$ ;  $N_{c,k}$  denotes the total number of segment-specific topics in conversation  $c$  assigned topic  $k$  and  $N_k$  denotes the number of conversational topics assigned topic  $k$ .  $TW_{k,w}$  denotes the number of times the shared topic  $k$  is assigned to word  $w$  in the vocabulary. Marginal counts are represented with  $\cdot$  and  $*$  represents all hyperparameters. The conditional distribution for  $z_{c,t,n}$  is  $P(z_{c,t,n} = k \mid w_{c,t,n} = w, \mathbf{z}^{-c,t,n}, \mathbf{w}^{-c,t,n}, \mathbf{l}, *) \propto$

$$\frac{N_{c,s_t,k}^{-c,t,n} + \alpha_c \frac{N_{c,k}^{-c,t,n} + \alpha_0 \frac{N_{c,t,n}^{-c,t,n} + \frac{\alpha_c}{K}}{N_{c,t,n}^{-c,t,n} + \alpha_0}}{N_{c,s_t,\cdot}^{-c,t,n} + \alpha_c} \times \begin{cases} \frac{TW_{k,w}^{-c,t,n} + \lambda}{TW_{k,\cdot}^{-c,t,n} + V\lambda}, \\ \frac{1}{V} & k \text{ new.} \end{cases} \quad (2)$$

Here  $V$  is the size of the vocabulary,  $K$  is the current number of shared topics and the superscript  $^{-c,t,n}$  denotes counts without considering  $w_{c,t,n}$ . In Equation 2, the first factor is proportional to the probability of sampling a path according to the minimal path assumption; the second factor is proportional to the likelihood of observing  $w$  given the sampled topic. Since an uninformed prior is used, when a new topic is sampled, all tokens are equiprobable.

### 3.2 Sampling Topic Shifts

Sampling the topic shift variable  $l_{c,t}$  requires us to consider merging or splitting segments. We use  $\mathbf{k}_{c,t}$  to denote the shared topic indices of all tokens in turn  $t$  of conversation  $c$ ;  $S_{a_{c,t},x}$  to denote the number of times speaker  $a_{c,t}$  is assigned the topic shift with value  $x \in \{0, 1\}$ ;  $J_{c,s}^x$  to denote the number of topics in segment  $s$  of conversation  $c$  if  $l_{c,t} = x$  and  $N_{c,s,j}^x$  to denote the number of tokens assigned to the segment-specific topic  $j$  when  $l_{c,t} = x$ .<sup>4</sup> Again, the superscript  $^{-c,t}$  is used to denote exclusion of turn  $t$  of conversation  $c$  in the corresponding counts.

Recall that the topic shift is a binary variable. We use 0 to represent the case that the topic distribution is identical to the previous turn. We sample this assignment  $P(l_{c,t} = 0 \mid \mathbf{l}^{-c,t}, \mathbf{w}, \mathbf{k}, \mathbf{a}, *) \propto$

$$\frac{S_{a_{c,t},0}^{-c,t} + \gamma}{S_{a_{c,t},\cdot}^{-c,t} + 2\gamma} \times \frac{\alpha_c^{J_{c,s_t}^0} \prod_{j=1}^{J_{c,s_t}^0} (N_{c,s_t,j}^0 - 1)!}{\prod_{x=1}^{N_{c,s_t,\cdot}^0} (x - 1 + \alpha_c)}. \quad (3)$$

<sup>4</sup>Deterministically knowing the path assignments is the primary efficiency motivation for using the minimal path assumption. The alternative is to explicitly sample the path assignments, which is more complicated (for both notation and computation). This option is spelled in full detail in the supplementary material.

In Equation 3, the first factor is proportional to the probability of assigning a topic shift of value 0 to speaker  $a_{c,t}$  and the second factor is proportional to the joint probability of all topics in segment  $s_t$  of conversation  $c$  when  $l_{c,t} = 0$ .

The other alternative is for the topic shift to be 1, which represents the introduction of a new distribution over topics *inside* an existing segment. We sample this as  $P(l_{c,t} = 1 \mid \mathbf{l}^{-c,t}, \mathbf{w}, \mathbf{k}, \mathbf{a}, *) \propto$

$$\frac{S_{a_{c,t},1}^{-c,t} + \gamma}{S_{a_{c,t},\cdot}^{-c,t} + 2\gamma} \times \left( \frac{\alpha_c^{J_{c,(s_t-1)}^1} \prod_{j=1}^{J_{c,(s_t-1)}^1} (N_{c,(s_t-1),j}^1 - 1)!}{\prod_{x=1}^{N_{c,(s_t-1),\cdot}^1} (x - 1 + \alpha_c)} \frac{\alpha_c^{J_{c,s_t}^1} \prod_{j=1}^{J_{c,s_t}^1} (N_{c,s_t,j}^1 - 1)!}{\prod_{x=1}^{N_{c,s_t,\cdot}^1} (x - 1 + \alpha_c)} \right). \quad (4)$$

As above, the first factor in Equation 4 is proportional to the probability of assigning a topic shift of value 1 to speaker  $a_{c,t}$ ; the second factor in the big bracket is proportional to the joint distribution of the topics in segments  $s_t - 1$  and  $s_t$ . In this case  $l_{c,t} = 1$  means splitting the current segment, which results in two joint probabilities for two segments.

## 4 Datasets

This section introduces the three corpora we use. We preprocess the data to remove stopwords and remove turns containing fewer than five tokens.

**The ICSI Meeting Corpus:** The *ICSI Meeting Corpus* (Janin et al., 2003) is 75 transcribed meetings. For evaluation, we used a standard set of reference segmentations (Galley et al., 2003) of 25 meetings. Segmentations are *binary*, i.e., each point of the document is either a segment boundary or not, and on average each meeting has 8 segment boundaries. After preprocessing, there are 60 unique speakers and the vocabulary contains 3346 non-stopword tokens.

**The 2008 Presidential Election Debates** Our second dataset contains three annotated presidential debates (Boydston et al., 2011) between Barack Obama and John McCain and a vice presidential debate between Joe Biden and Sarah Palin. Each turn is one of two types: *questions* ( $Q$ ) from the moderator or *responses* ( $R$ ) from a candidate. Each clause in a turn is coded with a *Question Topic* ( $T_Q$ ) and a *Response Topic* ( $T_R$ ). Thus, a turn has a list of  $T_Q$ 's and  $T_R$ 's both of length equal to the number of clauses in the turn. Topics are from the Policy Agendas Topics

Speaker	Type	Turn clauses	$T_Q$	$T_R$
Brokaw	$Q$	Sen. Obama, [...] Are you saying [...] that the American economy is going to get much worse before it gets better and they ought to be prepared for that?	1	N/A
Obama	$R$	No, I am confident about the American economy.	1	1
		[...] But most importantly, we're going to have to help ordinary families be able to stay in their homes, make sure that they can pay their bills [...]	1	14
Brokaw	$Q$	Sen. McCain, in all candor, do you think the economy is going to get worse before it gets better?	1	N/A
McCain	$R$	[...] I think if we act effectively, if we stabilize the housing market—which I believe we can,	1	14
		if we go out and buy up these bad loans, so that people can have a new mortgage at the new value of their home	1	14
		I think if we get rid of the cronyism and special interest influence in Washington so we can act more effectively. [...]	1	20

Table 1: Example turns from the annotated 2008 election debates. The topics ( $T_Q$  and  $T_R$ ) are from the Policy Agendas Topics Codebook which contains the following codes of topic: Macroeconomics (1), Housing & Community Development (14), Government Operations (20).

Codebook, a manual inventory of 19 major topics and 225 subtopics.<sup>5</sup> Table 1 shows an example annotation.

To get reference segmentations, we assign each turn a real value from 0 to 1 indicating how much a turn changes the topic. For a question-typed turn, the score is the fraction of clause topics not appearing in the previous turn; for response-typed turns, the score is the fraction of clause topics that do not appear in the corresponding question. This results in a set of *non-binary* reference segmentations. For evaluation metrics that require binary segmentations, we create a binary segmentation by setting a turn as a segment boundary if the computed score is 1. This threshold is chosen to include only true segment boundaries.

**CNN’s Crossfire** *Crossfire* was a weekly U.S. television “talking heads” program engineered to incite heated arguments (hence the name). Each episode features two recurring hosts, two guests, and clips from the week’s news. Our *Crossfire* dataset contains 1134 transcribed episodes aired between 2000 and 2004.<sup>6</sup> There are 2567 unique speakers. Unlike the previous two datasets, *Crossfire* does not have explicit topic segmentations, so we use it to explore speaker-specific characteristics (Section 6).

## 5 Topic Segmentation Experiments

In this section, we examine how well SITS can replicate annotations of when new topics are introduced.

<sup>5</sup> <http://www.policyagendas.org/page/topic-codebook>

<sup>6</sup> <http://www.cs.umd.edu/~vietan/topicshift/crossfire.zip>

We discuss metrics for evaluating an algorithm’s segmentation against a gold annotation, describe our experimental setup, and report those results.

**Evaluation Metrics** To evaluate segmentations, we use  $P_k$  (Beeferman et al., 1999) and WindowDiff (WD) (Pevzner and Hearst, 2002). Both metrics measure the probability that two points in a document will be incorrectly separated by a segment boundary. Both techniques consider all spans of length  $k$  in the document and count whether the two endpoints of the window are (im)properly segmented against the gold segmentation.

However, these metrics have drawbacks. First, they require both hypothesized and reference segmentations to be binary. Many algorithms (e.g., probabilistic approaches) give *non-binary* segmentations where candidate boundaries have real-valued scores (e.g., probability or confidence). Thus, evaluation requires arbitrary thresholding to binarize soft scores. To be fair, thresholds are set so the number of segments are equal to a predefined value (Purver et al., 2006; Galley et al., 2003).

To overcome these limitations, we also use *Earth Mover’s Distance* (EMD) (Rubner et al., 2000), a metric that measures the distance between two distributions. The EMD is the minimal cost to transform one distribution into the other. Each segmentation can be considered a multi-dimensional distribution where each candidate boundary is a dimension. In EMD, a distance function across features allows partial credit for “near miss” segment boundaries. In

addition, because EMD operates on distributions, we can compute the distance between non-binary hypothesized segmentations with binary or real-valued reference segmentations. We use the FastEMD implementation (Pele and Werman, 2009).

**Experimental Methods** We applied the following methods to discover topic segmentations in a document:

- **TextTiling** (Hearst, 1997) is one of the earliest general-purpose topic segmentation algorithms, sliding a fixed-width window to detect major changes in lexical similarity.
- **P-NoSpeaker-S**: parametric version without speaker identity run on each conversation (Purver et al., 2006)
- **P-NoSpeaker-M**: parametric version without speaker identity run on all conversations
- **P-SITS**: the parametric version of SITS with speaker identity run on all conversations
- **NP-HMM**: the HMM-based nonparametric model which a single topic per turn. This model can be considered a Sticky HDP-HMM (Fox et al., 2008) with speaker identity.
- **NP-SITS**: the nonparametric version of SITS with speaker identity run on all conversations.

**Parameter Settings and Implementations** In our experiment, all parameters of TextTiling are the same as in (Hearst, 1997). For statistical models, Gibbs sampling with 10 randomly initialized chains is used. Initial hyperparameter values are sampled from  $U(0, 1)$  to favor sparsity; statistics are collected after 500 burn-in iterations with a lag of 25 iterations over a total of 5000 iterations; and slice sampling (Neal, 2003) optimizes hyperparameters.

**Results and Analysis** Table 2 shows the performance of various models on the topic segmentation problem, using the ICSI corpus and the 2008 debates.

Consistent with previous results, probabilistic models outperform TextTiling. In addition, among the probabilistic models, the models that had access to speaker information consistently segment better than those lacking such information, supporting our assertion that there is benefit to modeling conversation as a *social* process. Furthermore, NP-SITS outperforms NP-HMM in both experiments, suggesting that using a distribution over topics to turns is better than using a single topic. This is consistent with parametric results reported in (Purver et al., 2006).

The contribution of speaker identity seems more valuable in the debate setting. Debates are characterized by strong rewards for setting the agenda; dodging a question or moving the debate toward an oppo-

nent’s weakness can be useful strategies (Boydston et al., 2011). In contrast, meetings (particularly low-stakes ICSI meetings) are characterized by pragmatic rather than strategic topic shifts. Second, agenda-setting roles are clearer in formal debates; a moderator is tasked with setting the agenda and ensuring the conversation does not wander too much.

The nonparametric model does best on the smaller debate dataset. We suspect that an evaluation that directly accessed the topic quality, either via prediction (Teh et al., 2006) or interpretability (Chang et al., 2009) would favor the nonparametric model more.

## 6 Evaluating Topic Shift Tendency

In this section, we focus on the ability of SITS to capture speaker-level attributes. Recall that SITS associates with each speaker a topic shift tendency  $\pi$  that represents the probability of asserting a new topic in the conversation. While topic segmentation is a well studied problem, there are no established quantitative measurements of an individual’s ability to control a conversation. To evaluate whether the tendency is capturing meaningful characteristics of speakers, we compare our inferred tendencies against insights from political science.

**2008 Elections** To obtain a posterior estimate of  $\pi$  (Figure 3) we create 10 chains with hyperparameters sampled from the uniform distribution  $U(0, 1)$  and averaged  $\pi$  over 10 chains (as described in Section 5). In these debates, Ifill is the moderator of the debate between Biden and Palin; Brokaw, Lehrer and Schieffer are the three moderators of three debates between Obama and McCain. Here “Question” denotes questions from audiences in “town hall” debate. The role of this “speaker” can be considered equivalent to the debate moderator.

The topic shift tendencies of moderators are much higher than for candidates. In the three debates between Obama and McCain, the moderators—Brokaw, Lehrer and Schieffer—have significantly higher scores than both candidates. This is a useful reality check, since in a debate the moderators are the ones asking questions and literally controlling the topical focus. Interestingly, in the vice-presidential debate, the score of moderator Ifill is only slightly higher than those of Palin and Biden; this is consistent with media commentary characterizing her as a

Table 2: Results on the topic segmentation task. Lower is better. The parameter  $k$  is the window size of the metrics  $P_k$  and WindowDiff chosen to replicate previous results.

weak moderator.<sup>7</sup> Similarly, the “Question” speaker had a relatively high variance, consistent with an amalgamation of many distinct speakers.

These topic shift tendencies suggest that all candidates manage to succeed at some points in setting and controlling the debate topics. Our model gives Obama a slightly higher score than McCain, consistent with social science claims (Boydston et al., 2011) that Obama had the lead in setting the agenda over McCain. Table 4 shows of SITS-detected topic shifts.

**Crossfire** Crossfire, unlike the debates, has many speakers. This allows us to examine more closely what we can learn about speakers’ topic shift tendency. We verified that SITS can segment topics, and assuming that changing the topic is useful for a speaker, how can we characterize who does so effectively? We examine the relationship between topic shift tendency, social roles, and political ideology.

To focus on frequent speakers, we filter out speakers with fewer than 30 turns. Most speakers have relatively small  $\pi$ , with the mode around 0.3. There are, however, speakers with very high topic shift tendencies. Table 5 shows the speakers having the highest values according to SITS.

We find that there are three general patterns for who influences the course of a conversation in *Crossfire*. First, there are structural “speakers” the show uses to frame and propose new topics. These are

<sup>7</sup> <http://harpers.org/archive/2008/10/hbc-90003659>

Table 3: Topic shift tendency  $\pi$  of speakers in the 2008 Presidential Election Debates (larger means greater tendency)

audience questions, news clips (e.g. many of Gore’s and Bush’s turns from 2000), and voice overs. That SITS is able to recover these is reassuring. Second, the stable of regular hosts receives high topic shift tendencies, which is reasonable given their experience with the format and ostensible moderation roles (in practice they also stoke lively discussion).

The remaining class is more interesting. The remaining non-hosts with high topic shift tendency are relative moderates on the political spectrum:

- John Kasich, one of few Republicans to support the assault weapons ban and now governor of Ohio, a swing state
- Christine Todd Whitman, former Republican governor of New Jersey, a very Democratic state
- John McCain, who before 2008 was known as a “maverick” for working with Democrats (e.g. Russ Feingold)

This suggests that, despite *Crossfire*’s tendency to create highly partisan debates, those who are able to work across the political spectrum may best be able to influence the topic under discussion in highly polarized contexts. Table 4 shows detected topic shifts from these speakers; two of these examples (McCain and Whitman) show disagreement of Republicans with President Bush. In the other, Kasich is defending a Republican plan (school vouchers) popular with traditional Democratic constituencies.

## 7 Related and Future Work

In the realm of statistical models, a number of techniques incorporate social connections and identity to explain content in social networks (Chang and Blei,

	Previous turn	Turn detected as shifting topic
Debates Dataset	PALIN: Your question to him was whether he supported <i>gay marriage</i> and my answer is the same as his and it is that I do not.	IFILL: Wonderful. You agree. On that note, let’s move to <i>foreign policy</i> . You both have sons who are in Iraq or on their way to Iraq. You, Governor Palin, have said that you would like to see a real clear plan for an exit strategy. [...]
	MCCAIN: I think that Joe Biden is qualified in many respects. ...	SCHIEFFER: [...] Let’s talk about <i>energy</i> and <i>climate control</i> . Every president since Nixon has said what both of you [...]
	IFILL: So, Governor, as vice president, there’s nothing that you have promised [...] that you wouldn’t take off the table because of this <i>financial crisis</i> we’re in?	BIDEN: Again, let me—let’s talk about those tax breaks. [Obama] voted for an energy bill because, for the first time, it had real support for alternative energy. [...] on eliminating the tax breaks for the oil companies, Barack Obama voted to eliminate them. [...]
Crossfire Dataset	PRESS: But what do you say, governor, to Governor Bush and [...] your party who would let politicians and not medical scientists decide what <i>drugs</i> are distributed [...]	WHITMAN: Well I disagree with them on this particular issues [...] that’s important to me that George Bush stands for education of our children [...] I care about tax policy, I care about the environment. I care about all the issues where he has a proven record in Texas [...]
	WEXLER: [...] They need a Medicare prescription drug plan [...] Talk about schools, [...] Al Gore has got a real plan. George Bush offers us vouchers. Talk about the environment. [...] Al Gore is right on in terms of the majority of Americans, but George Bush [...]	KASICH: [...] I want to talk about choice. [...] George Bush believes that, if schools fail, parents ought to have a right to get their kids out of those schools and give them a chance and an opportunity for success. Gore says “no way” [...] Social Security. George Bush says [...] direct it the way federal employees do [...] Al Gore says “No way” [...] That’s real choice. That’s real bottom-up, not a bureaucratic approach, the way we run this country.
	PRESS: Senator, Senator Breaux mentioned that it’s President Bush’s aim to start on education [...] [McCain] [...] said he was going to do introduce the legislation the first day of the first week of the new administration. [...]	MCCAIN: After one of closest elections in our nation’s history, there is one thing the American people are unanimous about They want their government back. We can do that by ridding politics of large, unregulated contributions that give special interests a seat at the table while average Americans are stuck in the back of the room.

2009) and scientific corpora (Rosen-Zvi et al., 2004). However, these models ignore the temporal evolution of content, treating documents as static.

Models that do investigate the evolution of topics over time typically ignore the identify of the speaker. For example: models having sticky topics over n-grams (Johnson, 2010), sticky HDP-HMM (Fox et al., 2008); models that are an amalgam of sequential models and topic models (Griffiths et al., 2005; Wal-

lach, 2006; Gruber et al., 2007; Ahmed and Xing, 2008; Boyd-Graber and Blei, 2008; Du et al., 2010); or explicit models of time or other relevant features as a distinct latent variable (Wang and McCallum, 2006; Eisenstein et al., 2010).

In contrast, SITS jointly models topic and individuals’ tendency to control a conversation. Not only does SITS outperform other models using standard computational linguistics baselines, but it also proposes intriguing hypotheses for social scientists.

Associating each speaker with a scalar that models their tendency to change the topic does improve performance on standard tasks, but it’s inadequate to fully describe an individual. Modeling individuals’ perspective (Paul and Girju, 2010), “side” (Thomas et al., 2006), or personal preferences for topics (Grimmer, 2009) would enrich the model and better illuminate the interaction of influence and topic.

Statistical analysis of political discourse can help discover patterns that political scientists, who often work via a “close reading,” might otherwise miss. We plan to work with social scientists to validate our implicit hypothesis that our topic shift tendency correlates well with intuitive measures of “influence.”

## Abstract

We propose a new approach to characterizing the timeline of a text: temporal dependency structures, where all the events of a narrative are linked via partial ordering relations like BEFORE, AFTER, OVERLAP and IDENTITY. We annotate a corpus of children’s stories with temporal dependency trees, achieving agreement (Krippendorff’s Alpha) of 0.856 on the event words, 0.822 on the links between events, and of 0.700 on the ordering relation labels. We compare two parsing models for temporal dependency structures, and show that a deterministic non-projective dependency parser outperforms a graph-based maximum spanning tree parser, achieving labeled attachment accuracy of 0.647 and labeled tree edit distance of 0.596. Our analysis of the dependency parser errors gives some insights into future research directions.

## 1 Introduction

There has been much recent interest in identifying events, times and their relations along the timeline, from event and time ordering problems in the TempEval shared tasks (Verhagen et al., 2007; Verhagen et al., 2010), to identifying time arguments of event structures in the Automated Content Extraction program (Linguistic Data Consortium, 2005; Gupta and Ji, 2009), to timestamping event intervals in the Knowledge Base Population shared task (Artiles et al., 2011; Amigó et al., 2011).

However, to date, this research has produced fragmented document timelines, because only specific types of temporal relations in specific contexts have

been targeted. For example, the TempEval tasks only looked at relations between events in the same or adjacent sentences (Verhagen et al., 2007; Verhagen et al., 2010), and the Automated Content Extraction program only looked at time arguments for specific types of events, like *being born* or *transferring money*.

In this article, we propose an approach to temporal information extraction that identifies a single connected timeline for a text. The temporal language in a text often fails to specify a total ordering over all the events, so we annotate the timelines as temporal dependency structures, where each event is a node in the dependency tree, and each edge between nodes represents a temporal ordering relation such as BEFORE, AFTER, OVERLAP or IDENTITY. We construct an evaluation corpus by annotating such temporal dependency trees over a set of children’s stories. We then demonstrate how to train a timeline extraction system based on dependency parsing techniques instead of the pair-wise classification approaches typical of prior work.

The main contributions of this article are:

- We propose a new approach to characterizing temporal structure via dependency trees.
- We produce an annotated corpus of temporal dependency trees in children’s stories.
- We design a non-projective dependency parser for inferring timelines from text.

The following sections first review some relevant prior work, then describe the corpus annotation and the dependency parsing algorithm, and finally present our evaluation results.

## 2 Related Work

Much prior work on the annotation of temporal information has constructed corpora with incomplete timelines. The TimeBank (Pustejovsky et al., 2003b; Pustejovsky et al., 2003a) provided a corpus annotated for all events and times, but temporal relations were only annotated when the relation was judged to be salient by the annotator. In the TempEval competitions (Verhagen et al., 2007; Verhagen et al., 2010), annotated texts were provided for a few different event and time configurations, for example, an event and a time in the same sentence, or two main-clause events from adjacent sentences. Bethard et al. (2007) proposed to annotate temporal relations one syntactic construction at a time, producing an initial corpus of only verbal events linked to events in subordinated clauses. One notable exception to this pattern of incomplete timelines is the work of Bramsen et al. (2006) where temporal structures were annotated as directed acyclic graphs. However they worked on a much coarser granularity, annotating not the ordering between individual events, but between multi-sentence segments of text.

In part because of the structure of the available training corpora, most existing temporal information extraction models formulate temporal linking as a pair-wise classification task, where each pair of events and/or times is examined and classified as having a temporal relation or not. Early work on the TimeBank took this approach (Boguraev and Ando, 2005), classifying relations between all events and times within 64 tokens of each other. Most of the top-performing systems in the TempEval competitions also took this pair-wise classification approach for both event-time and event-event temporal relations (Bethard and Martin, 2007; Cheng et al., 2007; UzZaman and Allen, 2010; Llorens et al., 2010). Systems have also tried to take advantage of more global information to ensure that the pair-wise classifications satisfy temporal logic transitivity constraints, using frameworks such as integer linear programming and Markov logic networks (Bramsen et al., 2006; Chambers and Jurafsky, 2008; Yoshikawa et al., 2009; UzZaman and Allen, 2010). Yet the basic approach is still centered around pair-wise classifications, not the complete temporal structure of a document.

Our work builds upon this prior research, both

improving the annotation approach to generate the fully connected timeline of a story, and improving the models for timeline extraction using dependency parsing techniques. We use the annotation scheme introduced in more detail in Bethard et al. (2012), which proposes to annotate temporal relations as dependency links between head events and dependent events. This annotation scheme addresses the issues of incoherent and incomplete annotations by guaranteeing that all events in a plot are connected along a single timeline. These connected timelines allow us to design new models for timeline extraction in which we jointly infer the temporal structure of the text and the labeled temporal relations. We employ methods from syntactic dependency parsing, adapting them to our task by including features typical of temporal relation labeling models.

## 3 Corpus Annotation

The corpus of stories for children was drawn from the fables collection of (McIntyre and Lapata, 2009)<sup>1</sup> and annotated as described in (Bethard et al., 2012). In this section we illustrate the main annotation principles for coherent temporal annotation. As an example story, consider:

Two Travellers were on the road together, when a Bear suddenly appeared on the scene. Before he observed them, one made for a tree at the side of the road, and climbed up into the branches and hid there. The other was not so nimble as his companion; and, as he could not escape, he threw himself on the ground and pretended to be dead. . . [37.txt]

Figure 1 shows the temporal dependency structure that we expect our annotators to identify in this story.

The annotators were provided with guidelines both for which kinds of words should be identified as events, and for which kinds of events should be linked by temporal relations. For identifying event words, the standard TimeML guidelines for annotating events (Pustejovsky et al., 2003a) were augmented with two additional guidelines:

<sup>1</sup>Data available at <http://homepages.inf.ed.ac.uk/s0233364/McIntyreLapata09/>

Figure 1: Event timeline for the story of the Travellers and the Bear. Nodes are events and edges are temporal relations. Edges denote temporal relations signaled by linguistic cues in the text. Temporal relations that can be inferred via transitivity are not shown.

- Skip negated, modal or hypothetical events (e.g. *could not escape*, *dead in pretended to be dead*).
- For phrasal events, select the single word that best paraphrases the meaning (e.g. in *used to snap* the event should be *snap*, in *kept perfectly still* the event should be *still*).

For identifying the temporal dependencies (i.e. the ordering relations between event words), the annotators were instructed to link each event in the story to a single nearby event, similar to what has been observed in reading comprehension studies (Johnson-Laird, 1980; Brewer and Lichtenstein, 1982). When there were several reasonable nearby events to choose from, the annotators were instructed to choose the temporal relation that was easiest to infer from the text (e.g. preferring relations with explicit cue words like *before*). A set of six temporal relations was used: BEFORE, AFTER, INCLUDES, IS-INCLUDED, IDENTITY or OVERLAP.

Two annotators annotated temporal dependency structures in the first 100 fables of the McIntyre-Lapata collection and measured inter-annotator agreement by Krippendorff’s Alpha for nominal data (Krippendorff, 2004; Hayes and Krippendorff, 2007). For the resulting annotated corpus annotators achieved Alpha of 0.856 on the event words, 0.822 on the links between events, and of 0.700 on the ordering relation labels. Thus, we concluded that the temporal dependency annotation paradigm was reliable, and the resulting corpus of 100 fables<sup>2</sup> could be used to

<sup>2</sup>Available from <http://www.bethard.info/data/fables-100-temporal-dependency.xml>

train a temporal dependency parsing model.

## 4 Parsing Models

We consider two different approaches to learning a temporal dependency parser: a shift-reduce model (Nivre, 2008) and a graph-based model (McDonald et al., 2005). Both models take as input a sequence of event words and produce as output a tree structure where the events are linked via temporal relations. Formally, a parsing model is a function ( $W \rightarrow \Pi$ ) where  $W = w_1w_2 \dots w_n$  is a sequence of event words, and  $\pi \in \Pi$  is a dependency tree  $\pi = (V, E)$  where:

- $V = W \cup \{Root\}$ , that is, the vertex set of the graph is the set of words in  $W$  plus an artificial root node.
- $E = \{(w_h, r, w_d) : w_h \in V, w_d \in V, r \in R = \{\text{BEFORE, AFTER, INCLUDES, IS\_INCLUDED, IDENTITY, OVERLAP}\}\}$ , that is, in the edge set of the graph, each edge is a link between a dependent word and its head word, labeled with a temporal relation.
- $(w_h, r, w_d) \in E \implies w_d \neq Root$ , that is, the artificial root node has no head.
- $(w_h, r, w_d) \in E \implies ((w'_h, r', w_d) \in E \implies w_h = w'_h \wedge r = r')$ , that is, for every node there is at most one head and one relation label.
- $E$  contains no (non-empty) subset of arcs  $(w_h, r_i, w_i), (w_i, r_j, w_j), \dots, (w_k, r_l, w_h)$ , that is, there are no cycles in the graph.

SHIFT	Move all of $L_2$ and the head of $Q$ onto $L_1$ $([a_1 \dots a_i], [b_1 \dots b_j], [w_k w_{k+1} \dots], E) \rightarrow ([a_1 \dots a_i b_1 \dots b_j w_k], [], [w_{k+1} \dots], E)$
NO-ARC	Move the head of $L_1$ to the head of $L_2$ $([a_1 \dots a_i a_{i+1}], [b_1 \dots b_j], Q, E) \rightarrow ([a_1 \dots a_i], [a_{i+1} b_1 \dots b_j], Q, E)$
LEFT-ARC	Create a relation where the head of $L_1$ depends on the head of $Q$ Not applicable if $a_{i+1}$ is the root or already has a head, or if there is a path connecting $w_k$ and $a_{i+1}$ $([a_1 \dots a_i a_{i+1}], [b_1 \dots b_j], [w_k \dots], E) \rightarrow ([a_1 \dots a_i], [a_{i+1} b_1 \dots b_j], [w_k \dots], E \cup (w_k, r, a_{i+1}))$
RIGHT-ARC	Create a relation where the head of $Q$ depends on the head of $L_1$ Not applicable if $w_k$ is the root or already has a head, or if there is a path connecting $w_k$ and $a_{i+1}$ $([a_1 \dots a_i a_{i+1}], [b_1 \dots b_j], [w_k \dots], E) \rightarrow ([a_1 \dots a_i], [a_{i+1} b_1 \dots b_j], [w_k \dots], E \cup (a_{i+1}, r, w_k))$

Table 1: Transition system for Covington-style shift-reduce dependency parsers.

#### 4.1 Shift-Reduce Parsing Model

Shift-reduce dependency parsers start with an input queue of unlinked words, and link them into a tree by repeatedly choosing and performing actions like shifting a node to a stack, or popping two nodes from the stack and linking them. Shift-reduce parsers are typically defined in terms of configurations and a transition system, where the configurations describe the current internal state of the parser, and the transition system describes how to get from one state to another. Formally, a deterministic shift-reduce dependency parser is defined as  $(C, T, C_F, \text{INIT}, \text{TREE})$  where:

- $C$  is the set of possible parser configurations  $c_i$
- $T \subseteq (C \rightarrow C)$  is the set of transitions  $t_i$  from one configuration  $c_j$  to another  $c_{j+1}$  allowed by the parser
- $\text{INIT} \in (W \rightarrow C)$  is a function from the input words to an initial parser configuration
- $C_F \subseteq C$  are the set of final parser configurations  $c_F$  where the parser is allowed to terminate
- $\text{TREE} \in (C_F \rightarrow \Pi)$  is a function that extracts a dependency tree  $\pi$  from a final parser state  $c_F$

Given this formalism and an oracle  $o \in (C \rightarrow T)$ , which can choose a transition given the current configuration of the parser, dependency parsing can be accomplished by Algorithm 1. For temporal dependency parsing, we adopt the Covington set of transitions (Covington, 2001) as it allows for parsing the non-projective trees, which may also contain ‘‘crossing’’ edges, that occasionally occur in our annotated corpus. Our parser is therefore defined as:

---

#### Algorithm 1 Deterministic parsing with an oracle.

---

```

 $c \leftarrow \text{INIT}(W)$ 
while  $c \notin C_F$  do
   $t \leftarrow o(c)$ 
   $c \leftarrow t(c)$ 
end while
return  $\text{TREE}(c)$ 

```

---

- $c = (L_1, L_2, Q, E)$  is a parser configuration, where  $L_1$  and  $L_2$  are lists for temporary storage,  $Q$  is the queue of input words, and  $E$  is the set of identified edges of the dependency tree.
- $T = \{\text{SHIFT}, \text{NO-ARC}, \text{LEFT-ARC}, \text{RIGHT-ARC}\}$  is the set of transitions described in Table 1.
- $\text{INIT}(W) = ([\text{Root}], [], [w_1, w_2, \dots, w_n], \emptyset)$  puts all input words on the queue and the artificial root on  $L_1$ .
- $C_F = \{(L_1, L_2, Q, E) \in C : L_1 = \{W \cup \{\text{Root}\}\}, L_2 = Q = \emptyset\}$  accepts final states where the input words have been moved off of the queue and lists and into the edges in  $E$ .
- $\text{TREE}((L_1, L_2, Q, E)) = (W \cup \{\text{Root}\}, E)$  extracts the final dependency tree.

The oracle  $o$  is typically defined as a machine learning classifier, which characterizes a parser configuration  $c$  in terms of a set of features. For temporal dependency parsing, we learn a Support Vector Machine classifier (Yamada and Matsumoto, 2003) using the features described in Section 5.

#### 4.2 Graph-Based Parsing Model

One shortcoming of the shift-reduce dependency parsing approach is that each transition decision

Figure 2: A setting for the graph-based parsing model: an initial dense graph  $G$  (left) with edge scores  $\text{SCORE}(e)$ . The resulting dependency tree as a spanning tree with the highest score over the edges (right).

made by the model is final, and cannot be revisited to search for more globally optimal trees. Graph-based models are an alternative dependency parsing model, which assembles a graph with weighted edges between all pairs of words, and selects the tree-shaped subset of this graph that gives the highest total score (Fig. 2). Formally, a graph-based parser follows Algorithm 2, where:

- $W' = W \cup \{Root\}$
- $\text{SCORE} \in ((W' \times R \times W) \rightarrow \mathfrak{R})$  is a function for scoring edges
- $\text{SPANNINGTREE}$  is a function for selecting a subset of edges that is a tree that spans over all the nodes of the graph.

---

**Algorithm 2** Graph-based dependency parsing

---

$E \leftarrow \{(e, \text{SCORE}(e)) : e \in (W' \times R \times W)\}$   
 $G \leftarrow (W', E)$   
**return**  $\text{SPANNINGTREE}(G)$

---

The  $\text{SPANNINGTREE}$  function is usually defined using one of the efficient search techniques for finding a maximum spanning tree. For temporal dependency parsing, we use the Chu-Liu-Edmonds algorithm (Chu and Liu, 1965; Edmonds, 1967) which solves this problem by iteratively selecting the edge with the highest weight and removing edges that would create cycles. The result is the globally optimal maximum spanning tree for the graph (Georgiadis, 2003).

The  $\text{SCORE}$  function is typically defined as a machine learning model that scores an edge based on a set of features. For temporal dependency parsing, we learn a model to predict edge scores via the Margin Infused Relaxed Algorithm (MIRA) (Crammer and Singer, 2003; Crammer et al., 2006) using the set of features defined in Section 5.

## 5 Feature Design

The proposed parsing algorithms both rely on machine learning methods. The shift-reduce parser (SRP) trains a machine learning classifier as the oracle  $o \in (C \rightarrow T)$  to predict a transition  $t$  from a parser configuration  $c = (L_1, L_2, Q, E)$ , using node features such as the heads of  $L_1$ ,  $L_2$  and  $Q$ , and edge features from the already predicted temporal relations in  $E$ . The graph-based maximum spanning tree (MST) parser trains a machine learning model to predict  $\text{SCORE}(e)$  for an edge  $e = (w_i, r_j, w_k)$ , using features of the nodes  $w_i$  and  $w_k$ . The full set of features proposed for both parsing models, derived from the state-of-the-art systems for temporal relation labeling, is presented in Table 2. Note that both models share features that look at the nodes, while only the shift-reduce parser has features for previously classified edges.

## 6 Evaluations

Evaluations were performed using 10-fold cross-validation on the fables annotated in Section 3. The corpus contains 100 fables, a total of 14,279 tokens and a total of 1136 annotated temporal relations. As

Temporal relation labels of $a_i$ and its leftmost and rightmost dependents	√	
Temporal relation labels of $a_{i-1}$ 's leftmost and rightmost dependents	√	
Temporal relation labels of $b_1$ and its leftmost and rightmost dependents	√	

Table 2: Features for the shift-reduce parser (SRP) and the graph-based maximum spanning tree (MST) parser. The √\* features are extracted from the heads of  $L_1$ ,  $L_2$  and  $Q$  for SRP and from each node of the edge for MST.

only 40 instances of OVERLAP relations were annotated when neither INCLUDES nor IS\_INCLUDED label matched, for evaluation purposes all instances of these relations were merged into the temporally coarse OVERLAP relation. Thus, the total number of OVERLAP relations in the corpus grew from 40 to 258 annotations in total.

To evaluate the parsing models (SRP and MST) we proposed two baselines. Both are based on the assumption of linear temporal structures of narratives as the temporal ordering process that was evidenced by studies in human text rewriting (Hickmann, 2003). The proposed baselines are:

- **LinearSeq:** A model that assumes all events occur in the order they are written, adding links between each pair of adjacent events, and labeling all links with the relation BEFORE.
- **ClassifySeq:** A model that links each pair of adjacent events, but trains a pair-wise classifier to predict the relation label for each pair. The

classifier is a support vector machine trained using the same features as the MST parser. This is an approximation of prior work, where the pairs of events to classify with a temporal relation were given as an input to the system. (Note that Section 6.2 will show that for our corpus, applying the model only to adjacent pairs of events is quite competitive for just getting the basic unlabeled link structure right.)

The Shift-Reduce parser (SRP; Section 4.1) and the graph-based, maximum spanning tree parser (MST; Section 4.2) are compared to these baselines.

## 6.1 Evaluation Criteria and Metrics

Model performance was evaluated using standard evaluation criteria for parser evaluations:

**Unlabeled Attachment Score (UAS)** The fraction of events whose head events were correctly predicted. This measures whether the correct pairs of events were linked, but not if they were linked by the correct relations.

**Labeled Attachment Score (LAS)** The fraction of events whose head events were correctly predicted with the correct relations. This measures both whether the correct pairs of events were linked and whether their temporal ordering is correct.

**Tree Edit Distance** In addition to the UAS and LAS the *tree edit distance* score has been recently introduced for evaluating dependency structures (Tsarfaty et al., 2011). The tree edit distance score for a tree  $\pi$  is based on the following operations  $\lambda \in \Lambda : \Lambda = \{\text{DELETE}, \text{INSERT}, \text{RELABEL}\}$ :

- $\lambda = \text{DELETE}$  delete a non-root node  $v$  in  $\pi$  with parent  $u$ , making the children of  $v$  the children of  $u$ , inserted in the place of  $v$  as a subsequence in the left-to-right order of the children of  $u$ .
- $\lambda = \text{INSERT}$  insert a node  $v$  as a child of  $u$  in  $\pi$  making it the parent of a consecutive subsequence of the children of  $u$ .
- $\lambda = \text{RELABEL}$  change the label of node  $v$  in  $\pi$

Any two trees  $\pi_1$  and  $\pi_2$  can be turned one into another by a sequence of edit operations  $\{\lambda_1, \dots, \lambda_n\}$ .

	UAS	LAS	UTEDS	LTEDS
LinearSeq	0.830	0.581	0.689	0.549
ClassifySeq	0.830	0.581	0.689	0.549
MST	0.837	0.614*	0.710	0.571
SRP	0.830	0.647*†	0.712	0.596*

Table 3: Performance levels of temporal structure parsing methods. A \* indicates that the model outperforms LinearSeq and ClassifiedSeq at  $p < 0.01$  and a † indicates that the model outperforms MST at  $p < 0.05$ .

Taking the shortest such sequence, the tree edit distance is calculated as the sum of the edit operation costs divided by the size of the tree (i.e. the number of words in the sentence). For temporal dependency trees, we assume each operation costs 1.0. The final score subtracts the edit distance from 1 so that a perfect tree has score 1.0. The *labeled* tree edit distance score (LTEDS) calculates sequences over the tree with all its labeled temporal relations, while the *unlabeled* tree edit distance score (UTEDS) treats all edges as if they had the same label.

## 6.2 Results

Table 3 shows the results of the evaluation. The unlabeled attachment score for the LinearSeq baseline was 0.830, suggesting that annotators were most often linking adjacent events. At the same time, the labeled attachment score was 0.581, indicating that even in fables, the stories are not simply linear, that is, there are many relations other than BEFORE. The ClassifySeq baseline performs identically to the LinearSeq baseline, which shows that the simple pairwise classifier was unable to learn anything beyond predicting all relations as BEFORE.

In terms of labeled attachment score, both dependency parsing models outperformed the baseline models – the maximum spanning tree parser achieved 0.614 LAS, and the shift-reduce parser achieved 0.647 LAS. The shift-reduce parser also outperformed the baseline models in terms of labeled tree edit distance, achieving 0.596 LTEDS vs. the baseline 0.549 LTEDS. These results indicate that dependency parsing models are a good fit to our whole-story timeline extraction task.

Finally, in comparing the two different dependency parsing models, we observe that the shift-reduce parser outperforms the maximum spanning

Error Type	Num.	%
OVERLAP → BEFORE	24	43.7
Attach to further head	18	32.7
Attach to nearer head	6	11.0
Other types of errors	7	12.6
Total	55	100

Table 4: Error distribution from the analysis of 55 errors of the Shift-Reduce parsing model.

tree parser in terms of labeled attachment score (0.647 vs. 0.614). It has been argued that graph-based models like the maximum spanning tree parser should be able to produce more globally consistent and correct dependency trees, yet we do not observe that here. A likely explanation for this phenomenon is that the shift-reduce parsing model allows for features describing previous parse decisions (similar to the incremental nature of human parse decisions), while the joint nature of the maximum spanning tree parser does not.

## 6.3 Error Analysis

To better understand the errors our model is still making, we examined two folds (55 errors in total in 20% of the evaluation data) and identified the major categories of errors:

- **OVERLAP → BEFORE:** The model predicts the correct head, but predicts its label as BEFORE, while the correct label is OVERLAP.
- **Attach to further head:** The model predicts the wrong head, and predicts as the head an event that is further away than the true head.
- **Attach to nearer head:** The model predicts the wrong head, and predicts as the head an event that is closer than the true head.

Table 4 shows the distribution of the errors over these categories. The two most common types of errors, OVERLAP → BEFORE and *Attach to further head*, account for 76.4% of all the errors.

The most common type of error is predicting a BEFORE relation when the correct answer is an OVERLAP relation. Figure 3 shows an example of such an error, where the model predicts that the Spendthrift *stood* before he *saw*, while the annotator indicates that the seeing happened during the

Figure 3: An OVERLAP  $\rightarrow$  BEFORE parser error. True links are solid lines; the parser error is the dotted line.

Figure 4: Parser errors attaching to further away heads. True links are solid lines; parser errors are dotted lines.

time in which he was standing. An analysis of these OVERLAP  $\rightarrow$  BEFORE errors suggests that they occur in scenarios like this one, where the duration of one event is significantly longer than the duration of another, but there are no direct cues for these duration differences. We also observe these types of errors when one event has many sub-events, and therefore the duration of the main event typically includes the durations of all the sub-events. It might be possible to address these kinds of errors by incorporating automatically extracted event duration information (Pan et al., 2006; Gusev et al., 2011).

The second most common error type of the model is the prediction of a head event that is further away than the head identified by the annotators. Figure 4 gives an example of such an error, where the model predicts that the *gathering* includes the *smarting*, instead of that the *gathering* includes the *stung*. The second error in the figure is also of the same type. In 65% of the cases where this type of error occurs, it occurs after the parser had already made a label classification error such as BEFORE  $\rightarrow$  OVERLAP. So these errors may be in part due to the sequential nature of shift-reduce parsing, where early errors propagate and cause later errors.

## 7 Discussion and Conclusions

In this article, we have presented an approach to temporal information extraction that represents the time-

line of a story as a temporal dependency tree. We have constructed an evaluation corpus where such temporal dependencies have been annotated over a set of 100 children’s stories. We have introduced two dependency parsing techniques for extracting story timelines and have shown that both outperform a rule-based baseline and a prior-work-inspired pair-wise classification baseline. Comparing the two dependency parsing models, we have found that a shift-reduce parser, which more closely mirrors the incremental processing of our human annotators, outperforms a graph-based maximum spanning tree parser. Our error analysis of the shift-reduce parser revealed that being able to estimate differences in event durations may play a key role in improving parse quality.

We have focused on children’s stories in this study, in part because they typically have simpler temporal structures (though not so simple that our rule-based baseline could parse them accurately). In most of our fables, there were only one or two characters with at most one or two simultaneous sequences of actions. In other domains, the timeline of a text is likely to be more complex. For example, in clinical records, descriptions of patients may jump back and forth between the patient history, the current examination, and procedures that have not yet happened.

In future work, we plan to investigate how to best apply the dependency structure approach to such domains. One approach might be to first group events into their *narrative containers* (Pustejovsky and Stubbs, 2011), for example, grouping together all events linked to the time of a patient’s examination. Then within each narrative container, our dependency parsing approach could be applied. Another approach might be to join the individual timeline trees into a document-wide tree via discourse relations or relations to the document creation time. Work on how humans incrementally process such timelines in text may help to decide which of these approaches holds the most promise.

# Labeling Documents with Timestamps: Learning from their Time Expressions

Nathanael Chambers

Department of Computer Science  
United States Naval Academy  
nchamber@usna.edu

## Abstract

Temporal reasoners for document understanding typically assume that a document's creation date is known. Algorithms to ground relative time expressions and order events often rely on this timestamp to assist the learner. Unfortunately, the timestamp is not always known, particularly on the Web. This paper addresses the task of automatic document timestamping, presenting two new models that incorporate rich linguistic features about time. The first is a discriminative classifier with new features extracted from the text's time expressions (e.g., 'since 1999'). This model alone improves on previous generative models by 77%. The second model learns probabilistic constraints between time expressions and the *unknown* document time. Imposing these learned constraints on the discriminative model further improves its accuracy. Finally, we present a new experiment design that facilitates easier comparison by future work.

## 1 Introduction

This paper addresses a relatively new task in the NLP community: automatic document dating. Given a document with unknown origins, what characteristics of its text indicate the year in which the document was written? This paper proposes a learning approach that builds constraints from a document's use of time expressions, and combines them with a new discriminative classifier that greatly improves previous work.

The temporal reasoning community has long depended on document timestamps to ground rela-

tive time expressions and events (Mani and Wilson, 2000; Llidó et al., 2001). For instance, consider the following passage from the TimeBank corpus (Pustejovsky et al., 2003):

And while there was no profit *this year* from discontinued operations, *last year* they contributed 34 million, before tax.

Reconstructing the timeline of events from this document requires extensive temporal knowledge, most notably, the document's creation date to ground its relative expressions (e.g., *this year* = 2012). Not only did the latest TempEval competitions (Verhagen et al., 2007; Verhagen et al., 2009) include tasks to link events to the (known) document creation time, but state-of-the-art event-event ordering algorithms also rely on these timestamps (Chambers and Jurafsky, 2008; Yoshikawa et al., 2009). This knowledge is assumed to be available, but unfortunately this is not often the case, particularly on the Web.

Document timestamps are growing in importance to the information retrieval (IR) and management communities as well. Several IR applications depend on knowledge of when documents were posted, such as computing document relevance (Li and Croft, 2003; Dakka et al., 2008) and labeling search queries with temporal profiles (Diaz and Jones, 2004; Zhang et al., 2009). Dating documents is similarly important to processing historical and heritage collections of text. Some of the early work that motivates this paper arose from the goal of automatically grounding documents in their historical contexts (de Jong et al., 2005; Kanhabua and Norvag, 2008; Kumar et al., 2011). This paper builds on their work

by incorporating more linguistic knowledge and explicit reasoning into the learner.

The first part of this paper describes a novel learning approach to document dating, presenting a discriminative model and rich linguistic features that have not been applied to document dating. Further, we introduce new features specific to absolute time expressions. Our model outperforms the generative models of previous work by 77%.

The second half of this paper describes a novel learning algorithm that orders time expressions against the unknown timestamp. For instance, the phrase *the second quarter of 1999* might be labeled as being *before* the timestamp. These labels impose constraints on the possible timestamp and narrow down its range of valid dates. We combine these constraints with our discriminative learner and see another relative improvement in accuracy by 9%.

## 2 Previous Work

Most work on dating documents has come from the IR and knowledge management communities interested in dating documents with unknown origins. de Jong et al. (2005) was among the first to automatically label documents with dates. They learned unigram language models (LMs) for specific time periods and scored articles with log-likelihood ratio scores. Kanhabua and Norvag (2008; 2009) extended this approach with the same model, but expanded its unigrams with POS tags, collocations, and tf-idf scores. They also integrated search engine results as features, but did not see an improvement. Both works evaluated on the news genre.

Recent work by Kumar et al. (2011) focused on dating Gutenberg short stories. As above, they learned unigram LMs, but instead measured the KL-divergence between a document and a time period’s LM. Our proposed models differ from this work by applying rich linguistic features, discriminative models, and by focusing on how time expressions improve accuracy. We also study the news genre.

The only work we are aware of within the NLP community is that of Dalli and Wilks (2006). They computed probability distributions over different time periods (e.g., months and years) for each observed token. The work is similar to the above IR work in its bag of words approach to classification.

They focused on finding words that show periodic spikes (defined by the word’s standard deviation in its distribution over time), weighted with inverse document frequency scores. They evaluated on a subset of the Gigaword Corpus (Graff, 2002).

The experimental setup in the above work (except Kumar et al. who focus on fiction) all train on news articles from a particular time period, and test on articles in the same time period. This leads to possible overlap of training and testing data, particularly since news is often reprinted across agencies the same day. In fact, one of the systems in Kanhabua and Norvag (2008) simply searches for one training document that best matches a test document, and assigns its timestamp. We intentionally deviate from this experimental design and instead create temporally disjoint train/test sets (see Section 5).

Finally, we extend this previous work by focusing on aspects of language not yet addressed for document dating: linguistic structure and absolute time expressions. The majority of articles in our dataset contain time expressions (e.g., the year 1998), yet these have not been incorporated into the models despite their obvious connection to the article’s timestamp. This paper first describes how to include time expressions as traditional features, and then describes a more sophisticated temporal reasoning component that naturally fits into our classifier.

## 3 Timestamp Classifiers

Labeling documents with timestamps is similar to topic classification, but instead of choosing from topics, we choose the most likely year (or other granularity) in which it was written. We thus begin with a bag-of-words approach, reproducing the generative model used by both de Jong (2005) and Kanhabua and Norvag (2008; 2009). The subsequent sections then introduce our novel classifiers and temporal reasoners to compare against this model.

### 3.1 Language Models

The model of de Jong et al. (2005) uses the normalized log-likelihood ratio (NLLR) to score documents. It weights tokens by the ratio of their probability in a specific year to their probability over the entire corpus. The model thus requires an LM for each year and an LM for the entire corpus:

$$NLLR(D, Y) = \sum_{w \in D} P(w|D) * \log\left(\frac{P(w|Y)}{P(w|C)}\right) \quad (1)$$

where  $D$  is the target document,  $Y$  is the time span (e.g., a year), and  $C$  is the distribution of words in the corpus across all years. A document is labeled with the year that satisfies  $\operatorname{argmax}_Y NLLR(D, Y)$ . They adapted this model from earlier work in the IR community (Kraaij, 2004). We apply Dirichlet-smoothing to the language models (as in de Jong et al.), although the exact choice of  $\alpha$  did not significantly alter the results, most likely due to the large size of our training corpus. Kanhabua and Norvag added an entropy factor to the summation, but we did not see an improvement in our experiments.

The unigrams  $w$  are lowercased tokens. We will refer to this de Jong et al. model as the **Unigram NLLR**. Follow-up work by Kanhabua and Norvag (2008) applied two filtering techniques to the unigrams in the model:

1. **Word Classes**: include only nouns, verbs, and adjectives as labeled by a POS tagger
2. **IDF Filter**: include only the top-ranked terms by tf-idf score

We also tested with these filters, choosing a cutoff for the top-ranked terms that optimized performance on our development data. We also stemmed the words as Kanhabua and Norvag suggest. This model is the **Filtered NLLR**.

Kanhabua and Norvag also explored what they termed *collocation features*, but lacking details on how collocations were included (or learned), we could not reproduce this for comparison. However, we instead propose using NER labels to extract what may have counted as collocations in their data. Named entities are important to document dating due to the nature of people and places coming in and out of the news at precise moments in time. We compare the NER features against the Unigram and Filtered NLLR models in our final experiments.

### 3.2 Discriminative Models

In addition to reproducing the models from previous work, we also trained a new discriminative version with the same features. We used a MaxEnt model and evaluated with the same filtering methods based

on POS tags and tf-idf scores. The model performed best on the development data without any filtering or stemming. The final results (Section 6) only use the lowercased unigrams. Ultimately, this MaxEnt model vastly outperforms these NLLR models.

### 3.3 Models with Time Expressions

The above language modeling and MaxEnt approaches are token-based classifiers that one could apply to any topic classification domain. Barring other knowledge, the learners solely rely on the observed frequencies of unigrams in order to decide which class is most likely. However, document dating is not just a simple topic classification application, but rather relates to temporal phenomena that is often explicitly described in the text itself. Language contains words and phrases that discuss the very time periods we aim to recover. These expressions should be better incorporated into the learner.

#### 3.3.1 Motivation

Let the following snippet serve as a text example with an ambiguous creation time:

Then there's the fund-raiser at the American Museum of Natural History, which plans to welcome about 1,500 guests paying \$1,000 to \$5,000. Their tickets will entitle them to a preview of...the new Hayden Planetarium.

Without extremely detailed knowledge about the American Museum of Natural History, the events discussed here are difficult to place in time, let alone when the author reported it. However, time expressions are sometimes included, and the last sentence in the original text contains a helpful relative clause:

Their tickets will entitle them to a preview of...the new Hayden Planetarium, *which does not officially open until February 2000.*

This one clause is more valuable than the rest of the document, allowing us to infer that the document's timestamp is *before* February, 2000. An educated guess might surmise the article appeared in the year prior, 1999, which is the correct year. At the very least, this clause should eliminate all years after 2000 from consideration. Previous work on document dating does not integrate this information except to include the unigram '2000' in the model.

This paper discusses two complementary ways to learn and reason about this information. The first is to simply add richer time-based features into the model. The second is to build separate learners that can assign probabilities to entire ranges of dates, such as *all years following 2000* in the example above. We begin with the feature-based model.

### 3.3.2 Time Features

To our knowledge, the following time features have not been used in a document dating setting. We use the freely available Stanford Parser and NER system<sup>1</sup> to generate the syntactic interpretation for these features. We then train a MaxEnt classifier and compare against previous work.

**Typed Dependency:** The most basic time feature is including governors of year mentions and the relation between them. This covers important contexts that determine the semantics of the time frame, like prepositions. For example, consider the following context for the mention *1997*:

Torre, who watched the Kansas City Royals beat the Yankees, 13-6, on Friday for the first time since 1997.

The resulting feature is ‘*since pobj 1997*’.

**Typed Dependency POS:** Similar to Typed Dependency, this feature uses POS tags of the dependency relation’s governor. The feature from the previous example is now ‘*PP pobj 1997*’. This generalizes the features to capture time expressions with prepositions, as noun modifiers, or other constructs.

**Verb Tense:** An important syntactic feature for temporal positioning is the tense of the verb that dominates the time expression. A past tense verb situates the phrase *in 2003* differently than one in the future. We traverse the sentence’s parse tree until a governor with a VB\* tag is found, and determine its tense through hand constructed rules based on the structure of the parent VP. The verb tense feature takes a value of *past*, *present*, *future*, or *undetermined*.

**Verb Path:** The verb path feature is the dependency path from the nearest verb to the year expression. The following snippet will include the feature, ‘*expected prep in pobj 2002*’.

<sup>1</sup><http://nlp.stanford.edu/software>

### Finance Article from Jan. 2002

Text Snippet	Relation to 2002
...started a hedge fund before the market peaked in 2000.	before
The peak in economic activity was the 4th quarter of 1999.	before
...might have difficulty in the latter part of 2002.	simultaneous

Figure 1: Three year mentions and their relation to the document creation year. Relations can be correctly identified for training using known document timestamps.

Supervising them is Vice President Hu Jintao, who appears to be Jiang’s favored successor if he retires from leadership as expected in 2002.

**Named Entities:** Although not directly related to time expressions, we also include n-grams of tokens that are labeled by an NER system using Person, Organization, or Location. People and places are often discussed during specific time periods, particularly in the news genre. Collecting named entity mentions will differentiate between an article discussing a *bill* and one discussing the US President, *Bill Clinton*. We extract NER features as sequences of uninterrupted tokens labeled with the same NER tag, ignoring unigrams (since unigrams are already included in the base model). Using the Verb Path example above, the bigram feature *Hu Jintao* is included.

## 4 Learning Time Constraints

This section departs from the above *document* classifiers and instead classifies individual emphyyear mentions. The goal is to automatically learn **temporal constraints** on the document’s timestamp.

Instead of predicting a single year for a document, a temporal constraint predicts a range of years. Each time mention, such as ‘*not since 2009*’, is a constraint representing its relation to the document’s timestamp. For example, the mentioned year ‘2009’ must occur *before* the year of document creation. This section builds a classifier to label time mentions with their relations (e.g., before, after, or simultaneous with the document’s timestamp), enabling these mentions to constrain the document classifiers described above. Figure 1 gives an example of time mentions and the desired labels we wish to learn.

To better motivate the need for constraints, let

Figure 2: Distribution over years for a single document as output by a MaxEnt classifier.

Figure 2 illustrate a typical distribution output by a document classifier for a training document. Two of the years appear likely (1999 and 2001), however, the document contains a time expression that seems to impose a strict constraint that should eliminate 2001 from consideration:

Their tickets will entitle them to a preview of...the new Hayden Planetarium, which does not officially open until February 2000.

The clause *until February 2000* in a present tense context may not definitively identify the document’s timestamp (1999 is a good guess), but as discussed earlier, it should remove all future years beyond 2000 from consideration. We thus want to impose a constraint based on this phrase that says, loosely, ‘this document was likely written before 2000’.

The document classifiers described in previous sections cannot capture such ordering information. Our new time features in Section 3.3.2 add richer time information (such as *until pobj 2000* and *open prep until pobj 2000*), but they compete with many other features that can mislead the final classification. An independent constraint learner may push the document classifier in the right direction.

#### 4.1 Constraint Types

We learn several types of constraints between each year mention and the document’s timestamp. Year mentions are defined as tokens with exactly four digits, numerically between 1900 and 2100. Let  $T$  be the document timestamp’s year, and  $M$  the year mention. We define three **core relations**:

1. **Before** Timestamp:  $M < T$
2. **After** Timestamp:  $M > T$
3. **Same** as Timestamp:  $M == T$

We also experiment with 7 **fine-grained relations**:

1. **One year Before** Timestamp:  $M == T - 1$
2. **Two years Before** Timestamp:  $M == T - 2$
3. **Three+ years Before** Timestamp:  $M < T - 2$
4. **One year After** Timestamp:  $M == T + 1$
5. **Two years After** Timestamp:  $M == T + 2$
6. **Three+ years After** Timestamp:  $M > T + 2$
7. **Same Year and Timestamp**:  $M == T$

Obviously the more fine-grained a relation, the better it can inform a classifier. We experiment with these two granularities to compare performance.

The learning process is a typical training environment where year mentions are treated as labeled training examples. Labels for year mentions are automatically computed by comparing the actual timestamp of the training document (all documents in Gigaword have dates) with the integer value of the year token. For example, a document written in 1997 might contain the phrase, “in the year 2000”. The year token (2000) is thus *three+ years after* the timestamp (1997). We use this relation for the year mention as a labeled training example.

Ultimately, we want to use similar syntactic constructs in training so that “in the year 2000” and “in the year 2003” mutually inform each other. We thus compute the label for each time expression, and replace the integer year with the generic *YEAR* token to generalize mentions. The text for this example becomes “in the year *YEAR*” (labeled as *three+ years after*). We train a MaxEnt model on each year mention, to be described next. Table 2 gives the overall counts for the core relations in our training data. The vast majority of year mentions are references to the future (e.g. after the timestamp).

#### 4.2 Constraint Learner

The features we use to classify year mentions are given in Table 1. The same time features in the document classifier of Section 3.3.2 are included, as well as several others specific to this constraint task.

We use a MaxEnt classifier trained on the individual year mentions. Documents often contain multiple (and different) year mentions; all are included in training and testing. This classifier labels mentions with relations, but in order to influence the document classifier, we need to map the relations to individual

### Time Constraint Features

Typed Dep.	Same as Section 3.3.2
Verb Tense	Same as Section 3.3.2
Verb Path	Same as Section 3.3.2
Decade	The decade of the year mention
Bag of Words	Unigrams in the year’s sentence
n-gram	The 4-gram and 3-gram that end with the year
n-gram POS	The 4-gram and 3-gram of POS tags that end with the year

Table 1: Features used to classify year expressions.

Constraint	Count
After Timestamp	1,203,010
Before Timestamp	168,185
Same as Timestamp	141,201

Table 2: Training size of year mentions (and their relation to the document timestamp) in Gigaword’s NYT section.

year predictions. Let  $T_d$  be the set of mentions in document  $d$ . We represent a MaxEnt classifier by  $P_Y(R|t)$  for a time mention  $t \in T_d$  and possible relations  $R$ . We map this distribution over relations to a distribution over years by defining  $P_{year}(Y|d)$ :

$$P_{year}(y|d) = \frac{1}{Z(T_d)} \sum_{t \in T_d} P_Y(\text{rel}(\text{val}(t) - y)|t) \quad (2)$$

$$\text{rel}(x) = \begin{cases} \textit{before} & \text{if } x < 0 \\ \textit{after} & \text{if } x > 0 \\ \textit{simultaneous} & \text{otherwise} \end{cases} \quad (3)$$

where  $\text{val}(t)$  is the integer year of the year mention and  $Z(T_d)$  is the partition function. The  $\text{rel}(\text{val}(t) - y)$  function simply determines if the year mention  $t$  (e.g., 2003) is before, after, or overlaps the year we are predicting for the document’s unknown timestamp  $y$ . We use a similar function for the seven fine-grained relations. Figure 3 visually illustrates how  $P_{year}(y|d)$  is constructed from three year mentions.

### 4.3 Joint Classifier

Finally, given the document classifiers of Section 3 and the constraint classifier just defined in Section 4, we create a joint model combining the two with the following linear interpolation:

$$P(y|d) = \lambda P_{doc}(y|d) + (1 - \lambda) P_{year}(y|d) \quad (4)$$

where  $y$  is a year, and  $d$  is the document.  $\lambda$  was set to 0.35 by maximizing accuracy on the dev set. See

Figure 4: Development set accuracy and  $\lambda$  values.

Figure 4. This optimal  $\lambda = .35$  weights the constraint classifier higher than the document classifier.

## 5 Datasets

This paper uses the New York Times section of the Gigaword Corpus (Graff, 2002) for evaluation. Most previous work on document dating evaluates on the news genre, so we maintain the pattern for consistency. Unfortunately, we cannot compare to these previous experiments because of differing evaluation setups. Dalli and Wilks (2006) is most similar in their use of Gigaword, but they chose a random set of documents that cannot be reproduced. We instead define specific segments of the corpus for evaluation.

The main goal for this experiment setup was to establish specific training, development, and test sets. One of the potential difficulties in testing with news articles is that the same story is often reprinted with very minimal (or no) changes. Over 10% of the documents in the New York Times section of the Gigaword Corpus are exact or approximate duplicates of another document in the corpus<sup>2</sup>. A training set for document dating must not include duplicates from the test set.

We adopt the intuition behind the experimental setup used in other NLP domains, like parsing, where the entire test set is from a contiguous section of the corpus (as opposed to randomly selected examples across the corpus). As the parsing community trains on sections 2-21 of the Penn Treebank (Marcus et al., 1993) and tests on section 23, we create Gigaword sections by isolating specific months.

<sup>2</sup>*Approximate duplicate* is defined as an article whose first two sentences exactly match the first two of another article. Only the second matched document is counted as a duplicate.

### Year Distributions for Three Time Expressions

Figure 3: Three year mentions in a document and the distributions output by the learner. The document is from 2002. The dots indicate the *before*, *same*, and *after* relation probabilities. The combination of three constraints results in a final distribution that gives the years 2001 and 2002 the highest probability. This distribution can help a document classifier make a more informed final decision.

<b>Training</b>	Jan-May and Sep-Dec
<b>Development</b>	July
<b>Testing</b>	June and August

In other words, the development set includes documents from July 1995, July 1996, July 1997, etc. We chose the dev/test sets to be in the middle of the year so that the training set includes documents on both temporal sides of the test articles. We include years 1995-2001 and 2004-2006, but skip 2002 and 2003 due to their abnormally small size compared to the other years.

Finally, we experiment in a balanced data setting, training and testing on the same number of documents from each year. The test set includes 11,300 documents in each year (months June and August) for a total of 113,000 test documents. The development set includes 7,300 from July of each year. Training includes approximately 75,000 documents in each year with some years slightly less than 75,000 due to their smaller size in the corpus. The total number of training documents for the 10 evaluated years is 725,468. The full list of documents is online at [www.usna.edu/Users/cs/nchamber/data/timestamp](http://www.usna.edu/Users/cs/nchamber/data/timestamp).

## 6 Experiments and Results

We experiment on the Gigaword corpus as described in Section 5. Documents are tokenized and parsed with the Stanford Parser. The year in the timestamp is retrieved from the document's Gigaword ID which contains the year and day the article was re-

trieved. Year mentions are extracted from documents by matching all tokens with exactly four digits whose integer is in the range of 1900 and 2100.

The MaxEnt classifiers are also from the Stanford toolkit, and both the document and year mention classifiers use its default settings (quadratic prior). The  $\lambda$  factor in the joint classifier is optimized on the development set as described in Section 4.3. We also found that dev results improved when training ignores the border months of Jan, Feb, and Dec. The features described in this paper were selected solely by studying performance on the development set. The final reported results come from running on the test set once at the end of this study.

Table 3 shows the results on the Test set for all document classifiers. We measure accuracy to compare overall performance since the test set is a balanced set (each year has the same number of test documents). **Unigram NLLR** and **Filtered NLLR** are the language model implementations of previous work as described in Section 3.1. **MaxEnt Unigram** is our new discriminative model for this task. **MaxEnt Time** is the discriminative model with rich time features (but not NER) as described in Section 3.3.2 (**Time+NER** includes NER). Finally, the **Joint** model is the combined document and year mention classifiers as described in Section 4.3. Table 4 shows the F1 scores of the Joint model by year.

Our new MaxEnt model outperforms previous work by 55% relative accuracy. Incorporating time features further improves the relative accuracy by

Model	Overall Accuracy
Random Guess	10.0%
Unigram NLLR	24.1%
Filtered NLLR	29.1%
MaxEnt Unigram	45.1%
MaxEnt Time	48.3%
MaxEnt Time+NER	51.4%
Joint	53.4%

Table 3: Performance as measured by accuracy. The predicted year must exactly match the actual year.

	95	96	97	98	99	00	01	02
<b>P</b>	.57	.49	.52	.48	.47	.51	.51	.59
<b>R</b>	.54	.56	.62	.44	.48	.48	.46	.57
<b>F1</b>	.55	.52	.57	.46	.48	.49	.48	.58

Table 4: Yearly results for the Joint model. 2005/06 are omitted due to space, with F1 .56 and .63, respectively.

7%, and adding NER by another 6%. Total relative improvement in accuracy is thus almost 77% from the Time+NER model over Filtered NLLR. Further, the temporal constraint model increases this best classifier by another 3.9%. All improvements are statistically significant ( $p < 0.000001$ , McNemar’s test, 2-tailed). Table 6 shows that performance increased most on the documents that contain at least one year mention (60% of the corpus).

Finally, Table 5 shows the results of the temporal constraint classifiers on year mentions. Not surprisingly, the fine-grained performance is quite a bit lower than the core relations. The full Joint results in Table 3 use the three core relations, but the seven fine-grained relations give approximately the same results. Its lower accuracy is mitigated by the finer granularity (i.e., the majority class baseline is lower).

## 7 Discussion

The main contribution of this paper is the discriminative model (54% improvement) and a new set of

	<b>P</b>	<b>R</b>	<b>F1</b>
Before Timestamp	.95	.98	.96
Same as Timestamp	.73	.57	.64
After Timestamp	.84	.81	.82
Overall Accuracy	<b>92.2%</b>		
Fine-Grained Accuracy	<b>70.1%</b>		

Table 5: Precision, recall, and F1 for the core relations. Accuracy for both core and fine-grained.

	All	With Year Mentions
MaxEnt Unigram	45.1%	46.1%
MaxEnt Time+NER	51.4%	54.3%
Joint	53.4%	57.7%

Table 6: Accuracy on all documents and documents with at least one year mention (about 60% of the corpus).

features for document dating (14% improvement). Such a large performance boost makes clear that the log likelihood and entropy approaches from previous work are not as effective as discriminative models on a large training corpus. Further, token-based features do not capture the implicit references to time in language. Our richer syntax-based features only apply to year mentions, but this small textual phenomena leads to a surprising 13% relative improvement in accuracy. Table 6 shows that a significant chunk of this improvement comes from documents containing year mentions, as expected.

The year constraint learner also improved performance. Although most of its features are in the document classifier, by learning constraints it captures a different picture of time that a traditional document classifier does not address. Combining this picture with the document classifier leads to another 3.9% relative improvement. Although we focused on year mentions here, there are several avenues for future study, including explorations of how other types of time expressions might inform the task. These constraints might also have applications to the ordering tasks of recent TempEval competitions.

Finally, we presented a new evaluation setup for this task. Previous work depended on having training documents in the same week and day of the test documents. We argued that this may not be an appropriate assumption in some domains, and particularly problematic for the news genre. Our proposed evaluation setup instead separates training and testing data across months. The results show that log-likelihood ratio scores do not work as well in this environment. We hope our explicit train/test environment encourages future comparison and progress on document dating.

## Abstract

Although much work on relation extraction has aimed at obtaining static facts, many of the target relations are actually *fluents*, as their validity is naturally anchored to a certain time period. This paper proposes a methodological approach to temporally anchored relation extraction. Our proposal performs distant supervised learning to extract a set of relations from a natural language corpus, and anchors each of them to an interval of temporal validity, aggregating evidence from documents supporting the relation. We use a rich graph-based document-level representation to generate novel features for this task. Results show that our implementation for temporal anchoring is able to achieve a 69% of the upper bound performance imposed by the relation extraction step. Compared to the state of the art, the overall system achieves the highest precision reported.

## 1 Introduction

A question that arises when extracting a relation is how to capture its temporal validity: Can we assign a period of time when the obtained relation held? As pointed out in (Ling and Weld, 2010), while much research in automatic relation extraction has focused on distilling static facts from text, many of the target relations are in fact *fluents*, dynamic relations whose truth value is dependent on time (Russell and Norvig, 2010).

The *Temporally anchored relation extraction* problem consists in, given a natural language text document corpus,  $C$ , a target entity,  $e$ , and a target

relation,  $r$ , extracting from the corpus the value of that relation for the entity, and a temporal interval for which the relation was valid.

In this paper, we introduce a methodological approach to temporal anchoring of relations automatically extracted from unrestricted text. Our system (see Figure 1) extracts relational facts from text using distant supervision (Mintz et al., 2009) and then anchors the relation to an interval of temporal validity. The intuition is that a distant supervised system can effectively extract relations from the source text collection, and a straightforward date aggregation can then be applied to anchor them. We propose a four step process for temporal anchoring: (1) represent temporal evidence; (2) select temporal information relevant to the relation; (3) decide how a relational fact and its relevant temporal information are themselves related; and (4) aggregate imprecise temporal intervals across multiple documents. In contrast with previous approaches that aim at intra-document temporal information extraction (Ling and Weld, 2010), we focus on mining a corpus aggregating temporal evidences across the supporting documents.

We address the following research questions: (1) Validate whether distant supervised learning is suitable for the task, and evaluate its shortcomings. (2) Explore whether the use of features extracted from a document-level rich representation could improve distant supervised learning. (3) Compare the use of document metadata against temporal expressions within the document for relation temporal anchoring. (4) Analyze how, in a pipeline architecture, the propagation of errors limits the overall system's

Figure 1: System overview diagram.

performance.

The representation we use for temporal information is detailed in section 2; the rich document-level representation we exploit is described in section 3. For a query entity and target relation, the system first performs relation extraction (section 4); then, we find and aggregate time constraint evidence for the same relation across different documents, to establish a temporal validity anchor interval (section 5). Empirical comparative evaluation of our approach is introduced in section 6; while some related work is shown in section 7 and conclusions in section 8.

## 2 Temporal Anchors

We will denominate *relation instance* a triple  $\langle \text{entity}, \text{relation name}, \text{value} \rangle$ . We aim at anchoring relation instances to their temporal validity. We need a representation flexible enough to capture the imprecise temporal information available in text, but expressed in a structured style. Allen’s (1983) interval-based algebra for temporal representation and reasoning, underlies much research, such as the Tempeval challenges (Verhagen et al., 2007; Pustejovsky and Verhagen, 2009). Our task is different, as we focus on obtaining the temporal interval associated to a fact, rather than reasoning about the

temporal relations among the events appearing in a single text.

Let us assume that each relation instance is valid during a certain temporal interval,  $I = [t_0, t_f]$ . This sharp temporal interval fails to capture the imprecision of temporal boundaries conveyed in natural language text. The Temporal Slot Filling task at TAC-KBP 2011 (Ji et al., 2011) proposed a 4-tuple representation that we will refer to as *imprecise anchor intervals*. An imprecise temporal interval is defined as an ordered 4-tuple of time points:  $(t_1, t_2, t_3, t_4)$ , with the following semantics: the relation is true for a period which starts at some point between  $t_1$  and  $t_2$  and ends between  $t_3$  and  $t_4$ . It should hold that:  $t_1 \leq t_2$ ,  $t_3 \leq t_4$ , and  $t_1 \leq t_4$ . Any of the four endpoints can be left unconstrained ( $t_1$  or  $t_3$  would be  $-\infty$ , and  $t_2$  or  $t_4$  would be  $+\infty$ ). This representation is flexible and expressive, although it cannot capture certain types of information (Ji et al., 2011).

## 3 Document Representation

We use a rich document representation that employs a graph structure obtained by augmenting the syntactic dependency analysis of the document with semantic information.

A document  $D$  is represented as a *document graph*  $G_D$ ; with node set  $V_D$  and edge set,  $E_D$ . Each node  $v \in V_D$  represents a *chunk* of text, which is a sequence of words<sup>1</sup>. Each node is labeled with a dictionary of attributes, some of which are common for every node: the words it contains, their part-of-speech annotations (POS) and lemmas. Also, a representative *descriptor*, which is a normalized string value, is generated from the chunks in the node. Certain nodes are also annotated with one or more *types*. There are three families of types: Events (verbs that describe an action, annotated with tense, polarity and aspect); standardized Time Expressions; and Named Entities, with additional annotations such as gender or age.

Edges in the document graph,  $e \in E_D$ , represent four kinds of relations between the nodes:

- Syntactic: a dependency relation.
- Coreference: indicates that two chunks refer to

<sup>1</sup>Most chunks consist in one word; we join words into a chunk (and a node) in two cases: a multi-word named entity and a verb and its auxiliaries.

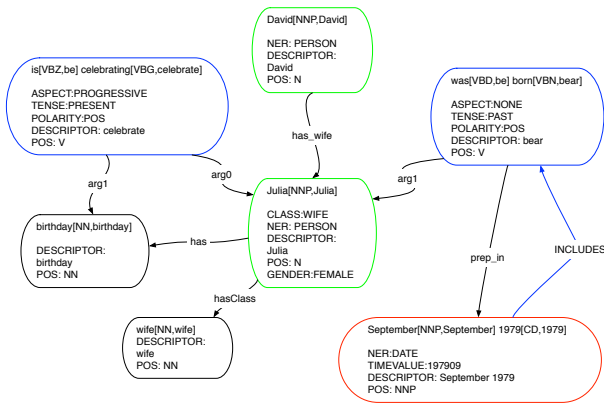

Figure 2: Collapsed document graph representation,  $G_C$ , for the sample text document “David’s wife, Julia, is celebrating her birthday. She was born in September 1979”.

the same *discourse referent*.

- Semantic relations between two nodes, such as `hasClass`, `hasProperty` and `hasAge`.
- Temporal relations between events and time expressions.

The processing includes dependency parsing, named entity recognition and coreference resolution, done with the Stanford CoreNLP software (Klein and Manning, 2003); and events and temporal information extraction, via the TARSQI Toolkit (Verhagen et al., 2005).

The document graph  $G_D$  is then further transformed into a *collapsed document graph*,  $G_C$ . Each node of  $G_C$  clusters together coreferent nodes, representing a *discourse referent*. Thus, a node  $u$  in  $G_C$  is a cluster of nodes  $u_1, \dots, u_k$  of  $G_D$ . There is an edge  $(u, v)$  in  $G_C$  if there was an edge between any of the nodes clustered into  $u$  and any of the nodes  $v_1, \dots, v_{k'}$ . The coreference edges do not appear in this representation. Additional semantic information is also blended into this representation: normalization of genitives, semantic class indicators inferred from appositions and genitives, and gender annotation inferred from pronouns. A final graph example can be seen in Figure 2.

## 4 Distant Supervised Relation Extraction

To perform relation extraction, our proposal follows a distant supervision approach (Mintz et al., 2009), which has also inspired other slot filling systems (Agirre et al., 2009; Surdeanu et al., 2010). We capture long distance relations by introducing

a document-level representation and deriving novel features from deep syntactic and semantic analysis.

**Seed harvesting.** From a reference Knowledge Base (KB), we extract a set of relation triples or *seeds*:  $\langle \text{entity}, \text{relation}, \text{value} \rangle$ , where the *relation* is one of the target relations. Our document-level distant supervision assumption is that if entity and value are found in a document graph (see section 3), and there is a path connecting them, then the document expresses the relation.

**Relation candidates gathering.** From a seed triple, we retrieve candidate documents that contain both the entity and value, within a span of 20 tokens, using a standard IR approach. Then, entity and value are matched to the document graph representation. We first use approximate string comparison to find nodes matching the seed entity. After an entity node has been found we use local breadth-first-search (BFS) to find a matching value and the shortest connecting path between them. We enforce the Named Entity type of entity and value to match a expected type, predefined for the relation.

Our procedure traverses the document graph looking for entity and value nodes meeting those conditions; when found, we generate features for a *positive example* for the relation<sup>2</sup>. If we encounter a node that matches the expected NE type of the relation, but does not match the seed value, we generate a *negative example* for that relation.

**Training.** From positive and negative examples, we generate binary features; some of them are inspired by previous work (Surdeanu and Ciaramita, 2007; Mintz et al., 2009; Riedel et al., 2010; Surdeanu et al., 2010), and others are novel, taking advantage of our graph representation. Table 1 summarizes our choice of features. Features appearing in less than 5 training examples were discarded.

**Relation instance extraction.** Given an input entity and a target relation, we aim at finding a filler value for a relation instance. This task is known as Slot Filling. From the set of retrieved documents relevant to the query entity, represented as document graphs,

<sup>2</sup>From the collapsed document graph representation we obtained an average of 9213 positive training examples per slot; from the uncollapsed document graph, a slightly lower average of 8178.5 positive examples per slot.

Feature name	Description
path	dependency path between ENTITY and VALUE in the sentence
$X$ -annotation	NE annotations for $X$
$X$ -pos	Part-of-speech annotations for $X$
$X$ -gov	Governor of $X$ in the dependency path
$X$ -mod	Modifiers of $X$ in the dependency path
$X$ -has_age	$X$ is a NE, with an age attribute
$X$ -has_class- $C$	$X$ is a NE, with a class $C$
$X$ -property- $P$	$X$ is a NE, and it has a property $P$
$X$ -has- $Y$	$X$ is a NE, with a possessive relation with another NE, $Y$
$X$ -is- $Y$	$X$ is a NE, in a copula with another NE, $Y$
$X$ -gender- $G$	$X$ is a NE, and it has gender $G$
$V$ -tense	Tense of the verb $V$ in the path
$V$ -aspect	Aspect of the verb $V$ in the path
$V$ -polarity	Polarity (positive or negative) of the verb $V$

Table 1: Features included in the model.  $X$  stands for ENTITY and VALUE. Verb features are generated from the verbs,  $V$ , identified in the path between ENTITY and VALUE.

we locate matching entities and start a local BFS of candidate values, generating for them an unlabelled example. For each of the relations to extract, a binary classifier (extractor) decides whether the example is a valid relation instance. For each particular relation classifier, only candidates with the expected entity and value types for the relation were used in the application phase. Each extractor was a SVM classifier with linear kernel (Joachims, 2002). All learning parameters were set to their default values.

The classification process yields a predicted class label, plus a real number indicating the margin. We performed an aggregation phase to sum the margins over distinct occurrences of the same extracted value. The rationale is that when the same value is extracted from more than one document, we should accumulate that evidence.

The output of this phase is the set of extracted relations (positive for each of the classifiers), plus the documents where the same fact was detected (*supporting documents*).

## 5 Temporal Anchoring of Relations

In this section, we propose and discuss a unified methodological approach for temporal anchoring of relations. We assume the input is a relation instance and a set of *supporting documents*. The task is establishing a imprecise temporal anchor interval for the relation.

We present a four-step methodological approach: (1) representation of intra-document temporal information; (2) selection of relevant temporal information for the relation; (3) mapping of the link between relational fact and temporal information into an interval; and (4) aggregation of imprecise intervals.

**Temporal representation.** The first methodological step is to obtain and represent the available intra-document temporal information; the input is a document, and the task is to identify temporal signals and possible *links* among them. We use the term *link* for a relation between a temporal expression (a date) and an event; we want to avoid confusion with the term *relation* (a relational fact extracted from text).

In our particular implementation:

- We use TARSQI to extract temporal expressions and link them to events. In particular, TARSQI uses the following temporal links: *included*, *simultaneous*, *after*, *before*, *begun\_by* or *ended*.
- We focus also on the syntactic pattern [*Event-preposition-Time*] within the lexical context of the candidate entity and value.
- Both are normalized into one from a set of predefined temporal links: *within*, *throughout*, *beginning*, *ending*, *after* and *before*.

**Selection of temporal evidence.** For each document and relational instance, we have to select those temporal expressions that are relevant.

- Document-level metadata.** The default value we use is the *document creation time* (DCT), if available. The underlying assumption is that there is a *within* link from each fact expressed in the text and the document creation time.
- Temporal expressions.** Temporal evidence comes also from the temporal expressions present in the context of a relation. In our particular implementation, we followed a straightforward approach, looking for the time expression closest in the document graph to the shortest path between the entity and value nodes. This search is performed via a limited depth BFS, starting from the nodes in the path, in order from value to entity.

**Mapping of temporal links into intervals.** The third step is deciding how a relational fact and its relevant temporal information are themselves related. We have to map this information, expressed in text,

Temporal link	Constraints mapping
Before	$t_4 = first$
After	$t_1 = last$
Within and Throughout	$t_2 = first$ and $t_3 = last$
Beginning	$t_1 = first$ and $t_2 = last$
Ending	$t_3 = first$ and $t_4 = last$

Table 2: Mapping from time expression and temporal relation to temporal constraints.

to a temporal representation. We will use the imprecise anchor intervals described in section 2.

Let  $T$  be a temporal expression identified in the document or its metadata. Now, the mapping of temporal constraints depends on the temporal link to the time expression identified; also, the semantics of the event have to be considered in order to decide the *time period* associated to a relation instance. This step is important because the event could refer just to the beginning of the relation, its ending, or both. For instance, it is obvious that having the event *marry* is different to having the event *divorce*, when deciding the temporal constraints associated to the *spouse* relation.

Table 2 shows our particular mapping between temporal links and constraints. In particular, for the default document creation time, we suppose that a relation which appears in a document with creation time  $d$  held true at least in that date; that is, we are assuming a *within* link, and we map  $t_2 = d$ ,  $t_3 = d$ .

### Inter-document temporal evidence aggregation.

The last step is aggregating all the time constraints found for the same relation and value across different documents. If we found that a relation started after two dates  $d$  and  $d'$ , where  $d' > d$ , the closest constraint to the real start of the relation is  $d'$ . Mapped to temporal constraints, it means that we would choose the biggest  $t_1$  possible. Following the same reasoning, we would want to maximize  $t_3$ . On the other side, when a relation started before two dates  $d_2$  and  $d'_2$ , where  $d'_2 > d_2$ , the closest constraint is  $d_2$  and we would choose the smallest  $t_2$ . In summary, we will maximize  $t_1$  and  $t_3$  and minimize  $t_2$  and  $t_4$ , so we will narrow the margins.

## 6 Evaluation

We have used for our evaluation the dataset compiled within the TAC-KBP 2011 Temporal Slot Filling Task (Ji et al., 2011). We employed as initial

KB the one distributed to participants in the task, which has been compiled from Wikipedia infoboxes. It contains 898 triples  $\langle entity, slot\_type, value \rangle$  for 100 different entities and up to 8 different slots (relations) per entity<sup>3</sup>. This gold standard contains the correct responses pooled from the participant systems plus a set of responses manually found by annotators. Each triple has associated a temporal anchor. The relations had to be extracted from a domain-general collection of 1.7 million documents. Our system was one of the five that took part in the task. We have evaluated the overall system and the two main components of the architecture: Relation Extraction, and Temporal Anchoring of the relations. Due to space limitations, the description of our implementation is very concise; refer to (Garrido et al., 2011) for further details.

### 6.1 Evaluation of Relation Extraction

System response in the relation extraction step consists in a set of triples  $\langle entity, slot\_type, value \rangle$ . Performance is measured using precision, recall and F-measure (harmonic mean) with respect to the 898 triples in the key. Target relations (slots) are potentially *list-valued*, that is, more than one value can be valid for a relation (possibly at different points in time). Only correct values yield any score, and redundant triples are ignored.

**Experiments.** We run two different system settings for the relation extraction step. They differ in the document representation used (detailed in section 3), in order to empirically assess whether clustering of discourse referents into single nodes benefits the extraction. In SETTING 1, each document is represented as a document graph,  $G_D$ , while in SETTING 2 collapsed document graph representation,  $G_C$ , is employed.

**Results.** Results are shown in Table 3 in the column *Relation Extraction*. Both settings have a similar performance with a slight increase in the case of graphs with clustered referents. Although precision is close to 0.5, recall is lower than 0.1. We have studied the limits of the assumptions our approach

<sup>3</sup>There are 7 *person* relations: *cities\_of\_residence*, *state-or-provinces\_of\_residence*, *countries\_of\_residence*, *employee\_of*, *member\_of*, *title*, *spouse*, and an *organization* relation: *top\_members/employees*.

is based on. First, our standard retrieval component performance limits the overall system’s. As a matter of example, if we retrieve the first 100 documents per entity, we find relevant documents only for 62% of the triples in the key. This number means that no matter how good relation extraction method is, 38% of relations will not be found.

Second, the *distant supervision assumption* underlying our approach is that for a seed relation instance  $\langle \text{entity}, \text{relation}, \text{value} \rangle$ , any textual mention of *entity* and *value* expresses the *relation*. It has been shown that this assumption is more often violated when training knowledge base and document collection are of different type, e.g. Wikipedia and news-wire (Riedel et al., 2010). We have realized that a more determinant factor is the relation itself and the type of arguments it takes. We randomly sampled 100 training examples per relation, and manually inspected them to assess if they were indeed mentions of the relation. While for the relation *cities\_of\_residence* only 30% of the training examples are expressing the relation, for *spouse* the number goes up to 59%. For *title*, up to 90% of the examples are correct. This fact explains, at least partially, the zeros we obtain for some relations.

## 6.2 Evaluation of Temporal Anchoring

Under the evaluation metrics proposed by TAC-KBP 2011, if the value of the relation instance is judged as correct, the score for temporal anchoring depends on how well the returned interval matches the one provided in the key. More precisely, let the correct imprecise anchor interval in the gold standard key be  $S_k = (k_1, k_2, k_3, k_4)$  and the system response be  $S = (r_1, r_2, r_3, r_4)$ . The absence of a constraint in  $t_1$  or  $t_3$  is treated as a value of  $-\infty$ ; the absence of a constraint in  $t_2$  or  $t_4$  is treated as a value of  $+\infty$ . Then, let  $d_i = |k_i - r_i|$ , for  $i \in 1, \dots, 4$ , be the difference, a real number *measured in years*. The score for the system response is:

$$Q(S) = \frac{1}{4} \sum_{i=1}^4 \frac{1}{1 + d_i}$$

The score for a target relation  $Q(r)$  is computed by summing  $Q(S)$  over all unique instances of the relation whose value is correct. If the gold standard contains  $N$  responses, and the system output  $M$  responses, then precision is:  $P = Q(r)/M$ , and recall:

$R = Q(r)/N$ ;  $F_1$  is the harmonic mean of  $P$  and  $R$ .

**Experiments.** We evaluated two different settings for the temporal anchoring step; both use the collapsed document graph representation,  $G_C$  (SETTING 2). The goal of the experiment is two-fold. First, test the strength of the *document creation time* as evidence for temporal anchoring. Second, test how hard this metadata-level baseline is to beat using contextual temporal expressions.

The SETTING 2-I assumes a *within* temporal link between the document creation time and any relation expressed inside the document, and aggregates this information across the documents that we have identified as supporting the relation. The SETTING 2-II considers documents content in order to extract temporal links from the context of the text that expresses the relation. If no temporal expression is found, the date of the document is used as default. Temporal links from all supporting documents are mapped into intervals and aggregated as detailed in section 5.

The performance on relation extraction is an upper bound for temporal anchoring, attainable if temporal anchoring is perfect. Thus, we also evaluate the temporal anchoring performance as the percentage the final system achieves with respect to the relation extraction upper bound.

**Results.** Results are shown in Table 3 under column *Temporal Anchoring*. They are low, due to the upper bound that error propagation in candidate retrieval and relation extraction imposes upon this step: temporally anchoring alone achieves 69% of its upper bound. This value corresponds to the baseline SETTING 2-I, showing its strength. The difference with SETTING 2-II shows that this baseline is difficult to beat by considering temporal evidence inside the document content. There is a reason for this. The temporal link mapping into time intervals does not depend only on the type of link, but also on the semantics of the text that expresses the relation as we pointed out above. We have to decide how to transform the link between relation and temporal expression into a temporal interval. Learning a model for this is a hard open research problem that has a strong adversary in the baseline proposed.

### 6.3 Comparative Evaluation

Our approach was compared with the other four participants at the KBP Temporal Slot Filling Task 2011. Table 4 shows results sorted by F-measure in comparison to our two settings (described above). These official results correspond to a previous dataset containing 712 triples<sup>4</sup>.

As shown in column *Filled* our approach returns less triples than other systems, explaining low recall. However, our system achieves the highest precision for the complete task of temporally anchored relation extraction. Despite low recall, our system obtains the third best  $F_1$  value. This is a very promising result, since several directions can be explored to consider more candidates and increase recall.

## 7 Related Work

Compiling a Knowledge Base of temporally anchored facts is an open research challenge (Weikum et al., 2011). Despite the vast amount of research focusing on understanding temporal expressions and

their relation to events in natural language, the complete problem of temporally anchored relation extraction remains relatively unexplored. Also, while much research has focused on single-document extraction, it seems clear that extracting temporally anchored relations needs the aggregation of evidences across multiple documents.

There have been attempts to extend an existing knowledge base. Wang et al. (2010) use regular expressions to mine Wikipedia infoboxes and categories and it is not suited for unrestricted text. An earlier attempt (Zhang et al., 2008), is specific for business and difficult to generalize to other relations. Two recent promising works are more related to our research. Wang et al. (2011) uses manually defined patterns to collect candidate facts and explicit dates, and re-rank them using a graph label propagation algorithm; their approach is complementary to ours, as our aim is not to harvest temporal facts but to extract the relations in which a query entity takes part; unlike us, they require entity, value, and an explicit date to appear in the same sentence. Talukdar et al. (2012) focus on the partial task of temporally anchoring already known facts, showing the usefulness of the document creation time as temporal signal, aggregated across documents.

Earlier work has dealt mainly with partial aspects of the problem. The TempEval community focused on the classification of the temporal links between pairs of events, or an event and a temporal expression; using shallow features (Mani et al., 2003; Lapata and Lascarides, 2004; Chambers et al., 2007), or syntactic-based structured features (Bethard and Martin, 2007; Puşcaşu, 2007; Cheng et al., 2007).

Aggregating evidence across different documents

<sup>4</sup>Slot-fillers from human assessors were not considered

to temporally anchor facts has been explored in settings different to Information Extraction, such as answering of definition questions (Paşca, 2008) or extracting possible dates of well-known historical events (Schockaert et al., 2010).

Temporal inference or reasoning to solve conflicting temporal expressions and induce temporal order of events has been used in TempEval (Tatu and Srikanth, 2008; Yoshikawa et al., 2009) and ACE (Gupta and Ji, 2009) tasks, but focused on single-document extraction. Ling et al. (2010), use cross-event joint inference to extract temporal facts, but only inside a single document.

Evaluation campaigns, such as ACE and TAC-KBP 2011 have had an important role in promoting this research. While ACE required only to identify time expressions and classify their relation to events, KBP requires to infer explicitly the start/end time of relations, which is a realistic approach in the context of building time-aware knowledge bases. KBP represents an important step for the evaluation of temporal information extraction systems. In general, the participant systems adapted existing slot filling systems, adding a temporal classification component: distant supervised (Chen et al., 2010; Surdeanu et al., 2010) on manually-defined patterns (Byrne and Dunnion, 2010).

## 8 Conclusions

This paper introduces the problem of extracting, from unrestricted natural language text, relational knowledge anchored to a temporal span, aggregating temporal evidence from a collection of documents. Although compiling time-aware knowledge bases is an important open challenge (Weikum et al., 2011), it has remained unexplored until very recently (Wang et al., 2011; Talukdar et al., 2012).

We have elucidated the two challenges of the task, namely relation extraction and temporal anchoring of the extracted relations.

We have studied how, in a pipeline architecture, the propagation of errors limits the overall system’s performance. The performance attainable in the full task is limited by the quality of the output of the three main phases: retrieval of candidate passages/documents, extraction of relations and temporal anchoring of those.

We have also studied the limits of the distant supervision approach to relation extraction, showing empirically that its performance depends not only on the nature of reference knowledge base and document corpus (Riedel et al., 2010), but also on the relation to be extracted. Given a relation between two arguments, if it is not dominant among textual expressions of those arguments, the distant supervision assumption will be more often violated.

We have introduced a novel graph-based document level representation, that has allowed us to generate new features for the task of relation extraction, capturing long distance structured contexts. Our results show how, in a document level syntactic representation, it yields better results to collapse coreferent nodes.

We have presented a methodological approach to temporal anchoring composed of: (1) intra-document temporal information representation; (2) selection of relation-dependent relevant temporal information; (3) mapping of temporal links to an interval representation; and (4) aggregation of imprecise intervals.

Our proposal has been evaluated within a framework that allows for comparability. It has been able to extract temporally anchored relational information with the highest precision among the participant systems taking part in the competitive evaluation TAC-KBP 2011.

For the temporal anchoring sub-problem, we have demonstrated the strength of the document creation time as a temporal signal. It is possible to achieve a performance of 69% of the upper-bound imposed by relation extraction by assuming that any relation mentioned in a document held at the document creation time (there is a *within* link between the relational fact and the document creation time). This baseline has proved stronger than extracting and analyzing the temporal expressions present in the document content.

## Abstract

Learning entailment rules is fundamental in many semantic-inference applications and has been an active field of research in recent years. In this paper we address the problem of learning transitive graphs that describe entailment rules between predicates (termed *entailment graphs*). We first identify that entailment graphs exhibit a “tree-like” property and are very similar to a novel type of graph termed *forest-reducible graph*. We utilize this property to develop an iterative efficient approximation algorithm for learning the graph edges, where each iteration takes linear time. We compare our approximation algorithm to a recently-proposed state-of-the-art exact algorithm and show that it is more efficient and scalable both theoretically and empirically, while its output quality is close to that given by the optimal solution of the exact algorithm.

## 1 Introduction

Performing textual inference is in the heart of many semantic inference applications such as Question Answering (QA) and Information Extraction (IE). A prominent generic paradigm for textual inference is Textual Entailment (TUE) (Dagan et al., 2009). In TUE, the goal is to recognize, given two text fragments termed *text* and *hypothesis*, whether the hypothesis can be inferred from the text. For example, the text “Cyprus was invaded by the Ottoman Empire in 1571” implies the hypothesis “The Ottomans attacked Cyprus”.

Semantic inference applications such as QA and IE crucially rely on *entailment rules* (Ravichandran

and Hovy, 2002; Shinyama and Sekine, 2006) or equivalently *inference rules*, that is, rules that describe a directional inference relation between two fragments of text. An important type of entailment rule specifies the entailment relation between natural language *predicates*, e.g., the entailment rule ‘ $X \text{ invade } Y \rightarrow X \text{ attack } Y$ ’ can be helpful in inferring the aforementioned hypothesis. Consequently, substantial effort has been made to learn such rules (Lin and Pantel, 2001; Sekine, 2005; Szpektor and Dagan, 2008; Schoenmackers et al., 2010).

Textual entailment is inherently a *transitive* relation, that is, the rules ‘ $x \rightarrow y$ ’ and ‘ $y \rightarrow z$ ’ imply the rule ‘ $x \rightarrow z$ ’. Accordingly, Berant et al. (2010) formulated the problem of learning entailment rules as a graph optimization problem, where nodes are predicates and edges represent entailment rules that respect transitivity. Since finding the optimal set of edges respecting transitivity is NP-hard, they employed Integer Linear Programming (ILP) to find the exact solution. Indeed, they showed that applying global transitivity constraints improves rule learning comparing to methods that ignore graph structure. More recently, Berant et al. (Berant et al., 2011) introduced a more efficient exact algorithm, which decomposes the graph into connected components and then applies an ILP solver over each component.

Despite this progress, finding the exact solution remains NP-hard – the authors themselves report they were unable to solve some graphs of rather moderate size and that the coverage of their method is limited. Thus, scaling their algorithm to data sets with tens of thousands of predicates (e.g., the extractions of Fader et al. (2011)) is unlikely.

In this paper we present a novel method for learning the edges of entailment graphs. Our method computes much more efficiently an approximate solution that is empirically almost as good as the exact solution. To that end, we first (Section 3) conjecture and empirically show that entailment graphs exhibit a “tree-like” property, i.e., that they can be *reduced* into a structure similar to a directed forest.

Then, we present in Section 4 our iterative approximation algorithm, where in each iteration a node is removed and re-attached back to the graph in a locally-optimal way. Combining this scheme with our conjecture about the graph structure enables a linear algorithm for node re-attachment. Section 5 shows empirically that this algorithm is by orders of magnitude faster than the state-of-the-art exact algorithm, and that though an optimal solution is not guaranteed, the area under the precision-recall curve drops by merely a point.

To conclude, the contribution of this paper is twofold: First, we define a novel modeling assumption about the tree-like structure of entailment graphs and demonstrate its validity. Second, we exploit this assumption to develop a polynomial approximation algorithm for learning entailment graphs that can scale to much larger graphs than in the past. Finally, we note that learning entailment graphs bears strong similarities to related tasks such as Taxonomy Induction (Snow et al., 2006) and Ontology induction (Poon and Domingos, 2010), and thus our approach may improve scalability in these fields as well.

## 2 Background

Until recently, work on learning entailment rules between predicates considered each rule independently of others and did not exploit global dependencies. Most methods utilized the distributional similarity hypothesis that states that semantically similar predicates occur with similar arguments (Lin and Pantel, 2001; Szpektor et al., 2004; Yates and Etzioni, 2009; Schoenmackers et al., 2010). Some methods extracted rules from lexicographic resources such as WordNet (Szpektor and Dagan, 2009) or FrameNet (Bob and Rambow, 2009; Ben Aharon et al., 2010), and others assumed that semantic relations between predicates can be deduced from their co-occurrence in a corpus via manually-constructed

patterns (Chklovski and Pantel, 2004).

Recently, Berant et al. (2010; 2011) formulated the problem as the problem of learning global *entailment graphs*. In entailment graphs, nodes are predicates (e.g., ‘*X attack Y*’) and edges represent entailment rules between them (‘*X invade Y*  $\rightarrow$  *X attack Y*’). For every pair of predicates  $i, j$ , an entailment score  $w_{ij}$  was learned by training a classifier over distributional similarity features. A positive  $w_{ij}$  indicated that the classifier believes  $i \rightarrow j$  and a negative  $w_{ij}$  indicated that the classifier believes  $i \not\rightarrow j$ . Given the graph nodes  $V$  (corresponding to the predicates) and the weighting function  $w : V \times V \rightarrow \mathbb{R}$ , they aim to find the edges of a graph  $\mathcal{G} = (V, E)$  that maximize the objective  $\sum_{(i,j) \in E} w_{ij}$  under the constraint that the graph is *transitive* (i.e., for every node triplet  $(i, j, k)$ , if  $(i, j) \in E$  and  $(j, k) \in E$ , then  $(i, k) \in E$ ).

Berant et al. proved that this optimization problem, which we term *Max-Trans-Graph*, is NP-hard, and so described it as an Integer Linear Program (ILP). Let  $x_{ij}$  be a binary variable indicating the existence of an edge  $i \rightarrow j$  in  $E$ . Then,  $\mathcal{X} = \{x_{ij} : i \neq j\}$  are the variables of the following ILP for Max-Trans-Graph:

$$\begin{aligned} \arg \max_{\mathcal{X}} \quad & \sum_{i \neq j} w_{ij} \cdot x_{ij} & (1) \\ \text{s.t.} \quad & \forall_{i,j,k \in V} x_{ij} + x_{jk} - x_{ik} \leq 1 \\ & \forall_{i,j \in V} x_{ij} \in \{0, 1\} \end{aligned}$$

The objective function is the sum of weights over the edges of  $\mathcal{G}$  and the constraint  $x_{ij} + x_{jk} - x_{ik} \leq 1$  on the binary variables enforces that whenever  $x_{ij} = x_{jk} = 1$ , then also  $x_{ik} = 1$  (transitivity).

Since ILP is NP-hard, applying an ILP solver directly does not scale well because the number of variables is  $O(|V|^2)$  and the number of constraints is  $O(|V|^3)$ . Thus, even a graph with  $\sim 80$  nodes (predicates) has more than half a million constraints. Consequently, in (Berant et al., 2011), they proposed a method that efficiently decomposes the graph into smaller components and applies an ILP solver on each component separately using a cutting-plane procedure (Riedel and Clarke, 2006). Although this method is exact and improves scalability, it does not guarantee an efficient solution. When the graph does not decompose into sufficiently small components, and the weights generate many violations of

transitivity, solving Max-Trans-Graph becomes intractable. To address this problem, we present in this paper a method for approximating the optimal set of edges within each component and show that it is much more efficient and scalable both theoretically and empirically.

Do and Roth (2010) suggested a method for a related task of learning taxonomic relations between terms. Given a pair of terms, a small graph is constructed and constraints are imposed on the graph structure. Their work, however, is geared towards scenarios where relations are determined on-the-fly for a given pair of terms and no global knowledge base is explicitly constructed. Thus, their method easily produces solutions where global constraints, such as transitivity, are violated.

Another approximation method that violates transitivity constraints is LP relaxation (Martins et al., 2009). In LP relaxation, the constraint  $x_{ij} \in \{0, 1\}$  is replaced by  $0 \leq x_{ij} \leq 1$ , transforming the problem from an ILP to a Linear Program (LP), which is polynomial. An LP solver is then applied on the problem, and variables  $x_{ij}$  that are assigned a fractional value are rounded to their nearest integer and so many violations of transitivity easily occur. The solution when applying LP relaxation is not a transitive graph, but nevertheless we show for comparison in Section 5 that our method is much faster.

Last, we note that transitive relations have been explored in adjacent fields such as Temporal Information Extraction (Ling and Weld, 2010), Ontology Induction (Poon and Domingos, 2010), and Co-reference Resolution (Finkel and Manning, 2008).

### 3 Forest-reducible Graphs

The entailment relation, described by entailment graphs, is typically from a “semantically-specific” predicate to a more “general” one. Thus, intuitively, the topology of an entailment graph is expected to be “tree-like”. In this section we first formalize this intuition and then empirically analyze its validity. This property of entailment graphs is an interesting topological observation on its own, but also enables the efficient approximation algorithm of Section 4.

For a directed edge  $i \rightarrow j$  in a directed acyclic graphs (DAG), we term the node  $i$  a *child* of node  $j$ , and  $j$  a *parent* of  $i$ . A *directed forest* is a DAG

Figure 1: A fragment of an entailment graph (a), its SCC graph (b) and its reduced graph (c). Nodes are predicates with typed variables (see Section 5), which are omitted in (b) and (c) for compactness.

where all nodes have no more than one parent.

The entailment graph in Figure 1a (subgraph from the data set described in Section 5) is clearly not a directed forest – it contains a cycle of size two comprising the nodes ‘ $X \text{ common in } Y$ ’ and ‘ $X \text{ frequent in } Y$ ’, and in addition the node ‘ $X \text{ be epidemic in } Y$ ’ has 3 parents. However, we can convert it to a directed forest by applying the following operations. Any directed graph  $\mathcal{G}$  can be converted into a *Strongly-Connected-Component (SCC)* graph in the following way: every strongly connected component (a set of semantically-equivalent predicates, in our graphs) is contracted into a single node, and an edge is added from SCC  $S_1$  to SCC  $S_2$  if there is an edge in  $\mathcal{G}$  from some node in  $S_1$  to some node in  $S_2$ . The SCC graph is always a DAG (Cormen et al., 2002), and if  $\mathcal{G}$  is transitive then the SCC graph is also transitive. The graph in Figure 1b is the SCC graph of the one in

Figure 2: A fragment of an entailment graph that is not an FRG.

Figure 1a, but is still not a directed forest since the node ‘ $X$  be epidemic in  $Y$ ’ has two parents.

The *transitive closure* of a directed graph  $\mathcal{G}$  is obtained by adding an edge from node  $i$  to node  $j$  if there is a path in  $\mathcal{G}$  from  $i$  to  $j$ . The *transitive reduction* of  $\mathcal{G}$  is obtained by removing all edges whose absence does not affect its transitive closure. In DAGs, the result of transitive reduction is unique (Aho et al., 1972). We thus define the *reduced graph*  $\mathcal{G}_{red} = (V_{red}, E_{red})$  of a directed graph  $\mathcal{G}$  as the transitive reduction of its SCC graph. The graph in Figure 1c is the reduced graph of the one in Figure 1a and is a directed forest. We say a graph is a *forest-reducible graph (FRG)* if all nodes in its reduced form have no more than one parent.

We now hypothesize that entailment graphs are FRGs. The intuition behind this assumption is that the predicate on the left-hand-side of a unidirectional entailment rule has a more specific meaning than the one on the right-hand-side. For instance, in Figure 1a ‘ $X$  be epidemic in  $Y$ ’ (where ‘ $X$ ’ is a type of disease and ‘ $Y$ ’ is a country) is more specific than ‘ $X$  common in  $Y$ ’ and ‘ $X$  frequent in  $Y$ ’, which are equivalent, while ‘ $X$  occur in  $Y$ ’ is even more general. Accordingly, the reduced graph in Figure 1c is an FRG. We note that this is not always the case: for example, the entailment graph in Figure 2 is not an FRG, because ‘ $X$  annex  $Y$ ’ entails both ‘ $Y$  be part of  $X$ ’ and ‘ $X$  invade  $Y$ ’, while the latter two do not entail one another. However, we hypothesize that this scenario is rather uncommon. Consequently, a natural variant of the Max-Trans-Graph problem is to restrict the required output graph of the optimization problem (1) to an FRG. We term this problem *Max-Trans-Forest*.

To test whether our hypothesis holds empirically we performed the following analysis. We sampled 7 gold standard entailment graphs from the data set

described in Section 5, manually transformed them into FRGs by deleting a minimal number of edges, and measured recall over the set of edges in each graph (precision is naturally 1.0, as we only delete gold standard edges). The lowest recall value obtained was 0.95, illustrating that deleting a very small proportion of edges converts an entailment graph into an FRG. Further support for the practical validity of this hypothesis is obtained from our experiments in Section 5. In these experiments we show that exactly solving Max-Trans-Graph and Max-Trans-Forest (with an ILP solver) results in nearly identical performance.

An ILP formulation for Max-Trans-Forest is simple – a transitive graph is an FRG if all nodes in its reduced graph have no more than one parent. It can be verified that this is equivalent to the following statement: for every triplet of nodes  $i, j, k$ , if  $i \rightarrow j$  and  $i \rightarrow k$ , then either  $j \rightarrow k$  or  $k \rightarrow j$  (or both). Therefore, the ILP is formulated by adding this linear constraint to ILP (1):

$$\forall_{i,j,k \in V} x_{ij} + x_{ik} + (1 - x_{jk}) + (1 - x_{kj}) \leq 3 \quad (2)$$

We note that despite the restriction to FRGs, Max-Trans-Forest is an NP-hard problem by a reduction from the X3C problem (Garey and Johnson, 1979). We omit the reduction details for brevity.

## 4 Sequential Approximation Algorithms

In this section we present *Tree-Node-Fix*, an efficient approximation algorithm for Max-Trans-Forest, as well as *Graph-Node-Fix*, an approximation for Max-Trans-Graph.

### 4.1 Tree-Node-Fix

The scheme of Tree-Node-Fix (TNF) is the following. First, an initial FRG is constructed, using some initialization procedure. Then, at each iteration a single node  $v$  is *re-attached* (see below) to the FRG in a way that improves the objective function. This is repeated until the value of the objective function cannot be improved anymore by re-attaching a node.

*Re-attaching* a node  $v$  is performed by removing  $v$  from the graph and connecting it back with a better set of edges, while maintaining the constraint that it is an FRG. This is done by considering all possible edges from/to the other graph nodes and choosing

Figure 3: (a) Inserting  $v$  into a component  $c \in V_{red}$ . (b) Inserting  $v$  as a child of  $c$  and a parent of a subset of  $c$ 's children in  $\mathcal{G}_{red}$ . (b') A node  $d$  that is a descendant but not a child of  $c$  can not choose  $v$  as a parent, as  $v$  becomes its second parent. (c) Inserting  $v$  as a new root.

the *optimal* subset, while the rest of the graph remains fixed. Formally, let  $S_{v-in} = \sum_{i \neq v} w_{iv} \cdot x_{iv}$  be the sum of scores over  $v$ 's incoming edges and  $S_{v-out} = \sum_{k \neq v} w_{vk} \cdot x_{vk}$  be the sum of scores over  $v$ 's outgoing edges. Re-attachment amounts to optimizing a linear objective:

$$\arg \max_{\mathcal{X}_v} (S_{v-in} + S_{v-out}) \quad (3)$$

where the variables  $\mathcal{X}_v \subseteq \mathcal{X}$  are indicators for all pairs of nodes involving  $v$ . We approximate a solution for (1) by iteratively optimizing the simpler objective (3). Clearly, at each re-attachment the value of the objective function cannot decrease, since the optimization algorithm considers the previous graph as one of its candidate solutions.

We now show that re-attaching a node  $v$  is linear. To analyze  $v$ 's re-attachment, we consider the structure of the directed forest  $\mathcal{G}_{red}$  just *before*  $v$  is re-inserted, and examine the possibilities for  $v$ 's insertion relative to that structure. We start by defining some helpful notations. Every node  $c \in V_{red}$  is a connected component in  $\mathcal{G}$ . Let  $v_c \in c$  be an arbitrary representative node in  $c$ . We denote by  $S_{v-in}(c)$  the sum of weights from all nodes in  $c$  and their descendants to  $v$ , and by  $S_{v-out}(c)$  the sum of weights from  $v$  to all nodes in  $c$  and their ancestors:

$$S_{v-in}(c) = \sum_{i \in c} w_{iv} + \sum_{k \notin c} w_{kv} x_{kv_c}$$

$$S_{v-out}(c) = \sum_{i \in c} w_{vi} + \sum_{k \notin c} w_{vk} x_{v_c k}$$

Note that  $\{x_{v_c k}, x_{kv_c}\}$  are edge indicators in  $\mathcal{G}$  and not  $\mathcal{G}_{red}$ . There are two possibilities for re-attaching  $v$  – either it is inserted into an existing component  $c \in V_{red}$  (Figure 3a), or it forms a new component. In the latter, there are also two cases: either  $v$  is inserted as a child of a component  $c$  (Fig-

ure 3b), or not and then it becomes a root in  $\mathcal{G}_{red}$  (Figure 3c). We describe the details of these 3 cases:

**Case 1:** Inserting  $v$  into a component  $c \in V_{red}$ . In this case we add in  $\mathcal{G}$  edges from all nodes in  $c$  and their descendants to  $v$  and from  $v$  to all nodes in  $c$  and their ancestors. The score (3) in this case is

$$s_1(c) \triangleq S_{v-in}(c) + S_{v-out}(c) \quad (4)$$

**Case 2:** Inserting  $v$  as a child of some  $c \in V_{red}$ . Once  $c$  is chosen as the parent of  $v$ , choosing  $v$ 's children in  $\mathcal{G}_{red}$  is substantially constrained. A node that is not a descendant of  $c$  can not become a child of  $v$ , since this would create a new path from that node to  $c$  and would require by transitivity to add a corresponding directed edge to  $c$  (but all graph edges not connecting  $v$  are fixed). Moreover, only a direct child of  $c$  can choose  $v$  as a parent instead of  $c$  (Figure 3b), since for any other descendant of  $c$ ,  $v$  would become a second parent, and  $\mathcal{G}_{red}$  will no longer be a directed forest (Figure 3b'). Thus, this case requires adding in  $\mathcal{G}$  edges from  $v$  to all nodes in  $c$  and their ancestors, and also for each new child of  $v$ , denoted by  $d \in V_{red}$ , we add edges from all nodes in  $d$  and their descendants to  $v$ . Crucially, although the number of possible subsets of  $c$ 's children in  $\mathcal{G}_{red}$  is exponential, the fact that they are independent trees in  $\mathcal{G}_{red}$  allows us to go over them one by one, and decide for each one whether it will be a child of  $v$  or not, depending on whether  $S_{v-in}(d)$  is positive. Therefore, the score (3) in this case is:

$$s_2(c) \triangleq S_{v-out}(c) + \sum_{d \in \text{child}(c)} \max(0, S_{v-in}(d)) \quad (5)$$

where  $\text{child}(c)$  are the children of  $c$ .

**Case 3:** Inserting  $v$  as a new root in  $\mathcal{G}_{red}$ . Similar to case 2, only roots of  $\mathcal{G}_{red}$  can become children of  $v$ . In this case for each chosen root  $r$  we add in  $\mathcal{G}$  edges from the nodes in  $r$  and their descendants to  $v$ . Again, each root can be examined independently. Therefore, the score (3) of re-attaching  $v$  is:

$$s_3 \triangleq \sum_r \max(0, S_{v-in}(r)) \quad (6)$$

where the summation is over the roots of  $\mathcal{G}_{red}$ .

It can be easily verified that  $S_{v-in}(c)$  and  $S_{v-out}(c)$  satisfy the recursive definitions:

---

**Algorithm 1** Computing optimal re-attachment

---

**Input:** FRG  $\mathcal{G} = (V, E)$ , function  $w$ , node  $v \in V$ **Output:** optimal re-attachment of  $v$ 

- 1: remove  $v$  and compute  $G_{red} = (V_{red}, E_{red})$ .
  - 2: for all  $c \in V_{red}$  in post-order compute  $S_{v-in}(c)$  (Eq. 7)
  - 3: for all  $c \in V_{red}$  in pre-order compute  $S_{v-out}(c)$  (Eq. 8)
  - 4: case 1:  $s_1 = \max_{c \in V_{red}} s_1(c)$  (Eq. 4)
  - 5: case 2:  $s_2 = \max_{c \in V_{red}} s_2(c)$  (Eq. 5)
  - 6: case 3: compute  $s_3$  (Eq. 6)
  - 7: re-attach  $v$  according to  $\max(s_1, s_2, s_3)$ .
- 

$$S_{v-in}(c) = \sum_{i \in c} w_{iv} + \sum_{d \in \text{child}(c)} S_{v-in}(d), \quad c \in V_{red} \quad (7)$$

$$S_{v-out}(c) = \sum_{i \in c} w_{vi} + S_{v-out}(p), \quad c \in V_{red} \quad (8)$$

where  $p$  is the parent of  $c$  in  $\mathcal{G}_{red}$ . These recursive definitions allow to compute in linear time  $S_{v-in}(c)$  and  $S_{v-out}(c)$  for all  $c$  (given  $\mathcal{G}_{red}$ ) using dynamic programming, before going over the cases for re-attaching  $v$ .  $S_{v-in}(c)$  is computed going over  $V_{red}$  leaves-to-root (post-order), and  $S_{v-out}(c)$  is computed going over  $V_{red}$  root-to-leaves (pre-order).

Re-attachment is summarized in Algorithm 1. Computing an SCC graph is linear (Cormen et al., 2002) and it is easy to verify that transitive reduction in FRGs is also linear (Line 1). Computing  $S_{v-in}(c)$  and  $S_{v-out}(c)$  (Lines 2-3) is also linear, as explained. Cases 1 and 3 are trivially linear and in case 2 we go over the children of all nodes in  $V_{red}$ . As the reduced graph is a forest, this simply means going over all nodes of  $V_{red}$ , and so the entire algorithm is linear.

Since re-attachment is linear, re-attaching all nodes is quadratic. Thus if we bound the number of iterations over all nodes, the overall complexity is quadratic. This is dramatically more efficient and scalable than applying an ILP solver. In Section 5 we ran TNF until convergence and the maximal number of iterations over graph nodes was 8.

## 4.2 Graph-node-fix

Next, we show Graph-Node-Fix (GNF), a similar approximation that employs the same re-attachment strategy but does not assume the graph is an FRG. Thus, re-attachment of a node  $v$  is done with an ILP solver. Nevertheless, the ILP in GNF is simpler than (1), since we consider only candidate edges

Figure 4: Three types of transitivity constraint violations.

involving  $v$ . Figure 4 illustrates the three types of possible transitivity constraint violations when re-attaching  $v$ . The left side depicts a violation when  $(i, k) \notin E$ , expressed by the constraint in (9) below, and the middle and right depict two violations when the edge  $(i, k) \in E$ , expressed by the constraints in (10). Thus, the ILP is formulated by adding the following constraints to the objective function (3):

$$\forall_{i,k \in V \setminus \{v\}} \text{ if } (i, k) \notin E, \quad x_{iv} + x_{vk} \leq 1 \quad (9)$$

$$\text{ if } (i, k) \in E, \quad x_{vi} \leq x_{vk}, \quad x_{kv} \leq x_{iv} \quad (10)$$

$$x_{iv}, x_{vk} \in \{0, 1\} \quad (11)$$

Complexity is exponential due to the ILP solver; however, the ILP size is reduced by an order of magnitude to  $O(|V|)$  variables and  $O(|V|^2)$  constraints.

## 4.3 Adding local constraints

For some pairs of predicates  $i, j$  we sometimes have prior knowledge whether  $i$  entails  $j$  or not. We term such pairs *local constraints*, and incorporate them into the aforementioned algorithms in the following way. In all algorithms that apply an ILP solver, we add a constraint  $x_{ij} = 1$  if  $i$  entails  $j$  or  $x_{ij} = 0$  if  $i$  does not entail  $j$ . Similarly, in TNF we incorporate local constraints by setting  $w_{ij} = \infty$  or  $w_{ij} = -\infty$ .

## 5 Experiments and Results

In this section we empirically demonstrate that TNF is more efficient than other baselines and its output quality is close to that given by the optimal solution.

### 5.1 Experimental setting

In our experiments we utilize the data set released by Berant et al. (2011). The data set contains 10 entailment graphs, where graph nodes are *typed predicates*. A typed predicate (e.g., ‘ $X_{disease} occur in Y_{country}$ ’) includes a predicate and two *typed variables* that specify the semantic type of the arguments. For instance, the typed variable  $X_{disease}$  can be instantiated by arguments such as ‘*flu*’ or ‘*diabetes*’. The data set contains 39,012 potential edges,

of which 3,427 are annotated as edges (valid entailment rules) and 35,585 are annotated as non-edges.

The data set also contains, for every pair of predicates  $i, j$  in every graph, a *local score*  $s_{ij}$ , which is the output of a classifier trained over distributional similarity features. A positive  $s_{ij}$  indicates that the classifier believes  $i \rightarrow j$ . The weighting function for the graph edges  $w$  is defined as  $w_{ij} = s_{ij} - \lambda$ , where  $\lambda$  is a single parameter controlling graph sparseness: as  $\lambda$  increases,  $w_{ij}$  decreases and becomes negative for more pairs of predicates, rendering the graph more sparse. In addition, the data set contains a set of *local constraints* (see Section 4.3).

We implemented the following algorithms for learning graph edges, where in all of them the graph is first decomposed into components according to Berant et al’s method, as explained in Section 2.

**No-trans** Local scores are used without transitivity constraints – an edge  $(i, j)$  is inserted iff  $w_{ij} > 0$ .

**Exact-graph** Berant et al.’s exact method (2011) for Max-Trans-Graph, which utilizes an ILP solver<sup>1</sup>.

**Exact-forest** Solving Max-Trans-Forest exactly by applying an ILP solver (see Eq. 2).

**LP-relax** Solving Max-Trans-Graph approximately by applying LP-relaxation (see Section 2) on each graph component. We apply the LP solver within the same cutting-plane procedure as Exact-graph to allow for a direct comparison. This also keeps memory consumption manageable, as otherwise all  $|V|^3$  constraints must be explicitly encoded into the LP. As mentioned, our goal is to present a method for learning transitive graphs, while LP-relax produces solutions that violate transitivity. However, we run it on our data set to obtain empirical results, and to compare run-times against TNF.

**Graph-Node-Fix (GNF)** Initialization of each component is performed in the following way: if the graph is very sparse, i.e.  $\lambda \geq C$  for some constant  $C$  (set to 1 in our experiments), then solving the graph exactly is not an issue and we use Exact-graph. Otherwise, we initialize by applying Exact-graph in a sparse configuration, i.e.,  $\lambda = C$ .

**Tree-Node-Fix (TNF)** Initialization is done as in GNF, except that if it generates a graph that is not an FRG, it is corrected by a simple heuristic: for every node in the reduced graph  $\mathcal{G}_{red}$  that has more than

Figure 5: Run-time in seconds for various  $-\lambda$  values.

one parent, we choose from its current parents the single one whose SCC is composed of the largest number of nodes in  $\mathcal{G}$ .

We evaluate algorithms by comparing the set of gold standard edges with the set of edges learned by each algorithm. We measure recall, precision and  $F_1$  for various values of the sparseness parameter  $\lambda$ , and compute the area under the precision-recall Curve (AUC) generated. Efficiency is evaluated by comparing run-times.

## 5.2 Results

We first focus on run-times and show that TNF is efficient and has potential to scale to large data sets.

Figure 5 compares run-times<sup>2</sup> of Exact-graph, GNF, TNF, and LP-relax as  $-\lambda$  increases and the graph becomes denser. Note that the y-axis is in logarithmic scale. Clearly, Exact-graph is extremely slow and run-time increases quickly. For  $\lambda = 0.3$  run-time was already 12 hours and we were unable to obtain results for  $\lambda < 0.3$ , while in TNF we easily got a solution for any  $\lambda$ . When  $\lambda = 0.6$ , where both Exact-graph and TNF achieve best  $F_1$ , TNF is 10 times faster than Exact-graph. When  $\lambda = 0.5$ , TNF is 50 times faster than Exact-graph and so on. Most importantly, run-time for GNF and TNF increases much more slowly than for Exact-graph.

<sup>1</sup>We use the Gurobi optimization package in all experiments.

<sup>2</sup>Run on a multi-core 2.5GHz server with 32GB of RAM.

Figure 6: Precision (y-axis) vs. recall (x-axis) curve. Maximal  $F_1$  on the curve is .43 for Exact-graph, .41 for TNF, and .34 for No-trans. AUC in the recall range 0-0.5 is .32 for Exact-graph, .31 for TNF, and .26 for No-trans.

Run-time of LP-relax is also bad compared to TNF and GNF. Run-time increases more slowly than Exact-graph, but still very fast comparing to TNF. When  $\lambda = 0.6$ , LP-relax is almost 10 times slower than TNF, and when  $\lambda = -0.1$ , LP-relax is 200 times slower than TNF. This points to the difficulty of scaling LP-relax to large graphs.

As for the quality of learned graphs, Figure 6 provides a precision-recall curve for Exact-graph, TNF and No-trans (GNF and LP-relax are omitted from the figure and described below to improve readability). We observe that both Exact-graph and TNF substantially outperform No-trans and that TNF’s graph quality is only slightly lower than Exact-graph (which is extremely slow). Following Berant et al., we report in the caption the maximal  $F_1$  on the curve and AUC in the recall range 0-0.5 (the widest range for which we have results for all algorithms). Note that compared to Exact-graph, TNF reduces AUC by a point and the maximal  $F_1$  score by 2 points only.

GNF results are almost identical to those of TNF (maximal  $F_1=0.41$ , AUC: 0.31), and in fact for all  $\lambda$  configurations TNF outperforms GNF by no more than one  $F_1$  point. As for LP-relax, results are just slightly lower than Exact-graph (maximal  $F_1$ : 0.43, AUC: 0.32), but its output is not a transitive graph,

and as shown above run-time is quite slow. Last, we note that the results of Exact-forest are almost identical to Exact-graph (maximal  $F_1$ : 0.43), illustrating that assuming that entailment graphs are FRGs (Section 3) is reasonable in this data set.

To conclude, TNF learns transitive entailment graphs of good quality much faster than Exact-graph. Our experiment utilized an available data set of moderate size; However, we expect TNF to scale to large data sets (that are currently unavailable), where other baselines would be impractical.

## 6 Conclusion

Learning large and accurate resources of entailment rules is essential in many semantic inference applications. Employing transitivity has been shown to improve rule learning, but raises issues of efficiency and scalability.

The first contribution of this paper is a novel modeling assumption that entailment graphs are very similar to FRGs, which is analyzed and validated empirically. The main contribution of the paper is an efficient polynomial approximation algorithm for learning entailment rules, which is based on this assumption. We demonstrate empirically that our method is by orders of magnitude faster than the state-of-the-art exact algorithm, but still produces an output that is almost as good as the optimal solution.

We suggest our method as an important step towards scalable acquisition of precise entailment resources. In future work, we aim to evaluate TNF on large graphs that are automatically generated from huge corpora. This of course requires substantial efforts of pre-processing and test-set annotation. We also plan to examine the benefit of TNF in learning similar structures, e.g., taxonomies or ontologies.

## Abstract

Comprehending action preconditions and effects is an essential step in modeling the dynamics of the world. In this paper, we express the semantics of precondition relations extracted from text in terms of planning operations. The challenge of modeling this connection is to ground language at the level of relations. This type of grounding enables us to create high-level plans based on language abstractions. Our model jointly learns to predict precondition relations from text and to perform high-level planning guided by those relations. We implement this idea in the reinforcement learning framework using feedback automatically obtained from plan execution attempts. When applied to a complex virtual world and text describing that world, our relation extraction technique performs on par with a supervised baseline, yielding an F-measure of 66% compared to the baseline’s 65%. Additionally, we show that a high-level planner utilizing these extracted relations significantly outperforms a strong, text unaware baseline – successfully completing 80% of planning tasks as compared to 69% for the baseline.<sup>1</sup>

## 1 Introduction

Understanding action preconditions and effects is a basic step in modeling the dynamics of the world. For example, having *seeds* is a precondition for growing *wheat*. Not surprisingly, preconditions have been extensively explored in various sub-fields of AI. However, existing work on action models has largely focused on tasks and techniques specific to individual sub-fields with little or no interconnection between them. In NLP, precondition relations have been studied in terms of the linguistic mechanisms

<sup>1</sup>The code, data and experimental setup for this work are available at <http://groups.csail.mit.edu/rbg/code/planning>

Figure 1: Text description of preconditions and effects (a), and the low-level actions connecting them (b).

that realize them, while in classical planning, these relations are viewed as a part of world dynamics. In this paper, we bring these two parallel views together, grounding the linguistic realization of these relations in the semantics of planning operations.

The challenge and opportunity of this fusion comes from the mismatch between the abstractions of human language and the granularity of planning primitives. Consider, for example, text describing a virtual world such as Minecraft<sup>2</sup> and a formal description of that world using planning primitives. Due to the mismatch in granularity, even the simple relations between *wood*, *pickaxe* and *stone* described in the sentence in Figure 1a results in dozens of low-level planning actions in the world, as can be seen in Figure 1b. While the text provides a high-level description of world dynamics, it does not provide sufficient details for successful plan execution. On the other hand, planning with low-level actions does not suffer from this limitation, but is computationally intractable for even moderately complex tasks. As a consequence, in many practical domains, planning algorithms rely on manually-crafted high-level

<sup>2</sup><http://www.minecraft.net/>

abstractions to make search tractable (Ghallab et al., 2004; Lekavý and Návrat, 2007).

The central idea of our work is to express the semantics of precondition relations extracted from text in terms of planning operations. For instance, the precondition relation between pickaxe and stone described in the sentence in Figure 1a indicates that plans which involve obtaining stone will likely need to first obtain a pickaxe. The novel challenge of this view is to model grounding at the level of relations, in contrast to prior work which focused on object-level grounding. We build on the intuition that the validity of precondition relations extracted from text can be informed by the execution of a low-level planner.<sup>3</sup> This feedback can enable us to learn these relations without annotations. Moreover, we can use the learned relations to guide a high level planner and ultimately improve planning performance.

We implement these ideas in the reinforcement learning framework, wherein our model jointly learns to predict precondition relations from text and to perform high-level planning guided by those relations. For a given planning task and a set of candidate relations, our model repeatedly predicts a sequence of subgoals where each subgoal specifies an attribute of the world that must be made true. It then asks the low-level planner to find a plan between each consecutive pair of subgoals in the sequence. The observed feedback – whether the low-level planner succeeded or failed at each step – is utilized to update the policy for both text analysis and high-level planning.

We evaluate our algorithm in the Minecraft virtual world, using a large collection of user-generated online documents as our source of textual information. Our results demonstrate the strength of our relation extraction technique – while using planning feedback as its only source of supervision, it achieves a precondition relation extraction accuracy on par with that of a supervised SVM baseline. Specifically, it yields an F-score of 66% compared to the 65% of the baseline. In addition, we show that these extracted relations can be used to improve the performance of a high-level planner. As baselines

<sup>3</sup>If a planner can find a plan to successfully obtain stone after obtaining a pickaxe, then a pickaxe is likely a precondition for stone. Conversely, if a planner obtains stone without first obtaining a pickaxe, then it is likely not a precondition.

for this evaluation, we employ the Metric-FF planner (Hoffmann and Nebel, 2001),<sup>4</sup> as well as a text-unaware variant of our model. Our results show that our text-driven high-level planner significantly outperforms all baselines in terms of completed planning tasks – it successfully solves 80% as compared to 41% for the Metric-FF planner and 69% for the text unaware variant of our model. In fact, the performance of our method approaches that of an oracle planner which uses manually-annotated preconditions.

## 2 Related Work

**Extracting Event Semantics from Text** The task of extracting preconditions and effects has previously been addressed in the context of lexical semantics (Sil et al., 2010; Sil and Yates, 2011). These approaches combine large-scale distributional techniques with supervised learning to identify desired semantic relations in text. Such combined approaches have also been shown to be effective for identifying other relationships between events, such as causality (Girju and Moldovan, 2002; Chang and Choi, 2006; Blanco et al., 2008; Beamer and Girju, 2009; Do et al., 2011).

Similar to these methods, our algorithm capitalizes on surface linguistic cues to learn preconditions from text. However, our only source of supervision is the feedback provided by the planning task which utilizes the predictions. Additionally, we not only identify these relations in text, but also show they are valuable in performing an external task.

**Learning Semantics via Language Grounding** Our work fits into the broad area of grounded language acquisition, where the goal is to learn linguistic analysis from a situated context (Oates, 2001; Siskind, 2001; Yu and Ballard, 2004; Fleischman and Roy, 2005; Mooney, 2008a; Mooney, 2008b; Branavan et al., 2009; Liang et al., 2009; Vogel and Jurafsky, 2010). Within this line of work, we are most closely related to the reinforcement learning approaches that learn language by interacting with an external environment (Branavan et al., 2009; Branavan et al., 2010; Vogel and Jurafsky, 2010; Branavan et al., 2011).

A **pickaxe**, which is used to harvest **stone**, can be made from **wood**.

#### Precondition Relations:

#### Plan Subgoal Sequence:

Figure 2: A high-level plan showing two subgoals in a precondition relation. The corresponding sentence is shown above.

The key distinction of our work is the use of grounding to learn abstract pragmatic relations, i.e. to learn linguistic patterns that describe relationships between objects in the world. This supplements previous work which grounds words to objects in the world (Branavan et al., 2009; Vogel and Jurafsky, 2010). Another important difference of our setup is the way the textual information is utilized in the situated context. Instead of getting step-by-step instructions from the text, our model uses text that describes general knowledge about the domain structure. From this text, it extracts relations between objects in the world which hold independently of any given task. Task-specific solutions are then constructed by a planner that relies on these relations to perform effective high-level planning.

**Hierarchical Planning** It is widely accepted that high-level plans that factorize a planning problem can greatly reduce the corresponding search space (Newell et al., 1959; Bacchus and Yang, 1994). Previous work in planning has studied the theoretical properties of valid abstractions and proposed a number of techniques for generating them (Jonsson and Barto, 2005; Wolfe and Barto, 2005; Mehta et al., 2008; Barry et al., 2011). In general, these techniques use static analysis of the low-level domain to induce effective high-level abstractions. In contrast, our focus is on learning the abstraction from natural language. Thus our technique is complementary to past work, and can benefit from human knowledge about the domain structure.

### 3 Problem Formulation

Our task is two-fold. First, given a text document describing an environment, we wish to extract a set of precondition/effect relations implied by the text. Second, we wish to use these induced relations to determine an action sequence for completing a given task in the environment.

We formalize our task as illustrated in Figure 2. As input, we are given a world defined by the tuple  $\langle S, A, T \rangle$ , where  $S$  is the set of possible world states,  $A$  is the set of possible actions and  $T$  is a deterministic state transition function. Executing action  $a$  in state  $s$  causes a transition to a new state  $s'$  according to  $T(s' | s, a)$ . States are represented using propositional logic predicates  $x_i \in X$ , where each state is simply a set of such predicates, i.e.  $s \subset X$ .

The objective of the text analysis part of our task is to automatically extract a set of valid precondition/effect relationships from a given document  $d$ . Given our definition of the world state, preconditions and effects are merely single term predicates,  $x_i$ , in this world state. We assume that we are given a seed mapping between a predicate  $x_i$ , and the word types in the document that reference it (see Table 3 for examples). Thus, for each predicate pair  $\langle x_k, x_l \rangle$ , we want to utilize the text to predict whether  $x_k$  is a precondition for  $x_l$ ; i.e.,  $x_k \rightarrow x_l$ . For example, from the text in Figure 2, we want to predict that possessing a pickaxe is a precondition for possessing stone. Note that this relation implies the reverse as well, i.e.  $x_l$  can be interpreted as the effect of an action sequence performed on state  $x_k$ .

Each planning goal  $g \in G$  is defined by a starting state  $s_0^g$ , and a final goal state  $s_f^g$ . This goal state is represented by a set of predicates which need to be made true. In the planning part of our task our objective is to find a sequence of actions  $\vec{a}$  that connect  $s_0^g$  to  $s_f^g$ . Finally, we assume document  $d$  does not contain step-by-step instructions for any individual task, but instead describes general facts about the given world that are useful for a wide variety of tasks.

### 4 Model

The key idea behind our model is to leverage textual descriptions of preconditions and effects to guide the construction of high level plans. We define a high-level plan as a sequence of *subgoals*, where each

subgoal is represented by a single-term predicate,  $x_i$ , that needs to be set in the corresponding world state – e.g. `have(wheat)=true`. Thus the set of possible subgoals is defined by the set of all possible single-term predicates in the domain. In contrast to low-level plans, the transition between these subgoals can involve multiple low-level actions. Our algorithm for textually informed high-level planning operates in four steps:

1. Use text to predict the preconditions of each subgoal. These predictions are for the entire domain and are not goal specific.
2. Given a planning goal and the induced preconditions, predict a subgoal sequence that achieves the given goal.
3. Execute the predicted sequence by giving each pair of consecutive subgoals to a low-level planner. This planner, treated as a black-box, computes the low-level plan actions necessary to transition from one subgoal to the next.
4. Update the model parameters, using the low-level planner’s success or failure as the source of supervision.

We formally define these steps below.

**Modeling Precondition Relations** Given a document  $d$ , and a set of subgoal pairs  $\langle x_i, x_j \rangle$ , we want to predict whether subgoal  $x_i$  is a precondition for  $x_j$ . We assume that precondition relations are generally described within single sentences. We first use our seed grounding in a preprocessing step where we extract all predicate pairs where both predicates are mentioned in the same sentence. We call this set the *Candidate Relations*. Note that this set will contain many invalid relations since co-occurrence in a sentence does not necessarily imply a valid precondition relation.<sup>5</sup> Thus for each sentence,  $\vec{w}_k$ , associated with a given *Candidate Relation*,  $x_i \rightarrow x_j$ , our task is to predict whether the sentence indicates the relation. We model this decision via a log linear distribution as follows:

$$p(x_i \rightarrow x_j \mid \vec{w}_k, q_k; \theta_c) \propto e^{\theta_c \cdot \phi_c(x_i, x_j, \vec{w}_k, q_k)}, \quad (1)$$

where  $\theta_c$  is the vector of model parameters. We compute the feature function  $\phi_c$  using the seed

<sup>5</sup>In our dataset only 11% of *Candidate Relations* are valid.

**Input:** A document  $d$ , Set of planning tasks  $G$ ,  
Set of candidate precondition relations  $C_{all}$ ,  
Reward function  $r()$ , Number of iterations  $T$

**Initialization:** Model parameters  $\theta_x = 0$  and  $\theta_c = 0$ .

```

for  $i = 1 \dots T$  do
  Sample valid preconditions:
   $C \leftarrow \emptyset$ 
  foreach  $\langle x_i, x_j \rangle \in C_{all}$  do
    foreach Sentence  $\vec{w}_k$  containing  $x_i$  and  $x_j$  do
       $v \sim p(x_i \rightarrow x_j \mid \vec{w}_k, q_k; \theta_c)$ 
      if  $v = 1$  then  $C = C \cup \langle x_i, x_j \rangle$ 
    end
  end
  Predict subgoal sequences for each task g.
  foreach  $g \in G$  do
    Sample subgoal sequence  $\vec{x}$  as follows:
    for  $t = 1 \dots n$  do
      Sample next subgoal:
       $x_t \sim p(x \mid x_{t-1}, s_0^g, s_f^g, C; \theta_x)$ 
      Construct low-level subtask from  $x_{t-1}$  to  $x_t$ 
      Execute low-level planner on subtask
    end
    Update subgoal prediction model using Eqn. 2
  end
  Update text precondition model using Eqn. 3
end

```

Algorithm 1: A policy gradient algorithm for parameter estimation in our model.

grounding, the sentence  $\vec{w}_k$ , and a given dependency parse  $q_k$  of the sentence. Given these per-sentence decisions, we predict the set of all valid precondition relations,  $C$ , in a deterministic fashion. We do this by considering a precondition  $x_i \rightarrow x_j$  as valid if it is predicted to be valid by at least one sentence.

**Modeling Subgoal Sequences** Given a planning goal  $g$ , defined by initial and final goal states  $s_0^g$  and  $s_f^g$ , our task is to predict a sequence of subgoals  $\vec{x}$  which will achieve the goal. We condition this decision on our predicted set of valid preconditions  $C$ , by modeling the distribution over sequences  $\vec{x}$  as:

$$p(\vec{x} \mid s_0^g, s_f^g, C; \theta_x) = \prod_{t=1}^n p(x_t \mid x_{t-1}, s_0^g, s_f^g, C; \theta_x),$$

$$p(x_t \mid x_{t-1}, s_0^g, s_f^g, C; \theta_x) \propto e^{\theta_x \cdot \phi_x(x_t, x_{t-1}, s_0^g, s_f^g, C)}.$$

Here we assume that subgoal sequences are Markovian in nature and model individual subgoal predictions using a log-linear model. Note that in con-

trast to Equation 1 where the predictions are goal-agnostic, these predictions are goal-specific. As before,  $\theta_x$  is the vector of model parameters, and  $\phi_x$  is the feature function. Additionally, we assume a special stop symbol,  $x_\emptyset$ , which indicates the end of the subgoal sequence.

**Parameter Update** Parameter updates in our model are done via reinforcement learning. Specifically, once the model has predicted a subgoal sequence for a given goal, the sequence is given to the low-level planner for execution. The success or failure of this execution is used to compute the reward signal  $r$  for parameter estimation. This predict-execute-update cycle is repeated until convergence. We assume that our reward signal  $r$  strongly correlates with the correctness of model predictions. Therefore, during learning, we need to find the model parameters that maximize expected future reward (Sutton and Barto, 1998). We perform this maximization via stochastic gradient ascent, using the standard policy gradient algorithm (Williams, 1992; Sutton et al., 2000).

We perform two separate policy gradient updates, one for each model component. The objective of the text component of our model is purely to predict the validity of preconditions. Therefore, subgoal pairs  $\langle x_k, x_l \rangle$ , where  $x_l$  is reachable from  $x_k$ , are given positive reward. The corresponding parameter update, with learning rate  $\alpha_c$ , takes the following form:

$$\Delta\theta_c \leftarrow \alpha_c r \left[ \phi_c(x_i, x_j, \vec{w}_k, q_k) - \mathbb{E}_{p(x_{i'} \rightarrow x_{j'} | \cdot)} \left[ \phi_c(x_{i'}, x_{j'}, \vec{w}_k, q_k) \right] \right]. \quad (2)$$

The objective of the planning component of our model is to predict subgoal sequences that successfully achieve the given planning goals. Thus we directly use plan-success as a binary reward signal, which is applied to each subgoal decision in a sequence. This results in the following update:

$$\Delta\theta_x \leftarrow \alpha_x r \sum_t \left[ \phi_x(x_t, x_{t-1}, s_0^g, s_f^g, C) - \mathbb{E}_{p(x'_t | \cdot)} \left[ \phi_x(x'_t, x_{t-1}, s_0^g, s_f^g, C) \right] \right], \quad (3)$$

where  $t$  indexes into the subgoal sequence and  $\alpha_x$  is the learning rate.

Table 1: A comparison of complexity between Minecraft and some domains used in the IPC-2011 sequential satisficing track. In the Minecraft domain, the number of objects, predicate types, and actions is significantly larger.

## 5 Applying the Model

We apply our method to Minecraft, a grid-based virtual world. Each grid location represents a tile of either land or water and may also contain resources. Users can freely move around the world, harvest resources and craft various tools and objects from these resources. The dynamics of the world require certain resources or tools as prerequisites for performing a given action, as can be seen in Figure 3. For example, a user must first craft a *bucket* before they can collect *milk*.

**Defining the Domain** In order to execute a traditional planner on the Minecraft domain, we define the domain using the Planning Domain Definition Language (PDDL) (Fox and Long, 2003). This is the standard task definition language used in the International Planning Competitions (IPC).<sup>6</sup> We define as predicates all aspects of the game state – for example, the location of resources in the world, the resources and objects possessed by the player, and the player’s location. Our subgoals  $x_i$  and our task goals  $s_f^g$  map directly to these predicates. This results in a domain with significantly greater complexity than those solvable by traditional low-level planners. Table 1 compares the complexity of our domain with some typical planning domains used in the IPC.

<sup>6</sup><http://ipc.icaps-conference.org/>

**Low-level Planner** As our low-level planner we employ Metric-FF (Hoffmann and Nebel, 2001), the state-of-the-art baseline used in the 2008 International Planning Competition. Metric-FF is a forward-chaining heuristic state space planner. Its main heuristic is to simplify the task by ignoring operator delete lists. The number of actions in the solution for this simplified task is then used as the goal distance estimate for various search strategies.

**Features** The two components of our model leverage different types of information, and as a result, they each use distinct sets of features. The text component features  $\phi_c$  are computed over sentences and their dependency parses. The Stanford parser (de Marneffe et al., 2006) was used to generate the dependency parse information for each sentence. Examples of these features appear in Table 2. The sequence prediction component takes as input both the preconditions induced by the text component as well as the planning state and the previous subgoal. Thus  $\phi_x$  contains features which check whether two subgoals are connected via an induced precondition relation, in addition to features which are simply the Cartesian product of domain predicates.

## 6 Experimental Setup

**Datasets** As the text description of our virtual world, we use documents from the Minecraft Wiki,<sup>7</sup> the most popular information source about the game. Our manually constructed seed grounding of predicates contains 74 entries, examples of which can be seen in Table 3. We use this seed grounding to identify a set of 242 sentences that reference predicates in the Minecraft domain. This results in a set of 694 *Candidate Relations*. We also manually annotated the relations expressed in the text, identifying 94 of the *Candidate Relations* as valid. Our corpus contains 979 unique word types and is composed of sentences with an average length of 20 words.

We test our system on a set of 98 problems that involve collecting resources and constructing objects in the Minecraft domain – for example, fishing, cooking and making furniture. To assess the complexity of these tasks, we manually constructed high-level plans for these goals and solved them using the Metric-FF planner. On average, the execu-

Table 2: Example text features. A subgoal pair  $\langle x_i, x_j \rangle$  is first mapped to word tokens using a small grounding table. Words and dependencies are extracted along paths between mapped target words. These are combined with path directions to generate the text features.

Domain Predicate	Noun Phrases
have(plank)	wooden plank, wood plank
have(stone)	stone, cobblestone
have(iron)	iron ingot

Table 3: Examples in our seed grounding table. Each predicate is mapped to one or more noun phrases that describe it in the text.

tion of the sequence of low-level plans takes 35 actions, with 3 actions for the shortest plan and 123 actions for the longest. The average branching factor is 9.7, leading to an average search space of more than  $10^{34}$  possible action sequences. For evaluation purposes we manually identify a set of *Gold Relations* consisting of all precondition relations that are valid in this domain, including those not discussed in the text.

**Evaluation Metrics** We use our manual annotations to evaluate the type-level accuracy of relation extraction. To evaluate our high-level planner, we use the standard measure adopted by the IPC. This evaluation measure simply assesses whether the planner completes a task within a predefined time.

**Baselines** To evaluate the performance of our relation extraction, we compare against an SVM classifier<sup>8</sup> trained on the *Gold Relations*. We test the SVM baseline in a leave-one-out fashion.

To evaluate the performance of our text-aware high-level planner, we compare against five baselines. The first two baselines – *FF* and *No Text* – do not use any textual information. The *FF* baseline directly runs the Metric-FF planner on the given task, while the *No Text* baseline is a variant of our model that learns to plan in the reinforcement learning framework. It uses the same state-level features

<sup>7</sup>[http://www.minecraftwiki.net/wiki/Minecraft\\_Wiki/](http://www.minecraftwiki.net/wiki/Minecraft_Wiki/)

<sup>8</sup>SVM<sup>light</sup> (Joachims, 1999) with default parameters.

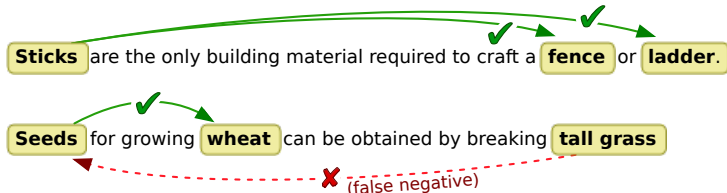

Figure 4: Examples of precondition relations predicted by our model from text. Check marks (✓) indicate correct predictions, while a cross (✗) marks the incorrect one – in this case, a valid relation that was predicted as invalid by our model. Note that each pair of highlighted noun phrases in a sentence is a *Candidate Relation*, and pairs that are not connected by an arrow were correctly predicted to be invalid by our model.

Figure 5: The performance of our model and a supervised SVM baseline on the precondition prediction task. Also shown is the F-Score of the full set of *Candidate Relations* which is used unmodified by *All Text*, and is given as input to our model. Our model’s F-score, averaged over 200 trials, is shown with respect to learning iterations.

as our model, but does not have access to text.

The *All Text* baseline has access to the full set of 694 *Candidate Relations*. During learning, our full model refines this set of relations, while in contrast the *All Text* baseline always uses the full set.

The two remaining baselines constitute the upper bound on the performance of our model. The first, *Manual Text*, is a variant of our model which directly uses the links derived from manual annotations of preconditions in text. The second, *Gold*, has access to the *Gold Relations*. Note that the connections available to *Manual Text* are a subset of the *Gold* links, because the text does not specify all relations.

**Experimental Details** All experimental results are averaged over 200 independent runs for both our model as well as the baselines. Each of these trials is run for 200 learning iterations with a maximum subgoal sequence length of 10. To find a low-level plan between each consecutive pair of subgoals, our high-level planner internally uses Metric-FF. We give Metric-FF a one-minute timeout to find such a low-level plan. To ensure that the comparison

Method	% Plans
FF	40.8
No text	69.4
All text	75.5
<b>Full model</b>	<b>80.2</b>
Manual text	84.7
Gold connection	87.1

Table 4: Percentage of tasks solved successfully by our model and the baselines. All performance differences between methods are statistically significant at  $p \leq .01$ .

between the high-level planners and the FF baseline is fair, the FF baseline is allowed a runtime of 2,000 minutes. This is an upper bound on the time that our high-level planner can take over the 200 learning iterations, with subgoal sequences of length at most 10 and a one minute timeout. Lastly, during learning we initialize all parameters to zero, use a fixed learning rate of 0.0001, and encourage our model to explore the state space by using the standard  $\epsilon$ -greedy exploration strategy (Sutton and Barto, 1998).

## 7 Results

**Relation Extraction** Figure 5 shows the performance of our method on identifying preconditions in text. We also show the performance of the supervised SVM baseline. As can be seen, after 200 learning iterations, our model achieves an F-Measure of 66%, equal to the supervised baseline. These results support our hypothesis that planning feedback is a powerful source of supervision for analyzing a given text corpus. Figure 4 shows some examples of sentences and the corresponding extracted relations.

**Planning Performance** As shown in Table 4 our text-enriched planning model outperforms the text-free baselines by more than 10%. Moreover, the performance improvement of our model over the *All Text* baseline demonstrates that the accuracy of the

Figure 6: Percentage of problems solved by various models on Easy and Hard problem sets.

extracted text relations does indeed impact planning performance. A similar conclusion can be reached by comparing the performance of our model and the *Manual Text* baseline.

The difference in performance of 2.35% between *Manual Text* and *Gold* shows the importance of the precondition information that is missing from the text. Note that *Gold* itself does not complete all tasks – this is largely because the Markov assumption made by our model does not hold for all tasks.<sup>9</sup>

Figure 6 breaks down the results based on the difficulty of the corresponding planning task. We measure problem complexity in terms of the low-level steps needed to implement a manually constructed high-level plan. Based on this measure, we divide the problems into two sets. As can be seen, all of the high-level planners solve almost all of the easy problems. However, performance varies greatly on the more challenging tasks, directly correlating with planner sophistication. On these tasks our model outperforms the *No Text* baseline by 28% and the *All Text* baseline by 11%.

**Feature Analysis** Figure 7 shows the top five positive features for our model and the SVM baseline. Both models picked up on the words that indicate precondition relations in this domain. For instance, the word *use* often occurs in sentences that describe the resources required to make an object, such as “bricks are items used to craft brick blocks”. In addition to lexical features, dependency information is also given high weight by both learners. An example

<sup>9</sup>When a given task has two non-trivial preconditions, our model will choose to satisfy one of the two first, and the Markov assumption blinds it to the remaining precondition, preventing it from determining that it must still satisfy the other.

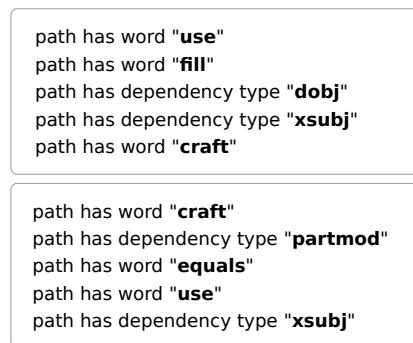

Figure 7: The top five positive features on words and dependency types learned by our model (above) and by SVM (below) for precondition prediction.

of this is a feature that checks for the direct object dependency type. This analysis is consistent with prior work on event semantics which shows lexico-syntactic features are effective cues for learning text relations (Blanco et al., 2008; Beamer and Girju, 2009; Do et al., 2011).

## 8 Conclusions

In this paper, we presented a novel technique for inducing precondition relations from text by grounding them in the semantics of planning operations. While using planning feedback as its only source of supervision, our method for relation extraction achieves a performance on par with that of a supervised baseline. Furthermore, relation grounding provides a new view on classical planning problems which enables us to create high-level plans based on language abstractions. We show that building high-level plans in this manner significantly outperforms traditional techniques in terms of task completion.

## Abstract

Our research aims at building computational models of word meaning that are perceptually grounded. Using computer vision techniques, we build visual and multimodal distributional models and compare them to standard textual models. Our results show that, while visual models with state-of-the-art computer vision techniques perform worse than textual models in general tasks (accounting for semantic relatedness), they are as good or better models of the meaning of words with visual correlates such as color terms, even in a nontrivial task that involves nonliteral uses of such words. Moreover, we show that visual and textual information are tapping on different aspects of meaning, and indeed combining them in multimodal models often improves performance.

## 1 Introduction

Traditional semantic space models represent meaning on the basis of word co-occurrence statistics in large text corpora (Turney and Pantel, 2010). These models (as well as virtually all work in computational lexical semantics) rely on verbal information only, while human semantic knowledge also relies on non-verbal experience and representation (Louwerse, 2011), crucially on the information gathered through perception. Recent developments in computer vision make it possible to computationally model one vital human perceptual channel: vision (Mooney, 2008). A few studies have begun to use visual information extracted from images as part of distributional semantic models (Bergsma and Van

Durme, 2011; Bergsma and Goebel, 2011; Bruni et al., 2011; Feng and Lapata, 2010; Leong and Mihalcea, 2011). These preliminary studies all focus on how vision may help text-based models in general terms, by evaluating performance on, for instance, word similarity datasets such as WordSim353.

This paper contributes to connecting language and perception, focusing on how to exploit visual information to build better models of word meaning, in three ways: (1) We carry out a systematic comparison of models using textual, visual, and both types of information. (2) We evaluate the models on general semantic relatedness tasks and on two specific tasks where visual information is highly relevant, as they focus on color terms. (3) Unlike previous work, we study the impact of using different kinds of visual information for these semantic tasks.

Our results show that, while visual models with state-of-the-art computer vision techniques perform worse than textual models in general semantic tasks, they are as good or better models of the meaning of words with visual correlates such as color terms, even in a nontrivial task that involves nonliteral uses of such words. Moreover, we show that visual and textual information are tapping on different aspects of meaning, such that they are complementary sources of information, and indeed combining them in multimodal models often improves performance. We also show that “hybrid” models exploiting the patterns of co-occurrence of words as tags of the same images can be a powerful surrogate of visual information under certain circumstances.

The rest of the paper is structured as follows. Section 2 introduces the textual, visual, multimodal,

and hybrid models we use for our experiments. We present our experiments in sections 3 to 5. Section 6 reviews related work, and section 7 finishes with conclusions and future work.

## 2 Distributional semantic models

### 2.1 Textual models

For the current project, we constructed a set of textual distributional models that implement various standard ways to extract them from a corpus, chosen to be representative of the state of the art. In all cases, occurrence and co-occurrence statistics are extracted from the freely available ukWaC and Wackypedia corpora combined (size: 1.9B and 820M tokens, respectively).<sup>1</sup> Moreover, in all models the raw co-occurrence counts are transformed into nonnegative Local Mutual Information (LMI) scores.<sup>2</sup> Finally, in all models we harvest vector representations for the same words (lemmas), namely the top 20K most frequent nouns, 5K most frequent adjectives and 5K most frequent verbs in the combined corpora (for coherence with the vision-based models, that cannot exploit contextual information to distinguish nouns and adjectives, we merge nominal and adjectival usages of the color adjectives in the text-based models as well). The same 30K target nouns, verbs and adjectives are also employed as contextual elements.

The **Window2** and **Window20** models are based on counting co-occurrences with collocates within a window of fixed width, in the tradition of HAL (Lund and Burgess, 1996). Window2 records sentence-internal co-occurrence with the nearest 2 content words to the left and right of each target concept, a narrow context definition expected to capture taxonomic relations. Window20 considers a larger window of 20 words to the left and right of the target, and should capture broader topical relations. The **Document** model corresponds to a “topic-based” approach in which words are represented as distributions over documents. It is based on a word-by-document matrix, recording the distribution of the

<sup>1</sup><http://wacky.sslmit.unibo.it/>

<sup>2</sup>LMI is obtained by multiplying raw counts by Pointwise Mutual Information, and it is a close approximation to the Log-Likelihood Ratio (Evert, 2005). It counteracts the tendency of PMI to favour extremely rare events.

30K target words across the 30K documents in the concatenated corpus that have the largest cumulative LMI mass. This model is thus akin to traditional Latent Semantic Analysis (Landauer and Dumais, 1997), without dimensionality reduction.

We add to the models we constructed the freely available Distributional Memory (**DM**) model,<sup>3</sup> that has been shown to reach state-of-the-art performance in many semantic tasks (Baroni and Lenci, 2010). DM is an example of a more complex text-based model that exploits lexico-syntactic and dependency relations between words (see Baroni and Lenci’s article for details), and we use it as an instance of a grammar-based model. DM is based on the same corpora we used plus the 100M-word British National Corpus,<sup>4</sup> and it also uses LMI scores.

### 2.2 Visual models

The visual models use information extracted from images instead of textual corpora. We use image data where each image is associated with one or more words or **tags** (we use “tag” for each word associated to the image, and “label” for the set of tags of an image). We use the ESP-Game dataset,<sup>5</sup> containing 100K images labeled through a game with a purpose in which two people partnered online must independently and rapidly agree on an appropriate word to label randomly selected images. Once a word is entered by both partners in a certain number of game matches, that word is added to the label for that image, and it becomes a taboo word for the following rounds of the game (von Ahn and Dabbish, 2004). There are 20,515 distinct tags in the dataset, with an average of 4 tags per image. We build one vector with visual features for each tag in the dataset.

The visual features are extracted with the use of a standard bag-of-visual-words (**BoVW**) representation of images, inspired by NLP (Sivic and Zisserman, 2003; Csurka et al., 2004; Nister and Stewenius, 2006; Bosch et al., 2007; Yang et al., 2007). This approach relies on the notion of a common vocabulary of “visual words” that can serve as discrete representations for all images. Contrary to what hap-

<sup>3</sup><http://cllc.cimec.unitn.it/dm>

<sup>4</sup><http://www.natcorp.ox.ac.uk/>

<sup>5</sup><http://www.espgame.org>

pens in NLP, where words are (mostly) discrete and easy to identify, in vision the visual words need to be first defined. The process is completely inductive. In a nutshell, BoVW works as follows. From every image in a dataset, relevant areas are identified and a low-level feature vector (called a “descriptor”) is built to represent each area. These vectors, living in what is sometimes called a *descriptor space*, are then grouped into a number of clusters. Each cluster is treated as a discrete visual word, and the clusters will be the *vocabulary* of visual words used to represent all the images in the collection. Now, given a new image, the nearest visual word is identified for each descriptor extracted from it, such that the image can be represented as a BoVW feature vector, by counting the instances of each visual word in the image (note that an occurrence of a low-level descriptor vector in an image, after mapping to the nearest cluster, will increment the count of a single dimension of the higher-level BoVW vector). In our work, the representation of each word (tag) is also a BoVW vector. The values of each dimension are obtained by summing the occurrences of the relevant visual word in all the images tagged with the word. Again, raw counts are transformed into Local Mutual Information scores. The process to extract visual words and use them to create image-based vectors to represent (real) words is illustrated in Figure 1, for a hypothetical example in which there is only one image in the collection labeled with the word *horse*.

Figure 1: Procedure to build a visual representation for a word, exemplified with SIFT features.

We extract descriptor features of two types.<sup>6</sup> First, the standard Scale-Invariant Feature Transform (**SIFT**) feature vectors (Lowe, 1999; Lowe, 2004), good at characterizing parts of objects. Second, **LAB** features (Fairchild, 2005), which encode only color information. We also experimented with other visual features, such as those focusing on edges (Canny, 1986), texture (Zhu et al., 2002), and shapes (Oliva and Torralba, 2001), but they were not useful for the color tasks. Moreover, we experimented also with different color scales, such as LUV, HSV and RGB, obtaining significantly worse performance compared to LAB. Further details on feature extraction follow.

SIFT features are designed to be invariant to image scale and rotation, and have been shown to provide a robust matching across affine distortion, noise and change in illumination. The version of SIFT features that we use is sensitive to color (RGB scale; LUV, LAB and OPPONENT gave worse results). We automatically identified keypoints for each image and extracted SIFT features on a regular grid defined around the keypoint with five pixels spacing, at four multiple scales (10, 15, 20, 25 pixel radii), zeroing the low contrast ones. To obtain the visual word vocabulary, we cluster the SIFT feature vectors with the standardly used *k*-means clustering algorithm. We varied the number *k* of visual words between 500 and 2,500 in steps of 500.

For the SIFT-based representation of images, we used spatial histograms to introduce weak *geometry* (Grauman and Darrell, 2005; Lazebnik et al., 2006), dividing the image into several (spatial) regions, representing each region in terms of BoVW, and then concatenating the vectors. In our experiments, the spatial regions were obtained by dividing the image in  $4 \times 4$ , for a total of 16 regions (other values and a global representation did not perform as well). Note that, following standard practice, descriptor clustering was performed ignoring the region partition, but the resulting visual words correspond to different dimensions in the concatenated BoVW vectors, depending on the region in which they occur. Consequently, a vocabulary of *k* visual words results in BoVW vectors with  $k \times 16$  dimensions.

<sup>6</sup>We use VLFeat (<http://www.vlfeat.org/>) for feature extraction (Vedaldi and Fulkerson, 2008).

The LAB color space plots image data in 3 dimensions along 3 independent (orthogonal) axes, one for brightness (luminance) and two for color (chrominance). Luminance corresponds closely to brightness as recorded by the brain-eye system; the chrominance (red-green and yellow-blue) axes mimic the oppositional color sensations the retina reports to the brain (Szeliski, 2010). LAB features are densely sampled for each pixel. Also here we use the  $k$ -means algorithm to build the descriptor space. We varied the number of  $k$  visual words between 128 and 1,024 in steps of 128.

### 2.3 Multimodal models

To assemble the textual and visual representations in multimodal semantic spaces, we concatenate the two vectors after normalizing them. We use the linear weighted combination function proposed by Bruni et al. (2011): Given a word that is present both in the textual model and in the visual model, we separately normalize the two vectors  $F_t$  and  $F_v$  and we combine them as follows:

$$F = \alpha \times F_t \oplus (1 - \alpha) \times F_v$$

where  $\oplus$  is the vector concatenate operator. The weighting parameter  $\alpha$  ( $0 \leq \alpha \leq 1$ ) is tuned on the MEN development data (2,000 word pairs; details on the MEN dataset in the next section). We find the optimal value to be close to  $\alpha = 0.5$  for most model combinations, suggesting that textual and visual information should have similar weight. Our implementation of the proposed method is open source and publicly available.<sup>7</sup>

### 2.4 Hybrid models

We further introduce hybrid models that exploit the patterns of co-occurrence of words as tags of the same images. Like textual models, these models are based on word co-occurrence; like visual models, they consider co-occurrence in images (image labels). In one model (**ESP-Win**, analogous to window-based models), words tagging an image were represented in terms of co-occurrence with the other tags in the image label (Baroni and Lenci (2008) are a precedent for the use of ESP-Win). The other (**ESP-Doc**, analogous to document-based

models) represented words in terms of their co-occurrence with images, using each image as a different dimension. This information is very easy to extract, as it does not require the sophisticated techniques used in computer vision. We expected these models to perform very bad; however, as we will show, they perform relatively well in all but one of the tasks tested.

## 3 Textual and visual models as general semantic models

We test the models just presented in two different ways: First, as general models of word meaning, testing their correlation to human judgements on word similarity and relatedness (this section). Second, as models of the meaning of color terms (sections 4 and 5).

We use one standard dataset (**WordSim353**) and one new dataset (**MEN**). WordSim353 (Finkelstein et al., 2002) is a widely used benchmark constructed by asking 16 subjects to rate a set of 353 word pairs on a 10-point similarity scale and averaging the ratings (*dollar/buck* receives a high 9.22 average rating, *professor/cucumber* a low 0.31). MEN is a new evaluation benchmark with a better coverage of our multimodal semantic models.<sup>8</sup> It contains 3,000 pairs of randomly selected words that occur as ESP tags (pairs sampled to ensure a balanced range of relatedness levels according to a text-based semantic score). Each pair is scored on a  $[0, 1]$ -normalized semantic relatedness scale via ratings obtained by crowdsourcing on the Amazon Mechanical Turk (refer to the online MEN documentation for more details). For example, *cold/frost* has a high 0.9 MEN score, *eat/hair* a low 0.1. We evaluate the models in terms of their Spearman correlation to the human ratings. Our models have a perfect MEN coverage and a coverage of 252 WordSim pairs.

We used the development set of MEN to test the effect of varying the number  $k$  of visual words in SIFT and LAB. We restrict the discussion to SIFT with the optimal  $k$  (2.5K words) and to LAB with the optimal (256), lowest (128), and highest  $k$  (1024). We report the results of the multimodal

<sup>8</sup>An updated version of MEN is available from <http://clic.cimec.unitn.it/~elia.bruni/MEN.html>. The version used here contained 10 judgements per word pair.

<sup>7</sup><https://github.com/s2m/FUSE>

models built with these visual models and the best textual models (Window2 and Window20).

Columns WS and MEN in Table 1 report correlations with the WordSim and MEN ratings, respectively. As expected, because they are more mature and capture a broader range of semantic information, textual models perform much better than purely visual models. Also as expected, SIFT features outperform the simpler LAB features for this task.

A first indication that visual information helps is the fact that, for MEN, multimodal models perform best. Note that all models that are sensitive to visual information perform better for MEN than for WordSim, and the reverse is true for textual models. Because of its design, word pairs in MEN can be expected to be more imageable than those in WordSim, so the visual information is more relevant for this dataset. Also recall that we did some parameter tuning on held-out MEN data.

Surprisingly, hybrid models perform quite well: They are around 10 points worse than textual and multimodal models for WordSim, and only slightly worse than multimodal models for MEN.

## 4 Experiment 1: Discovering the color of concrete objects

In Experiment 1, we test the hypothesis that the relation between words denoting concrete things and words denoting their typical color is reflected by the distance of the corresponding vectors better when the models are sensitive to visual information.

### 4.1 Method

Two authors labeled by consensus a list of concrete nouns (extracted from the BLESS dataset<sup>9</sup> and the nouns in the BNC occurring with color terms more than 100 times) with one of the 11 colors from the basic set proposed by Berlin and Kay (1969): *black, blue, brown, green, grey, orange, pink, purple, red, white, yellow*. Objects that do not have an obvious characteristic color (*computer*) and those with more than one characteristic color (*zebra, bear*) were eliminated. Moreover, only nouns covered by all the models were preserved. The final list con-

Table 1: Results of the textual, visual, multimodal, and hybrid models on the general semantic tasks (first two columns, section 3; Pearson  $\rho$ ) and Experiments 1 (E1, section 4) and 2 (E2, section 5). E1 reports the median rank of the correct color and the number of top matches (in parentheses), and E2 the average difference in normalized cosines between literal and nonliteral adjective-noun phrases, with the significance of a t-test (\*\*\* for  $p < 0.001$ , \*\*  $< 0.01$ , \*  $< 0.05$ ).

tains 52 nouns.<sup>10</sup> Some random examples are *fog–grey, crow–black, wood–brown, parsley–green, and grass–green*.

For evaluation, we measured the cosine of each noun with the 11 basic color words in the space produced by each model, and recorded the rank of the correct color in the resulting ordered list.

### 4.2 Results

Column E1 in Table 1 reports the median rank for each model (the smaller the rank, the better the model), as well as the number of exact matches (that is, number of nouns for which the model ranks the correct color first).

Discovering knowledge such that grass is green is arguably a simple task but Experiment 1 shows

<sup>10</sup>Dataset available from the second author’s webpage, under resources.

that textual models fail this simple task, with median ranks around 3.<sup>11</sup> This is consistent with the findings in Baroni and Lenci (2008) that standard distributional models do not capture the association between concrete concepts and their typical attributes. Visual models, as expected, are better at capturing the association between concepts and visual attributes. In fact, all models that are sensitive to visual information achieve median rank 1.

Multimodal models do not increase performance with respect to visual models: For instance, both W2-LAB<sub>128</sub> and W20-LAB<sub>128</sub> have the same median rank and number of exact matches as LAB<sub>128</sub> alone. Textual information in this case is not complementary to visual information, but simply poorer.

Also note that LAB features do better than SIFT features. This is probably due to the fact that Experiment 1 is basically about identifying a large patch of color. The SIFT features we are using are also sensitive to color, but they seem to be misguided by the other cues that they extract from images. For example, pigs are pink in LAB space but brown in SIFT space, perhaps because SIFT focused on the color of the typical environment of a pig. We can thus confirm that, by limiting multimodal spaces to SIFT features, as has been done until now in the literature, we are missing important semantic information, such as the color information that we can mine with LAB.

Again we find that hybrid models do very well, in fact in this case they have the top performance, as they perform better than LAB<sub>128</sub> (the difference, which can be noticed in the number of exact matches, is highly significant according to a paired Mann-Whitney test, with  $p < 0.001$ ).

## 5 Experiment 2

Experiment 2 requires more sophisticated information than Experiment 1, as it involves distinguishing between literal and nonliteral uses of color terms.

---

<sup>11</sup>We also experimented with a model based on direct co-occurrence of adjectives and nouns, obtaining promising results in a preliminary version of Exp. 1. We abandoned this approach because such a model inherently lacks scalability, as it will not generalize behind cases where the training data contain direct examples of co-occurrences of the target pairs.

## 5.1 Method

We test the performance of the different models with a dataset consisting of color adjective-noun phrases, randomly drawn from the most frequent 8K nouns and 4K adjectives in the concatenated ukWaC, Wackypedia, and BNC corpora (four color terms are not among these, so the dataset includes phrases for *black*, *blue*, *brown*, *green*, *red*, *white*, and *yellow* only). These were tagged by consensus by two human judges as **literal** (*white towel*, *black feather*) or **nonliteral** (*white wine*, *white musician*, *green future*). Some phrases had both literal and nonliteral uses, such as *blue book* in “book that is blue” vs. “automobile price guide”. In these cases, only the most common sense (according to the judges) was taken into account for the present experiment. The dataset consists of 370 phrases, of which our models cover 342, 227 literal and 115 nonliteral.<sup>12</sup>

The prediction is that, in good semantic models, literal uses will in general result in a higher similarity between the noun and color term vectors: A white towel is white, while wine or musicians are not white in the same manner. We test this prediction by comparing the average cosine between the color term and the nouns across the literal and nonliteral pairs (similar results were obtained in an evaluation in terms of prediction accuracy of a simple classifier).

## 5.2 Results

Column E2 in Table 1 summarizes the results of the experiment, reporting the mean difference between the normalized cosines (that is, how large the difference is between the literal and nonliteral uses of color terms), as well as the significance of the differences according to a t-test. Window-based models perform best among textual models, particularly Window20, while the rest can’t discriminate between the two uses. This is particularly striking for the Document model, which performs quite well in general semantic tasks but bad in visual tasks.

Visual models are all able to discriminate between the two uses, suggesting that indeed visual information can capture nonliteral aspects of meaning. However, in this case SIFT features perform much better than LAB features, as Experiment 2 involves

---

<sup>12</sup>Dataset available upon request to the second author.

tackling much more sophisticated information than Experiment 1. This is consistent with the fact that, for LAB, a lower  $k$  (lower granularity of the information) performs better for Experiment 1 and a higher  $k$  (higher granularity) for Experiment 2.

One crucial question to ask, given the goals of our research, is whether textual and visual models are doing essentially the same job, only using different types of information. Note that, in this case, multimodal models increase performance over the individual modalities, and are the best models for this task. This suggests that the information used in the individual models is complementary, and indeed there is no correlation between the cosines obtained with the best textual and visual models (Pearson’s  $\rho = .09$ ,  $p = .11$ ).

Figure 2 depicts the results broken down by color.<sup>13</sup> Both modalities can capture the differences for *black* and *green*, probably because nonliteral uses of these color terms have also clear textual correlates (more concretely, topical correlates, as they are related to race and ecology, respectively).<sup>14</sup> Significantly, however, vision can capture nonliteral uses of *blue* and *red*, while text can’t. Note that these uses (*blue note*, *shark*, *shield*, *red meat*, *district*, *face*) do not have a clear topical correlate, and thus it makes sense that vision does a better job.

Finally, note that for this more sophisticated task, hybrid models perform quite bad, which shows their limitations as models of word meaning.<sup>15</sup> Overall,

<sup>13</sup>*Yellow* and *brown* are excluded because the dataset contains only one and two instances of nonliteral cases for these terms, respectively. The significance of the differences as explained in the text has been tested via t-tests.

<sup>14</sup>It’s not entirely clear why neither modality can capture the differences for *white*; for text, it may be because the nonliteral cases are not so tied to race as is the cases for *black*, but they also contain many other types of nonliteral uses, such as type-referring (*white wine/rice/cell*) or metonymical ones (*white smile*).

<sup>15</sup>The hybrid model that performs best in the color tasks is ESP-Doc. This model can only detect a relation between an adjective and a noun if they directly co-occur in the label of at least one image (a “document” in this setting). The more direct co-occurrences there are, the more related the words will be for the model. This works for Exp. 1: Since the ESP labels are lists of what subjects saw in a picture, and the adjectives of Exp. 1 are typical colors of objects, there is a high co-occurrence, as all but one adjective-noun pairs co-occur in at least one ESP label. For the model to perform well in Exp. 2 too, literal phrases should occur in the same labels and non-literal pairs should not. We

our results suggest that co-occurrence in an image label can be used as a surrogate of true visual information to some extent, but the behavior of hybrid models depends on ad-hoc aspects of the labeled dataset, and, from an empirical perspective, they are more limited than truly multimodal models, because they require large amounts of rich verbal picture descriptions to reach good coverage.

## 6 Related work

There is an increasing amount of work in computer vision that exploits text-derived information for image retrieval and annotation tasks (Farhadi et al., 2010; Kulkarni et al., 2011). One particular technique inspired by NLP that has acted as a very effective proxy from CV to NLP is precisely the BoVW. Recently, NLPers have begun exploiting BoVW to enrich distributional models that represent word meaning with visual features automatically extracted from images (Feng and Lapata, 2010; Bruni et al., 2011; Leong and Mihalcea, 2011). Previous work in this area relied on SIFT features only, whereas we have enriched the visual representation of words with other kinds of features from computer vision, namely, color-related features (LAB). Moreover, earlier evaluation of multimodal models has focused only on standard word similarity tasks (using mainly WordSim353), whereas we have tested them on both general semantic tasks and specific tasks that tap directly into aspects of semantics (such as color) where we expect visual information to be crucial.

The most closely related work to ours is that recently presented by Özbal et al. (2011). Like us, Özbal and colleagues use both a textual model and a visual model (as well as Google adjective-noun co-occurrence counts) to find the typical color of an object. However, their visual model works by analyzing pictures associated with an object, and determining the color of the object directly by image analysis. We attempt the more ambitious goal of separately associating a vector to nouns and adjectives, and de-

find no such difference (89% of adjective-noun pairs co-occur in at least one image in the literal set, 86% in the nonliteral set), because many of the relevant pairs describe concrete concepts that, while not necessarily of the “right” literal colour, are perfectly fit to be depicted in images (“blue shark”, “black boy”, “white wine”).

Figure 2: Discrimination of literal (L) vs. nonliteral (N) uses by the best visual and textual models.

termining the color of an object by the nearness of the noun denoting the object to the color term. In other words, we are trying to model the meaning of color *terms* and how they relate to other words, and not to directly extract the color of an object from pictures depicting them. Our second experiment is connected to the literature on the automated detection of figurative language (Shutova, 2010). There is in particular some similarity with the tasks studied by Turney et al. (2011). Turney and colleagues try, among other things, to distinguish literal and metaphorical usages of adjectives when combined with nouns, including the highly visual adjective *dark* (*dark hair* vs. *dark humour*). Their method, based on automatically quantifying the degree of abstractness of the noun, is complementary to ours. Future work could combine our approach and theirs.

## 7 Conclusion

We have presented evidence that distributional semantic models based on text, while providing a good general semantic representation of word meaning, can be outperformed by models using visual information for semantic aspects of words where vision is relevant. More generally, this suggests that computer vision is mature enough to significantly contribute to perceptually grounded computational models of language. We have also shown

that different types of visual features (LAB, SIFT) are appropriate for different tasks. Future research should investigate automated methods to discover which (if any) kind of visual information should be highlighted in which task, more sophisticated multimodal models, visual properties other than color, and larger color datasets, such as the one recently introduced by Mohammad (2011).

# A Class-Based Agreement Model for Generating Accurately Inflected Translations

Spence Green

denero@google.com

## Abstract

When automatically translating from a weakly inflected source language like English to a target language with richer grammatical features such as gender and dual number, the output commonly contains morpho-syntactic agreement errors. To address this issue, we present a target-side, class-based agreement model. Agreement is promoted by scoring a sequence of fine-grained morpho-syntactic classes that are predicted during decoding for each translation hypothesis. For English-to-Arabic translation, our model yields a +1.04 BLEU average improvement over a state-of-the-art baseline. The model does not require bitext or phrase table annotations and can be easily implemented as a feature in many phrase-based decoders.

## 1 Introduction

Languages vary in the degree to which surface forms reflect grammatical relations. English is a weakly inflected language: it has a narrow verbal paradigm, restricted nominal inflection (plurals), and only the vestiges of a case system. Consequently, translation *into* English—which accounts for much of the machine translation (MT) literature (Lopez, 2008)—often involves some amount of morpho-syntactic dimensionality reduction. Less attention has been paid to what happens during translation *from* English: richer grammatical features such as gender, dual number, and overt case are effectively latent variables that must be inferred during decoding. Consider the output of Google Translate for the simple English sentence in Fig. 1. The correct translation is a monotone mapping of the input. However, in Arabic, SVO word order requires both gender and number agreement between the subject *السيارة* ‘the car’ and verb *يذهب* ‘go’. The MT system selects the correct verb stem, but with masculine inflection. Although the translation has

(1) *السيارة يذهب بسرعة*  
the-car<sub>SG.DEF.FEM</sub> go<sub>SG.MASC</sub> with-speed<sub>SG.FEM</sub>  
*The car goes quickly*

Figure 1: Ungrammatical Arabic output of Google Translate for the English input *The car goes quickly*. The subject should agree with the verb in both gender and number, but the verb has masculine inflection. For clarity, the Arabic tokens are arranged left-to-right.

the correct semantics, it is ultimately ungrammatical. This paper addresses the problem of generating text that conforms to morpho-syntactic agreement rules.

Agreement relations that cross statistical phrase boundaries are not explicitly modeled in most phrase-based MT systems (Avramidis and Koehn, 2008). We address this shortcoming with an agreement model that scores sequences of fine-grained morpho-syntactic *classes*. First, bound morphemes in translation hypotheses are segmented. Next, the segments are labeled with classes that encode both syntactic category information (i.e., parts of speech) and grammatical features such as number and gender. Finally, agreement is promoted by scoring the predicted class sequences with a generative Markov model.

Our model scores hypotheses *during decoding*. Unlike previous models for scoring syntactic relations, our model does not require bitext annotations, phrase table features, or decoder modifications. The model can be implemented using the feature APIs of popular phrase-based decoders such as Moses (Koehn et al., 2007) and Phrasal (Cer et al., 2010).

Intuition might suggest that the standard *n*-gram language model (LM) is sufficient to handle agreement phenomena. However, LM statistics are sparse, and they are made sparser by morphological variation. For English-to-Arabic translation, we achieve a +1.04 BLEU average improvement by tiling our model on top of a large LM.

It has also been suggested that this setting requires morphological generation because the bitext may not contain all inflected variants (Minkov et al., 2007; Toutanova et al., 2008; Fraser et al., 2012). However, using lexical coverage experiments, we show that there is ample room for translation quality improvements through better *selection* of forms that already exist in the translation model.

## 2 A Class-based Model of Agreement

### 2.1 Morpho-syntactic Agreement

*Morpho-syntactic agreement* refers to a relationship between two sentence elements *a* and *b* that must have at least one matching grammatical feature.<sup>1</sup> Agreement relations tend to be defined for particular syntactic configurations such as verb-subject, noun-adjective, and pronoun-antecedent. In some languages, agreement affects the surface forms of the words. For example, from the perspective of generative grammatical theory, the lexicon entry for the Arabic nominal السيارة ‘the car’ contains a feminine gender feature. When this nominal appears in the subject argument position, the verb-subject agreement relationship triggers feminine inflection of the verb.

Our model treats agreement as a sequence of scored, pairwise relations between adjacent words. Of course, this assumption excludes some agreement phenomena, but it is sufficient for many common cases. We focus on English-Arabic translation as an example of a translation direction that expresses substantially more morphological information in the target. These relations are best captured in a target-side model because they are mostly unobserved (from lexical clues) in the English source.

The agreement model scores sequences of morpho-syntactic word classes, which express grammatical features relevant to agreement. The model has three components: a segmenter, a tagger, and a scorer.

### 2.2 Morphological Segmentation

Segmentation is a procedure for converting raw surface forms to component morphemes. In some languages, agreement relations exist between *bound morphemes*, which are syntactically independent yet phonologically dependent morphemes. For example,

<sup>1</sup>We use *morpho-syntactic* and *grammatical* agreement interchangeably, as is common in the literature.

Figure 2: Segmentation and tagging of the Arabic token وسيكتبونها ‘and they will write it’. This token has four segments with conflicting grammatical features. For example, the number feature is singular for the pronominal object and plural for the verb. Our model segments the raw token, tags each segment with a morpho-syntactic class (e.g., “Pron+Fem+Sg”), and then scores the class sequences.

the single raw token in Fig. 2 contains at least four grammatically independent morphemes. Because the morphemes bear conflicting grammatical features and basic parts of speech (POS), we need to segment the token before we can evaluate agreement relations.<sup>2</sup>

Segmentation is typically applied as a bitext pre-processing step, and there is a rich literature on the effect of different segmentation schemata on translation quality (Koehn and Knight, 2003; Habash and Sadat, 2006; El Kholy and Habash, 2012). Unlike previous work, we segment each translation hypothesis as it is generated (i.e., during decoding). This permits greater modeling flexibility. For example, it may be useful to count tokens with bound morphemes as a unit during phrase extraction, but to score segmented morphemes separately for agreement.

We treat segmentation as a character-level sequence modeling problem and train a linear-chain conditional random field (CRF) model (Lafferty et al., 2001). As a pre-processing step, we group contiguous non-native characters (e.g., Latin characters in Arabic text). The model assigns four labels:

- **I**: Continuation of a morpheme
- **O**: Outside morpheme (whitespace)
- **B**: Beginning of a morpheme
- **F**: Non-native character(s)

<sup>2</sup>Segmentation also improves translation of compounding languages such as German (Dyer, 2009) and Finnish (Macherey et al., 2011).

Translation Model	
$e$	Target sequence of $I$ words
$f$	Source sequence of $J$ words
$a$	Sequence of $K$ phrase alignments for $\langle e, f \rangle$
$\Pi$	Permutation of the alignments for target word order $e$
$h$	Sequence of $M$ feature functions
$\lambda$	Sequence of learned weights for the $M$ features
$H$	A priority queue of hypotheses
Class-based Agreement Model	
$t \in T$	Set of morpho-syntactic classes
$s \in S$	Set of all word segments
$\theta_{seg}$	Learned weights for the CRF-based segmenter
$\theta_{tag}$	Learned weights for the CRF-based tagger
$\phi_o, \phi_t$	CRF potential functions (emission and transition)
$\tau$	Sequence of $I$ target-side predicted classes
$\pi$	$T$ dimensional (log) prior distribution over classes
$\hat{s}$	Sequence of $I$ word segments
$\sigma$	Model state: a tagged segment $\langle s, t \rangle$

Figure 3: Notation used in this paper. The convention  $e_i^I$  indicates a subsequence of a length  $I$  sequence.

The features are indicators for (character, position, label) triples for a five character window and bigram label transition indicators.

This formulation is inspired by the classic “IOB” text chunking model (Ramshaw and Marcus, 1995), which has been previously applied to Chinese segmentation (Peng et al., 2004). It can be learned from gold-segmented data, generally applies to languages with bound morphemes, and does not require a hand-compiled lexicon.<sup>3</sup> Moreover, it has only four labels, so Viterbi decoding is very fast. We learn the parameters  $\theta_{seg}$  using a quasi-Newton (QN) procedure with  $l_1$  (lasso) regularization (Andrew and Gao, 2007).

### 2.3 Morpho-syntactic Tagging

After segmentation, we tag each segment with a fine-grained morpho-syntactic class. For this task we also train a standard CRF model on full sentences with gold classes and segmentation. We use the same QN procedure as before to obtain  $\theta_{tag}$ .

A translation derivation is a tuple  $\langle e, f, a \rangle$  where  $e$  is the target,  $f$  is the source, and  $a$  is an alignment between the two. The CRF tagging model predicts a target-side class sequence  $\tau^*$

$$\tau^* = \arg \max_{\tau} \sum_{i=1}^I \theta_{tag} \cdot \{ \phi_o(\tau_i, i, e) + \phi_t(\tau_i, \tau_{i-1}) \}$$

where further notation is defined in Fig. 3.

<sup>3</sup>Mada, the standard tool for Arabic segmentation (Habash and Rambow, 2005), relies on a manually compiled lexicon.

**Set of Classes** The tagger assigns morpho-syntactic classes, which are coarse POS categories refined with grammatical features such as gender and definiteness. The coarse categories are the universal POS tag set described by Petrov et al. (2012). More than 25 treebanks (in 22 languages) can be automatically mapped to this tag set, which includes “Noun” (nominals), “Verb” (verbs), “Adj” (adjectives), and “ADP” (pre- and post-positions). Many of these treebanks also contain per-token morphological annotations. It is easy to combine the coarse categories with selected grammatical annotations.

For Arabic, we used the coarse POS tags plus definiteness and the so-called phi features (gender, number, and person).<sup>4</sup> For example, السيارة ‘the car’ would be tagged “Noun+Def+Sg+Fem”. We restricted the set of classes to observed combinations in the training data, so the model implicitly disallows incoherent classes like “Verb+Def”.

**Features** The tagging CRF includes emission features  $\phi_o$  that indicate a class  $\tau_i$  appearing with various orthographic characteristics of the word sequence being tagged. In typical CRF inference, the entire observation sequence is available throughout inference, so these features can be scored on observed words in an arbitrary neighborhood around the current position  $i$ . However, we conduct CRF inference in tandem with the translation decoding procedure (§3), creating an environment in which subsequent words of the observation are not available; the MT system has yet to generate the rest of the translation when the tagging features for a position are scored. Therefore, we only define emission features on the observed words at the current and previous positions of a class:  $\phi_o(\tau_i, e_i, e_{i-1})$ .

The emission features are word types, prefixes and suffixes of up to three characters, and indicators for digits and punctuation. None of these features are language specific.

Bigram transition features  $\phi_t$  encode local agreement relations. For example, the model learns that the Arabic class “Noun+Fem” is followed by “Adj+Fem” and not “Adj+Masc” (noun-adjective gender agreement).

<sup>4</sup>Case is also relevant to agreement in Arabic, but it is mostly indicated by diacritics, which are absent in unvocalized text.

## 2.4 Word Class Sequence Scoring

The CRF tagger model defines a conditional distribution  $p(\tau|e; \theta_{tag})$  for a class sequence  $\tau$  given a sentence  $e$  and model parameters  $\theta_{tag}$ . That is, the sample space is over class—not word—sequences. However, in MT, we seek a measure of sentence quality  $q(e)$  that is comparable *across* different hypotheses on the beam (much like the  $n$ -gram language model score). Discriminative model scores have been used as MT features (Galley and Manning, 2009), but we obtained better results by scoring the 1-best class sequences with a generative model. We trained a simple add-1 smoothed bigram language model over gold class sequences in the same treebank training data:

$$q(e) = p(\tau) = \prod_{i=1}^I p(\tau_i | \tau_{i-1})$$

We chose a bigram model due to the aggressive recombination strategy in our phrase-based decoder. For contexts in which the LM is guaranteed to back off (for instance, after an unseen bigram), our decoder maintains only the minimal state needed (perhaps only a single word). In less restrictive decoders, higher order scoring models could be used to score longer-distance agreement relations.

We integrate the segmentation, tagging, and scoring models into a self-contained component in the translation decoder.

## 3 Inference during Translation Decoding

Scoring the agreement model as part of translation decoding requires a novel inference procedure. Crucially, the inference procedure does not measurably affect total MT decoding time.

### 3.1 Phrase-based Translation Decoding

We consider the standard phrase-based approach to MT (Och and Ney, 2004). The distribution  $p(e|f)$  is modeled directly using a log-linear model, yielding the following decision rule:

$$e^* = \arg \max_{e, a, \Pi} \left\{ \sum_{m=1}^M \lambda_m h_m(e, f, a, \Pi) \right\} \quad (1)$$

This decoding problem is NP-hard, thus a beam search is often used (Fig. 4). The beam search relies on three operations, two of which affect the agreement model:

**Input:** implicitly defined search space  
generate initial hypotheses and add to  $H$   
set  $H_{final}$  to  $\emptyset$   
while  $H$  is not empty:  
  set  $H_{ext}$  to  $\emptyset$   
  for each hypothesis  $\eta$  in  $H$ :  
    if  $\eta$  is a goal hypothesis:  
      add  $\eta$  to  $H_{final}$   
    else Extend  $\eta$  and add to  $H_{ext}$      ▶ Score agreement  
  Recombine and Prune  $H_{ext}$   
  set  $H$  to  $H_{ext}$   
**Output:** argmax of  $H_{final}$

Figure 4: Breadth-first beam search algorithm of Och and Ney (2004). Typically, a hypothesis stack  $H$  is maintained for each unique source coverage set.

**Input:**  $(e_1^I, n, is\_goal)$   
run segmenter on attachment  $e_{n+1}^I$  to get  $\hat{s}_1^L$   
get model state  $\sigma = \langle s, t \rangle$  for translation prefix  $e_1^n$   
initialize  $\pi$  to  $-\infty$   
set  $\pi(t) = 0$   
compute  $\tau^*$  from parameters  $\langle s, \hat{s}_1^L, \pi, is\_goal \rangle$   
compute  $q(e_{n+1}^I) = p(\tau^*)$  under the generative LM  
set model state  $\sigma_{new} = \langle \hat{s}_L, \tau_L^* \rangle$  for prefix  $e_1^I$   
**Output:**  $q(e_{n+1}^I)$

Figure 5: Procedure for scoring agreement for each hypothesis generated during the search algorithm of Fig. 4. In the extended hypothesis  $e_1^I$ , the index  $n + 1$  indicates the start of the new attachment.

- Extend a hypothesis with a new phrase pair
- Recombine hypotheses with identical states

We assume familiarity with these operations, which are described in detail in (Och and Ney, 2004).

### 3.2 Agreement Model Inference

The class-based agreement model is implemented as a feature function  $h_m$  in Eq. (1). Specifically, when Extend generates a new hypothesis, we run the algorithm shown in Fig. 5. The inputs are a translation hypothesis  $e_1^I$ , an index  $n$  distinguishing the *prefix* from the *attachment*, and a flag indicating if their concatenation is a goal hypothesis.

The beam search maintains state for each derivation, the score of which is a linear combination of the feature values. States in this program depend on some amount of lexical history. With a trigram language model, the state might be the last two words of the translation prefix. Recombine can be applied to any two hypotheses with equivalent states. As a

result, two hypotheses with different full prefixes—and thus potentially different sequences of agreement relations—can be recombined.

**Incremental Greedy Decoding** Decoding with the CRF-based tagger model in this setting requires some slight modifications to the Viterbi algorithm. We make a greedy approximation that permits recombination and works well in practice. The agreement model state is the *last tagged segment*  $\langle s, t \rangle$  of the concatenated hypothesis. We tag a new attachment by assuming a prior distribution  $\pi$  over the starting position such that  $\pi(t) = 0$  and  $-\infty$  for all other classes, a deterministic distribution in the tropical semiring. This forces the Viterbi path to go through  $t$ . We only tag the final boundary symbol for goal hypotheses.

To accelerate tagger decoding in our experiments, we also used tagging dictionaries for frequently observed word types. For each word type observed more than 100 times in the training data, we restricted the set of possible classes to the set of observed classes.

### 3.3 Translation Model Features

The agreement model score is one decoder feature function. The output of the procedure in Fig. 5 is the log probability of the class sequence of each attachment. Summed over all attachments, this gives the log probability of the whole class sequence.

We also add a new length penalty feature. To discriminate between hypotheses that might have the same number of raw tokens, but different underlying segmentations, we add a penalty equal to the length difference between the segmented and unsegmented attachments  $|\hat{s}_1^L| - |e_{n+1}^L|$ .

## 4 Related Work

We compare our class-based model to previous approaches to scoring syntactic relations in MT.

**Unification-based Formalisms** Agreement rules impose syntactic and semantic constraints on the structure of sentences. A principled way to model these constraints is with a unification-based grammar (UBG). Johnson (2003) presented algorithms for learning and parsing with stochastic UBGs. However, training data for these formalisms remains extremely limited, and it is unclear how to learn such knowledge-rich representations from unlabeled data. One partial

solution is to manually extract unification rules from phrase-structure trees. Williams and Koehn (2011) annotated German trees, and extracted translation rules from them. They then specified manual unification rules, and applied a penalty according to the number of unification failures in a hypothesis. In contrast, our class-based model does not require any manual rules and scores similar agreement phenomena as probabilistic sequences.

**Factored Translation Models** Factored translation models (Koehn and Hoang, 2007) facilitate a more data-oriented approach to agreement modeling. Words are represented as a vector of features such as lemma and POS. The bitext is annotated with separate models, and the annotations are saved during phrase extraction. Hassan et al. (2007) noticed that the target-side POS sequences could be scored, much as we do in this work. They used a target-side LM over Combinatorial Categorical Grammar (CCG) supertags, along with a penalty for the number of operator violations, and also modified the phrase probabilities based on the tags. However, Birch et al. (2007) showed that this approach captures the same re-ordering phenomena as lexicalized re-ordering models, which were not included in the baseline. Birch et al. (2007) then investigated source-side CCG supertag features, but did not show an improvement for Dutch-English.

Subotin (2011) recently extended factored translation models to hierarchical phrase-based translation and developed a discriminative model for predicting target-side morphology in English-Czech. His model benefited from gold morphological annotations on the target-side of the 8M sentence bitext.

In contrast to these methods, our model does not affect phrase extraction and does not require annotated translation rules.

**Class-based LMs** Class-based LMs (Brown et al., 1992) reduce lexical sparsity by placing words in equivalence classes. They have been widely used for speech recognition, but not for MT. Och (1999) showed a method for inducing bilingual word classes that placed each phrase pair into a two-dimensional equivalence class. To our knowledge, Uszkoreit and Brants (2008) are the only recent authors to show an improvement in a state-of-the-art MT system using class-based LMs. They used a classical exchange algorithm for clustering, and learned 512 classes from

a large monolingual corpus. Then they mixed the classes into a word-based LM. However, both Och (1999) and Uszkoreit and Brants (2008) relied on automatically induced classes. It is unclear if their classes captured agreement information.

Monz (2011) recently investigated parameter estimation for POS-based language models, but his classes did not include inflectional features.

**Target-Side Syntactic LMs** Our agreement model is a form of syntactic LM, of which there is a long history of research, especially in speech processing.<sup>5</sup> Syntactic LMs have traditionally been too slow for scoring during MT decoding. One exception was the quadratic-time dependency language model presented by Galley and Manning (2009). They applied a quadratic time dependency parser to every hypothesis during decoding. However, to achieve quadratic running time, they permitted ill-formed trees (e.g., parses with multiple roots). More recently, Schwartz et al. (2011) integrated a right-corner, incremental parser into Moses. They showed a large improvement for Urdu-English, but decoding slowed by three orders of magnitude.<sup>6</sup> In contrast, our class-based model encodes shallow syntactic information without a noticeable effect on decoding time.

Our model can be viewed as a way to score local syntactic relations without extensive decoder modifications. For long-distance relations, Shen et al. (2010) proposed a new decoder that generates target-side dependency trees. The target-side structure enables scoring hypotheses with a trigram dependency LM.

## 5 Experiments

We first evaluate the Arabic segmenter and tagger components independently, then provide English-Arabic translation quality results.

### 5.1 Intrinsic Evaluation of Components

**Experimental Setup** All experiments use the Penn Arabic Treebank (ATB) (Maamouri et al., 2004) parts 1–3 divided into training/dev/test sections according to the canonical split (Rambow et al., 2005).<sup>7</sup>

<sup>5</sup>See (Zhang, 2009) for a comprehensive survey.

<sup>6</sup>In principle, their parser should run in linear time. An implementation issue may account for the decoding slowdown. (*p.c.*)

<sup>7</sup>LDC catalog numbers: LDC2008E61 (ATBp1v4), LDC2008E62 (ATBp2v3), and LDC2008E22 (ATBp3v3.1).

	FULL (%)	INCREMENTAL (%)
Segmenter	98.6	–
Tagger	96.3	96.2

Table 1: Intrinsic evaluation accuracy [%] (development set) for Arabic segmentation and tagging.

The ATB contains clitic-segmented text with *per-segment* morphological analyses (in addition to phrase-structure trees, which we discard). For training the segmenter, we used markers in the vocalized section to construct the IOB character sequences. For training the tagger, we automatically converted the ATB morphological analyses to the fine-grained class set. This procedure resulted in 89 classes.

For the segmentation evaluation, we report *per-character* labeling accuracy.<sup>8</sup> For the tagger, we report *per-token* accuracy.

**Results** Tbl. 1 shows development set accuracy for two settings. FULL is a standard evaluation in which features may be defined over the whole sentence. This includes next-character segmenter features and next-word tagger features. INCREMENTAL emulates the MT setting in which the models are restricted to current and previous observation features. Since the segmenter operates at the character level, we can use the same feature set. However, next-observation features must be removed from the tagger. Nonetheless, tagging accuracy only decreases by 0.1%.

### 5.2 Translation Quality

**Experimental Setup** Our decoder is based on the phrase-based approach to translation (Och and Ney, 2004) and contains various feature functions including phrase relative frequency, word-level alignment statistics, and lexicalized re-ordering models (Tillmann, 2004; Och et al., 2004). We tuned the feature weights on a development set using lattice-based minimum error rate training (MERT) (Macherey et al.,

The data was pre-processed with packages from the Stanford Arabic parser (Green and Manning, 2010). The corpus split is available at <http://nlp.stanford.edu/projects/arabic.shtml>.

<sup>8</sup>We ignore orthographic re-normalization performed by the annotators. For example, they converted the contraction ‘ل’ // back to ‘ل ال’ / Al. As a result, we can report accuracy since the guess and gold segmentations have equal numbers of non-whitespace characters.

	MT04 (tune)		MT02		MT03		MT05		Avg

<i>#sentences</i>	1797		1360		3157

Table 3: Mixed genre test set results (BLEU-4 [%]). The MT06 result is statistically significant at  $p \leq 0.01$ ; MT08 is significant at  $p \leq 0.02$ . The genres are: nw, broadcast news (bn), newsgroups (ng), and weblog (wb).

2008). For each set of results, we initialized MERT with uniform feature weights.

We trained the translation model on 502 million words of parallel text collected from a variety of sources, including the Web. Word alignments were induced using a hidden Markov model based alignment model (Vogel et al., 1996) initialized with bilinear parameters from IBM Model 1 (Brown et al., 1993). Both alignment models were trained using two iterations of the expectation maximization algorithm. Our distributed 4-gram language model was trained on 600 million words of Arabic text, also collected from many sources including the Web (Brants et al., 2007).

For development and evaluation, we used the NIST Arabic-English data sets, each of which contains one set of Arabic sentences and multiple English references. To reverse the translation direction for each data set, we chose the first English reference as the source and the Arabic as the reference.

The NIST sets come in two varieties: newswire (MT02-05) and mixed genre (MT06,08). Newswire contains primarily Modern Standard Arabic (MSA), while the mixed genre data sets also contain transcribed speech and web text. Since the ATB contains MSA, and significant lexical and syntactic differences

may exist between MSA and the mixed genres, we achieved best results by tuning on MT04, the largest newswire set.

We evaluated translation quality with BLEU-4 (Papineni et al., 2002) and computed statistical significance with the approximate randomization method of Riezler and Maxwell (2005).<sup>9</sup>

## 6 Discussion of Translation Results

Tbl. 2 shows translation quality results on newswire, while Tbl. 3 contains results for mixed genres. The baseline is our standard system feature set. For comparison, +POS indicates our class-based model trained on the 11 coarse POS tags only (e.g., “Noun”). Finally, +POS+Agr shows the class-based model with the fine-grained classes (e.g., “Noun+Fem+Sg”).

The best result—a +1.04 BLEU average gain—was achieved when the class-based model training data, MT tuning set, and MT evaluation set contained the same genre. We realized smaller, yet statistically significant, gains on the mixed genre data sets. We tried tuning on both MT06 and MT08, but obtained insignificant gains. In the next section, we investigate this issue further.

**Tuning with a Treebank-Trained Feature** The class-based model is trained on the ATB, which is predominantly MSA text. This data set is syntactically regular, meaning that it does not have highly dialectal content, foreign scripts, disfluencies, etc. Conversely, the mixed genre data sets contain more irregularities. For example, 57.4% of MT06 comes from non-newswire genres. Of the 764 newsgroup sentences, 112 contain some Latin script tokens, while others contain very little morphology:

<sup>9</sup>With the implementation of Clark et al. (2011), available at: <http://github.com/jhclark/multeval>.

- (2) تفاح خل كوب 1/2 اخلطي  
 mix 1/2 cup vinegar apple  
*Mix 1/2 cup apple vinegar*
- (3) ماتش ميوزك برنامج بدأ MusicMatch  
 start program miozik maatsh MusicMatch  
*Start the program music match (MusicMatch)*

In these imperatives, there are no lexically marked agreement relations to score. Ex. (2) is an excerpt from a recipe that appears in full in MT06. Ex. (3) is part of usage instructions for the MusicMatch software. The ATB contains few examples like these, so our class-based model probably does not effectively discriminate between alternative hypotheses for these types of sentences.

**Phrase Table Coverage** In a standard phrase-based system, effective translation into a highly inflected target language requires that the phrase table contain the inflected word forms necessary to construct an output with correct agreement. If the requisite words are not present in the search space of the decoder, then no feature function would be sufficient to enforce morpho-syntactic agreement.

During development, we observed that the phrase table of our large-scale English-Arabic system did often contain the inflected forms that we desired the system to select. In fact, correctly agreeing alternatives often appeared in  $n$ -best translation lists. To verify this observation, we computed the lexical coverage of the MT05 reference sentences in the decoder search space. The statistics below report the token-level recall of reference unigrams:<sup>10</sup>

- Baseline system translation output: 44.6%
- Phrase pairs matching source  $n$ -grams: 67.8%

The bottom category includes all lexical items that the decoder could produce in a translation of the source. This large gap between the unigram recall of the actual translation output (top) and the lexical coverage of the phrase-based model (bottom) indicates that translation performance can be improved dramatically by altering the translation model through features such as ours, without expanding the search space of the decoder.

<sup>10</sup>To focus on possibly inflected word forms, we excluded numbers and punctuation from this analysis.

**Human Evaluation** We also manually evaluated the MT05 output for improvements in agreement.<sup>11</sup> Our system produced different output from the baseline for 785 (74.3%) sentences. We randomly sampled 100 of these sentences and counted agreement errors of all types. The baseline contained 78 errors, while our system produced 66 errors, a statistically significant 15.4% error reduction at  $p \leq 0.01$  according to a paired  $t$ -test.

In our output, a frequent source of remaining errors was the case of so-called “deflected agreement”: inanimate plural nouns require feminine singular agreement with modifiers. On the other hand, animate plural nouns require the sound plural, which is indicated by an appropriate masculine or feminine suffix. For example, the inanimate plural *الولايات* ‘states’ requires the singular feminine adjective *المتحدة* ‘united’, not the sound plural *المتحدات*. The ATB does not contain animacy annotations, so our agreement model cannot discriminate between these two cases. However, Alkuhlani and Habash (2011) have recently started annotating the ATB for animacy, and our model could benefit as more data is released.

## 7 Conclusion and Outlook

Our class-based agreement model improves translation quality by promoting local agreement, but with a minimal increase in decoding time and no additional storage requirements for the phrase table. The model can be implemented with a standard CRF package, trained on existing treebanks for many languages, and integrated easily with many MT feature APIs. We achieved best results when the model training data, MT tuning set, and MT evaluation set contained roughly the same genre. Nevertheless, we also showed an improvement, albeit less significant, on mixed genre evaluation sets.

In principle, our class-based model should be more robust to unseen word types and other phenomena that make non-newswire genres challenging. However, our analysis has shown that for Arabic, these genres typically contain more Latin script and transliterated words, and thus there is less morphology to score. One potential avenue of future work would be to adapt our component models to new genres by self-training them on the target side of a large bitext.

<sup>11</sup>The annotator was the first author.

## Abstract

In this paper we show how to train statistical machine translation systems on real-life tasks using only non-parallel monolingual data from two languages. We present a modification of the method shown in (Ravi and Knight, 2011) that is scalable to vocabulary sizes of several thousand words. On the task shown in (Ravi and Knight, 2011) we obtain better results with only 5% of the computational effort when running our method with an  $n$ -gram language model. The efficiency improvement of our method allows us to run experiments with vocabulary sizes of around 5,000 words, such as a non-parallel version of the VERBMOBIL corpus. We also report results using data from the monolingual French and English GIGAWORD corpora.

## 1 Introduction

It has long been a vision of science fiction writers and scientists to be able to universally communicate in all languages. In these visions, even previously unknown languages can be learned automatically from analyzing foreign language input.

In this work, we attempt to learn statistical translation models from only monolingual data in the source and target language. The reasoning behind this idea is that the elements of languages share statistical similarities that can be automatically identified and matched with other languages.

This work is a big step towards large-scale and large-vocabulary unsupervised training of statistical translation models. Previous approaches have faced constraints in vocabulary or data size. We show how

to scale unsupervised training to real-life translation tasks and how large-scale experiments can be done. Monolingual data is more readily available, if not abundant compared to true parallel or even just translated data. Learning from only monolingual data in real-life translation tasks could improve especially low resource language pairs where few or no parallel texts are available.

In addition to that, this approach offers the opportunity to decipher new or unknown languages and derive translations based solely on the available monolingual data. While we do tackle the full unsupervised learning task for MT, we make some very basic assumptions about the languages we are dealing with:

1. We have large amounts of data available in source and target language. This is not a very strong assumption as books and text on the internet are readily available for almost all languages.
2. We can divide the given text in tokens and sentence-like units. This implies that we know enough about the language to tokenize and sentence-split a given text. Again, for the vast majority of languages, this is not a strong restriction.
3. The writing system is one-dimensional left-to-right. It has been shown (Lin and Knight, 2006) that the writing direction can be determined separately and therefore this assumption does not pose a real restriction.

Previous approaches to unsupervised training for SMT prove feasible only for vocabulary sizes up to around 500 words (Ravi and Knight, 2011) and data

---

\*Author now at Google Inc., amauser@google.com.

sets of roughly 15,000 sentences containing only about 4 tokens per sentence on average. Real data as it occurs in texts such as web pages or news texts does not meet any of these characteristics.

In this work, we will develop, describe, and evaluate methods for large vocabulary unsupervised learning of machine translation models suitable for real-world tasks. The remainder of this paper is structured as follows: In Section 2, we will review the related work and describe how our approach extends existing work. Section 3 describes the model and training criterion used in this work. The implementation and the training of this model is then described in Section 5 and experimentally evaluated in Section 6.

## 2 Related Work

Unsupervised training of statistical translations systems without parallel data and related problems have been addressed before. In this section, we will review previous approaches and highlight similarities and differences to our work. Several steps have been made in this area, such as (Knight and Yamada, 1999), (Ravi and Knight, 2008), or (Snyder et al., 2010), to name just a few. The main difference of our work is, that it allows for much larger vocabulary sizes and more data to be used than previous work while at the same time not being dependent on seed lexica and/or any other knowledge of the languages.

Close to the methods described in this work, Ravi and Knight (2011) treat training and translation without parallel data as a deciphering problem. Their best performing approach uses an EM-Algorithm to train a generative word based translation model. They perform experiments on a Spanish/English task with vocabulary sizes of about 500 words and achieve a performance of around 20 BLEU compared to 70 BLEU obtained by a system that was trained on parallel data. Our work uses the same training criterion and is based on the same generative story. However, we use a new training procedure whose critical parts have constant time and memory complexity with respect to the vocabulary size so that our methods can scale to much larger vocabulary sizes while also being faster.

In a different approach, Koehn and Knight (2002)

induce a bilingual lexicon from only non-parallel data. To achieve this they use a seed lexicon which they systematically extend by using orthographic as well as distributional features such as context, and frequency. They perform their experiments on non-parallel German-English news texts, and test their mappings against a bilingual lexicon. We use a greedy method similar to (Koehn and Knight, 2002) for extending a given lexicon, and we implicitly also use the frequency as a feature. However, we perform fully unsupervised training and do not start with a seed lexicon or use linguistic features.

Similarly, Haghghi et al. (2008) induce a one-to-one translation lexicon only from non-parallel monolingual data. Also starting with a seed lexicon, they use a generative model based on canonical correlation analysis to systematically extend the lexicon using context as well as spelling features. They evaluate their method on a variety of tasks, ranging from inherently parallel data (EUROPARL) to unrelated corpora (100k sentences of the GIGAWORD corpus). They report F-measure scores of the induced entries between 30 to 70. As mentioned above, our work neither uses a seed lexicon nor orthographic features.

## 3 Translation Model

In this section, we describe the statistical training criterion and the translation model that is trained using monolingual data. In addition to the mathematical formulation of the model we describe approximations used.

Throughout this work, we denote the source language words as  $f$  and target language words as  $e$ . The source vocabulary is  $V_f$  and we write the size of this vocabulary as  $|V_f|$ . The same notation holds for the target vocabulary with  $V_e$  and  $|V_e|$ .

As training criterion for the translation model's parameters  $\theta$ , Ravi and Knight (2011) suggest

$$\arg \max_{\theta} \left\{ \prod_f \sum_e P(e) \cdot p_{\theta}(f|e) \right\} \quad (1)$$

We would like to obtain  $\theta$  from Equation 1 using the EM Algorithm (Dempster et al., 1977). This becomes increasingly difficult with more complex translation models. Therefore, we use a simplified

translation model that still contains all basic phenomena of a generic translation process. We formulate the translation process with the same generative story presented in (Ravi and Knight, 2011):

1. Stochastically generate the target sentence according to an  $n$ -gram language model.
2. Insert NULL tokens between any two adjacent positions of the target string with uniform probability.
3. For each target token  $e_i$  (including NULL) choose a foreign translation  $f_i$  (including NULL) with probability  $P_\theta(f_i|e_i)$ .
4. Locally reorder any two adjacent foreign words  $f_{i-1}, f_i$  with probability  $P(\text{SWAP}) = 0.1$ .
5. Remove the remaining NULL tokens.

In practice, however, it is not feasible to deal with the full parameter table  $P_\theta(f_i|e_i)$  which models the lexicon. Instead we only allow translation models where for each *source* word  $f$  the number of words  $e'$  with  $P(f|e') \neq 0$  is below some fixed value. We will refer to this value as the *maximum number of candidates* of the translation model and denote it with  $N_C$ . Note that for a given  $e$  this does not necessarily restrict the number of entries  $P(f'|e) \neq 0$ . Also note that with a fixed value of  $N_C$ , time and memory complexity of the EM step is  $\mathcal{O}(1)$  with respect to  $|V_e|$  and  $|V_f|$ .

In the following we divide the problem of maximizing Equation 1 into two parts:

1. Determining a set of active lexicon entries.
2. Choosing the translation probabilities for the given set of active lexicon entries.

The second task can be achieved by running the EM algorithm on the restricted translation model. We deal with the first task in the following section.

#### 4 Monolingual Context Similarity

As described in Section 3 we need some mechanism to iteratively choose an active set of translation candidates. Based on the assumption that some of the active candidates and their respective probabilities are already correct, we induce new active candidates. In the context of information retrieval, Salton et al. (1975) introduce a document space where each

document identified by one or more index terms is represented by a high dimensional vector of term weights. Given two vectors  $v_1$  and  $v_2$  of two documents it is then possible to calculate a similarity coefficient between those given documents (which is usually denoted as  $s(v_1, v_2)$ ). Similar to this we represent source and target words in a high dimensional vector space of target word weights which we call *context vectors* and use a similarity coefficient to find possible translation pairs. We first initialize these context vectors using the following procedure:

1. Using only the monolingual data for the target language, prepare the context vectors  $v_{e_i}$  with entries  $v_{e_i, e_j}$ :
  - (a) Initialize all  $v_{e_i, e_j} = 0$
  - (b) For each target sentence  $E$ :
    - For each word  $e_i$  in  $E$ :
    - For each word  $e_j \neq e_i$  in  $E$ :
$$v_{e_i, e_j} = v_{e_i, e_j} + 1.$$
  - (c) Normalize each vector  $v_{e_i}$  such that  $\sum_{e_j} (v_{e_i, e_j})^2 \stackrel{!}{=} 1$  holds.

Using the notation  $\underline{e}_i = (e_j : v_{e_i, e_j}, \dots)$  these vectors might for example look like

$$\underline{work} = (early : 0.2, late : 0.1, \dots)$$

$$\underline{time} = (early : 0.2, late : 0.2, \dots).$$

2. Prepare context vectors  $v_{f_i, e_j}$  for the source language using only the monolingual data for the source language and the translation model's current parameter estimate  $\theta$ :
  - (a) Initialize all  $v_{f_i, e_j} = 0$
  - (b) Let  $\tilde{E}_\theta(F)$  denote the most probable translation of the foreign sentence  $F$  obtained by using the current estimate  $\theta$ .
  - (c) For each source sentence  $F$ :
    - For each word  $f_i$  in  $F$ :
    - For each word  $e_j \neq E_\theta(f_i)$ <sup>1</sup> in  $E_\theta(F)$ :
$$v_{f_i, e_j} = v_{f_i, e_j} + 1$$
  - (d) Normalize each vector  $v_{f_i}$  such that  $\sum_{e_j} (v_{f_i, e_j})^2 \stackrel{!}{=} 1$  holds.

<sup>1</sup>denoting that  $e_j$  is not the translation of  $f_i$  in  $E_\theta(F)$

Adapting the notation described above, these vectors might for example look like

$$\begin{aligned} \underline{Arbeit} &= (\text{early} : 0.25, \text{late} : 0.05, \dots) \\ \underline{Zeit} &= (\text{early} : 0.15, \text{late} : 0.25, \dots) \end{aligned}$$

Once we have set up the context vectors  $v_e$  and  $v_f$ , we can retrieve translation candidates for some source word  $f$  by finding those words  $e'$  that maximize the similarity coefficient  $s(v_{e'}, v_f)$ , as well as candidates for a given target word  $e$  by finding those words  $f'$  that maximize  $s(v_e, v_{f'})$ . In our implementation we use the Euclidean distance

$$d(v_e, v_f) = \|v_e - v_f\|_2. \quad (2)$$

as *distance* measure.<sup>2</sup> The normalization of context vectors described above is motivated by the fact that the context vectors should be invariant with respect to the absolute number of occurrences of words.<sup>3</sup>

Instead of just finding the best candidates for a given word, we are interested in an assignment that involves all source and target words, minimizing the sum of distances between the assigned words. In case of a one-to-one mapping the problem of assigning translation candidates such that the sum of distances is minimal can be solved optimally in polynomial time using the *hungarian algorithm* (Kuhn, 1955). In our case we are dealing with a many-to-many assignment that needs to satisfy the *maximum number of candidates* constraints. For this, we solve the problem in a greedy fashion by simply choosing the best pairs  $(e, f)$  first. As soon as a target word  $e$  or source word  $f$  has reached the limit of maximum candidates, we skip all further candidates for that word  $e$  (or  $f$  respectively). This step involves calculating and sorting all  $|V_e| \cdot |V_f|$  distances which can be done in time  $\mathcal{O}(V^2 \cdot \log(V))$ , with  $V = \max(|V_e|, |V_f|)$ . A simplified example of this procedure is depicted in Figure 1. The example already shows that the assignment obtained by this algorithm is in general not optimal.

<sup>2</sup>We then obtain pairs  $(e, f)$  that *minimize*  $d$ .

<sup>3</sup>This gives the same similarity ordering as using unnormalized vectors with the *cosine similarity measure*  $\frac{v_e \cdot v_f}{\|v_e\|_2 \cdot \|v_f\|_2}$  which can be interpreted as measuring the cosine of the angle between the vectors, see (Manning et al., 2008). Still it is noteworthy that this procedure is not equivalent to the *tf-IDF* context vectors described in (Salton et al., 1975).

Figure 1: Hypothetical example for a greedy one-to-one assignment of translation candidates. The optimal assignment would contain (time,Zeit) and (work,Arbeit).

## 5 Training Algorithm and Implementation

Given the model presented in Section 3 and the methods illustrated in Section 4, we now describe how to train this model.

As described in Section 4, the overall procedure is divided into two alternating steps: After initialization we first perform EM training of the translation model for 20-30 iterations using a 2-gram or 3-gram language model in the target language. With the obtained best translations we induce new translation candidates using context similarity. This procedure is depicted in Figure 2.

### 5.1 Initialization

Let  $N_C$  be the maximum number of candidates per source word we allow,  $V_e$  and  $V_f$  be the target/source vocabulary and  $r(e)$  and  $r(f)$  the frequency rank of a source/target word. Each word  $f \in V_f$  with frequency rank  $r(f)$  is assigned to all words  $e \in V_e$  with frequency rank

$$r(e) \in [\text{start}(f), \text{end}(f)] \quad (3)$$

where

$$\text{start}(f) = \max(0, \min(|V_e| - N_c, \left\lfloor \frac{|V_e|}{|V_f|} \cdot r(f) - \frac{N_c}{2} \right\rfloor)) \quad (4)$$

$$\text{end}(f) = \min(\text{start}(f) + N_c, |V_e|). \quad (5)$$

This defines a diagonal beam<sup>4</sup> when visualizing the lexicon entries in a matrix where both source and target words are sorted by their frequency rank. However, note that the result of sorting by frequency

<sup>4</sup>The diagonal has some artifacts for the highest and lowest frequency ranks. See, for example, left side of Figure 2.

Figure 2: Visualization of the training procedure. The big rectangles represent word lexica in different stages of the training procedure. The small rectangles represent word pairs  $(e, f)$  for which  $e$  is a translation candidate of  $f$ , while dots represent word pairs  $(e, f)$  for which this is not the case. Source and target words are sorted by frequency so that the most frequent source words appear on the very left, and the most frequent target words appear at the very bottom.

and thus the frequency ranks are not unique when there are words with the same frequency. In this case, we initially obtain some not further specified frequency ordering, which is then kept throughout the procedure.

This initialization proves useful as we show by taking an IBM1 lexicon  $P(f|e)$  extracted on the parallel VERBMOBIL corpus (Wahlster, 2000): For each word  $e$  we calculate the weighted rank difference

$$\Delta r_{\text{avg}}(e) = \sum_f P(f|e) \cdot |(r(e) - r(f))| \quad (6)$$

and count how many of those weighted rank differences are smaller than a given value  $\frac{N_C}{2}$ . Here we see that for about 1% of the words the weighted rank difference lies within  $N_C = 50$ , and even about 3% for  $N_C = 150$  respectively. This shows that the initialization provides a first solid guess of possible translations.

## 5.2 EM Algorithm

The generative story described in Section 3 is implemented as a cascade of a permutation, insertion, lexicon, deletion and language model finite state transducers using OpenFST (Allauzen et al., 2007). Our FST representation of the LM makes use of failure transitions as described in (Allauzen et al., 2003). We use the forward-backward algorithm on the composed transducers to efficiently train the lexicon model using the EM algorithm.

## 5.3 Context Vector Step

Given the trained parameters  $\theta$  from the previous run of the EM algorithm we set the context vectors  $v_e$

and  $v_f$  up as described in Section 4. We then calculate and sort all  $|V_e| \cdot |V_f|$  distances which proves feasible in a few CPU hours even for vocabulary sizes of more than 50,000 words. This is achieved with the GNU SORT tool, which uses external sorting for sorting large amounts of data.

To set up the new lexicon we keep the  $\lfloor \frac{N_C}{2} \rfloor$  best translations for each source word with respect to  $P(e|f)$ , which we obtained in the previous EM run. Experiments showed that it is helpful to also limit the number of candidates per target words. We therefore prune the resulting lexicon using  $P(f|e)$  to a maximum of  $\lfloor \frac{N'_C}{2} \rfloor$  candidates per target word afterwards. Then we fill the lexicon with new candidates using the previously sorted list of candidate pairs such that the final lexicon has at most  $N_C$  candidates per source word and at most  $N'_C$  candidates per target word. We set  $N'_C$  to some value  $N'_C > N_C$ . All experiments in this work were run with  $N'_C = 300$ . Values of  $N'_C \approx N_C$  seem to produce poorer results. Not limiting the number of candidates per target word at all also typically results in weaker performance. After the lexicon is filled with candidates, we initialize the probabilities to be uniform. With this new lexicon the process is iterated starting with the EM training.

## 6 Experimental Evaluation

We evaluate our method on three different corpora.

At first we apply our method to non-parallel Spanish/English data that is based on the OPUS corpus (Tiedemann, 2009) and that was also used in (Ravi and Knight, 2011). We show that our method performs better by 1.6 BLEU than the best performing method described in (Ravi and Knight, 2011) while

Name	Lang.	Sent.	Words	Voc.
OPUS	Spanish	13,181	39,185	562
	English	19,770	61,835	411
VERBMOBIL	German	27,861	282,831	5,964
	English	27,862	294,902	3,723
GIGAWORD	French	100,000	1,725,993	68,259
	English	100,000	1,788,025	64,621

Table 1: Statistics of the corpora used in this paper.

being approximately 15 to 20 times faster than their  $n$ -gram based approach.

After that we apply our method to a non-parallel version of the German/English VERBMOBIL corpus, which has a vocabulary size of 6,000 words on the German side, and 3,500 words on the target side and which thereby is approximately one order of magnitude larger than the previous OPUS experiment.

We finally run our system on a subset of the non-parallel French/English GIGAWORD corpus, which has a vocabulary size of 60,000 words for both French and English. We show first interesting results on such a big task.

In case of the OPUS and VERBMOBIL corpus, we evaluate the results using BLEU (Papineni et al., 2002) and TER (Snover et al., 2006) to reference translations. We report all scores in percent. For BLEU higher values are better, for TER lower values are better. We also compare the results on these corpora to a system trained on parallel data.

In case of the GIGAWORD corpus we show lexicon entries obtained during training.

## 6.1 OPUS Subtitle Corpus

### 6.1.1 Experimental Setup

We apply our method to the corpus described in Table 6. This exact corpus was also used in (Ravi and Knight, 2011). The best performing methods in (Ravi and Knight, 2011) use the full  $411 \times 579$  lexicon model and apply standard EM training. Using a 2-gram LM they obtain 15.3 BLEU and with a whole segment LM, they achieve 19.3 BLEU. In comparison to this baseline we run our algorithm with  $N_C = 50$  candidates per source word for both, a 2-gram and a 3-gram LM. We use 30 EM iterations

between each context vector step. For both cases we run 7 EM+Context cycles.

### 6.1.2 Results

Figure 3 and Figure 4 show the evolution of BLEU and TER scores for applying our method using a 2-gram and a 3-gram LM.

In case of the 2-gram LM (Figure 3) the translation quality increases until it reaches a plateau after 5 EM+Context cycles. In case of the 3-gram LM (Figure 4) the statement only holds with respect to TER. It is notable that during the first iterations TER only improves very little until a large chunk of the language unravels after the third iteration. This behavior may be caused by the fact that the corpus only provides a relatively small amount of context information for each word, since sentence lengths are 3-4 words on average.

Figure 3: Results on the OPUS corpus with a 2-gram LM,  $N_C = 50$ , and 30 EM iterations between each context vector step. The dashed line shows the best result using a 2-gram LM in (Ravi and Knight, 2011).

Table 2 summarizes these results and compares them with (Ravi and Knight, 2011). Our 3-gram based method performs by 1.6 BLEU better than their best system which is a statistically significant improvement at 95% confidence level. Furthermore, Table 2 compares the CPU time needed for training. Our 3-gram based method is 15-20 times faster than running the EM based training procedure presented in (Ravi and Knight, 2011) with a 3-gram LM<sup>5</sup>.

<sup>5</sup>(Ravi and Knight, 2011) only report results using a 2-gram LM and a whole-segment LM.

Figure 4: Results on the OPUS corpus with a 3-gram LM,  $N_C = 50$ , and 30 EM iterations between each context vector step. The dashed line shows the best result using a whole-segment LM in (Ravi and Knight, 2011)

Method	CPU	BLEU	TER
EM, 2-gram LM 411 cand. p. source word (Ravi and Knight, 2011)	$\approx 850h^6$	15.3	—
EM, Whole-segment LM 411 cand. p. source word (Ravi and Knight, 2011)	$-^7$	19.3	—
EM+Context, 2-gram LM 50 cand. p. source word (this work)	<b>50h<sup>8</sup></b>	<b>15.2</b>	<b>66.6</b>
EM+Context, 3-gram LM 50 cand. p. source word (this work)	<b>200h<sup>8</sup></b>	<b>20.9</b>	<b>64.5</b>

Table 2: Results obtained on the OPUS corpus.

To summarize: Our method is significantly faster than  $n$ -gram LM based approaches and obtains better results than any previously published method.

<sup>6</sup>Estimated by running full EM using the 2-gram LM using our implementation for 90 Iterations yielding 15.2 BLEU.

<sup>7</sup> $\approx 4,000h$  when running full EM using a 3-gram LM, using our implementation. Estimated by running only the first iteration and by assuming that the final result will be obtained after 90 iterations. However, (Ravi and Knight, 2011) report results using a whole segment LM, assigning  $P(e) > 0$  only to sequences seen in training. This seems to work for the given task but we believe that it can not be a general replacement for higher order  $n$ -gram LMs.

<sup>8</sup>Estimated by running our method for  $5 \times 30$  iterations.

## 6.2 VERBMOBIL Corpus

### 6.2.1 Experimental Setup

The VERBMOBIL corpus is a German/English corpus dealing with short sentences for making appointments. We prepared a non-parallel subset of the original VERBMOBIL (Wahlster, 2000) by splitting the corpus into two parts and then selecting only the German side from the first half, and the English side from the second half such that the target side is not the translation of the source side. The source and target vocabularies of the resulting non-parallel corpus are both more than 9 times bigger compared to the OPUS vocabularies. Also the total amount of word tokens is more than 5 times larger compared to the OPUS corpus. Table 6 shows the statistics of this corpus. We run our method for 5 EM+Context cycles (30 EM iterations each) using a 2-gram LM. After that we run another five EM+Context cycles using a 3-gram LM.

### 6.2.2 Results

Our results on the VERBMOBIL corpus are summarized in Table 3. Even on this more complex task our method achieves encouraging results: The

Method	BLEU	TER
$5 \times 30$ Iterations EM+Context 50 cand. p. source word, 2-gram LM	<b>11.7</b>	<b>67.4</b>
$+ 5 \times 30$ Iterations EM+Context 50 cand. p. source word, 3-gram LM	<b>15.5</b>	<b>63.2</b>

Table 3: Results obtained on the VERBMOBIL corpus.

translation quality increases from iteration to iteration until the algorithm finally reaches 11.7 BLEU using only the 2-gram LM. Running further five cycles using a 3-gram LM achieves a final performance of 15.5 BLEU. Och (2002) reports results of 48.2 BLEU for a single-word based translation system and 56.1 BLEU using the alignment template approach, both trained on parallel data. However, it should be noted that our experiment only uses 50% of the original VERBMOBIL training data to simulate a truly non-parallel setup.

Iter.	$e$	$p(f_1 e)$	$f_1$	$p(f_2 e)$	$f_2$	$p(f_3 e)$	$f_3$	$p(f_4 e)$	$f_4$	$p(f_5 e)$	$f_5$
1.	<b>the</b>	0.43	<i>la</i>	0.31	<i>l'</i>	0.11	<i>une</i>	0.04	<i>le</i>	0.04	<i>les</i>
2.	<b>several</b>	0.57	<i>plusieurs</i>	0.21	<i>les</i>	0.09	<i>des</i>	0.03	<i>nombreuses</i>	0.02	<i>deux</i>
3.	<b>where</b>	0.63	<i>où</i>	0.17	<i>mais</i>	0.06	<i>indique</i>	0.04	<i>précise</i>	0.02	<i>appelle</i>
4.	<b>see</b>	0.49	<i>éviter</i>	0.09	<i>effet</i>	0.09	<i>voir</i>	0.05	<i>envisager</i>	0.04	<i>dire</i>
5.	<b>January</b>	0.25	<i>octobre</i>	0.22	<i>mars</i>	0.09	<i>juillet</i>	0.07	<i>août</i>	0.07	<i>janvier</i>
–	<b>Germany</b>	0.24	<i>Italie</i>	0.12	<i>Espagne</i>	0.06	<i>Japon</i>	0.05	<i>retour</i>	0.05	<i>Suisse</i>

Table 4: Lexicon entries obtained by running our method on the non-parallel GIGAWORD corpus. The first column shows in which iteration the algorithm found the first correct translations  $f$  (compared to a parallelly trained lexicon) among the top 5 candidates

## 6.3 GIGAWORD

### 6.3.1 Experimental Setup

This setup is based on a subset of the monolingual GIGAWORD corpus. We selected 100,000 French sentences from the news agency *AFP* and 100,000 sentences from the news agency *Xinhua*. To have a more reliable set of training instances, we selected only sentences with more than 7 tokens. Note that these corpora form true non-parallel data which, besides the length filtering, were not specifically pre-selected or pre-processed. More details on these non-parallel corpora are summarized in Table 6. The vocabularies have a size of approximately 60,000 words which is more than 100 times larger than the vocabularies of the OPUS corpus. Also it incorporates more than 25 times as many tokens as the OPUS corpus.

After initialization, we run our method with  $N_C = 150$  candidates per source word for 20 EM iterations using a 2-gram LM. After the first context vector step with  $N_C = 50$  we run another  $4 \times 20$  iterations with  $N_C = 50$  with a 2-gram LM.

### 6.3.2 Results

Table 4 shows example lexicon entries we obtained. Note that we obtained these results by using purely non-parallel data, and that we neither used a seed lexicon, nor orthographic features to assign e.g. numbers or proper names: All results are obtained using 2-gram statistics and the context of words only. We find the results encouraging and think that they show the potential of large-scale unsupervised techniques for MT in the future.

## 7 Conclusion

We presented a method for learning statistical machine translation models from non-parallel data. The key to our method lies in limiting the translation model to a limited set of translation candidates and then using the EM algorithm to learn the probabilities. Based on the translations obtained with this model we obtain new translation candidates using a context vector approach. This method increased the training speed by a factor of 10-20 compared to methods known in literature and also resulted in a 1.6 BLEU point increase compared to previous approaches. Due to this efficiency improvement we were able to tackle larger tasks, such as a non-parallel version of the VERBMOBIL corpus having a nearly 10 times larger vocabulary. We also had a look at first results of our method on an even larger Task, incorporating a vocabulary of 60,000 words. We have shown that, using a limited set of translation candidates, we can significantly reduce the computational complexity of the learning task. This work serves as a big step towards large-scale unsupervised training for statistical machine translation systems.

## Acknowledgements

This work was realized as part of the Quaero Programme, funded by OSEO, French State agency for innovation. The authors would like to thank Sujith Ravi and Kevin Knight for providing us with the OPUS subtitle corpus and David Rybach for kindly sharing his knowledge about the OpenFST library.

## Abstract

In this paper, we demonstrate that accurate machine translation is possible without the concept of “words,” treating MT as a problem of transformation between character strings. We achieve this result by applying phrasal inversion transduction grammar alignment techniques to character strings to train a character-based translation model, and using this in the phrase-based MT framework. We also propose a look-ahead parsing algorithm and substring-informed prior probabilities to achieve more effective and efficient alignment. In an evaluation, we demonstrate that character-based translation can achieve results that compare to word-based systems while effectively translating unknown and uncommon words over several language pairs.

## 1 Introduction

Traditionally, the task of statistical machine translation (SMT) is defined as translating a source sentence  $f_1^J = \{f_1, \dots, f_J\}$  to a target sentence  $e_1^I = \{e_1, \dots, e_I\}$ , where each element of  $f_1^J$  and  $e_1^I$  is assumed to be a word in the source and target languages. However, the definition of a “word” is often problematic. The most obvious example of this lies in languages that do not separate words with white space such as Chinese, Japanese, or Thai, in which the choice of a segmentation standard has a large effect on translation accuracy (Chang et al., 2008). Even for languages with explicit word

The first author is now affiliated with the Nara Institute of Science and Technology.

boundaries, all machine translation systems perform at least some precursory form of tokenization, splitting punctuation and words to prevent the sparsity that would occur if punctuated and non-punctuated words were treated as different entities. Sparsity also manifests itself in other forms, including the large vocabularies produced by morphological productivity, word compounding, numbers, and proper names. A myriad of methods have been proposed to handle each of these phenomena individually, including morphological analysis, stemming, compound breaking, number regularization, optimizing word segmentation, and transliteration, which we outline in more detail in Section 2.

These difficulties occur because we are translating sequences of *words* as our basic unit. On the other hand, Vilar et al. (2007) examine the possibility of instead treating each sentence as sequences of *characters* to be translated. This method is attractive, as it is theoretically able to handle all sparsity phenomena in a single unified framework, but has only been shown feasible between similar language pairs such as Spanish-Catalan (Vilar et al., 2007), Swedish-Norwegian (Tiedemann, 2009), and Thai-Lao (Sornlertlamvanich et al., 2008), which have a strong co-occurrence between single characters. As Vilar et al. (2007) state and we confirm, accurate translations cannot be achieved when applying traditional translation techniques to character-based translation for less similar language pairs.

In this paper, we propose improvements to the alignment process tailored to character-based machine translation, and demonstrate that it is, in fact, possible to achieve translation accuracies that ap-

proach those of traditional word-based systems using only character strings. We draw upon recent advances in many-to-many alignment, which allows for the automatic choice of the length of units to be aligned. As these units may be at the character, subword, word, or multi-word phrase level, we conjecture that this will allow for better character alignments than one-to-many alignment techniques, and will allow for better translation of uncommon words than traditional word-based models by breaking down words into their component parts.

We also propose two improvements to the many-to-many alignment method of Neubig et al. (2011). One barrier to applying many-to-many alignment models to character strings is training cost. In the inversion transduction grammar (ITG) framework (Wu, 1997), which is widely used in many-to-many alignment, search is cumbersome for longer sentences, a problem that is further exacerbated when using characters instead of words as the basic unit. As a step towards overcoming this difficulty, we increase the efficiency of the beam-search technique of Saers et al. (2009) by augmenting it with look-ahead probabilities in the spirit of A\* search. Secondly, we describe a method to seed the search process using counts of all substring pairs in the corpus to bias the phrase alignment model. We do this by defining prior probabilities based on these substring counts within the Bayesian phrasal ITG framework.

An evaluation on four language pairs with differing morphological properties shows that for distant language pairs, character-based SMT can achieve translation accuracy comparable to word-based systems. In addition, we perform ablation studies, showing that these results were not possible without the proposed enhancements to the model. Finally, we perform a qualitative analysis, which finds that character-based translation can handle unsegmented text, conjugation, and proper names in a unified framework with no additional processing.

## 2 Related Work on Data Sparsity in SMT

As traditional SMT systems treat all words as single tokens without considering their internal structure, major problems of data sparsity occur for less frequent tokens. In fact, it has been shown that there is a direct negative correlation between vocabulary

size (and thus sparsity) of a language and translation accuracy (Koehn, 2005). Sparsity causes trouble for alignment models, both in the form of incorrectly aligned uncommon words, and in the form of garbage collection, where uncommon words in one language are incorrectly aligned to large segments of the sentence in the other language (Och and Ney, 2003). Unknown words are also a problem during the translation process, and the default approach is to map them as-is into the target sentence.

This is a major problem in agglutinative languages such as Finnish or compounding languages such as German. Previous works have attempted to handle morphology, decompounding and regularization through lemmatization, morphological analysis, or unsupervised techniques (Nießen and Ney, 2000; Brown, 2002; Lee, 2004; Goldwater and McClosky, 2005; Talbot and Osborne, 2006; Mermer and Akin, 2010; Macherey et al., 2011). It has also been noted that it is more difficult to translate into morphologically rich languages, and methods for modeling target-side morphology have attracted interest in recent years (Bojar, 2007; Subotin, 2011).

Another source of data sparsity that occurs in all languages is proper names, which have been handled by using cognates or transliteration to improve translation (Knight and Graehl, 1998; Kondrak et al., 2003; Finch and Sumita, 2007), and more sophisticated methods for named entity translation that combine translation and transliteration have also been proposed (Al-Onaizan and Knight, 2002).

Choosing word units is also essential for creating good translation results for languages that do not explicitly mark word boundaries, such as Chinese, Japanese, and Thai. A number of works have dealt with this word segmentation problem in translation, mainly focusing on Chinese-to-English translation (Bai et al., 2008; Chang et al., 2008; Zhang et al., 2008b; Chung and Gildea, 2009; Nguyen et al., 2010), although these works generally assume that a word segmentation exists in one language (English) and attempt to optimize the word segmentation in the other language (Chinese).

We have enumerated these related works to demonstrate the myriad of data sparsity problems and proposed solutions. Character-based translation has the potential to handle all of the phenomena in the previously mentioned research in a single

unified framework, requiring no language specific tools such as morphological analyzers or word segmenters. However, while the approach is attractive conceptually, previous research has only been shown effective for closely related language pairs (Vilar et al., 2007; Tiedemann, 2009; Sornlertlamvanich et al., 2008). In this work, we propose effective alignment techniques that allow character-based translation to achieve accurate translation results for both close and distant language pairs.

### 3 Alignment Methods

SMT systems are generally constructed from a parallel corpus consisting of target language sentences  $\mathcal{E}$  and source language sentences  $\mathcal{F}$ . The first step of training is to find alignments  $\mathcal{A}$  for the words in each sentence pair.

We represent our target and source sentences as  $e_1^I$  and  $f_1^J$ .  $e_i$  and  $f_j$  represent single elements of the target and source sentences respectively. These may be words in word-based alignment models or single characters in character-based alignment models.<sup>1</sup> We define our alignment as  $\mathbf{a}_1^K$ , where each element is a span  $a_k = \langle s, t, u, v \rangle$  indicating that the target string  $e_s, \dots, e_t$  and source string  $f_u, \dots, f_v$  are aligned to each-other.

#### 3.1 One-to-Many Alignment

The most well-known and widely-used models for bitext alignment are for one-to-many alignment, including the IBM models (Brown et al., 1993) and HMM alignment model (Vogel et al., 1996). These models are by nature directional, attempting to find the alignments that maximize the conditional probability of the target sentence  $P(e_1^I | f_1^J, \mathbf{a}_1^K)$ . For computational reasons, the IBM models are restricted to aligning each word on the target side to a single word on the source side. In the formalism presented above, this means that each  $e_i$  must be included in at most one span, and for each span  $u = v$ . Traditionally, these models are run in both directions and combined using heuristics to create many-to-many alignments (Koehn et al., 2003).

However, in order for one-to-many alignment methods to be effective, each  $f_j$  must contain

<sup>1</sup>Some previous work has also performed alignment using morphological analyzers to normalize or split the sentence into morpheme streams (Corston-Oliver and Gamon, 2004).

enough information to allow for effective alignment with its corresponding elements in  $e_1^I$ . While this is often the case in word-based models, for character-based models this assumption breaks down, as there is often no clear correspondence between characters.

#### 3.2 Many-to-Many Alignment

On the other hand, in recent years, there have been advances in many-to-many alignment techniques that are able to align multi-element chunks on both sides of the translation (Marcu and Wong, 2002; DeNero et al., 2008; Blunsom et al., 2009; Neubig et al., 2011). Many-to-many methods can be expected to achieve superior results on character-based alignment, as the aligner can use information about substrings, which may correspond to letters, morphemes, words, or short phrases.

Here, we focus on the model presented by Neubig et al. (2011), which uses Bayesian inference in the phrasal inversion transduction grammar (ITG, Wu (1997)) framework. ITGs are a variety of synchronous context free grammar (SCFG) that allows for many-to-many alignment to be achieved in polynomial time through the process of biparsing, which we explain more in the following section. Phrasal ITGs are ITGs that allow for non-terminals that can emit phrase pairs with multiple elements on both the source and target sides. It should be noted that there are other many-to-many alignment methods that have been used for simultaneously discovering morphological boundaries over multiple languages (Snyder and Barzilay, 2008; Naradowsky and Toutanova, 2011), but these have generally been applied to single words or short phrases, and it is not immediately clear that they will scale to aligning full sentences.

### 4 Look-Ahead Biparsing

In this work, we experiment with the alignment method of Neubig et al. (2011), which can achieve competitive accuracy with a much smaller phrase table than traditional methods. This is important in the character-based translation context, as we would like to use phrases that contain large numbers of characters without creating a phrase table so large that it cannot be used in actual decoding. In this framework, training is performed using sentence-

Figure 1: (a) A chart with inside probabilities in boxes and forward/backward probabilities marking the surrounding arrows. (b) Spans with corresponding look-aheads added, and the minimum probability underlined. Lightly and darkly shaded spans will be trimmed when the beam is  $\log(P) \geq -3$  and  $\log(P) \geq -6$  respectively.

wise block sampling, acquiring a sample for each sentence by first performing bottom-up biparsing to create a chart of probabilities, then performing top-down sampling of a new tree based on the probabilities in this chart.

An example of a chart used in this parsing can be found in Figure 1 (a). Within each cell of the chart spanning  $e_s^t$  and  $f_u^v$  is an “inside” probability  $I(a_{s,t,u,v})$ . This probability is the combination of the generative probability of each phrase pair  $P_t(e_s^t, f_u^v)$  as well as the sum the probabilities over all shorter spans in straight and inverted order<sup>2</sup>

$$\begin{aligned}
 I(a_{s,t,u,v}) &= P_t(e_s^t, f_u^v) \\
 &+ \sum_{s \leq S \leq t} \sum_{u \leq U \leq v} P_x(\text{str}) I(a_{s,S,u,U}) I(a_{S,t,U,v}) \\
 &+ \sum_{s \leq S \leq t} \sum_{u \leq U \leq v} P_x(\text{inv}) I(a_{s,S,U,v}) I(a_{S,t,u,U})
 \end{aligned}$$

where  $P_x(\text{str})$  and  $P_x(\text{inv})$  are the probability of straight and inverted ITG productions.

While the exact calculation of these probabilities can be performed in  $O(n^6)$  time, where  $n$  is the

<sup>2</sup> $P_t$  can be specified according to Bayesian statistics as described by Neubig et al. (2011).

length of the sentence, this is impractical for all but the shortest sentences. Thus it is necessary to use methods to reduce the search space such as beam-search based chart parsing (Saers et al., 2009) or slice sampling (Blunsom and Cohn, 2010).<sup>3</sup>

In this section we propose the use of a look-ahead probability to increase the efficiency of this chart parsing. Taking the example of Saers et al. (2009), spans are pushed onto a different queue based on their size, and queues are processed in ascending order of size. Agendas can further be trimmed based on a histogram beam (Saers et al., 2009) or probability beam (Neubig et al., 2011) compared to the best hypothesis  $\hat{a}$ . In other words, we have a queue discipline based on the inside probability, and all spans  $a_k$  where  $I(a_k) < cI(\hat{a})$  are pruned.  $c$  is a constant describing the width of the beam, and a smaller constant probability will indicate a wider beam.

This method is insensitive to the existence of competing hypotheses when performing pruning. Figure 1 (a) provides an example of why it is unwise to ignore competing hypotheses during beam pruning. Particularly, the alignment “les/1960s” competes with the high-probability alignment “les/the,” so intuitively should be a good candidate for pruning. However its probability is only slightly higher than “années/1960s,” which has no competing hypotheses and thus should not be trimmed.

In order to take into account competing hypotheses, we can use for our queue discipline not only the inside probability  $I(a_k)$ , but also the outside probability  $O(a_k)$ , the probability of generating all spans other than  $a_k$ , as in A\* search for CFGs (Klein and Manning, 2003), and tic-tac-toe pruning for word-based ITGs (Zhang and Gildea, 2005). As the calculation of the actual outside probability  $O(a_k)$  is just as expensive as parsing itself, it is necessary to approximate this with heuristic function  $O^*$  that can be calculated efficiently.

Here we propose a heuristic function that is designed specifically for phrasal ITGs and is computable with worst-case complexity of  $n^2$ , compared with the  $n^3$  amortized time of the tic-tac-toe pruning

<sup>3</sup>Applying beam-search before sampling will sample from an improper distribution, although Metropolis-in-Gibbs sampling (Johnson et al., 2007) can be used to compensate. However, we found that this had no significant effect on results, so we omit the Metropolis-in-Gibbs step for experiments.

algorithm described by (Zhang et al., 2008a). During the calculation of the phrase generation probabilities  $P_t$ , we save the best inside probability  $I^*$  for each monolingual span.

$$I_e^*(s, t) = \max_{\{\tilde{u}=\langle\tilde{s},\tilde{t},\tilde{u},\tilde{v}\rangle;\tilde{s}=s,\tilde{t}=t\}} P_t(\tilde{a})$$

$$I_f^*(u, v) = \max_{\{\tilde{a}=\langle\tilde{s},\tilde{t},\tilde{u},\tilde{v}\rangle;\tilde{u}=u,\tilde{v}=v\}} P_t(\tilde{a})$$

For each language independently, we calculate forward probabilities  $\alpha$  and backward probabilities  $\beta$ . For example,  $\alpha_e(s)$  is the maximum probability of the span  $(0, s)$  of  $e$  that can be created by concatenating together consecutive values of  $I_e^*$ :

$$\alpha_e(s) = \max_{\{S_1, \dots, S_x\}} I_e^*(0, S_1) I_e^*(S_1, S_2) \dots I_e^*(S_x, s).$$

Backwards probabilities and probabilities over  $f$  can be defined similarly. These probabilities are calculated for  $e$  and  $f$  independently, and can be calculated in  $n^2$  time by processing each  $\alpha$  in ascending order, and each  $\beta$  in descending order in a fashion similar to that of the forward-backward algorithm. Finally, for any span, we define the outside heuristic as the minimum of the two independent look-ahead probabilities over each language

$$O^*(a_{s,t,u,v}) = \min(\alpha_e(s) * \beta_e(t), \alpha_f(u) * \beta_f(v)).$$

Looking again at Figure 1 (b), it can be seen that the relative probability difference between the highest probability span “les/the” and the spans “années/1960s” and “60/1960s” decreases, allowing for tighter beam pruning without losing these good hypotheses. In contrast, the relative probability of “les/1960s” remains low as it is in conflict with a high-probability alignment, allowing it to be discarded.

## 5 Substring Prior Probabilities

While the Bayesian phrasal ITG framework uses the previously mentioned phrase distribution  $P_t$  during search, it also allows for definition of a phrase pair prior probability  $P_{prior}(e_s^t, f_u^v)$ , which can efficiently seed the search process with a bias towards phrase pairs that satisfy certain properties. In this section, we overview an existing method used to calculate these prior probabilities, and also propose a new way to calculate priors based on substring co-occurrence statistics.

### 5.1 Word-based Priors

Previous research on many-to-many translation has used IBM model 1 probabilities to bias phrasal alignments so that phrases whose member words are good translations are also aligned. As a representative of this existing method, we adopt a base measure similar to that used by DeNero et al. (2008):

$$P_{m1}(e, f) = M_0(e, f) P_{pois}(|e|; \lambda) P_{pois}(|f|; \lambda)$$

$$M_0(e, f) = (P_{m1}(f|e) P_{uni}(e) P_{m1}(e|f) P_{uni}(f))^{\frac{1}{2}}.$$

$P_{pois}$  is the Poisson distribution with the average length parameter  $\lambda$ , which we set to 0.01.  $P_{m1}$  is the word-based (or character-based) Model 1 probability, which can be efficiently calculated using the dynamic programming algorithm described by Brown et al. (1993). However, for reasons previously stated in Section 3, these methods are less satisfactory when performing character-based alignment, as the amount of information contained in a character does not allow for proper alignment.

### 5.2 Substring Co-occurrence Priors

Instead, we propose a method for using raw substring co-occurrence statistics to bias alignments towards substrings that often co-occur in the entire training corpus. This is similar to the method of Cromieres (2006), but instead of using these co-occurrence statistics as a heuristic alignment criterion, we incorporate them as a prior probability in a statistical model that can take into account mutual exclusivity of overlapping substrings in a sentence.

We define this prior probability using three counts over substrings  $c(e)$ ,  $c(f)$ , and  $c(e, f)$ .  $c(e)$  and  $c(f)$  count the total number of sentences in which the substrings  $e$  and  $f$  occur respectively.  $c(e, f)$  is a count of the total number of sentences in which the substring  $e$  occurs on the target side, and  $f$  occurs on the source side. We perform the calculation of these statistics using enhanced suffix arrays, a data structure that can efficiently calculate all substrings in a corpus (Abouelhoda et al., 2004).<sup>4</sup>

While suffix arrays allow for efficient calculation of these statistics, storing all co-occurrence counts  $c(e, f)$  is an unrealistic memory burden for larger

<sup>4</sup>Using the open-source implementation esaxx <http://code.google.com/p/esaxx/>

corpora. In order to reduce the amount of memory used, we discount every count by a constant  $d$ , which we set to 5. This has a dual effect of reducing the amount of memory needed to hold co-occurrence counts by removing values for which  $c(e, f) < d$ , as well as preventing over-fitting of the training data. In addition, we heuristically prune values for which the conditional probabilities  $P(e|f)$  or  $P(f|e)$  are less than some fixed value, which we set to 0.1 for the reported experiments.

To determine how to combine  $c(e)$ ,  $c(f)$ , and  $c(e, f)$  into prior probabilities, we performed preliminary experiments testing methods proposed by previous research including plain co-occurrence counts, the Dice coefficient, and  $\chi$ -squared statistics (Cromieres, 2006), as well as a new method of defining substring pair probabilities to be proportional to bidirectional conditional probabilities

$$P_{cooc}(e, f) = P_{cooc}(e|f)P_{cooc}(f|e)/Z \\ = \left( \frac{c(e, f) - d}{c(f) - d} \right) \left( \frac{c(e, f) - d}{c(e) - d} \right) / Z$$

for all substring pairs where  $c(e, f) > d$  and where  $Z$  is a normalization term equal to

$$Z = \sum_{\{e, f; c(e, f) > d\}} P_{cooc}(e|f)P_{cooc}(f|e).$$

The experiments showed that the bidirectional conditional probability method gave significantly better results than all other methods, so we adopt this for the remainder of our experiments.

It should be noted that as we are using discounting, many substring pairs will be given zero probability according to  $P_{cooc}$ . As the prior is only supposed to bias the model towards good solutions and not explicitly rule out any possibilities, we linearly interpolate the co-occurrence probability with the one-to-many Model 1 probability, which will give at least some probability mass to all substring pairs

$$P_{prior}(e, f) = \lambda P_{cooc}(e, f) + (1 - \lambda)P_{m1}(e, f).$$

We put a Dirichlet prior ( $\alpha = 1$ ) on the interpolation coefficient  $\lambda$  and learn it during training.

## 6 Experiments

In order to test the effectiveness of character-based translation, we performed experiments over a variety of language pairs and experimental settings.

### 6.1 Experimental Setup

We use a combination of four languages with English, using freely available data. We selected French-English, German-English, Finnish-English data from EuroParl (Koehn, 2005), with development and test sets designated for the 2005 ACL shared task on machine translation.<sup>5</sup> We also did experiments with Japanese-English Wikipedia articles from the Kyoto Free Translation Task (Neubig, 2011) using the designated training and tuning sets, and reporting results on the test set. These languages were chosen as they have a variety of interesting characteristics. French has some inflection, but among the test languages has the strongest one-to-one correspondence with English, and is generally considered easy to translate. German has many compound words, which must be broken apart to translate properly into English. Finnish is an agglutinative language with extremely rich morphology, resulting in long words and the largest vocabulary of the languages in EuroParl. Japanese does not have any clear word boundaries, and uses logographic characters, which contain more information than phonetic characters.

With regards to data preparation, the EuroParl data was pre-tokenized, so we simply used the tokenized data as-is for the training and evaluation of all models. For word-based translation in the Kyoto task, training was performed using the provided tokenization scripts. For character-based translation, no tokenization was performed, using the original text for both training and decoding. For both tasks, we selected as training data all sentences for which both

Table 2: Translation results in word-based BLEU, character-based BLEU, and METEOR for the GIZA++ and phrasal ITG models for word and character-based translation, with bold numbers indicating a statistically insignificant difference from the best system according to the bootstrap resampling method at  $p = 0.05$  (Koehn, 2004).

source and target were 100 characters or less,<sup>6</sup> the total size of which is shown in Table 1. In character-based translation, white spaces between words were treated as any other character and not given any special treatment. Evaluation was performed on tokenized and lower-cased data.

For alignment, we use the GIZA++ implementation of one-to-many alignment<sup>7</sup> and the pialign implementation of the phrasal ITG models<sup>8</sup> modified with the proposed improvements. For GIZA++, we used the default settings for word-based alignment, but used the HMM model for character-based alignment to allow for alignment of longer sentences. For pialign, default settings were used except for character-based ITG alignment, which used a probability beam of  $10^{-4}$  instead  $10^{-10}$ .<sup>9</sup> For decoding, we use the Moses decoder,<sup>10</sup> using the default settings except for the stack size, which we set to 1000 instead of 200. Minimum error rate training was performed to maximize word-based BLEU score for all systems.<sup>11</sup> For language models, word-based translation uses a word 5-gram model, and character-based translation uses a character 12-gram model, both smoothed using interpolated Kneser-Ney.

<sup>6</sup>100 characters is an average of 18.8 English words

<sup>7</sup><http://code.google.com/p/giza-pp/>

<sup>8</sup><http://phontron.com/pialign/>

<sup>9</sup>Improvement by using a beam larger than  $10^{-4}$  was marginal, especially with co-occurrence prior probabilities.

<sup>10</sup><http://statmt.org/moses/>

<sup>11</sup>We chose this set-up to minimize the effect of tuning criterion on our experiments, although it does indicate that we must have access to tokenized data for the development set.

## 6.2 Quantitative Evaluation

Table 2 presents a quantitative analysis of the translation results for each of the proposed methods. As previous research has shown that it is more difficult to translate into morphologically rich languages than into English (Koehn, 2005), we perform experiments translating in both directions for all language pairs. We evaluate translation quality using BLEU score (Papineni et al., 2002), both on the word and character level (with  $n = 4$ ), as well as METEOR (Denkowski and Lavie, 2011) on the word level.

It can be seen that character-based translation with all of the proposed alignment improvements greatly exceeds character-based translation using one-to-many alignment, confirming that substring-based information is necessary for accurate alignments. When compared with word-based translation, character-based translation achieves better, comparable, or inferior results on character-based BLEU, comparable or inferior results on METEOR, and inferior results on word-based BLEU. The differences between the evaluation metrics are due to the fact that character-based translation often gets words mostly correct other than one or two letters. These are given partial credit by character-based BLEU (and to a lesser extent METEOR), but marked entirely wrong by word-based BLEU.

Interestingly, for translation into English, character-based translation achieves higher accuracy compared to word-based translation on Japanese and Finnish input, followed by German,

	fi-en	ja-en

Table 4: The major gains of character-based translation, unknown, hyphenated, and uncommon words.

and finally French. This confirms that character-based translation is performing well on languages that have long words or ambiguous boundaries, and less well on language pairs with relatively strong one-to-one correspondence between words.

### 6.3 Qualitative Evaluation

In addition, we performed a subjective evaluation of Japanese-English and Finnish-English translations. Two raters evaluated 100 sentences each, assigning a score of 0-5 based on how well the translation conveys the information contained in the reference. We focus on shorter sentences of 8-16 English words to ease rating and interpretation. Table 3 shows that the results are comparable, with no significant difference in average scores for either language pair.

Table 4 shows a breakdown of the sentences for which character-based translation received a score of at 2+ points more than word-based. It can be seen that character-based translation is properly handling sparsity phenomena. On the other hand, word-based translation was generally stronger with reordering and lexical choice of more common words.

### 6.4 Effect of Alignment Method

In this section, we compare the translation accuracies for character-based translation using the phrasal ITG model with and without the proposed improvements of substring co-occurrence priors and look-ahead parsing as described in Sections 4 and 5.2.

	fi-en	en-fi	ja-en	en-ja
ITG +cooc +look	<b>28.94</b>	<b>25.31</b>	<b>24.58</b>	<b>35.71</b>
ITG +cooc -look	28.51	24.24	<b>24.32</b>	<b>35.74</b>
ITG -cooc +look	<b>28.65</b>	24.49	<b>24.36</b>	35.05
ITG -cooc -look	27.45	23.30	23.57	34.50

Table 5: METEOR scores for alignment with and without look-ahead and co-occurrence priors.

Figure 5 shows METEOR scores<sup>12</sup> for experiments translating Japanese and Finnish. It can be seen that the co-occurrence prior gives gains in all cases, indicating that substring statistics are effectively seeding the ITG aligner. The introduced look-ahead probabilities improve accuracy significantly when substring co-occurrence counts are not used, and slightly when co-occurrence counts are used. More importantly, they allow for more aggressive beam pruning, increasing sampling speed from 1.3 sent/s to 2.5 sent/s for Finnish, and 6.8 sent/s to 11.6 sent/s for Japanese.

## 7 Conclusion and Future Directions

This paper demonstrated that character-based translation can act as a unified framework for handling difficult problems in translation: morphology, compound words, transliteration, and segmentation.

One future challenge includes scaling training up to longer sentences, which can likely be achieved through methods such as the heuristic span pruning of Haghighi et al. (2009) or sentence splitting of Vilar et al. (2007). Monolingual data could also be used to improve estimates of our substring-based prior. In addition, error analysis showed that word-based translation performed better than character-based translation on reordering and lexical choice, indicating that improved decoding (or pre-ordering) and language modeling tailored to character-based translation will likely greatly improve accuracy. Finally, we plan to explore the middle ground between word-based and character based translation, allowing for the flexibility of character-based translation, while using word boundary information to increase efficiency and accuracy.

<sup>12</sup>Similar results were found for character and word-based BLEU, but are omitted for lack of space.

## Abstract

Long-span features, such as syntax, can improve language models for tasks such as speech recognition and machine translation. However, these language models can be difficult to use in practice because of the time required to generate features for rescoring a large hypothesis set. In this work, we propose substructure sharing, which saves duplicate work in processing hypothesis sets with redundant hypothesis structures. We apply substructure sharing to a dependency parser and part of speech tagger to obtain significant speedups, and further improve the accuracy of these tools through up-training. When using these improved tools in a language model for speech recognition, we obtain significant speed improvements with both  $N$ -best and hill climbing rescoring, and show that up-training leads to WER reduction.

## 1 Introduction

Language models (LM) are crucial components in tasks that require the generation of coherent natural language text, such as automatic speech recognition (ASR) and machine translation (MT). While traditional LMs use word  $n$ -grams, where the  $n - 1$  previous words predict the next word, newer models integrate long-span information in making decisions. For example, incorporating long-distance dependencies and syntactic structure can help the LM better predict words by complementing the predictive power of  $n$ -grams (Chelba and Jelinek, 2000; Collins et al., 2005; Filimonov and Harper, 2009; Kuo et al., 2009).

The long-distance dependencies can be modeled in either a *generative* or a *discriminative* framework. Discriminative models, which directly distinguish correct from incorrect hypothesis, are particularly attractive because they allow the inclusion of arbitrary features (Kuo et al., 2002; Roark et al., 2007; Collins et al., 2005); these models with syntactic information have obtained state of the art results.

However, both generative and discriminative LMs with long-span dependencies can be slow, for they often cannot work directly with lattices and require *rescoring* large  $N$ -best lists (Khudanpur and Wu, 2000; Collins et al., 2005; Kuo et al., 2009). For discriminative models, this limitation applies to training as well. Moreover, the non-local features used in rescoring are usually extracted via auxiliary tools – which in the case of syntactic features include part of speech taggers and parsers – from a set of ASR system hypotheses. Separately applying auxiliary tools to each  $N$ -best list hypothesis leads to major inefficiencies as many hypotheses differ only slightly.

Recent work on hill climbing algorithms for ASR lattice rescoring iteratively searches for a higher-scoring hypothesis in a local neighborhood of the current-best hypothesis, leading to a much more efficient algorithm in terms of the number,  $N$ , of hypotheses evaluated (Rastrow et al., 2011b); the idea also leads to a discriminative hill climbing training algorithm (Rastrow et al., 2011a). Even so, the reliance on auxiliary tools slow LM application to the point of being impractical for real time systems. While faster auxiliary tools are an option, they are usually less accurate.

In this paper, we propose a general modifica-

tion to the decoders used in auxiliary tools to utilize the commonalities among the set of generated hypotheses. The key idea is to share substructure states in transition based structured prediction algorithms, i.e. algorithms where final structures are composed of a sequence of multiple individual decisions. We demonstrate our approach on a local Perceptron based part of speech tagger (Tsuruoka et al., 2011) and a shift reduce dependency parser (Sagae and Tsujii, 2007), yielding significantly faster tagging and parsing of ASR hypotheses. While these simpler structured prediction models are faster, we compensate for the model’s simplicity through up-training (Petrov et al., 2010), yielding auxiliary tools that are both fast and accurate. The result is significant speed improvements and a reduction in word error rate (WER) for both  $N$ -best list and the already fast hill climbing rescoring. The net result is arguably the first syntactic LM fast enough to be used in a *real time ASR system*.

## 2 Syntactic Language Models

There have been several approaches to include syntactic information in both generative and discriminative language models.

For generative LMs, the syntactic information must be part of the generative process. Structured language modeling incorporates syntactic parse trees to identify the head words in a hypothesis for modeling dependencies beyond  $n$ -grams. Chelba and Jelinek (2000) extract the two previous exposed head words at each position in a hypothesis, along with their non-terminal tags, and use them as context for computing the probability of the current position. Khudanpur and Wu (2000) exploit such syntactic head word dependencies as features in a maximum entropy framework. Kuo et al. (2009) integrate syntactic features into a neural network LM for Arabic speech recognition.

Discriminative models are more flexible since they can include arbitrary features, allowing for a wider range of long-span syntactic dependencies. Additionally, discriminative models are directly trained to resolve the acoustic confusion in the decoded hypotheses of an ASR system. This flexibility and training regime translate into better performance. Collins et al. (2005) uses the Perceptron algorithm to train a global linear discriminative model

which incorporates long-span features, such as head-to-head dependencies and part of speech tags.

**Our Language Model.** We work with a discriminative LM with long-span dependencies. We use a global linear model with Perceptron training. We rescore the hypotheses (lattices) generated by the ASR decoder—in a framework most similar to that of Rastrow et al. (2011a).

The LM score  $\mathcal{S}(\mathbf{w}, \mathbf{a})$  for each hypothesis  $\mathbf{w}$  of a speech utterance with acoustic sequence  $\mathbf{a}$  is based on the baseline ASR system score  $b(\mathbf{w}, \mathbf{a})$  (initial  $n$ -gram LM score and the acoustic score) and  $\alpha_0$ , the weight assigned to the baseline score.<sup>1</sup> The score is defined as:

$$\begin{aligned} \mathcal{S}(\mathbf{w}, \mathbf{a}) &= \alpha_0 \cdot b(\mathbf{w}, \mathbf{a}) + F(\mathbf{w}, \mathbf{s}^1, \dots, \mathbf{s}^m) \\ &= \alpha_0 \cdot b(\mathbf{w}, \mathbf{a}) + \sum_{i=1}^d \alpha_i \cdot \Phi_i(\mathbf{w}, \mathbf{s}^1, \dots, \mathbf{s}^m) \end{aligned}$$

where  $F$  is the discriminative LM’s score for the hypothesis  $\mathbf{w}$ , and  $\mathbf{s}^1, \dots, \mathbf{s}^m$  are candidate syntactic structures associated with  $\mathbf{w}$ , as discussed below. Since we use a linear model, the score is a weighted linear combination of the *count* of activated features of the word sequence  $\mathbf{w}$  and its associated structures:  $\Phi_i(\mathbf{w}, \mathbf{s}^1, \dots, \mathbf{s}^m)$ . Perceptron training learns the parameters  $\alpha$ . The baseline score  $b(\mathbf{w}, \mathbf{a})$  can be a feature, yielding the dot product notation:  $\mathcal{S}(\mathbf{w}, \mathbf{a}) = \langle \alpha, \Phi(\mathbf{a}, \mathbf{w}, \mathbf{s}^1, \dots, \mathbf{s}^m) \rangle$  Our LM uses features from the dependency tree and part of speech (POS) tag sequence. We use the method described in Kuo et al. (2009) to identify the two previous exposed head words,  $h_{-2}, h_{-1}$ , at each position  $i$  in the input hypothesis and include the following syntactic based features into our LM:

1.  $(h_{-2}.w \circ h_{-1}.w \circ w_i), (h_{-1}.w \circ w_i), (w_i)$
2.  $(h_{-2}.t \circ h_{-1}.t \circ t_i), (h_{-1}.t \circ t_i), (t_i), (t_i w_i)$

where  $h.w$  and  $h.t$  denote the word identity and the POS tag of the corresponding exposed head word.

### 2.1 Hill Climbing Rescoring

We adopt the so called hill climbing framework of Rastrow et al. (2011b) to improve both training and rescoring time as much as possible by reducing the

<sup>1</sup>We tune  $\alpha_0$  on development data (Collins et al., 2005).

number  $N$  of explored hypotheses. We summarize it below for completeness.

Given a speech utterance’s lattice  $\mathcal{L}$  from a first pass ASR decoder, the neighborhood  $\mathcal{N}(\mathbf{w}, i)$  of a hypothesis  $\mathbf{w} = w_1 w_2 \dots w_n$  at position  $i$  is defined as the set of all paths in the lattice that may be obtained by editing  $w_i$ : deleting it, substituting it, or inserting a word to its left. In other words, it is the “distance-1-at-position  $i$ ” neighborhood of  $\mathbf{w}$ . Given a position  $i$  in a word sequence  $\mathbf{w}$ , all hypotheses in  $\mathcal{N}(\mathbf{w}, i)$  are rescored using the long-span model and the hypothesis  $\hat{\mathbf{w}}'(i)$  with the highest score becomes the new  $\mathbf{w}$ . The process is repeated with a new position – scanned left to right – until  $\mathbf{w} = \hat{\mathbf{w}}'(1) = \dots = \hat{\mathbf{w}}'(n)$ , i.e. when  $\mathbf{w}$  itself is the highest scoring hypothesis in all its 1-neighborhoods, and can not be further improved using the model. Incorporating this into training yields a discriminative hill climbing algorithm (Rastrow et al., 2011a).

### 3 Incorporating Syntactic Structures

Long-span models – generative or discriminative,  $N$ -best or hill climbing – rely on auxiliary tools, such as a POS tagger or a parser, for extracting features for each hypothesis during rescoring, and during training for discriminative models. The top- $m$  candidate structures associated with the  $i^{\text{th}}$  hypothesis, which we denote as  $\mathbf{s}_i^1, \dots, \mathbf{s}_i^m$ , are generated by these tools and used to score the hypothesis:  $F(\mathbf{w}_i, \mathbf{s}_i^1, \dots, \mathbf{s}_i^m)$ . For example,  $\mathbf{s}_i^j$  can be a part of speech tag or a syntactic dependency. We formally define this sequential processing as:

$$\begin{aligned} \mathbf{w}_1 &\xrightarrow{\text{tool}(s)} \mathbf{s}_1^1, \dots, \mathbf{s}_1^m \xrightarrow{\text{LM}} F(\mathbf{w}_1, \mathbf{s}_1^1, \dots, \mathbf{s}_1^m) \\ \mathbf{w}_2 &\xrightarrow{\text{tool}(s)} \mathbf{s}_2^1, \dots, \mathbf{s}_2^m \xrightarrow{\text{LM}} F(\mathbf{w}_2, \mathbf{s}_2^1, \dots, \mathbf{s}_2^m) \\ &\vdots \\ \mathbf{w}_k &\xrightarrow{\text{tool}(s)} \mathbf{s}_k^1, \dots, \mathbf{s}_k^m \xrightarrow{\text{LM}} F(\mathbf{w}_k, \mathbf{s}_k^1, \dots, \mathbf{s}_k^m) \end{aligned}$$

Here,  $\{\mathbf{w}_1, \dots, \mathbf{w}_k\}$  represents a set of ASR output hypotheses that need to be rescored. For each hypothesis, we apply an external tool (e.g. parser) to generate associated structures  $\mathbf{s}_i^1, \dots, \mathbf{s}_i^m$  (e.g. dependencies.) These are then passed to the language model along with the word sequence for scoring.

### 3.1 Substructure Sharing

While long-span LMs have been empirically shown to improve WER over  $n$ -gram LMs, the computational burden prohibits long-span LMs in practice, particularly in real-time systems. A major complexity factor is due to processing 100s or 1000s of hypotheses for each speech utterance, even during hill climbing, each of which must be POS tagged and parsed. However, the candidate hypotheses of an utterance share equivalent substructures, especially in hill climbing methods due to the locality present in the neighborhood generation. Figure 1 demonstrates such repetition in an  $N$ -best list ( $N=10$ ) and a hill climbing neighborhood hypothesis set for a speech utterance from broadcast news. For example, the word “ENDORSE” occurs within the same local context in all hypotheses and should receive the same part of speech tag in each case. Processing each hypothesis separately wastes time.

We propose a general algorithmic approach to reduce the complexity of processing a hypothesis set by sharing common substructures among the hypotheses. Critically, unlike many lattice parsing algorithms, our approach is general and produces exact output. We first present our approach and then demonstrate its generality by applying it to a dependency parser and part of speech tagger.

We work with structured prediction models that produce output from a series of local decisions: a transition model. We begin in initial state  $\pi_0$  and terminate in a possible final state  $\pi_f$ . All states along the way are chosen from the possible states  $\Pi$ . A transition (or action)  $\omega \in \Omega$  advances the decoder from state to state, where the transition  $\omega_i$  changes the state from  $\pi_i$  to  $\pi_{i+1}$ . The sequence of states  $\{\pi_0 \dots \pi_i, \pi_{i+1} \dots \pi_f\}$  can be mapped to an output (the model’s prediction.) The choice of action  $\omega$  is given by a learning algorithm, such as a maximum-entropy classifier, support vector machine or Perceptron, trained on labeled data. Given the previous  $k$  actions up to  $\pi_i$ , the classifier  $g : \Pi \times \Omega^k \rightarrow \mathbb{R}^{|\Omega|}$  assigns a score to each possible action, which we can interpret as a probability:  $p_g(\omega_i | \pi_i, \omega_{i-1} \omega_{i-2} \dots \omega_{i-k})$ . These actions are applied to transition to new states  $\pi_{i+1}$ . We note that state definitions can encode the  $k$  previous actions, which simplifies the probability to  $p_g(\omega_i | \pi_i)$ . The

Figure 1: Example of repeated substructures in candidate hypotheses.

score of the new state is then

$$p(\pi_{i+1}) = p_g(\omega_i | \pi_i) \cdot p(\pi_i) \quad (1)$$

Classification decisions require a feature representation of  $\pi_i$ , which is provided by feature functions  $\mathbf{f} : \Pi \rightarrow \mathcal{Y}$ , that map states to features. Features are conjoined with actions for multi-class classification, so  $p_g(\omega_i | \pi_i) = p_g(\mathbf{f}(\pi) \circ \omega_i)$ , where  $\circ$  is a conjunction operation. In this way, states can be summarized by features.

*Equivalent states* are defined as two states  $\pi$  and  $\pi'$  with an identical feature representation:

$$\pi \equiv \pi' \quad \text{iff} \quad \mathbf{f}(\pi) = \mathbf{f}(\pi')$$

If two states are equivalent, then  $g$  imposes the same distribution over actions. We can benefit from this substructure redundancy, both within and between hypotheses, by saving these distributions in memory, sharing a distribution computed just once across equivalent states. A similar idea of equivalent states is used by Huang and Sagae (2010), except they use equivalence to facilitate dynamic programming for shift-reduce parsing, whereas we generalize it for improving the processing time of similar hypotheses in general models. Following Huang and Sagae, we define *kernel features* as the smallest set of atomic features  $\tilde{\mathbf{f}}(\pi)$  such that,

$$\tilde{\mathbf{f}}(\pi) = \tilde{\mathbf{f}}(\pi') \quad \Rightarrow \quad \pi \equiv \pi'. \quad (2)$$

Equivalent distributions are stored in a *hash table*  $H : \Pi \rightarrow \Omega \times \mathbb{R}$ ; the hash keys are the states and the values are distributions<sup>2</sup> over actions:  $\{\omega, p_g(\omega | \pi)\}$ .

<sup>2</sup>For pure greedy search (deterministic search) we need only retain the best action, since the distribution is only used in probabilistic search, such as beam search or best-first algorithms.

$H$  caches equivalent states in a hypothesis set and re-sets for each new utterance. For each state, we first check  $H$  for equivalent states before computing the action distribution; each cache hit reduces decoding time. Distributing hypotheses  $w_i$  across different CPU threads is another way to obtain speedups, and we can still benefit from substructure sharing by storing  $H$  in shared memory.

We use  $h(\pi) = \sum_{i=1}^{|\tilde{\mathbf{f}}(\pi)|} \text{int}(f_i(\pi))$  as the hash function, where  $\text{int}(f_i(\pi))$  is an integer mapping of the  $i^{\text{th}}$  kernel feature. For integer typed features the mapping is trivial, for string typed features (e.g. a POS tag identity) we use a mapping of the corresponding vocabulary to integers. We empirically found that this hash function is very effective and yielded very few collisions.

To apply substructure sharing to a transition based model, we need only define the set of states  $\Pi$  (including  $\pi_0$  and  $\pi_f$ ), actions  $\Omega$  and kernel feature functions  $\tilde{\mathbf{f}}$ . The resulting speedup depends on the amount of substructure duplication among the hypotheses, which we will show is significant for ASR lattice rescoring. Note that our algorithm is not an approximation; we obtain the same output  $\{s_i^j\}$  as we would without any sharing. We now apply this algorithm to dependency parsing and POS tagging.

### 3.2 Dependency Parsing

We use the best-first probabilistic shift-reduce dependency parser of Sagae and Tsujii (2007), a transition-based parser (Kübler et al., 2009) with a MaxEnt classifier. Dependency trees are built by processing the words left-to-right and the classifier assigns a distribution over the actions at each step. States are defined as  $\pi = \{S, Q\}$ :  $S$  is a stack of

Kernel features $\mathbf{f}(\pi)$ for state $\pi = \{S, Q\}$ $S = s_0, s_1, \dots$ & $Q = q_0, q_1, \dots$				
(1)	$s_0.w$	$s_0.t$	$s_0.r$	(5) $t_{s_0-1}$ $t_{s_1+1}$
		$s_0.lch.t$	$s_0.lch.r$	
		$s_0.rch.t$	$s_0.rch.r$	
(2)	$s_1.w$	$s_1.t$	$s_1.r$	(6) $\text{dist}(s_0, s_1)$ $\text{dist}(q_0, s_0)$
		$s_1.lch.t$	$s_1.lch.r$	
		$s_1.rch.t$	$s_1.rch.r$	
(3)	$s_2.w$	$s_2.t$	$s_2.r$	
(4)	$q_0.w$	$q_0.t$		(7) $s_0.nch$ $s_1.nch$
	$q_1.w$	$q_1.t$		
	$q_2.w$			

Table 1: Kernel features for defining parser states.  $s_i.w$  denotes the head-word in a subtree and  $t$  its POS tag.  $s_i.lch$  and  $s_i.rch$  are the leftmost and rightmost children of a subtree.  $s_i.r$  is the dependency label that relates a subtree head-word to its dependent.  $s_i.nch$  is the number of children of a subtree.  $q_i.w$  and  $q_i.t$  are the word and its POS tag in the queue.  $\text{dist}(s_0, s_1)$  is the linear distance between the head-words of  $s_0$  and  $s_1$ .

subtrees  $s_0, s_1, \dots$  ( $s_0$  is the top tree) and  $Q$  are words in the input word sequence. The initial state is  $\pi_0 = \{\emptyset, \{w_0, w_1, \dots\}\}$ , and final states occur when  $Q$  is empty and  $S$  contains a single tree (the output).

$\Omega$  is determined by the set of dependency labels  $r \in \mathcal{R}$  and one of three transition types:

- *Shift*: remove the head of  $Q$  ( $w_j$ ) and place it on the top of  $S$  as a singleton tree (only  $w_j$ .)
- *Reduce-Left<sub>r</sub>*: replace the top two trees in  $S$  ( $s_0$  and  $s_1$ ) with a tree formed by making the root of  $s_1$  a dependent of the root of  $s_0$  with label  $r$ .
- *Reduce-Right<sub>r</sub>*: same as *Reduce-Left<sub>r</sub>* except reverses  $s_0$  and  $s_1$ .

Table 1 shows the kernel features used in our dependency parser. See Sagae and Tsujii (2007) for a complete list of features.

Goldberg and Elhadad (2010) observed that parsing time is dominated by feature extraction and score calculation. Substructure sharing reduces these steps for equivalent states, which are persistent throughout a candidate set. Note that there are far fewer kernel features than total features, hence the hash function calculation is very fast.

We summarize substructure sharing for dependency parsing in Algorithm 1. We extend the definition of states to be  $\{S, Q, p\}$  where  $p$  denotes the score of the state: the probability of the action sequence that resulted in the current state. Also, fol-

lowing Sagae and Tsujii (2007) a heap is used to maintain states prioritized by their scores, for applying the best-first strategy. For each step, a state from the top of the heap is considered and all actions (and scores) are either retrieved from  $H$  or computed using  $g$ .<sup>3</sup> We use  $\pi_{\text{new}} \leftarrow \pi_{\text{current}} \times \omega$  to denote the operation of extending a state by an action  $\omega \in \Omega^4$ .

### 3.3 Part of Speech Tagging

We use the part of speech (POS) tagger of Tsuruoka et al. (2011), a transition based model with a Perceptron and a lookahead heuristic process. The tagger processes  $\mathbf{w}$  left to right. States are defined as  $\pi_i = \{c_i, \mathbf{w}\}$ : a sequence of assigned tags up to  $w_i$  ( $c_i = t_1 t_2 \dots t_{i-1}$ ) and the word sequence  $\mathbf{w}$ .  $\Omega$  is defined simply as the set of possible POS tags ( $\mathcal{T}$ ) that can be applied. The final state is reached once all the positions are tagged. For  $\mathbf{f}$  we use the features of Tsuruoka et al. (2011). The kernel features are  $\mathbf{f}(\pi_i) = \{t_{i-2}, t_{i-1}, w_{i-2}, w_{i-1}, w_i, w_{i+1}, w_{i+2}\}$ . While the tagger extracts prefix and suffix features, it suffices to look at  $w_i$  for determining state equivalence. The tagger is deterministic (greedy) in that it only considers the best tag at each step, so we do not store scores. However, this tagger uses a depth-

<sup>3</sup> Sagae and Tsujii (2007) use a beam strategy to increase speed. Search space pruning is achieved by filtering heap states for probability greater than  $\frac{1}{b}$  the probability of the most likely state in the heap with the same number of actions. We use  $b = 100$  for our experiments.

<sup>4</sup>We note that while we have demonstrated substructure sharing for **dependency** parsing, the same improvements can be made to a shift-reduce constituent parser (Sagae and Lavie, 2006).

Figure 2: POS tagger with lookahead search of  $d=1$ . At  $w_i$  the search considers the current state and next state.

first search lookahead procedure to select the best action at each step, which considers future decisions up to depth  $d^5$ . An example for  $d = 1$  is shown in Figure 2. Using  $d = 1$  for the lookahead search strategy, we modify the kernel features since the decision for  $w_i$  is affected by the state  $\pi_{i+1}$ . The kernel features in position  $i$  should be  $\tilde{\mathbf{f}}(\pi_i) \cup \tilde{\mathbf{f}}(\pi_{i+1})$ :

$$\tilde{\mathbf{f}}(\pi_i) = \{t_{i-2}, t_{i-1}, w_{i-2}, w_{i-1}, w_i, w_{i+1}, w_{i+2}, w_{i+3}\}$$

## 4 Up-Training

While we have fast decoding algorithms for the parsing and tagging, the simpler underlying models can lead to worse performance. Using more complex models with higher accuracy is impractical because they are slow. Instead, we seek to improve the accuracy of our fast tools.

To achieve this goal we use up-training, in which a more complex model is used to improve the accuracy of a simpler model. We are given two models,  $M_1$  and  $M_2$ , as well as a large collection of unlabeled text. Model  $M_1$  is slow but very accurate while  $M_2$  is fast but obtains lower accuracy. Up-training applies  $M_1$  to tag the unlabeled data, which is then used as training data for  $M_2$ . Like self-training, a model is retrained on automatic output, but here the output comes from a more accurate model. Petrov et al. (2010) used up-training as a domain adaptation technique: a constituent parser – which is more robust to domain changes – was used to label a new domain, and a fast dependency parser

<sup>5</sup> Tsuruoka et al. (2011) shows that the lookahead search improves the performance of the local “history-based” models for different NLP tasks

was trained on the automatically labeled data. We use a similar idea where our goal is to recover the accuracy lost from using simpler models. Note that while up-training uses two models, it differs from co-training since we care about improving only one model ( $M_2$ ). Additionally, the models can vary in different ways. For example, they could be the same algorithm with different pruning methods, which can lead to faster but less accurate models.

We apply up-training to improve the accuracy of both our fast POS tagger and dependency parser. We parse a large corpus of text with a very accurate but very slow constituent parser and use the resulting data to up-train our tools. We will demonstrate empirically that up-training improves these fast models to yield better WER results.

## 5 Related Work

The idea of efficiently processing a hypothesis set is similar to “lattice-parsing”, in which a parser consider an entire lattice at once (Hall, 2005; Chempalier et al., 1999). These methods typically constrain the parsing space using heuristics, which are often model specific. In other words, they search in the joint space of word sequences present in the lattice and their syntactic analyses; they are not guaranteed to produce a syntactic analysis for all hypotheses. In contrast, substructure sharing is a general purpose method that we have applied to two different algorithms. The output is identical to processing each hypothesis separately and output is generated for each hypothesis. Hall (Hall, 2005) uses a lattice parsing strategy which aims to compute the marginal probabilities of all word sequences in the lattice by summing over syntactic analyses of each word sequence. The parser sums over multiple parses of a word sequence implicitly. The lattice parser therefore, is itself a language model. In contrast, our tools are completely separated from the ASR system, which allows the system to create whatever features are needed. This independence means our tools are useful for other tasks, such as machine translation. These differences make substructure sharing a more attractive option for efficient algorithms.

While Huang and Sagae (2010) use the notion of “equivalent states”, they do so for dynamic programming in a shift-reduce parser to broaden the search space. In contrast, we use the idea to identify sub-

structures across inputs, where our goal is efficient parsing in general. Additionally, we extend the definition of equivalent states to general transition based structured prediction models, and demonstrate applications beyond parsing as well as the novel setting of hypothesis set parsing.

## 6 Experiments

Our ASR system is based on the 2007 IBM Speech transcription system for the GALE Distillation Go/No-go Evaluation (Chen et al., 2006) with state of the art discriminative acoustic models. See Table 2 for a data summary. We use a modified Kneser-Ney (KN) backoff 4-gram baseline LM. Word-lattices for discriminative training and rescoring come from this baseline ASR system.<sup>6</sup> The long-span discriminative LM’s baseline feature weight ( $\alpha_0$ ) is tuned on dev data and hill climbing (Rastrow et al., 2011a) is used for training and rescoring. The dependency parser and POS tagger are trained on supervised data and up-trained on data labeled by the CKY-style bottom-up constituent parser of Huang et al. (2010), a state of the art broadcast news (BN) parser, with phrase structures converted to labeled dependencies by the Stanford converter.

While accurate, the parser has a huge grammar (32GB) from using products of latent variable grammars and requires  $O(l^3)$  time to parse a sentence of length  $l$ . Therefore, we could not use the constituent parser for ASR rescoring since utterances can be very long, although the shorter up-training text data was not a problem.<sup>7</sup> We evaluate both unlabeled (UAS) and labeled dependency accuracy (LAS).

### 6.1 Results

Before we demonstrate the speed of our models, we show that up-training can produce accurate and fast models. Figure 3 shows improvements to parser accuracy through up-training for different amount of (randomly selected) data, where the last column indicates constituent parser score (91.4% UAS). We use the POS tagger to generate tags for dependency training to match the test setting. While there is a large difference between the constituent and dependency parser without up-training (91.4%

Figure 3: Up-training results for dependency parsing for varying amounts of data (number of words.) The first column is the dependency parser with supervised training only and the last column is the constituent parser (after converting to dependency trees.)

vs. 86.2% UAS), up-training can cut the difference by 44% to 88.5%, and improvements saturate around 40m words (about 2m sentences.)<sup>8</sup> The dependency parser remains much smaller and faster; the up-trained dependency model is 700MB with 6m features compared with 32GB for constituency model. Up-training improves the POS tagger’s accuracy from 95.9% to 97%, when trained on the POS tags produced by the constituent parser, which has a tagging accuracy of 97.2% on BN.

We train the syntactic discriminative LM, with head-word and POS tag features, using the faster parser and tagger and then rescore the ASR hypotheses. Table 3 shows the decoding speedups as well as the WER reductions compared to the baseline LM. Note that up-training improvements lead to WER reductions. Detailed speedups on substructure sharing are shown in Table 4; the POS tagger achieves a 5.3 times speedup, and the parser a 5.7 speedup without changing the output. We also observed speedups during training (not shown due to space.)

The above results are for the already fast hill climbing decoding, but substructure sharing can also be used for  $N$ -best list rescoring. Figure 4 (logarithmic scale) illustrates the time for the parser and tagger to process  $N$ -best lists of varying size, with more substantial speedups for larger lists. For example, for  $N=100$  (a typical setting) the parsing time re-

<sup>6</sup>For training a 3-gram LM is used to increase confusions.

<sup>7</sup>Speech utterances are longer as they are not as effectively sentence segmented as text.

<sup>8</sup>Better performance is due to the exact CKY-style – compared with best-first and beam-search and that the constituent parser uses the product of huge self-trained grammars.

Usage	Data	Size
Acoustic model training	Hub4 acoustic train	153k uttr, 400 hrs
Baseline LM training: modified KN 4-gram	TDT4 closed captions+EARS BN03 closed caption	193m words
Disc. LM training: long-span w/hill climbing	Hub4 (length <50)	115k uttr, 2.6m words
Baseline feature ( $\alpha_0$ ) tuning	dev04f BN data	2.5 hrs
Supervised training: dep. parser, POS tagger	Ontonotes BN treebank+ WSJ Penn treebank	1.3m words, 59k sent.
Supervised training: constituent parser	Ontonotes BN treebank + WSJ Penn treebank	1.3m words, 59k sent.
Up-training: dependency parser, POS tagger	TDT4 closed captions+EARS BN03 closed caption	193m words available
Evaluation: up-training	BN treebank test (following Huang et al. (2010))	20k words, 1.1k sent.
Evaluation: ASR transcription	rt04 BN evaluation	4 hrs, 45k words

Table 2: A summary of the data for training and evaluation. The Ontonotes corpus is from Weischedel et al. (2008).

Figure 4: Elapsed time for (a) parsing and (b) POS tagging the  $N$ -best lists with and without substructure sharing.

LM	WER	Substr. Share (sec)	
		No	Yes
Baseline 4-gram	15.1	-	-
Syntactic LM + up-train	14.8 <b>14.6</b>	8,658	<b>1,648</b>

Table 3: Speedups and WER for hill climbing rescoring. Substructure sharing yields a 5.3 times speedup. The times for with and without up-training are nearly identical, so we include only one set for clarity. Time spent is dominated by the parser, so the faster parser accounts for much of the overall speedup. Timing information includes neighborhood generation and LM rescoring, so it is more than the sum of the times in Table 4.

duces from about 20,000 seconds to 2,700 seconds, about 7.4 times as fast.

## 7 Conclusion

The computational complexity of accurate syntactic processing can make structured language models impractical for applications such as ASR that require scoring hundreds of hypotheses per input. We have

	Substr. Share		Speedup
	No	Yes	
Parser	8,237.2	<b>1,439.5</b>	5.7
POS tagger	213.3	<b>40.1</b>	5.3

Table 4: Time in seconds for the parser and POS tagger to process hypotheses during hill climbing rescoring.

presented substructure sharing, a general framework that greatly improves the speed of syntactic tools that process candidate hypotheses. Furthermore, we achieve improved performance through up-training. The result is a large speedup in rescoring time, even on top of the already fast hill climbing framework, and reductions in WER from up-training. Our results make long-span syntactic LMs practical for real-time ASR, and can potentially impact machine translation decoding as well.

## Acknowledgments

Thanks to Kenji Sagae for sharing his shift-reduce dependency parser and the anonymous reviewers for helpful comments.

## Abstract

During early language acquisition, infants must learn both a lexicon and a model of phonetics that explains how lexical items can vary in pronunciation—for instance “the” might be realized as [ði] or [ðə]. Previous models of acquisition have generally tackled these problems in isolation, yet behavioral evidence suggests infants acquire lexical and phonetic knowledge simultaneously. We present a Bayesian model that clusters together phonetic variants of the same lexical item while learning both a language model over lexical items and a log-linear model of pronunciation variability based on articulatory features. The model is trained on transcribed surface pronunciations, and learns by bootstrapping, without access to the true lexicon. We test the model using a corpus of child-directed speech with realistic phonetic variation and either gold standard or automatically induced word boundaries. In both cases modeling variability improves the accuracy of the learned lexicon over a system that assumes each lexical item has a unique pronunciation.

## 1 Introduction

Infants acquiring their first language confront two difficult cognitive problems: building a lexicon of word forms, and learning basic phonetics and phonology. The two tasks are closely related: knowing what sounds can substitute for one another helps in clustering together variant pronunciations of the same word, while knowing the environments in which particular words can occur helps determine which sound changes are meaningful and which are not (Feldman

(a) intended:	/ju want wʌn/	/want e kʊki/
(b) surface:	[jə wãʔ wʌn]	[wan ə kʊki]
(c) unsegmented:	[jəwãʔwʌn]	[wanəkʊki]
(d) idealized:	/juwantwʌn/	/wantekʊki/

Figure 1: The utterances *you want one? want a cookie?* represented (a) using a canonical phonemic encoding for each word and (b) as they might be pronounced phonetically. Lines (c) and (d) remove the word boundaries (but not utterance boundaries) from (b) and (a), respectively.

et al., 2009). For instance, if an infant who already knows the word [ju] “you” encounters a new word [jə], they must decide whether it is a new lexical item or a variant of the word they already know. Evidence for the correct conclusion comes from the pronunciation (many English vowels are reduced to [ə] in unstressed positions) and the context—if the next word is “want”, “you” is a plausible choice.

To date, most models of infant language learning have focused on either lexicon-building or phonetic learning in isolation. For example, many models of word segmentation implicitly or explicitly build a lexicon while segmenting the input stream of phonemes into word tokens; in nearly all cases the phonemic input is created from an orthographic transcription using a phonemic dictionary, thus abstracting away from any phonetic variability (Brent, 1999; Venkataraman, 2001; Swingley, 2005; Goldwater et al., 2009, among others). As illustrated in Figure 1, these models attempt to infer line (a) from line (d). However, (d) is an idealization: real speech has variability, and behavioral evidence suggests that infants are still learning about the phonetics and phonology of their language even after beginning to segment words, rather than learning to neutralize

the variations first and acquiring the lexicon afterwards (Feldman et al., 2009, and references therein).

Based on this evidence, a more realistic model of early language acquisition should propose a method of inferring the *intended* forms (Figure 1a) from the *unsegmented surface* forms (1c) while also learning a model of phonetic variation relating the intended and surface forms (a) and (b). Previous models with similar goals have learned from an artificial corpus with a small vocabulary (Driesen et al., 2009; Räsänen, 2011) or have modeled variability only in vowels (Feldman et al., 2009); to our knowledge, this paper is the first to use a naturalistic infant-directed corpus while modeling variability in all segments, and to incorporate word-level context (a bigram language model). Our main contribution is a joint lexical-phonetic model that infers intended forms from *segmented* surface forms; we test the system using input with either gold standard word boundaries or boundaries induced by an existing unsupervised segmentation model (Goldwater et al., 2009). We show that in both cases modeling variability improves the accuracy of the learned lexicon over a system that assumes each intended form has a unique surface form.

Our model is conceptually similar to those used in speech recognition and other applications: we assume the intended tokens are generated from a bigram language model and then distorted by a noisy channel, in particular a log-linear model of phonetic variability. But unlike speech recognition, we have no (intended-form, surface-form) training pairs to train the phonetic model, nor even a dictionary of intended-form strings to train the language model. Instead, we initialize the noise model using feature weights based on universal linguistic principles (e.g., a surface phone is likely to share articulatory features with the intended phone) and use a bootstrapping process to iteratively infer the intended forms and retrain the language model and noise model. While we do not claim that the particular inference mechanism we use is cognitively plausible, our positive results further support the claim that infants can and do acquire phonetics and the lexicon in concert.

## 2 Related work

Our work is inspired by the lexical-phonetic model of Feldman et al. (2009). They extend a model for

clustering acoustic tokens into phonetic categories (Vallabha et al., 2007) by adding a lexical level that simultaneously clusters word tokens (which contain the acoustic tokens) into lexical entries. Including the lexical level improves the model’s phonetic categorization, and a follow-up study on artificial language learning (Feldman, 2011) supports the claim that human learners use lexical knowledge to distinguish meaningful from unimportant phonetic contrasts. Feldman et al. (2009) use a real-valued representation for vowels (formant values), but assume no variability in consonants, and treat each word token independently. In contrast, our model uses a symbolic representation for sounds, but models variability in *all* segment types and incorporates a bigram word-level language model.

To our knowledge, the only other lexicon-building systems that also learn about phonetic variability are those of Driesen et al. (2009) and Räsänen (2011). These systems learn to represent lexical items and their variability from a discretized representation of the speech stream, but they are tested on an artificial corpus with only 80 vocabulary items that was constructed so as to “avoid strong word-to-word dependencies” (Räsänen, 2011). Here, we use a naturalistic corpus, demonstrating that lexical-phonetic learning is possible in this more general setting and that word-level context information is important for doing so.

Several other related systems work directly from the acoustic signal and many of these do use naturalistic corpora. However, they do not learn at both the lexical and phonetic/acoustic level. For example, Park and Glass (2008), Aimetti (2009), Jansen et al. (2010), and McInnes and Goldwater (2011) present lexicon-building systems that use hard-coded acoustic similarity measures rather than *learning* about variability, and they only extract and cluster a few frequent words. On the phonetic side, Varadarajan et al. (2008) and Dupoux et al. (2011) describe systems that learn phone-like units but without the benefit of top-down information.

A final line of related work is on word segmentation. In addition to the models mentioned in Section 1, which use phonemic input, a few models of word segmentation have been tested using phonetic input (Fleck, 2008; Rytting, 2007; Daland and Pierrehumbert, 2010). However, they do not cluster segmented

Figure 2: Our generative model of the surface tokens  $s$  from intended tokens  $x$ , which occur with left and right contexts  $l$  and  $r$ .

word tokens into lexical items (none of these models even maintains an explicit lexicon), nor do they model or learn from phonetic variation in the input.

### 3 Lexical-phonetic model

Our lexical-phonetic model is defined using the standard noisy channel framework: first a sequence of intended word tokens is generated using a language model, and then each token is transformed by a probabilistic finite-state transducer to produce the observed surface sequence. In this section, we present the model in a hierarchical Bayesian framework to emphasize its similarity to existing models, in particular those of Feldman et al. (2009) and Goldwater et al. (2009). In our actual implementation, however, we use approximation and MAP point estimates to make our inference process more tractable; we discuss these simplifications in Section 4.

Our observed data consists of a (segmented) sequence of surface words  $s_1 \dots s_n$ . We wish to recover the corresponding sequence of intended words  $x_1 \dots x_n$ . As shown in Figure 2,  $s_i$  is produced from  $x_i$  by a transducer  $T$ :  $s_i \sim T(x_i)$ , which models phonetic changes. Each  $x_i$  is sampled from a distribution  $\theta$  which represents word frequencies, and its left and right context words,  $l_i$  and  $r_i$ , are drawn from distributions conditioned on  $x_i$ , in order to capture information about the environments in which  $x_i$  appears:  $l_i \sim P_L(x_i), r_i \sim P_R(x_i)$ . Because the number of word types is not known in advance,  $\theta$  is drawn from a Dirichlet process  $DP(\alpha)$ , and  $P_L(x)$  and  $P_R(x)$  have Pitman-Yor priors with concentration parameter  $\theta$  and discount  $d$  (Teh, 2006).

Our generative model of  $x_i$  is unusual for two reasons. First, we treat each  $x_i$  independently rather than linking them via a Markov chain. This makes the model deficient, since  $l_i$  overlaps with  $x_{i-1}$  and so forth, generating each token twice. During inference, however, we will never compute the joint probability of all the data at once, only the probabilities of subsets of the variables with particular intended word forms  $u$  and  $v$ . As long as no two of these words are adjacent, the deficiency will have no effect. We make this independence assumption for computational reasons—when deciding whether to merge  $u$  and  $v$  into a single lexical entry, we compute the change in estimated probability for their contexts, but not the effect on other words for which  $u$  and  $v$  themselves appear as context words.

Also unusual is that we factor the joint probability  $(l, x, r)$  as  $p(x)p(l|x)p(r|x)$  rather than as a left-to-right chain  $p(l)p(x|l)p(r|x)$ . Given our independence assumption above, these two quantities are mathematically equivalent, so the difference matters only because we are using smoothed estimates. Our factorization leads to a symmetric treatment of left and right contexts, which simplifies implementation: we can store all the context parameters locally as  $P_L(\cdot|x)$  rather than distributed over various  $P(x|\cdot)$ .

Next, we explain our transducer  $T$ . A weighted finite-state transducer (WFST) is a variant of a finite-state automaton (Pereira et al., 1994) that reads an input string symbol-by-symbol and probabilistically produces an output string; thus it can be used to specify a conditional probability on output strings given an input. Our WFST (Figure 3) computes a weighted edit distance, and is implemented using OpenFST (Allauzen et al., 2007). It contains a state for each triplet of (*previous*, *current*, *next*) phones; conditioned on this state, it emits a character *output* which can be thought of as a possible surface realization of *current* in its particular environment. The *output* can be the empty string  $\epsilon$ , in which case *current* is deleted. The machine can also insert characters at any point in the string, by transitioning to an insert state (*previous*,  $\epsilon$ , *current*) and then returning while emitting some new character.

The transducer is parameterized by the probabilities of the arcs. For instance, all arcs leaving the state  $(\bullet, \delta, i)$  consume the character  $\delta$  and emit some character  $c$  with probability  $p(c|\bullet, \delta, i)$ . Following

Figure 3: The fragment of the transducer responsible for input string [ǔi] “the”. “...” represents an output arc for each possible character, including the empty string  $\epsilon$ ;  $\bullet$  is the word boundary marker.

Dreyer et al. (2008), we parameterize these distributions with a log-linear model. The model features are based on articulatory phonetics and distinguish three dimensions of sound production: voicing, place of articulation and manner of articulation.

Features are generated from four positional templates (Figure 4):  $(curr) \rightarrow out$ ,  $(prev, curr) \rightarrow out$ ,  $(curr, next) \rightarrow out$  and  $(prev, curr, next) \rightarrow out$ . Each template is instantiated once per articulatory dimension, with  $prev$ ,  $curr$ ,  $next$  and  $out$  replaced by their values for that dimension: for instance, there are two voicing values, *voiced* and *unvoiced*<sup>1</sup> and the  $(curr) \rightarrow out$  template for [ǔ] producing [d] would be instantiated as  $(voiced) \rightarrow voiced$ . To capture trends specific to particular sounds, each template is instantiated again using the actual symbol for  $curr$  and articulatory values for everything else (e.g., [ǔ]  $\rightarrow$  *unvoiced*). An additional template,  $\rightarrow out$ , captures the marginal frequency of the output symbol. There are also faithfulness features, *same-sound*, *same-voice*, *same-place* and *same-manner* which check if  $curr$  is exactly identical to  $out$  or shares the exact value of a particular feature.

Our choice of templates and features is based on standard linguistic principles: we expect that changing only a single articulatory dimension will be more acceptable than changing several, and that the articulatory dimensions of context phones are important because of assimilatory and dissimilatory processes (Hayes, 2011). In modern phonetics and phonology, these generalizations are usually expressed as Optimality Theory constraints; log-linear models such as ours have previously been used to implement stochas-

<sup>1</sup>We use seven place values and five manner values (stop, nasal stop, fricative, vowel, other). Empty segments like  $\epsilon$  and  $\bullet$  are assigned a special value “no-value” for all features.

Figure 4: Some features generated for  $(\bullet, \ddot{u}, i) \rightarrow d$ . Each black factor node corresponds to a positional template. The features instantiated for the  $(curr) \rightarrow out$  and  $\rightarrow out$  template are shown in full, and we show some of the features for the  $(curr, next) \rightarrow out$  template.

tic Optimality Theory models (Goldwater and Johnson, 2003; Hayes and Wilson, 2008).

## 4 Inference

Global optimization of the model posterior is difficult; instead we use Viterbi EM (Spitkovsky et al., 2010; Allahverdyan and Galstyan, 2011). We begin with a simple initial transducer and alternate between two phases: clustering together surface forms, and reestimating the transducer parameters. We iterate this procedure until convergence (when successive clustering phases find nearly the same set of merges); this tends to take about 5 or 6 iterations.

In our clustering phase, we improve the model posterior as much as possible by greedily making *type merges*, where, for a pair of intended word forms  $u$  and  $v$ , we replace all instances of  $x_i = u$  with  $x_i = v$ . We maintain the invariant that each intended word form’s most common surface form must be itself; this biases the model toward solutions with low distortion in the transducer.

### 4.1 Scoring merges

We write the change in the log posterior probability of the model resulting from a type merge of  $u$  to  $v$  as  $\Delta(u, v)$ , which factors into two terms, one depending on the surface string and the transducer, and the other depending on the string of intended words. In order to ensure that each intended word form’s most common surface form is itself, we define  $\Delta(u, v) = -\infty$  if  $u$  is more common than  $v$ .

We write the log probability of  $x$  being transduced to  $s$  as  $T(s|x)$ . If we merge  $u$  into  $v$ , we no longer

need to produce any surface forms from  $u$ , but instead we must derive them from  $v$ . If  $\#(\cdot)$  counts the occurrences of some event in the current state of the model, the transducer component of  $\Delta$  is:

$$\Delta_T = \sum_s \#(x_i=u, s_i=s)(T(s|v) - T(s|u)) \quad (1)$$

This term is typically negative, voting against a merge, since  $u$  is more similar to itself than to  $v$ .

The language modeling term relating to the intended string again factors into multiple components. The probability of a particular  $l_i, x_i, r_i$  can be broken into  $p(x_i)p(l_i|x_i)p(r_i|x_i)$  according to the model. We deal first with the  $p(x_i)$  unigram term, considering all tokens where  $x_i \in \{u, v\}$  and computing the probability  $p_u = p(x_i = u|x_i \in \{u, v\})$ . By definition of a Dirichlet process, the marginal over a subset of the variables will be Dirichlet, so for  $\alpha > 1$  we have the MAP estimate:

$$p_u = \frac{\#(x_i=u) + \alpha - 1}{\#(x_i \in \{u, v\}) + 2(\alpha - 1)} \quad (2)$$

$p_v = p(x_i = v|x_i \in \{u, v\})$  is computed similarly. If we decide to merge  $u$  into  $v$ , however, the probability  $p(x_i = v|x_i \in \{u, v\})$  becomes 1. The change in log-probability resulting from the merge is closely related to the entropy of the distribution:

$$\Delta_U = -\#(x_i=u) \log(p_u) - \#(x_i=v) \log(p_v) \quad (3)$$

This change must be positive and favors merging.

Next, we consider the change in probability from the left contexts (the derivations for right contexts are equivalent). If  $u$  and  $v$  are separate words, we generate their left contexts from different distributions  $p(l|u)$  and  $p(l|v)$ , while if they are merged, we must generate all the contexts from the same distribution  $p(l|\{u, v\})$ . This change is:

$$\begin{aligned} \Delta_L = & \sum_l \#(l, u) \{ \log(p(l|\{u, v\})) - \log(p(l|u)) \} \\ & + \sum_l \#(l, v) \{ \log(p(l|\{u, v\})) - \log(p(l|v)) \} \end{aligned}$$

In a full Bayesian model, we would integrate over the parameters of these distributions; instead, we use Kneser-Ney smoothing (Kneser and Ney, 1995) which has been shown to approximate the MAP solution of a hierarchical Pitman-Yor model (Teh, 2006;

Goldwater et al., 2006). The Kneser-Ney discount<sup>2</sup>  $d$  is a tunable parameter of our system, and controls whether the term favors merging or not. If  $d$  is small,  $p(l|u)$  and  $p(l|v)$  are close to their maximum-likelihood estimates, and  $\Delta_L$  is similar to a Jensen-Shannon divergence; it is always negative and discourages mergers. As  $d$  increases, however,  $p(l|u)$  for rare words approaches the prior distribution; in this case, merging two words may result in better posterior parameters than estimating both separately, since the combined estimate loses less mass to discounting.

Because neither the transducer nor the language model are perfect models of the true distribution, they can have incompatible dynamic ranges. Often, the transducer distribution is too peaked; to remedy this, we downweight the transducer probability by  $\lambda$ , a parameter of our model, which we set to .5. Downweighting of the acoustic model versus the LM is typical in speech recognition (Bahl et al., 1980).

To summarize, the full change in posterior is:

$$\Delta(u, v) = \Delta_U + \Delta_L + \Delta_R + \lambda \Delta_T \quad (4)$$

There are four parameters. The transducer regularization  $r = 1$  and unigram prior  $\alpha = 2$ , which we set ad-hoc, have little impact on performance. The Kneser-Ney discount  $d = 2$  and transducer downweight  $\lambda = .5$  have more influence and were tuned on development data.

## 4.2 Clustering algorithm

In the clustering phase, we start with an initial solution in which each surface form is its own intended pronunciation and iteratively improve this solution by merging together word types, picking (approximately) the best merger at each point.

We begin by computing a set of *candidate* mergers for each surface word type  $u$ . This step saves time by quickly rejecting mergers which are certain to get very low transducer scores. We reject a pair  $u, v$  if the difference in their length is greater than 4, or if both words are longer than 4 segments, but, when we consider them as unordered bags of segments, the Dice coefficient between them is less than .5.

For each word  $u$  and all its candidates  $v$ , we compute  $\Delta(u, v)$  as in Equation 4. We keep track of the

<sup>2</sup>We use one discount, rather than several as in modified KN.

**Input:** vocabulary of surface forms  $u$   
**Input:**  $C(u)$ : candidate intended forms of  $u$   
**Output:**  $intend(u)$ : intended form of  $u$   
**foreach**  $u \in vocab$  **do**  
  // initialization  
   $v^*(u) \leftarrow \operatorname{argmax}_{v \in C(u)} \Delta(u, v)$ ;  
   $\Delta^*(u) \leftarrow \Delta(u, v^*(u))$   
   $intend(u) \leftarrow u$   
  add  $u$  to queue  $Q$  with priority  $\Delta^*(u)$   
**while**  $top(Q) > -\infty$  **do**  
   $u \leftarrow pop(Q)$   
  recompute  $v^*(u), \Delta^*(u)$   
  **if**  $\Delta^*(u) > 0$  **then**  
    // merge  $u$  with best merger  
     $intend(u) \leftarrow v^*(u)$   
    update  $\Delta(x, u) \quad \forall x : v^*(x) = u$   
    remove  $u$  from  $C(x) \quad \forall x$   
    update  $\Delta(x, v) \quad \forall x : v^*(x) = v$   
    update  $\Delta(v, x) \quad \forall x \in C(v)$   
    **if** updated  $\Delta > \Delta^*$  for any words **then**  
      | reset  $\Delta^*, v^*$  for those words  
    // (these updates can  
      increase a word's priority  
      from  $-\infty$ )  
  **else if**  $\Delta^*(u) \neq -\infty$  **then**  
    // reject but leave in queue  
     $\Delta^*(u) \leftarrow -\infty$

**Algorithm 1:** Our clustering phase.

current best target  $v^*(u)$  and best score  $\Delta^*(u)$ , using a priority queue. At each step of the algorithm, we pop the  $u$  with the current best  $\Delta^*(u)$ , recompute its scores, and then merge it with  $v^*(u)$  if doing so would improve the model posterior. In an exact algorithm, we would then need to recompute most of the other scores, since merging  $u$  and  $v^*(u)$  affects other words for which  $u$  and  $v^*(u)$  are candidates, and also words for which they appear in the context set. However, recomputing all these scores would be extremely time-consuming.<sup>3</sup> Therefore, we recompute scores for only those words where the previous best merger was either  $u$  or  $v^*(u)$ . (If the best merge would *not* improve the probability, we reject it, but since its score might increase if we merge  $v^*(u)$ , we leave  $u$  in the queue, setting its  $\Delta$  score to  $-\infty$ ; this score will be updated if we merge  $v^*(u)$ .)

Since we recompute the exact scores  $\Delta(u, v)$  immediately before merging  $u$ , the algorithm is guaran-

<sup>3</sup>The transducer scores can be cached since they depend only on surface forms, but the language model scores cannot.

teed never to reduce the posterior probability. It can potentially make changes in the wrong order, since not all the  $\Delta$ s are recomputed in each step, but most changes do not affect one another, so performing them out of order has no impact. Empirically, we find that mutually exclusive changes (usually of the form  $(u, v)$  and  $(v, w)$ ) tend to differ enough in initial score that they are evaluated in the correct order.

### 4.3 Training the transducer

To train the transducer on a set of mappings between surface and intended forms, we find the maximum-probability state sequence for each mapping (another application of Viterbi EM) and extract features for each state and its output. Learning weights is then a maximum-entropy problem, which we solve using Orthant-wise Limited-memory Quasi-Newton.<sup>4</sup>

To construct our initial transducer, we first learn weights for the marginal distribution on surface sounds by training the max-ent system with only the bias features active. Next, we manually set weights (Table 1) for insertions and deletions, which do not appear on the surface, and for faithfulness features. Other features get an initial weight of 0.

## 5 Experiments

### 5.1 Dataset

Our corpus is a processed version of the Bernstein-Ratner corpus (Bernstein-Ratner, 1987) from CHILDES (MacWhinney, 2000), which contains orthographic transcriptions of parent-child dyads with infants aged 13-23 months. Brent and Cartwright (1996) created a phonemic version of this corpus by extracting all infant-directed utterances and converted them to a phonemic transcription using a dictionary. This version, which contains 9790 utterances (33399 tokens, 1321 types), is now standard for word segmentation, but contains no phonetic variability.

Since producing a close phonetic transcription of this data would be impractical, we instead construct an approximate phonetic version using information from the Buckeye corpus (Pitt et al., 2007). Buckeye is a corpus of adult-directed conversational American English, and has been phonetically transcribed

<sup>4</sup>We use the implementation of Andrew and Gao (2007) with an  $l_2$  regularizer and regularization parameter  $r = 1$ ; although this could be tuned, in practice it has little effect on results.

Feature	Weight
output-is- $x$	marginal $p(x)$
output-is- $\epsilon$	0
same-sound	5
same- $\{\text{place, voice, manner}\}$	2
insertion	-3

Table 1: Initial transducer weights.

“about”	ahbawt:15, bawt:9, ihbawt:4, ahbawd:4, ihbawd:4, ahbaat:2, baw:1, ahbaht:1, erbawd:1, bawd:1, ahbaad:1, ahpaat:1, bah:1, baht:1, ah:1, ahbahd:1, ehbaat:1, ahbaed:1, ihbaht:1, baot:1
“wanna”	waanah:94, waanih:37, wahnah:16, waan:13, wahnah:8, wahnih:5, wahnay:3, waanlih:3, wehnih:2, waaneh:2, waonih:2, waaah:1, wuhnih:1, wahn:1, waantah:1, waanaa:1, wowih:1, waiih:1, wah:1, waaniy:1

by hand to indicate realistic pronunciation variability. To create our phonetic corpus, we replace each phonemic word in the Bernstein-Ratner-Brent corpus with a phonetic pronunciation of that word sampled from the empirical distribution of pronunciations in Buckeye (Table 2). If the word never occurs in Buckeye, we use the original phonemic version.

Our corpus is not completely realistic as a sample of child-directed speech. Since each pronunciation is sampled independently, it lacks coarticulation and prosodic effects, and the distribution of pronunciations is derived from adult-directed rather than child-directed speech. Nonetheless, it represents phonetic variability more realistically than the Bernstein-Ratner-Brent corpus, while still maintaining the lexical characteristics of infant-directed speech (as compared to the Buckeye corpus, with its much larger vocabulary and more complex language model).

We conduct our development experiments on the first 8000 input utterances, holding out the remaining 1790 for evaluation. For evaluation experiments, we run the system on all 9790 utterances, reporting scores on only the last 1790.

## 5.2 Metrics

We evaluate our results by generalizing the three segmentation metrics from Goldwater et al. (2009): word boundary F-score, word token F-score, and lexicon (word type) F-score.

Figure 5: System scores over 5 iterations.

In our first set of experiments we evaluate how well our system clusters together surface forms derived from the same intended form, assuming gold standard word boundaries. We do not evaluate the induced intended forms directly against the gold standard intended forms—we want to evaluate cluster memberships and not labels. Instead we compute a one-to-one mapping between our induced lexical items and the gold standard, maximizing the agreement between the two (Haghighi and Klein, 2006). Using this mapping, we compute *mapped token F-score*<sup>5</sup> and *lexicon F-score*.

In our second set of experiments, we use unknown word boundaries and evaluate the segmentations. We report the standard word boundary F and *unlabeled word token F* as well as mapped F. The unlabeled token score counts correctly segmented tokens, whether assigned a correct intended form or not.

## 5.3 Known word boundaries

We first run our system with known word boundaries (Table 3). As a baseline, we treat every surface token as its own intended form (*none*). This baseline has fairly high accuracy; 65% of word tokens receive the most common pronunciation for their intended form.<sup>6</sup> As an upper bound, we find the best intended form for each surface type (*type unbound*). This correctly resolves 91% of tokens; the remaining error is due to homophones (surface types corresponding to more than one intended form). We also test our sys-

<sup>5</sup>When using the gold word boundaries, the precision and recall are equal and this is the same as the accuracy; in segmentation experiments the two differ, because with fewer segmentation boundaries, the system proposes fewer tokens. Only correctly segmented tokens which are also mapped to the correct form count as matches.

<sup>6</sup>The lexicon recall is not quite 100% because one rare word appears only as a homophone of another word.

System	Tok F	Lex P	Lex R	Lex F
none	65.4	50.2	99.7	66.7
initializer	75.2	83.2	73.3	78.0
system	79.2	87.1	75.9	81.1
oracle trans.	82.7	88.7	83.8	86.2
type ubound	91.0	97.5	98.0	97.7

Table 3: Results on 1790 utterances (known boundaries).

	Boundaries			Unlabeled Tokens		
	P	R	F	P	R	F
no var.	90.1	80.3	84.9	74.5	68.7	71.5
w/var.	70.4	93.5	80.3	56.5	69.7	62.4

Table 4: Degradation in `dpseg` segmentation performance caused by pronunciation variation.

	Mapped Tokens			Lexicon (types)		
	P	R	F	P	R	F
none	39.8	49.0	43.9	37.7	49.1	42.6
init	42.2	52.0	56.5	50.1	40.8	45.0
sys	44.2	54.5	48.8	48.6	43.1	45.7

Table 5: Results on 1790 utterances (induced boundaries).

tem using an oracle transducer (*oracle trans.*)—the transducer estimated from the upper-bound mapping. This scores 83%, showing that our articulatory feature set captures most, but not all, of the available information. At the beginning of bootstrapping, our system (*init*) scores 75%, but this improves to 79% after five iterations of reestimation (*system*). Most learning occurs in the first two or three iterations (Figure 5).

To determine the importance of different parts of our system, we run a few ablation tests on development data. Context information is critical to obtain a good solution; setting  $\Delta_L$  and  $\Delta_R$  to 0 lowers our dev token F-score from 83% to 75%. Initializing all feature weights to 0 yields a poor initial solution (18% dev token F instead of 75%), but after learning the result is only slightly lower than using the weights in Table 1 (78% rather than 80%), showing that the system is quite robust to initialization.

#### 5.4 Unknown word boundaries

As a simple extension of our model to the case of unknown word boundaries, we interleave it with an existing model of word segmentation, `dpseg` (Gold-

water et al., 2009).<sup>7</sup> In each iteration, we run the segmenter, then bootstrap our model for five iterations on the segmented output. We then concatenate the intended word sequence proposed by our model to produce the next iteration’s segmenter input.

Phonetic variation is known to reduce the performance of `dpseg` (Fleck, 2008; Boruta et al., 2011) and our experiments confirm this (Table 4). Using induced word boundaries also makes it harder to recover the lexicon (Table 5), lowering the baseline F-score from 67% to 43%. Nevertheless, our system improves the lexicon F-score to 46%, with token F rising from 44% to 49%, demonstrating the system’s ability to work without gold word boundaries. Unfortunately, performing multiple iterations between the segmenter and lexical-phonetic learner has little further effect; we hope to address this issue in future.

## 6 Conclusion

We have presented a noisy-channel model that simultaneously learns a lexicon, a bigram language model, and a model of phonetic variation, while using only the noisy surface forms as training data. It is the first model of lexical-phonetic acquisition to include word-level context and to be tested on an infant-directed corpus with realistic phonetic variability. Whether trained using gold standard or automatically induced word boundaries, the model recovers lexical items more effectively than a system that assumes no phonetic variability; moreover, the use of word-level context is key to the model’s success. Ultimately, we hope to extend the model to jointly infer word boundaries along with lexical-phonetic knowledge, and to work directly from acoustic input. However, we have already shown that lexical-phonetic learning from a broad-coverage corpus is possible, supporting the claim that infants acquire lexical and phonetic knowledge simultaneously.

# Discriminative Pronunciation Modeling: A Large-Margin, Feature-Rich Approach

Hao Tang, Joseph Keshet, and Karen Livescu

Toyota Technological Institute at Chicago

Chicago, IL USA

{haotang, jkeshet, klivescu}@ttic.edu

## Abstract

We address the problem of learning the mapping between words and their possible pronunciations in terms of sub-word units. Most previous approaches have involved generative modeling of the distribution of pronunciations, usually trained to maximize likelihood. We propose a discriminative, feature-rich approach using large-margin learning. This approach allows us to optimize an objective closely related to a discriminative task, to incorporate a large number of complex features, and still do inference efficiently. We test the approach on the task of lexical access; that is, the prediction of a word given a phonetic transcription. In experiments on a subset of the Switchboard conversational speech corpus, our models thus far improve classification error rates from a previously published result of 29.1% to about 15%. We find that large-margin approaches outperform conditional random field learning, and that the Passive-Aggressive algorithm for large-margin learning is faster to converge than the Pegasos algorithm.

## 1 Introduction

One of the problems faced by automatic speech recognition, especially of conversational speech, is that of modeling the mapping between words and their possible pronunciations in terms of sub-word units such as phones. While pronunciation dictionaries provide each word's *canonical* pronunciation(s) in terms of phoneme strings, running speech often includes pronunciations that differ greatly from

the dictionary. For example, some pronunciations of “probably” in the Switchboard conversational speech database are [p r aa b iy], [p r aa l iy], [p r ay], and [p ow ih] (Greenberg et al., 1996). While some words (e.g., common words) are more prone to such variation than others, the effect is extremely general: In the phonetically transcribed portion of Switchboard, fewer than half of the word tokens are pronounced canonically (Fosler-Lussier, 1999). In addition, pronunciation variants sometimes include sounds not present in the dictionary at all, such as nasalized vowels (“can’t” → [k ae\_n n t]) or fricatives introduced due to incomplete consonant closures (“legal” → [l iy g\_fr ix l]).<sup>1</sup> This variation makes pronunciation modeling one of the major challenges facing speech recognition (McAllaster et al., 1998; Jurafsky et al., 2001; Saraçlar and Khudanpur, 2004; Bourlard et al., 1999).<sup>2</sup>

Most efforts to address the problem have involved either learning alternative pronunciations and/or their probabilities (Holter and Svendsen, 1999) or using phonetic transformation (substitution, insertion, and deletion) rules, which can come from linguistic knowledge or be learned from data (Riley et al., 1999; Hazen et al., 2005; Hutchinson and Droppo, 2011). These have produced some improvements in recognition performance. However, they also tend to cause additional confusability due to the introduction of additional homonyms (Fosler-

<sup>1</sup>We use the ARPAbet phonetic alphabet with additional diacritics, such as [ \_n ] for nasalization and [ \_fr ] for frication.

<sup>2</sup>This problem is separate from the grapheme-to-phoneme problem, in which pronunciations are predicted from a word's spelling; here, we assume the availability of a dictionary of canonical pronunciations as is usual in speech recognition.

Lussier et al., 2002). Some other alternatives are articulatory pronunciation models, in which words are represented as multiple parallel sequences of articulatory features rather than single sequences of phones, and which outperform phone-based models on some tasks (Livescu and Glass, 2004; Jyothi et al., 2011); and models for learning edit distances between dictionary and actual pronunciations (Ristad and Yianilos, 1998; Filali and Bilmes, 2005).

All of these approaches are generative—i.e., they provide distributions over possible pronunciations given the canonical one(s)—and they are typically trained by maximizing the likelihood over training data. In some recent work, discriminative approaches have been proposed, in which an objective more closely related to the task at hand is optimized. For example, (Vinyals et al., 2009; Korkmazskiy and Juang, 1997) optimize a minimum classification error (MCE) criterion to learn the weights (equivalently, probabilities) of alternative pronunciations for each word; (Schramm and Beyerlein, 2001) use a similar approach with discriminative model combination. In this work, the weighted alternatives are then used in a standard (generative) speech recognizer. In other words, these approaches optimize generative models using discriminative criteria.

We propose a general, flexible discriminative approach to pronunciation modeling, rather than discriminatively optimizing a generative model. We formulate a linear model with a large number of word-level and subword-level feature functions, whose weights are learned by optimizing a discriminative criterion. The approach is related to the recently proposed segmental conditional random field (SCRF) approach to speech recognition (Zweig et al., 2011). The main differences are that we optimize large-margin objective functions, which lead to sparser, faster, and better-performing models than conditional random field optimization in our experiments; and we use a large set of different feature functions tailored to pronunciation modeling.

In order to focus attention on the pronunciation model alone, our experiments focus on a task that measures only the mapping between words and subword units. Pronunciation models have in the past been tested using a variety of measures. For generative models, phonetic error rate of generated pronunciations (Venkataramani and Byrne, 2001) and

phone- or frame-level perplexity (Riley et al., 1999; Jyothi et al., 2011) are appropriate measures. For our discriminative models, we consider the task of *lexical access*; that is, prediction of a single word given its pronunciation in terms of sub-word units (Fissore et al., 1989; Jyothi et al., 2011). This task is also sometimes referred to as “pronunciation recognition” (Ristad and Yianilos, 1998) or “pronunciation classification” (Filali and Bilmes, 2005.) As we show below, our approach outperforms both traditional phonetic rule-based models and the best previously published results on our data set obtained with generative articulatory approaches.

## 2 Problem setting

We define a *pronunciation of a word* as a representation of the way it is produced by a speaker in terms of some set of linguistically meaningful sub-word units. A pronunciation can be, for example, a sequence of phones or multiple sequences of *articulatory features* such as nasality, voicing, and tongue and lip positions. For purposes of this paper, we will assume that a pronunciation is a single sequence of units, but the approach applies to other representations. We distinguish between two types of pronunciations of a word: (i) *canonical* pronunciations, the ones typically found in the dictionary, and (ii) *surface* pronunciations, the ways a speaker may actually produce the word. In the task of *lexical access* we are given a surface pronunciation of a word, and our goal is to predict the word.

Formally, we define a pronunciation as a sequence of sub-word units  $\bar{p} = (p_1, p_2, \dots, p_K)$ , where  $p_k \in \mathcal{P}$  for all  $1 \leq k \leq K$  and  $\mathcal{P}$  is the set of all sub-word units. The index  $k$  can represent either a fixed-length frame or a variable-length segment.  $\mathcal{P}^*$  denotes the set of all finite-length sequences over  $\mathcal{P}$ . We denote a word by  $w \in \mathcal{V}$  where  $\mathcal{V}$  is the vocabulary. Our goal is to find a function  $f : \mathcal{P}^* \rightarrow \mathcal{V}$  that takes as input a surface pronunciation and returns the word from the vocabulary that was spoken.

In this paper we propose a discriminative supervised learning approach for learning the function  $f$  from a training set of pairs  $(\bar{p}, w)$ . We aim to find a function  $f$  that performs well on the training set as well as on unseen examples. Let  $\hat{w} = f(\bar{p})$  be the predicted word given the pronunciation  $\bar{p}$ . We assess the quality of the function  $f$  by the *zero-one loss*: if

$w \neq \hat{w}$  then the error is one, otherwise the error is zero. The goal of the learning process is to minimize the expected zero-one loss, where the expectation is taken with respect to a fixed but unknown distribution over words and surface pronunciations. In the next section we present a learning algorithm that aims to minimize the expected zero-one loss.

### 3 Algorithm

Similarly to previous work in structured prediction (Taskar et al., 2003; Tsochantaridis et al., 2005), we construct the function  $f$  from a predefined set of  $N$  feature functions,  $\{\phi_j\}_{j=1}^N$ , each of the form  $\phi_j : \mathcal{P}^* \times \mathcal{V} \rightarrow \mathbb{R}$ . Each feature function takes a surface pronunciation  $\bar{p}$  and a proposed word  $w$  and returns a scalar which, intuitively, should be correlated with whether the pronunciation  $\bar{p}$  corresponds to the word  $w$ . The feature functions map pronunciations of different lengths along with a proposed word to a vector of fixed dimension in  $\mathbb{R}^N$ . For example, one feature function might measure the Levenshtein distance between the pronunciation  $\bar{p}$  and the canonical pronunciation of the word  $w$ . This feature function counts the minimum number of edit operations (insertions, deletions, and substitutions) that are needed to convert the surface pronunciation to the canonical pronunciation; it is low if the surface pronunciation is close to the canonical one and high otherwise.

The function  $f$  maximizes a score relating the word  $w$  to the pronunciation  $\bar{p}$ . We restrict ourselves to scores that are linear in the feature functions, where each  $\phi_j$  is scaled by a weight  $\theta_j$ :

$$\sum_{j=1}^N \theta_j \phi_j(\bar{p}, w) = \boldsymbol{\theta} \cdot \boldsymbol{\phi}(\bar{p}, w),$$

where we have used vector notation for the feature functions  $\boldsymbol{\phi} = (\phi_1, \dots, \phi_N)$  and for the weights  $\boldsymbol{\theta} = (\theta_1, \dots, \theta_N)$ . Linearity is not a very strong restriction, since the feature functions can be arbitrarily non-linear. The function  $f$  is defined as the word  $w$  that maximizes the score,

$$f(\bar{p}) = \operatorname{argmax}_{w \in \mathcal{V}} \boldsymbol{\theta} \cdot \boldsymbol{\phi}(\bar{p}, w).$$

Our goal in learning  $\boldsymbol{\theta}$  is to minimize the expected zero-one loss:

$$\boldsymbol{\theta}^* = \operatorname{argmin}_{\boldsymbol{\theta}} \mathbb{E}_{(\bar{p}, w) \sim \rho} [\mathbb{1}_{w \neq f(\bar{p})}],$$

where  $\mathbb{1}_{\pi}$  is 1 if predicate  $\pi$  holds and 0 otherwise, and where  $\rho$  is an (unknown) distribution from which the examples in our training set are sampled i.i.d. Let  $S = \{(\bar{p}_1, w_1), \dots, (\bar{p}_m, w_m)\}$  be the training set. Instead of working directly with the zero-one loss, which is non-smooth and non-convex, we use the surrogate hinge loss, which upper-bounds the zero-one loss:

$$L(\boldsymbol{\theta}, \bar{p}_i, w_i) = \max_{w \in \mathcal{V}} \left[ \mathbb{1}_{w_i \neq w} - \boldsymbol{\theta} \cdot \boldsymbol{\phi}(\bar{p}_i, w_i) + \boldsymbol{\theta} \cdot \boldsymbol{\phi}(\bar{p}_i, w) \right]. \quad (1)$$

Finding the weight vector  $\boldsymbol{\theta}$  that minimizes the  $\ell^2$ -regularized average of this loss function is the structured support vector machine (SVM) problem (Taskar et al., 2003; Tsochantaridis et al., 2005):

$$\boldsymbol{\theta}^* = \operatorname{argmin}_{\boldsymbol{\theta}} \frac{\lambda}{2} \|\boldsymbol{\theta}\|^2 + \frac{1}{m} \sum_{i=1}^m L(\boldsymbol{\theta}, \bar{p}_i, w_i), \quad (2)$$

where  $\lambda$  is a user-defined tuning parameter that balances between regularization and loss minimization.

In practice, we have found that solving the quadratic optimization problem given in Eq. (2) converges very slowly using standard methods such as stochastic gradient descent (Shalev-Shwartz et al., 2007). We use a slightly different algorithm, the Passive-Aggressive (PA) algorithm (Crammer et al., 2006), whose average loss is comparable to that of the structured SVM solution (Keshet et al., 2007).

The Passive-Aggressive algorithm is an efficient online algorithm that, under some conditions, can be viewed as a dual-coordinate ascent minimizer of Eq. (2) (The connection to dual-coordinate ascent can be found in (Hsieh et al., 2008)). The algorithm begins by setting  $\boldsymbol{\theta} = \mathbf{0}$  and proceeds in rounds. In the  $t$ -th round the algorithm picks an example  $(\bar{p}_i, w_i)$  from  $S$  at random uniformly without replacement. Denote by  $\boldsymbol{\theta}^{t-1}$  the value of the weight vector before the  $t$ -th round. Let  $\hat{w}_i^t$  denote the predicted word for the  $i$ -th example according to  $\boldsymbol{\theta}^{t-1}$ :

$$\hat{w}_i^t = \operatorname{argmax}_{w \in \mathcal{V}} \boldsymbol{\theta}^{t-1} \cdot \boldsymbol{\phi}(\bar{p}_i, w) + \mathbb{1}_{w_i \neq w}.$$

Let  $\Delta \boldsymbol{\phi}_i^t = \boldsymbol{\phi}(\bar{p}_i, w_i) - \boldsymbol{\phi}(\bar{p}_i, \hat{w}_i^t)$ . Then the algorithm updates the weight vector  $\boldsymbol{\theta}^t$  as follows:

$$\boldsymbol{\theta}^t = \boldsymbol{\theta}^{t-1} + \alpha_i^t \Delta \boldsymbol{\phi}_i^t \quad (3)$$

where

$$\alpha_i^t = \min \left\{ \frac{1}{\lambda m}, \frac{\mathbb{1}_{w_i \neq \hat{w}_i^t} - \boldsymbol{\theta} \cdot \Delta \phi_i^t}{\|\Delta \phi_i^t\|} \right\}.$$

In practice we iterate over the  $m$  examples in the training set several times; each such iteration is an *epoch*. The final weight vector is set to the average over all weight vectors during training.

An alternative loss function that is often used to solve structured prediction problems is the *log-loss*:

$$L(\boldsymbol{\theta}, \bar{p}_i, w_i) = -\log P_{\boldsymbol{\theta}}(w_i | \bar{p}_i) \quad (4)$$

where the probability is defined as

$$P_{\boldsymbol{\theta}}(w_i | \bar{p}_i) = \frac{e^{\boldsymbol{\theta} \cdot \phi(\bar{p}_i, w_i)}}{\sum_{w \in \mathcal{V}} e^{\boldsymbol{\theta} \cdot \phi(\bar{p}_i, w)}}.$$

Minimization of Eq. (2) under the log-loss results in a probabilistic model commonly known as a conditional random field (CRF) (Lafferty et al., 2001). By taking the sub-gradient of Eq. (4), we can obtain an update rule similar to the one shown in Eq. (3).

## 4 Feature functions

Before defining the feature functions, we define some notation. Suppose  $\bar{p} \in \mathcal{P}^*$  is a sequence of sub-word units. We use  $\bar{p}_{1:n}$  to denote the  $n$ -gram substring  $p_1 \dots p_n$ . The two substrings  $\bar{a}$  and  $\bar{b}$  are said to be equal if they have the same length and  $a_i = b_i$  for  $1 \leq i \leq n$ . For a given sub-word unit  $n$ -gram  $\bar{u} \in \mathcal{P}^n$ , we use the shorthand  $\bar{u} \in \bar{p}$  to mean that we can find  $\bar{u}$  in  $\bar{p}$ ; i.e., there exists an index  $i$  such that  $\bar{p}_{i:i+n} = \bar{u}$ . We use  $|\bar{p}|$  to denote the length of the sequence  $\bar{p}$ .

We assume we have a pronunciation dictionary, which is a set of words and their baseforms. We access the dictionary through the function *pron*, which takes a word  $w \in \mathcal{V}$  and returns a set of baseforms.

### 4.1 TF-IDF feature functions

Term frequency (TF) and inverse document frequency (IDF) are measures that have been heavily used in information retrieval to search for documents using word queries (Salton et al., 1975). Similarly to (Zweig et al., 2010), we adapt TF and IDF by treating a sequence of sub-word units as a “document” and  $n$ -gram sub-sequences as “words.” In this analogy, we use sub-sequences in surface pronunciations to “search” for baseforms in the dictionary. These

features measure the frequency of each  $n$ -gram in observed pronunciations of a given word in the training set, along with the discriminative power of the  $n$ -gram. These features are therefore only meaningful for words actually observed in training.

The term frequency of a sub-word unit  $n$ -gram  $\bar{u} \in \mathcal{P}^n$  in a sequence  $\bar{p}$  is the length-normalized frequency of the  $n$ -gram in the sequence:

$$\text{TF}_{\bar{u}}(\bar{p}) = \frac{1}{|\bar{p}| - |\bar{u}| + 1} \sum_{i=1}^{|\bar{p}| - |\bar{u}| + 1} \mathbb{1}_{\bar{u} = \bar{p}_{i:i+|\bar{u}|-1}}.$$

Next, define the set of words in the training set that contain the  $n$ -gram  $\bar{u}$  as  $\mathcal{V}_{\bar{u}} = \{w \in \mathcal{V} \mid (\bar{p}, w) \in S, \bar{u} \in \bar{p}\}$ . The inverse document frequency (IDF) of an  $n$ -gram  $\bar{u}$  is defined as

$$\text{IDF}_{\bar{u}} = \log \frac{|\mathcal{V}|}{|\mathcal{V}_{\bar{u}}|}.$$

IDF represents the discriminative power of an  $n$ -gram: An  $n$ -gram that occurs in few words is better at word discrimination than a very common  $n$ -gram.

Finally, we define word-specific features using TF and IDF. Suppose the vocabulary is indexed:  $\mathcal{V} = \{w_1, \dots, w_n\}$ . Define  $\bar{e}_w$  as a binary vector with elements

$$(\bar{e}_w)_i = \mathbb{1}_{w_i = w}.$$

We define the TF-IDF feature function of  $\bar{u}$  as

$$\phi_{\bar{u}}(\bar{p}, w) = (\text{TF}_{\bar{u}}(\bar{p}) \times \text{IDF}_{\bar{u}}) \otimes \bar{e}_w,$$

where  $\otimes : \mathbb{R}^{a \times b} \times \mathbb{R}^{c \times d} \rightarrow \mathbb{R}^{ac \times bd}$  is the tensor product. We therefore have as many TF-IDF feature functions as we have  $n$ -grams. In practice, we only consider  $n$ -grams of a certain order (e.g., bigrams).

The following toy example demonstrates how the TF-IDF features are computed. Suppose we have  $\mathcal{V} = \{\text{problem, probably}\}$ . The dictionary maps “problem” to /pcl p r aa bcl b l ax m/ and “probably” to /pcl p r aa bcl b l iy/, and our input is  $(\bar{p}, w) = ([p r aa b l iy], \text{problem})$ . Then for the bigram /l iy/, we have  $\text{TF}_{/l iy/}(\bar{p}) = 1/5$  (one out of five bigrams in  $\bar{p}$ ), and  $\text{IDF}_{/l iy/} = \log(2/1)$  (one word out of two in the dictionary). The indicator vector is  $\bar{e}_{\text{problem}} = [1 \ 0]^T$ , so the final feature is

$$\phi_{/l iy/}(\bar{p}, w) = \begin{bmatrix} \frac{1}{5} \log \frac{2}{1} \\ 0 \end{bmatrix}.$$

## 4.2 Length feature function

The length feature functions measure how the length of a word’s surface form tends to deviate from the baseform. These functions are parameterized by  $a$  and  $b$  and are defined as

$$\phi_{a \leq \Delta \ell < b}(\bar{p}, w) = \mathbb{1}_{a \leq \Delta \ell < b} \otimes \bar{e}_w,$$

where  $\Delta \ell = |\bar{p}| - |\bar{v}|$ , for some baseform  $\bar{v} \in \text{pron}(w)$ . The parameters  $a$  and  $b$  can be either positive or negative, so the model can learn whether the surface pronunciations of a word tend to be longer or shorter than the baseform. Like the TF-IDF features, this feature is only meaningful for words actually observed in training.

As an example, suppose we have  $\mathcal{V} = \{\text{problem, probably}\}$ , and the word “probably” has two baseforms, /pcl p r aa bcl b l iy/ (of length eight) and /pcl p r aa bcl b ax bcl b l iy/ (of length eleven). If we are given an input  $(\bar{p}, w) = ([\text{pcl p r aa bcl l ax m}], \text{probably})$ , whose length of the surface form is eight, then the length features for the ranges  $0 \leq \Delta \ell < 1$  and  $-3 \leq \Delta \ell < -2$  are

$$\begin{aligned} \phi_{0 \leq \Delta \ell < 1}(\bar{p}, w) &= [0 \quad 1]^\top, \\ \phi_{-3 \leq \Delta \ell < -2}(\bar{p}, w) &= [0 \quad 1]^\top, \end{aligned}$$

respectively. Other length features are all zero.

## 4.3 Phonetic alignment feature functions

Beyond the length, we also measure specific phonetic deviations from the dictionary. We define phonetic alignment features that count the (normalized) frequencies of phonetic insertions, phonetic deletions, and substitutions of one surface phone for another baseform phone. Given  $(\bar{p}, w)$ , we use dynamic programming to align the surface form  $\bar{p}$  with all of the baseforms of  $w$ . Following (Riley et al., 1999), we encode a phoneme/phone with a 4-tuple: consonant manner, consonant place, vowel manner, and vowel place. Let the dash symbol “-” be a gap in the alignment (corresponding to an insertion/deletion). Given  $p, q \in \mathcal{P} \cup \{-\}$ , we say that a pair  $(p, q)$  is a deletion if  $p \in \mathcal{P}$  and  $q = -$ , is an insertion if  $p = -$  and  $q \in \mathcal{P}$ , and is a substitution if both  $p, q \in \mathcal{P}$ . Given  $p, q \in \mathcal{P} \cup \{-\}$ , let  $(s_1, s_2, s_3, s_4)$  and  $(t_1, t_2, t_3, t_4)$  be the corresponding 4-tuple encoding of  $p$  and  $q$ , respectively. The

	p	r	aa	pcl	p	er	l	iy	
pcl	p	r	aa	bcl	b	-	l	iy	
	p	r	aa	pcl	p	er	-	-	l iy
pcl	p	r	aa	bcl	b	ax	bcl	b	l iy

Table 1: Possible alignments of [p r aa pcl p er l iy] with two baseforms of “probably” in the dictionary.

similarity between  $p$  and  $q$  is defined as

$$s(p, q) = \begin{cases} 1, & \text{if } p = - \text{ or } q = -; \\ \sum_{i=1}^4 \mathbb{1}_{s_i=t_i}, & \text{otherwise.} \end{cases}$$

Consider aligning  $\bar{p}$  with the  $K_w = |\text{pron}(w)|$  baseforms of  $w$ . Define the length of the alignment with the  $k$ -th baseform as  $L_k$ , for  $1 \leq k \leq K_w$ . The resulting alignment is a sequence of pairs  $(a_{k,1}, b_{k,1}), \dots, (a_{k,L_k}, b_{k,L_k})$ , where  $a_{k,i}, b_{k,i} \in \mathcal{P} \cup \{-\}$  for  $1 \leq i \leq L_k$ . Now we define the alignment features, given  $p, q \in \mathcal{P} \cup \{-\}$ , as

$$\phi_{p \rightarrow q}(\bar{p}, w) = \frac{1}{Z_p} \sum_{k=1}^{K_w} \sum_{i=1}^{L_k} \mathbb{1}_{a_{k,i}=p, b_{k,i}=q},$$

where the normalization term is

$$Z_p = \begin{cases} \sum_{k=1}^{K_w} \sum_{i=1}^{L_k} \mathbb{1}_{a_{k,i}=p}, & \text{if } p \in \mathcal{P}; \\ |\bar{p}| \cdot K_w & \text{if } p = -. \end{cases}$$

The normalization for insertions differs from the normalization for substitutions and deletions, so that the resulting values always lie between zero and one.

As an example, consider the input pair  $(\bar{p}, w) = ([\text{p r aa pcl p er l iy}], \text{probably})$  and suppose there are two baseforms of the word “probably” in the dictionary. Let one possible alignments be the one shown in Table 1. Since /p/ occurs four times in the alignments and two of them are aligned to [b], the feature for  $p \rightarrow b$  is then  $\phi_{p \rightarrow b}(\bar{p}, w) = 2/4$ .

Unlike the TF-IDF feature functions and the length feature functions, the alignment feature functions can assign a non-zero score to words that are not seen at training time (but are in the dictionary), as long as there is a good alignment with their baseforms. The weights given to the alignment features are the analogue of substitution, insertion, and deletion rule probabilities in traditional phone-based pronunciation models such as (Riley et al., 1999); they can also be seen as a generalized version of the Levenshtein features of (Zweig et al., 2011).

#### 4.4 Dictionary feature function

The dictionary feature is an indicator of whether a pronunciation is an exact match to a baseform, which also generalizes to words unseen in training. We define the dictionary feature as

$$\phi_{\text{dict}}(\bar{p}, w) = \mathbb{1}_{\bar{p} \in \text{pron}(w)}.$$

For example, assume there is a baseform /pɫ p r aa bɫ b l iy/ for the word “probably” in the dictionary, and  $\bar{p} = \text{/pɫ p r aa bɫ b l iy/}$ . Then  $\phi_{\text{dict}}(\bar{p}, \text{probably}) = 1$ , while  $\phi_{\text{dict}}(\bar{p}, \text{problem}) = 0$ .

#### 4.5 Articulatory feature functions

Articulatory models represented as dynamic Bayesian networks (DBNs) have been successful in the past on the lexical access task (Livescu and Glass, 2004; Jyothi et al., 2011). In such models, pronunciation variation is seen as the result of asynchrony between the articulators (lips, tongue, etc.) and deviations from the intended articulatory positions. Given a sequence  $\bar{p}$  and a word  $w$ , we use the DBN to produce an alignment at the articulatory level, which is a sequence of 7-tuples, representing the articulatory variables<sup>3</sup> lip opening, tongue tip location and opening, tongue body location and opening, velum opening, and glottis opening. We extract three kinds of features from the output—substitutions, asynchrony, and log-likelihood.

The substitution features are similar to the phonetic alignment features in Section 4.3, except that the alignment is not a sequence of pairs but a sequence of 14-tuples (7 for the baseform and 7 for the surface form). The DBN model is based on articulatory phonology (Browman and Goldstein, 1992), in which there are no insertions and deletions, only substitutions (apparent insertions and deletions are accounted for by articulatory asynchrony). Formally, consider the seven sets of articulatory variable values  $F_1, \dots, F_7$ . For example,  $F_1$  could be all of the values of lip opening,  $F_1 = \{\text{closed, critical, narrow, wide}\}$ . Let  $\mathcal{F} = \{F_1, \dots, F_7\}$ . Consider an articulatory variable  $F \in \mathcal{F}$ . Suppose the alignment for  $F$  is  $(a_1, b_1), \dots, (a_L, b_L)$ , where  $L$

<sup>3</sup>We use the term “articulatory variable” for the “articulatory features” of (Livescu and Glass, 2004; Jyothi et al., 2011), in order to avoid confusion with our feature functions.

is the length of the alignment and  $a_i, b_i \in F$ , for  $1 \leq i \leq L$ . Here the  $a_i$  are the intended articulatory variable values according to the baseform, and the  $b_i$  are the corresponding realized values. For each  $a, b \in F$  we define a substitution feature function:

$$\phi_{a \rightarrow b}(\bar{p}, w) = \frac{1}{L} \sum_{i=1}^L \mathbb{1}_{a_i=a, b_i=b}.$$

The asynchrony features are also extracted from the DBN alignments. Articulators are not always synchronized, which is one cause of pronunciation variation. We measure this by looking at the phones that two articulators are aiming to produce, and find the time difference between them. Formally, we consider two articulatory variables  $F_h, F_k \in \mathcal{F}$ . Let the alignment between the two variables be  $(a_1, b_1), \dots, (a_L, b_L)$ , where now  $a_i \in F_h$  and  $b_i \in F_k$ . Each  $a_i$  and  $b_i$  can be mapped back to the corresponding phone index  $t_{h,i}$  and  $t_{k,i}$ , for  $1 \leq i \leq L$ . The average degree of asynchrony is then defined as

$$\text{async}(F_h, F_k) = \frac{1}{L} \sum_{i=1}^L (t_{h,i} - t_{k,i}).$$

More generally, we compute the average asynchrony between any two sets of variables  $\mathcal{F}_1, \mathcal{F}_2 \subset \mathcal{F}$  as

$$\text{async}(\mathcal{F}_1, \mathcal{F}_2) = \frac{1}{L} \sum_{i=1}^L \left[ \frac{1}{|\mathcal{F}_1|} \sum_{F_h \in \mathcal{F}_1} t_{h,i} - \frac{1}{|\mathcal{F}_2|} \sum_{F_k \in \mathcal{F}_2} t_{k,i} \right].$$

We then define the asynchrony features as

$$\phi_{a \leq \text{async}(\mathcal{F}_1, \mathcal{F}_2) \leq b} = \mathbb{1}_{a \leq \text{async}(\mathcal{F}_1, \mathcal{F}_2) \leq b}.$$

Finally, the log-likelihood feature is the DBN alignment score, shifted and scaled so that the value lies between zero and one,

$$\phi_{\text{dbn-LL}}(\bar{p}, w) = \frac{\mathcal{L}(\bar{p}, w) - h}{c},$$

where  $\mathcal{L}$  is the log-likelihood function of the DBN,  $h$  is the shift, and  $c$  is the scale.

Note that none of the DBN features are word-specific, so that they generalize to words in the dictionary that are unseen in the training set.

## 5 Experiments

All experiments are conducted on a subset of the Switchboard conversational speech corpus that has

been labeled at a fine phonetic level (Greenberg et al., 1996); these phonetic transcriptions are the input to our lexical access models. The data subset, phone set  $\mathcal{P}$ , and dictionary are the same as ones previously used in (Livescu and Glass, 2004; Jyothi et al., 2011). The dictionary contains 3328 words, consisting of the 5000 most frequent words in Switchboard, excluding ones with fewer than four phones in their baseforms. The baseforms use a similar, slightly smaller phone set (lacking, e.g., nasalization). We measure performance by error rate (ER), the proportion of test examples predicted incorrectly.

The TF-IDF features used in the experiments are based on phone bigrams. For all of the articulatory DBN features, we use the DBN from (Livescu, 2005) (the one in (Jyothi et al., 2011) is more sophisticated and may be used in future work). For the asynchrony features, the articulatory pairs are  $(\mathcal{F}_1, \mathcal{F}_2) \in \{(\{\text{tongue tip}\}, \{\text{tongue body}\}), (\{\text{lip opening}\}, \{\text{tongue tip, tongue body}\}), (\{\text{lip opening, tongue tip, tongue body}\}, \{\text{glottis, velum}\})\}$ , as in (Livescu, 2005). The parameters  $(a, b)$  of the length and asynchrony features are drawn from  $(a, b) \in \{(-3, -2), (-2, -1), \dots, (2, 3)\}$ .

We compare the CRF<sup>4</sup>, Passive-Aggressive (PA), and Pegasus learning algorithms. The regularization parameter  $\lambda$  is tuned on the development set. We run all three algorithms for multiple epochs and pick the best epoch based on development set performance.

For the first set of experiments, we use the same division of the corpus as in (Livescu and Glass, 2004; Jyothi et al., 2011) into a 2492-word training set, a 165-word development set, and a 236-word test set. To give a sense of the difficulty of the task, we test two simple baselines. One is a lexicon lookup: If the surface form is found in the dictionary, predict the corresponding word; otherwise, guess randomly. For a second baseline, we calculate the Levenshtein (0-1 edit) distance between the input pronunciation and each dictionary baseform, and predict the word corresponding to the baseform closest to the input. The results are shown in the first two rows of Table 2. We can see that, by adding just the Levenshtein distance, the error rate drops signifi-

<sup>4</sup>We use the term ‘‘CRF’’ since the learning algorithm corresponds to CRF learning, although the task is multiclass classification rather than a sequence or structure prediction task.

Model	ER
lexicon lookup (from (Livescu, 2005))	59.3%
lexicon + Levenshtein distance	41.8%
(Jyothi et al., 2011)	29.1%
CRF/DP+	21.5%
PA/DP+	<b>15.2%</b>
Pegasus/DP+	<b>14.8%</b>
PA/ALL	<b>15.2%</b>

Table 2: Lexical access error rates (ER) on the same data split as in (Livescu and Glass, 2004; Jyothi et al., 2011). Models labeled X/Y use learning algorithm X and feature set Y. The feature set DP+ contains TF-IDF, DP alignment, dictionary, and length features. The set ALL contains DP+ and the articulatory DBN features. The best results are in bold; the differences among them are insignificant (according to McNemar’s test with  $p = .05$ ).

icantly. However, both baselines do quite poorly.

Table 2 shows the best previous result on this data set from the articulatory model of Jyothi et al., which greatly improves over our baselines as well as over a much more complex phone-based model (Jyothi et al., 2011). The remaining rows of Table 2 give results with our feature functions and various learning algorithms. The best result for PA/DP+ (the PA algorithm using all features besides the DBN features) on the development set is with  $\lambda = 100$  and 5 epochs. Tested on the test set, this model improves over (Jyothi et al., 2011) by 13.9% absolute (47.8% relative). The best result for Pegasus with the same features on the development set is with  $\lambda = 0.01$  and 10 epochs. On the test set, this model gives a 14.3% absolute improvement (49.1% relative). CRF learning with the same features performs about 6% worse than the corresponding PA and Pegasus models.

The single-threaded running time for PA/DP+ and Pegasus/DP+ is about 40 minutes per epoch, measured on a dual-core AMD 2.4GHz CPU with 8GB of memory; for CRF, it takes about 100 minutes for each epoch, which is almost entirely because the weight vector  $\theta$  is less sparse with CRF learning. In the PA and Pegasus algorithms, we only update  $\theta$  for the most confusable word, while in CRF learning, we sum over all words. In our case, the number of non-zero entries in  $\theta$  for PA and Pegasus is around 800,000; for CRF, it is over 4,000,000. Though PA and Pegasus take roughly the same amount of time per epoch, Pegasus tends to require more epochs to

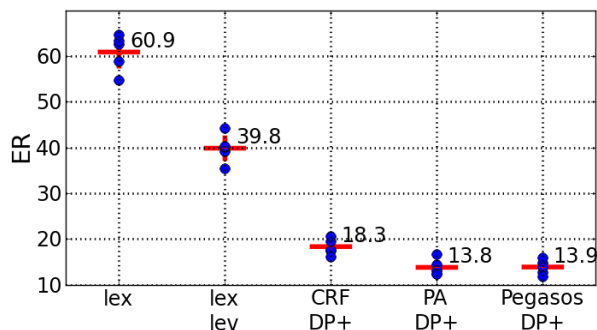

Figure 1: 5-fold cross validation (CV) results. The lexicon lookup baseline is labeled *lex*; *lex + lev* = lexicon lookup with Levenshtein distance. Each point corresponds to the test set error rate for one of the 5 data splits. The horizontal red line marks the mean of the results with means labeled, and the vertical red line indicates the mean plus and minus one standard deviation.

achieve the same performance as PA.

For the second experiment, we perform 5-fold cross-validation. We combine the training, development, and test sets from the previous experiment, and divide the data into five folds. We take three folds for training, one fold for tuning  $\lambda$  and the best epoch, and the remaining fold for testing. The results on the test fold are shown in Figure 1, which compares the learning algorithms, and Figure 2, which compares feature sets. Overall, the results are consistent with our first experiment. The feature selection experiments in Figure 2 shows that the TF-IDF features alone are quite weak, while the dynamic programming alignment features alone are quite good. Combining the two gives close to our best result. Although the marginal improvement gets smaller as we add more features, in general performance keeps improving the more features we add.

## 6 Discussion

The results in Section 5 are the best obtained thus far on the lexical access task on this conversational data set. Large-margin learning, using the Passive-Aggressive and Pegasus algorithms, has benefits over CRF learning for our task: It produces sparser models, is faster, and produces better lexical access results. In addition, the PA algorithm is faster than Pegasus on our task, as it requires fewer epochs.

Our ultimate goal is to incorporate such models into complete speech recognizers, that is to predict word sequences from acoustics. This requires (1)

Figure 2: Feature selection results for five-fold cross validation. In the figure, phone bigram TF-IDF is labeled *p2*; phonetic alignment with dynamic programming is labeled *DP*. The dots and lines are as defined in Figure 1.

extension of the model and learning algorithm to word sequences and (2) feature functions that relate acoustic measurements to sub-word units. The extension to sequences can be done analogously to segmental conditional random fields (SCRFs). The main difference between SCRFs and our approach would be the large-margin learning, which can be straightforwardly applied to sequences. To incorporate acoustics, we can use feature functions based on classifiers of sub-word units, similarly to previous work on CRF-based speech recognition (Gunawardana et al., 2005; Morris and Fosler-Lussier, 2008; Prabhavalkar et al., 2011). Richer, longer-span (e.g., word-level) feature functions are also possible.

Thus far we have restricted the pronunciation-to-word score to linear combinations of feature functions. This can be extended to non-linear combinations using a kernel. This may be challenging in a high-dimensional feature space. One possibility is to approximate the kernels as in (Keshet et al., 2011). Additional extensions include new feature functions, such as context-sensitive alignment features, and joint inference and learning of the alignment models embedded in the feature functions.

## Abstract

The integration of multiword expressions in a parsing procedure has been shown to improve accuracy in an artificial context where such expressions have been perfectly pre-identified. This paper evaluates two empirical strategies to integrate multiword units in a real constituency parsing context and shows that the results are not as promising as has sometimes been suggested. Firstly, we show that pre-grouping multiword expressions before parsing with a state-of-the-art recognizer improves multiword recognition accuracy and unlabeled attachment score. However, it has no statistically significant impact in terms of F-score as incorrect multiword expression recognition has important side effects on parsing. Secondly, integrating multiword expressions in the parser grammar followed by a reranker specific to such expressions slightly improves all evaluation metrics.

## 1 Introduction

The integration of Multiword Expressions (MWE) in real-life applications is crucial because such expressions have the particularity of having a certain level of idiomaticity. They form complex lexical units which, if they are considered, should significantly help parsing.

From a theoretical point of view, the integration of multiword expressions in the parsing procedure has been studied for different formalisms: Head-Driven Phrase Structure Grammar (Copestake *et al.*, 2002), Tree Adjoining Grammars (Schuler and Joshi, 2011), etc. From an empirical point of

view, their incorporation has also been considered such as in (Nivre and Nilsson, 2004) for dependency parsing and in (Arun and Keller, 2005) in constituency parsing. Although experiments always relied on a corpus where the MWEs were perfectly pre-identified, they showed that pre-grouping such expressions could significantly improve parsing accuracy. Recently, Green *et al.* (2011) proposed integrating the multiword expressions directly in the grammar without pre-recognizing them. The grammar was trained with a reference treebank where MWEs were annotated with a specific non-terminal node.

Our proposal is to evaluate two discriminative strategies in a real constituency parsing context: (a) pre-grouping MWE before parsing; this would be done with a state-of-the-art recognizer based on Conditional Random Fields; (b) parsing with a grammar including MWE identification and then reranking the output parses thanks to a Maximum Entropy model integrating MWE-dedicated features. (a) is the direct realistic implementation of the standard approach that was shown to reach the best results (Arun and Keller, 2005). We will evaluate if real MWE recognition (MWER) still positively impacts parsing, i.e., whether incorrect MWER does not negatively impact the overall parsing system. (b) is a more innovative approach to MWER (despite not being new in parsing): we select the final MWE segmentation after parsing in order to explore as many parses as possible (as opposed to method (a)). The experiments were carried out on the French Treebank (Abeillé *et al.*, 2003) where MWEs are annotated.

The paper is organized as follows: section 2 is an overview of the multiword expressions and their identification in texts; section 3 presents the two different strategies and their associated models; section 4 describes the resources used for our experiments (the corpus and the lexical resources); section 5 details the features that are incorporated in the models; section 6 reports on the results obtained.

## 2 Multiword expressions

### 2.1 Overview

Multiword expressions are lexical items made up of multiple lexemes that undergo idiosyncratic constraints and therefore offer a certain degree of idiomatity. They cover a wide range of linguistic phenomena: fixed and semi-fixed expressions, light verb constructions, phrasal verbs, named entities, etc. They may be contiguous (e.g. *traffic light*) or discontinuous (e.g. *John took your argument into account*). They are often divided into two main classes: multiword expressions defined through linguistic idiomatity criteria (*lexicalized phrases* in the terminology of Sag *et al.* (2002)) and those defined by statistical ones (i.e. simple collocations). Most linguistic criteria used to determine whether a combination of words is a MWE are based on syntactic and semantic tests such as the ones described in (Gross, 1986). For instance, the utterance *at night* is a MWE because it does display a strict lexical restriction (*\*at day*, *\*at afternoon*) and it does not accept any inserting material (*\*at cold night*, *\*at present night*). Such linguistically defined expressions may overlap with collocations which are the combinations of two or more words that cooccur more often than by chance. Collocations are usually identified through statistical association measures. A detailed description of MWEs can be found in (Baldwin and Nam, 2010).

In this paper, we focus on contiguous MWEs that form a lexical unit which can be marked by a part-of-speech tag (e.g. *at night* is an adverb, *because of* is a preposition). They can undergo limited morphological and lexical variations – e.g. *traffic (light+lights)*, *(apple+orange+...) juice* – and usually do not allow syntactic variations<sup>1</sup> such as inserts (e.g. *\*at*

<sup>1</sup>Such MWEs may very rarely accept inserts, often limited to single word modifiers: e.g. *in the short term*, *in the very short*

*cold night*). Such expressions can be analyzed at the lexical level. In what follows, we use the term *compounds* to denote such expressions.

### 2.2 Identification

The idiomatity property of MWEs makes them both crucial for Natural Language Processing applications and difficult to predict. Their actual identification in texts is therefore fundamental. There are different ways for achieving this objective. The simpler approach is lexicon-driven and consists in looking the MWEs up in an existing lexicon, such as in (Silberztein, 2000). The main drawback is that this procedure entirely relies on a lexicon and is unable to discover unknown MWEs. The use of collocation statistics is therefore useful. For instance, for each candidate in the text, Watrin and François (2011) compute on the fly its association score from an external ngram base learnt from a large raw corpus, and tag it as MWE if the association score is greater than a threshold. They reach excellent scores in the framework of a keyword extraction task. Within a validation framework (i.e. with the use of a reference corpus annotated in MWEs), Ramisch *et al.* (2010) developed a Support Vector Machine classifier integrating features corresponding to different collocation association measures. The results were rather low on the Genia corpus and Green *et al.* (2011) confirmed these bad results on the French Treebank. This can be explained by the fact that such a method does not make any distinctions between the different types of MWEs and the reference corpora are usually limited to certain types of MWEs. Furthermore, the lexicon-driven and collocation-driven approaches do not take the context into account, and therefore cannot discard some of the incorrect candidates. A recent trend is to couple MWE recognition with a linguistic analyzer: a POS tagger (Constant and Sigogne, 2011) or a parser (Green *et al.*, 2011). Constant and Sigogne (2011) trained a unified Conditional Random Fields model integrating different standard tagging features and features based on external lexical resources. They show a general tagging accuracy of 94% on the French Treebank. In terms of Multiword expression recognition, the accuracy was not

*term.*

clearly evaluated, but seemed to reach around 70-80% F-score. Green *et al.* (2011) proposed to include the MWER in the grammar of the parser. To do so, the MWEs in the training treebank were annotated with specific non-terminal nodes. They used a Tree Substitution Grammar instead of a Probabilistic Context-free Grammar (PCFG) with latent annotations in order to capture lexicalized rules as well as general rules. They showed that this formalism was more relevant to MWER than PCFG (71% F-score vs. 69.5%). Both methods have the advantage of being able to discover new MWEs on the basis of lexical and syntactic contexts. In this paper, we will take advantage of the methods described in this section by integrating them as features of a MWER model.

### 3 Two strategies, two discriminative models

#### 3.1 Pre-grouping Multiword Expressions

MWER can be seen as a sequence labelling task (like chunking) by using an IOB-like annotation scheme (Ramshaw and Marcus, 1995). This implies a theoretical limitation: recognized MWEs must be contiguous. The proposed annotation scheme is therefore theoretically weaker than the one proposed by Green *et al.* (2011) that integrates the MWER in the grammar and allows for discontinuous MWEs. Nevertheless, in practice, the compounds we are dealing with are very rarely discontinuous and if so, they solely contain a single word insert that can be easily integrated in the MWE sequence. Constant and Sigogne (2011) proposed to combine MWE segmentation and part-of-speech tagging into a single sequence labelling task by assigning to each token a tag of the form TAG+X where TAG is the part-of-speech (POS) of the lexical unit the token belongs to and X is either B (i.e. the token is at the beginning of the lexical unit) or I (i.e. for the remaining positions): *John/N+B hates/V+B traffic/N+B jams/N+I*. In this paper, as our task consists in jointly locating and tagging MWEs, we limited the POS tagging to MWEs only (TAG+B/TAG+I), simple words being tagged by O (outside): *John/O hates/O traffic/N+B jams/N+I*.

For such a task, we used Linear chain Conditional Random Fields (CRF) that are discriminative prob-

abilistic models introduced by Lafferty *et al.* (2001) for sequential labelling. Given an input sequence of tokens  $x = (x_1, x_2, \dots, x_N)$  and an output sequence of labels  $y = (y_1, y_2, \dots, y_N)$ , the model is defined as follows:

$$P_\lambda(y|x) = \frac{1}{Z(x)} \cdot \sum_t \sum_k \log \lambda_k \cdot f_k(t, y_t, y_{t-1}, x)$$

where  $Z(x)$  is a normalization factor depending on  $x$ . It is based on  $K$  features each of them being defined by a binary function  $f_k$  depending on the current position  $t$  in  $x$ , the current label  $y_t$ , the preceding one  $y_{t-1}$  and the whole input sequence  $x$ . The tokens  $x_i$  of  $x$  integrate the lexical value of this token but can also integrate basic properties which are computable from this value (for example: whether it begins with an upper case, it contains a number, its tags in an external lexicon, etc.). The feature is activated if a given configuration between  $t, y_t, y_{t-1}$  and  $x$  is satisfied (i.e.  $f_k(t, y_t, y_{t-1}, x) = 1$ ). Each feature  $f_k$  is associated with a weight  $\lambda_k$ . The weights are the parameters of the model, to be estimated. The features used for MWER will be described in section 5.

#### 3.2 Reranking

Discriminative reranking consists in reranking the  $n$ -best parses of a baseline parser with a discriminative model, hence integrating features associated with each node of the candidate parses. Charniak and Johnson (2005) introduced different features that showed significant improvement in general parsing accuracy (e.g. around +1 point in English). Formally, given a sentence  $s$ , the reranker selects the best candidate parse  $p$  among a set of candidates  $P(s)$  with respect to a scoring function  $V_\theta$ :

$$p^* = \operatorname{argmax}_{p \in P(s)} V_\theta(p)$$

The set of candidates  $P(s)$  corresponds to the  $n$ -best parses generated by the baseline parser. The scoring function  $V_\theta$  is the scalar product of a parameter vector  $\theta$  and a feature vector  $f$ :

$$V_\theta(p) = \theta \cdot f(p) = \sum_{j=1}^m \theta_j \cdot f_j(p)$$

where  $f_j(p)$  corresponds to the number of occurrences of the feature  $f_j$  in the parse  $p$ . According to

Charniak and Johnson (2005), the first feature  $f_1$  is the probability of  $p$  provided by the baseline parser. The vector  $\theta$  is estimated during the training stage from a reference treebank and the baseline parser outputs.

In this paper, we slightly deviate from the original reranker usage, by focusing on improving MWER in the context of parsing. Given the  $n$ -best parses, we want to select the one with the best MWE segmentation by keeping the overall parsing accuracy as high as possible. We therefore used MWE-dedicated features that we describe in section 5. The training stage was performed by using a Maximum entropy algorithm as in (Charniak and Johnson, 2005).

## 4 Resources

### 4.1 Corpus

The French Treebank<sup>2</sup> [FTB] (Abeillé *et al.*, 2003) is a syntactically annotated corpus made up of journalistic articles from *Le Monde* newspaper. We used the latest edition of the corpus (June 2010) that we preprocessed with the Stanford Parser preprocessing tools (Green *et al.*, 2011). It contains 473,904 tokens and 15,917 sentences. One benefit of this corpus is that its compounds are marked. Their annotation was driven by linguistic criteria such as the ones in (Gross, 1986). Compounds are identified with a specific non-terminal symbol "MWX" where X is the part-of-speech of the expression. They have a flat structure made of the part-of-speech of their components as shown in figure 1.

Figure 1: Subtree of MWE *part de marché* (market share): The MWN node indicates that it is a multiword noun; it has a flat internal structure N P N (noun – preposition – noun)

The French Treebank is composed of 435,860 lexical units (34,178 types). Among them, 5.3% are compounds (20.8% for types). In addition, 12.9%

<sup>2</sup><http://www.llf.cnrs.fr/Gens/Abeille/French-Treebank-fr.php>

of the tokens belong to a MWE, which, on average, has 2.7 tokens. The non-terminal tagset is composed of 14 part-of-speech labels and 24 phrasal ones (including 11 MWE labels). The train/dev/test split is the same as in (Green *et al.*, 2011): 1,235 sentences for test, 1,235 for development and 13,347 for training. The development and test sections are the same as those generally used for experiments in French, e.g. (Candito and Crabbé, 2009).

### 4.2 Lexical resources

French is a resource-rich language as attested by the existing morphological dictionaries which include compounds. In this paper, we use two large-coverage general-purpose dictionaries: Dela (Courtois, 1990; Courtois *et al.*, 1997) and Leff (Sagot, 2010). The Dela was manually developed in the 90's by a team of linguists. We used the distribution freely available in the platform Unitex<sup>3</sup> (Paumier, 2011). It is composed of 840,813 lexical entries including 104,350 multiword ones (91,030 multiword nouns). The compounds present in the resources respect the linguistic criteria defined in (Gross, 1986). The leff is a freely available dictionary<sup>4</sup> that has been automatically compiled by drawing from different sources and that has been manually validated. We used a version with 553,138 lexical entries including 26,311 multiword ones (22,673 multiword nouns). Their different modes of acquisition makes those two resources complementary. In both, lexical entries are composed of a inflected form, a lemma, a part-of-speech and morphological features. The Dela has an additional feature for most of the multiword entries: their syntactic surface form. For instance, *eau de vie* (brandy) has the feature NDN because it has the internal flat structure noun – preposition *de* – noun.

In order to compare compounds in these lexical resources with the ones in the French Treebank, we applied on the development corpus the dictionaries and the lexicon extracted from the training corpus. By a simple look-up, we obtained a preliminary lexicon-based MWE segmentation. The results are provided in table 1. They show that the use of external resources may improve recall, but they lead

<sup>3</sup><http://igm.univ-mlv.fr/~unitex>

<sup>4</sup><http://atoll.inria.fr/~sagot/leff.html>

to a decrease in precision as numerous MWEs in the dictionaries are not encoded as such in the reference corpus; in addition, the FTB suffers from some inconsistency in the MWE annotations.

	T	L	D	T+L	T+D	T+L+D
recall	75.9	31.7	59.0	77.3	83.4	84.0
precision	61.2	52.0	55.6	58.7	51.2	49.9
f-score	67.8	39.4	57.2	66.8	63.4	62.6

Table 1: Simple context-free application of the lexical resources on the development corpus: T is the MWE lexicon of the training corpus, L is the lefff, D is the Dela. The given scores solely evaluate MWE segmentation and not tagging.

In terms of statistical collocations, Watrin and François (2011) described a system that lists all the potential nominal collocations of a given sentence along with their association measure. The authors provided us with a list of 17,315 candidate nominal collocations occurring in the French treebank with their log-likelihood and their internal flat structure.

## 5 MWE-dedicated Features

The two discriminative models described in section 3 require MWE-dedicated features. In order to make these models comparable, we use two comparable sets of feature templates: one adapted to sequence labelling (CRF-based MWER) and the other one adapted to reranking (MaxEnt-based reranker). The MWER templates are instantiated at each position of the input sequence. The reranker templates are instantiated only for the nodes of the candidate parse tree, which are leaves dominated by a MWE node (i.e. the node has a MWE ancestor). We define a template  $T$  as follows:

- MWER: for each position  $n$  in the input sequence  $x$ ,

$$T = f(x, n)/y_n$$

- RERANKER: for each leaf (in position  $n$ ) dominated by a MWE node  $m$  in the current parse tree  $p$ ,

$$T = f(p, n)/label(m)/pos(p, n)$$

where  $f$  is a function to be defined;  $y_n$  is the output label at position  $n$ ;  $label(m)$  is the label of node  $m$  and  $pos(p, n)$  indicates the position of the word corresponding to  $n$  in the MWE sequence: B (starting position), I (remaining positions).

## 5.1 Endogenous Features

Endogenous features are features directly extracted from properties of the words themselves or from a tool learnt from the training corpus (e.g. a tagger).

**Word n-grams.** We use word unigrams and bigrams in order to capture multiwords present in the training section and to extract lexical cues to discover new MWEs. For instance, the bigram *coup de* is often the prefix of compounds such as *coup de pied* (kick), *coup de foudre* (love at first sight), *coup de main* (help).

**POS n-grams.** We use part-of-speech unigrams and bigrams in order to capture MWEs with irregular syntactic structures that might indicate the idiomacity of a word sequence. For instance, the POS sequence *preposition – adverb* associated with the compound *depuis peu* (recently) is very unusual in French. We also integrated mixed bigrams made up of a word and a part-of-speech.

**Specific features.** Due to their different use, each model integrates some specific features. In order to deal with unknown words and special tokens, we incorporate standard tagging features in the CRF: lowercase forms of the words, word prefixes of length 1 to 4, word suffixes of length 1 to 4, whether the word is capitalized, whether the token has a digit, whether it is an hyphen. We also add label bigrams. The reranker models integrate features associated with each MWE node, the value of which is the compound itself.

## 5.2 Exogenous Features

Exogenous features are features that are not entirely derived from the (reference) corpus itself. They are computed from external data (in our case, our lexical resources). The lexical resources might be useful to discover new expressions: usually, expressions that have standard syntax like nominal compounds and are difficult to predict from the endogenous features. The resources are applied to the corpus through a lexical analysis that generates, for each sentence, a finite-state automaton TFSA which represents all the possible analyses. The features are computed from the automaton TFSA.

**Lexicon-based features.** We associate each word with its part-of-speech tags found in our external morphological lexicon. All tags of a word constitute

an ambiguity class *ac*. If the word belongs to a compound, the compound tag is also incorporated in the ambiguity class. For instance, the word *night* (either a simple noun or a simple adjective) in the context *at night*, is associated with the class *adj\_noun\_adv+I* as it is located inside a compound adverb. This feature is directly computed from TFSA. The lexical analysis can lead to a preliminary MWE segmentation by using a shortest path algorithm that gives priority to compound analyses. This segmentation is also a source of features: a word belonging to a compound segment is assigned different properties such as the segment part-of-speech *mwt* and its syntactic structure *mws* encoded in the lexical resource, its relative position *mwpos* in the segment ('B' or 'I').

**Collocation-based features.** In our collocation resource, each candidate collocation of the French treebank is associated with its internal syntactic structure and its association score (log-likelihood). We divided these candidates into two classes: those whose score is greater than a threshold and the other ones. Therefore, a given word in the corpus can be associated with different properties whether it belongs to a potential collocation: the class *c* and the internal structure *cs* of the collocation it belongs to, its position *cpos* in the collocation (B: beginning; I: remaining positions; O: outside). We manually set the threshold to 150 after some tuning on the development corpus.

All feature templates are given in table 2.

Endogenous Features
$w(n+i), i \in \{-2, -1, 0, 1, 2\}$
$w(n+i)/w(n+i+1), i \in \{-2, -1, 0, 1\}$
$t(n+i), i \in \{-2, -1, 0, 1, 2\}$
$t(n+i)/t(n+i+1), i \in \{-2, -1, 0, 1\}$
$w(n+i)/t(n+j), (i, j) \in \{(1, 0), (0, 1), (-1, 0), (0, -1)\}$
Exogenous Features
$ac(n)$
$mwt(n)/mwpos(n)$
$mws(n)/mwpos(n)$
$c(n)/cs(n)/cpos(n)$

Table 2: Feature templates (*f*) used both in the MWER and the reranker models: *n* is the current position in the sentence,  $w(i)$  is the word at position *i*;  $t(i)$  is the part-of-speech tag of  $w(i)$ ; if the word at absolute position *i* is part of a compound in the Shortest Path Segmentation,  $mwt(i)$  and  $mws(i)$  are respectively the part-of-speech tag and the internal structure of the compound,  $mwpos(i)$  indicates its relative position in the compound (B or I).

## 6 Evaluation

### 6.1 Experiment Setup

We carried out 3 different experiments. We first tested a standalone MWE recognizer based on CRF. We then combined MWE pregrouping based on this recognizer and the Berkeley parser<sup>5</sup> (Petrov *et al.*, 2006) trained on the FTB where the compounds were concatenated (BKyc). Finally, we combined the Berkeley parser trained on the FTB where the compounds are annotated with specific non-terminals (BKY), and the reranker. In all experiments, we varied the set of features: *endo* are all endogenous features; *coll* and *lex* include all endogenous features plus collocation-based features and lexicon-based ones, respectively; *all* is composed of both endogenous and exogenous features. The CRF recognizer relies on the software *Wapiti*<sup>6</sup> (Lavergne *et al.*, 2010) to train and apply the model, and on the software *Unitex* (Paumier, 2011) to apply lexical resources. The part-of-speech tagger used to extract POS features was *lgtagger*<sup>7</sup> (Constant and Sigogne, 2011). To train the reranker, we used a MaxEnt algorithm<sup>8</sup> as in (Charniak and Johnson, 2005).

Results are reported using several standard measures, the  $F_1$  score, *unlabeled attachment* and *Leaf Ancestor* scores. The labeled  $F_1$  score [F1]<sup>9</sup>, defined by the standard protocol called PARSEVAL (Black *et al.*, 1991), takes into account the bracketing and labeling of nodes. The *unlabeled attachment score* [UAS] evaluates the quality of unlabeled

<sup>5</sup>We used the version adapted to French in the software *Bonsai* (Candito and Crabbé, 2009): [http://alpage.inria.fr/statgram/frdep/fr\\_stat\\_dep\\_parsing.html](http://alpage.inria.fr/statgram/frdep/fr_stat_dep_parsing.html). The original version is available at: <http://code.google.com/p/berkeleyparser/>. We trained the parser as follows: right binarization, no parent annotation, six split-merge cycles and default random seed initialisation (8).

<sup>6</sup>Wapiti can be found at <http://wapiti.limsi.fr/>. It was configured as follows: rprop algorithm, default L1-penalty value (0.5), default L2-penalty value (0.00001), default stopping criterion value (0.02%).

<sup>7</sup>Available at <http://igm.univ-mlv.fr/mconstan/research/software/>.

<sup>8</sup>We used the following mathematical libraries PETSc and TAO, freely available at <http://www.mcs.anl.gov/petsc/> and <http://www.mcs.anl.gov/research/projects/tao/>

<sup>9</sup>*Evalb* tool available at <http://nlp.cs.nyu.edu/evalb/>. We also used the evaluation by category implemented in the class *EvalbByCat* in the Stanford Parser.

dependencies between words of the sentence<sup>10</sup>. And finally, the *Leaf-Ancestor* score [LA]<sup>11</sup> (Sampson, 2003) computes the similarity between all paths (sequence of nodes) from each terminal node to the root node of the tree. The global score of a generated parse is equal to the average score of all terminal nodes. Punctuation tokens are ignored in all metrics. The quality of MWE identification was evaluated by computing the F<sub>1</sub> score on MWE nodes. We also evaluated the MWE segmentation by using the unlabeled F<sub>1</sub> score (U). In order to compare both approaches, parse trees generated by BKyc were automatically transformed in trees with the same MWE annotation scheme as the trees generated by BKY.

In order to establish the statistical significance of results between two parsing experiments in terms of F<sub>1</sub> and UAS, we used a unidirectional t-test for two independent samples<sup>12</sup>. The statistical significance between two MWE identification experiments was established by using the McNemar-s test (Gillick and Cox, 1989). The results of the two experiments are considered statistically significant with the computed value  $p < 0.01$ .

## 6.2 Standalone Multiword recognition

The results of the standalone MWE recognizer are given in table 3. They show that the lexicon-based system (*lex*) reaches the best score. Accuracy is improved by an absolute gain of +6.7 points as compared with BKY parser. The strictly endogenous system has a +4.9 point absolute gain, +5.4 points when collocations are added. That shows that most of the work is done by fully automatically acquired features (as opposed to features coming from a manually constructed lexicon). As expected, lexicon-based features lead to a 5.3 point recall improvement (with respect to non-lexicon based features) whereas precision is stable. The more precise system is the base one because it almost solely detects compounds present in the training corpus; nevertheless, it is unable to capture new MWEs (it has the

<sup>10</sup>This score is computed by using the tool available at <http://ilk.uvt.nl/conll/software.html>. The constituent trees are automatically converted into dependency trees with the tool *Bonsai*.

<sup>11</sup>*Leaf-ancestor assessment* tool available at <http://www.grsampson.net/Resources.html>

<sup>12</sup>Dan Bikel’s tool available at <http://www.cis.upenn.edu/~dbikel/software.html>.

lowest recall). BKY parser has the best recall among the non lexicon-based systems, i.e. it is the best one to discover new compounds as it is able to precisely detect irregular syntactic structures that are likely to be MWEs. Nevertheless, as it does not have a lexicalized strategy, it is not able to filter out incorrect candidates; the precision is therefore very low (the worst).

	P	R	F <sub>1</sub>	F <sub>1</sub> ≤ 40	U
base	<b>78.0</b>	68.3	72.8	71.2	74.3
endo	75.5	74.5	75.0	74.0	76.3
coll	76.6	74.4	75.5	74.9	77.0
lex	76.0	79.8	<b>77.8</b>	<b>77.8</b>	<b>79.0</b>
all	76.2	79.2	77.7	77.3	78.8
BKY	67.6	75.1	71.1	70.7	72.5
Stanford*	-	-	-	70.1	-
DP-TSG*	-	-	-	71.1	-

Table 3: MWE identification with CRF: *base* are the features corresponding to token properties and word n-grams. The differences between all systems are statistically significant with respect to McNemar’s test (Gillick and Cox, 1989), except *lex/all* and *all/coll*; *lex/coll* is "border-line". The results of the systems based on the Stanford Parser and the Tree Substitution Parser (DP-TSG) are reported from (Green *et al.*, 2011).

## 6.3 Combination of Multiword Expression Recognition and Parsing

We tested and compared the two proposed discriminative strategies by varying the sets of MWE-dedicated features. The results are reported in table 4. Table 5 compares the parsing systems, by showing the score differences between each of the tested system and the BKY parser.

Strat.	Feat.	Parser	F <sub>1</sub>	LA	UAS	F <sub>1</sub> (MWE)
-	-	BKY	80.61	92.91	82.99	71.1
pre	-	BKYc	75.47	91.10	76.74	0.0
pre	endo	BKYc	80.23	92.69	83.62	74.9
pre	coll	BKYc	80.32	92.73	83.77	75.5
pre	lex	BKYc	80.66	92.81	<b>84.16</b>	<b>77.4</b>
pre	all	BKYc	80.51	92.77	84.05	77.2
post	endo	BKY	80.87	92.94	83.49	72.9
post	coll	BKY	80.71	92.85	83.16	71.2
post	lex	BKY	<b>81.08</b>	<b>92.98</b>	83.98	74.5
post	all	BKY	81.03	92.96	83.97	74.3
pre	gold	BKYc	83.73	93.77	90.08	95.8

Table 4: Parsing evaluation: *pre* indicates a MWE pre-grouping strategy, whereas *post* is a reranking strategy with  $n = 50$ . The feature *gold* means that we have applied the parser on a gold MWE segmentation.

	$\Delta F_1$		$\Delta UAS$		$\Delta F_1(MWE)$	
	pre	post	pre	post	pre	post
endo	-0.38	+0.26	+0.63	+0.50	+3.8	+1.8
coll	-0.29	+0.10	+0.78	+0.17	+4.4	+0.1
lex	+0.05	+0.47	+1.17	+0.99	+6.3	+3.4

Table 5: Comparison of the strategies with respect to BKY parser.

Firstly, we note that the accuracy of the best realistic parsers is much lower than that of a parser with a golden MWE segmentation<sup>13</sup> (-2.65 and -5.92 respectively in terms of F-score and UAS), which shows the importance of not neglecting MWE recognition in the framework of parsing. Furthermore, pre-grouping has no statistically significant impact on the F-score<sup>14</sup>, whereas reranking leads to a statistically significant improvement (except for collocations). Both strategies also lead to a statistically significant UAS increase. Whereas both strategies improve the MWE recognition, pre-grouping is much more accurate (+2-4%); this might be due to the fact that an unlexicalized parser is limited in terms of compound identification, even within  $n$ -best analyses (cf. Oracle in table 6). The benefits of lexicon-based features are confirmed in this experiment, whereas the use of collocations in the reranking strategy seems to be rejected.

	endo	coll	lex	all	oracle
n=1	80.61 (71.1)				
n=5	80.74 (71.5)	<b>80.88</b> (71.7)	81.03 (73.4)	<b>81.05</b> (73.3)	83.17 (74.6)
n=20	<b>80.98</b> (72.9)	80.72 (70.6)	81.09 (73.6)	81.01 (73.0)	84.76 (75.5)
n=50	80.87 (72.9)	80.71 (71.2)	81.08 (74.5)	81.03 (74.3)	85.21 (76.4)
n=100	80.69 (72.0)	80.53 (70.0)	<b>81.12</b> (74.4)	80.93 (73.7)	<b>85.54</b> (76.4)

Table 6: Reranker  $F_1$  evaluation with respect to  $n$  and the types of features. The  $F_1(MWE)$  is given in parenthesis.

Table 7 shows the results by category. It indicates that both discriminative strategies are of interest in locating multiword adjectives, determiners and prepositions; the pre-grouping method appears to be particularly relevant for multiword nouns and

<sup>13</sup>The  $F_1(MWE)$  is not 100% with a golden segmentation because of tagging errors by the parser.

<sup>14</sup>Note that we observe an increase of +0.5 in  $F_1$  on the development corpus with lexicon-based features.

adverbs. However, it performs very poorly in multiword verb recognition. In terms of standard parsing accuracy, the pre-grouping approach has a very heterogeneous impact: Adverbial and Adjective Modifier phrases tend to be more accurate; verbal kernels and higher level constituents such as relative and subordinate clauses see their accuracy level drop, which shows that pre-recognition of MWE can have a negative impact on general parsing accuracy as MWE errors propagate to higher level constituents.

cat	#gold	BKY	endo (pre)	lex (pre)	endo (post)	lex (post)

## 7 Conclusions and Future Work

In this paper, we evaluated two discriminative strategies to integrate Multiword Expression Recognition in probabilistic parsing: (a) pre-grouping MWEs with a state-of-the-art recognizer and (b) MWE identification with a reranker after parsing. We showed that MWE pre-grouping significantly improves compound recognition and unlabeled dependency annotation, which implies that this strategy could be useful for dependency parsing. The reranking procedure evenly improves all evaluation scores. Future work could consist in combining both strategies: pre-grouping could suggest a set of potential MWE segmentations in order to make it more flexible for a parser; final decisions would then be made by the reranker.

## Acknowledgments

The authors are very grateful to Spence Green for his useful help on the treebank, and to Jennifer Thewissen for her careful proof-reading.

# Utilizing Dependency Language Models for Graph-based Dependency Parsing Models

Wenliang Chen, Min Zhang\* and Haizhou Li

Human Language Technology, Institute for Infocomm Research, Singapore  
{wechen, mzhang, hli}@i2r.a-star.edu.sg

## Abstract

Most previous graph-based parsing models increase decoding complexity when they use high-order features due to exact-inference decoding. In this paper, we present an approach to enriching high-order feature representations for graph-based dependency parsing models using a dependency language model and beam search. The dependency language model is built on a large-amount of additional auto-parsed data that is processed by a baseline parser. Based on the dependency language model, we represent a set of features for the parsing model. Finally, the features are efficiently integrated into the parsing model during decoding using beam search. Our approach has two advantages. Firstly we utilize rich high-order features defined over a view of large scope and additional large raw corpus. Secondly our approach does not increase the decoding complexity. We evaluate the proposed approach on English and Chinese data. The experimental results show that our new parser achieves the best accuracy on the Chinese data and comparable accuracy with the best known systems on the English data.

## 1 Introduction

In recent years, there are many data-driven models that have been proposed for dependency parsing (McDonald and Nivre, 2007). Among them, graph-based dependency parsing models have achieved state-of-the-art performance for a wide range of languages as shown in recent CoNLL shared tasks

(Buchholz and Marsi, 2006; Nivre et al., 2007). In the graph-based models, dependency parsing is treated as a structured prediction problem in which the graphs are usually represented as factored structures. The information of the factored structures decides the features that the models can utilize. There are several previous studies that exploit high-order features that lead to significant improvements.

McDonald et al. (2005) and Covington (2001) develop models that represent first-order features over a single arc in graphs. By extending the first-order model, McDonald and Pereira (2006) and Carreras (2007) exploit second-order features over two adjacent arcs in second-order models. Koo and Collins (2010) further propose a third-order model that uses third-order features. These models utilize higher-order feature representations and achieve better performance than the first-order models. But this achievement is at the cost of the higher decoding complexity, from  $O(n^2)$  to  $O(n^4)$ , where  $n$  is the length of the input sentence. Thus, it is very hard to develop higher-order models further in this way.

How to enrich high-order feature representations without increasing the decoding complexity for graph-based models becomes a very challenging problem in the dependency parsing task. In this paper, we solve this issue by enriching the feature representations for a graph-based model using a dependency language model (DLM) (Shen et al., 2008). The  $N$ -gram DLM has the ability to predict the next child based on the  $N-1$  immediate previous children and their head (Shen et al., 2008). The basic idea behind is that we use the DLM to evaluate whether a valid dependency tree (McDonald and Nivre, 2007)

---

\*Corresponding author

is well-formed from a view of large scope. The parsing model searches for the final dependency trees by considering the original scores and the scores of DLM.

In our approach, the DLM is built on a large amount of auto-parsed data, which is processed by an original first-order parser (McDonald et al., 2005). We represent the features based on the DLM. The DLM-based features can capture the N-gram information of the parent-children structures for the parsing model. Then, they are integrated directly in the decoding algorithms using beam-search. Our new parsing model can utilize rich high-order feature representations but without increasing the complexity.

To demonstrate the effectiveness of the proposed approach, we conduct experiments on English and Chinese data. The results indicate that the approach greatly improves the accuracy. In summary, we make the following contributions:

- We utilize the dependency language model to enhance the graph-based parsing model. The DLM-based features are integrated directly into the beam-search decoder.
- The new parsing model uses the rich high-order features defined over a view of large scope and an additional large raw corpus, but without increasing the decoding complexity.
- Our parser achieves the best accuracy on the Chinese data and comparable accuracy with the best known systems on the English data.

## 2 Dependency language model

Language models play a very important role for statistical machine translation (SMT). The standard N-gram based language model predicts the next word based on the  $N - 1$  immediate previous words. However, the traditional N-gram language model can not capture long-distance word relations. To overcome this problem, Shen et al. (2008) proposed a dependency language model (DLM) to exploit long-distance word relations for SMT. The N-gram DLM predicts the next child of a head based on the  $N - 1$  immediate previous children and the head itself. In this paper, we define a DLM, which is similar to the one of Shen et al. (2008), to score entire dependency trees.

An input sentence is denoted by  $x = (x_0, x_1, \dots, x_i, \dots, x_n)$ , where  $x_0 = ROOT$  and does not depend on any other token in  $x$  and each token  $x_i$  refers to a word. Let  $y$  be a dependency tree for  $x$  and  $H(y)$  be a set that includes the words that have at least one dependent. For each  $x_h \in H(y)$ , we have a dependency structure  $D_h = (x_{Lk}, \dots, x_{L1}, x_h, x_{R1}, \dots, x_{Rm})$ , where  $x_{Lk}, \dots, x_{L1}$  are the children on the left side from the farthest to the nearest and  $x_{R1}, \dots, x_{Rm}$  are the children on the right side from the nearest to the farthest. Probability  $P(D_h)$  is defined as follows:

$$P(D_h) = P_L(D_h) \times P_R(D_h) \quad (1)$$

Here  $P_L$  and  $P_R$  are left and right side generative probabilities respectively. Suppose, we use a N-gram dependency language model.  $P_L$  is defined as follows:

$$\begin{aligned} P_L(D_h) \approx & P_{Lc}(x_{L1}|x_h) \\ & \times P_{Lc}(x_{L2}|x_{L1}, x_h) \\ & \times \dots \\ & \times P_{Lc}(x_{Lk}|x_{L(k-1)}, \dots, x_{L(k-N+1)}, x_h) \end{aligned} \quad (2)$$

where the approximation is based on the  $n$ th order Markov assumption. The right side probability is similar. For a dependency tree, we calculate the probability as follows:

$$P(y) = \prod_{x_h \in H(y)} P(D_h) \quad (3)$$

In this paper, we use a linear model to calculate the scores for the parsing models (defined in Section 3.1). Accordingly, we reform Equation 3. We define  $\mathbf{f}_{DLM}$  as a high-dimensional feature representation which is based on arbitrary features of  $P_{Lc}$ ,  $P_{Rc}$  and  $x$ . Then, the DLM score of tree  $y$  is in turn computed as the inner product of  $\mathbf{f}^{DLM}$  with a corresponding weight vector  $\mathbf{w}^{DLM}$ .

$$score^{DLM}(y) = \mathbf{f}^{DLM} \cdot \mathbf{w}^{DLM} \quad (4)$$

## 3 Parsing with dependency language model

In this section, we propose a parsing model which includes the dependency language model by extending the model of McDonald et al. (2005).

### 3.1 Graph-based parsing model

The graph-based parsing model aims to search for the maximum spanning tree (MST) in a graph (McDonald et al., 2005). We write  $(x_i, x_j) \in y$  if there is a dependency in tree  $y$  from word  $x_i$  to word  $x_j$  ( $x_i$  is the head and  $x_j$  is the dependent). A graph, denoted by  $G_x$ , consists of a set of nodes  $V_x = \{x_0, x_1, \dots, x_i, \dots, x_n\}$  and a set of arcs (edges)  $E_x = \{(x_i, x_j) | i \neq j, x_i \in V_x, x_j \in (V_x - x_0)\}$ , where the nodes in  $V_x$  are the words in  $x$ . Let  $T(G_x)$  be the set of all the subgraphs of  $G_x$  that are valid dependency trees (McDonald and Nivre, 2007) for sentence  $x$ .

The formulation defines the score of a dependency tree  $y \in T(G_x)$  to be the sum of the edge scores,

$$s(x, y) = \sum_{g \in y} \text{score}(\mathbf{w}, x, g) \quad (5)$$

where  $g$  is a spanning subgraph of  $y$ .  $g$  can be a single dependency or adjacent dependencies. Then  $y$  is represented as a set of factors. The model scores each factor using a weight vector  $\mathbf{w}$  that contains the weights for the features to be learned during training using the Margin Infused Relaxed Algorithm (MIRA) (Crammer and Singer, 2003; McDonald and Pereira, 2006). The scoring function is

$$\text{score}(\mathbf{w}, x, g) = \mathbf{f}(x, g) \cdot \mathbf{w} \quad (6)$$

where  $\mathbf{f}(x, g)$  is a high-dimensional feature representation which is based on arbitrary features of  $g$  and  $x$ .

The parsing model finds a *maximum spanning tree* (MST), which is the highest scoring tree in  $T(G_x)$ . The task of the decoding algorithm for a given sentence  $x$  is to find  $y^*$ ,

$$y^* = \arg \max_{y \in T(G_x)} s(x, y) = \arg \max_{y \in T(G_x)} \sum_{g \in y} \text{score}(\mathbf{w}, x, g)$$

### 3.2 Add DLM scores

In our approach, we consider the scores of the DLM when searching for the maximum spanning tree. Then for a given sentence  $x$ , we find  $y_{DLM}^*$ ,

$$y_{DLM}^* = \arg \max_{y \in T(G_x)} \left( \sum_{g \in y} \text{score}(\mathbf{w}, x, g) + \text{score}^{DLM}(y) \right)$$

After adding the DLM scores, the new parsing model can capture richer information. Figure 1 illustrates the changes. In the original first-order parsing model, we only utilize the information of single arc  $(x_h, x_{L(k-1)})$  for  $x_{L(k-1)}$  as shown in Figure 1-(a). If we use 3-gram DLM, we can utilize the additional information of the two previous children (nearer to  $x_h$  than  $x_{L(k-1)}$ ):  $x_{L(k-2)}$  and  $x_{L(k-3)}$  as shown in Figure 1-(b).

Figure 1: Adding the DLM scores to the parsing model

### 3.3 DLM-based feature templates

We define DLM-based features for  $D_h = (x_{Lk}, \dots, x_{L1}, x_h, x_{R1}, \dots, x_{Rm})$ . For each child  $x_{ch}$  on the left side, we have  $P_{Lc}(x_{ch} | \text{HIS})$ , where HIS refers to the  $N - 1$  immediate previous right children and head  $x_h$ . Similarly, we have  $P_{Rc}(x_{ch} | \text{HIS})$  for each child on the right side. Let  $P_u(x_{ch} | \text{HIS})$  ( $P_u(ch)$  in short) be one of the above probabilities. We use the map function  $\Phi(P_u(ch))$  to obtain the predefined discrete value (defined in Section 5.3). The feature templates are outlined in Table 1, where TYPE refers to one of the types:  $P_L$  or  $P_R$ , h\_pos refers to the part-of-speech tag of  $x_h$ , h\_word refers to the lexical form of  $x_h$ , ch\_pos refers to the part-of-speech tag of  $x_{ch}$ , and ch\_word refers to the lexical form of  $x_{ch}$ .

## 4 Decoding

In this section, we turn to the problem of adding the DLM in the decoding algorithm. We propose two ways: (1) Rescoring, in which we rescore the K-best list with the DLM-based features; (2) Intersect,

$\langle \Phi(P_u(ch)), \text{TYPE} \rangle$
$\langle \Phi(P_u(ch)), \text{TYPE}, h\_pos \rangle$
$\langle \Phi(P_u(ch)), \text{TYPE}, h\_word \rangle$
$\langle \Phi(P_u(ch)), \text{TYPE}, ch\_pos \rangle$
$\langle \Phi(P_u(ch)), \text{TYPE}, ch\_word \rangle$
$\langle \Phi(P_u(ch)), \text{TYPE}, h\_pos, ch\_pos \rangle$
$\langle \Phi(P_u(ch)), \text{TYPE}, h\_word, ch\_word \rangle$

Table 1: DLM-based feature templates

in which we add the DLM-based features in the decoding algorithm directly.

#### 4.1 Rescoring

We add the DLM-based features into the decoding procedure by using the rescoring technique used in (Shen et al., 2008). We can use an original parser to produce the K-best list. This method has the potential to be very fast. However, because the performance of this method is restricted to the K-best list, we may have to set K to a high number in order to find the best parsing tree (with DLM) or a tree acceptable close to the best (Shen et al., 2008).

#### 4.2 Intersect

Then, we add the DLM-based features in the decoding algorithm directly. The DLM-based features are generated online during decoding.

For our parser, we use the decoding algorithm of McDonald et al. (2005). The algorithm was extensions of the parsing algorithm of (Eisner, 1996), which was a modified version of the CKY chart parsing algorithm. Here, we describe how to add the DLM-based features in the first-order algorithm. The second-order and higher-order algorithms can be extended by the similar way.

The parsing algorithm independently parses the left and right dependents of a word and combines them later. There are two types of chart items (McDonald and Pereira, 2006): 1) a *complete item* in which the words are unable to accept more dependents in a certain direction; and 2) an *incomplete item* in which the words can accept more dependents in a certain direction. In the algorithm, we create both types of chart items with two directions for all the word pairs in a given sentence. The direction of a dependency is from the head to the dependent. The right (left) direction indicates the dependent is on the right (left) side of the head. Larger chart items are

created from pairs of smaller ones in a bottom-up style. In the following figures, complete items are represented by triangles and incomplete items are represented by trapezoids. Figure 2 illustrates the cubic parsing actions of the algorithm (Eisner, 1996) in the right direction, where  $s$ ,  $r$ , and  $t$  refer to the start and end indices of the chart items. In Figure 2-(a), all the items on the left side are complete and the algorithm creates the incomplete item (trapezoid on the right side) of  $s - t$ . This action builds a dependency relation from  $s$  to  $t$ . In Figure 2-(b), the item of  $s - r$  is incomplete and the item of  $r - t$  is complete. Then the algorithm creates the complete item of  $s - t$ . In this action, all the children of  $r$  are generated. In Figure 2, the longer vertical edge in a triangle or a trapezoid corresponds to the subroot of the structure (spanning chart). For example,  $s$  is the subroot of the span  $s - t$  in Figure 2-(a). For the left direction case, the actions are similar.

Figure 2: Cubic parsing actions of Eisner (Eisner, 1996)

Then, we add the DLM-based features into the parsing actions. Because the parsing algorithm is in the bottom-up style, the nearer children are generated earlier than the farther ones of the same head. Thus, we calculate the left or right side probability for a new child when a new dependency relation is built. For Figure 2-(a), we add the features of  $P_{Rc}(x_t|HIS)$ . Figure 3 shows the structure, where  $c_{Rs}$  refers to the current children (nearer than  $x_t$ ) of  $x_s$ . In the figure, HIS includes  $c_{Rs}$  and  $x_s$ .

Figure 3: Add DLM-based features in cubic parsing

We use beam search to choose the one having the overall best score as the final parse, where  $K$  spans are built at each step (Zhang and Clark, 2008). At each step, we perform the parsing actions in the current beam and then choose the best  $K$  resulting spans for the next step. The time complexity of the new decoding algorithm is  $O(Kn^3)$  while the original one is  $O(n^3)$ , where  $n$  is the length of the input sentence. With the rich feature set in Table 1, the running time of Intersect is longer than the time of Rescoring. But Intersect considers more combination of spans with the DLM-based features than Rescoring that is only given a  $K$ -best list.

## 5 Implementation Details

### 5.1 Baseline parser

We implement our parsers based on the MSTParser<sup>1</sup>, a freely available implementation of the graph-based model proposed by (McDonald and Pereira, 2006). We train a first-order parser on the training data (described in Section 6.1) with the features defined in McDonald et al. (2005). We call this first-order parser Baseline parser.

### 5.2 Build dependency language models

We use a large amount of unannotated data to build the dependency language model. We first perform word segmentation (if needed) and part-of-speech tagging. After that, we obtain the word-segmented sentences with the part-of-speech tags. Then the sentences are parsed by the Baseline parser. Finally, we obtain the auto-parsed data.

Given the dependency trees, we estimate the probability distribution by relative frequency:

$$P_u(x_{ch}|\text{HIS}) = \frac{\text{count}(x_{ch}, \text{HIS})}{\sum_{x'_{ch}} \text{count}(x'_{ch}, \text{HIS})} \quad (7)$$

No smoothing is performed because we use the mapping function for the feature representations.

### 5.3 Mapping function

We can define different mapping functions for the feature representations. Here, we use a simple way. First, the probabilities are sorted in decreasing order. Let  $No(P_u(ch))$  be the position number of  $P_u(ch)$  in the sorted list. The mapping function is:

$$\Phi(P_u(ch)) = \begin{cases} PH & \text{if } No(P_u(ch)) \leq \text{TOP10} \\ PM & \text{if } \text{TOP10} < No(P_u(ch)) \leq \text{TOP30} \\ PL & \text{if } \text{TOP30} < No(P_u(ch)) \\ PO & \text{if } P_u(ch) = 0 \end{cases}$$

where TOP10 and TOP 30 refer to the position numbers of top 10% and top 30% respectively. The numbers, 10% and 30%, are tuned on the development sets in the experiments.

## 6 Experiments

We conducted experiments on English and Chinese data.

### 6.1 Data sets

For English, we used the Penn Treebank (Marcus et al., 1993) in our experiments. We created a standard data split: sections 2-21 for training, section 22 for development, and section 23 for testing. Tool ‘‘Penn2Malt’’<sup>2</sup> was used to convert the data into dependency structures using a standard set of head rules (Yamada and Matsumoto, 2003). Following the work of (Koo et al., 2008), we used the MXPOST (Ratnaparkhi, 1996) tagger trained on training data to provide part-of-speech tags for the development and the test set, and used 10-way jackknifing to generate part-of-speech tags for the training set. For the unannotated data, we used the BLLIP corpus (Charniak et al., 2000) that contains about 43 million words of WSJ text.<sup>3</sup> We used the MXPOST tagger trained on training data to assign part-of-speech tags and used the Baseline parser to process the sentences of the BLLIP corpus.

For Chinese, we used the Chinese Treebank (CTB) version 4.0<sup>4</sup> in the experiments. We also used the ‘‘Penn2Malt’’ tool to convert the data and created a data split: files 1-270 and files 400-931 for training, files 271-300 for testing, and files 301-325 for development. We used gold standard segmentation and part-of-speech tags in the CTB. The data partition and part-of-speech settings were chosen to match previous work (Chen et al., 2008; Yu et al., 2008; Chen et al., 2009). For the unannotated data, we used the XIN\_CMN portion of Chinese Gigaword<sup>5</sup> Version 2.0 (LDC2009T14) (Huang, 2009),

<sup>2</sup><http://w3.msi.vxu.se/~nivre/research/Penn2Malt.html>

<sup>3</sup>We ensured that the text used for extracting subtrees did not include the sentences of the Penn Treebank.

<sup>4</sup><http://www.cis.upenn.edu/~chinese/>.

<sup>5</sup>We excluded the sentences of the CTB data from the Gigaword data

<sup>1</sup><http://mstparser.sourceforge.net>

which has approximately 311 million words whose segmentation and POS tags are given. We discarded the annotations due to the differences in annotation policy between CTB and this corpus. We used the MMA system (Kruengkrai et al., 2009) trained on the training data to perform word segmentation and POS tagging and used the Baseline parser to parse all the sentences in the data.

## 6.2 Features for basic and enhanced parsers

The previous studies have defined four types of features: (FT1) the first-order features defined in McDonald et al. (2005), (FT2SB) the second-order parent-siblings features defined in McDonald and Pereira (2006), (FT2GC) the second-order parent-child-grandchild features defined in Carreras (2007), and (FT3) the third-order features defined in (Koo and Collins, 2010).

We used the first- and second-order parsers of the MSTParser as the basic parsers. Then we enhanced them with other higher-order features using beam-search. Table 2 shows the feature settings of the systems, where MST1/2 refers to the basic first-/second-order parser and MSTB1/2 refers to the enhanced first-/second-order parser. MSTB1 and MSTB2 used the same feature setting, but used different order models. This resulted in the difference of using FT2SB (beam-search in MSTB1 vs exact-inference in MSTB2). We used these four parsers as the Baselines in the experiments.

System	Features
MST1	(FT1)
MSTB1	(FT1)+(FT2SB+FT2GC+FT3)
MST2	(FT1+FT2SB)
MSTB2	(FT1+FT2SB)+(FT2GC+FT3)

Table 2: Baseline parsers

We measured the parser quality by the unlabeled attachment score (UAS), i.e., the percentage of tokens (excluding all punctuation tokens) with the correct HEAD. In the following experiments, we used “Inter” to refer to the parser with Intersect, and “Rescore” to refer to the parser with Rescoring.

## 6.3 Development experiments

Since the setting of K (for beam search) affects our parsers, we studied its influence on the development

set for English. We added the DLM-based features to MST1. Figure 4 shows the UAS curves on the development set, where K is beam size for Intersect and K-best for Rescoring, the X-axis represents K, and the Y-axis represents the UAS scores. The parsing performance generally increased as the K increased. The parser with Intersect always outperformed the one with Rescoring.

Figure 4: The influence of K on the development data

K	1	2	4	8	16
English	157.1	247.4	351.9	462.3	578.2

Table 3: The parsing times on the development set (seconds for all the sentences)

Table 3 shows the parsing times of Intersect on the development set for English. By comparing the curves of Figure 4, we can see that, while using larger K reduced the parsing speed, it improved the performance of our parsers. In the rest of the experiments, we set K=8 in order to obtain the high accuracy with reasonable speed and used Intersect to add the DLM-based features.

N	0	1	2	3	4
English	91.30	91.87	92.52	92.72	92.72
Chinese	87.36	87.96	89.33	89.92	90.40

Table 4: Effect of different N-gram DLMs

Then, we studied the effect of adding different N-gram DLMs to MST1. Table 4 shows the results. From the table, we found that the parsing performance roughly increased as the N increased. When N=3 and N=4, the parsers obtained the same scores for English. For Chinese, the parser obtained the best score when N=4. Note that the size of the Chinese unannotated data was larger than that of English. In the rest of the experiments, we used 3-gram for English and 4-gram for Chinese.

## 6.4 Main results on English data

We evaluated the systems on the testing data for English. The results are shown in Table 5, where -DLM refers to adding the DLM-based features to the Baselines. The parsers using the DLM-based features consistently outperformed the Baselines. For the basic models (MST1/2), we obtained absolute improvements of 0.94 and 0.63 points respectively. For the enhanced models (MSTB1/2), we found that there were 0.63 and 0.66 points improvements respectively. The improvements were significant in McNemar’s Test ( $p < 10^{-5}$ ) (Nivre et al., 2004).

Order1	UAS	Order2	UAS
MST1	90.95	MST2	91.71
MST-DLM1	91.89	MST-DLM2	92.34
MSTB1	91.92	MSTB2	92.10
MSTB-DLM1	92.55	MSTB-DLM2	92.76

Table 5: Main results for English

## 6.5 Main results on Chinese data

The results are shown in Table 6, where the abbreviations used are the same as those in Table 5. As in the English experiments, the parsers using the DLM-based features consistently outperformed the Baselines. For the basic models (MST1/2), we obtained absolute improvements of 4.28 and 3.51 points respectively. For the enhanced models (MSTB1/2), we got 3.00 and 2.93 points improvements respectively. We obtained large improvements on the Chinese data. The reasons may be that we use the very large amount of data and 4-gram DLM that captures high-order information. The improvements were significant in McNemar’s Test ( $p < 10^{-7}$ ).

Order1	UAS	Order2	UAS
MST1	86.38	MST2	88.11
MST-DLM1	90.66	MST-DLM2	91.62
MSTB1	88.38	MSTB2	88.66
MSTB-DLM1	91.38	MSTB-DLM2	91.59

Table 6: Main results for Chinese

## 6.6 Compare with previous work on English

Table 7 shows the performance of the graph-based systems that were compared, where McDonald06 refers to the second-order parser of McDonald

and Pereira (2006), Koo08-standard refers to the second-order parser with the features defined in Koo et al. (2008), Koo10-model1 refers to the third-order parser with model1 of Koo and Collins (2010), Koo08-dep2c refers to the second-order parser with cluster-based features of (Koo et al., 2008), Suzuki09 refers to the parser of Suzuki et al. (2009), Chen09-ord2s refers to the second-order parser with subtree-based features of Chen et al. (2009), and Zhou11 refers to the second-order parser with web-derived selectional preference features of Zhou et al. (2011).

The results showed that our MSTB-DLM2 obtained the comparable accuracy with the previous state-of-the-art systems. Koo10-model1 (Koo and Collins, 2010) used the third-order features and achieved the best reported result among the supervised parsers. Suzuki2009 (Suzuki et al., 2009) reported the best reported result by combining a Semi-supervised Structured Conditional Model (Suzuki and Isozaki, 2008) with the method of (Koo et al., 2008). However, their decoding complexities were higher than ours and we believe that the performance of our parser can be further enhanced by integrating their methods with our parser.

Type	System	UAS	Cost
G	McDonald06	91.5	$O(n^3)$
	Koo08-standard	92.02	$O(n^4)$
	Koo10-model1	93.04	$O(n^4)$
S	Koo08-dep2c	93.16	$O(n^4)$
	Suzuki09	93.79	$O(n^4)$
	Chen09-ord2s	92.51	$O(n^3)$
	Zhou11	92.64	$O(n^4)$
D	MSTB-DLM2	92.76	$O(Kn^3)$

Table 7: Relevant results for English. G denotes the supervised graph-based parsers, S denotes the graph-based parsers with semi-supervised methods, D denotes our new parsers

## 6.7 Compare with previous work on Chinese

Table 8 shows the comparative results, where Chen08 refers to the parser of (Chen et al., 2008), Yu08 refers to the parser of (Yu et al., 2008), Zhao09 refers to the parser of (Zhao et al., 2009), and Chen09-ord2s refers to the second-order parser with subtree-based features of Chen et al. (2009). The results showed that our score for this data was the

best reported so far and significantly higher than the previous scores.

System	UAS
Chen08	86.52
Yu08	87.26
Zhao09	87.0
Chen09-ord2s	89.43
MSTB-DLM2	91.59

Table 8: Relevant results for Chinese

## 7 Analysis

Dependency parsers tend to perform worse on heads which have many children. Here, we studied the effect of DLM-based features for this structure. We calculated the number of children for each head and listed the accuracy changes for different numbers. We compared the MST-DLM1 and MST1 systems on the English data. The accuracy is the percentage of heads having all the correct children.

Figure 5 shows the results for English, where the X-axis represents the number of children, the Y-axis represents the accuracies, OURS refers to MST-DLM1, and Baseline refers to MST1. For example, for heads having two children, Baseline obtained 89.04% accuracy while OURS obtained 89.32%. From the figure, we found that OURS achieved better performance consistently in all cases and when the larger the number of children became, the more significant the performance improvement was.

Figure 5: Improvement relative to numbers of children

## 8 Related work

Several previous studies related to our work have been conducted.

Koo et al. (2008) used a clustering algorithm to produce word clusters on a large amount of unannotated data and represented new features based on the clusters for dependency parsing models. Chen et al. (2009) proposed an approach that extracted partial tree structures from a large amount of data and used them as the additional features to improve dependency parsing. Their approaches were still restricted in a small number of arcs in the graphs. Suzuki et al. (2009) presented a semi-supervised learning approach. They extended a Semi-supervised Structured Conditional Model (SS-SCM)(Suzuki and Isozaki, 2008) to the dependency parsing problem and combined their method with the approach of Koo et al. (2008). In future work, we may consider apply their methods on our parsers to improve further.

Another group of methods are the co-training/self-training techniques. McClosky et al. (2006) presented a self-training approach for phrase structure parsing. Sagae and Tsujii (2007) used the co-training technique to improve performance. First, two parsers were used to parse the sentences in unannotated data. Then they selected some sentences which have the same trees produced by those two parsers. They retrained a parser on newly parsed sentences and the original labeled data. We are able to use the output of our systems for co-training/self-training techniques.

## 9 Conclusion

We have presented an approach to utilizing the dependency language model to improve graph-based dependency parsing. We represent new features based on the dependency language model and integrate them in the decoding algorithm directly using beam-search. Our approach enriches the feature representations but without increasing the decoding complexity. When tested on both English and Chinese data, our parsers provided very competitive performance compared with the best systems on the English data and achieved the best performance on the Chinese data in the literature.

## Abstract

We introduce a spectral learning algorithm for latent-variable PCFGs (Petrov et al., 2006). Under a separability (singular value) condition, we prove that the method provides consistent parameter estimates.

## 1 Introduction

Statistical models with hidden or latent variables are of great importance in natural language processing, speech, and many other fields. The EM algorithm is a remarkably successful method for parameter estimation within these models: it is simple, it is often relatively efficient, and it has well understood formal properties. It does, however, have a major limitation: it has no guarantee of finding the global optimum of the likelihood function. From a theoretical perspective, this means that the EM algorithm is not guaranteed to give consistent parameter estimates. From a practical perspective, problems with local optima can be difficult to deal with.

Recent work has introduced polynomial-time learning algorithms (and consistent estimation methods) for two important cases of hidden-variable models: Gaussian mixture models (Dasgupta, 1999; Vempala and Wang, 2004) and hidden Markov models (Hsu et al., 2009). These algorithms use spectral methods: that is, algorithms based on eigenvector decompositions of linear systems, in particular singular value decomposition (SVD). In the general case, learning of HMMs or GMMs is intractable (e.g., see Terwijn, 2002). Spectral methods finesse the problem of intractability by assuming separability conditions. For example, the algorithm of Hsu et al. (2009) has a sample complexity that is polynomial in  $1/\sigma$ , where  $\sigma$  is the minimum singular value of an underlying decomposition. These methods are not susceptible to problems with local maxima, and give consistent parameter estimates.

In this paper we derive a spectral algorithm for learning of latent-variable PCFGs (L-PCFGs) (Petrov et al., 2006; Matsuzaki et al., 2005). Our

method involves a significant extension of the techniques from Hsu et al. (2009). L-PCFGs have been shown to be a very effective model for natural language parsing. Under a separation (singular value) condition, our algorithm provides consistent parameter estimates; this is in contrast with previous work, which has used the EM algorithm for parameter estimation, with the usual problems of local optima.

The parameter estimation algorithm (see figure 4) is simple and efficient. The first step is to take an SVD of the training examples, followed by a projection of the training examples down to a low-dimensional space. In a second step, empirical averages are calculated on the training example, followed by standard matrix operations. On test examples, simple (tensor-based) variants of the inside-outside algorithm (figures 2 and 3) can be used to calculate probabilities and marginals of interest.

Our method depends on the following results:

- *Tensor form of the inside-outside algorithm.* Section 5 shows that the inside-outside algorithm for L-PCFGs can be written using tensors. Theorem 1 gives conditions under which the tensor form calculates inside and outside terms correctly.

- *Observable representations.* Section 6 shows that under a singular-value condition, there is an *observable form* for the tensors required by the inside-outside algorithm. By an observable form, we follow the terminology of Hsu et al. (2009) in referring to quantities that can be estimated directly from data where values for latent variables are unobserved. Theorem 2 shows that tensors derived from the observable form satisfy the conditions of theorem 1.

- *Estimating the model.* Section 7 gives an algorithm for estimating parameters of the observable representation from training data. Theorem 3 gives a sample complexity result, showing that the estimates converge to the true distribution at a rate of  $1/\sqrt{M}$  where  $M$  is the number of training examples.

The algorithm is strikingly different from the EM algorithm for L-PCFGs, both in its basic form, and in its consistency guarantees. The techniques de-

veloped in this paper are quite general, and should be relevant to the development of spectral methods for estimation in other models in NLP, for example alignment models for translation, synchronous PCFGs, and so on. The tensor form of the inside-outside algorithm gives a new view of basic calculations in PCFGs, and may itself lead to new models.

## 2 Related Work

For work on L-PCFGs using the EM algorithm, see Petrov et al. (2006), Matsuzaki et al. (2005), Pereira and Schabes (1992). Our work builds on methods for learning of HMMs (Hsu et al., 2009; Foster et al., 2012; Jaeger, 2000), but involves several extensions: in particular in the tensor form of the inside-outside algorithm, and observable representations for the tensor form. Balle et al. (2011) consider spectral learning of finite-state transducers; Lague et al. (2012) considers spectral learning of head automata for dependency parsing. Parikh et al. (2011) consider spectral learning algorithms of tree-structured directed bayes nets.

## 3 Notation

Given a matrix  $A$  or a vector  $v$ , we write  $A^\top$  or  $v^\top$  for the associated transpose. For any integer  $n \geq 1$ , we use  $[n]$  to denote the set  $\{1, 2, \dots, n\}$ . For any row or column vector  $y \in \mathbb{R}^m$ , we use  $\text{diag}(y)$  to refer to the  $(m \times m)$  matrix with diagonal elements equal to  $y_h$  for  $h = 1 \dots m$ , and off-diagonal elements equal to 0. For any statement  $\Gamma$ , we use  $[[\Gamma]]$  to refer to the indicator function that is 1 if  $\Gamma$  is true, and 0 if  $\Gamma$  is false. For a random variable  $X$ , we use  $\mathbb{E}[X]$  to denote its expected value.

We will make (quite limited) use of tensors:

**Definition 1** A tensor  $C \in \mathbb{R}^{(m \times m \times m)}$  is a set of  $m^3$  parameters  $C_{i,j,k}$  for  $i, j, k \in [m]$ . Given a tensor  $C$ , and a vector  $y \in \mathbb{R}^m$ , we define  $C(y)$  to be the  $(m \times m)$  matrix with components  $[C(y)]_{i,j} = \sum_{k \in [m]} C_{i,j,k} y_k$ . Hence  $C$  can be interpreted as a function  $C : \mathbb{R}^m \rightarrow \mathbb{R}^{(m \times m)}$  that maps a vector  $y \in \mathbb{R}^m$  to a matrix  $C(y)$  of dimension  $(m \times m)$ .

In addition, we define the tensor  $C_* \in \mathbb{R}^{(m \times m \times m)}$  for any tensor  $C \in \mathbb{R}^{(m \times m \times m)}$  to have values

$$[C_*]_{i,j,k} = C_{k,j,i}$$

Finally, for vectors  $x, y, z \in \mathbb{R}^m$ ,  $xy^\top z^\top$  is the tensor  $D \in \mathbb{R}^{m \times m \times m}$  where  $D_{j,k,l} = x_j y_k z_l$  (this is analogous to the outer product:  $[xy^\top]_{j,k} = x_j y_k$ ).

## 4 L-PCFGs: Basic Definitions

This section gives a definition of the L-PCFG formalism used in this paper. An L-PCFG is a 5-tuple  $(\mathcal{N}, \mathcal{I}, \mathcal{P}, m, n)$  where:

- $\mathcal{N}$  is the set of non-terminal symbols in the grammar.  $\mathcal{I} \subset \mathcal{N}$  is a finite set of *in-terminals*.  $\mathcal{P} \subset \mathcal{N}$  is a finite set of *pre-terminals*. We assume that  $\mathcal{N} = \mathcal{I} \cup \mathcal{P}$ , and  $\mathcal{I} \cap \mathcal{P} = \emptyset$ . Hence we have partitioned the set of non-terminals into two subsets.

- $[m]$  is the set of possible hidden states.
- $[n]$  is the set of possible words.
- For all  $a \in \mathcal{I}$ ,  $b \in \mathcal{N}$ ,  $c \in \mathcal{N}$ ,  $h_1, h_2, h_3 \in [m]$ , we have a context-free rule  $a(h_1) \rightarrow b(h_2) c(h_3)$ .
- For all  $a \in \mathcal{P}$ ,  $h \in [m]$ ,  $x \in [n]$ , we have a context-free rule  $a(h) \rightarrow x$ .

Hence each in-terminal  $a \in \mathcal{I}$  is always the left-hand-side of a binary rule  $a \rightarrow b c$ ; and each pre-terminal  $a \in \mathcal{P}$  is always the left-hand-side of a rule  $a \rightarrow x$ . Assuming that the non-terminals in the grammar can be partitioned this way is relatively benign, and makes the estimation problem cleaner.

We define the set of possible “skeletal rules” as  $\mathcal{R} = \{a \rightarrow b c : a \in \mathcal{I}, b \in \mathcal{N}, c \in \mathcal{N}\}$ . The parameters of the model are as follows:

- For each  $a \rightarrow b c \in \mathcal{R}$ , and  $h \in [m]$ , we have a parameter  $q(a \rightarrow b c | h, a)$ . For each  $a \in \mathcal{P}$ ,  $x \in [n]$ , and  $h \in [m]$ , we have a parameter  $q(a \rightarrow x | h, a)$ . For each  $a \rightarrow b c \in \mathcal{R}$ , and  $h, h' \in [m]$ , we have parameters  $s(h' | h, a \rightarrow b c)$  and  $t(h' | h, a \rightarrow b c)$ .

These definitions give a PCFG, with rule probabilities

$$p(a(h_1) \rightarrow b(h_2) c(h_3) | a(h_1)) = q(a \rightarrow b c | h_1, a) \times s(h_2 | h_1, a \rightarrow b c) \times t(h_3 | h_1, a \rightarrow b c)$$

$$\text{and } p(a(h) \rightarrow x | a(h)) = q(a \rightarrow x | h, a).$$

In addition, for each  $a \in \mathcal{I}$ , for each  $h \in [m]$ , we have a parameter  $\pi(a, h)$  which is the probability of non-terminal  $a$  paired with hidden variable  $h$  being at the root of the tree.

An L-PCFG defines a distribution over parse trees as follows. A *skeletal tree* (s-tree) is a sequence of rules  $r_1 \dots r_N$  where each  $r_i$  is either of the form  $a \rightarrow b c$  or  $a \rightarrow x$ . The rule sequence forms a top-down, left-most derivation under a CFG with skeletal rules. See figure 1 for an example.

A *full tree* consists of an s-tree  $r_1 \dots r_N$ , together with values  $h_1 \dots h_N$ . Each  $h_i$  is the value for

Figure 1: An s-tree, and its sequence of rules. (For convenience we have numbered the nodes in the tree.)

the hidden variable for the left-hand-side of rule  $r_i$ . Each  $h_i$  can take any value in  $[m]$ .

Define  $a_i$  to be the non-terminal on the left-hand-side of rule  $r_i$ . For any  $i \in \{2 \dots N\}$  define  $\text{pa}(i)$  to be the index of the rule above node  $i$  in the tree. Define  $L \subset [N]$  to be the set of nodes in the tree which are the left-child of some parent, and  $R \subset [N]$  to be the set of nodes which are the right-child of some parent. The probability mass function (PMF) over full trees is then

$$\begin{aligned}
 p(r_1 \dots r_N, h_1 \dots h_N) &= \pi(a_1, h_1) \\
 &\times \prod_{i=1}^N q(r_i | h_i, a_i) \times \prod_{i \in L} s(h_i | h_{\text{pa}(i)}, r_{\text{pa}(i)}) \\
 &\times \prod_{i \in R} t(h_i | h_{\text{pa}(i)}, r_{\text{pa}(i)}) \quad (1)
 \end{aligned}$$

The PMF over s-trees is  $p(r_1 \dots r_N) = \sum_{h_1 \dots h_N} p(r_1 \dots r_N, h_1 \dots h_N)$ .

In the remainder of this paper, we make use of matrix form of parameters of an L-PCFG, as follows:

- For each  $a \rightarrow b c \in \mathcal{R}$ , we define  $Q^{a \rightarrow b c} \in \mathbb{R}^{m \times m}$  to be the matrix with values  $q(a \rightarrow b c | h, a)$  for  $h = 1, 2, \dots, m$  on its diagonal, and 0 values for its off-diagonal elements. Similarly, for each  $a \in \mathcal{P}$ ,  $x \in [n]$ , we define  $Q^{a \rightarrow x} \in \mathbb{R}^{m \times m}$  to be the matrix with values  $q(a \rightarrow x | h, a)$  for  $h = 1, 2, \dots, m$  on its diagonal, and 0 values for its off-diagonal elements.
- For each  $a \rightarrow b c \in \mathcal{R}$ , we define  $S^{a \rightarrow b c} \in \mathbb{R}^{m \times m}$  where  $[S^{a \rightarrow b c}]_{h', h} = s(h' | h, a \rightarrow b c)$ .
- For each  $a \rightarrow b c \in \mathcal{R}$ , we define  $T^{a \rightarrow b c} \in \mathbb{R}^{m \times m}$  where  $[T^{a \rightarrow b c}]_{h', h} = t(h' | h, a \rightarrow b c)$ .
- For each  $a \in \mathcal{I}$ , we define the vector  $\pi^a \in \mathbb{R}^m$  where  $[\pi^a]_h = \pi(a, h)$ .

## 5 Tensor Form of the Inside-Outside Algorithm

Given an L-PCFG, two calculations are central:

**Inputs:** s-tree  $r_1 \dots r_N$ , L-PCFG  $(\mathcal{N}, \mathcal{I}, \mathcal{P}, m, n)$ , parameters

- $C^{a \rightarrow b c} \in \mathbb{R}^{(m \times m \times m)}$  for all  $a \rightarrow b c \in \mathcal{R}$
- $c_{a \rightarrow x}^\infty \in \mathbb{R}^{(1 \times m)}$  for all  $a \in \mathcal{P}, x \in [n]$
- $c_a^1 \in \mathbb{R}^{(m \times 1)}$  for all  $a \in \mathcal{I}$ .

**Algorithm:** (calculate the  $f^i$  terms bottom-up in the tree)

- For all  $i \in [N]$  such that  $a_i \in \mathcal{P}$ ,  $f^i = c_{r_i}^\infty$
- For all  $i \in [N]$  such that  $a_i \in \mathcal{I}$ ,  $f^i = f^\gamma C^{r_i}(f^\beta)$  where  $\beta$  is the index of the left child of node  $i$  in the tree, and  $\gamma$  is the index of the right child.

**Return:**  $f^1 c_{a_1}^1 = p(r_1 \dots r_N)$

Figure 2: The tensor form for calculation of  $p(r_1 \dots r_N)$ .

1. For a given s-tree  $r_1 \dots r_N$ , calculate  $p(r_1 \dots r_N)$ .
2. For a given input sentence  $x = x_1 \dots x_N$ , calculate the marginal probabilities

$$\mu(a, i, j) = \sum_{\tau \in \mathcal{T}(x): (a, i, j) \in \tau} p(\tau)$$

for each non-terminal  $a \in \mathcal{N}$ , for each  $(i, j)$  such that  $1 \leq i \leq j \leq N$ .

Here  $\mathcal{T}(x)$  denotes the set of all possible s-trees for the sentence  $x$ , and we write  $(a, i, j) \in \tau$  if non-terminal  $a$  spans words  $x_i \dots x_j$  in the parse tree  $\tau$ .

The marginal probabilities have a number of uses. Perhaps most importantly, for a given sentence  $x = x_1 \dots x_N$ , the parsing algorithm of Goodman (1996) can be used to find

$$\arg \max_{\tau \in \mathcal{T}(x)} \sum_{(a, i, j) \in \tau} \mu(a, i, j)$$

This is the parsing algorithm used by Petrov et al. (2006), for example. In addition, we can calculate the probability for an input sentence,  $p(x) = \sum_{\tau \in \mathcal{T}(x)} p(\tau)$ , as  $p(x) = \sum_{a \in \mathcal{I}} \mu(a, 1, N)$ .

Variants of the inside-outside algorithm can be used for problems 1 and 2. This section introduces a novel form of these algorithms, using tensors. This is the first step in deriving the spectral estimation method.

The algorithms are shown in figures 2 and 3. Each algorithm takes the following inputs:

1. A tensor  $C^{a \rightarrow b c} \in \mathbb{R}^{(m \times m \times m)}$  for each rule  $a \rightarrow b c$ .
2. A vector  $c_{a \rightarrow x}^\infty \in \mathbb{R}^{(1 \times m)}$  for each rule  $a \rightarrow x$ .

3. A vector  $c_a^1 \in \mathbb{R}^{(m \times 1)}$  for each  $a \in \mathcal{I}$ .

The following theorem gives conditions under which the algorithms are correct:

**Theorem 1** Assume that we have an L-PCFG with parameters  $Q^{a \rightarrow x}, Q^{a \rightarrow b c}, T^{a \rightarrow b c}, S^{a \rightarrow b c}, \pi^a$ , and that there exist matrices  $G^a \in \mathbb{R}^{(m \times m)}$  for all  $a \in \mathcal{N}$  such that each  $G^a$  is invertible, and such that:

1. For all rules  $a \rightarrow b c$ ,  $C^{a \rightarrow b c}(y) = G^c T^{a \rightarrow b c} \text{diag}(y G^b S^{a \rightarrow b c}) Q^{a \rightarrow b c} (G^a)^{-1}$
2. For all rules  $a \rightarrow x$ ,  $c_{a \rightarrow x}^\infty = 1^\top Q^{a \rightarrow x} (G^a)^{-1}$
3. For all  $a \in \mathcal{I}$ ,  $c_a^1 = G^a \pi^a$

Then: 1) The algorithm in figure 2 correctly computes  $p(r_1 \dots r_N)$  under the L-PCFG. 2) The algorithm in figure 3 correctly computes the marginals  $\mu(a, i, j)$  under the L-PCFG.

*Proof:* See section 9.1.  $\square$

## 6 Estimating the Tensor Model

A crucial result is that it is possible to directly estimate parameters  $C^{a \rightarrow b c}$ ,  $c_{a \rightarrow x}^\infty$  and  $c_a^1$  that satisfy the conditions in theorem 1, from a training sample consisting of s-trees (i.e., trees where hidden variables are unobserved). We first describe random variables underlying the approach, then describe observable representations based on these random variables.

### 6.1 Random Variables Underlying the Approach

Each s-tree with  $N$  rules  $r_1 \dots r_N$  has  $N$  nodes. We will use the s-tree in figure 1 as a running example.

Each node has an associated rule: for example, node 2 in the tree in figure 1 has the rule  $\text{NP} \rightarrow \text{D N}$ . If the rule at a node is of the form  $a \rightarrow b c$ , then there are left and right *inside trees* below the left child and right child of the rule. For example, for node 2 we have a left inside tree rooted at node 3, and a right inside tree rooted at node 4 (in this case the left and right inside trees both contain only a single rule production, of the form  $a \rightarrow x$ ; however in the general case they might be arbitrary subtrees).

In addition, each node has an *outside tree*. For node 2, the outside tree is

**Inputs:** Sentence  $x_1 \dots x_N$ , L-PCFG  $(\mathcal{N}, \mathcal{I}, \mathcal{P}, m, n)$ , parameters  $C^{a \rightarrow b c} \in \mathbb{R}^{(m \times m \times m)}$  for all  $a \rightarrow b c \in \mathcal{R}$ ,  $c_{a \rightarrow x}^\infty \in \mathbb{R}^{(1 \times m)}$  for all  $a \in \mathcal{P}, x \in [n]$ ,  $c_a^1 \in \mathbb{R}^{(m \times 1)}$  for all  $a \in \mathcal{I}$ .

**Data structures:**

- Each  $\alpha^{a,i,j} \in \mathbb{R}^{1 \times m}$  for  $a \in \mathcal{N}, 1 \leq i \leq j \leq N$  is a row vector of inside terms.
- Each  $\beta^{a,i,j} \in \mathbb{R}^{m \times 1}$  for  $a \in \mathcal{N}, 1 \leq i \leq j \leq N$  is a column vector of outside terms.
- Each  $\mu(a, i, j) \in \mathbb{R}$  for  $a \in \mathcal{N}, 1 \leq i \leq j \leq N$  is a marginal probability.

**Algorithm:**

(Inside base case)  $\forall a \in \mathcal{P}, i \in [N], \alpha^{a,i,i} = c_{a \rightarrow x_i}^\infty$   
 (Inside recursion)  $\forall a \in \mathcal{I}, 1 \leq i < j \leq N,$

$$\alpha^{a,i,j} = \sum_{k=i}^{j-1} \sum_{a \rightarrow b c} \alpha^{c,k+1,j} C^{a \rightarrow b c} (\alpha^{b,i,k})$$

(Outside base case)  $\forall a \in \mathcal{I}, \beta^{a,1,n} = c_a^1$   
 (Outside recursion)  $\forall a \in \mathcal{N}, 1 \leq i \leq j \leq N,$

$$\beta^{a,i,j} = \sum_{k=1}^{i-1} \sum_{b \rightarrow c a} C^{b \rightarrow c a} (\alpha^{c,k,i-1}) \beta^{b,k,j}$$

$$+ \sum_{k=j+1}^N \sum_{b \rightarrow a c} C_*^{b \rightarrow a c} (\alpha^{c,j+1,k}) \beta^{b,i,k}$$

(Marginals)  $\forall a \in \mathcal{N}, 1 \leq i \leq j \leq N,$

$$\mu(a, i, j) = \alpha^{a,i,j} \beta^{a,i,j} = \sum_{h \in [m]} \alpha_h^{a,i,j} \beta_h^{a,i,j}$$

Figure 3: The tensor form of the inside-outside algorithm, for calculation of marginal terms  $\mu(a, i, j)$ .

The outside tree contains everything in the s-tree  $r_1 \dots r_N$ , excluding the subtree below node  $i$ .

Our random variables are defined as follows. First, we select a random internal node, from a random tree, as follows:

- Sample an s-tree  $r_1 \dots r_N$  from the PMF  $p(r_1 \dots r_N)$ . Choose a node  $i$  uniformly at random from  $[N]$ .

If the rule  $r_i$  for the node  $i$  is of the form  $a \rightarrow b c$ , we define random variables as follows:

- $R_1$  is equal to the rule  $r_i$  (e.g.,  $\text{NP} \rightarrow \text{D N}$ ).
- $T_1$  is the inside tree rooted at node  $i$ .  $T_2$  is the inside tree rooted at the left child of node  $i$ , and  $T_3$  is the inside tree rooted at the right child of node  $i$ .
- $H_1, H_2, H_3$  are the hidden variables associated with node  $i$ , the left child of node  $i$ , and the right child of node  $i$  respectively.

- $A_1, A_2, A_3$  are the labels for node  $i$ , the left child of node  $i$ , and the right child of node  $i$  respectively. (E.g.,  $A_1 = \text{NP}$ ,  $A_2 = \text{D}$ ,  $A_3 = \text{N}$ .)

- $O$  is the outside tree at node  $i$ .

- $B$  is equal to 1 if node  $i$  is at the root of the tree (i.e.,  $i = 1$ ), 0 otherwise.

If the rule  $r_i$  for the selected node  $i$  is of the form  $a \rightarrow x$ , we have random variables  $R_1, T_1, H_1, A_1, O, B$  as defined above, but  $H_2, H_3, T_2, T_3, A_2$ , and  $A_3$  are not defined.

We assume a function  $\psi$  that maps outside trees  $o$  to feature vectors  $\psi(o) \in \mathbb{R}^{d'}$ . For example, the feature vector might track the rule directly above the node in question, the word following the node in question, and so on. We also assume a function  $\phi$  that maps inside trees  $t$  to feature vectors  $\phi(t) \in \mathbb{R}^d$ . As one example, the function  $\phi$  might be an indicator function tracking the rule production at the root of the inside tree. Later we give formal criteria for what makes good definitions of  $\psi(o)$  or  $\phi(t)$ . One requirement is that  $d' \geq m$  and  $d \geq m$ .

In tandem with these definitions, we assume projection matrices  $U^a \in \mathbb{R}^{(d \times m)}$  and  $V^a \in \mathbb{R}^{(d' \times m)}$  for all  $a \in \mathcal{N}$ . We then define additional random variables  $Y_1, Y_2, Y_3, Z$  as

$$Y_1 = (U^{a_1})^\top \phi(T_1) \quad Z = (V^{a_1})^\top \psi(O)$$

$$Y_2 = (U^{a_2})^\top \phi(T_2) \quad Y_3 = (U^{a_3})^\top \phi(T_3)$$

where  $a_i$  is the value of the random variable  $A_i$ . Note that  $Y_1, Y_2, Y_3, Z$  are all in  $\mathbb{R}^m$ .

## 6.2 Observable Representations

Given the definitions in the previous section, our representation is based on the following matrix, tensor and vector quantities, defined for all  $a \in \mathcal{N}$ , for all rules of the form  $a \rightarrow b c$ , and for all rules of the form  $a \rightarrow x$  respectively:

$$\begin{aligned} \Sigma^a &= \mathbf{E}[Y_1 Z^\top | A_1 = a] \\ D^{a \rightarrow b c} &= \mathbf{E} \left[ [[R_1 = a \rightarrow b c]] Y_3 Z^\top Y_2^\top | A_1 = a \right] \\ d_{a \rightarrow x}^\infty &= \mathbf{E} \left[ [[R_1 = a \rightarrow x]] Z^\top | A_1 = a \right] \end{aligned}$$

Assuming access to functions  $\phi$  and  $\psi$ , and projection matrices  $U^a$  and  $V^a$ , these quantities can be estimated directly from training data consisting of a set of s-trees (see section 7).

Our observable representation then consists of:

$$C^{a \rightarrow b c}(y) = D^{a \rightarrow b c}(y) (\Sigma^a)^{-1} \quad (2)$$

$$c_{a \rightarrow x}^\infty = d_{a \rightarrow x}^\infty (\Sigma^a)^{-1} \quad (3)$$

$$c_a^1 = \mathbf{E} [[A_1 = a]] Y_1 | B = 1 \quad (4)$$

We next introduce conditions under which these quantities satisfy the conditions in theorem 1.

The following definition will be important:

**Definition 2** For all  $a \in \mathcal{N}$ , we define the matrices  $I^a \in \mathbb{R}^{(d \times m)}$  and  $J^a \in \mathbb{R}^{(d' \times m)}$  as

$$[I^a]_{i,h} = \mathbf{E}[\phi_i(T_1) | H_1 = h, A_1 = a]$$

$$[J^a]_{i,h} = \mathbf{E}[\psi_i(O) | H_1 = h, A_1 = a]$$

In addition, for any  $a \in \mathcal{N}$ , we use  $\gamma^a \in \mathbb{R}^m$  to denote the vector with  $\gamma_h^a = P(H_1 = h | A_1 = a)$ .

The correctness of the representation will rely on the following conditions being satisfied (these are parallel to conditions 1 and 2 in Hsu et al. (2009)):

**Condition 1**  $\forall a \in \mathcal{N}$ , the matrices  $I^a$  and  $J^a$  are of full rank (i.e., they have rank  $m$ ). For all  $a \in \mathcal{N}$ , for all  $h \in [m]$ ,  $\gamma_h^a > 0$ .

**Condition 2**  $\forall a \in \mathcal{N}$ , the matrices  $U^a \in \mathbb{R}^{(d \times m)}$  and  $V^a \in \mathbb{R}^{(d' \times m)}$  are such that the matrices  $G^a = (U^a)^\top I^a$  and  $K^a = (V^a)^\top J^a$  are invertible.

The following lemma justifies the use of an SVD calculation as one method for finding values for  $U^a$  and  $V^a$  that satisfy condition 2:

**Lemma 1** Assume that condition 1 holds, and for all  $a \in \mathcal{N}$  define

$$\Omega^a = \mathbf{E}[\phi(T_1) (\psi(O))^\top | A_1 = a] \quad (5)$$

Then if  $U^a$  is a matrix of the  $m$  left singular vectors of  $\Omega^a$  corresponding to non-zero singular values, and  $V^a$  is a matrix of the  $m$  right singular vectors of  $\Omega^a$  corresponding to non-zero singular values, then condition 2 is satisfied.

*Proof sketch:* It can be shown that  $\Omega^a = I^a \text{diag}(\gamma^a) (J^a)^\top$ . The remainder is similar to the proof of lemma 2 in Hsu et al. (2009).  $\square$

The matrices  $\Omega^a$  can be estimated directly from a training set consisting of s-trees, assuming that we have access to the functions  $\phi$  and  $\psi$ .

We can now state the following theorem:

**Theorem 2** Assume conditions 1 and 2 are satisfied. For all  $a \in \mathcal{N}$ , define  $G^a = (U^a)^\top I^a$ . Then under the definitions in Eqs. 2-4:

1. For all rules  $a \rightarrow b c$ ,  $C^{a \rightarrow b c}(y) = G^c T^{a \rightarrow b c} \text{diag}(y G^b S^{a \rightarrow b c}) Q^{a \rightarrow b c} (G^a)^{-1}$
2. For all rules  $a \rightarrow x$ ,  $c_{a \rightarrow x}^\infty = 1^\top Q^{a \rightarrow x} (G^a)^{-1}$ .
3. For all  $a \in \mathcal{N}$ ,  $c_a^1 = G^a \pi^a$

*Proof:* The following identities hold (see section 9.2):

$$D^{a \rightarrow b c}(y) = \quad (6)$$

$$G^c T^{a \rightarrow b c} \text{diag}(y G^b S^{a \rightarrow b c}) Q^{a \rightarrow b c} \text{diag}(\gamma^a) (K^a)^\top$$

$$d_{a \rightarrow x}^\infty = 1^\top Q^{a \rightarrow x} \text{diag}(\gamma^a) (K^a)^\top \quad (7)$$

$$\Sigma^a = G^a \text{diag}(\gamma^a) (K^a)^\top \quad (8)$$

$$c_a^1 = G^a \pi^a \quad (9)$$

Under conditions 1 and 2,  $\Sigma^a$  is invertible, and  $(\Sigma^a)^{-1} = ((K^a)^\top)^{-1} (\text{diag}(\gamma^a))^{-1} (G^a)^{-1}$ . The identities in the theorem follow immediately.  $\square$

## 7 Deriving Empirical Estimates

Figure 4 shows an algorithm that derives estimates of the quantities in Eqs 2, 3, and 4. As input, the algorithm takes a sequence of tuples  $(r^{(i,1)}, t^{(i,1)}, t^{(i,2)}, t^{(i,3)}, o^{(i)}, b^{(i)})$  for  $i \in [M]$ .

These tuples can be derived from a training set consisting of s-trees  $\tau_1 \dots \tau_M$  as follows:

- $\forall i \in [M]$ , choose a single node  $j_i$  uniformly at random from the nodes in  $\tau_i$ . Define  $r^{(i,1)}$  to be the rule at node  $j_i$ .  $t^{(i,1)}$  is the inside tree rooted at node  $j_i$ . If  $r^{(i,1)}$  is of the form  $a \rightarrow b c$ , then  $t^{(i,2)}$  is the inside tree under the left child of node  $j_i$ , and  $t^{(i,3)}$  is the inside tree under the right child of node  $j_i$ . If  $r^{(i,1)}$  is of the form  $a \rightarrow x$ , then  $t^{(i,2)} = t^{(i,3)} = \text{NULL}$ .  $o^{(i)}$  is the outside tree at node  $j_i$ .  $b^{(i)}$  is 1 if node  $j_i$  is at the root of the tree, 0 otherwise.

Under this process, assuming that the s-trees  $\tau_1 \dots \tau_M$  are i.i.d. draws from the distribution  $p(\tau)$  over s-trees under an L-PCFG, the tuples  $(r^{(i,1)}, t^{(i,1)}, t^{(i,2)}, t^{(i,3)}, o^{(i)}, b^{(i)})$  are i.i.d. draws from the joint distribution over the random variables  $R_1, T_1, T_2, T_3, O, B$  defined in the previous section.

The algorithm first computes estimates of the projection matrices  $U^a$  and  $V^a$ : following lemma 1, this is done by first deriving estimates of  $\Omega^a$ , and then taking SVDs of each  $\Omega^a$ . The matrices are then used to project inside and outside trees

$t^{(i,1)}, t^{(i,2)}, t^{(i,3)}, o^{(i)}$  down to  $m$ -dimensional vectors  $y^{(i,1)}, y^{(i,2)}, y^{(i,3)}, z^{(i)}$ ; these vectors are used to derive the estimates of  $C^{a \rightarrow b c}$ ,  $c_{a \rightarrow x}^\infty$ , and  $c_a^1$ .

We now state a PAC-style theorem for the learning algorithm. First, for a given L-PCFG, we need a couple of definitions:

- $\Lambda$  is the minimum absolute value of any element of the vectors/matrices/tensors  $c_a^1, d_{a \rightarrow x}^\infty, D^{a \rightarrow b c}, (\Sigma^a)^{-1}$ . (Note that  $\Lambda$  is a function of the projection matrices  $U^a$  and  $V^a$  as well as the underlying L-PCFG.)

- For each  $a \in \mathcal{N}$ ,  $\sigma^a$  is the value of the  $m$ 'th largest singular value of  $\Omega^a$ . Define  $\sigma = \min_a \sigma^a$ .

We then have the following theorem:

**Theorem 3** Assume that the inputs to the algorithm in figure 4 are i.i.d. draws from the joint distribution over the random variables  $R_1, T_1, T_2, T_3, O, B$ , under an L-PCFG with distribution  $p(r_1 \dots r_N)$  over s-trees. Define  $m$  to be the number of latent states in the L-PCFG. Assume that the algorithm in figure 4 has projection matrices  $\hat{U}^a$  and  $\hat{V}^a$  derived as left and right singular vectors of  $\Omega^a$ , as defined in Eq. 5. Assume that the L-PCFG, together with  $\hat{U}^a$  and  $\hat{V}^a$ , has coefficients  $\Lambda > 0$  and  $\sigma > 0$ . In addition, assume that all elements in  $c_a^1, d_{a \rightarrow x}^\infty, D^{a \rightarrow b c}$ , and  $\Sigma^a$  are in  $[-1, +1]$ . For any s-tree  $r_1 \dots r_N$  define  $\hat{p}(r_1 \dots r_N)$  to be the value calculated by the algorithm in figure 3 with inputs  $\hat{c}_a^1, \hat{d}_{a \rightarrow x}^\infty, \hat{C}^{a \rightarrow b c}$  derived from the algorithm in figure 4. Define  $R$  to be the total number of rules in the grammar of the form  $a \rightarrow b c$  or  $a \rightarrow x$ . Define  $M_a$  to be the number of training examples in the input to the algorithm in figure 4 where  $r^{i,1}$  has non-terminal  $a$  on its left-hand-side. Under these assumptions, if for all  $a$

$$M_a \geq \frac{128m^2}{(\sqrt{2N+1} + \epsilon - 1)^2 \Lambda^2 \sigma^4} \log \left( \frac{2mR}{\delta} \right)$$

Then

$$1 - \epsilon \leq \left| \frac{\hat{p}(r_1 \dots r_N)}{p(r_1 \dots r_N)} \right| \leq 1 + \epsilon$$

A similar theorem (omitted for space) states that  $1 - \epsilon \leq \left| \frac{\hat{\mu}(a,i,j)}{\mu(a,i,j)} \right| \leq 1 + \epsilon$  for the marginals.

The condition that  $\hat{U}^a$  and  $\hat{V}^a$  are derived from  $\Omega^a$ , as opposed to the sample estimate  $\hat{\Omega}^a$ , follows Foster et al. (2012). As these authors note, similar techniques to those of Hsu et al. (2009) should be

applicable in deriving results for the case where  $\hat{\Omega}^a$  is used in place of  $\Omega^a$ .

*Proof sketch:* The proof is similar to that of Foster et al. (2012). The basic idea is to first show that under the assumptions of the theorem, the estimates  $\hat{c}_a^1$ ,  $\hat{d}_{a \rightarrow x}^\infty$ ,  $\hat{D}^{a \rightarrow b c}$ ,  $\hat{\Sigma}^a$  are all close to the underlying values being estimated. The second step is to show that this ensures that  $\frac{\hat{p}(r_1 \dots r_{N'})}{p(r_1 \dots r_{N'})}$  is close to 1.  $\square$

The method described of selecting a single tuple  $(r^{(i,1)}, t^{(i,1)}, t^{(i,2)}, t^{(i,3)}, o^{(i)}, b^{(i)})$  for each s-tree ensures that the samples are i.i.d., and simplifies the analysis underlying theorem 3. In practice, an implementation should most likely use all nodes in all trees in training data; by Rao-Blackwellization we know such an algorithm would be better than the one presented, but the analysis of how much better would be challenging. It would almost certainly lead to a faster rate of convergence of  $\hat{p}$  to  $p$ .

## 8 Discussion

There are several potential applications of the method. The most obvious is parsing with L-PCFGs.<sup>1</sup> The approach should be applicable in other cases where EM has traditionally been used, for example in semi-supervised learning. Latent-variable HMMs for sequence labeling can be derived as special case of our approach, by converting tagged sequences to right-branching skeletal trees.

The sample complexity of the method depends on the minimum singular values of  $\Omega^a$ ; these singular values are a measure of how well correlated  $\psi$  and  $\phi$  are with the unobserved hidden variable  $H_1$ . Experimental work is required to find a good choice of values for  $\psi$  and  $\phi$  for parsing.

## 9 Proofs

This section gives proofs of theorems 1 and 2. Due to space limitations we cannot give full proofs; instead we provide proofs of some key lemmas. A long version of this paper will give the full proofs.

### 9.1 Proof of Theorem 1

First, the following lemma leads directly to the correctness of the algorithm in figure 2:

<sup>1</sup>Parameters can be estimated using the algorithm in figure 4; for a test sentence  $x_1 \dots x_N$  we can first use the algorithm in figure 3 to calculate marginals  $\mu(a, i, j)$ , then use the algorithm of Goodman (1996) to find  $\arg \max_{\tau \in \mathcal{T}(x)} \sum_{(a,i,j) \in \tau} \mu(a, i, j)$ .

**Inputs:** Training examples  $(r^{(i,1)}, t^{(i,1)}, t^{(i,2)}, t^{(i,3)}, o^{(i)}, b^{(i)})$  for  $i \in \{1 \dots M\}$ , where  $r^{(i,1)}$  is a context free rule;  $t^{(i,1)}$ ,  $t^{(i,2)}$  and  $t^{(i,3)}$  are inside trees;  $o^{(i)}$  is an outside tree; and  $b^{(i)} = 1$  if the rule is at the root of tree, 0 otherwise. A function  $\phi$  that maps inside trees  $t$  to feature-vectors  $\phi(t) \in \mathbb{R}^d$ . A function  $\psi$  that maps outside trees  $o$  to feature-vectors  $\psi(o) \in \mathbb{R}^{d'}$ .

**Algorithm:**

Define  $a_i$  to be the non-terminal on the left-hand side of rule  $r^{(i,1)}$ . If  $r^{(i,1)}$  is of the form  $a \rightarrow b c$ , define  $b_i$  to be the non-terminal for the left-child of  $r^{(i,1)}$ , and  $c_i$  to be the non-terminal for the right-child.

(Step 0: Singular Value Decompositions)

- Use the algorithm in figure 5 to calculate matrices  $\hat{U}^a \in \mathbb{R}^{(d \times m)}$  and  $\hat{V}^a \in \mathbb{R}^{(d' \times m)}$  for each  $a \in \mathcal{N}$ .

(Step 1: Projection)

- For all  $i \in [M]$ , compute  $y^{(i,1)} = (\hat{U}^{a_i})^\top \phi(t^{(i,1)})$ .
- For all  $i \in [M]$  such that  $r^{(i,1)}$  is of the form  $a \rightarrow b c$ , compute  $y^{(i,2)} = (\hat{U}^{b_i})^\top \phi(t^{(i,2)})$  and  $y^{(i,3)} = (\hat{U}^{c_i})^\top \phi(t^{(i,3)})$ .
- For all  $i \in [M]$ , compute  $z^{(i)} = (\hat{V}^{a_i})^\top \psi(o^{(i)})$ .

(Step 2: Calculate Correlations)

- For each  $a \in \mathcal{N}$ , define  $\delta_a = 1 / \sum_{i=1}^M [[a_i = a]]$
- For each rule  $a \rightarrow b c$ , compute  $\hat{D}^{a \rightarrow b c} = \delta_a \times \sum_{i=1}^M [[r^{(i,1)} = a \rightarrow b c]] y^{(i,2)} (z^{(i)})^\top (y^{(i,1)})^\top$
- For each rule  $a \rightarrow x$ , compute  $\hat{d}_{a \rightarrow x}^\infty = \delta_a \times \sum_{i=1}^M [[r^{(i,1)} = a \rightarrow x]] (z^{(i)})^\top$
- For each  $a \in \mathcal{N}$ , compute  $\hat{\Sigma}^a = \delta_a \times \sum_{i=1}^M [[a_i = a]] y^{(i,1)} (z^{(i)})^\top$

(Step 3: Compute Final Parameters)

- For all  $a \rightarrow b c$ ,  $\hat{C}^{a \rightarrow b c}(y) = \hat{D}^{a \rightarrow b c}(y) (\hat{\Sigma}^a)^{-1}$
- For all  $a \rightarrow x$ ,  $\hat{c}_{a \rightarrow x}^\infty = \hat{d}_{a \rightarrow x}^\infty (\hat{\Sigma}^a)^{-1}$
- For all  $a \in \mathcal{I}$ ,  $\hat{c}_a^1 = \frac{\sum_{i=1}^M [[a_i = a \text{ and } b^{(i)} = 1]] y^{(i,1)}}{\sum_{i=1}^M [[b^{(i)} = 1]]}$

Figure 4: The spectral learning algorithm.

**Inputs:** Identical to algorithm in figure 4.

**Algorithm:**

- For each  $a \in \mathcal{N}$ , compute  $\hat{\Omega}^a \in \mathbb{R}^{(d' \times d)}$  as

$$\hat{\Omega}^a = \frac{\sum_{i=1}^M [[a_i = a]] \phi(t^{(i,1)}) (\psi(o^{(i)}))^\top}{\sum_{i=1}^M [[a_i = a]]}$$

and calculate a singular value decomposition of  $\hat{\Omega}^a$ .

- For each  $a \in \mathcal{N}$ , define  $\hat{U}^a \in \mathbb{R}^{m \times d}$  to be a matrix of the left singular vectors of  $\hat{\Omega}^a$  corresponding to the  $m$  largest singular values. Define  $\hat{V}^a \in \mathbb{R}^{m \times d'}$  to be a matrix of the right singular vectors of  $\hat{\Omega}^a$  corresponding to the  $m$  largest singular values.

Figure 5: Singular value decompositions.

**Lemma 2** Assume that conditions 1-3 of theorem 1 are satisfied, and that the input to the algorithm in figure 2 is an  $s$ -tree  $r_1 \dots r_N$ . Define  $a_i$  for  $i \in [N]$  to be the non-terminal on the left-hand-side of rule  $r_i$ , and  $t_i$  for  $i \in [N]$  to be the  $s$ -tree with rule  $r_i$  at its root. Finally, for all  $i \in [N]$ , define the row vector  $b^i \in \mathbb{R}^{(1 \times m)}$  to have components

$$b_h^i = P(T_i = t_i | H_i = h, A_i = a_i)$$

for  $h \in [m]$ . Then for all  $i \in [N]$ ,  $f^i = b^i (G^{(a_i)})^{-1}$ . It follows immediately that

$$f^1 c_{a_1}^1 = b^1 (G^{(a_1)})^{-1} G^{a_1} \pi_{a_1} = p(r_1 \dots r_N) \quad \square$$

This lemma shows a direct link between the vectors  $f^i$  calculated in the algorithm, and the terms  $b_h^i$ , which are terms calculated by the conventional inside algorithm: each  $f^i$  is a linear transformation (through  $G^{(a_i)}$ ) of the corresponding vector  $b^i$ .

*Proof:* The proof is by induction.

First consider the base case. For any leaf—i.e., for any  $i$  such that  $a_i \in \mathcal{P}$ —we have  $b_h^i = q(r_i | h, a_i)$ , and it is easily verified that  $f^i = b^i (G^{(a_i)})^{-1}$ .

The inductive case is as follows. For all  $i \in [N]$  such that  $a_i \in \mathcal{I}$ , by the definition in the algorithm,

$$\begin{aligned} f^i &= f^\gamma C^{r_i} (f^\beta) \\ &= f^\gamma G^{a_\gamma} T^{r_i} \text{diag}(f^\beta G^{a_\beta} S^{r_i}) Q^{r_i} (G^{a_i})^{-1} \end{aligned}$$

Assuming by induction that  $f^\gamma = b^\gamma (G^{(a_\gamma)})^{-1}$  and  $f^\beta = b^\beta (G^{(a_\beta)})^{-1}$ , this simplifies to

$$f^i = \kappa^r \text{diag}(\kappa^l) Q^{r_i} (G^{a_i})^{-1} \quad (10)$$

where  $\kappa^r = b^\gamma T^{r_i}$ , and  $\kappa^l = b^\beta S^{r_i}$ .  $\kappa^r$  is a row vector with components  $\kappa_h^r = \sum_{h' \in [m]} b_{h'}^\gamma T_{h',h}^{r_i} = \sum_{h' \in [m]} b_{h'}^\gamma t(h' | h, r_i)$ . Similarly,  $\kappa^l$  is a row vector with components equal to  $\kappa_h^l = \sum_{h' \in [m]} b_{h'}^\beta S_{h',h}^{r_i} = \sum_{h' \in [m]} b_{h'}^\beta s(h' | h, r_i)$ . It can then be verified that  $\kappa^r \text{diag}(\kappa^l) Q^{r_i}$  is a row vector with components equal to  $\kappa_h^r \kappa_h^l q(r_i | h, a_i)$ .

But  $b_h^i = q(r_i | h, a_i) \times \left( \sum_{h' \in [m]} b_{h'}^\gamma t(h' | h, r_i) \right) \times \left( \sum_{h' \in [m]} b_{h'}^\beta s(h' | h, r_i) \right) = q(r_i | h, a_i) \kappa_h^r \kappa_h^l$ , hence  $\kappa^r \text{diag}(\kappa^l) Q^{r_i} = b^i$  and the inductive case follows immediately from Eq. 10.  $\square$

Next, we give a similar lemma, which implies the correctness of the algorithm in figure 3:

**Lemma 3** Assume that conditions 1-3 of theorem 1 are satisfied, and that the input to the algorithm in figure 3 is a sentence  $x_1 \dots x_N$ . For any  $a \in \mathcal{N}$ , for any  $1 \leq i \leq j \leq N$ , define  $\bar{\alpha}^{a,i,j} \in \mathbb{R}^{(1 \times m)}$  to have components  $\bar{\alpha}_h^{a,i,j} = p(x_i \dots x_j | h, a)$  for  $h \in [m]$ . In addition, define  $\bar{\beta}^{a,i,j} \in \mathbb{R}^{(m \times 1)}$  to have components  $\bar{\beta}_h^{a,i,j} = p(x_1 \dots x_{i-1}, a(h), x_{j+1} \dots x_N)$  for  $h \in [m]$ . Then for all  $i \in [N]$ ,  $\alpha^{a,i,j} = \bar{\alpha}^{a,i,j} (G^a)^{-1}$  and  $\beta^{a,i,j} = G^a \bar{\beta}^{a,i,j}$ . It follows that for all  $(a, i, j)$ ,

$$\begin{aligned} \mu(a, i, j) &= \bar{\alpha}^{a,i,j} (G^a)^{-1} G^a \bar{\beta}^{a,i,j} = \bar{\alpha}^{a,i,j} \bar{\beta}^{a,i,j} \\ &= \sum_h \bar{\alpha}_h^{a,i,j} \bar{\beta}_h^{a,i,j} = \sum_{\tau \in \mathcal{T}(x): (a,i,j) \in \tau} p(\tau) \quad \square \end{aligned}$$

Thus the vectors  $\alpha^{a,i,j}$  and  $\beta^{a,i,j}$  are linearly related to the vectors  $\bar{\alpha}^{a,i,j}$  and  $\bar{\beta}^{a,i,j}$ , which are the inside and outside terms calculated by the conventional form of the inside-outside algorithm.

The proof is by induction, and is similar to the proof of lemma 2; for reasons of space it is omitted.

## 9.2 Proof of the Identity in Eq. 6

We now prove the identity in Eq. 6, used in the proof of theorem 2. For reasons of space, we do not give the proofs of identities 7-9: the proofs are similar.

The following identities can be verified:

$$\begin{aligned} P(R_1 = a \rightarrow b \ c | H_1 = h, A_1 = a) &= q(a \rightarrow b \ c | h, a) \\ \mathbf{E}[Y_{3,j} | H_1 = h, R_1 = a \rightarrow b \ c] &= E_{j,h}^{a \rightarrow b \ c} \\ \mathbf{E}[Z_k | H_1 = h, R_1 = a \rightarrow b \ c] &= K_{k,h}^a \\ \mathbf{E}[Y_{2,l} | H_1 = h, R_1 = a \rightarrow b \ c] &= F_{l,h}^{a \rightarrow b \ c} \end{aligned}$$

where  $E^{a \rightarrow b \ c} = G^c T^{a \rightarrow b \ c}$ ,  $F^{a \rightarrow b \ c} = G^b S^{a \rightarrow b \ c}$ .

$Y_3$ ,  $Z$  and  $Y_2$  are independent when conditioned on  $H_1, R_1$  (this follows from the independence assumptions in the L-PCFG), hence

$$\begin{aligned} \mathbf{E}[[[R_1 = a \rightarrow b \ c]] Y_{3,j} Z_k Y_{2,l} | H_1 = h, A_1 = a] \\ = q(a \rightarrow b \ c | h, a) E_{j,h}^{a \rightarrow b \ c} K_{k,h}^a F_{l,h}^{a \rightarrow b \ c} \end{aligned}$$

Hence (recall that  $\gamma_h^a = P(H_1 = h | A_1 = a)$ ),

$$\begin{aligned} D_{j,k,l}^{a \rightarrow b \ c} &= \mathbf{E}[[[R_1 = a \rightarrow b \ c]] Y_{3,j} Z_k Y_{2,l} | A_1 = a] \\ &= \sum_h \gamma_h^a \mathbf{E}[[[R_1 = a \rightarrow b \ c]] Y_{3,j} Z_k Y_{2,l} | H_1 = h, A_1 = a] \\ &= \sum_h \gamma_h^a q(a \rightarrow b \ c | h, a) E_{j,h}^{a \rightarrow b \ c} K_{k,h}^a F_{l,h}^{a \rightarrow b \ c} \quad (11) \end{aligned}$$

from which Eq. 6 follows.  $\square$

## Abstract

We address the issue of consuming heterogeneous annotation data for Chinese word segmentation and part-of-speech tagging. We empirically analyze the diversity between two representative corpora, i.e. Penn Chinese Treebank (CTB) and PKU's People's Daily (PPD), on manually mapped data, and show that their linguistic annotations are systematically different and highly compatible. The analysis is further exploited to improve processing accuracy by (1) integrating systems that are respectively trained on heterogeneous annotations to reduce the approximation error, and (2) re-training models with high quality automatically converted data to reduce the estimation error. Evaluation on the CTB and PPD data shows that our novel model achieves a relative error reduction of 11% over the best reported result in the literature.

## 1 Introduction

A majority of data-driven NLP systems rely on large-scale, manually annotated corpora that are important to train statistical models but very expensive to build. Nowadays, for many tasks, multiple heterogeneous annotated corpora have been built and publicly available. For example, the Penn Treebank is popular to train PCFG-based parsers, while the Redwoods Treebank is well known for HPSG research; the Propbank is favored to build general semantic role labeling systems, while the FrameNet is attractive for predicate-specific labeling. The anno-

This work is mainly finished when the first author was in Saarland University and DFKI. Both authors are the corresponding authors.

tation schemes in different projects are usually different, since the underlying linguistic theories vary and have different ways to explain the same language phenomena. Though statistical NLP systems usually are not bound to specific annotation standards, almost all of them assume homogeneous annotation in the training corpus. The co-existence of heterogeneous annotation data therefore presents a new challenge to the consumers of such resources.

There are two essential characteristics of heterogeneous annotations that can be utilized to reduce two main types of errors in statistical NLP, i.e. the approximation error that is due to the intrinsic suboptimality of a model and the estimation error that is due to having only finite training data. First, heterogeneous annotations are (similar but) *different* as a result of different annotation schemata. Systems respectively trained on heterogeneous annotation data can produce different but relevant linguistic analysis. This suggests that complementary features from heterogeneous analysis can be derived for disambiguation, and therefore the approximation error can be reduced. Second, heterogeneous annotations are (different but) *similar* because their linguistic analysis is highly correlated. This implies that appropriate conversions between heterogeneous corpora could be reasonably accurate, and therefore the estimation error can be reduced by reason of the increase of reliable training data.

This paper explores heterogeneous annotations to reduce both approximation and estimation errors for Chinese word segmentation and part-of-speech (POS) tagging, which are fundamental steps for more advanced Chinese language processing tasks. We empirically analyze the diversity between two representative popular heterogeneous corpora, i.e.

Penn Chinese Treebank (CTB) and PKU’s People’s Daily (PPD). To that end, we manually label 200 sentences from CTB with PPD-style annotations.<sup>1</sup> Our analysis confirms the aforementioned two properties of heterogeneous annotations. Inspired by the sub-word tagging method introduced in (Sun, 2011), we propose a structure-based stacking model to fully utilize heterogeneous word structures to reduce the approximation error. In particular, joint word segmentation and POS tagging is addressed as a two step process. First, character-based taggers are respectively trained on heterogeneous annotations to produce multiple analysis. The outputs of these taggers are then merged into sub-word sequences, which are further re-segmented and tagged by a sub-word tagger. The sub-word tagger is designed to refine the tagging result with the help of heterogeneous annotations. To reduce the estimation error, we employ a learning-based approach to convert complementary heterogeneous data to increase labeled training data for the target task. Both the character-based tagger and the sub-word tagger can be refined by re-training with automatically converted data.

We conduct experiments on the CTB and PPD data, and compare our system with state-of-the-art systems. Our structure-based stacking model achieves an f-score of 94.36, which is superior to a feature-based stacking model introduced in (Jiang et al., 2009). The converted data can also enhance the baseline model. A simple character-based model can be improved from 93.41 to 94.11. Since the two treatments are concerned with reducing different types of errors and thus not fully overlapping, the combination of them gives a further improvement. Our final system achieves an f-score of 94.68, which yields a relative error reduction of 11% over the best published result (94.02).

## 2 Joint Chinese Word Segmentation and POS Tagging

Different from English and other Western languages, Chinese is written without explicit word delimiters such as space characters. To find and classify the

---

<sup>1</sup>The first 200 sentences of the development data for experiments are selected. This data set is submitted as a supplemental material for research purposes.

basic language units, i.e. words, word segmentation and POS tagging are important initial steps for Chinese language processing. Supervised learning with specifically defined training data has become a dominant paradigm. Joint approaches that resolve the two tasks simultaneously have received much attention in recent research. Previous work has shown that joint solutions led to accuracy improvements over pipelined systems by avoiding segmentation error propagation and exploiting POS information to help segmentation (Ng and Low, 2004; Jiang et al., 2008a; Zhang and Clark, 2008; Sun, 2011).

Two kinds of approaches are popular for joint word segmentation and POS tagging. The first is the “character-based” approach, where basic processing units are characters which compose words (Jiang et al., 2008a). In this kind of approach, the task is formulated as the classification of characters into POS tags with boundary information. For example, the label *B-NN* indicates that a character is located at the begging of a noun. Using this method, POS information is allowed to interact with segmentation. The second kind of solution is the “word-based” method, also known as semi-Markov tagging (Zhang and Clark, 2008; Zhang and Clark, 2010), where the basic predicting units are words themselves. This kind of solver sequentially decides whether the local sequence of characters makes up a word as well as its possible POS tag. Solvers may use previously predicted words and their POS information as clues to process a new word.

In addition, we proposed an effective and efficient stacked sub-word tagging model, which combines strengths of both character-based and word-based approaches (Sun, 2011). First, different character-based and word-based models are trained to produce multiple segmentation and tagging results. Second, the outputs of these coarse-grained models are merged into sub-word sequences, which are further bracketed and labeled with POS tags by a fine-grained sub-word tagger. Their solution can be viewed as utilizing stacked learning to integrate heterogeneous models.

Supervised segmentation and tagging can be improved by exploiting rich linguistic resources. Jiang et al. (2009) presented a preliminary study for annotation ensemble, which motivates our research as well as similar investigations for other NLP tasks,

e.g. parsing (Niu et al., 2009; Sun et al., 2010). In their solution, heterogeneous data is used to train an auxiliary segmentation and tagging system to produce informative features for target prediction. Our previous work (Sun and Xu, 2011) and Wang et al. (2011) explored unlabeled data to enhance strong supervised segmenters and taggers. Both of their work fall into the category of feature induction based semi-supervised learning. In brief, their methods harvest useful string knowledge from unlabeled or automatically analyzed data, and apply the knowledge to design new features for discriminative learning.

### 3 About Heterogeneous Annotations

For Chinese word segmentation and POS tagging, supervised learning has become a dominant paradigm. Much of the progress is due to the development of both corpora and machine learning techniques. Although several institutions to date have released their segmented and POS tagged data, acquiring sufficient quantities of high quality training examples is still a major bottleneck. The annotation schemes of existing lexical resources are different, since the underlying linguistic theories vary. Despite the existence of multiple resources, such data cannot be simply put together for training systems, because almost all of statistical NLP systems assume homogeneous annotation. Therefore, it is not only interesting but also important to study how to fully utilize heterogeneous resources to improve Chinese lexical processing.

There are two main types of errors in statistical NLP: (1) the approximation error that is due to the intrinsic suboptimality of a model and (2) the estimation error that is due to having only finite training data. Take Chinese word segmentation for example. Our previous analysis (Sun, 2010) shows that one main intrinsic disadvantage of character-based model is the difficulty in incorporating the whole word information, while one main disadvantage of word-based model is the weak ability to express word formation. In both models, the significant decrease of the prediction accuracy of out-of-vocabulary (OOV) words indicates the impact of the estimation error. The two essential characteristics about systematic diversity of heterogeneous annota-

tions can be utilized to reduce both approximation and estimation errors.

#### 3.1 Analysis of the CTB and PPD Standards

This paper focuses on two representative popular corpora for Chinese lexical processing: (1) the Penn Chinese Treebank (CTB) and (2) the PKU's People's Daily data (PPD). To analyze the diversity between their annotation standards, we pick up 200 sentences from CTB and manually label them according to the PPD standard. Specially, we employ a PPD-style segmentation and tagging system to automatically label these 200 sentences. A linguistic expert who deeply understands the PPD standard then manually checks the automatic analysis and corrects its errors.

These 200 sentences are segmented as 3886 and 3882 words respectively according to the CTB and PPD standards. The average lengths of word tokens are almost the same. However, the word boundaries or the definitions of words are different. 3561 word tokens are consistently segmented by both standards. In other words, 91.7% CTB word tokens share the same word boundaries with 91.6% PPD word tokens. Among these 3561 words, there are 552 punctuations that are simply consistently segmented. If punctuations are filtered out to avoid overestimation of consistency, 90.4% CTB words have same boundaries with 90.3% PPD words. The boundaries of words that are differently segmented are *compatible*. Among all annotations, only one cross-bracketing occurs. The statistics indicates that the two heterogeneous segmented corpora are systematically different, and confirms the aforementioned two properties of heterogeneous annotations.

Table 1 is the mapping between CTB-style tags and PPD-style tags. For the definition and illustration of these tags, please refers to the annotation guidelines<sup>2</sup>. The statistics after colons are how many times this POS tag pair appears among the 3561 words that are consistently segmented. From this table, we can see that (1) there is no one-to-one mapping between their heterogeneous word classification but (2) the mapping between heterogeneous tags is not very uncertain. This simple analysis indicates

<sup>2</sup>Available at <http://www.cis.upenn.edu/~chinese/posguide.3rd.ch.pdf> and [http://www.icl.pku.edu.cn/icl\\_groups/corpus/spec.htm](http://www.icl.pku.edu.cn/icl_groups/corpus/spec.htm).

that the two POS tagged corpora also hold the two properties of heterogeneous annotations. The differences between the POS annotation standards are systematic. The annotations in CTB are treebank-driven, and thus consider more functional (dynamic) information of basic lexical categories. The annotations in PPD are lexicon-driven, and thus focus on more *static* properties of words. Limited to the document length, we only illustrate the annotation of verbs and nouns for better understanding of the differences.

- The CTB tag **VV** indicates common verbs that are mainly labeled as verbs (v) too according to the PPD standard. However, these words can be also tagged as nominal categories (a, vn, n). The main reason is that there are a large number of Chinese adjectives and nouns that can be realized as predicates without linking verbs.
- The tag **NN** indicates common nouns in CTB. Some of them are labeled as verbal categories (vn, v). The main reason is that a majority of Chinese *verbs* could be realized as subjects and objects without form changes.

## 4 Structure-based Stacking

### 4.1 Reducing the Approximation Error via Stacking

Each annotation data set alone can yield a predictor that can be taken as a mechanism to produce structured texts. With different training data, we can construct multiple heterogeneous systems. These systems produce similar linguistic analysis which holds the same high level linguistic principles but differ in details. A very simple idea to take advantage of heterogeneous structures is to design a predictor which can predict a more accurate target structure based on the input, the less accurate target structure and complementary structures. This idea is very close to stacked learning (Wolpert, 1992), which is well developed for ensemble learning, and successfully applied to some NLP tasks, e.g. dependency parsing (Nivre and McDonald, 2008; Torres Martins et al., 2008).

Formally speaking, our idea is to include two “levels” of processing. The first level includes one

AS ⇒ u:44;	CD ⇒ m:134;

Table 1: Mapping between CTB and PPD POS Tags.

or more base predictors  $f_1, \dots, f_K$  that are independently built on different training data. The second level processing consists of an inference function  $h$  that takes as input  $\langle \mathbf{x}, f_1(\mathbf{x}), \dots, f_K(\mathbf{x}) \rangle^3$  and outputs a final prediction  $h(\mathbf{x}, f_1(\mathbf{x}), \dots, f_K(\mathbf{x}))$ . The only difference between model ensemble and *annotation ensemble* is that the output spaces of model ensemble are the same while the output spaces of annotation ensemble are different. This framework is general and flexible, in the sense that it assumes almost nothing about the individual systems and take them as black boxes.

### 4.2 A Character-based Tagger

With IOB2 representation (Ramshaw and Marcus, 1995), the problem of joint segmentation and tagging can be regarded as a character classification task. Previous work shows that the character-based approach is an effective method for Chinese lexical processing. Both of our feature- and structure-based stacking models employ base character-based taggers to generate multiple segmentation and tagging results. Our base tagger use a discriminative sequential classifier to predict the POS tag with positional information for each character. Each character can be assigned one of two possible boundary tags: “B” for a character that begins a word and “I” for a character that occurs in the middle of a word. We denote

<sup>3</sup> $\mathbf{x}$  is a given Chinese sentence.

a candidate character token  $c_i$  with a fixed window  $c_{i-2}c_{i-1}c_i c_{i+1}c_{i+2}$ . The following features are used for classification:

- Character unigrams:  $c_k$  ( $i - l \leq k \leq i + l$ )
- Character bigrams:  $c_k c_{k+1}$  ( $i - l \leq k < i + l$ )

### 4.3 Feature-based Stacking

Jiang et al. (2009) introduced a feature-based stacking solution for annotation ensemble. In their solution, an auxiliary tagger  $CTag_{ppd}$  is trained on a complementary corpus, i.e. PPD, to assist the target CTB-style tagging. To refine the character-based tagger  $CTag_{ctb}$ , PPD-style character labels are directly incorporated as new features. The stacking model relies on the ability of discriminative learning method to explore informative features, which play central role to boost the tagging performance. To compare their feature-based stacking model and our structure-based model, we implement a similar system  $CTag_{ppd \rightarrow ctb}$ . Apart from character uni/bigram features, the PPD-style character labels are used to derive the following features to enhance our CTB-style tagger:

- Character label unigrams:  $c_k^{ppd}$  ( $i - l^{ppd} \leq k \leq i + l^{ppd}$ )
- Character label bigrams:  $c_k^{ppd} c_{k+1}^{ppd}$  ( $i - l^{ppd} \leq k < i + l^{ppd}$ )

In the above descriptions,  $l$  and  $l^{ppd}$  are the window sizes of features, which can be tuned on development data.

### 4.4 Structure-based Stacking

We propose a novel structured-based stacking model for the task, in which heterogeneous word structures are used not only to generate features but also to derive a sub-word structure. Our work is inspired by the stacked sub-word tagging model introduced in (Sun, 2011). Their work is motivated by the diversity of heterogeneous models, while our work is motivated by the diversity of heterogeneous annotations. The workflow of our new system is shown in Figure 1. In the first phase, one character-based CTB-style tagger ( $CTag_{ctb}$ ) and one character-based PPD-style tagger ( $CTag_{ppd}$ ) are respectively trained to produce heterogeneous

Figure 1: Sub-word tagging based on heterogeneous taggers.

word boundaries. In the second phase, this system first combines the two segmentation and tagging results to get sub-words which maximize the agreement about word boundaries. Finally, a fine-grained sub-word tagger ( $STag_{ctb}$ ) is applied to bracket sub-words into words and also to label their POS tags. We can also apply a PPD-style sub-word tagger. To compare with previous work, we specially concentrate on the *PPD-to-CTB* adaptation.

Following (Sun, 2011), the intermediate sub-word structures is defined to maximize the agreement of  $CTag_{ctb}$  and  $CTag_{ppd}$ . In other words, the goal is to make merged sub-words as large as possible but not overlap with any predicted word produced by the two taggers. If the position between two continuous characters is predicted as a word boundary by any segmenter, this position is taken as a separation position of the sub-word sequence. This strategy makes sure that it is still possible to correctly *re-segment* the strings of which the boundaries are disagreed with by the heterogeneous segmenters in the sub-word tagging stage.

To train the sub-word tagger  $STag_{ctb}$ , features are formed making use of both CTB-style and PPD-style POS tags provided by the character-based taggers. In the following description, “C” refers to the content of a sub-word; “ $T_{ctb}$ ” and “ $T_{ppd}$ ” refers to the positional POS tags generated from  $CTag_{ctb}$  and  $CTag_{ppd}$ ;  $l_C$ ,  $l_T^{ctb}$  and  $l_T^{ppd}$  are the window sizes. For convenience, we denote a sub-word with its con-

text  $\dots s_{i-1} s_i s_{i+1} \dots$ , where  $s_i$  is the current token. The following features are applied:

- Unigram features:  $C(s_k)$  ( $i - l_C \leq k \leq +l_C$ ),  $T_{ctb}(s_k)$  ( $i - l_T^{ctb} \leq k \leq i + l_T^{ctb}$ ),  $T_{ppd}(s_k)$  ( $i - l_T^{ppd} \leq k \leq i + l_T^{ppd}$ )
- Bigram features:  $C(s_k)C(s_{k+1})$  ( $i - l_C \leq k < i + l_C$ ),  $T_{ctb}(s_k)T_{ctb}(s_{k+1})$  ( $i - l_T^{ctb} \leq k < i + l_T^{ctb}$ ),  $T_{ppd}(s_k)T_{ppd}(s_{k+1})$  ( $i - l_T^{ppd} \leq k < i + l_T^{ppd}$ )
- $C(s_{i-1})C(s_{i+1})$  (if  $l_C \geq 1$ ),  $T_{ctb}(s_{i-1})T_{ctb}(s_{i+1})$  (if  $l_T^{ctb} \geq 1$ ),  $T_{ppd}(s_{i-1})T_{ppd}(s_{i+1})$  (if  $l_T^{ppd} \geq 1$ )
- Word formation features: character  $n$ -gram prefixes and suffixes for  $n$  up to 3.

**Cross-validation**  $CTag_{ctb}$  and  $CTag_{ppd}$  are directly trained on the original training data, i.e. the CTB and PPD data. Cross-validation technique has been proved necessary to generate the training data for sub-word tagging, since it deals with the training/test mismatch problem (Sun, 2011). To construct training data for the new heterogeneous sub-word tagger, a 10-fold *cross-validation* on the original CTB data is performed too.

## 5 Data-driven Annotation Conversion

It is possible to acquire high quality labeled data for a specific annotation standard by exploring existing heterogeneous corpora, since the annotations are normally highly compatible. Moreover, the exploitation of additional (pseudo) labeled data aims to reduce the estimation error and enhances a NLP system in a different way from stacking. We therefore expect the improvements are not much overlapping and the combination of them can give a further improvement.

The stacking models can be viewed as annotation converters: They take as input complementary structures and produce as output target structures. In other words, the stacking models actually learn statistical models to transform the lexical representations. We can acquire informative extra samples by processing the PPD data with our stacking models. Though the converted annotations are imperfect, they are still helpful to reduce the estimation error.

**Character-based Conversion** The feature-based stacking model  $CTag_{ppd \rightarrow ctb}$  maps the input character sequence  $\mathbf{c}$  and its PPD-style character label sequence to the corresponding CTB-style character label sequence. This model by itself can be taken as a corpus conversion model to transform a PPD-style analysis to a CTB-style analysis. By processing the auxiliary corpus  $D_{ppd}$  with  $CTag_{ppd \rightarrow ctb}$ , we acquire a new labeled data set  $D'_{ctb} = D_{ppd \rightarrow ctb}^{CTag_{ppd \rightarrow ctb}}$ . We can re-train the  $CTag_{ctb}$  model with both original and converted data  $D_{ctb} \cup D'_{ctb}$ .

**Sub-word-based Conversion** Similarly, the structure-based stacking model can be also taken as a corpus conversion model. By processing the auxiliary corpus  $D_{ppd}$  with  $STag_{ctb}$ , we acquire a new labeled data set  $D''_{ctb} = D_{ppd \rightarrow ctb}^{STag_{ctb}}$ . We can re-train the  $STag_{ctb}$  model with  $D_{ctb} \cup D''_{ctb}$ . If we use the gold PPD-style labels of  $D''_{ctb}$  to extract sub-words, the new model will overfit to the gold PPD-style labels, which are unavailable at test time. To avoid this training/test mismatch problem, we also employ a 10-fold cross validation procedure to add noise.

It is not a new topic to convert corpus from one formalism to another. A well known work is transforming Penn Treebank into resources for various deep linguistic processing, including LTAG (Xia, 1999), CCG (Hockenmaier and Steedman, 2007), HPSG (Miyao et al., 2004) and LFG (Cahill et al., 2002). Such work for corpus conversion mainly leverages rich sets of hand-crafted rules to convert corpora. The construction of linguistic rules is usually time-consuming and the rules are not full coverage. Compared to rule-based conversion, our statistical converters are much easier to build and empirically perform well.

## 6 Experiments

### 6.1 Setting

Previous studies on joint Chinese word segmentation and POS tagging have used the CTB in experiments. We follow this setting in this paper. We use CTB 5.0 as our main corpus and define the training, development and test sets according to (Jiang et al., 2008a; Jiang et al., 2008b; Kruegkrai et al., 2009; Zhang and Clark, 2010; Sun, 2011). Jiang et

al. (2009) present a preliminary study for the annotation adaptation topic, and conduct experiments with the extra PPD data<sup>4</sup>. In other words, the CTB-style annotation is the target analysis while the PPD-style annotation is the complementary/auxiliary analysis. Our experiments for annotation ensemble follows their setting to lead to a fair comparison of our system and theirs. A CRF learning toolkit, wapiti<sup>5</sup> (Lavergne et al., 2010), is used to resolve sequence labeling problems. Among several parameter estimation methods provided by wapiti, our auxiliary experiments indicate that the “rprop-” method works best. Three metrics are used for evaluation: precision (P), recall (R) and balanced f-score (F) defined by  $2PR/(P+R)$ . Precision is the relative amount of correct words in the system output. Recall is the relative amount of correct words compared to the gold standard annotations. A token is considered to be correct if its boundaries match the boundaries of a word in the gold standard and their POS tags are identical.

## 6.2 Results of Stacking

Table 2 summarizes the segmentation and tagging performance of the baseline and different stacking models. The baseline of the character-based joint solver ( $CTag_{ctb}$ ) is competitive, and achieves an f-score of 92.93. By using the character labels from a heterogeneous solver ( $CTag_{ppd}$ ), which is trained on the PPD data set, the performance of this character-based system ( $CTag_{ppd \rightarrow ctb}$ ) is improved to 93.67. This result confirms the importance of a heterogeneous structure. Our structure-based stacking solution is effective and outperforms the feature-based stacking. By better exploiting the heterogeneous word boundary structures, our sub-word tagging model achieves an f-score of 94.03 ( $l_T^{ctb}$  and  $l_T^{ppd}$  are tuned on the development data and both set to 1).

The contribution of the auxiliary tagger is two-fold. On one hand, the heterogeneous solver provides structural information, which is the basis to construct the sub-word sequence. On the other hand, this tagger provides additional POS information, which is helpful for disambiguation. To eval-

<sup>4</sup>[http://ic1.pku.edu.cn/ic1\\_res/](http://ic1.pku.edu.cn/ic1_res/)

<sup>5</sup><http://wapiti.limsi.fr/>

Devel.	P	R	F
$CTag_{ctb}$	93.28%	92.58%	92.93
$CTag_{ppd \rightarrow ctb}$	93.89%	93.46%	93.67
$STag_{ctb}$	94.07%	93.99%	94.03

Table 2: Performance of different stacking models on the development data.

uate these two contributions, we do another experiment by just using the heterogeneous word boundary structures without the POS information. The f-score of this type of sub-word tagging is 93.73. This result indicates that both the word boundary and POS information are helpful.

## 6.3 Learning Curves

We do additional experiments to evaluate the effect of heterogeneous features as the amount of PPD data is varied. Table 3 summarizes the f-score change. The feature-based model works well only when a considerable amount of heterogeneous data is available. When a small set is added, the performance is even lower than the baseline (92.93). The structure-based stacking model is more robust and obtains consistent gains regardless of the size of the complementary data.

#CTB	#PPD	PPD $\rightarrow$ CTB	
		$CTag$	$STag$
18104	7381	92.21	93.26
18104	14545	93.22	93.82
18104	21745	93.58	93.96
18104	28767	93.55	93.87
18104	35996	93.67	94.03
9052	9052	92.10	92.40

Table 3: F-scores relative to sizes of training data. Sizes (shown in column #CTB and #PPD) are numbers of sentences in each training corpus.

## 6.4 Results of Annotation Conversion

The stacking models can be viewed as data-driven annotation converting models. However they are not trained on “real” labeled samples. Although the target representation (CTB-style analysis in our case) is gold standard, the input representation (PPD-style analysis in our case) is labeled by a automatic tagger  $CTag_{ppd}$ . To make clear whether these stacking

models trained with noisy inputs can *tolerate* perfect inputs, we evaluate the two stacking models on our manually converted data. The accuracies presented in Table 4 indicate that though the conversion models are learned by applying noisy data, they can refine target tagging with gold auxiliary tagging. Another interesting thing is that the gold PPD-style analysis does not help the sub-word tagging model as much as the character tagging model.

	Auto PPD	Gold PPD
CTag <sub>ppd→ctb</sub>	93.69	95.19
STag <sub>ctb</sub>	94.14	94.70

Table 4: F-scores with gold PPD-style tagging on the manually converted data.

### 6.5 Results of Re-training

Table 5 shows accuracies of re-trained models. Note that a sub-word tagger is built on character taggers, so when we re-train a sub-word system, we should consider whether or not re-training base character taggers. The error rates decrease as automatically converted data is added to the training pool, especially for the character-based tagger CTag<sub>ctb</sub>. When the base CTB-style tagging is improved, the final tagging is improved in the end. The re-training does not help the sub-word tagging much; the improvement is very modest.

CTag <sub>ctb</sub>	STag <sub>ctb</sub>	P(%)	R(%)	F
$D_{ctb} \cup D'_{ctb}$	--	94.46	94.06	94.26
$D_{ctb} \cup D'_{ctb}$	$D_{ctb}$	94.61	94.43	94.52
$D_{ctb}$	$D_{ctb} \cup D''_{ctb}$	94.05	94.08	94.06
$D_{ctb} \cup D'_{ctb}$	$D_{ctb} \cup D''_{ctb}$	94.71	94.53	94.62

Table 5: Performance of re-trained models on the development data.

### 6.6 Comparison to the State-of-the-Art

Table 6 summarizes the tagging performance of different systems. The baseline of the character-based tagger is competitive, and achieve an f-score of 93.41. By better using the heterogeneous word boundary structures, our sub-word tagging model achieves an f-score of 94.36. Both character and sub-word tagging model can be enhanced with automatically converted corpus. With the pseudo labeled

data, the performance goes up to 94.11 and 94.68. These results are also better than the best published result on the same data set that is reported in (Jiang et al., 2009).

Test	P	R	F
(Sun, 2011)	--	--	94.02
(Jiang et al., 2009)	--	--	94.02
(Wang et al., 2011)	--	--	94.18 <sup>6</sup>
Character model	93.31%	93.51%	93.41
+Re-training	93.93%	94.29%	94.11
Sub-word model	94.10%	94.62%	94.36
+Re-training	<b>94.42%</b>	<b>94.93%</b>	<b>94.68</b>

Table 6: Performance of different systems on the test data.

## 7 Conclusion

Our theoretical and empirical analysis of two representative popular corpora highlights two essential characteristics of heterogeneous annotations which are explored to reduce approximation and estimation errors for Chinese word segmentation and POS tagging. We employ stacking models to incorporate features derived from heterogeneous analysis and apply them to convert heterogeneous labeled data for re-training. The appropriate application of heterogeneous annotations leads to a significant improvement (a relative error reduction of 11%) over the best performance for this task. Although our discussion is for a specific task, the key idea to leverage heterogeneous annotations to reduce the approximation error with stacking models and the estimation error with automatically converted corpora is very general and applicable to other NLP tasks.

[ws@pku.edu.cn](mailto:ws@pku.edu.cn), [uszkoreit@dfki.de](mailto:uszkoreit@dfki.de)

## Abstract

From the perspective of structural linguistics, we explore paradigmatic and syntagmatic lexical relations for Chinese POS tagging, an important and challenging task for Chinese language processing. Paradigmatic lexical relations are explicitly captured by word clustering on large-scale unlabeled data and are used to design new features to enhance a discriminative tagger. Syntagmatic lexical relations are implicitly captured by constituent parsing and are utilized via system combination. Experiments on the Penn Chinese Treebank demonstrate the importance of both paradigmatic and syntagmatic relations. Our linguistically motivated approaches yield a relative error reduction of 18% in total over a state-of-the-art baseline.

## 1 Introduction

In grammar, a part-of-speech (POS) is a linguistic category of words, which is generally defined by the syntactic or morphological behavior of the word in question. Automatically assigning POS tags to words plays an important role in parsing, word sense disambiguation, as well as many other NLP applications. Many successful tagging algorithms developed for English have been applied to many other languages as well. In some cases, the methods work well without large modifications, such as for German. But a number of augmentations and changes become necessary when dealing with highly inflected or agglutinative languages, as well as analytic languages, of which Chinese is the focus

---

This work is mainly finished when this author (corresponding author) was in Saarland University and DFKI.

of this paper. The Chinese language is characterized by the lack of formal devices such as morphological tense and number that often provide important clues for syntactic processing tasks. While state-of-the-art tagging systems have achieved accuracies above 97% on English, Chinese POS tagging has proven to be more challenging and obtained accuracies about 93-94% (Tseng et al., 2005b; Huang et al., 2007, 2009; Li et al., 2011).

It is generally accepted that Chinese POS tagging often requires more sophisticated language processing techniques that are capable of drawing inferences from more subtle linguistic knowledge. From a linguistic point of view, meaning arises from the differences between linguistic units, including words, phrases and so on, and these differences are of two kinds: paradigmatic (concerning substitution) and syntagmatic (concerning positioning). The distinction is a key one in structuralist semiotic analysis. Both paradigmatic and syntagmatic lexical relations have a great impact on POS tagging, because the *value* of a word is determined by the two relations. Our error analysis of a state-of-the-art Chinese POS tagger shows that the lack of both paradigmatic and syntagmatic lexical knowledge accounts for a large part of tagging errors.

This paper is concerned with capturing paradigmatic and syntagmatic lexical relations to advance the state-of-the-art of Chinese POS tagging. First, we employ unsupervised word clustering to explore paradigmatic relations that are encoded in large-scale unlabeled data. The word clusters are then explicitly utilized to design new features for POS tagging. Second, we study the possible impact of syntagmatic relations on POS tagging by comparatively analyzing a (syntax-free) sequential tagging model

and a (syntax-based) chart parsing model. Inspired by the analysis, we employ a full parser to implicitly capture syntagmatic relations and propose a *Bootstrap Aggregating* (Bagging) model to combine the complementary strengths of a sequential tagger and a parser.

We conduct experiments on the Penn Chinese Treebank and Chinese Gigaword. We implement a discriminative sequential classification model for POS tagging which achieves the state-of-the-art accuracy. Experiments show that this model are significantly improved by word cluster features in accuracy across a wide range of conditions. This confirms the importance of the paradigmatic relations. We then present a comparative study of our tagger and the Berkeley parser, and show that the combination of the two models can significantly improve tagging accuracy. This demonstrates the importance of the syntagmatic relations. Cluster-based features and the Bagging model result in a relative error reduction of 18% in terms of the word classification accuracy.

## 2 State-of-the-Art

### 2.1 Previous Work

Many algorithms have been applied to computationally assigning POS labels to English words, including hand-written rules, generative HMM tagging and discriminative sequence labeling. Such methods have been applied to many other languages as well. In some cases, the methods work well without large modifications, such as German POS tagging. But a number of augmentations and changes became necessary when dealing with Chinese that has little, if any, inflectional morphology. While state-of-the-art tagging systems have achieved accuracies above 97% on English, Chinese POS tagging has proven to be more challenging and obtains accuracies about 93-94% (Tseng et al., 2005b; Huang et al., 2007, 2009; Li et al., 2011).

Both discriminative and generative models have been explored for Chinese POS tagging (Tseng et al., 2005b; Huang et al., 2007, 2009). Tseng et al. (2005a) introduced a maximum entropy based model, which includes morphological features for unknown word recognition. Huang et al. (2007) and Huang et al. (2009) mainly focused on the gener-

ative HMM models. To enhance a HMM model, Huang et al. (2007) proposed a re-ranking procedure to include extra morphological and syntactic features, while Huang et al. (2009) proposed a latent variable inducing model. Their evaluations on the Chinese Treebank show that Chinese POS tagging obtains an accuracy of about 93-94%.

### 2.2 Our Discriminative Sequential Model

According to the *ACL Wiki*, all state-of-the-art English POS taggers are based on discriminative sequence labeling models, including structure perceptron (Collins, 2002; Shen et al., 2007), maximum entropy (Toutanova et al., 2003) and SVM (Gimnez and Mrquez, 2004). A discriminative learner is easy to be extended with arbitrary features and therefore suitable to recognize more new words. Moreover, a majority of the POS tags are locally dependent on each other, so the Markov assumption can well captures the syntactic relations among words. Discriminative learning is also an appropriate solution for Chinese POS tagging, due to its flexibility to include knowledge from multiple linguistic sources.

To deeply analyze the POS tagging problem for Chinese, we implement a discriminative sequential model. A first order linear-chain CRF model is used to resolve the sequential classification problem. We choose the CRF learning toolkit *wapiti*<sup>1</sup> (Lavergne et al., 2010) to train models. In our experiments, we employ a feature set which draws upon information sources such as word forms and characters that constitute words. To conveniently illustrate, we denote a word in focus with a fixed window  $w_{-2}w_{-1}ww_{+1}w_{+2}$ , where  $w$  is the current token. Our features includes:

Word unigrams:  $w_{-2}, w_{-1}, w, w_{+1}, w_{+2}$ ;  
Word bigrams:  $w_{-2}w_{-1}, w_{-1}w, ww_{+1}, w_{+1}w_{+2}$ ;  
In order to better handle unknown words, we extract morphological features: character  $n$ -gram prefixes and suffixes for  $n$  up to 3.

### 2.3 Evaluation

#### 2.3.1 Setting

Penn Chinese Treebank (CTB) (Xue et al., 2005) is a popular data set to evaluate a number of Chinese NLP tasks, including word segmentation (Sun and

<sup>1</sup><http://wapiti.limsi.fr/>

Xu, 2011), POS tagging (Huang et al., 2007, 2009), constituency parsing (Zhang and Clark, 2009; Wang et al., 2006) and dependency parsing (Zhang and Clark, 2008; Huang and Sagae, 2010; Li et al., 2011). In this paper, we use CTB 6.0 as the labeled data for the study. The corpus was collected during different time periods from different sources with a diversity of topics. In order to obtain a representative split of data sets, we define the training, development and test sets following two settings. To compare our tagger with the state-of-the-art, we conduct an experiment using the data setting of (Huang et al., 2009). For detailed analysis and evaluation, we conduct further experiments following the setting of the CoNLL 2009 shared task. The setting is provided by the principal organizer of the CTB project, and considers many annotation details. This setting is more robust for evaluating Chinese language processing algorithms.

### 2.3.2 Overall Performance

Table 1 summarizes the per token classification accuracy (Acc.) of our tagger and results reported in (Huang et al., 2009). Huang et al. (2009) introduced a bigram HMM model with latent variables (*Bigram HMM-LA* in the table) for Chinese tagging. Compared to earlier work (Tseng et al., 2005a; Huang et al., 2007), this model achieves the state-of-the-art accuracy. Despite of simplicity, our discriminative POS tagging model achieves a state-of-the-art performance, even better.

System	Acc.
Trigram HMM (Huang et al., 2009)	93.99%
Bigram HMM-LA (Huang et al., 2009)	94.53%
Our tagger	94.69%

Table 1: Tagging accuracies on the test data (setting 1).

## 2.4 Motivating Analysis

For the following experiments, we only report results on the development data of the CoNLL setting.

### 2.4.1 Correlating Tagging Accuracy with Word Frequency

Table 2 summarizes the prediction accuracy on the development data with respect to the word frequency on the training data. To avoid overestimating the tagging accuracy, these statistics exclude all

punctuations. From this table, we can see that words with low frequency, especially the out-of-vocabulary (OOV) words, are hard to label. However, when a word is very frequently used, its behavior is very complicated and therefore hard to predict. A typical example of such words is the language-specific function word “的.” This analysis suggests that a main topic to enhance Chinese POS tagging is to bridge the gap between the infrequent words and frequent words.

Freq.	Acc.
0	83.55%
1-5	89.31%
6-10	90.20%
11-100	94.88%
101-1000	96.26%
1001-	93.65%

Table 2: Tagging accuracies relative to word frequency.

### 2.4.2 Correlating Tagging Accuracy with Span Length

A word projects its grammatical property to its maximal projection and it syntactically governs all words under the span of its maximal projection. The words under the span of current token thus reflect its syntactic behavior and good clues for POS tagging. Table 3 shows the tagging accuracies relative to the length of the spans. We can see that with the increase of the number of words governed by the token, the difficulty of its POS prediction increase. This analysis suggests that syntagmatic lexical relations plays a significant role in POS tagging, and sometimes words located far from the current token affect its tagging much.

Len.	Acc.
1-2	93.79%
3-4	93.39%
5-6	92.19%
7-	94.18%

Table 3: Tagging accuracies relative to span length.

## 3 Capturing Paradigmatic Relations via Word Clustering

To bridge the gap between high and low frequency words, we employ word clustering to acquire

the knowledge about paradigmatic lexical relations from large-scale texts. Our work is also inspired by the successful application of word clustering to named entity recognition (Miller et al., 2004) and dependency parsing (Koo et al., 2008).

### 3.1 Word Clustering

Word clustering is a technique for partitioning sets of words into subsets of syntactically or semantically similar words. It is a very useful technique to capture paradigmatic or substitutional similarity among words.

#### 3.1.1 Clustering Algorithms

Various clustering techniques have been proposed, some of which, for example, perform automatic word clustering optimizing a maximum-likelihood criterion with iterative clustering algorithms. In this paper, we focus on distributional word clustering that is based on the assumption that words that appear in similar contexts (especially surrounding words) tend to have similar meanings. They have been successfully applied to many NLP problems, such as language modeling.

**Brown Clustering** Our first choice is the bottom-up agglomerative word clustering algorithm of (Brown et al., 1992) which derives a hierarchical clustering of words from unlabeled data. This algorithm generates a hard clustering – each word belongs to exactly one cluster. The input to the algorithm is sequences of words  $w_1, \dots, w_n$ . Initially, the algorithm starts with each word in its own cluster. As long as there are at least two clusters left, the algorithm merges the two clusters that maximizes the quality of the resulting clustering. The quality is defined based on a class-based bigram language model as follows.

$$P(w_i|w_1, \dots, w_{i-1}) \approx p(C(w_i)|C(w_{i-1}))p(w_i|C(w_i))$$

where the function  $C$  maps a word  $w$  to its class  $C(w)$ . We use a publicly available package<sup>2</sup> (Liang et al., 2005) to train this model.

**MKCLS Clustering** We also do experiments by using another popular clustering method based on

<sup>2</sup><http://cs.stanford.edu/~pliang/software/brown-cluster-1.2.zip>

the exchange algorithm (Kneser and Ney, 1993). The objective function is maximizing the likelihood  $\prod_{i=1}^n P(w_i|w_1, \dots, w_{i-1})$  of the training data given a partially class-based bigram model of the form

$$P(w_i|w_1, \dots, w_{i-1}) \approx p(C(w_i)|w_{i-1})p(w_i|C(w_i))$$

We use the publicly available implementation MKCLS<sup>3</sup> (Och, 1999) to train this model.

We choose to work with these two algorithms considering their prior success in other NLP applications. However, we expect that our approach can function with other clustering algorithms.

#### 3.1.2 Data

Chinese Gigaword is a comprehensive archive of newswire text data that has been acquired over several years by the Linguistic Data Consortium (LDC). The large-scale unlabeled data we use in our experiments comes from the Chinese Gigaword (LDC2005T14). We choose the Mandarin news text, i.e. Xinhua newswire. This data covers all news published by Xinhua News Agency (the largest news agency in China) from 1991 to 2004, which contains over 473 million characters.

#### 3.1.3 Pre-processing: Word Segmentation

Different from English and other Western languages, Chinese is written without explicit word delimiters such as space characters. To find the basic language units, i.e. words, segmentation is a necessary pre-processing step for word clustering. Previous research shows that character-based segmentation models trained on labeled data are reasonably accurate (Sun, 2010). Furthermore, as shown in (Sun and Xu, 2011), appropriate string knowledge acquired from large-scale unlabeled data can significantly enhance a supervised model, especially for the prediction of out-of-vocabulary (OOV) words. In this paper, we employ such supervised and semi-supervised segmenters<sup>4</sup> to process raw texts.

### 3.2 Improving Tagging with Cluster Features

Our discriminative sequential tagger is easy to be extended with arbitrary features and therefore suitable to explore additional features derived from other

<sup>3</sup><http://code.google.com/p/giza-pp/>

<sup>4</sup><http://www.coli.uni-saarland.de/~wsun/ccws.tgz>

sources. We propose to use of word clusters as substitutes for word forms to assist the POS tagger. We are relying on the ability of the discriminative learning method to explore informative features, which play a central role in boosting the tagging performance. 5 clustering-based uni/bi-gram features are added:  $w_{-1}$ ,  $w$ ,  $w_{+1}$ ,  $w_{-1}w$ ,  $w_{-1}w_{+1}$ .

### 3.3 Evaluation

Features	Data	Brown	MKCLS
Baseline	CoNLL	94.48%	
+c100	+1991-1995(S)	94.77%	94.83%
+c500	+1991-1995(S)	94.84%	94.93%
+c1000	+1991-1995(S)	--	94.95%
+c100	+1991-1995(SS)	94.90%	94.97%
+c500	+1991-1995(SS)	94.94%	94.88%
+c1000	+1991-1995(SS)	94.89%	94.94%
+c100	+1991-2000(SS)	94.82%	94.93%
+c500	+1991-2000(SS)	94.92%	94.99%
+c1000	+1991-2000(SS)	94.90%	95.00%
+c100	+1991-2004(SS)	--	94.87%
+c500	+1991-2004(SS)	--	<b>95.02%</b>
+c1000	+1991-2004(SS)	--	94.97%

Table 4: Tagging accuracies with different features. *S*: supervised segmentation; *SS*: semi-supervised segmentation.

Table 4 summarizes the tagging results on the development data with different feature configurations. In this table, the symbol “+” in the *Features* column means current configuration contains both the baseline features and new cluster-based features; the number is the total number of the clusters; the symbol “+” in the *Data* column means which portion of the Gigaword data is used to cluster words; the symbol “S” and “SS” in parentheses denote (s)upervised and (s)emi-(s)upervised word segmentation. For example, “+1991-2000(S)” means the data from 1991 to 2000 are processed by a supervised segmenter and used for clustering. From this table, we can clearly see the impact of word clustering features on POS tagging. The new features lead to substantial improvements over the strong supervised baseline. Moreover, these increases are consistent regardless of the clustering algorithms. Both clustering algorithms contributes to the overall performance equivalently. A natural strategy for extending current experiments is to include both clustering results together, or to include more than one cluster granularity. However, we find no further improvement. For

each clustering algorithm, there are not much differences among different sizes of the total clustering numbers. When a comparable amount of unlabeled data (five years’ data) is used, the further increase of the unlabeled data for clustering does not lead to much changes of the tagging performance.

### 3.4 Learning Curves

Size	Baseline	+Cluster
4.5K	90.10%	91.93%
9K	92.91%	93.94%
13.5K	93.88%	94.60%
18K	94.24%	94.77%

Table 5: Tagging accuracies relative to sizes of training data. Size=#sentences in the training corpus.

We do additional experiments to evaluate the effect of the derived features as the amount of labeled training data is varied. We also use the “+c500(MKCLS)+1991-2004(SS)” setting for these experiments. Table 5 summarizes the accuracies of the systems when trained on smaller portions of the labeled data. We can see that the new features obtain consistent gains regardless of the size of the training set. The error is reduced significantly on all data sets. In other words, the word cluster features can significantly reduce the amount of labeled data required by the learning algorithm. The relative reduction is greatest when smaller amounts of the labeled data are used, and the effect lessens as more labeled data is added.

### 3.5 Analysis

Word clustering derives paradigmatic relational information from unlabeled data by grouping words into different sets. As a result, the contribution of word clustering to POS tagging is two-fold. On the one hand, word clustering captures and abstracts context information. This new linguistic *knowledge* is thus helpful to better correlate a word in a certain context to its POS tag. On the other hand, the clustering of the OOV words to some extent fights the sparse data problem by correlating an OOV word with in-vocabulary (IV) words through their classes. To evaluate the two contributions of the word clustering, we limit entries of the clustering lexicon to only contain IV words, i.e. words appearing in the training corpus. Using this constrained lexicon,

we train a new “+c500(MKCLS)+1991-2004(SS)” model and report its prediction power in Table 6. The gap between the baseline and +*IV clustering* models can be viewed as the contribution of the first effect, while the gap between the +*IV clustering* and +*All clustering* models can be viewed as the second contribution. This result indicates that the improved predictive power partially comes from the new interpretation of a POS tag through a clustering, and partially comes from its memory of OOV words that appears in the unlabeled data.

	Baseline	+IV Clustering	+All clustering
Acc.	94.48%	94.70%(↑0.22)	95.02%(↑0.32)

Table 6: Tagging accuracies with IV clustering.

Table 7 shows the recall of OOV words on the development data set. Only the word types appearing more than 10 times are reported. The recall of all OOV words are improved, especially of proper nouns (NR) and common verbs (VV). Another interesting fact is that almost all of them are content words. This table is also helpful to understand the impact of the clustering information on the prediction of OOV words.

## 4 Capturing Syntagmatic Relations via Constituency Parsing

Syntactic analysis, especially the full and deep one, reflects syntagmatic relations of words and phrases of sentences. We present a series of empirical studies of the tagging results of our *syntax-free* sequential tagger and a *syntax-based* chart parser<sup>5</sup>, aiming at illuminating more precisely the impact of information about phrase-structures on POS tagging. The analysis is helpful to understand the role of syntagmatic lexical relations in POS prediction.

### 4.1 Comparing Tagging and PCFG-LA Parsing

The majority of the state-of-the-art constituent parsers are based on generative PCFG learning, with lexicalized (Collins, 2003; Charniak, 2000) or latent annotation (PCFG-LA) (Matsuzaki et al., 2005; Petrov et al., 2006; Petrov and Klein, 2007) refinements. Compared to lexicalized parsers, the PCFG-LA parsers leverages on an automatic procedure to

<sup>5</sup>Both the tagger and the parser are trained on the same portion from CTB.

	#Words	Baseline	+Clustering	$\Delta$
AD	21	33.33%	42.86%	<
CD	249	97.99%	98.39%	<
JJ	86	3.49%	26.74%	<
NN	1028	91.05%	91.34%	<
NR	863	81.69%	88.76%	<
NT	25	60.00%	68.00%	<
VA	15	33.33%	53.33%	<
VV	402	67.66%	72.39%	<

Table 7: The tagging recall of OOV words.

learn refined grammars and are therefore more robust to parse non-English languages that are not well studied. For Chinese, a PCFG-LA parser achieves the state-of-the-art performance and defeat many other types of parsers (Zhang and Clark, 2009). For full parsing, the Berkeley parser<sup>6</sup>, an open source implementation of the PCFG-LA model, is used for experiments. Table 8 shows their overall and detailed performance.

#### 4.1.1 Content Words vs. Function Words

Table 8 gives a detailed comparison regarding different word types. For each type of word, we report the accuracy of both solvers and compare the difference. The majority of the words that are better labeled by the tagger are content words, including nouns (NN, NR, NT), numbers (CD, OD), predicates (VA, VC, VE), adverbs (AD), nominal modifiers (JJ), and so on. In contrast, most of the words that are better predicted by the parser are function words, including most particles (DEC, DEG, DER, DEV, AS, MSP), prepositions (P, BA) and coordinating conjunction (CC).

#### 4.1.2 Open Classes vs. Close Classes

POS can be divided into two broad supercategories: closed class types and open class types. Open classes accept the addition of new morphemes (words), through such processes as compounding, derivation, inflection, coining, and borrowing. On the other hand closed classes are those that have relatively fixed membership. For example, nouns and verbs are open classes because new nouns and verbs are continually coined or borrowed from other languages, while *DEC/DEG* are two closed classes because only the function word “的” is assigned to

<sup>6</sup><http://code.google.com/p/berkeleyparser/>

	Parser<Tagger	Parser>Tagger	
♠ AD	94.15<94.71	♡ AS	98.54>98.44
♠ CD	94.66<97.52	♡ BA	96.15>92.52
	CS 91.12<92.12	♡ CC	93.80>90.58
	ETC 99.65<100.0	♡ DEC	85.78>81.22
♠ JJ	81.35<84.65	♡ DEG	88.94>85.96

them. The discriminative model can conveniently include many features, especially features related to the word formation, which are important to predict words of open classes. Table 9 summarizes the tagging accuracies relative to IV and OOV words. On the whole, the Berkeley parser processes IV words slightly better than our tagger, but processes OOV words significantly worse. The numbers in this table clearly shows the main weakness of the Berkeley parser is the the predictive power of the OOV words.

	IV	OOV
Tagger	95.22%	81.59%
Parser	95.38%	64.77%

Table 9: Tagging accuracies of the IV and OOV words.

#### 4.1.3 Local Disambiguation vs. Global Disambiguation

Closed class words are generally function words that tend to occur frequently and often have structuring uses in grammar. These words have little lexical meaning or have ambiguous meaning, but instead serve to express grammatical relationships with other words within a sentence. They signal the structural relationships that words have to one another and are the glue that holds sentences together. Thus, they serve as important elements to the structures of sentences. The disambiguation of these

words normally require more syntactic clues, which is very hard and inappropriate for a sequential tagger to capture. Based on global grammatical inference of the whole sentence, the full parser is relatively good at dealing with structure related ambiguities.

We conclude that discriminative sequential tagging model can better capture local syntactic and morphological information, while the full parser can better capture global syntactic structural information. The discriminative tagging model are limited by the Markov assumption and inadequate to correctly label structure related words.

#### 4.2 Enhancing POS Tagging via Bagging

The diversity analysis suggests that we may improve parsing by simply combining the tagger and the parser. Bootstrap aggregating (Bagging) is a machine learning ensemble meta-algorithm to improve classification and regression models in terms of stability and classification accuracy (Breiman, 1996). It also reduces variance and helps to avoid overfitting. We introduce a Bagging model to integrate different POS tagging models. In the training phase, given a training set  $D$  of size  $n$ , our model generates  $m$  new training sets  $D_i$  of size  $63.2\% \times n$  by sampling examples from  $D$  without replacement. Namely no example will be repeated in each  $D_i$ . Each  $D_i$  is separately used to train a tagger and a parser. Using this strategy, we can get  $2m$  weak solvers. In the tagging phase, the  $2m$  models outputs  $2m$  tagging results, each word is assigned one POS label. The final tagging is the voting result of these  $2m$  labels. There may be equal number of different tags. In this case, our system prefer the first label they met.

#### 4.3 Evaluation

We evaluate our combination model on the same data set used above. Figure 1 shows the influence of  $m$  in the Bagging algorithm. Because each new data set  $D_i$  in bagging algorithm is generated by a random procedure, the performance of all Bagging experiments are not the same. To give a more stable evaluation, we repeat 5 experiments for each  $m$  and show the averaged accuracy. We can see that the Bagging model taking both sequential tagging and chart parsing models as basic systems outperform the baseline systems and the Bagging model taking either model in isolation as basic systems. An

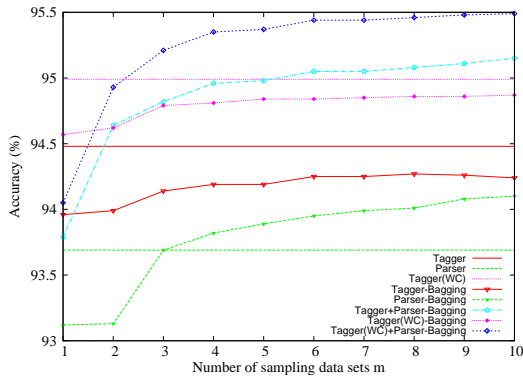

Figure 1: Tagging accuracies of Bagging models. *Tagger-Bagging* and *Tagger(WC)-Bagging* means that the Bagging system built on the tagger with and without word clusters. *Parser-Bagging* is named in the same way. *Tagger+Paser-Bagging* and *Tagger(WC)+Paser-Bagging* means that the Bagging systems are built on both tagger and parser.

interesting phenomenon is that the Bagging method can also improve the parsing model, but there is a decrease while only combining taggers.

## 5 Combining Both

We have introduced two separate improvements for Chinese POS tagging, which capture different types of lexical relations. We therefore expect further improvement by combining both enhancements, since their contributions to the task is different. We still use a Bagging model to integrate the discriminative tagger and the Berkeley parser. The only difference between current experiment and previous experiment is that the sub-tagging models are trained with help of word clustering features. Figure 1 also shows the performance of the new Bagging model on the development data set. We can see that the improvements that come from two ways, namely capturing syntagmatic and paradigmatic relations, are not much overlapping and the combination of them gives more.

Table 10 shows the performance of different systems evaluated on the test data. The final result is remarkable. The word clustering features and the Bagging model result in a relative error reduction of 18% in terms of the classification accuracy. The significant improvement of the POS tagging also help successive language processing. Results in Table

Systems	Acc.
Baseline	94.33%
Tagger(WC)	94.85%
Tagger+Parser( $m = 15$ )	94.96%
Tagger(WC)+Parser( $m = 15$ )	95.34%

Table 10: Tagging accuracies on the test data (CoNLL).

11 indicate that the parsing accuracy of the Berkeley parser can be simply improved by inputting the Berkeley parser with the POS Bagging results. Although the combination with a syntax-based tagger is very effective, there are two weaknesses: (1) a syntax-based model relies on linguistically rich syntactic annotations that are not easy to acquire; (2) a syntax-based model is computationally expensive which causes efficiency difficulties.

Tagger	LP	LR	F
Berkeley	82.71%	80.57%	81.63
Bagging( $m = 15$ )	82.96%	81.44%	82.19

Table 11: Parsing accuracies on the test data. (CoNLL)

## 6 Conclusion

We hold a view of structuralist linguistics and study the impact of paradigmatic and syntagmatic lexical relations on Chinese POS tagging. First, we harvest word partition information from large-scale raw texts to capture paradigmatic relations and use such knowledge to enhance a supervised tagger via feature engineering. Second, we comparatively analyze syntax-free and syntax-based models and employ a Bagging model to integrate a sequential tagger and a chart parser to capture syntagmatic relations that have a great impact on non-local disambiguation. Both enhancements significantly improve the state-of-the-art of Chinese POS tagging. The final model results in an error reduction of 18% over a state-of-the-art baseline.

## Abstract

We present a joint model for Chinese word segmentation and new word detection. We present high dimensional new features, including word-based features and enriched edge (label-transition) features, for the joint modeling. As we know, training a word segmentation system on large-scale datasets is already costly. In our case, adding high dimensional new features will further slow down the training speed. To solve this problem, we propose a new training method, adaptive online gradient descent based on feature frequency information, for very fast online training of the parameters, even given large-scale datasets with high dimensional features. Compared with existing training methods, our training method is an order magnitude faster in terms of training time, and can achieve equal or even higher accuracies. The proposed fast training method is a general purpose optimization method, and it is not limited in the specific task discussed in this paper.

## 1 Introduction

Since Chinese sentences are written as continuous sequences of characters, segmenting a character sequence into words is normally the first step in the pipeline of Chinese text processing. The major problem of Chinese word segmentation is the ambiguity. Chinese character sequences are normally ambiguous, and new words (out-of-vocabulary words) are a major source of the ambiguity. A typical category of new words is named entities, including organization names, person names, location names, and so on.

In this paper, we present high dimensional new features, including word-based features and enriched edge (label-transition) features, for the joint modeling of Chinese word segmentation (CWS) and new word detection (NWD). While most of the state-of-the-art CWS systems used semi-Markov conditional random fields or latent variable conditional random fields, we simply use a single first-order conditional random fields (CRFs) for the joint modeling. The semi-Markov CRFs and latent variable CRFs relax the Markov assumption of CRFs to express more complicated dependencies, and therefore to achieve higher disambiguation power. Alternatively, our plan is not to relax Markov assumption of CRFs, but to exploit more complicated dependencies via using refined high-dimensional features. The advantage of our choice is the simplicity of our model. As a result, our CWS model can be more efficient compared with the heavier systems, and with similar or even higher accuracy because of using refined features.

As we know, training a word segmentation system on large-scale datasets is already costly. In our case, adding high dimensional new features will further slow down the training speed. To solve this challenging problem, we propose a new training method, adaptive online gradient descent based on feature frequency information (ADF), for very fast word segmentation with new word detection, even given large-scale datasets with high dimensional features. In the proposed training method, we try to use more refined learning rates. Instead of using a single learning rate (a scalar) for all weights, we extend the learning rate scalar to a learning rate vector based on feature frequency information in the updating. By doing so, each weight has

its own learning rate adapted on feature frequency information. We will show that this can significantly improve the convergence speed of online learning. We approximate the learning rate vector based on *feature frequency information in the updating process*. Our proposal is based on the intuition that a feature with higher frequency in the training process should be with a learning rate that is decayed faster. Based on this intuition, we will show the formalized training algorithm later. We will show in experiments that our solution is an order magnitude faster compared with exiting learning methods, and can achieve equal or even higher accuracies.

The contribution of this work is as follows:

- We propose a general purpose fast online training method, ADF. The proposed training method requires only a few passes to complete the training.
- We propose a joint model for Chinese word segmentation and new word detection.
- Compared with prior work, our system achieves better accuracies on both word segmentation and new word detection.

## 2 Related Work

First, we review related work on word segmentation and new word detection. Then, we review popular online training methods, in particular stochastic gradient descent (SGD).

### 2.1 Word Segmentation and New Word Detection

Conventional approaches to Chinese word segmentation treat the problem as a sequential labeling task (Xue, 2003; Peng et al., 2004; Tseng et al., 2005; Asahara et al., 2005; Zhao et al., 2010). To achieve high accuracy, most of the state-of-the-art systems are heavy probabilistic systems using semi-Markov assumptions or latent variables (Andrew, 2006; Sun et al., 2009b). For example, one of the state-of-the-art CWS system is the latent variable conditional random field (Sun et al., 2008; Sun and Tsujii, 2009) system presented in Sun et al. (2009b). It is a heavy probabilistic model and it is slow in training. A few other state-of-the-art CWS systems are using semi-Markov perceptron methods or voting systems based on multiple semi-Markov

perceptron segmenters (Zhang and Clark, 2007; Sun, 2010). Those semi-Markov perceptron systems are moderately faster than the heavy probabilistic systems using semi-Markov conditional random fields or latent variable conditional random fields. However, a disadvantage of the perceptron style systems is that they can not provide probabilistic information.

On the other hand, new word detection is also one of the important problems in Chinese information processing. Many statistical approaches have been proposed (J. Nie and Jin, 1995; Chen and Bai, 1998; Wu and Jiang, 2000; Peng et al., 2004; Chen and Ma, 2002; Zhou, 2005; Goh et al., 2003; Fu and Luke, 2004; Wu et al., 2011). New word detection is normally considered as a separate process from segmentation. There were studies trying to solve this problem jointly with CWS. However, the current studies are limited. Integrating the two tasks would benefit both segmentation and new word detection. Our method provides a convenient framework for doing this. Our new word detection is not a stand-alone process, but an integral part of segmentation.

### 2.2 Online Training

The most representative online training method is the SGD method. The SGD uses a small randomly-selected subset of the training samples to approximate the gradient of an objective function. The number of training samples used for this approximation is called the batch size. By using a smaller batch size, one can update the parameters more frequently and speed up the convergence. The extreme case is a batch size of 1, and it gives the maximum frequency of updates, which we adopt in this work. Then, the model parameters are updated in such a way:

$$\mathbf{w}_{t+1} = \mathbf{w}_t + \gamma_t \nabla_{\mathbf{w}_t} \mathcal{L}_{stoch}(\mathbf{z}_i, \mathbf{w}_t), \quad (1)$$

where  $t$  is the update counter,  $\gamma_t$  is the learning rate, and  $\mathcal{L}_{stoch}(\mathbf{z}_i, \mathbf{w}_t)$  is the stochastic loss function based on a training sample  $\mathbf{z}_i$ .

There were accelerated versions of SGD, including stochastic meta descent (Vishwanathan et al., 2006) and periodic step-size adaptation online learning (Hsu et al., 2009). Compared with those two methods, our proposal is fundamentally

different. Those two methods are using 2nd-order gradient (Hessian) information for accelerated training, while our accelerated training method does not need such 2nd-order gradient information, which is costly and complicated. Our ADF training method is based on feature frequency adaptation, and there is no prior work on using feature frequency information for accelerating online training.

Other online training methods includes averaged SGD with feedback (Sun et al., 2010; Sun et al., 2011), latent variable perceptron training (Sun et al., 2009a), and so on. Those methods are less related to this paper.

### 3 System Architecture

#### 3.1 A Joint Model Based on CRFs

First, we briefly review CRFs. CRFs are proposed as a method for structured classification by solving “the label bias problem” (Lafferty et al., 2001). Assuming a feature function that maps a pair of observation sequence  $\mathbf{x}$  and label sequence  $\mathbf{y}$  to a global feature vector  $\mathbf{f}$ , the probability of a label sequence  $\mathbf{y}$  conditioned on the observation sequence  $\mathbf{x}$  is modeled as follows (Lafferty et al., 2001):

$$P(\mathbf{y}|\mathbf{x}, \mathbf{w}) = \frac{\exp\{\mathbf{w}^\top \mathbf{f}(\mathbf{y}, \mathbf{x})\}}{\sum_{\mathbf{y}'} \exp\{\mathbf{w}^\top \mathbf{f}(\mathbf{y}', \mathbf{x})\}}, \quad (2)$$

where  $\mathbf{w}$  is a parameter vector.

Given a training set consisting of  $n$  labeled sequences,  $\mathbf{z}_i = (\mathbf{x}_i, \mathbf{y}_i)$ , for  $i = 1 \dots n$ , parameter estimation is performed by maximizing the objective function,

$$\mathcal{L}(\mathbf{w}) = \sum_{i=1}^n \log P(\mathbf{y}_i|\mathbf{x}_i, \mathbf{w}) - R(\mathbf{w}). \quad (3)$$

The first term of this equation represents a conditional log-likelihood of a training data. The second term is a regularizer for reducing overfitting. We employed an L2 prior,  $R(\mathbf{w}) = \frac{\|\mathbf{w}\|^2}{2\sigma^2}$ . In what follows, we denote the conditional log-likelihood of each sample  $\log P(\mathbf{y}_i|\mathbf{x}_i, \mathbf{w})$  as  $\ell(\mathbf{z}_i, \mathbf{w})$ . The final objective function is as follows:

$$\mathcal{L}(\mathbf{w}) = \sum_{i=1}^n \ell(\mathbf{z}_i, \mathbf{w}) - \frac{\|\mathbf{w}\|^2}{2\sigma^2}. \quad (4)$$

Since no word list can be complete, new word identification is an important task in Chinese NLP. New words in input text are often incorrectly segmented into single-character or other very short words (Chen and Bai, 1998). This phenomenon will also undermine the performance of Chinese word segmentation. We consider here new word detection as an integral part of segmentation, aiming to improve both segmentation and new word detection: detected new words are added to the word list lexicon in order to improve segmentation. Based on our CRF word segmentation system, we can compute a probability for each segment. When we find some word segments are of reliable probabilities yet they are not in the existing word list, we then treat those “confident” word segments as new words and add them into the existing word list. Based on preliminary experiments, we treat a word segment as a new word if its probability is larger than 0.5. Newly detected words are re-incorporated into word segmentation for improving segmentation accuracies.

#### 3.2 New Features

Here, we will describe high dimensional new features for the system.

##### 3.2.1 Word-based Features

There are two ideas in deriving the refined features. The first idea is to exploit word features for node features of CRFs. Note that, although our model is a Markov CRF model, we can still use word features to learn word information in the training data. To derive word features, first of all, our system automatically collect a list of word unigrams and bigrams from the training data. To avoid overfitting, we only collect the word unigrams and bigrams whose frequency is larger than 2 in the training set. This list of word unigrams and bigrams are then used as a unigram-dictionary and a bigram-dictionary to generate word-based *unigram* and *bigram* features. The word-based features are indicator functions that fire when the local character sequence matches a word unigram or bigram occurred in the training data. The word-based feature templates derived for the label  $y_i$  are as follows:

- $\text{unigram1}(\mathbf{x}, y_i) \leftarrow [x_{j,i}, y_i]$ , if the character sequence  $x_{j,i}$  matches a word  $w \in \mathbb{U}$ ,

with the constraint  $i - 6 < j < i$ . The item  $x_{j,i}$  represents the character sequence  $x_j \dots x_i$ .  $\mathbb{U}$  represents the unigram-dictionary collected from the training data.

- $\text{unigram2}(\mathbf{x}, y_i) \leftarrow [x_{i,k}, y_i]$ , if the character sequence  $x_{i,k}$  matches a word  $w \in \mathbb{U}$ , with the constraint  $i < k < i + 6$ .
- $\text{bigram1}(\mathbf{x}, y_i) \leftarrow [x_{j,i-1}, x_{i,k}, y_i]$ , if the word bigram candidate  $[x_{j,i-1}, x_{i,k}]$  hits a word bigram  $[w_i, w_j] \in \mathbb{B}$ , and satisfies the aforementioned constraints on  $j$  and  $k$ .  $\mathbb{B}$  represents the word bigram dictionary collected from the training data.
- $\text{bigram2}(\mathbf{x}, y_i) \leftarrow [x_{j,i}, x_{i+1,k}, y_i]$ , if the word bigram candidate  $[x_{j,i}, x_{i+1,k}]$  hits a word bigram  $[w_i, w_j] \in \mathbb{B}$ , and satisfies the aforementioned constraints on  $j$  and  $k$ .

We also employ the traditional character-based features. For each label  $y_i$ , we use the feature templates as follows:

- Character unigrams locating at positions  $i - 2$ ,  $i - 1$ ,  $i$ ,  $i + 1$  and  $i + 2$
- Character bigrams locating at positions  $i - 2$ ,  $i - 1$ ,  $i$  and  $i + 1$
- Whether  $x_j$  and  $x_{j+1}$  are identical, for  $j = i - 2, \dots, i + 1$
- Whether  $x_j$  and  $x_{j+2}$  are identical, for  $j = i - 3, \dots, i + 1$

The latter two feature templates are designed to detect character or word reduplication, a morphological phenomenon that can influence word segmentation in Chinese.

### 3.2.2 High Dimensional Edge Features

The node features discussed above are based on a single label  $y_i$ . CRFs also have edge features that are based on label transitions. The second idea is to incorporate local observation information of  $\mathbf{x}$  in edge features. For traditional implementation of CRF systems (e.g., the HCRF package), usually the edges features contain only the information of  $y_{i-1}$  and  $y_i$ , and without the information of

the observation sequence (i.e.,  $\mathbf{x}$ ). The major reason for this simple realization of edge features in traditional CRF implementation is for reducing the dimension of features. Otherwise, there can be an explosion of edge features in some tasks. For example, in part-of-speech tagging tasks, there can be more than 40 labels and more than 1,600 types of label transitions. Therefore, incorporating local observation information into the edge feature will result in an explosion of edge features, which is 1,600 times larger than the number of feature templates.

Fortunately, for our task, the label set is quite small,  $\mathbb{Y} = \{\text{B}, \text{I}, \text{E}\}$ <sup>1</sup>. There are only nine possible label transitions:  $\mathbb{T} = \mathbb{Y} \times \mathbb{Y}$  and  $|\mathbb{T}| = 9$ .<sup>2</sup> As a result, the feature dimension will have nine times increase over the feature templates, if we incorporate local observation information of  $\mathbf{x}$  into the edge features. In this way, we can effectively combine observation information of  $\mathbf{x}$  with label transitions  $y_{i-1}y_i$ . We simply used the same templates of node features for deriving the new edge features. We found adding new edge features significantly improves the disambiguation power of our model.

## 4 Adaptive Online Gradient Descent based on Feature Frequency Information

As we will show in experiments, the training of the CRF model with high-dimensional new features is quite expensive, and the existing training method is not good enough. To solve this issue, we propose a fast online training method: adaptive online gradient descent based on feature frequency information (ADF). The proposed method is easy to implement.

For high convergence speed of online learning, we try to use more refined learning rates than the SGD training. Instead of using a single learning rate (a scalar) for all weights, we extend the learning rate scalar to a learning rate vector, which has the same dimension of the weight vector  $\mathbf{w}$ . The learning rate vector is automatically adapted based on feature frequency information. By doing so, each weight

<sup>1</sup>B means *beginning of a word*, I means *inside a word*, and E means *end of a word*. The B, I, E labels have been widely used in previous work of Chinese word segmentation (Sun et al., 2009b).

<sup>2</sup>The operator  $\times$  means a Cartesian product between two sets.

---

Figure 1: The proposed ADF online learning algorithm.  $q, c, \alpha,$  and  $\beta$  are hyper-parameters.  $q$  is an integer representing window size.  $c$  is for initializing the learning rates.  $\alpha$  and  $\beta$  are the upper and lower bounds of a scalar, with  $0 < \beta < \alpha < 1$ .

has its own learning rate, and we will show that this can significantly improve the convergence speed of online learning.

In our proposed online learning method, the update formula is as follows:

$$\mathbf{w}_{t+1} = \mathbf{w}_t + \boldsymbol{\gamma}_t \cdot \mathbf{g}_t. \quad (5)$$

The update term  $\mathbf{g}_t$  is the gradient term of a randomly sampled instance:

$$\mathbf{g}_t = \nabla_{\mathbf{w}_t} \mathcal{L}_{stoch}(\mathbf{z}_i, \mathbf{w}_t) = \nabla_{\mathbf{w}_t} \left\{ \ell(\mathbf{z}_i, \mathbf{w}_t) - \frac{\|\mathbf{w}_t\|^2}{2n\sigma^2} \right\}.$$

In addition,  $\boldsymbol{\gamma}_t \in \mathbb{R}_+^f$  is a positive vector-valued learning rate and  $\cdot$  denotes component-wise (Hadamard) product of two vectors.

We learn the learning rate vector  $\boldsymbol{\gamma}_t$  based on *feature frequency information in the updating*

*process*. Our proposal is based on the intuition that a feature with higher frequency in the training process should be with a learning rate that decays faster. In other words, we assume a high frequency feature observed in the training process should have a small learning rate, and a low frequency feature should have a relatively larger learning rate in the training. Our assumption is based on the intuition that a weight with higher frequency is more adequately trained, hence smaller learning rate is preferable for fast convergence.

Given a window size  $q$  (number of samples in a window), we use a vector  $\mathbf{v}$  to record the feature frequency. The  $k$ 'th entry  $\mathbf{v}_k$  corresponds to the frequency of the feature  $k$  in this window. Given a feature  $k$ , we use  $u$  to record the normalized frequency:

$$u = \mathbf{v}_k / q.$$

For each feature, an adaptation factor  $\eta$  is calculated based on the normalized frequency information, as follows:

$$\eta = \alpha - u(\alpha - \beta),$$

where  $\alpha$  and  $\beta$  are the upper and lower bounds of a scalar, with  $0 < \beta < \alpha < 1$ . As we can see, a feature with higher frequency corresponds to a smaller scalar via linear approximation. Finally, the learning rate is updated as follows:

$$\boldsymbol{\gamma}_k \leftarrow \eta \boldsymbol{\gamma}_k.$$

With this setting, different features will correspond to different adaptation factors based on feature frequency information. Our ADF algorithm is summarized in Figure 1.

The ADF training method is efficient, because the additional computation (compared with SGD) is only the derivation of the learning rates, which is simple and efficient. As we know, the regularization of SGD can perform efficiently via the optimization based on sparse features (Shalev-Shwartz et al., 2007). Similarly, the derivation of  $\boldsymbol{\gamma}_t$  can also perform efficiently via the optimization based on sparse features.

#### 4.1 Convergence Analysis

Prior work on convergence analysis of existing online learning algorithms (Murata, 1998; Hsu et

	#W.T.	#Word	#C.T.	#Char
MSR	$8.8 \times 10^4$	$2.4 \times 10^6$	$5 \times 10^3$	$4.1 \times 10^6$
CU	$6.9 \times 10^4$	$1.5 \times 10^6$	$5 \times 10^3$	$2.4 \times 10^6$
PKU	$5.5 \times 10^4$	$1.1 \times 10^6$	$5 \times 10^3$	$1.8 \times 10^6$

Table 1: Details of the datasets. *W.T.* represents *word types*; *C.T.* represents *character types*.

al., 2009) can be extended to the proposed ADF training method. We can show that the proposed ADF learning algorithm has reasonable convergence properties.

When we have the smallest learning rate  $\gamma_{t+1} = \beta\gamma_t$ , the expectation of the obtained  $\mathbf{w}_t$  is

$$E(\mathbf{w}_t) = \mathbf{w}^* + \prod_{m=1}^t (\mathbf{I} - \gamma_0 \beta^m \mathbf{H}(\mathbf{w}^*)) (\mathbf{w}_0 - \mathbf{w}^*),$$

where  $\mathbf{w}^*$  is the optimal weight vector, and  $\mathbf{H}$  is the Hessian matrix of the objective function. The rate of convergence is governed by the largest eigenvalue of the function  $\mathbf{C}_t = \prod_{m=1}^t (\mathbf{I} - \gamma_0 \beta^m \mathbf{H}(\mathbf{w}^*))$ . Then, we can derive a bound of rate of convergence.

**Theorem 1** Assume  $\phi$  is the largest eigenvalue of the function  $\mathbf{C}_t = \prod_{m=1}^t (\mathbf{I} - \gamma_0 \beta^m \mathbf{H}(\mathbf{w}^*))$ . For the proposed ADF training, its convergence rate is bounded by  $\phi$ , and we have

$$\phi \leq \exp \left\{ \frac{\gamma_0 \lambda \beta}{\beta - 1} \right\},$$

where  $\lambda$  is the minimum eigenvalue of  $\mathbf{H}(\mathbf{w}^*)$ .

## 5 Experiments

### 5.1 Data and Metrics

We used benchmark datasets provided by the second International Chinese Word Segmentation Bakeoff to test our proposals. The datasets are from Microsoft Research Asia (MSR), City University of Hongkong (CU), and Peking University (PKU). Details of the corpora are listed in Table 1. We did not use any extra resources such as common surnames, parts-of-speech, and semantics.

Four metrics were used to evaluate segmentation results: recall ( $R$ , the percentage of gold standard output words that are correctly segmented by the decoder), precision ( $P$ , the percentage of words in the decoder output that are segmented correctly), balanced F-score defined by  $2PR/(P + R)$ , and recall of new word detection (NWD recall). For more detailed information on the corpora, refer to Emerson (2005).

### 5.2 Features, Training, and Tuning

We employed the feature templates defined in Section 3.2. The feature sets are huge. There are  $2.4 \times 10^7$  features for the MSR data,  $4.1 \times 10^7$  features for the CU data, and  $4.7 \times 10^7$  features for the PKU data. To generate word-based features, we extracted high-frequency word-based unigram and bigram lists from the training data.

As for training, we performed gradient descent

Figure 2: F-score curves on the MSR, CU, and PKU datasets: ADF learning vs. SGD and LBFGS training methods.

with our proposed training method. To compare with existing methods, we chose two popular training methods, a batch training one and an online training one. The batch training method is the Limited-Memory BFGS (LBFGS) method (Nocedal and Wright, 1999). The online baseline training method is the SGD method, which we have introduced in Section 2.2.

For the ADF training method, we need to tune the hyper-parameters  $q$ ,  $c$ ,  $\alpha$ , and  $\beta$ . Based on automatic tuning within the training data (validation in the training data), we found it is proper to set  $q = n/10$  ( $n$  is the number of training samples),  $c = 0.1$ ,  $\alpha = 0.995$ , and  $\beta = 0.6$ . To reduce overfitting, we employed an  $L_2$  Gaussian weight prior (Chen and Rosenfeld, 1999) for all training methods. We varied the  $\sigma$  with different values (e.g., 1.0, 2.0, and 5.0), and finally set the value to 1.0 for all training methods.

### 5.3 Results and Discussion

First, we performed incremental evaluation in this order: Baseline (word segmentation model with SGD training); Baseline + New features; Baseline + New features + New word detection; Baseline + New features + New word detection + ADF training (replacing SGD training). The results are shown in Table 2.

As we can see, the new features improved performance on both word segmentation and new word detection. However, we also noticed that the training cost became more expensive via adding high dimensional new features. Adding new word detection function further improved the segmentation quality and the new word recognition recall. Finally, by using the ADF training method, the training speed is much faster than the SGD training method. The ADF method can achieve empirical optimum in only a few passes, yet with better segmentation accuracies than the SGD training with 50 passes.

To get more details of the proposed training method, we compared it with SGD and LBFGS training methods based on an identical platform, by varying the number of passes. The comparison was based on the same platform: Baseline + New features + New word detection. The F-score curves of the training methods are shown in Figure 2. Impressively, the ADF training method reached empirical convergence in only a few passes, while the SGD and LBFGS training converged much slower, requiring more than 50 passes. The ADF training is about an order magnitude faster than the SGD online training and more than an order magnitude faster than the LBFGS batch training.

Finally, we compared our method with the state-

of-the-art systems reported in the previous papers. The statistics are listed in Table 3. *Best05* represents the best system of the Second International Chinese Word Segmentation Bakeoff on the corresponding data; *CRF + rule-system* represents confidence-based combination of CRF and rule-based models, presented in Zhang et al. (2006). *Prob.* indicates whether or not the system can provide probabilistic information. As we can see, our method achieved similar or even higher F-scores, compared with the best systems reported in previous papers. Note that, our system is a single Markov model, while most of the state-of-the-art systems are complicated heavy systems, with model-combinations (e.g., voting of multiple segmenters), semi-Markov relaxations, or latent-variables.

## 6 Conclusions and Future Work

In this paper, we presented a joint model for Chinese word segmentation and new word detection. We presented new features, including word-based features and enriched edge features, for the joint modeling. We showed that the new features can improve the performance on the two tasks.

On the other hand, the training of the model, especially with high-dimensional new features, became quite expensive. To solve this problem,

we proposed a new training method, ADF training, for very fast training of CRFs, even given large-scale datasets with high dimensional features. We performed experiments and showed that our new training method is an order magnitude faster than existing optimization methods. Our final system can learn highly accurate models with only a few passes in training. The proposed fast learning method is a general algorithm that is not limited in this specific task. As future work, we plan to apply this fast learning method on other large-scale natural language processing tasks.

## Acknowledgments

## Abstract

In this paper, we propose innovative representations for automatic classification of verbs according to mainstream linguistic theories, namely VerbNet and FrameNet. First, syntactic and semantic structures capturing essential lexical and syntactic properties of verbs are defined. Then, we design advanced similarity functions between such structures, i.e., semantic tree kernel functions, for exploiting distributional and grammatical information in Support Vector Machines. The extensive empirical analysis on VerbNet class and frame detection shows that our models capture meaningful syntactic/semantic structures, which allows for improving the state-of-the-art.

## 1 Introduction

Verb classification is a fundamental topic of computational linguistics research given its importance for understanding the role of verbs in conveying semantics of natural language (NL). Additionally, generalization based on verb classification is central to many NL applications, ranging from shallow semantic parsing to semantic search or information extraction. Currently, a lot of interest has been paid to two verb categorization schemes: VerbNet (Schuler, 2005) and FrameNet (Baker et al., 1998), which has also fostered production of many automatic approaches to predicate argument extraction.

Such work has shown that syntax is necessary for helping to predict the roles of verb arguments and consequently their verb sense (Gildea and Jurafsky, 2002; Pradhan et al., 2005; Gildea and Palmer, 2002). However, the definition of models for optimally combining lexical and syntactic constraints is

still far from being accomplished. In particular, the exhaustive design and experimentation of lexical and syntactic features for learning verb classification appears to be computationally problematic. For example, the verb **order** can belong to the two VerbNet classes:

- The class 60.1, i.e., *order someone to do something* as shown in: *The Illinois Supreme Court **ordered** the commission to audit Commonwealth Edison's construction expenses and refund any unreasonable expenses.*
- The class 13.5.1: *order or request something like* in: *... Michelle blabs about it to a sandwich man while **ordering** lunch over the phone.*

Clearly, the syntactic realization can be used to discern the cases above but it would not be enough to correctly classify the following verb occurrence: *.. ordered the lunch to be delivered ..* in Verb class 13.5.1. For such a case, selectional restrictions are needed. These have also been shown to be useful for semantic role classification (Zapirain et al., 2010). Note that their coding in learning algorithms is rather complex: we need to take into account syntactic structures, which may require an exponential number of syntactic features (i.e., all their possible substructures). Moreover, these have to be enriched with lexical information to trigger lexical preference.

In this paper, we tackle the problem above by studying innovative representations for automatic verb classification according to VerbNet and FrameNet. We define syntactic and semantic structures capturing essential lexical and syntactic properties of verbs. Then, we apply similarity between

such structures, i.e., kernel functions, which can also exploit distributional lexical semantics, to train automatic classifiers. The basic idea of such functions is to compute the similarity between two verbs in terms of all the possible substructures of their syntactic frames. We define and automatically extract a lexicalized approximation of the latter. Then, we apply kernel functions that jointly model structural and lexical similarity so that syntactic properties are combined with generalized lexemes. The nice property of kernel functions is that they can be used in place of the scalar product of feature vectors to train algorithms such as Support Vector Machines (SVMs). This way SVMs can learn the association between syntactic (sub-) structures whose lexical arguments are generalized and target verb classes, i.e., they can also learn selectional restrictions.

We carried out extensive experiments on verb class and frame detection which showed that our models greatly improve on the state-of-the-art (up to about 13% of relative error reduction). Such results are nicely assessed by manually inspecting the most important substructures used by the classifiers as they largely correlate with syntactic frames defined in VerbNet.

In the rest of the paper, Sec. 2 reports on related work, Sec. 3 and Sec. 4 describe previous and our models for syntactic and semantic similarity, respectively, Sec. 5 illustrates our experiments, Sec. 6 discusses the output of the models in terms of error analysis and important structures and finally Sec. 7 derives the conclusions.

## 2 Related work

Our target task is verb classification but at the same time our models exploit distributional models as well as structural kernels. The next three subsections report related work in such areas.

**Verb Classification.** The introductory verb classification example has intuitively shown the complexity of defining a comprehensive feature representation. Hereafter, we report on analysis carried out in previous work.

It has been often observed that verb senses tend to show different selectional constraints in a specific argument position and the above verb *order* is a clear example. In the direct object position of the example sentence for the first sense 60.1 of *order*, we found

*commission* in the role PATIENT of the predicate. It clearly satisfies the +ANIMATE/+ORGANIZATION restriction on the PATIENT role. This is not true for the direct object dependency of the alternative sense 13.5.1, which usually expresses the THEME role, with unrestricted type selection. When properly generalized, the direct object information has thus been shown highly predictive about verb sense distinctions.

In (Brown et al., 2011), the so called *dynamic dependency neighborhoods* (DDN), i.e., the set of verbs that are typically collocated with a direct object, are shown to be more helpful than lexical information (e.g., WordNet). The set of typical verbs taking a noun  $n$  as a direct object is in fact a strong characterization for semantic similarity, as all the nouns  $m$  similar to  $n$  tend to collocate with the same verbs. This is true also for other syntactic dependencies, among which the direct object dependency is possibly the strongest cue (as shown for example in (Dligach and Palmer, 2008)).

In order to generalize the above DDN feature, distributional models are ideal, as they are designed to model all the collocations of a given noun, according to large scale corpus analysis. Their ability to capture lexical similarity is well established in WSD tasks (e.g. (Schutze, 1998)), thesauri harvesting (Lin, 1998), semantic role labeling (Croce et al., 2010)) as well as information retrieval (e.g. (Furnas et al., 1988)).

**Distributional Models (DMs).** These models follow the distributional hypothesis (Firth, 1957) and characterize lexical meanings in terms of *context of use*, (Wittgenstein, 1953). By inducing geometrical notions of vectors and norms through corpus analysis, they provide a topological definition of semantic similarity, i.e., distance in a space. DMs can capture the similarity between words such as *delegation*, *deputation* or *company* and *commission*. In case of sense 60.1 of the verb *order*, DMs can be used to suggest that the role PATIENT can be inherited by all these words, as suitable *Organisations*.

In supervised language learning, when few examples are available, DMs support cost-effective lexical generalizations, often outperforming knowledge based resources (such as WordNet, as in (Pantel et al., 2007)). Obviously, the choice of the context

type determines the type of targeted semantic properties. Wider contexts (e.g., entire documents) are shown to suggest topical relations. Smaller contexts tend to capture more specific semantic aspects, e.g. the syntactic behavior, and better capture paradigmatic relations, such as synonymy. In particular, word space models, as described in (Sahlgren, 2006), define contexts as the words appearing in a  $n$ -sized window, centered around a target word. Co-occurrence counts are thus collected in a words-by-words matrix, where each element records the number of times two words co-occur within a single window of word tokens. Moreover, robust weighting schemas are used to smooth counts against too frequent co-occurrence pairs: Pointwise Mutual Information (PMI) scores (Turney and Pantel, 2010) are commonly adopted.

**Structural Kernels.** Tree and sequence kernels have been successfully used in many NLP applications, e.g., parse reranking and adaptation, (Collins and Duffy, 2002; Shen et al., 2003; Toutanova et al., 2004; Kudo et al., 2005; Titov and Henderson, 2006), chunking and dependency parsing, e.g., (Kudo and Matsumoto, 2003; Daumé III and Marcu, 2004), named entity recognition, (Cumby and Roth, 2003), text categorization, e.g., (Cancedda et al., 2003; Gliozzo et al., 2005), and relation extraction, e.g., (Zelenko et al., 2002; Bunescu and Mooney, 2005; Zhang et al., 2006).

Recently, DMs have been also proposed in integrated syntactic-semantic structures that feed advanced learning functions, such as the semantic tree kernels discussed in (Bloehdorn and Moschitti, 2007a; Bloehdorn and Moschitti, 2007b; Mehdad et al., 2010; Croce et al., 2011).

### 3 Structural Similarity Functions

In this paper we model verb classifiers by exploiting previous technology for kernel methods. In particular, we design new models for verb classification by adopting algorithms for structural similarity, known as Smoothed Partial Tree Kernels (SPTKs) (Croce et al., 2011). We define new innovative structures and similarity functions based on LSA.

The main idea of SPTK is rather simple: (i) measuring the similarity between two trees in terms of the number of shared subtrees; and (ii) such number also includes similar fragments whose lexical nodes

are just related (so they can be different). The contribution of (ii) is proportional to the lexical similarity of the tree lexical nodes, where the latter can be evaluated according to distributional models or also lexical resources, e.g., WordNet.

In the following, we define our models based on previous work on LSA and SPTKs.

#### 3.1 LSA as lexical similarity model

Robust representations can be obtained through intelligent dimensionality reduction methods. In LSA the original word-by-context matrix  $M$  is decomposed through Singular Value Decomposition (SVD) (Landauer and Dumais, 1997; Golub and Kahan, 1965) into the product of three new matrices:  $U$ ,  $S$ , and  $V$  so that  $S$  is diagonal and  $M = USV^T$ .  $M$  is then approximated by  $M_k = U_k S_k V_k^T$ , where only the first  $k$  columns of  $U$  and  $V$  are used, corresponding to the first  $k$  greatest singular values. This approximation supplies a way to project a generic term  $w_i$  into the  $k$ -dimensional space using  $W = U_k S_k^{1/2}$ , where each row corresponds to the representation vectors  $\vec{w}_i$ . The original statistical information about  $M$  is captured by the new  $k$ -dimensional space, which preserves the global structure while removing low-variance dimensions, i.e., distribution noise. Given two words  $w_1$  and  $w_2$ , the term similarity function  $\sigma$  is estimated as the cosine similarity between the corresponding projections  $\vec{w}_1, \vec{w}_2$  in the LSA space, i.e.  $\sigma(w_1, w_2) = \frac{\vec{w}_1 \cdot \vec{w}_2}{\|\vec{w}_1\| \|\vec{w}_2\|}$ . This is known as *Latent Semantic Kernel (LSK)*, proposed in (Cristianini et al., 2001), as it defines a positive semi-definite Gram matrix  $G = \sigma(w_1, w_2) \forall w_1, w_2$  (Shawe-Taylor and Cristianini, 2004).  $\sigma$  is thus a valid kernel and can be combined with other kernels, as discussed in the next session.

#### 3.2 Tree Kernels driven by Semantic Similarity

To our knowledge, two main types of tree kernels exploit lexical similarity: the syntactic semantic tree kernel defined in (Bloehdorn and Moschitti, 2007a) applied to constituency trees and the smoothed partial tree kernels (SPTKs) defined in (Croce et al., 2011), which generalizes the former. We report the definition of the latter as we modified it for our purposes. SPTK computes the number of common substructures between two trees  $T_1$  and  $T_2$  without explicitly considering the whole fragment space. Its

Figure 1: Constituency Tree (CT) representation of verbs.

Figure 2: Representation of verbs according to the Grammatical Relation Centered Tree (GRCT)

general equations are reported hereafter:

$$TK(T_1, T_2) = \sum_{n_1 \in N_{T_1}} \sum_{n_2 \in N_{T_2}} \Delta(n_1, n_2), \quad (1)$$

where  $N_{T_1}$  and  $N_{T_2}$  are the sets of the  $T_1$ 's and  $T_2$ 's nodes, respectively and  $\Delta(n_1, n_2)$  is equal to the number of common fragments rooted in the  $n_1$  and  $n_2$  nodes<sup>1</sup>. The  $\Delta$  function determines the richness of the kernel space and thus induces different tree kernels, for example, the syntactic tree kernel (STK) (Collins and Duffy, 2002) or the partial tree kernel (PTK) (Moschitti, 2006).

The algorithm for SPTK's  $\Delta$  is the following: if  $n_1$  and  $n_2$  are leaves then  $\Delta_\sigma(n_1, n_2) = \mu\lambda\sigma(n_1, n_2)$ ; else

$$\Delta_\sigma(n_1, n_2) = \mu\sigma(n_1, n_2) \times \left( \lambda^2 + \sum_{\vec{I}_1, \vec{I}_2, l(\vec{I}_1)=l(\vec{I}_2)} \lambda^{d(\vec{I}_1)+d(\vec{I}_2)} \prod_{j=1}^{l(\vec{I}_1)} \Delta_\sigma(c_{n_1}(\vec{I}_{1j}), c_{n_2}(\vec{I}_{2j})) \right), \quad (2)$$

where (1)  $\sigma$  is any similarity between nodes, e.g., between their lexical labels; (2)  $\lambda, \mu \in [0, 1]$  are decay factors; (3)  $c_{n_1}(h)$  is the  $h^{th}$  child of the node  $n_1$ ; (4)  $\vec{I}_1$  and  $\vec{I}_2$  are two sequences of indexes, i.e.,  $\vec{I} = (i_1, i_2, \dots, l(I))$ , with  $1 \leq i_1 < i_2 < \dots < i_{l(I)}$ ; and (5)  $d(\vec{I}_1) = \vec{I}_{1l(\vec{I}_1)} - \vec{I}_{11} + 1$  and  $d(\vec{I}_2) = \vec{I}_{2l(\vec{I}_2)} - \vec{I}_{21} + 1$ . Note that, as shown in (Croce et al., 2011), the average running time of SPTK is sub-quadratic in the number of the tree nodes. In the next section we show how we exploit the class of SPTKs, for verb classification.

<sup>1</sup>To have a similarity score between 0 and 1, a normalization in the kernel space, i.e.  $\frac{TK(T_1, T_2)}{\sqrt{TK(T_1, T_1) \times TK(T_2, T_2)}}$  is applied.

## 4 Verb Classification Models

The design of SPTK-based algorithms for our verb classification requires the modeling of two different aspects: (i) a tree representation for the verbs; and (ii) the lexical similarity suitable for the task. We also modified SPTK to apply different similarity functions to different nodes to introduce flexibility.

### 4.1 Verb Structural Representation

The implicit feature space generated by structural kernels and the corresponding notion of similarity between verbs obviously depends on the input structures. In the cases of STK, PTK and SPTK different tree representations lead to engineering more or less expressive linguistic feature spaces.

With the aim of capturing syntactic features, we started from two different parsing paradigms: phrase and dependency structures. For example, for representing the first example of the introduction, we can use the constituency tree (CT) in Figure 1, where the target verb node is enriched with the TARGET label. Here, we apply tree pruning to reduce the computational complexity of tree kernels as it is proportional to the number of nodes in the input trees. Accordingly, we only keep the subtree dominated by the target VP by pruning from it all the S-nodes along with their subtrees (i.e., all nested sentences are removed). To further improve generalization, we lemmatize lexical nodes and add generalized POS-Tags, i.e., noun (n::), verb (v::), adjective (::a), determiner (::d) and so on, to them. This is useful for constraining similarity to be only contributed by lexical pairs of the same grammatical category.

Figure 3: Representation of verbs according to the Lexical Centered Tree (LCT)

To encode dependency structure information in a tree (so that we can use it in tree kernels), we use (i) lexemes as nodes of our tree, (ii) their dependencies as edges between the nodes and (iii) the dependency labels, e.g., grammatical functions (GR), and POS-Tags, again as tree nodes. We designed two different tree types: (i) in the first type, GR are central nodes from which dependencies are drawn and all the other features of the central node, i.e., lexical surface form and its POS-Tag, are added as additional children. An example of the GR Centered Tree (GRCT) is shown in Figure 2, where the POS-Tags and lexemes are children of GR nodes. (ii) The second type of tree uses lexicals as central nodes on which both GR and POS-Tag are added as the right-most children. For example, Figure 3 shows an example of a Lexical Centered Tree (LCT). For both trees, the pruning strategy only preserves the verb node, its direct ancestors (father and siblings) and its descendants up to two levels (i.e., direct children and grandchildren of the verb node). Note that, our dependency tree can capture the semantic head of the verbal argument along with the main syntactic construct, e.g., *to audit*.

#### 4.2 Generalized node similarity for SPTK

We have defined the new similarity  $\sigma_\tau$  to be used in Eq. 2, which makes SPTK more effective as shown by Alg. 1.  $\sigma_\tau$  takes two nodes  $n_1$  and  $n_2$  and applies a different similarity for each node type. The latter is derived by  $\tau$  and can be: GR (i.e., SYNT), POS-Tag (i.e., POS) or a lexical (i.e., LEX) type. In our experiment, we assign 0/1 similarity for SYNT and POS nodes according to string matching. For LEX type, we apply a lexical similarity learned with LSA to only pairs of lexicals associated with the same POS-Tag. It should be noted that the type-based similarity allows for potentially applying a different similarity for each node. Indeed, we also tested an amplification factor, namely, leaf weight ( $lw$ ), which amplifies the matching values of the leaf nodes.

---

#### Algorithm 1 $\sigma_\tau(n_1, n_2, lw)$

---

```

 $\sigma_\tau \leftarrow 0$ ,
if  $\tau(n_1) = \tau(n_2) = \text{SYNT} \wedge \text{label}(n_1) = \text{label}(n_2)$  then
   $\sigma_\tau \leftarrow 1$ 
end if
if  $\tau(n_1) = \tau(n_2) = \text{POS} \wedge \text{label}(n_1) = \text{label}(n_2)$  then
   $\sigma_\tau \leftarrow 1$ 
end if
if  $\tau(n_1) = \tau(n_2) = \text{LEX} \wedge \text{pos}(n_1) = \text{pos}(n_2)$  then
   $\sigma_\tau \leftarrow \sigma_{\text{LEX}}(n_1, n_2)$ 
end if
if  $\text{leaf}(n_1) \wedge \text{leaf}(n_2)$  then
   $\sigma_\tau \leftarrow \sigma_\tau \times lw$ 
end if
return  $\sigma_\tau$ 

```

---

## 5 Experiments

In these experiments, we tested the impact of our different verb representations using different kernels, similarities and parameters. We also compared with simple bag-of-words (BOW) models and the state-of-the-art.

### 5.1 General experimental setup

We consider two different corpora: one for VerbNet and the other for FrameNet. For the former, we used the same verb classification setting of (Brown et al., 2011). Sentences are drawn from the Semlink corpus (Loper et al., 2007), which consists of the Prop-Banked Penn Treebank portions of the Wall Street Journal. It contains 113K verb instances, 97K of which are verbs represented in at least one VerbNet class. Semlink includes 495 verbs, whose instances are labeled with more than one class (including one single VerbNet class or none). We used all instances of the corpus for a total of 45,584 instances for 180 verb classes. When instances labeled with the *none* class are not included, the number of examples becomes 23,719.

The second corpus refers to FrameNet frame classification. The training and test data are drawn from the FrameNet 1.5 corpus<sup>2</sup>, which consists of 135K sentences annotated according the frame semantics

<sup>2</sup><http://framenet.icsi.berkeley.edu>

(Baker et al., 1998). We selected the subset of frames containing more than 100 sentences annotated with a verbal predicate for a total of 62,813 sentences in 187 frames (i.e., very close to the VerbNet datasets). For both the datasets, we used 70% of instances for training and 30% for testing.

Our verb (multi) classifier is designed with the *one-vs-all* (Rifkin and Klautau, 2004) multi-classification schema. This uses a set of binary SVM classifiers, one for each verb class (frame)  $i$ . The sentences whose verb is labeled with the class  $i$  are positive examples for the classifier  $i$ . The sentences whose verbs are compatible with the class  $i$  but evoking a different class or labeled with *none* (no current verb class applies) are added as negative examples. In the classification phase the binary classifiers are applied by (i) only considering classes that are compatible with the target verbs; and (ii) selecting the class associated with the maximum positive SVM margin. If all classifiers provide a negative score the example is labeled with *none*.

To learn the binary classifiers of the schema above, we coded our modified SPTK in SVM-Light-TK<sup>3</sup> (Moschitti, 2006). The parameterization of each classifier is carried on a held-out set (30% of the training) and is concerned with the setting of the trade-off parameter (option -c) and the leaf weight ( $lw$ ) (see Alg. 1), which is used to linearly scale the contribution of the leaf nodes. In contrast, the cost-factor parameter of SVM-Light-TK is set as the ratio between the number of negative and positive examples for attempting to have a balanced Precision/Recall.

Regarding SPTK setting, we used the lexical similarity  $\sigma$  defined in Sec. 3.1. In more detail, LSA was applied to ukWak (Baroni et al., 2009), which is a large scale document collection made up of 2 billion tokens.  $M$  is constructed by applying POS tagging to build rows with pairs  $\langle \text{lemma}, ::\text{POS} \rangle$  (lemma::POS in brief). The contexts of such items are the columns of  $M$  and are short windows of size  $[-3, +3]$ , centered on the items. This allows for better capturing syntactic properties of words. The most frequent 20,000 items are selected along with their 20k contexts. The entries of  $M$  are the point-wise mutual

information between them. SVD reduction is then applied to  $M$ , with a dimensionality cut of  $l = 250$ .

For generating the CT, GRCT and LCT structures, we used the constituency trees generated by the Charniak parser (Charniak, 2000) and the dependency structures generated by the LTH syntactic parser (described in (Johansson and Nugues, 2008)).

The classification performance is measured with accuracy (i.e., the percentage of correct classification). We also derive statistical significance of the results by using the model described in (Yeh, 2000) and implemented in (Padó, 2006).

## 5.2 VerbNet and FrameNet Classification Results

To assess the performance of our settings, we also derive a simple baseline based on the bag-of-words (BOW) model. For it, we represent an instance of a verb in a sentence using all words of the sentence (by creating a special feature for the predicate word).

We also used sequence kernels (SK), i.e., PTK applied to a tree composed of a fake root and only one level of sentence words. For efficiency reasons<sup>4</sup>, we only consider the 10 words before and after the predicate with subsequence features of length up to 5.

Table 1 reports the accuracy of different models for VerbNet classification. It should be noted that: first, SK produces a much higher accuracy than BOW, i.e., 82.08 vs. 79.08. On one hand, this is

<sup>4</sup>The average running time of the SK is much higher than the one of PTK. When a tree is composed by only one level PTK collapses to SK.

	STK		PTK		SPTK

BOW				88.16%		
SK				89.86%		

Table 3: VerbNet accuracy without the *none* class

generally in contrast with standard text categorization tasks, for which n-gram models show accuracy comparable to the simpler BOW. On the other hand, it simply confirms that verb classification requires the dependency information between words (i.e., at least the sequential structure information provided by SK).

Second, SK is 2.56 percent points below the state-of-the-art achieved in (Brown et al., 2011) (BR), i.e., 82.08 vs. 84.64. In contrast, STK applied to our representation (CT, GRCT and LCT) produces comparable accuracy, e.g., 84.83, confirming that syntactic representation is needed to reach the state-of-the-art.

Third, PTK, which produces more general structures, improves over BR by almost 1.5 (statistically significant result) when using our dependency structures GRCT and LCT. CT does not produce the same improvement since it does not allow PTK to directly compare the lexical structure (lexemes are all leaf nodes in CT and to connect some pairs of them very large trees are needed).

Finally, the best model of SPTK (i.e., using LCT) improves over the best PTK (i.e., using LCT) by almost 1 point (statistically significant result): this difference is only given by lexical similarity. SPTK improves on the state-of-the-art by about 2.08 absolute percent points, which, given the high accuracy of the baseline, corresponds to 13.5% of relative error reduction.

We carried out similar experiments for frame classification. One interesting difference is that SK improves BOW by only 0.70, i.e., 4 times less than in the VerbNet setting. This suggests that word order around the predicate is more important for deriving the VerbNet class than the FrameNet frame. Additionally, LCT or GRCT seems to be invariant for both PTK and SPTK whereas the lexical similarity still produces a relevant improvement on PTK, i.e., 13% of relative error reduction, for an absolute accuracy of 93.78%. The latter improves over the state-

Figure 4: Learning curves: VerbNet accuracy with the *none* Class

of-the-art, i.e., 92.63% derived in (Giuglea and Moschitti, 2006), by using STK on CT on 133 frames.

We also carried out experiments to understand the role of the *none* class. Table 3 reports on the VerbNet classification without its instances. This is of course an unrealistic setting as it would assume that the current VerbNet release already includes all senses for English verbs. In the table, we note that the overall accuracy highly increases and the difference between models reduces. The similarities play no role anymore. This may suggest that SPTK can help in complex settings, where verb class characterization is more difficult. Another important role of SPTK models is their ability to generalize. To test this aspect, Figure 4 illustrates the learning curves of SPTK with respect to BOW and the accuracy achieved by BR (with a constant line). It is impressive to note that with only 40% of the data SPTK can reach the state-of-the-art.

## 6 Model Analysis and Discussion

We carried out analysis of system errors and its induced features. These can be examined by applying the reverse engineering tool<sup>5</sup> proposed in (Pighin and Moschitti, 2010; Pighin and Moschitti, 2009a; Pighin and Moschitti, 2009b), which extracts the most important features for the classification model. Many mistakes are related to false positives and negatives of the *none* class (about 72% of the errors). This class also causes data imbalance. Most errors are also due to lack of lexical information available to the SPTK kernel: (i) in 30% of the errors, the argument heads were proper nouns for which the lexical generalization provided by the DMs was not

available; and (ii) in 76% of the errors only 2 or less argument heads are included in the extracted tree, therefore tree kernels cannot exploit enough lexical information to disambiguate verb senses. Additionally, ambiguity characterizes errors where the system is linguistically consistent but the learned selectional preferences are not sufficient to separate verb senses. These errors are mainly due to the lack of contextual information. While error analysis suggests that further improvement is possible (e.g. by exploiting proper nouns), the type of generalizations currently achieved by SPTK are rather effective. Table 4 and 5 report the tree structures characterizing the most informative training examples of the two senses of the verb *order*, i.e. the VerbNet classes 13.5.1 (*make a request for something*) and 60 (*give instructions to or direct somebody to do something with authority*).

In line with the method discussed in (Pighin and Moschitti, 2009b), these fragments are extracted as they appear in most of the support vectors selected during SVM training. As easily seen, the two classes are captured by rather different patterns. The typical accusative form with an explicit direct object emerges as characterizing the sense 13.5.1, denoting the THEME role. All fragments of the sense 60 emphasize instead the sentential complement of the verb that in fact expresses the standard PROPOSITION role in VerbNet. Notice that tree fragments correspond to syntactic patterns. The a posteriori

Table 5: CT fragments

analysis of the learned models (i.e. the underlying support vectors) confirm very interesting grammatical generalizations, i.e. the capability of tree kernels to implicitly trigger useful linguistic inductions for complex semantic tasks. When SPTK are adopted, verb arguments can be lexically generalized into word classes, i.e., clusters of argument heads (e.g. *commission* vs. *delegation*, or *gift* vs. *present*). Automatic generation of such classes is an interesting direction for future research.

## 7 Conclusion

We have proposed new approaches to characterize verb classes in learning algorithms. The key idea is the use of structural representation of verbs based on syntactic dependencies and the use of structural kernels to measure similarity between such representations. The advantage of kernel methods is that they can be directly used in some learning algorithms, e.g., SVMs, to train verb classifiers. Very interestingly, we can encode distributional lexical similarity in the similarity function acting over syntactic structures and this allows for generalizing selection restrictions through a *sort of* (supervised) syntactic and semantic co-clustering.

The verb classification results show a large improvement over the state-of-the-art for both VerbNet and FrameNet, with a relative error reduction of about 13.5% and 16.0%, respectively. In the future, we plan to exploit the models learned from FrameNet and VerbNet to carry out automatic mapping of verbs from one theory to the other.

## Abstract

Previous research has conflicting conclusions on whether word sense disambiguation (WSD) systems can improve information retrieval (IR) performance. In this paper, we propose a method to estimate sense distributions for short queries. Together with the senses predicted for words in documents, we propose a novel approach to incorporate word senses into the language modeling approach to IR and also exploit the integration of synonym relations. Our experimental results on standard *TREC* collections show that using the word senses tagged by a supervised WSD system, we obtain significant improvements over a state-of-the-art IR system.

## 1 Introduction

Word sense disambiguation (WSD) is the task of identifying the correct meaning of a word in context. As a basic semantic understanding task at the lexical level, WSD is a fundamental problem in natural language processing. It can be potentially used as a component in many applications, such as machine translation (MT) and information retrieval (IR).

In recent years, driven by Senseval/Semeval workshops, WSD systems achieve promising performance. In the application of WSD to MT, research has shown that integrating WSD in appropriate ways significantly improves the performance of MT systems (Chan et al., 2007; Carpuat and Wu, 2007).

In the application to IR, WSD can bring two kinds of benefits. First, queries may contain ambiguous words (terms), which have multiple meanings. The

ambiguities of these query words can hurt retrieval precision. Identifying the correct meaning of the ambiguous words in both queries and documents can help improve retrieval precision. Second, query words may have tightly related meanings with other words not in the query. Making use of these relations between words can improve retrieval recall.

Overall, IR systems can potentially benefit from the correct meanings of words provided by WSD systems. However, in previous investigations of the usage of WSD in IR, different researchers arrived at conflicting observations and conclusions. Some of the early research showed a drop in retrieval performance by using word senses (Krovetz and Croft, 1992; Voorhees, 1993). Some other experiments observed improvements by integrating word senses in IR systems (Schütze and Pedersen, 1995; Gonzalo et al., 1998; Stokoe et al., 2003; Kim et al., 2004).

This paper proposes the use of word senses to improve the performance of IR. We propose an approach to annotate the senses for short queries. We incorporate word senses into the language modeling (LM) approach to IR (Ponte and Croft, 1998), and utilize sense synonym relations to further improve the performance. Our evaluation on standard *TREC*<sup>1</sup> data sets shows that supervised WSD outperforms two other WSD baselines and significantly improves IR.

The rest of this paper is organized as follows. In Section 2, we first review previous work using WSD in IR. Section 3 introduces the LM approach to IR, including the pseudo relevance feedback method. We describe our WSD system and the method of

<sup>1</sup><http://trec.nist.gov/>

generating word senses for query terms in Section 4, followed by presenting our novel method of incorporating word senses and their synonyms into the LM approach in Section 5. We present experiments and analyze the results in Section 6. Finally, we conclude in Section 7.

## 2 Related Work

Many previous studies have analyzed the benefits and the problems of applying WSD to IR. Krovetz and Croft (1992) studied the sense matches between terms in query and the document collection. They concluded that the benefits of WSD in IR are not as expected because query words have skewed sense distribution and the collocation effect from other query terms already performs some disambiguation. Sanderson (1994; 2000) used pseudowords to introduce artificial word ambiguity in order to study the impact of sense ambiguity on IR. He concluded that because the effectiveness of WSD can be negated by inaccurate WSD performance, high accuracy of WSD is an essential requirement to achieve improvement. In another work, Gonzalo *et al.* (1998) used a manually sense annotated corpus, SemCor, to study the effects of incorrect disambiguation. They obtained significant improvements by representing documents and queries with accurate senses as well as synsets (synonym sets). Their experiment also showed that with the synset representation, which included synonym information, WSD with an error rate of 40%–50% can still improve IR performance. Their later work (Gonzalo *et al.*, 1999) verified that part of speech (POS) information is discriminatory for IR purposes.

Several works attempted to disambiguate terms in both queries and documents with the senses predefined in hand-crafted sense inventories, and then used the senses to perform indexing and retrieval. Voorhees (1993) used the hyponymy (“IS-A”) relation in WordNet (Miller, 1990) to disambiguate the polysemous nouns in a text. In her experiments, the performance of sense-based retrieval is worse than stem-based retrieval on all test collections. Her analysis showed that inaccurate WSD caused the poor results.

Stokoe *et al.* (2003) employed a fine-grained WSD system with an accuracy of 62.1% to dis-

ambiguate terms in both the text collections and the queries in their experiments. Their evaluation on TREC collections achieved significant improvements over a standard term based vector space model. However, it is hard to judge the effect of word senses because of the overall poor performances of their baseline method and their system.

Instead of using fine-grained sense inventory, Kim *et al.* (2004) tagged words with 25 root senses of nouns in WordNet. Their retrieval method maintained the stem-based index and adjusted the term weight in a document according to its sense matching result with the query. They attributed the improvement achieved on TREC collections to their coarse-grained, consistent, and flexible sense tagging method. The integration of senses into the traditional stem-based index overcomes some of the negative impact of disambiguation errors.

Different from using predefined sense inventories, Schütze and Pedersen (1995) induced the sense inventory directly from the text retrieval collection. For each word, its occurrences were clustered into senses based on the similarities of their contexts. Their experiments showed that using senses improved retrieval performance, and the combination of word-based ranking and sense-based ranking can further improve performance. However, the clustering process of each word is a time consuming task. Because the sense inventory is collection dependent, it is also hard to expand the text collection without re-doing preprocessing.

Many studies investigated the expansion effects by using knowledge sources from thesauri. Some researchers achieved improvements by expanding the disambiguated query words with synonyms and some other information from WordNet (Voorhees, 1994; Liu *et al.*, 2004; Liu *et al.*, 2005; Fang, 2008). The usage of knowledge sources from WordNet in document expansion also showed improvements in IR systems (Cao *et al.*, 2005; Agirre *et al.*, 2010).

The previous work shows that the WSD errors can easily neutralize its positive effect. It is important to reduce the negative impact of erroneous disambiguation, and the integration of senses into traditional term index, such as stem-based index, is a possible solution. The utilization of semantic relations has proved to be helpful for IR. It is also interest-

ing to investigate the utilization of semantic relations among senses in IR.

### 3 The Language Modeling Approach to IR

This section describes the LM approach to IR and the pseudo relevance feedback approach.

#### 3.1 The language modeling approach

In the language modeling approach to IR, language models are constructed for each query  $q$  and each document  $d$  in a text collection  $C$ . The documents in  $C$  are ranked by the distance to a given query  $q$  according to the language models. The most commonly used language model in IR is the unigram model, in which terms are assumed to be independent of each other. In the rest of this paper, language model will refer to the unigram language model.

One of the commonly used measures of the similarity between query model and document model is negative Kullback-Leibler (KL) divergence (Lafferty and Zhai, 2001). With unigram model, the negative KL-divergence between model  $\theta_q$  of query  $q$  and model  $\theta_d$  of document  $d$  is calculated as follows:

$$\begin{aligned} -D(\theta_q||\theta_d) &= -\sum_{t \in V} p(t|\theta_q) \log \frac{p(t|\theta_q)}{p(t|\theta_d)} \\ &= \sum_{t \in V} p(t|\theta_q) \log p(t|\theta_d) - \sum_{t \in V} p(t|\theta_q) \log p(t|\theta_q) \\ &= \sum_{t \in V} p(t|\theta_q) \log p(t|\theta_d) + E(\theta_q), \end{aligned} \quad (1)$$

where  $p(t|\theta_q)$  and  $p(t|\theta_d)$  are the generative probabilities of a term  $t$  from the models  $\theta_q$  and  $\theta_d$ ,  $V$  is the vocabulary of  $C$ , and  $E(\theta_q)$  is the entropy of  $q$ .

Define  $tf(t, d)$  and  $tf(t, q)$  as the frequencies of  $t$  in  $d$  and  $q$ , respectively. Normally,  $p(t|\theta_q)$  is calculated with maximum likelihood estimation (MLE):

$$p(t|\theta_q) = \frac{tf(t, q)}{\sum_{t' \in q} tf(t', q)}. \quad (2)$$

In the calculation of  $p(t|\theta_d)$ , several smoothing methods have been proposed to overcome the data sparseness problem of a language model constructed from one document (Zhai and Lafferty, 2001b). For example,  $p(t|\theta_d)$  with the Dirichlet-prior smoothing can be calculated as follows:

$$p(t|\theta_d) = \frac{tf(t, d) + \mu p(t|\theta_C)}{\sum_{t' \in V} tf(t', d) + \mu}, \quad (3)$$

where  $\mu$  is the prior parameter in the Dirichlet-prior smoothing method, and  $p(t|\theta_C)$  is the probability of  $t$  in  $C$ , which is often calculated with MLE:

$$p(t|\theta_C) = \frac{\sum_{d' \in C} tf(t, d')}{\sum_{d' \in C} \sum_{t' \in V} tf(t', d')}.$$

#### 3.2 Pseudo relevance feedback

Pseudo relevance feedback (PRF) is widely used in IR to achieve better performance. It is constructed with two retrieval steps. In the first step, ranked documents are retrieved from  $C$  by a normal retrieval method with the original query  $q$ . In the second step, a number of terms are selected from the top  $k$  ranked documents  $D_q$  for query expansion, under the assumption that these  $k$  documents are relevant to the query. Then, the expanded query is used to retrieve the documents from  $C$ .

There are several methods to select expansion terms in the second step (Zhai and Lafferty, 2001a). For example, in Indri<sup>2</sup>, the terms are first ranked by the following score:

$$v(t, D_q) = \sum_{d \in D_q} \log \left( \frac{tf(t, d)}{|d|} \times \frac{1}{p(t|\theta_C)} \right),$$

as in Ponte (1998). Define  $p(q|\theta_d)$  as the probability score assigned to  $d$ . The top  $m$  terms  $T_q$  are selected with weights calculated based on the relevance model described in Lavrenko and Croft (2001):

$$w(t, D_q) = \sum_{d \in D_q} \left[ \frac{tf(t, d)}{|d|} \times p(q|\theta_d) \times p(\theta_d) \right],$$

which calculates the sum of weighted probabilities of  $t$  in each document. After normalization, the probability of  $t$  in  $\theta_q^r$  is calculated as follows:

$$p(t|\theta_q^r) = \frac{w(t, D_q)}{\sum_{t' \in T_q} w(t', D_q)}.$$

Finally, the relevance model is interpolated with the original query model:

$$p(t|\theta_q^{prf}) = \lambda p(t|\theta_q^r) + (1 - \lambda)p(t|\theta_q), \quad (4)$$

where parameter  $\lambda$  controls the amount of feedback. The new model  $\theta_q^{prf}$  is used to replace the original one  $\theta_q$  in Equation 1.

Collection enrichment (CE) (Kwok and Chan, 1998) is a technique to improve the quality of the feedback documents by making use of an external target text collection  $X$  in addition to the original target  $C$  in the first step of PRF. The usage of  $X$  is supposed to provide more relevant feedback documents and feedback query terms.

## 4 Word Sense Disambiguation

In this section, we first describe the construction of our WSD system. Then, we propose the method of assigning senses to query terms.

### 4.1 Word sense disambiguation system

Previous research shows that translations in another language can be used to disambiguate the meanings of words (Chan and Ng, 2005; Zhong and Ng, 2009). We construct our supervised WSD system directly from parallel corpora.

To generate the WSD training data, 7 parallel corpora were used, including *Chinese Treebank*, *FBIS Corpus*, *Hong Kong Hansards*, *Hong Kong Laws*, *Hong Kong News*, *Sinorama News Magazine*, and *Xinhua Newswire*. These corpora were already aligned at sentence level. We tokenized English texts with *Penn Treebank Tokenizer*, and performed word segmentation on Chinese texts. Then, word alignment was performed on the parallel corpora with the *GIZA++* software (Och and Ney, 2003).

For each English morphological root  $e$ , the English sentences containing its occurrences were extracted from the word aligned output of *GIZA++*, as well as the corresponding translations of these occurrences. To minimize noisy word alignment result, translations with no Chinese character were deleted, and we further removed a translation when it only appears once, or its frequency is less than 10 and also less than 1% of the frequency of  $e$ . Finally, only the most frequent 10 translations were kept for efficiency consideration.

The English part of the remaining occurrences were used as training data. Because multiple English words may have the same Chinese translation, to differentiate them, each Chinese translation is concatenated with the English morphological root to form a word sense. We employed a supervised WSD system, *IMS*<sup>3</sup>, to train the WSD models. *IMS* (Zhong and Ng, 2010) integrates multiple knowledge sources as features. We used MaxEnt as the machine learning algorithm. Finally, the system can disambiguate the words by assigning probabilities to different senses.

<sup>3</sup><http://nlp.comp.nus.edu.sg/software/ims>

### 4.2 Estimating sense distributions for query terms

In IR, both terms in queries and the text collection can be ambiguous. Hence, WSD is needed to disambiguate these ambiguous terms. In most cases, documents in a text collection are full articles. Therefore, a WSD system has sufficient context to disambiguate the words in the document. In contrast, queries are usually short, often with only two or three terms in a query. Short queries pose a challenge to WSD systems since there is insufficient context to disambiguate a term in a short query.

One possible solution to this problem is to find some text fragments that contain a query term. Suppose we already have a basic IR method which does not require any sense information, such as the stem-based LM approach. Similar to the PRF method, assuming that the top  $k$  documents retrieved by the basic method are relevant to the query, these  $k$  documents can be used to represent query  $q$  (Broder et al., 2007; Bendersky et al., 2010; He and Wu, 2011). We propose a method to estimate the sense probabilities of each query term of  $q$  from these top  $k$  retrieved documents.

Suppose the words in all documents of the text collection are disambiguated with a WSD system, and each word occurrence  $w$  in document  $d$  is assigned a vector of senses,  $S(w)$ . Define the probability of assigning sense  $s$  to  $w$  as  $p(w, s, d)$ . Given a query  $q$ , suppose  $D_q$  is the set of top  $k$  documents retrieved by the basic method, with the probability score  $p(q|\theta_d)$  assigned to  $d \in D_q$ .

---

```
Given a query term  $t \in q$ 
 $S(t, q) = \{\}$ 
 $sum = 0$ 
for each document  $d \in D_q$ 
  for each word occurrence  $w \in d$ , whose stem form is
  identical to the stem form of  $t$ 
    for each sense  $s \in S(w)$ 
       $S(t, q) = S(t, q) \cup \{s\}$ 
       $p(t, s, q) = p(t, s, q) + p(q|\theta_d) p(w, s, d)$ 
       $sum = sum + p(q|\theta_d) p(w, s, d)$ 
for each sense  $s \in S(t, q)$ 
   $p(t, s, q) = p(t, s, q) / sum$ 
Return  $S(t, q)$ , with probability  $p(t, s, q)$  for  $s \in S(t, q)$ 
```

---

Figure 1: Process of generating senses for query terms

Figure 1 shows the pseudocode of calculating the

sense distribution for a query term  $t$  in  $q$  with  $D_q$ , where  $S(t, q)$  is the set of senses assigned to  $t$  and  $p(t, s, q)$  is the probability of tagging  $t$  as sense  $s$ . Basically, we utilized the sense distribution of the words with the same stem form in  $D_q$  as a proxy to estimate the sense probabilities of a query term. The retrieval scores are used to weight the information from the corresponding retrieved documents in  $D_q$ .

## 5 Incorporating Senses into Language Modeling Approaches

In this section, we propose to incorporate senses into the LM approach to IR. Then, we describe the integration of sense synonym relations into our model.

### 5.1 Incorporating senses as smoothing

With the method described in Section 4.2, both the terms in queries and documents have been sense tagged. The next problem is to incorporate the sense information into the language modeling approach.

Suppose  $p(t, s, q)$  is the probability of tagging a query term  $t \in q$  as sense  $s$ , and  $p(w, s, d)$  is the probability of tagging a word occurrence  $w \in d$  as sense  $s$ . Given a query  $q$  and a document  $d$  in text collection  $C$ , we want to re-estimate the language models by making use of the sense information assigned to them.

Define the frequency of  $s$  in  $d$  as:

$$stf(s, d) = \sum_{w \in d} p(w, s, d),$$

and the frequency of  $s$  in  $C$  as:

$$stf(s, C) = \sum_{d \in C} stf(s, d).$$

Define the frequencies of sense set  $S$  in  $d$  and  $C$  as:

$$stf(S, d) = \sum_{s \in S} stf(s, d),$$

$$stf(S, C) = \sum_{s \in S} stf(s, C).$$

For a term  $t \in q$ , with senses  $S(t, q):\{s_1, \dots, s_n\}$ , suppose  $V:\{p(t, s_1, q), \dots, p(t, s_n, q)\}$  is the vector of probabilities assigned to the senses of  $t$  and  $W:\{stf(s_1, d), \dots, stf(s_n, d)\}$  is the vector of frequencies of  $S(t, q)$  in  $d$ . The function  $\cos(t, q, d)$  calculates the cosine similarity between vector  $V$  and vector  $W$ . Assume  $D$  is a set of documents in  $C$  which contain any sense in  $S(t, q)$ , we define function  $\overline{\cos}(t, q) = \sum_{d \in D} \cos(t, q, d) / |D|$ , which calculates the mean of the sense cosine similarities, and define function  $\Delta \cos(t, q, d) = \cos(t, q, d) -$

$\overline{\cos}(t, q)$ , which calculates the difference between  $\cos(t, q, d)$  and the corresponding mean value.

Given a query  $q$ , we re-estimate the term frequency of query term  $t$  in  $d$  with sense information integrated as smoothing:

$$tf_{sen}(t, d) = tf(t, d) + sen(t, q, d), \quad (5)$$

where function  $sen(t, q, d)$  is a measure of  $t$ 's sense information in  $d$ , which is defined as follows:

$$sen(t, q, d) = \alpha^{\Delta \cos(t, q, d)} stf(S(t, q), d). \quad (6)$$

In  $sen(t, q, d)$ , the last item  $stf(S(t, q), d)$  calculates the sum of the sense frequencies of  $t$  senses in  $d$ , which represents the amount of  $t$ 's sense information in  $d$ . The first item  $\alpha^{\Delta \cos(t, q, d)}$  is a weight of the sense information concerning the relative sense similarity  $\Delta \cos(t, q, d)$ , where  $\alpha$  is a positive parameter to control the impact of sense similarity. When  $\Delta \cos(t, q, d)$  is larger than zero, such that the sense similarity of  $d$  and  $q$  according to  $t$  is above the average, the weight for the sense information is larger than 1; otherwise, it is less than 1. The more similar they are, the larger the weight value. For  $t \notin q$ , because the sense set  $S(t, q)$  is empty,  $stf(S(t, q), d)$  equals to zero and  $tf_{sen}(t, d)$  is identical to  $tf(t, d)$ .

With sense incorporated, the term frequency is influenced by the sense information. Consequently, the estimation of probability of  $t$  in  $d$  becomes query specific:

$$p(t|\theta_d^{sen}) = \frac{tf_{sen}(t, d) + \mu p(t|\theta_C^{sen})}{\sum_{t' \in V} tf_{sen}(t', d) + \mu}, \quad (7)$$

where the probability of  $t$  in  $C$  is re-calculated as:

$$p(t|\theta_C^{sen}) = \frac{\sum_{d' \in C} tf_{sen}(t, d')}{\sum_{d' \in C} \sum_{t' \in V} tf_{sen}(t', d')}.$$

### 5.2 Expanding with synonym relations

Words usually have some semantic relations with others. Synonym relation is one of the semantic relations commonly used to improve IR performance. In this part, we further integrate the synonym relations of senses into the LM approach.

Suppose  $R(s)$  is the set of senses having synonym relation with sense  $s$ . Define  $S(q)$  as the set of senses of query  $q$ ,  $S(q) = \bigcup_{t \in q} S(t, q)$ , and define  $R(s, q) = R(s) - S(q)$ . We update the frequency of a query term  $t$  in  $d$  by integrating the synonym relations as follows:

$$tf_{syn}(t, d) = tf_{sen}(t, d) + syn(t, q, d), \quad (8)$$

where  $syn(t, q, d)$  is a function measuring the synonym information in  $d$ :

$$syn(t, q, d) = \sum_{s \in S(t)} \beta(s, q) p(t, s, q) stf(R(s, q), d).$$

The last item  $stf(R(s, q), d)$  in  $syn(t, q, d)$  is the sum of the sense frequencies of  $R(s, q)$  in  $d$ . Notice that the synonym senses already appearing in  $S(q)$  are not included in the calculation, because the information of these senses has been used in some other places in the retrieval function. The frequency of synonyms,  $stf(R(s, q), d)$ , is weighted by  $p(t, s, q)$  together with a scaling function  $\beta(s, q)$ :

$$\beta(s, q) = \min(1, \frac{stf(s, C)}{stf(R(s, q), C)}).$$

When  $stf(s, C)$ , the frequency of sense  $s$  in  $C$ , is less than  $stf(R(s, q), C)$ , the frequency of  $R(s, q)$  in  $C$ , the function  $\beta(s, q)$  scales down the impact of synonyms according to the ratio of these two frequencies. The scaling function makes sure that the overall impact of the synonym senses is not greater than the original word senses.

Accordingly, we have the probability of  $t$  in  $d$  updated to:

$$p(t|\theta_d^{syn}) = \frac{tf_{syn}(t, d) + \mu p(t|\theta_C^{syn})}{\sum_{t' \in V} tf_{syn}(t', d) + \mu}, \quad (9)$$

and the probability of  $t$  in  $C$  is calculated as:

$$p(t|\theta_C^{syn}) = \frac{\sum_{d' \in C} tf_{syn}(t, d')}{\sum_{d' \in C} \sum_{t' \in V} tf_{syn}(t', d')}.$$

With this language model, the probability of a query term in a document is enlarged by the synonyms of its senses; The more its synonym senses in a document, the higher the probability. Consequently, documents with more synonym senses of the query terms will get higher retrieval rankings.

## 6 Experiments

In this section, we evaluate and analyze the models proposed in Section 5 on standard TREC collections.

### 6.1 Experimental settings

We conduct experiments on the TREC collection. The text collection  $C$  includes the documents from TREC disk 4 and 5, minus the CR (Congressional Record) corpus, with 528,155 documents in total. In

addition, the other documents in TREC disk 1 to 5 are used as the external text collection  $X$ .

We use 50 queries from TREC6 Ad Hoc task as the development set, and evaluate on 50 queries from TREC7 Ad Hoc task, 50 queries from TREC8 Ad Hoc task, 50 queries from ROBUST 2003 (RB03), and 49 queries from ROBUST 2004 (RB04). In total, our test set includes 199 queries. We use the terms in the title field of TREC topics as queries. Table 1 shows the statistics of the five query sets. The first column lists the query topics, and the column *#qry* is the number of queries. The column *Ave* gives the average query length, and the column *Rels* is the total number of relevant documents.

Query Set	Topics	#qry	Ave	Rels
TREC6	301–350	50	2.58	4,290
TREC7	351–400	50	2.50	4,674
TREC8	401–450	50	2.46	4,728
RB03	601–650	50	3.00	1,658
RB04 <sup>4</sup>	651–700	49	2.96	2,062

Table 1: Statistics of query sets

We use the *Lemur* toolkit (Ogilvie and Callan, 2001) version 4.11 as the basic retrieval tool, and select the default unigram LM approach based on KL-divergence and Dirichlet-prior smoothing method in Lemur as our basic retrieval approach. Stop words are removed from queries and documents using the standard INQUERY stop words list (Allan et al., 2000), and then the Porter stemmer is applied to perform stemming. The stem forms are finally used for indexing and retrieval.

We set the smoothing parameter  $\mu$  in Equation 3 to 400 by tuning on TREC6 query set in a range of  $\{100, 400, 700, 1000, 1500, 2000, 3000, 4000, 5000\}$ . With this basic method, up to 10 top ranked documents  $D_q$  are retrieved for each query  $q$  from the extended text collection  $C \cup X$ , for the usage of performing PRF and generating query senses.

For PRF, we follow the implementation of Indri’s PRF method and further apply the CE technique as described in Section 3.2. The number of terms selected from  $D_q$  for expansion is tuned from range  $\{20, 25, 30, 35, 40\}$  and set to 25. The interpolation parameter  $\lambda$  in Equation 4 is set to 0.7 from range

<sup>4</sup>Topic 672 is eliminated, since it has no relevant document.

Table 2: Results on test set in MAP score. The first three rows show the results of the top participating systems, the next row shows the performance of the baseline method, and the rest rows are the results of our method with different settings. Single dagger (<sup>†</sup>) and double dagger (<sup>‡</sup>) indicate statistically significant improvement over *Stem<sub>prf</sub>* at the 95% and 99% confidence level with a two-tailed paired t-test, respectively. The best results are highlighted in bold.

{0.1, 0.2, ..., 0.9}. The CE-PRF method with this parameter setting is chosen as the baseline.

To estimate the sense distributions for terms in query  $q$ , the method described in Section 4.2 is applied with  $D_q$ . To disambiguate the documents in the text collection, besides the usage of the supervised WSD system described in Section 4.1, two WSD baseline methods, *Even* and *MFS*, are applied for comparison. The method *Even* assigns equal probabilities to all senses for each word, and the method *MFS* tags the words with their corresponding most frequent senses. The parameter  $\alpha$  in Equation 6 is tuned on *TREC6* from 1 to 10 in increment of 1 for each sense tagging method. It is set to 7, 6, and 9 for the supervised WSD method, the *Even* method, and the *MFS* method, respectively.

Notice that the sense in our WSD system is conducted with two parts, a morphological root and a Chinese translation. The Chinese parts not only disambiguate senses, but also provide clues of connections among different words. Assume that the senses with the same Chinese part are synonyms, therefore, we can generate a set of synonyms for each sense, and then utilize these synonym relations in the method proposed in Section 5.2.

## 6.2 Experimental results

For evaluation, we use average precision (AP) as the metric to evaluate the performance on each query  $q$ :

$$AP(q) = \frac{\sum_{r=1}^R [p(r)rel(r)]}{relevance(q)},$$

where  $relevance(q)$  is the number of documents relevant to  $q$ ,  $R$  is the number of retrieved documents,

$r$  is the rank,  $p(r)$  is the precision of the top  $r$  retrieved documents, and  $rel(r)$  equals to 1 if the  $r$ th document is relevant, and 0 otherwise. Mean average precision (MAP) is a metric to evaluate the performance on a set of queries  $Q$ :

$$MAP(Q) = \frac{\sum_{q \in Q} AP(q)}{|Q|},$$

where  $|Q|$  is the number of queries in  $Q$ .

We retrieve the top-ranked 1,000 documents for each query, and use the MAP score as the main comparing metric. In Table 2, the first four columns are the MAP scores of various methods on the TREC7, TREC8, RB03, and RB04 query sets, respectively. The column *Comb* shows the results on the union of the four test query sets. The first three rows list the results of the top three systems that participated in the corresponding tasks. The row *Stem<sub>prf</sub>* shows the performance of our baseline method, the stem-based CE-PRF method. The column *Impr* calculates the percentage improvement of each method over the baseline *Stem<sub>prf</sub>* in column *Comb*. The last column *#ret-rel* lists the total numbers of relevant documents retrieved by different methods.

The rows *Stem<sub>prf</sub>+{MFS, Even, WSD}* are the results of *Stem<sub>prf</sub>* incorporating with the senses generated for the original query terms, by applying the approach proposed in Section 5.1, with the *MFS* method, the *Even* method, and our supervised WSD method, respectively. Comparing to the baseline method, all methods with sense integrated achieve consistent improvements on all query sets. The usage of the supervised WSD method outperforms the other two WSD baselines, and it achieves sta-

tistically significant improvements over  $Stem_{prf}$  on TREC7, TREC8, and RB03.

The integration of senses into the baseline method has two aspects of impact. First, the morphological roots of senses conquer the irregular inflection problem. Thus, the documents containing the irregular inflections are retrieved when senses are integrated. For example, in topic 326 {*ferry sinkings*}, the stem form of *sinkings* is *sink*. As *sink* is an irregular verb, the usage of senses improves the retrieval recall by retrieving the documents containing the inflection forms *sunk*, *sank*, and *sunken*.

Second, the senses output by supervised WSD system help identify the meanings of query terms. Take topic 357 {*territorial waters dispute*} for example, the stem form of *waters* is *water* and its appropriate sense in this query should be water\_水域 (body of water) instead of the most frequent sense of water\_水 (H<sub>2</sub>O). In  $Stem_{prf}+WSD$ , we correctly identify the minority sense for this query term. In another example, topic 425 {*counterfeiting money*}, the stem form of *counterfeiting* is *counterfeit*. Although the most frequent sense counterfeit\_冒牌 (not genuine) is not wrong, another sense counterfeit\_伪钞 (forged money) is more accurate for this query term. The Chinese translation in the latter sense represents the meaning of the phrase in original query. Thus,  $Stem_{prf}+WSD$  outperforms the other two methods on this query by assigning the highest probability for this sense.

Overall, the performance of  $Stem_{prf}+WSD$  is better than  $Stem_{prf}+\{MFS, Even\}$  on 121 queries and 119 queries, respectively. The *t-test* at the confidence level of 99% indicates that the improvements are statistically significant.

The results of expanding with synonym relations in the above three methods are shown in the last three rows,  $Stem_{prf}+\{MFS, Even, WSD\}+Syn$ . The integration of synonym relations further improves the performance no matter what kind of sense tagging method is applied. The improvement varies with different methods on different query sets. As shown in the last column of Table 2, the number of relevant documents retrieved is increased for each method.  $Stem_{prf}+Even+Syn$  retrieves more relevant documents than  $Stem_{prf}+MFS+Syn$ , because the former method expands more senses. Overall, the improvement achieved by  $Stem_{prf}+WSD+Syn$  is

larger than the other two methods. It shows that the WSD technique can help choose the appropriate senses for synonym expansion.

Among the different settings,  $Stem_{prf}+WSD+Syn$  achieves the best performance. Its improvement over the baseline method is statistically significant at the 95% confidence level on RB04 and at the 99% confidence level on the other three query sets, with an overall improvement of 4.39%. It beats the best participated systems on three out of four query sets<sup>5</sup>, including *TREC7*, *TREC8*, and *RB03*.

## 7 Conclusion

This paper reports successful application of WSD to IR. We proposed a method for annotating senses to terms in short queries, and also described an approach to integrate senses into an LM approach for IR. In the experiment on four query sets of TREC collection, we compared the performance of a supervised WSD method and two WSD baseline methods. Our experimental results showed that the incorporation of senses improved a state-of-the-art baseline, a stem-based LM approach with PRF method. The performance of applying the supervised WSD method is better than the other two WSD baseline methods. We also proposed a method to further integrate the synonym relations to the LM approaches. With the integration of synonym relations, our best performance setting with the supervised WSD achieved an improvement of 4.39% over the baseline method, and it outperformed the best participating systems on three out of four query sets.

## Abstract

This paper addresses the search problem in textual inference, where systems need to infer one piece of text from another. A prominent approach to this task is attempts to transform one text into the other through a sequence of inference-preserving transformations, a.k.a. a proof, while estimating the proof's validity. This raises a search challenge of finding the best possible proof. We explore this challenge through a comprehensive investigation of prominent search algorithms and propose two novel algorithmic components specifically designed for textual inference: a gradient-style evaluation function, and a local-lookahead node expansion method. Evaluations, using the open-source system, BIUTEE, show the contribution of these ideas to search efficiency and proof quality.

## 1 Introduction

In many NLP settings it is necessary to identify that a certain semantic inference relation holds between two pieces of text. For example, in *paraphrase recognition* it is necessary to identify that the meanings of two text fragments are roughly equivalent. In *passage retrieval* for question answering, it is needed to detect text passages from which a satisfying answer can be inferred. A generic formulation for the inference relation between two texts is given by the *Recognizing Textual Entailment (RTE)* paradigm (Dagan et al., 2005), which is adapted here for our investigation. In this setting, a system is given two text fragments, termed “text” ( $T$ ) and “hy-

pothesis” ( $H$ ), and has to recognize whether the hypothesis is entailed by (inferred from) the text.

An appealing approach to such textual inferences is to explicitly transform  $T$  into  $H$ , using a sequence of transformations (Bar-Haim et al., 2007; Harmeling, 2009; Mehdad, 2009; Wang and Manning, 2010; Heilman and Smith, 2010; Stern and Dagan, 2011). Examples of such possible transformations are lexical substitutions (e.g. “letter”  $\rightarrow$  “message”) and predicate-template substitutions (e.g. “X [verb-active] Y”  $\rightarrow$  “Y [verb-passive] by X”), which are based on available knowledge resources. Another example is coreference substitutions, such as replacing “he” with “the employee” if a coreference resolver has detected that these two expressions corefer. Table 1 exemplifies this approach for a particular  $T$ - $H$  pair. The rationale behind this approach is that each transformation step should preserve inference validity, such that each text generated along this process is indeed inferred from the preceding one.

An inherent aspect in transformation-based inference is modeling the certainty that each inference step is valid. This is usually achieved by a cost-based or probabilistic model, which quantifies confidence in the validity of each individual transformation and consequently of the complete chain of inference.

Given a set of possible transformations, there may be many transformation sequences that would transform  $T$  to  $H$ . This creates a very large search space, where systems have to find the “best” transformation sequence – the one of lowest cost, or of highest probability. To the best of our knowledge, this search challenge has not been investigated yet in a substan-

#	Operation	Generated text
0	-	He received the letter from the secretary.
1	Coreference substitution	The employee received the letter from the secretary.
2	X received Y from Z $\rightarrow$ Y was sent to X by Z	The letter was sent to the employee by the secretary.
3	Y [verb-passive] by X $\rightarrow$ X [verb-active] Y	The secretary sent the letter to the employee.
4	X send Y $\rightarrow$ X deliver Y	The secretary delivered the letter to the employee.
5	letter $\rightarrow$ message	The secretary delivered the message to the employee.

Table 1: A sequence of transformations that transform the text “He received the letter from the secretary.” into the hypothesis “The secretary delivered the message to the employee.”. The knowledge required for such transformations is often obtained from available knowledge resources and NLP tools.

tial manner: each of the above-cited works described the search method they used, but none of them tried alternative methods while evaluating search performance. Furthermore, while experimenting with our own open-source inference system, BIUTEE<sup>1</sup>, we observed that search efficiency is a major issue, often yielding practically unsatisfactory run-times.

This paper investigates the search problem in transformation-based textual inference, naturally falling within the framework of heuristic AI (Artificial Intelligence) search. To facilitate such investigation, we formulate a generic search scheme which incorporates many search variants as special cases and enable a meaningful comparison between the algorithms. Under this framework, we identify special characteristics of the textual inference search space, that lead to the development of two novel algorithmic components: a special lookahead method for node expansion, named *local lookahead*, and a gradient-based evaluation function. Together, they yield a new search algorithm, which achieved substantially superior search performance in our evaluations.

The remainder of this paper is organized as follows. Section 2 provides an overview of transformation-based inference systems, AI search algorithms, and search methods realized in prior inference systems. Section 3 formulates the generic search scheme that we have investigated, which covers a broad range of known algorithms, and presents our own algorithmic contributions. These new algorithmic contributions were implemented in our system, BIUTEE. In Section 4 we evaluate them empirically, and show that they improve search efficiency as well as solution’s quality. Search performance is evaluated on two recent RTE benchmarks, in terms

<sup>1</sup>[www.cs.biu.ac.il/~nlp/downloads/biutee](http://www.cs.biu.ac.il/~nlp/downloads/biutee)

of runtime, ability to find lower-cost transformation chains and impact on overall inference.

## 2 Background

Applying sequences of transformations to recognize textual inference was suggested by several works. Such a sequence may be referred to as a *proof*, in the sense that it is used to “prove” the hypothesis from the text. Although various works along this line differ from each other in several respects, many of them share the common challenge of *finding* an optimal proof. The following paragraphs review the major research approaches in this direction. We focus on methods that perform transformations over parse trees, and highlight the search challenge with which they are faced.

### 2.1 Transformation-based textual inference

Several researchers suggested using various types of transformations in order to derive  $H$  from  $T$ . Some suggested a set of predefined transformations, for example, *insertion*, *deletion* and *substitution* of parse-tree nodes, by which any tree can be transformed to any other tree. These transformations were used by the open-source system *EDITS* (Mehdad, 2009), and by (Wang and Manning, 2010). Since the above mentioned transformations are limited in capturing certain interesting and prevalent semantic phenomena, an extended set of tree edit operations (e.g., relabel-edge, move-sibling, etc.) was proposed by Heilman and Smith (2010). Similarly, Harmeling (2009) suggested a heuristic set of 28 transformations, which include various types of node-substitutions as well as restructuring of the entire parse-tree.

In contrast to such predefined sets of transformations, knowledge oriented approaches were sug-

gested by Bar-Haim et al. (2007) and de Salvo Braz et al. (2005). Their transformations are defined by knowledge resources that contain a large amount of *entailment rules*, or *rewrite rules*, which are pairs of parse-tree fragments that entail one another. Typical examples for knowledge resources of such rules are *DIRT* (Lin and Pantel, 2001), and *TEASE* (Szpektor et al., 2004), as well as syntactic transformations constructed manually. In addition, they used knowledge-based lexical substitutions.

However, when only knowledge-based transformations are allowed, transforming the text into the hypothesis is impossible in many cases. This limitation is dealt by our open-source integrated framework, BIUTEE (Stern and Dagan, 2011), which incorporates knowledge-based transformations (entailment rules) with a set of predefined tree-edits. Motivated by the richer structure and search space provided by BIUTEE, we adopted it for our empirical investigations.

The semantic validity of transformation-based inference is usually modeled by defining a *cost* or a *probability estimation* for each transformation. Costs may be defined manually (Kouylekov and Magnini, 2005), but are usually learned automatically (Harmeling, 2009; Mehdad, 2009; Wang and Manning, 2010; Heilman and Smith, 2010; Stern and Dagan, 2011). A global cost (or probability estimation) for a complete sequence of transformations is typically defined as the sum of the costs of the involved transformations.

Finding the lowest cost proof, as needed for determining inference validity, is the focus of our research. Textual inference systems limited to the standard tree-edit operations (insertion, deletion, substitution) can use an exact algorithm that finds the optimal solution in polynomial time under certain constraints (Bille, 2005). Nevertheless, for the extended set of transformations it is unlikely that efficient exact algorithms for finding lowest-cost sequences are available (Heilman and Smith, 2010).

In this harder case, the problem can be viewed as an AI search problem. Each state in the search space is a parse-tree, where the *initial state* is the text parse-tree, the *goal state* is the hypothesis parse-tree, and we search for the shortest (in terms of costs) *path* of transformations from the initial state to the goal state. Next we briefly review major concepts

from the field of AI search and summarize some relevant proposed solutions.

## 2.2 Search Algorithms

Search algorithms find a path from an initial state to a goal state by *expanding* and *generating* states in a search space. The term *generating* a state refers to creating a data structure that represents it, while *expanding* a state means generating all its immediate derivations. In our domain, each state is a parse tree, which is expanded by performing all applicable transformations.

*Best-first search* is a common search framework. It maintains an *open list* (denoted hereafter as OPEN) containing all the generated states that have not been expanded yet. States in OPEN are prioritized by an *evaluation function*,  $f(s)$ . A best-first search algorithm iteratively removes the *best* state (according to  $f(s)$ ) from OPEN, and inserts new states being generated by expanding this best state. The evaluation function is usually a linear combination of the shortest path found from the start state to state  $s$ , denoted by  $g(s)$ , and a heuristic function, denoted by  $h(s)$ , which estimates the cost of reaching a goal state from  $s$ .

Many search algorithms can be viewed as special cases or variations of best-first search. The well-known A\* (Hart et al., 1968) algorithm is a best-first search that uses an evaluation function  $f(s) = g(s) + h(s)$ . Weighted A\* (Pohl, 1970) uses an evaluation function  $f(s) = w \cdot g(s) + h(s)$ , where  $w$  is a parameter, while pure heuristic search uses  $f(s) = h(s)$ . *K*-BFS (Felner et al., 2003) expands  $k$  states in each iteration. Beam search (Furcy and Koenig, 2005; Zhou and Hansen, 2005) limits the number of states stored in OPEN, while Greedy search limits OPEN to contain only the single best state generated in the current iteration.

The search algorithm has crucial impact on the quality of proof found by a textual inference system, as well as on its efficiency. Next, we describe search strategies used in prior works for textual inference.

## 2.3 Search in prior inference models

In spite of being a fundamental problem, prior solutions to the search challenge in textual inference were mostly ad-hoc. Furthermore, there was no investigation of alternative search methods, and no

evaluation of search efficiency and quality was reported. For example, in (Harmeling, 2009) the order by which the transformations are performed is predetermined, and in addition many possible derivations are discarded, to prevent exponential explosion. Handling the search problem in (Heilman and Smith, 2010) was by a variant of greedy search, driven by a similarity measure between the current parse-tree and the hypothesis, while ignoring the cost already paid. In addition, several constraints on the search space were implemented. In the earlier version of BIUTEE (Stern and Dagan, 2011)<sup>2</sup>, a version of beam search was incorporated, named hereafter BIUTEE-orig. This algorithm uses the evaluation function  $f(s) = g(s) + w_i \cdot h(s)$ , where in each iteration ( $i$ ) the value of  $w$  is increased, to ensure successful termination of the search. Nevertheless, its efficiency and quality were not investigated.

In this paper we consider several prominent search algorithms and evaluate their quality. The evaluation concentrates on two measures: the runtime required to find a proof, and proof quality (measured by its cost). In addition to evaluating standard search algorithms we propose two novel components specifically designed for proof-based textual inference and evaluate their contribution.

### 3 Search for Textual Inference

In this section we formalize our search problem and specify a unifying search scheme by which we test several search algorithms in a systematic manner. Then we propose two novel algorithmic components specifically designed for our problem. We conclude by presenting our new search algorithm which combines these two ideas.

#### 3.1 Inference and search space formalization

Let  $t$  be a parse tree, and let  $o$  be a transformation. Applying  $o$  on  $t$ , yielding  $t'$ , is denoted by  $t \vdash_o t'$ . If the underlying meaning of  $t'$  can indeed be inferred from the underlying meaning of  $t$ , then we refer to the application of  $o$  as *valid*. Let  $O = (o_1, o_2, \dots, o_n)$  be a sequence of transformations, such that  $t_0 \vdash_{o_1} t_1 \vdash_{o_2} t_2 \dots \vdash_{o_n} t_n$ . We write  $t_0 \vdash_O t_n$ , and say that  $t_n$  can be *proven* from

<sup>2</sup>More details in [www.cs.biu.ac.il/~nlp/downloads/biutee/search\\_ranlp\\_2011.pdf](http://www.cs.biu.ac.il/~nlp/downloads/biutee/search_ranlp_2011.pdf)

$t_0$  by applying the sequence  $O$ . The *proof* might be valid, if all the transformations involved are valid, or invalid otherwise.

An inference system specifies a *cost*,  $C(o)$ , for each transformation  $o$ . In most systems the costs are automatically learned. The interpretation of a high cost is that it is unlikely that applying  $o$  will be valid. The cost of a sequence  $O = (o_1, o_2, \dots, o_n)$  is defined as  $\sum_{i=1}^n C(o_i)$  (or, in some systems,  $\prod_{i=1}^n C(o_i)$ ). Denoting by  $t_T$  and  $t_H$  the text parse tree and the hypothesis parse tree, a proof system has to find a sequence  $O$  with minimal cost such that  $t_T \vdash_O t_H$ . This forms a search problem of finding the lowest-cost proof among all possible proofs.

The search space is defined as follows. A *state*  $s$  is a parse-tree. The *start state* is  $t_T$  and the *goal state* is  $t_H$ . In some systems any state  $s$  in which  $t_H$  is embedded is considered as goal as well.

Given a state  $s$ , let  $\{o^{(1)}, o^{(2)} \dots o^{(m)}\}$  be  $m$  transformations that can be applied on it. *Expanding*  $s$  means generating  $m$  new states,  $s^{(j)}$ ,  $j = 1 \dots m$ , such that  $s \vdash_{o^{(j)}} s^{(j)}$ . The number  $m$  is called *branching factor*. Our empirical observations on BIUTEE showed that its branching factor ranges from 2-3 for some states to about 30 for other states.

#### 3.2 Search Scheme

Our empirical investigation compares a range prominent search algorithms, described in Section 2. To facilitate such investigation, we formulate them in the following unifying scheme (Algorithm 1).

---

#### Algorithm 1 Unified Search Scheme

---

**Parameters:**  $f(\cdot)$ : state evaluation function  
 $expand(\cdot)$ : state generation function  
**Input:**  $k_{expand}$ : # states expanded in each iteration  
 $k_{maintain}$ : # states in OPEN in each iteration  
 $s_{init}$ : initial state

```

1: OPEN  $\leftarrow \{s_{init}\}$ 
2: repeat
3:   BEST  $\leftarrow k_{expand}$  best (according to  $f$ ) states in OPEN
4:   GENERATED  $\leftarrow \bigcup_{s \in \text{BEST}} expand(s)$ 
5:   OPEN  $\leftarrow (\text{OPEN} \setminus \text{Best}) \cup \text{GENERATED}$ 
6:   OPEN  $\leftarrow k_{maintain}$  best (according to  $f$ ) states in OPEN
7: until BEST contains the goal state

```

---

Initially, the open list, OPEN contains the initial state. Then, the *best*  $k_{expand}$  states from OPEN are chosen, according to the evaluation function  $f(s)$

Algorithm	$f()$	expand()	$k_{\text{maintain}}$	$k_{\text{expand}}$
A*	$g + h$	regular	$\infty$	1
Weighted A*	$g + w \cdot h$	regular	$\infty$	1
K-Weighted A*	$g + w \cdot h$	regular	$\infty$	$k > 1$
Pure Heuristic	$h$	regular	$\infty$	1
Greedy	$g + w \cdot h$	regular	1	1
Beam	$g + h$	regular	$k > 1$	$k > 1$
BIUTEE-orig	$g + w_i \cdot h$	regular	$k > 1$	$k > 1$
LLGS	$\frac{\Delta g}{\Delta h}$	local-lookahead	1	1

Table 2: Search algorithm mapped to the unified search scheme. “Regular” means generating all the states which can be generated by applying a single transformation. Alternative greedy implementations use  $f = h$ .

(line 3), and expanded using the *expansion function*  $\text{expand}(s)$ . In classical search algorithms,  $\text{expand}(s)$  means generating a set of states by applying all the possible state transition operators to  $s$ . Next, we remove from OPEN the states which were expanded, and add the newly generated states. Finally, we keep in OPEN only the best  $k_{\text{maintain}}$  states, according to the evaluation function  $f(s)$  (line 6). This process repeats until the goal state is found in BEST (line 7). Table 2 specifies how known search algorithms, described in Section 2, fit into the unified search scheme.

Since runtime efficiency is crucial in our domain, we focused on improving one of the simple but fast algorithms, namely, greedy search. To improve the quality of the proof found by greedy search, we introduce new algorithmic components for the expansion and evaluation functions, as described in the next two subsections, while maintaining efficiency by keeping  $k_{\text{maintain}} = k_{\text{expand}} = 1$ .

### 3.3 Evaluation function

In most domains, the heuristic function  $h(s)$  estimates the cost of the minimal-cost path from a current state,  $s$ , to a goal state. Having such a function, the value  $g(s) + h(s)$  estimates the expected total cost of a search path containing  $s$ . In our domain, it is yet unclear how to calculate such a heuristic function. Given a state  $s$ , systems typically estimate the difference (the gap) between  $s$  and the hypothesis  $t_H$  (the goal state). In BIUTEE this is quantified by the number of parse-tree nodes and edges of  $t_H$  that do not exist in  $s$ . However, this does not give an

estimation for the expected cost of the path (the sequence of transformations) from  $s$  to the goal state. This is because the number of nodes and edges that can be changed by a single transformation can vary from a single node to several nodes (e.g., by a lexical syntactic entailment rule). Moreover, even if two transformations change the same number of nodes and edges, their costs might be significantly different. Consequently, the measurement of the cost accumulated so far ( $g(s)$ ) and the remaining gap to  $t_H$  ( $h(s)$ ) are unrelated. We note that a more sophisticated heuristic function was suggested by Heilman and Smith (2010), based on tree-kernels. Nevertheless, this heuristic function, serving as  $h(s)$ , is still unrelated to the transformation costs ( $g(s)$ ).

We therefore propose a novel gradient-style function to overcome this difficulty. Our function is designed for a greedy search in which OPEN always contains a single state,  $s$ . Let  $s^j$  be a state generated from  $s$ , the cost of deriving  $s^j$  from  $s$  is  $\Delta_g(s^j) \equiv g(s^j) - g(s)$ . Similarly, the reduction in the value of the heuristic function is defined  $\Delta_h(s^j) \equiv h(s) - h(s^j)$ . Now, we define  $f_\Delta(s^j) \equiv \frac{\Delta_g(s^j)}{\Delta_h(s^j)}$ . Informally, this function measures how costly it is to derive  $s^j$  relative to the obtained decrease in the remaining gap to the goal state. For the edge case in which  $h(s) - h(s^j) \leq 0$ , we define  $f_\Delta(s^j) = \infty$ . Empirically, we show in our experiments that the function  $f_\Delta(s)$  performs better than the traditional functions  $f(s) = g(s) + h(s)$  and  $f_w(s) = g(s) + w \cdot h(s)$  in our domain.

### 3.4 Node expansion method

When examining the proofs produced by the above mentioned algorithms, we observed that in many cases a human could construct proofs that exhibit some internal structure, but were not revealed by the algorithms. Observe, for example, the proof in Table 1. It can be seen that transformations 2,3 and 4 strongly depend on each other. Applying transformation 3 requires first applying transformation 2, and similarly 4 could not be applied unless 2 and 3 are first applied. Moreover, there is no gain in applying transformations 2 and 3, unless transformation 4 is applied as well. On the other hand, transformation 1 does not depend on any other transformation. It may be performed at any point along the proof, and

moreover, changing all other transformations would not affect it.

Carefully examining many examples, we generalized this phenomenon as follows. Often, a sequence of transformations can be decomposed into a set of *coherent subsequences* of transformations, where in each subsequence the transformations strongly depend on each other, while different subsequences are independent. This phenomenon can be utilized in the following way: instead of searching for a complete sequence of transformations that transform  $t_T$  into  $t_H$ , we can iteratively search for independent coherent subsequences of transformations, such that a combination of these subsequences will transform  $t_T$  into  $t_H$ . This is somewhat similar to the technique of applying *macro* operators, which is used in automated planning (Botea et al., 2005) and puzzle solving (Korf, 1985).

One technique for finding such subsequences is to perform, for each state being expanded, a brute-force depth-limited search, also known as *lookahead* (Russell and Norvig, 2010; Bulitko and Lustrek, 2006; Korf, 1990; Stern et al., 2010). However, performing such lookahead might be slow if the branching factor is large. Fortunately, in our domain, coherent subsequences have the following characteristic which can be leveraged: typically, a transformation depends on a previous one only if it is performed over some nodes which were affected by the previous transformation. Accordingly, our proposed algorithm searches for coherent subsequences, in which each subsequent transformation must be applied to nodes that were affected by the previous transformation.

Formally, let  $o$  be a transformation that has been applied on a tree  $t$ , yielding  $t'$ .  $\sigma_{\text{affected}}(o, t')$  denotes the subset of nodes in  $t'$  which were affected (modified or created) by the application of  $o$ .

Next, for a transformation  $o$ , applied on a parse tree  $t$ , we define  $\sigma_{\text{required}}(t, o)$  as the subset of  $t$ 's nodes required for applying  $o$  (i.e., in the absence of these nodes,  $o$  could not be applied).

Finally, let  $t$  be a parse-tree and  $\sigma$  be a subset of its nodes.  $\text{enabled\_ops}(t, \sigma)$  is a function that returns the set of the transformations that can be applied on  $t$ , which require at least one of the nodes in  $\sigma$ . Formally,  $\text{enabled\_ops}(t, \sigma) \equiv \{o \in \mathcal{O} : \sigma \cap \sigma_{\text{required}}(t, o) \neq \emptyset\}$ , where  $\mathcal{O}$  is the set of trans-

formations that can be applied on  $t$ . In our algorithm,  $\sigma$  is the set of nodes that were affected by the preceding transformation of the constructed subsequence.

The recursive procedure described in Algorithm 2 generates all coherent subsequences of lengths up to  $d$ . It should be initially invoked with  $t$  - the current state (parse tree) being expanded,  $\sigma$  - the set of all its nodes,  $d$  - the maximal required length, and  $\emptyset$  as an empty initial sequence. We use  $O \cdot o$  as concatenation of an operation  $o$  to a subsequence  $O$ .

---

#### Algorithm 2 local-lookahead ( $t, \sigma, d, O$ )

---

```

1: if  $d = 0$  then
2:   return  $\emptyset$  (empty-set)
3: end if
4: SUBSEQUENCES  $\leftarrow \emptyset$ 
5: for all  $o \in \text{enabled\_ops}(t, \sigma)$  do
6:   Let  $t \vdash_o t'$ 
7:   Add  $\{O \cdot o\} \cup \text{local-lookahead}(t', \sigma_{\text{affected}}(o, t'), d-1, O \cdot o)$  to SUBSEQUENCES
8: end for
9: return SUBSEQUENCES

```

---

The loop in lines 5 - 8 iterates over transformations that can be applied on the input tree,  $t$ , requiring the same nodes that were affected by the previous transformation of the subsequence being constructed. Note that in the first call  $\text{enabled\_ops}(t, \sigma)$  contain all operations that can be applied on  $t$ , with no restriction. Applying an operation  $o$  results in a new subsequence  $O \cdot o$ . This subsequence will be part of the set of subsequences found by the procedure. In addition, it will be used in the next recursive call as the prefix of additional (longer) subsequences.

### 3.5 Local-lookahead gradient search

We are now ready to define our new algorithm LOCAL-LOOKAHEAD GRADIENT SEARCH (LLGS). In LLGS, like in greedy search,  $k_{\text{maintain}} = k_{\text{expand}} = 1$ .  $\text{expand}(s)$  is defined to return all states generated by subsequences found by the *local-lookahead* procedure, while the evaluation function is defined as  $f = f_{\Delta}$  (see last row of Table 2).

## 4 Evaluation

In this section we first evaluate the search performance in terms of efficiency (run time), the quality

of the found proofs (as measured by proof cost), and overall inference performance achieved through various search algorithms. Finally we analyze the contribution of our two novel components.

#### 4.1 Evaluation settings

We performed our experiments on the last two published RTE datasets: RTE-5 (2009) and RTE-6 (2010). The RTE-5 dataset is composed of a training and test corpora, each containing 600 text-hypothesis pairs, where in half of them the text entails the hypothesis and in the other half it does not. In RTE-6, each of the training and test corpora consists of 10 topics, where each topic contains 10 documents. Each corpus contains a set of hypotheses (211 in the training dataset, and 243 in the test dataset), along with a set of candidate entailing sentences for each hypothesis. The system has to find for each hypothesis which candidate sentences entail it. To improve speed and results, we used the filtering mechanism suggested by (Mirkin et al., 2009), which filters the candidate sentences by the Lucene IR engine<sup>3</sup>. Thus, only top 20 candidates per hypothesis were tested

Evaluation of each of the algorithms was performed by running BIUTEE while replacing BIUTEE-orig with this algorithm. We employed a comprehensive set of knowledge resources (available in BIUTEE’s web site): WordNet (Fellbaum, 1998), Directional similarity (Kotlerman et al., 2010), DIRT (Lin and Pantel, 2001) and generic syntactic rules. In addition, we used coreference substitutions, detected by ArkRef<sup>4</sup>.

We evaluated several known algorithms, described in Table 2 above, as well as BIUTEE-orig. The latter is a strong baseline, which outperforms known search algorithms in generating low cost proofs. We compared all the above mentioned algorithms to our novel one, LLGS.

We used the training dataset for parameter tuning, which controls the trade-off between speed and quality. For weighted A\*, as well as for greedy search, we used  $w = 6.0$ , since, for a few instances, lower values of  $w$  resulted in prohibitive runtime. For beam search we used  $k = 150$ , since higher val-

<sup>3</sup><http://lucene.apache.org>

<sup>4</sup>[www.ark.cs.cmu.edu/ARKref/](http://www.ark.cs.cmu.edu/ARKref/) See (Haghighi and Klein, 2009)

ues of  $k$  did not improve the proof cost on the training dataset. The value of  $d$  in LLGS was set to 3.  $d = 4$  yielded the same proof costs, but was about 3 times slower.

Since lower values of  $w$  could be used by weighted A\* for most instances, we also ran experiments where we varied the value of  $w$  according to the dovetailing method suggested in (Valenzano et al., 2010) (denoted *dovetailing WA\**) as follows. When weighted A\* has found a solution, we reran it with a new value of  $w$ , set to half of the previous value. The idea is to guide the search for lower cost solutions. This process was halted when the total number of states generated by all weighted A\* instances exceeded a predefined constant (set to 10,000).

#### 4.2 Search performance

This experiment evaluates the search algorithms in both efficiency (run-time) and proof quality. Efficiency is measured by the average CPU (Intel Xeon 2.5 GHz) run-time (in seconds) for finding a complete proof for a text-hypothesis instance, and by the average number of generated states along the search. Proof quality is measured by its cost.

The comparison of costs requires that all experiments are performed on the same model which was learned during training. Thus, in the training phase we used the original search of BIUTEE, and then ran the test phase with each algorithm separately. The results, presented in Table 3, show that our novel algorithm, LLGS, outperforms all other algorithms in finding lower cost proofs. The second best is BIUTEE-orig which is much slower by a factor of 3 (on RTE-5) to 8 (on RTE-6)<sup>5</sup>. While inherently fast algorithms, particularly greedy and pure heuristic, achieve faster running times, they achieve lower proof quality, as well as lower overall inference performance (see next subsection).

#### 4.3 Overall inference performance

In this experiment we test whether, and how much, finding better proofs, by a better search algorithm, improves overall success rate of the RTE system. Table 4 summarizes the results (accuracy in RTE-5

<sup>5</sup>Calculating T-test, we found that runtime improvement is statistically significant with  $p < 0.01$ , and  $p < 0.052$  for cost improvement over BIUTEE-orig.

Algorithm	Avg. time	Avg. generated	Avg. cost
Weighted A*	0.22 / <b>0.09</b>	301 / 143	1.11 / 10.52
Dovetailing WA*	7.85 / 8.53	9797 / 9979	1.05 / 10.28
Greedy	0.20 / 0.10	468 / <b>158</b>	1.10 / 10.55
Pure heuristic	<b>0.09</b> / 0.10	<b>123</b> / 167	1.35 / 12.51
Beam search	20.53 / 9.48	43925 / 18992	1.08 / 10.52
BIUTEE-orig	7.86 / 14.61	14749 / 22795	1.03 / 10.28
LLGS	2.76 / 1.72	1722 / 842	<b>0.95</b> / <b>10.14</b>

Table 3: Comparison of algorithms on RTE-5 / RTE-6

and F1 in RTE-6). We see that in RTE-5 LLGS outperforms all other algorithms, and BIUTEE-orig is the second best. This result is statistically significant with  $p < 0.02$  according to *McNemar* test. In RTE-6 we see that although LLGS tends to find lower cost proofs, as shown in Table 3, BIUTEE obtains slightly lower results when utilizing this algorithm.

Algorithm	RTE-5 accuracy %	RTE-6 F1 %
Weighted A*	59.50	48.20
Dovetailing WA*	60.83	49.01
Greedy	60.50	48.56
Pure heuristic	60.83	45.70
Beam search	61.33	48.58
BIUTEE-orig	60.67	<b>49.25</b>
LLGS	<b>64.00</b>	49.09

Table 4: Impact of algorithms on system success rate

#### 4.4 Component evaluation

In this experiment we examine separately our two novel components. We examined  $f_{\Delta}$  by running LLGS with alternative evaluation functions. The results, displayed in Table 5, show that using  $f_{\Delta}$  yields better proofs and also improves run time.

$f$	Avg. time	Avg. cost	Accuracy %
$f = g + h$	3.28	1.06	61.50
$f = g + w \cdot h$	3.30	1.07	61.33
$f = f_{\Delta}$	<b>2.76</b>	<b>0.95</b>	<b>64.0</b>

Table 5: Impact of  $f_{\Delta}$  on RTE-5.  $w = 6.0$ . Accuracy obtained by retraining with corresponding  $f$ .

Our *local-lookahead* (Subsection 3.4) was examined by running LLGS with alternative node expansion methods. One alternative to local-lookahead is standard expansion by generating all immediate derivations. Another alternative is to use the standard lookahead, in which a brute-force depth-limited

search is performed in each iteration, termed here “exhaustive lookahead”. The results, presented in Table 6, show that by avoiding any type of lookahead one can achieve fast runtime, while compromising proof quality. On the other hand, both exhaustive and local lookahead yield better proofs and accuracy, while local lookahead is more than 4 times faster than exhaustive lookahead.

lookahead	Avg. time	Avg. cost	Accuracy (%)
exhaustive	13.22	<b>0.95</b>	<b>64.0</b>
local	2.76	<b>0.95</b>	<b>64.0</b>
none	<b>0.24</b>	0.97	62.0

Table 6: Impact of local and global lookahead on RTE-5. Accuracy obtained by retraining with the corresponding lookahead method.

## 5 Conclusion

In this paper we investigated the efficiency and proof quality obtained by various search algorithms. Consequently, we observed special phenomena of the search space in textual inference and proposed two novel components yielding a new search algorithm, targeted for our domain. We have shown empirically that (1) this algorithm improves run time by factors of 3-8 relative to BIUTEE-orig, and by similar factors relative to standard AI-search algorithms that achieve similar proof quality; and (2) outperforms all other algorithms in finding low cost proofs.

In future work we plan to investigate other search paradigms, e.g., Monte-Carlo style approaches (Kocsis and Szepesvári, 2006), which do not fall under the AI search scheme covered in this paper. In addition, while our novel components were motivated by the search space of textual inference, we foresee their potential utility in other application areas for search, such as automated planning and scheduling.

## Abstract

This paper proposes a new discriminative training method in constructing phrase and lexicon translation models. In order to reliably learn a myriad of parameters in these models, we propose an expected BLEU score-based utility function with KL regularization as the objective, and train the models on a large parallel dataset. For training, we derive growth transformations for phrase and lexicon translation probabilities to iteratively improve the objective. The proposed method, evaluated on the Europarl German-to-English dataset, leads to a 1.1 BLEU point improvement over a state-of-the-art baseline translation system. In IWSLT 2011 Benchmark, our system using the proposed method achieves the best Chinese-to-English translation result on the task of translating TED talks.

## 1. Introduction

Discriminative training is an active area in statistical machine translation (SMT) (e.g., Och et al., 2002, 2003, Liang et al., 2006, Blunsom et al., 2008, Chiang et al., 2009, Foster et al., 2010, Xiao et al., 2011). Och (2003) proposed using a log-linear model to incorporate multiple features for translation, and proposed a minimum error rate training (MERT) method to train the feature weights to optimize a desirable translation metric.

While the log-linear model itself is discriminative, the phrase and lexicon translation features, which are among the most important components of SMT, are derived from either generative models or heuristics (Koehn et al., 2003, Brown et al., 1993). Moreover, the

parameters in the phrase and lexicon translation models are estimated by relative frequency or maximizing joint likelihood, which may not correspond closely to the translation measure, e.g., bilingual evaluation understudy (BLEU) (Papineni et al., 2002). Therefore, it is desirable to train all these parameters to directly maximize an objective that directly links to translation quality.

However, there are a large number of parameters in these models, making discriminative training for them non-trivial (e.g., Liang et al., 2006, Chiang et al., 2009). Liang et al. (2006) proposed a large set of lexical and Part-of-Speech features and trained the model weights associated with these features using perceptron. Since many of the reference translations are non-reachable, an empirical *local updating* strategy had to be devised to fix this problem by picking a *pseudo* reference. Many such non-desirable heuristics led to moderate gains reported in that work. Chiang et al. (2009) improved a syntactic SMT system by adding as many as ten thousand syntactic features, and used Margin Infused Relaxed Algorithm (MIRA) to train the feature weights. However, the number of parameters in common phrase and lexicon translation models is much larger.

In this work, we present a new, highly effective discriminative learning method for phrase and lexicon translation models. The training objective is an expected BLEU score, which is closely linked to translation quality. Further, we apply a Kullback–Leibler (KL) divergence regularization to prevent over-fitting.

For effective optimization, we derive updating formulas of growth transformation (GT) for phrase and lexicon translation probabilities. A GT is a transformation of the probabilities that guarantees strict non-decrease of the objective over each GT iteration unless a local maximum is reached. A

similar GT technique has been successfully used in speech recognition (Gopalakrishnan et al., 1991, Povey, 2004, He et al., 2008). Our work demonstrates that it works with large scale discriminative training of SMT model as well.

Our work is based on a phrase-based SMT system. Experiments on the Europarl German-to-English dataset show that the proposed method leads to a 1.1 BLEU point improvement over a strong baseline. The proposed method is also successfully evaluated on the IWSLT 2011 benchmark test set, where the task is to translate TED talks ([www.ted.com](http://www.ted.com)). Our experimental results on this open-domain spoken language translation task show that the proposed method leads to significant translation performance improvement over a state-of-the-art baseline, and the system using the proposed method achieved the best single system translation result in the Chinese-to-English MT track.

## 2. Related Work

One best known approach in discriminative training for SMT is proposed by Och (2003). In that work, multiple features, most of them are derived from generative models, are incorporated into a log-linear model, and the relative weights of them are tuned discriminatively on a small tuning set. However, in practice, this approach only works with a handful of parameters.

More closely related to our work, Liang et al. (2006) proposed a large set of lexical and Part-of-Speech features in addition to the phrase translation model. Weights of these features are trained using perceptron on a training set of 67K sentences. In that paper, the authors pointed out that forcing the model to update towards the reference translation could be problematic. This is because the hidden structure such as phrase segmentation and alignment could be abused if the system is forced to produce a reference translation. Therefore, instead of pushing the parameter update towards the reference translation (a.k.a. *bold updating*), the author proposed a *local updating* strategy where the model parameters are updated towards a pseudo-reference (i.e., the hypothesis in the n-best list that gives the best BLEU score). Experimental results showed that their approach outperformed a baseline by 0.8 BLEU point when using monotonic decoding, but there was no

significant gain over a stronger baseline with a full-distortion model. In our work, we use the expectation of BLEU scores as the objective. This avoids the heuristics of picking the updating reference and therefore gives a more principal way of setting the training objective.

As another closely related study, Chiang et al. (2009) incorporated about ten thousand syntactic features in addition to the baseline features. The feature weights are trained on a tuning set with 2010 sentences using MIRA. In our work, we have many more parameters to train, and the training is conducted on the entire training corpora. Our GT based optimization algorithm is highly parallelizable and efficient, which is the key for large scale discriminative training.

As a further related work, Rosti et al. (2011) have proposed using differentiable expected BLEU score as the objective to train system combination parameters. Other work related to the computation of expected BLEU in common with ours includes minimum Bayes risk approaches (Smith and Eisner 2006, Tromble et al., 2008) and lattice-based MERT (Macherey et al., 2008). In these earlier work, however, the phrase and lexicon translation models used remained unchanged.

Another line of research that is closely related to our work is phrase table refinement and pruning. Wuebker et al. (2010) proposed a method to train the phrase translation model using Expectation-Maximization algorithm with a *leave-one-out* strategy. The parallel sentences were forced to be aligned at the phrase level using the phrase table and other features as in a decoding process. Then the phrase translation probabilities were estimated based on the phrase alignments. To prevent overfitting, the statistics of phrase pairs from a particular sentence was excluded from the phrase table when aligning that sentence. However, as pointed out by Liang et al (2006), the same problem as in the *bold updating* existed, i.e., forced alignment between a source sentence and its reference translation was tricky, and the proposed alignment was likely to be unreliable. The method presented in this paper is free from this problem.

## 3. Phrase-based Translation System

The translation process of phrase-based SMT can be briefly described in three steps: segment source sentence into a sequence of phrases, translate each

source phrase to a target phrase, re-order target phrases into target sentence (Koehn et al., 2003).

In decoding, the optimal translation  $\hat{E}$  given the source sentence  $F$  is obtained according to

$$\hat{E} = \operatorname{argmax}_E P(E|F) \quad (1)$$

where

$$P(E|F) = \frac{1}{Z} \exp \left\{ \sum_m \lambda_m \log h_m(E, F) \right\} \quad (2)$$

and  $Z = \sum_E \exp \{ \sum_m \lambda_m \log h_m(E, F) \}$  is the normalization denominator to ensure that the probabilities sum to one. Note that we define the feature functions  $\{h_m(E, F)\}$  in log domain to simplify the notation in later sections. Feature weights  $\lambda = \{\lambda_m\}$  are usually tuned by MERT.

Features used in a phrase-based system usually include LM, reordering model, word and phrase counts, and phrase and lexicon translation models. Given the focus of this paper, we review only the phrase and lexicon translation models below.

### 3.1. Phrase translation model

A set of phrase pairs are extracted from word-aligned parallel corpus according to phrase extraction rules (Koehn et al., 2003). Phrase translation probabilities are then computed as relative frequencies of phrases over the training dataset. i.e., the probability of translating a source phrase  $\tilde{f}$  to a target phrase  $\tilde{e}$  is computed by

$$p(\tilde{e}|\tilde{f}) = \frac{C(\tilde{e}, \tilde{f})}{C(\tilde{f})} \quad (3)$$

where  $C(\tilde{e}, \tilde{f})$  is the joint counts of  $\tilde{e}$  and  $\tilde{f}$ , and  $C(\tilde{f})$  is the marginal counts of  $\tilde{f}$ .

In translation, the input sentence is segmented into  $K$  phrases, and the source-to-target forward phrase (FP) translation feature is scored as:

$$h_{FP}(E, F) = \prod_k p(\tilde{e}_k|\tilde{f}_k) \quad (4)$$

where  $\tilde{e}_k$  and  $\tilde{f}_k$  are the  $k$ -th phrase in  $E$  and  $F$ , respectively. The target-to-source (backward) phrase translation model is defined similarly.

### 3.2. Lexicon translation model

There are several variations in lexicon translation features (Ayan and Dorr 2006, Koehn et al., 2003, Quirk et al., 2005). We use the word translation table from IBM Model 1 (Brown et al., 1993) and compute the sum over all possible word alignments within a phrase pair without normalizing for length (Quirk et al., 2005). The source-to-target forward lexicon (FL) translation feature is:

$$h_{FL}(E, F) = \prod_k \prod_m \sum_r p(e_{k,m}|f_{k,r}) \quad (5)$$

where  $e_{k,m}$  is the  $m$ -th word of the  $k$ -th target phrase  $\tilde{e}_k$ ,  $f_{k,r}$  is the  $r$ -th word in the  $k$ -th source phrase  $\tilde{f}_k$ , and  $p(e_{k,m}|f_{k,r})$  is the probability of translating word  $f_{k,r}$  to word  $e_{k,m}$ . In IBM model 1, these probabilities are learned via maximizing a joint likelihood between the source and target sentences. The target-to-source (backward) lexicon translation model is defined similarly.

## 4. Maximum Expected-BLEU Training

### 4.1. Objective function

We denote by  $\theta$  the set of all the parameters to be optimized, including forward phrase and lexicon translation probabilities and their backward counterparts. For simplification of notation,  $\theta$  is formed as a matrix, where its elements  $\{\theta_{ij}\}$  are probabilities subject to  $\sum_j \theta_{ij} = 1$ . E.g., each row is a probability distribution.

The utility function over the entire training set is defined as:

$$U(\theta) = \sum_{E_1, \dots, E_N} P_\theta(E_1, \dots, E_N | F_1, \dots, F_N) \left( \sum_{n=1}^N BLEU(E_n, E_n^*) \right) \quad (6)$$

where  $N$  is the number of sentences in the training set,  $E_n^*$  is the reference translation of the  $n$ -th source sentence  $F_n$ , and  $E_n \in Hyp(F_n)$  that denotes the list of translation hypotheses of  $F_n$ . Since the sentences are independent with each other, the joint posterior can be decomposed:

$$P_\theta(E_1, \dots, E_N | F_1, \dots, F_N) = \prod_{n=1}^N P_\theta(E_n | F_n) \quad (7)$$

and  $P_{\theta}(E_n|F_n)$  is the posterior defined in (2), the subscript  $\theta$  indicates that it is computed based on the parameter set  $\theta$ .  $U(\theta)$  is proportional (with a factor of  $N$ ) to the expected sentence BLEU score over the entire training set, i.e., after some algebra,

$$U(\theta) = \sum_{n=1}^N \sum_{E_n} P_{\theta}(E_n|F_n) BLEU(E_n, E_n^*)$$

In a phrase-based SMT system, the total number of parameters of phrase and lexicon translation models, which we aim to learn discriminatively, is very large (see Table 1). Therefore, regularization is critical to prevent over-fitting. In this work, we regularize the parameters with KL regularization.

KL divergence is commonly used to measure the distance between two probability distributions. For the whole parameter set  $\theta$ , the KL regularization is defined in this work as the sum of KL divergence over the entire parameter space:

$$KL(\theta^0||\theta) = \sum_i \sum_j \theta_{ij}^0 \log \frac{\theta_{ij}^0}{\theta_{ij}} \quad (8)$$

where  $\theta^0$  is a constant prior parameter set. In training, we want to improve the utility function while keeping the changes of the parameters from  $\theta^0$  at minimum. Therefore, we design the objective function to be maximized as:

$$O(\theta) = \log U(\theta) - \tau \cdot KL(\theta^0||\theta) \quad (9)$$

where the prior model  $\theta^0$  in our approach is the relative-frequency-based phrase translation model and the maximum-likelihood-estimated IBM model 1 (word translation model).  $\tau$  is a hyper-parameter controlling the degree of regularization.

## 4.2. Optimization

In this section, we derived GT formulas for iteratively updating the parameters so as to optimize objective (9). GT is based on extended Baum-Welch (EBW) algorithm first proposed by Gopalakrishnan et al. (1991) and commonly used in speech recognition (e.g., He et al. 2008).

### 4.2.1. Extended Baum-Welch Algorithm

Baum-Eagon inequality (Baum and Eagon, 1967) gives the GT formula to iteratively maximize positive-coefficient polynomials of random

variables that are subject to sum-to-one constants. Baum-Welch algorithm is a model update algorithm for hidden Markov model which uses this GT. Gopalakrishnan et al. (1991) extended the algorithm to handle rational function, i.e., a ratio of two polynomials, which is more commonly encountered in discriminative training.

Here we briefly review EBW. Assuming a set of random variables  $\mathbf{p} = \{p_{ij}\}$  that subject to the constraint that  $\sum_j p_{ij} = 1$ , and assume  $g(\mathbf{p})$  and  $h(\mathbf{p})$  are two positive polynomial functions of  $\mathbf{p}$ , a GT of  $\mathbf{p}$  for the rational function  $r(\mathbf{p}) = \frac{g(\mathbf{p})}{h(\mathbf{p})}$  can be obtained through the following two steps:

i) Construct the auxiliary function:

$$f(\mathbf{p}) = g(\mathbf{p}) - r(\mathbf{p}')h(\mathbf{p}) \quad (10)$$

where  $\mathbf{p}'$  are the values from the previous iteration. Increasing  $f$  guarantees an increase of  $r$ , i.e.,  $h(\mathbf{p}) > 0$  and  $r(\mathbf{p}) - r(\mathbf{p}') = \frac{1}{h(\mathbf{p})}(f(\mathbf{p}) - f(\mathbf{p}'))$ .

ii) Derive GT formula for  $f(\mathbf{p})$

$$p_{ij} = \frac{p'_{ij} \left. \frac{\partial f(\mathbf{p})}{\partial p_{ij}} \right|_{\mathbf{p}=\mathbf{p}'} + D \cdot p'_{ij}}{\sum_j p'_{ij} \left. \frac{\partial f(\mathbf{p})}{\partial p_{ij}} \right|_{\mathbf{p}=\mathbf{p}'} + D} \quad (11)$$

where  $D$  is a smoothing factor.

### 4.2.2. GT of Translation Models

Now we derive the GTs of translation models for our objective. Since maximizing  $O(\theta)$  is equivalent to maximizing  $e^{O(\theta)}$ , we have the following auxiliary function:

$$R(\theta) = U(\theta) e^{-\tau \cdot KL(\theta^0||\theta)} \quad (12)$$

After substituting (2) and (7) into (6), and drop optimization irrelevant terms in KL regularization, we have  $R(\theta)$  in a rational function form:

$$R(\theta) = \frac{G(\theta) \cdot J(\theta)}{H(\theta)} \quad (13)$$

where  $H(\theta) = \sum_{E_1, \dots, E_N} \prod_{n=1}^N \prod_m h_m^{\lambda_m}(E_n, F_n)$ ,  $J(\theta) = \prod_i \prod_j \theta_{ij}^{\tau \theta_{ij}^0}$ , and  $G(\theta) =$

$\sum_{E_1, \dots, E_N} \prod_{n=1}^N \prod_m h_m^{\lambda_m}(E_n, F_n)$  ( $\sum_{n=1}^N BLEU(E_n, E_n^*)$ ) are all positive polynomials of  $\theta$ . Therefore, we can follow the two steps of EBW to derive the GT formulas for  $\theta$ .

If we denote by  $p_{ij}$  the probability of translating the source phrase  $i$  to the target phrase  $j$ . Then, the updating formula is (derivation omitted):

$$p_{ij} = \frac{\sum_n \sum_{E_n} \gamma_{FP}(E_n, n, i, j) + U(\theta') \tau_{FP} p_{ij}^0 + D_i p'_{ij}}{\sum_n \sum_{E_n} \sum_j \gamma_{FP}(E_n, n, i, j) + U(\theta') \tau_{FP} + D_i} \quad (14)$$

where  $\tau_{FP} = \tau / \lambda_{FP}$  and  $\gamma_{FP}(E_n, n, i, j) = P_{\theta'}(E_n | F_n) \cdot [BLEU(E_n, E_n^*) - U_n(\theta')] \cdot \sum_k \mathbf{1}(\tilde{f}_{n,k} = i, \tilde{e}_{n,k} = j)$ . In which  $U_n(\theta')$  takes a form similar to (6), but is the expected BLEU score for sentence  $n$  using models from the previous iteration.  $\tilde{f}_{n,k}$  and  $\tilde{e}_{n,k}$  are the  $k$ -th phrases of  $F_n$  and  $E_n$ , respectively.

The smoothing factor set of  $D_i$  according to the Baum-Eagon inequality is usually far too large for practical use. In practice, one general guide of setting  $D_i$  is to make all updated value positive. Similar to (Povey 2004), we set  $D_i$  by

$$D_i = \sum_n \sum_{E_n} \sum_j \max(0, -\gamma_{FP}(E_n, n, i, j)) \quad (15)$$

to ensure the denominator of (15) is positive. Further, we set a low-bound of  $D_i$  as  $\max_j \left\{ \frac{-\sum_n \sum_{E_n} \gamma_{FP}(E_n, n, i, j)}{p'_{ij}} \right\}$  to guarantee the numerator to be positive.

We denote by  $l_{ij}$  the probability of translating the source word  $i$  to the target word  $j$ . Then following the same derivation, we get the updating formula for forward lexicon translation model:

$$l_{ij} = \frac{\sum_n \sum_{E_n} \gamma_{FL}(E_n, n, i, j) + U(\theta') \tau_{FL} l_{ij}^0 + D_i l'_{ij}}{\sum_n \sum_{E_n} \sum_j \gamma_{FL}(E_n, n, i, j) + U(\theta') \tau_{FL} + D_i} \quad (16)$$

where  $\tau_{FL} = \tau / \lambda_{FL}$  and  $\gamma_{FL}(E_n, n, i, j) = P_{\theta'}(E_n | F_n) \cdot [BLEU(E_n, E_n^*) - U_n(\theta')] \cdot \sum_k \sum_m \mathbf{1}(e_{n,k,m} = j) \gamma(n, k, m, i)$ , and  $\gamma(n, k, m, i) = \frac{\sum_r \mathbf{1}(f_{n,k,r} = i) p'(e_{n,k,m} | f_{n,k,r})}{\sum_r p'(e_{n,k,m} | f_{n,k,r})}$ , in which  $f_{n,k,r}$  and  $e_{n,k,m}$  are the  $r$ -th and  $m$ -th word in the  $k$ -th phrase of the source sentence  $F_n$  and the target hypothesis  $E_n$ , respectively. Value of  $D_i$  is set in a

way similar to (15).

GTs for updating backward phrase and lexicon translation models can be derived in a similar way, and is omitted here.

### 4.3. Implementation issues

#### 4.3.1. Normalizing $\lambda$

The posterior  $p_{\theta'}(E_n | F_n)$  in the model updating formula is computed according to (2). In decoding, only the relative values of  $\lambda$  matters. However, the absolute value will affect the posterior distribution, e.g., an overly large absolute value of  $\lambda$  would lead to a very sharp posterior distribution. In order to control the sharpness of the posterior distribution, we normalize  $\lambda$  by its L1 norm:

$$\hat{\lambda}_m = \frac{\lambda_m}{\sum_m |\lambda_m|} \quad (17)$$

#### 4.3.2. Computing the sentence BLEU score

The commonly used BLEU-4 score is computed by

$$BLEU-4 = BP \cdot \exp\left(\frac{1}{4} \sum_{n=1}^4 \log p_n\right) \quad (18)$$

In the updating formula, we need to compute the sentence-level  $BLEU(E_n, E_n^*)$ . Since the matching count may be sparse at the sentence level, we smooth raw precisions of high-order  $n$ -grams by:

$$p_n = \frac{\#(n\text{-gram matched}) + \eta \cdot p_n^0}{\#(n\text{-gram}) + \eta} \quad (19)$$

where  $p_n^0$  is the prior value of  $p_n$ ,  $\eta$  is a smoothing factor usually takes a value of 5 and  $p_n^0$  can be set by  $p_n^0 = p_{n-1} \cdot p_{n-1} / p_{n-2}$ , for  $n = 3, 4$ .  $p_1$  and  $p_2$  are estimated empirically. Brevity penalty (BP) also plays a key role. Instead of clip it at 1, we use a non-clipped BP,  $BP = e^{(1-p_n^2)}$ , for sentence-level BLEU<sup>1</sup>. We further scale the reference length,  $r$ , by a factor such that the total length of references on the training set equals that of the baseline output<sup>2</sup>.

<sup>1</sup> This is to better approximate corpus-level BLEU, i.e., as discussed in (Chiang, et al., 2008), the per-sentence BP might effectively exceed unity in corpus-level BLEU computation.

<sup>2</sup> This is to focus the training on improving BLEU by improving  $n$ -gram match instead of by improving BP, e.g., this makes the BP of the baseline output already being perfect.

### 4.3.3. Training procedure

The parameter set  $\theta$  is optimized on the training set while the feature weights  $\lambda$  are tuned on a small tuning set<sup>3</sup>. Since  $\theta$  and  $\lambda$  affect the training of each other, we train them in alternation. I.e., at each iteration, we first fix  $\lambda$  and update  $\theta$ , then we re-tune  $\lambda$  given the new  $\theta$ . Due to mismatch between training and tuning data, the training process might not always converge. Therefore, we need a validation set to determine the stop point of training. At the end,  $\theta$  and  $\lambda$  that give the best score on the validation set are selected and applied to the test set. Fig. 1 gives a summary of the training procedure. Note that step 2 and 4 are parallelize-able across multiple processors.

## 5. Evaluation

In evaluating the proposed method, we use two separate datasets. We first describe the experiments with the *Europarl* dataset (Koehn 2002), followed by the experiments with the more recent IWSLT-2011 task (Federico et al., 2011).

### 5.1 Experimental setup in the Europarl task

In evaluating the proposed method, we use two separate datasets. First, we conduct experiments on the *Europarl* German-to-English dataset. The training corpus contains 751K sentence pairs, 21 words per sentence on average. 2000 sentences are provided in the development set. We use the first 1000 sentences for  $\lambda$  tuning, and the rest for validation. The test set consists of 2000 sentences.

<sup>3</sup> Usually, the tuning set matches the test condition better, and therefore is preferable for  $\lambda$  tuning.

To build the baseline phrase-based SMT system, we first perform word alignment on the training set using a hidden Markov model with lexicalized distortion (He 2007), then extract the phrase table from the word aligned bilingual texts (Koehn et al., 2003). The maximum phrase length is set to four. Other models used in the baseline system include lexicalized ordering model, word count and phrase count, and a 3-gram LM trained on the English side of the parallel training corpus. Feature weights are tuned by MERT. A fast beam-search phrase-based decoder (Moore and Quirk 2007) is used and the distortion limit is set to four. Details of the phrase and lexicon translation models are given in Table 1. This baseline achieves a BLEU score of 26.22% on the test set. This baseline system is also used to generate a 100-best list of the training corpus during maximum expected BLEU training.

Translation model	# parameters
Phrase models (fore. & back.)	9.2 M
Lexicon model (IBM-1 src-to-tgt)	12.9 M
Lexicon model (IBM-1 tgt-to-src)	11.9 M

Table 1. Summary of phrase and lexicon translation models

### 5.2 Experimental results on the Europarl task

During training, we first tune the regularization factor  $\tau$  based on the performance on the validation set. For simplicity reasons, the tuning of  $\tau$  makes use of only the phrase translation models. Table 2 reports the BLEU scores and gains over the baseline given different values of  $\tau$ . The results highlight the importance of regularization. While  $\tau = 5 \times 10^{-5}$  gives the best score on the validation set, the gain is shown to be substantially reduced to merely 0.2 BLEU point when  $\tau = 0$ , i.e., no regularization. We set the optimal value of  $\tau = 5 \times 10^{-5}$  in all remaining experiments.

Test on Validation Set	BLEU%	$\Delta BLEU\%$
Baseline	26.70	--
$\tau = 0$ (no regularization)	26.91	+0.21
$\tau = 1 \times 10^{-5}$	27.31	+0.61
$\tau = 5 \times 10^{-5}$	27.44	+0.74
$\tau = 10 \times 10^{-5}$	27.27	+0.57

Table 2. Results on degrees of regularizations. BLEU scores are reported on the validation set.  $\Delta BLEU$  denotes the gain over the baseline.

Fixing the optimal regularization factor  $\tau$ , we then study the relationship between the expected

sentence-level BLEU (Exp. BLEU) score of N-best lists and the corpus-level BLEU score of 1-best translations. The conjectured close relationship between the two is important in justifying our use of the former as the training objective. Fig. 2 shows these two scores on the training set over training iterations. Since the expected BLEU is affected by  $\lambda$  strongly, we fix the value of  $\lambda$  in order to make the expected BLEU comparable across different iterations. From Fig. 2 it is clear that the expected BLEU score correlates strongly with the real BLEU score, justifying its use as our training objective.

Figure 2. Expected sentence BLEU and 1-best corpus BLEU on the 751K sentence of training data.

Next, we study the effects of training the phrase translation probabilities and the lexicon translation probabilities according to the GT formulas presented in the preceding section. The breakdown results are shown in Table 3. Compared with the baseline, training phrase or lexicon models alone gives a gain of 0.7 and 0.5 BLEU points, respectively, on the test set. For a full training of both phrase and lexicon models, we adopt two learning schedules: update both models together at each iteration (*simultaneously*), or update them in two stages (*two-stage*), where the phrase models are trained first until reaching the best score on the validation set and then the lexicon models are trained. Both learning schedules give significant improvements over the baseline and also over training phrase or lexicon models alone. The *two-stage* training of both models gives the best result of 27.33%, outperforming the baseline by 1.1 BLEU points.

More detail of the two-stage training is provided in Fig. 3, where BLEU scores in each stage are shown as a function of the GT training iteration. The phrase translation probabilities (PT) are trained alone in the first stage, shown in blue color. After five iterations, the BLEU score on the validation set reaches the peak value, with further iteration giving BLEU score fluctuation. Hence, we perform lexicon model (LEX) training starting from the sixth iteration with the corresponding BLEU scores shown in red color in Fig. 3. The BLEU score is further improved by 0.4 points after additional three iterations of training the lexicon models. In total, nine iterations are performed to complete the two-stage GT training of all phrase and lexicon models.

BLEU (%)	validation	test
Baseline	26.70	26.22
Train phrase models alone	27.44	26.94*
Train lexicon models alone	27.36	26.71
Both models: <i>simultaneously</i>	27.65	27.13*
Both models: <i>two-stage</i>	27.82	27.33*

Table 3. Results on the Europarl German-to-English dataset. The BLEU measures from various settings of maximum expected BLEU training are compared with the baseline, where \* denotes that the gain over the baseline is statistically significant with a significance level > 99%, measured by paired bootstrap resampling method proposed by Koehn (2004).

Figure 3. BLEU scores on the validation set as a function of the GT training iteration in two-stage training of both the phrase translation models (PT) and the lexicon models (LEX). The BLEU scores on training phrase models are shown in blue, and on training lexicon models in red.

### 5.3 Experiments on the IWSLT2011 benchmark

As the second evaluation task, we apply our new method described in this paper to the 2011 IWSLT Chinese-to-English machine translation benchmark (Federico et al., 2011). The main focus of the IWSLT2011 Evaluation is the translation of TED talks ([www.ted.com](http://www.ted.com)). These talks are originally given in English. In the Chinese-to-English translation task, we are provided with human translated Chinese text with punctuations inserted. The goal is to match the human transcribed English speech with punctuations.

This is an open-domain spoken language translation task. The training data consist of 110K sentences in the transcripts of the TED talks and their translations, in English and Chinese, respectively. Each sentence consists of 20 words on average. Two development sets are provided, namely, dev2010 and tst2010. They consist of 934 sentences and 1664 sentences, respectively. We use dev2010 for  $\lambda$  tuning and tst2010 for validation. The test set tst2011 consists of 1450 sentences.

In our system, a primary phrase table is trained from the 110K TED parallel training data, and a 3-gram LM is trained on the English side of the parallel data. We are also provided additional out-of-domain data for potential usage. From them, we train a secondary 5-gram LM on 115M sentences of supplementary English data, and a secondary phrase table from 500K sentences selected from the supplementary UN corpus by the method proposed by Axelrod et al. (2011).

In carrying out the maximum expected BLEU training, we use 100-best list and tune the regularization factor to the optimal value of  $\tau = 1 \times 10^{-5}$ . We only train the parameters of the primary phrase table. The secondary phrase table and LM are excluded from the training process since the out-of-domain phrase table is less relevant to the TED translation task, and the large LM slows down the N-best generation process significantly.

At the end, we perform one final MERT to tune the relative weights with all features including the secondary phrase table and LM.

The translation results are presented in Table 4. The baseline is a phrase-based system with all features including the secondary phrase table and LM. The new system uses the same features except that the primary phrase table is discriminatively

trained using maximum expected-BLEU and GT optimization as described earlier in this paper. The results are obtained using the two-stage training schedule, including six iterations for training phrase translation models and two iterations for training lexicon translation models. The results in Table 4 show that the proposed method leads to an improvement of 1.2 BLEU point over the baseline. This gives the best single system result on this task.

BLEU (%)	Validation	Test
Baseline	11.48	14.68
Max expected BLEU training	12.39	15.92

Table 4. The translation results on IWSLT 2011 MT\_CE task.

## 6. Summary

The contributions of this work can be summarized as follows. First, we propose a new objective function (Eq. 9) for training of large-scale translation models, including phrase and lexicon models, with more parameters than all previous methods have attempted. The objective function consists of 1) the utility function of expected BLEU score, and 2) the regularization term taking the form of KL divergence in the parameter space. The expected BLEU score is closely linked to translation quality and the regularization is essential when many parameters are trained at scale. The importance of both is verified experimentally with the results presented in this paper.

Second, through non-trivial derivation, we show that the novel objective function of Eq. (9) is amenable to iterative GT updates, where each update is equipped with a closed-form formula.

Third, the new objective function and new optimization technique are successfully applied to two important machine translation tasks, with implementation issues resolved (e.g., training schedule and hyper-parameter tuning, etc.). The superior results clearly demonstrate the effectiveness of the proposed algorithm.

## Acknowledgments

The authors are grateful to Chris Quirk, Mei-Yuh Hwang, and Bowen Zhou for the assistance with the MT system and/or for the valuable discussions.

## Abstract

In this paper, we address the issue for learning better translation consensus in machine translation (MT) research, and explore the search of translation consensus from similar, rather than the same, source sentences or their spans. Unlike previous work on this topic, we formulate the problem as structured labeling over a much smaller graph, and we propose a novel structured label propagation for the task. We convert such graph-based translation consensus from similar source strings into useful features both for n-best output re-ranking and for decoding algorithm. Experimental results show that, our method can significantly improve machine translation performance on both IWSLT and NIST data, compared with a state-of-the-art baseline.

## 1 Introduction

Consensus in translation has gained more and more attention in recent years. The principle of consensus can be sketched as “a translation candidate is deemed more plausible if it is supported by other translation candidates.” The actual formulation of the principle depends on whether the translation candidate is a complete sentence or just a span of it, whether the candidate is the same as or similar to the supporting candidates, and whether the supporting candidates come from the same or different MT system.

Translation consensus is employed in those minimum Bayes risk (MBR) approaches where the loss function of a translation is defined with respect to all other translation candidates. That is, the translation with the minimal Bayes risk is the one to the greatest extent similar to other candidates. These approaches include the work of Kumar and Byrne (2004), which re-ranks the n-best output of a MT decoder, and the work of Tromble et al. (2008) and Kumar et al. (2009), which does MBR decoding for lattices and hypergraphs.

Others extend consensus among translations from the same MT system to those from different MT systems. Collaborative decoding (Li et al., 2009) scores the translation of a source span by its n-gram similarity to the translations by other systems. Hypothesis mixture decoding (Duan et al., 2011) performs a second decoding process where the search space is enriched with new hypotheses composed out of existing hypotheses from multiple systems.

All these approaches are about utilizing consensus among translations for the same (span of) source sentence. It should be noted that consensus among translations of similar source sentences/spans is also helpful for good candidate selection. Consider the examples in Figure 1. For the source (Chinese) span “五百元以下的茶”, the MT system produced the correct translation for the second sentence, but it failed to do so for the first one. If the translation of the first sentence could take into consideration the translation of the second sentence, which is similar to but not exactly the same as the first one, the final translation output may be improved.

Following this line of reasoning, a discriminative learning method is proposed to constrain the translation of an input sentence using

the most similar translation examples from translation memory (TM) systems (Ma et al., 2011). A classifier is applied to re-rank the n-best output of a decoder, taking as features the information about the agreement with those similar translation examples. Alexandrescu and Kirchhoff (2009) proposed a graph-based semi-supervised model to re-rank n-best translation output. Note that these two attempts are about translation consensus for similar sentences, and about re-ranking of n-best output. It is still an open question whether translation consensus for similar sentences/spans can be applied to the decoding process. Moreover, the method in Alexandrescu and Kirchhoff (2009) is formulated as a typical and simple label propagation, which leads to very large graph, thus making learning and search inefficient. (c.f. Section 3.)

In this paper, we attempt to leverage translation consensus among similar (spans of) source sentences in bilingual training data, by a novel graph-based model of translation consensus. Unlike Alexandrescu and Kirchhoff (2009), we reformulate the task of seeking translation consensus among source sentences as structured labeling. We propose a novel label propagation algorithm for structured labeling, which is much more efficient than simple label propagation, and derive useful MT decoder features out of it. We conduct experiments with IWSLT and NIST data, and experimental results show that, our method

can improve the translation performance significantly on both data sets, compared with a state-of-the-art baseline.

## 2 Graph-based Translation Consensus

Our MT system with graph-based translation consensus adopts the conventional log-linear model. For the source string  $f$ , the conditional probability of a translation candidate  $e$  is defined as:

$$p(e|f) = \frac{\exp(\sum_i(\lambda_i\psi_i(e, f)))}{\sum_{e' \in H(f)}(\exp(\sum_i(\lambda_i\psi_i(e', f))))} \quad (1)$$

where  $\psi$  is the feature vector,  $\lambda$  is the feature weights, and  $H(f)$  is the set of translation hypotheses in the search space.

Based on the commonly used features, two kinds of feature are added to equation (1), one is graph-based consensus features, which are about consensus among the translations of *similar* sentences/spans; the other is local consensus features, which are about consensus among the translations of the *same* sentence/span. We develop a structured label propagation method, which can calculate consensus statistics from translation candidates of similar source sentences/spans.

In the following, we explain why the standard, simple label propagation is not suitable for translation consensus, and then introduce how the problem is formulated as an instance of structured labeling, with the proposed structured label propagation algorithm, in section 3. Before elaborating how the graph model of consensus is constructed for both a decoder and N-best output re-ranking in section 5, we will describe how the consensus features and their feature weights can be trained in a semi-supervised way, in section 4.

## 3 Graph-based Structured Learning

In general, a graph-based model assigns labels to instances by considering the labels of similar instances. A graph is constructed so that each instance is represented by a node, and the weight of the edge between a pair of nodes represents the similarity between them. The gist of graph-based model is that, if two instances are connected by a strong edge, then their labels tend to be the same (Zhu, 2005).

In MT, the instances are source sentences or spans of source sentences, and the possible labels are their translation candidates. This scenario differs from the general case of graph-based model in two aspects. First, there are an indefinite, or even intractable, number of labels. Each of them is a string of words rather than a simple category. In the following we will call these labels as structured labels (Berlett et al., 2004). Second, labels are highly ‘instance-dependent’. In most cases, for any two different (spans of) source sentences, however small their difference is, their correct labels (translations) are not exactly the same. Therefore, the principle of graph-based translation consensus must be reformulated as, if two instances (source spans) are similar, then their labels (translations) tend to be similar (rather than the same).

Note that Alexandrescu and Kirchhoff (2009) do not consider translation as structured labeling. In their graph, a node does not represent only a source sentence but a pair of source sentence and its candidate translation, and there are only two possible labels for each node, namely, 1 (this is a good translation pair) and 0 (this is not a good translation pair). Thus their graph-based model is a normal example of the general graph-based model. The biggest problem of such a perspective is inefficiency. An average MT decoder considers a vast amount of translation candidates for each source sentence, and therefore the corresponding graph also contains a vast amount of nodes, thus rendering learning over a large dataset is infeasible.

### 3.1 Label Propagation for General Graph-based Models

A general graph-based model is iteratively trained by label propagation, in which  $p_{i,l}$ , the probability of label  $l$  for the node  $i$ , is updated with respect to the corresponding probabilities for  $i$ ’s neighboring nodes  $N(i)$ . In Zhu (2005), the updating rule is expressed in a matrix calculation. For convenience, the updating rule is expressed for each label here:

$$p_{i,l}^{t+1} = \sum_{j \in N(i)} T(i,j) p_{j,l}^t \quad (2)$$

where  $T(i,j)$ , the propagating probability, is defined as:

$$T(i,j) = \frac{w_{i,j}}{\sum_{j' \in N(i)} w_{i,j'}} \quad (3)$$

$w_{i,j}$  defines the weight of the edge, which is a similarity measure between nodes  $i$  and  $j$ .

Note that the graph contains nodes for training instances, whose correct labels are known. The probability of the correct label to each training instance is reset to 1 at the end of each iteration. With a suitable measure of instance/node similarity, it is expected that an unlabeled instance/node will find the most suitable label from similar labeled nodes.

### 3.2 Structured Label Propagation for Graph-based Learning

In structured learning like MT, different instances would not have the same correct label, and so the updating rule (2) is no longer valid, as the value of  $p_{i,l}$  should not be calculated based on  $p_{j,l}$ . Here we need a new updating rule so that  $p_{i,l}$  can be updated with respect to  $p_{j,l'}$ , where in general  $l \neq l'$ .

Let us start with the model in Alexandrescu and Kirchhoff (2009). According to them, a node in the graph represents the pair of some source sentence/span  $f$  and its translation candidate  $e$ . The updating rule (for the label 1 or 0) is:

$$p_{(f,e)}^{t+1} = \sum_{(f',e') \in NP(f,e)} T((f,e), (f',e')) p_{(f',e')}^t \quad (4)$$

where  $NP(f,e)$  is the set of neighbors of the node  $(f,e)$ .

When the problem is reformulated as structured labeling, each node represents the source sentence/span only, and the translation candidates become labels. The propagating probability  $T((f,e), (f',e'))$  has to be reformulated accordingly. A natural way is to decompose it into a component for nodes and a component for labels. Assuming that the two components are independent, then:

$$T((f,e), (f',e')) = T_s(f,f') T_l(e,e') \quad (5)$$

where  $T_s(f,f')$  is the propagating probability from source sentence/span  $f'$  to  $f$ , and  $T_l(e,e')$  is that from translation candidate  $e'$  to  $e$ .

The set of neighbors  $NP(f,e)$  of a pair  $(f,e)$  has also to be reformulated in terms of the set of neighbors  $N(f)$  of a source sentence/span  $f$ :

$$NP(f,e) = \{(f',e') | f' \in N(f), e' \in H(f')\} \quad (6)$$

where  $H(f')$  is the set of translation candidates for source  $f'$ . The new updating rule will then be:

$$\begin{aligned} p_{f,e}^{t+1} &= \sum_{f' \in N(f), e' \in H(f')} T_s(f, f') T_l(e, e') p_{f',e'}^t \\ &= \sum_{f' \in N(f)} \sum_{e' \in H(f')} T_s(f, f') T_l(e, e') p_{f',e'}^t \\ &= \sum_{f' \in N(f)} T_s(f, f') \sum_{e' \in H(f')} T_l(e, e') p_{f',e'}^t \quad (7) \end{aligned}$$

The new rule updates the probability of a translation  $e$  of a source sentence/span  $f$  with probabilities of similar translations  $e'$ 's of some similar source sentences/spans  $f'$ 's.

Propagation probability  $T_s(f, f')$  is as defined in equation (3), and  $T_l(e, e')$  is defined given some similarity measure  $sim(e, e')$  between labels  $e$  and  $e'$ :

$$T_l(e, e') = \frac{sim(e, e')}{\sum_{e'' \in H(f')} sim(e, e'')} \quad (8)$$

Note that rule (2) is a special case of rule (7), when  $sim(e, e')$  is defined as:

$$sim(e, e') = \begin{cases} 1 & \text{if } e = e'; \\ 0 & \text{otherwise;} \end{cases}$$

## 4 Features and Training

The last section sketched the structured label propagation algorithm. Before elaborating the details of how the actual graph is constructed, we would like to first introduce how the graph-based translation consensus can be used in an MT system.

### 4.1 Graph-based Consensus Features

The probability as estimated in equation (7) is taken as a group of new features in either a decoder or an n-best output re-ranker. We will call these features collectively as graph-based consensus features (GC):

$$\begin{aligned} GC(e, f) &= \\ \log \left( \sum_{f' \in N(f)} T_s(f, f') \sum_{e' \in H(f')} T_l(e, e') p_{f',e'}^t \right) \end{aligned} \quad (9)$$

Recall that,  $N(f)$  refers to source sentences/spans which are similar with  $f$ , and  $H(f')$  refers to

translation candidates of  $f'$ .  $p_{f',e'}$  is initialized with the translation posterior of  $e'$  given  $f'$ . The translation posterior is normalized in the n-best list. For the nodes representing the training sentence pairs, this posterior is fixed.  $T_l(e, e')$  is the propagating probability in equation (8), with the similarity measure  $sim(e, e')$  defined as the Dice co-efficient over the set of all n-grams in  $e$  and those in  $e'$ . That is,

$$sim(e, e') = Dice(NGr_n(e), NGr_n(e'))$$

where  $NGr_n(x)$  is the set of  $n$ -grams in string  $x$ , and  $Dice(A, B)$  is the Dice co-efficient over sets  $A$  and  $B$ :

$$Dice(A, B) = \frac{2|A \cap B|}{|A| + |B|}$$

We take  $1 \leq n \leq 4$  for similarity between translation candidates, thus leading to four features. The other propagating probability  $T_s(f, f')$ , as defined in equation (3), takes symmetrical sentence level BLEU as similarity measure<sup>1</sup>:

$$w_{f,f'} = \frac{1}{2} (BLEU_{sent}(f, f') + BLEU_{sent}(f', f))$$

where  $BLEU_{sent}(f, f')$  is defined as follows (Liang et al., 2006):

$$BLEU_{sent}(f, f') = \sum_{i=1}^4 \frac{i - BLEU(f, f')}{2^{4-i+1}} \quad (10)$$

where  $i - BLEU(f, f')$  is the IBM BLEU score computed over  $i$ -grams for hypothesis  $f$  using  $f'$  as reference.

In theory we could use other similarity measures such as edit distance, string kernel. Here simple n-gram similarity is used for the sake of efficiency.

### 4.2 Other Features

In addition to graph-based consensus features, we also propose local consensus features, defined over the n-best translation candidates as:

$$LC(e, f) = \log \left( \sum_{e' \in H(f)} p(e'|f) T_l(e, e') \right) \quad (11)$$

<sup>1</sup> BLEU is not symmetric, which means, different scores are obtained depending on which one is reference and which one is hypothesis.

where  $p(e'|f)$  is translation posterior. Like  $GC$ , there are four features with respect to the value of  $n$  in  $n$ -gram similarity measure.

We also use other fundamental features, such as translation probabilities, lexical weights, distortion probability, word penalty, and language model probability.

### 4.3 Training Method

When graph-based consensus is applied to an MT system, the graph will have nodes for training data, development (dev) data, and test data (details in Section 5). There is only one label/translation for each training data node. For each dev/test data node, the possible labels are the  $n$ -best translation candidates from the decoder. Note that there is mutual dependence between the consensus graph and the decoder. On the one hand, the MT decoder depends on the graph for the  $GC$  features. On the other hand, the graph needs the decoder to provide the translation candidates as possible labels, and their posterior probabilities as initial values of various  $p_{f,e}$ . Therefore, we can alternatively update graph-based consensus features and feature weights in the log-linear model.

---

#### Algorithm 1 Semi-Supervised Learning

---

```

 $GC^0 = 0;$ 
 $\lambda^t = \text{MERT}(S^{dev}, T^{dev}, GC^0);$ 
while not converged do
   $G^t = \text{CreatG}(S^{train}, T^{train}, S^{dev}, S^{test}, \lambda^t).$ 
   $GC^{t+1} = \text{StructLP}(G^t).$ 
   $\lambda^{t+1} = \text{MERT}(S^{dev}, T^{dev}, GC^{t+1})$ 
end while
return last  $(GC^t, \lambda^t)$ 

```

---

Algorithm 1 outlines our semi-supervised method for such alternative training. The entire process starts with a decoder without consensus features. Then a graph is constructed out of all training, dev, and test data. The subsequent structured label propagation provides  $GC$  feature values to the MT decoder. The decoder then adds the new features and re-trains all the feature weights by Minimum Error Rate Training (MERT) (Och, 2003). The decoder with new feature weights then provides new  $n$ -best candidates and their posteriors for constructing another consensus graph, which in turn gives rise to next round of

Figure 2. A toy graph constructed for re-ranking.

MERT. This alternation of structured label propagation and MERT stops when the BLEU score on dev data converges, or a pre-set limit (10 rounds) is reached.

## 5 Graph Construction

A technical detail is still needed to complete the description of graph-based consensus, namely, how the actual consensus graph is constructed. We will divide the discussion into two sections regarding how the graph is used.

### 5.1 Graph Construction for Re-Ranking

When graph-based consensus is used for re-ranking the  $n$ -best outputs of a decoder, each node in the graph corresponds to a complete sentence. A separate node is created for each source sentence in training data, dev data, and test data. For any node from training data (henceforth training node), it is labeled with the correct translation, and  $p_{f,e}$  is fixed as 1. If there are sentence pairs with the same source sentence but different translations, all the translations will be assigned as labels to that source sentence, and the corresponding probabilities are estimated by MLE. There is no edge between training nodes, since we suppose all the sentences of the training data are correct, and it is pointless to re-estimate the confidence of those sentence pairs.

Each node from dev/test data (henceforth test node) is unlabeled, but it will be given an  $n$ -best list of translation candidates as possible labels from a MT decoder. The decoder also provides translation posteriors as the initial confidences of

the labels. A test node can be connected to training nodes and other test nodes. If the source sentences of a test node and some other node are sufficiently similar, a similarity edge is created between them. In our experiment we measure similarity by symmetrical sentence level BLEU of source sentences, and 0.3 is taken as the threshold for edge creation.

Figure 2 shows a toy example graph. Each node is depicted as rectangle with the upper half showing the source sentence and the lower half showing the correct or possible labels. Training nodes are in grey while test nodes are in white. The edges between the nodes are weighted by the similarities between the corresponding source sentences.

## 5.2 Graph Construction for Decoding

Graph-based consensus can also be used in the decoding algorithm, by re-ranking the translation candidates of not only the entire source sentence but also every source span. Accordingly the graph does not contain only the nodes for source sentences but also the nodes for all source spans. It is needed to find the candidate labels for each source span.

It is not difficult to handle test nodes, since the purpose of MT decoder is to get all possible segmentations of a source sentence in dev/test data, search for the translation candidates of each source span, and calculate the probabilities of the candidates. Therefore, the cells in the search space of a decoder can be directly mapped as test nodes in the graph.

Training nodes can be handled similarly, by applying forced alignment. Forced alignment performs phrase segmentation and alignment of each sentence pair of the training data using the full translation system as in decoding (Wuebker et al., 2010). In simpler term, for each sentence pair in training data, a decoder is applied to the source side, and all the translation candidates that do not match any substring of the target side are deleted. The cells of in such a reduced search space of the decoder can be directly mapped as training nodes in the graph, just as in the case of test nodes. Note that, due to pruning in both decoding and translation model training, forced alignment may fail, i.e. the decoder may not be able to produce target side of a sentence pair. In such case we still map the cells in the search space as training nodes.

Figure 3. A toy example graph for decoding. Edges in dash line indicate relation between a span and its sub-span, whereas edges of solid line indicate source side similarity.

Note also that the shorter a source span is, the more likely it appears in more than one source sentence. All the translation candidates of the same source span in different source sentences are merged.

Edge creation is the same as that in graph construction for n-best re-ranking, except that two nodes are always connected if they are about a span and its sub-span. This exception ensures that shorter spans can always receive propagation from longer ones, and vice versa.

Figure 3 shows a toy example. There is one node for the training sentence "E A M N" and two nodes for the test sentences "E A B C" and "F D B C". All the other nodes represent spans. The node "M N" and "E A" are created according to the forced alignment result of the sentence "E A M N". As we see, the translation candidates for "M N" and "E A" are not the sub-strings from the target sentence of "E A M N". There are two kinds of edges. Dash lines are edges connecting nodes of a span and its sub-span, such as the one between "E A B C" and "E". Solid lines are edges connecting nodes with sufficient source side n-gram similarity, such as the one between "E A M N" and "E A B C".

## 6 Experiments and Results

In this section, graph-based translation consensus is tested on the Chinese to English translation tasks. The evaluation method is the case insensitive IBM BLEU-4 (Papineni et al., 2002). Significant testing is carried out using bootstrap re-sampling method proposed by Koehn (2004) with a 95% confidence level.

### 6.1 Experimental Data Setting and Baselines

We test our method with two data settings: one is IWSLT data set, the other is NIST data set. Our baseline decoder is an in-house implementation of Bracketing Transduction Grammar (Dekai Wu, 1997) (BTG) in CKY-style decoding with a lexical reordering model trained with maximum entropy (Xiong et al., 2006). The features we used are commonly used features as standard BTG decoder, such as translation probabilities, lexical weights, language model, word penalty and distortion probabilities.

Our IWSLT data is the IWSLT 2009 dialog task data set. The training data include the BTEC and SLDB training data. The training data contains 81k sentence pairs, 655k Chinese words and 806 English words. The language model is 5-gram language model trained with the target sentences in the training data. The test set is devset9, and the development set for MERT comprises both devset8 and the Chinese DIALOG set. The baseline results on IWSLT data are shown in Table 1.

	devset8+dialog	devset9
Baseline	48.79	44.73

Table 1. Baselines for IWSLT data

For the NIST data set, the bilingual training data we used is NIST 2008 training set excluding the Hong Kong Law and Hong Kong Hansard. The training data contains 354k sentence pairs, 8M Chinese words and 10M English words. The language model is 5-gram language model trained with the Giga-Word corpus plus the English sentences in the training data. The development data utilized to tune the feature weights of our decoder is NIST’03 evaluation set, and test sets are NIST’05 and NIST’08 evaluation sets. The baseline results on NIST data are shown in Table 2.

	NIST’03	NIST’05	NIST’08
Baseline	38.57	38.21	27.52

Table 2. Baselines for NIST data

### 6.2 Experimental Result

Table 3 shows the performance of our consensus-based re-ranking and decoding on the IWSLT data set. To perform consensus-based re-ranking, we first use the baseline decoder to get the n-best list for each sentence of development and test data, then we create graph using the n-best lists and training data as we described in section 5.1, and perform semi-supervised training as mentioned in section 4.3. As we can see from Table 3, our consensus-based re-ranking (G-Re-Rank) outperforms the baseline significantly, not only for the development data, but also for the test data.

Instead of using graph-based consensus confidence as features in the log-linear model, we perform structured label propagation (Struct-LP) to re-rank the n-best list directly, and the similarity measures for source sentences and translation candidates are symmetrical sentence level BLEU (equation (10)). Using Struct-LP, the performance is significantly improved, compared with the baseline, but not as well as G-Re-Rank.

	devset8+dialog	devset9
Baseline	48.79	44.73
Struct-LP	<b>49.86</b>	<b>45.54</b>
G-Re-Rank	<b>50.66</b>	<b>46.52</b>
G-Re-Rank-GC	<b>50.23</b>	<b>45.96</b>
G-Re-Rank-LC	<b>49.87</b>	<b>45.84</b>
G-Decode	<b>51.20</b>	<b>47.31</b>
G-Decode-GC	<b>50.46</b>	<b>46.21</b>
G-Decode-LC	<b>50.11</b>	<b>46.17</b>

Table 3. Consensus-based re-ranking and decoding for IWSLT data set. The results in bold type are significantly better than the baseline.

We use the baseline system to perform forced alignment procedure on the training data, and create span nodes using the derivation tree of the forced alignment. We also saved the spans of the sentences from development and test data, which will be used to create the responding nodes for consensus-based decoding. In such a way, we create the graph for decoding, and perform semi-

supervised training to calculate graph-based consensus features, and tune the weights for all the features we used. In Table 3, we can see that our consensus-based decoding (G-Decode) is much better than baseline, and also better than consensus-based re-ranking method. That is reasonable since the neighbor/local similarity features not only re-rank the final n-best output, but also the spans during decoding.

To test the contribution of each kind of features, we first remove all the local consensus features and perform consensus-based re-ranking and decoding (G-Re-Rank-GC and G-Decode-GC), and then we remove all the graph-based consensus features to test the contribution of local consensus features (G-Re-Rank-LC and G-Decode-LC). Without the graph-based consensus features, our consensus-based re-ranking and decoding is simplified into a consensus re-ranking and consensus decoding system, which only re-rank the candidates according to the consensus information of other candidates in the same n-best list.

From Table 3, we can see, the G-Re-Rank-LC and G-Decode-LC improve the performance of development data and test data, but not as much as G-Re-Rank and G-Decode do. G-Re-Rank-GC and G-Decode-GC improve the performance of machine translation according to the baseline. G-Re-Rank-GC does not achieve the same performance as G-Re-Rank-LC does. Compared with G-Decode-LC, the performance with G-Decode-GC is much better.

	NIST'03	NIST'05	NIST'08
Baseline	38.57	38.21	27.52
Struct-LP	38.79	38.52	28.06
G-Re-Rank	<b>39.21</b>	<b>38.93</b>	<b>28.18</b>
G-Re-Rank-GC	38.92	38.76	<b>28.21</b>
G-Re-Rank-LC	38.90	38.65	27.88
G-Decode	<b>39.62</b>	<b>39.17</b>	<b>28.76</b>
G-Decode-GC	<b>39.42</b>	<b>39.02</b>	<b>28.51</b>
G-Decode-LC	39.17	38.70	<b>28.20</b>

Table 4. Consensus-based re-ranking and decoding for NIST data set. The results in bold type are significantly better than the baseline.

We also conduct experiments on NIST data, and results are shown in Table 4. The consensus-based

re-ranking methods are performed in the same way as for IWSLT data, but for consensus-based decoding, the data set contains too many sentence pairs to be held in one graph for our machine. We apply the method of Alexandrescu and Kirchhoff (2009) to construct separate graphs for each development and test sentence without losing global connectivity information. We perform modified label propagation with the separate graphs to get the graph-based consensus for n-best list of each sentence, and the graph-based consensus will be recorded for the MERT to tune the weights.

From Table 4, we can see that, Struct-LP improves the performance slightly, but not significantly. Local consensus features (G-Re-Rank-LC and G-Decode-LC) improve the performance slightly. The combination of graph-based and local consensus features can improve the translation performance significantly on SMT re-ranking. With graph-based consensus features, G-Decode-GC achieves significant performance gain, and combined with local consensus features, G-Decode performance is improved farther.

## 7 Conclusion and Future Work

In this paper, we extend the consensus method by collecting consensus statistics, not only from translation candidates of the same source sentence/span, but also from those of similar ones. To calculate consensus statistics, we develop a novel structured label propagation method for structured learning problems, such as machine translation. Note that, the structured label propagation can be applied to other structured learning tasks, such as POS tagging and syntactic parsing. The consensus statistics are integrated into the conventional log-linear model as features. The features and weights are tuned with an iterative semi-supervised method. We conduct experiments on IWSLT and NIST data, and our method can improve the performance significantly.

In this paper, we only tried Dice co-efficient of n-grams and symmetrical sentence level BLEU as similarity measures. In the future, we will explore other consensus features and other similarity measures, which may take document level information, or syntactic and semantic information into consideration. We also plan to introduce feature to model the similarity of the source

sentences, which are reflected by only one score in our paper, and optimize the parameters with CRF model.

# Smaller Alignment Models for Better Translations: Unsupervised Word Alignment with the $\ell_0$ -norm

Ashish Vaswani    Liang Huang    David Chiang

## Abstract

Two decades after their invention, the IBM word-based translation models, widely available in the GIZA++ toolkit, remain the dominant approach to word alignment and an integral part of many statistical translation systems. Although many models have surpassed them in accuracy, none have supplanted them in practice. In this paper, we propose a simple extension to the IBM models: an  $\ell_0$  prior to encourage sparsity in the word-to-word translation model. We explain how to implement this extension efficiently for large-scale data (also released as a modification to GIZA++) and demonstrate, in experiments on Czech, Arabic, Chinese, and Urdu to English translation, significant improvements over IBM Model 4 in both word alignment (up to +6.7 F1) and translation quality (up to +1.4 BLEU).

## 1 Introduction

Automatic word alignment is a vital component of nearly all current statistical translation pipelines. Although state-of-the-art translation models use rules that operate on units bigger than words (like phrases or tree fragments), they nearly always use word alignments to drive extraction of those translation rules. The dominant approach to word alignment has been the IBM models (Brown et al., 1993) together with the HMM model (Vogel et al., 1996). These models are unsupervised, making them applicable to any language pair for which parallel text is available. Moreover, they are widely disseminated in the open-source GIZA++ toolkit (Och and Ney, 2004). These properties make them the default choice for most statistical MT systems.

In the decades since their invention, many models have surpassed them in accuracy, but none has supplanted them in practice. Some of these models are partially supervised, combining unlabeled parallel text with manually-aligned parallel text (Moore, 2005; Taskar et al., 2005; Riesa and Marcu, 2010). Although manually-aligned data is very valuable, it is only available for a small number of language pairs. Other models are unsupervised like the IBM models (Liang et al., 2006; Graça et al., 2010; Dyer et al., 2011), but have not been as widely adopted as GIZA++ has.

In this paper, we propose a simple extension to the IBM/HMM models that is unsupervised like the IBM models, is as scalable as GIZA++ because it is implemented on top of GIZA++, and provides significant improvements in both alignment and translation quality. It extends the IBM/HMM models by incorporating an  $\ell_0$  prior, inspired by the principle of minimum description length (Barron et al., 1998), to encourage sparsity in the word-to-word translation model (Section 2.2). This extension follows our previous work on unsupervised part-of-speech tagging (Vaswani et al., 2010), but enables it to scale to the large datasets typical in word alignment, using an efficient training method based on projected gradient descent (Section 2.3). Experiments on Czech-, Arabic-, Chinese- and Urdu-English translation (Section 3) demonstrate consistent significant improvements over IBM Model 4 in both word alignment (up to +6.7 F1) and translation quality (up to +1.4 BLEU). Our implementation has been released as a simple modification to the GIZA++ toolkit that can be used as a drop-in replacement for GIZA++ in any existing MT pipeline.

## 2 Method

We start with a brief review of the IBM and HMM word alignment models, then describe how to extend them with a smoothed  $\ell_0$  prior and how to efficiently train them.

### 2.1 IBM Models and HMM

Given a French string  $\mathbf{f} = f_1 \cdots f_j \cdots f_m$  and an English string  $\mathbf{e} = e_1 \cdots e_i \cdots e_\ell$ , these models describe the process by which the French string is generated by the English string via the alignment  $\mathbf{a} = a_1, \dots, a_j, \dots, a_m$ . Each  $a_j$  is a hidden variable, indicating which English word  $e_{a_j}$  the French word  $f_j$  is aligned to.

In IBM Model 1–2 and the HMM model, the joint probability of the French sentence and alignment given the English sentence is

$$P(\mathbf{f}, \mathbf{a} | \mathbf{e}) = \prod_{j=1}^m d(a_j | a_{j-1}, j) t(f_j | e_{a_j}). \quad (1)$$

The parameters of these models are the distortion probabilities  $d(a_j | a_{j-1}, j)$  and the translation probabilities  $t(f_j | e_{a_j})$ . The three models differ in their estimation of  $d$ , but the differences do not concern us here. All three models, as well as IBM Models 3–5, share the same  $t$ . For further details of these models, the reader is referred to the original papers describing them (Brown et al., 1993; Vogel et al., 1996).

Let  $\theta$  stand for all the parameters of the model. The standard training procedure is to find the parameter values that maximize the likelihood, or, equivalently, minimize the negative log-likelihood of the observed data:

$$\hat{\theta} = \arg \min_{\theta} (-\log P(\mathbf{f} | \mathbf{e}, \theta)) \quad (2)$$

$$= \arg \min_{\theta} \left( -\log \sum_{\mathbf{a}} P(\mathbf{f}, \mathbf{a} | \mathbf{e}, \theta) \right) \quad (3)$$

This is done using the Expectation-Maximization (EM) algorithm (Dempster et al., 1977).

### 2.2 MAP-EM with the $\ell_0$ -norm

Maximum likelihood training is prone to overfitting, especially in models with many parameters. In word alignment, one well-known manifestation of overfitting is that rare words can act as “garbage collectors”

(Moore, 2004), aligning to many unrelated words. This hurts alignment precision and rule-extraction recall. Previous attempted remedies include early stopping, smoothing (Moore, 2004), and posterior regularization (Graça et al., 2010).

We have previously proposed another simple remedy to overfitting in the context of unsupervised part-of-speech tagging (Vaswani et al., 2010), which is to minimize the size of the model using a smoothed  $\ell_0$  prior. Applying this prior to an HMM improves tagging accuracy for both Italian and English.

Here, our goal is to apply a similar prior in a word-alignment model to the word-to-word translation probabilities  $t(f | e)$ . We leave the distortion models alone, since they are not very large, and there is not much reason to believe that we can profit from compacting them.

With the addition of the  $\ell_0$  prior, the MAP (maximum *a posteriori*) objective function is

$$\hat{\theta} = \arg \min_{\theta} (-\log P(\mathbf{f} | \mathbf{e}, \theta) P(\theta)) \quad (4)$$

where

$$P(\theta) \propto \exp(-\alpha \|\theta\|_0^\beta) \quad (5)$$

and

$$\|\theta\|_0^\beta = \sum_{e,f} \left( 1 - \exp\left(-\frac{t(f|e)}{\beta}\right) \right) \quad (6)$$

is a smoothed approximation of the  $\ell_0$ -norm. The hyperparameter  $\beta$  controls the tightness of the approximation, as illustrated in Figure 1. Substituting back into (4) and dropping constant terms, we get the following optimization problem: minimize

$$-\log P(\mathbf{f} | \mathbf{e}, \theta) - \alpha \sum_{e,f} \exp\left(-\frac{t(f|e)}{\beta}\right) \quad (7)$$

subject to the constraints

$$\sum_f t(f|e) = 1 \quad \text{for all } e. \quad (8)$$

We can carry out the optimization in (7) with the MAP-EM algorithm (Bishop, 2006). EM and MAP-EM share the same E-step; the difference lies in the

Figure 1: The  $\ell_0$ -norm (top curve) and smoothed approximations (below) for  $\beta = 0.05, 0.1, 0.2$ .

M-step. For vanilla EM, the M-step is:

$$\hat{\theta} = \arg \min_{\theta} \left( - \sum_{e,f} E[C(e, f)] \log t(f | e) \right) \quad (9)$$

again subject to the constraints (8). The count  $C(e, f)$  is the number of times that  $f$  occurs aligned to  $e$ . For MAP-EM, it is:

$$\hat{\theta} = \arg \min_{\theta} \left( - \sum_{e,f} E[C(e, f)] \log t(f | e) - \alpha \sum_{e,f} \exp \frac{-t(f | e)}{\beta} \right) \quad (10)$$

This optimization problem is non-convex, and we do not know of a closed-form solution. Previously (Vaswani et al., 2010), we used ALGENCAN, a non-linear optimization toolkit, but this solution does not scale well to the number of parameters involved in word alignment models. Instead, we use a simpler and more scalable method which we describe in the next section.

### 2.3 Projected gradient descent

Following Schoenemann (2011b), we use projected gradient descent (PGD) to solve the M-step (but with the  $\ell_0$ -norm instead of the  $\ell_1$ -norm). Gradient projection methods are attractive solutions to constrained optimization problems, particularly when the constraints on the parameters are simple (Bertsekas, 1999). Let  $F(\theta)$  be the objective function in

(10); we seek to minimize this function. As in previous work (Vaswani et al., 2010), we optimize each set of parameters  $\{t(\cdot | e)\}$  separately for each English word type  $e$ . The inputs to the PGD are the expected counts  $E[C(e, f)]$  and the current word-to-word conditional probabilities  $\theta$ . We run PGD for  $K$  iterations, producing a sequence of intermediate parameter vectors  $\theta^1, \dots, \theta^k, \dots, \theta^K$ . Each iteration has two steps, a projection step and a line search.

**Projection step** In this step, we compute:

$$\bar{\theta}^k = [\theta^k - s \nabla F(\theta^k)]^{\Delta} \quad (11)$$

This moves  $\theta$  in the direction of steepest descent ( $\nabla F$ ) with step size  $s$ , and then the function  $[\cdot]^{\Delta}$  projects the resulting point onto the simplex; that is, it finds the nearest point that satisfies the constraints (8).

The gradient  $\nabla F(\theta^k)$  is

$$\frac{\partial F}{\partial t(f | e)} = - \frac{E[C(f, e)]}{t(f | e)} + \frac{\alpha}{\beta} \exp \frac{-t(f | e)}{\beta} \quad (12)$$

In contrast to Schoenemann (2011b), we use an  $O(n \log n)$  algorithm for the projection step due to Duchi et al. (2008), shown in Pseudocode 1.

---

**Pseudocode 1** Project input vector  $\mathbf{u} \in \mathbb{R}^n$  onto the probability simplex.

---

```

 $\mathbf{v} = \mathbf{u}$  sorted in non-increasing order
 $\rho = 0$ 
for  $i = 1$  to  $n$  do
  if  $v_i - \frac{1}{i} (\sum_{r=1}^i v_r - 1) > 0$  then
     $\rho = i$ 
  end if
end for
 $\eta = \frac{1}{\rho} (\sum_{r=1}^{\rho} v_r - 1)$ 
 $w_r = \max\{v_r - \eta, 0\}$  for  $1 \leq r \leq n$ 
return  $\mathbf{w}$ 

```

---

**Line search** Next, we move to a point between  $\theta^k$  and  $\bar{\theta}^k$  that satisfies the *Armijo condition*,

$$F(\theta^k + \delta_m) \leq F(\theta^k) + \sigma (\nabla F(\theta^k) \cdot \delta_m) \quad (13)$$

where  $\delta_m = \gamma^m (\bar{\theta}^k - \theta^k)$  and  $\sigma$  and  $\gamma$  are both constants in  $(0, 1)$ . We try values  $m = 1, 2, \dots$  until the Armijo condition (13) is satisfied or the limit  $m = 20$

---

**Pseudocode 2** Find a point between  $\theta^k$  and  $\bar{\theta}^k$  that satisfies the Armijo condition.

---

```

 $F_{min} = F(\theta^k)$ 
 $\theta_{min} = \theta^k$ 
for  $m = 1$  to  $20$  do
   $\delta_m = \gamma^m (\bar{\theta}^k - \theta^k)$ 
  if  $F(\theta^k + \delta_m) < F_{min}$  then
     $F_{min} = F(\theta^k + \delta_m)$ 
     $\theta_{min} = \theta^k + \delta_m$ 
  end if
  if  $F(\theta^k + \delta_m) \leq F(\theta^k) + \sigma (\nabla F(\theta^k) \cdot \delta_m)$  then
    break
  end if
end for
 $\theta^{k+1} = \theta_{min}$ 
return  $\theta^{k+1}$ 

```

---

is reached. (Note that we don't allow  $m = 0$  because this can cause  $\theta^k + \delta_m$  to land on the boundary of the probability simplex, where the objective function is undefined.) Then we set  $\theta^{k+1}$  to the point in  $\{\theta^k\} \cup \{\theta^k + \delta_m \mid 1 \leq m \leq 20\}$  that minimizes  $F$ . The line search algorithm is summarized in Pseudocode 2.

In our implementation, we set  $\gamma = 0.5$  and  $\sigma = 0.5$ . We keep  $s$  fixed for all PGD iterations; we experimented with  $s \in \{0.1, 0.5\}$  and did not observe significant changes in F-score. We run the projection step and line search alternately for at most  $K$  iterations, terminating early if there is no change in  $\theta^k$  from one iteration to the next. We set  $K = 35$  for the large Arabic-English experiment; for all other conditions, we set  $K = 50$ . These choices were made to balance efficiency and accuracy. We found that values of  $K$  between 30 and 75 were generally reasonable.

### 3 Experiments

To demonstrate the effect of the  $\ell_0$ -norm on the IBM models, we performed experiments on four translation tasks: Arabic-English, Chinese-English, and Urdu-English from the NIST Open MT Evaluation, and the Czech-English translation from the Workshop on Machine Translation (WMT) shared task. We measured the accuracy of word alignments generated by GIZA++ with and without the  $\ell_0$ -norm,

and also translation accuracy of systems trained using the word alignments. Across all tests, we found strong improvements from adding the  $\ell_0$ -norm.

#### 3.1 Training

We have implemented our algorithm as an open-source extension to GIZA++.<sup>1</sup> Usage of the extension is identical to standard GIZA++, except that the user can switch the  $\ell_0$  prior on or off, and adjust the hyperparameters  $\alpha$  and  $\beta$ .

For vanilla EM, we ran five iterations of Model 1, five iterations of HMM, and ten iterations of Model 4. For our approach, we first ran one iteration of Model 1, followed by four iterations of Model 1 with smoothed  $\ell_0$ , followed by five iterations of HMM with smoothed  $\ell_0$ . Finally, we ran ten iterations of Model 4.<sup>2</sup>

We used the following parallel data:

- Chinese-English: selected data from the constrained task of the NIST 2009 Open MT Evaluation.<sup>3</sup>
- Arabic-English: all available data for the constrained track of NIST 2009, excluding United Nations proceedings (LDC2004E13), ISI Automatically Extracted Parallel Text (LDC2007E08), and Ummah newswire text (LDC2004T18), for a total of 5.4+4.3 million words. We also experimented on a larger Arabic-English parallel text of 44+37 million words from the DARPA GALE program.
- Urdu-English: all available data for the constrained track of NIST 2009.

---

<sup>1</sup>The code can be downloaded from the first author's website at <http://www.isi.edu/~avaswani/giza-pp-10.html>.

<sup>2</sup>GIZA++ allows changing some heuristic parameters for efficient training. Currently, we set two of these to zero: `mincountincrease` and `probcutoff`. In the default setting, both are set to  $10^{-7}$ . We set `probcutoff` to 0 because we would like the optimization to learn the parameter values. For a fair comparison, we applied the same setting to our vanilla EM training as well. To test, we ran GIZA++ with the default setting on the smaller of our two Arabic-English datasets with the same number of iterations and found no change in F-score.

<sup>3</sup>LDC catalog numbers LDC2003E07, LDC2003E14, LDC2005E83, LDC2005T06, LDC2006E24, LDC2006E34, LDC2006E85, LDC2006E86, LDC2006E92, and LDC2006E93.

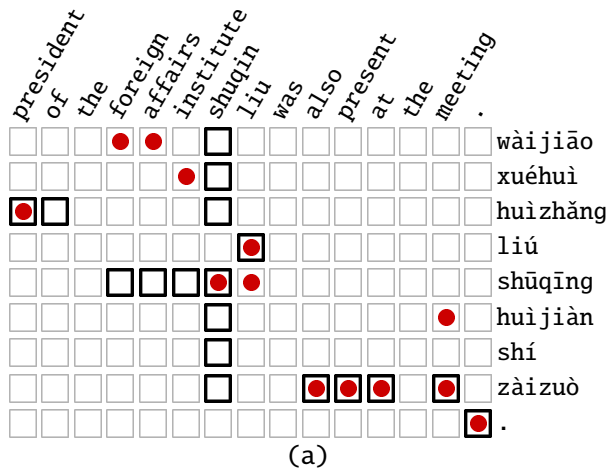

Figure 2: Smoothed- $\ell_0$  alignments (red circles) correct many errors in the baseline GIZA++ alignments (black squares), as shown in four Chinese-English examples (the red circles are almost perfect for these examples, except for minor mistakes such as liu-shūqīng and meeting-zàizuò in (a) and .-, in (c)). In particular, the baseline system demonstrates typical “garbage-collection” phenomena in proper name “shuqing” in both languages in (a), number “4000” and word “lái bīn” (lit. “guest”) in (b), word “troublesome” and “lù lù” (lit. “land-route”) in (c), and “blockhouses” and “diào bǎo” (lit. “bunker”) in (d). We found this garbage-collection behavior to be especially common with proper names, numbers, and uncommon words in both languages. Most interestingly, in (c), our smoothed- $\ell_0$  system correctly aligns “extremely” to “hěn hěn hěn hěn” (lit. “very very very very”) which is rare in the bitext.

task	data (M)	system	align F1 (%)	word trans (M)	$\tilde{\phi}_{sing.}$	B (%)		
						2008	2009	2010
Chi-Eng	9.6+12	baseline	73.2	3.5	6.2	28.7		
		$\ell_0$ -norm	76.5	2.0	3.3	29.5		
		difference	+3.3	-43%	-47%	+0.8		
Ara-Eng	5.4+4.3	baseline	65.0	3.1	4.5	39.8	42.5	
		$\ell_0$ -norm	70.8	1.8	1.8	41.1	43.7	
		difference	+5.9	-39%	-60%	+1.3	+1.2	
Ara-Eng	44+37	baseline	66.2	15	5.0	41.6	44.9	
		$\ell_0$ -norm	71.8	7.9	1.8	42.5	45.3	
		difference	+5.6	-47%	-64%	+0.9	+0.4	
Urd-Eng	1.7+1.5	baseline		1.7	4.5	25.3*	29.8	
		$\ell_0$ -norm		1.2	2.2	25.9*	31.2	
		difference		-29%	-51%	+0.6*	+1.4	
Cze-Eng	2.1+2.3	baseline	65.6	1.5	3.0		17.3	18.0
		$\ell_0$ -norm	72.3	1.0	1.4		17.9	18.4
		difference	+6.7	-33%	-53%		+0.6	+0.4

Table 1: Adding the  $\ell_0$ -norm to the IBM models improves both alignment and translation accuracy across four different language pairs. The *word trans* column also shows that the number of distinct word translations (i.e., the size of the lexical weighting table) is reduced. The  $\tilde{\phi}_{sing.}$  column shows the average fertility of once-seen source words. For Czech-English, the year refers to the WMT shared task; for all other language pairs, the year refers to the NIST Open MT Evaluation. \*Half of this test set was also used for tuning feature weights.

- Czech-English: A corpus of 4 million words of Czech-English data from the News Commentary corpus.<sup>4</sup>

We set the hyperparameters  $\alpha$  and  $\beta$  by tuning on gold-standard word alignments (to maximize F1) when possible. For Arabic-English and Chinese-English, we used 346 and 184 hand-aligned sentences from LDC2006E86 and LDC2006E93. Similarly, for Czech-English, 515 hand-aligned sentences were available (Bojar and Prokopová, 2006). But for Urdu-English, since we did not have any gold alignments, we used  $\alpha = 10$  and  $\beta = 0.05$ . We did not choose a large  $\alpha$ , as the dataset was small, and we chose a conservative value for  $\beta$ .

We ran word alignment in both directions and symmetrized using *grow-diag-final* (Koehn et al., 2003). For models with the smoothed  $\ell_0$  prior, we tuned  $\alpha$  and  $\beta$  separately in each direction.

### 3.2 Alignment

First, we evaluated alignment accuracy directly by comparing against gold-standard word alignments.

<sup>4</sup>This data is available at <http://statmt.org/wmt10>.

The results are shown in the *alignment F1* column of Table 1. We used balanced F-measure rather than alignment error rate as our metric (Fraser and Marcu, 2007).

Following Dyer et al. (2011), we also measured the average fertility,  $\tilde{\phi}_{sing.}$ , of once-seen source words in the symmetrized alignments. Our alignments show smaller fertility for once-seen words, suggesting that they suffer from “garbage collection” effects less than the baseline alignments do.

The fact that we had to use hand-aligned data to tune the hyperparameters  $\alpha$  and  $\beta$  means that our method is no longer completely unsupervised. However, our observation is that alignment accuracy is actually fairly robust to the choice of these hyperparameters, as shown in Table 2. As we will see below, we still obtained strong improvements in translation quality when hand-aligned data was unavailable.

We also tried generating 50 word classes using the tool provided in GIZA++. We found that adding word classes improved alignment quality a little, but more so for the baseline system (see Table 3). We used the alignments generated by training with word classes for our translation experiments.

$\beta$	model	$\alpha$								
		0	10	25	50	75	100	250	500	750
-	HMM	47.5								
	M4	52.1								
0.5	HMM		46.3	48.4	52.8	55.7	57.5	61.5	62.6	<b>62.7</b>
	M4		51.7	53.7	56.4	58.6	59.8	63.3	64.4	64.8
0.1	HMM		55.6	60.4	61.6	62.1	61.9	61.8	60.2	60.1
	M4		58.2	62.4	64.0	64.4	64.8	65.5	65.6	<b>65.9</b>
0.05	HMM		59.1	61.4	62.4	62.5	62.3	60.8	58.7	57.7
	M4		61.0	63.5	64.6	65.3	65.3	65.4	65.7	65.7
0.01	HMM		59.7	61.6	60.0	59.5	58.7	56.9	55.7	54.7
	M4		62.9	65.0	65.1	65.2	65.1	65.4	65.3	65.4
0.005	HMM		58.1	59.0	58.3	57.6	57.0	55.9	53.9	51.7
	M4		62.0	64.1	64.5	64.5	64.5	65.0	64.8	64.6
0.001	HMM		51.7	52.1	51.4	49.3	50.4	46.8	45.4	44.0
	M4		59.8	61.3	61.5	61.0	61.8	61.2	61.0	61.2

Table 2: Almost all hyperparameter settings achieve higher F-scores than the baseline IBM Model 4 and HMM model for Arabic-English alignment ( $\alpha = 0$ ).

direction	system	word classes?	
		no	yes
$P(f e)$	baseline	49.0	52.1
	$\ell_0$ -norm	<b>63.9</b>	<b>65.9</b>
	difference	+14.9	+13.8
$P(e f)$	baseline	64.3	65.2
	$\ell_0$ -norm	<b>69.2</b>	<b>70.3</b>
	difference	+4.9	+5.1

Table 3: Adding word classes improves the F-score in both directions for Arabic-English alignment by a little, for the baseline system more so than ours.

Figure 2 shows four examples of Chinese-English alignment, comparing the baseline with our smoothed- $\ell_0$  method. In all four cases, the baseline produces incorrect extra alignments that prevent good translation rules from being extracted while the smoothed- $\ell_0$  results are correct. In particular, the baseline system demonstrates typical “garbage collection” behavior (Moore, 2004) in all four examples.

### 3.3 Translation

We then tested the effect of word alignments on translation quality using the hierarchical phrase-based translation system Hiero (Chiang, 2007). We used a fairly standard set of features: seven inherited from Pharaoh (Koehn et al., 2003), a sec-

setting		align F1 (%)	B (%)	
$t(f e)$	$t(e f)$		2008	2009
1st	1st	70.8	41.1	43.7
1st	2nd	70.7	41.1	43.8
2nd	1st	70.7	40.7	44.1
2nd	2nd	70.9	41.1	44.2

Table 4: Optimizing hyperparameters on alignment F1 score does not necessarily lead to optimal B . The first two columns indicate whether we used the first- or second-best alignments in each direction (according to F1); the third column shows the F1 of the symmetrized alignments, whose corresponding B scores are shown in the last two columns.

ond language model, and penalties for the glue rule, identity rules, unknown-word rules, and two kinds of number/name rules. The feature weights were discriminatively trained using MIRA (Chiang et al., 2008). We used two 5-gram language models, one on the combined English sides of the NIST 2009 Arabic-English and Chinese-English constrained tracks (385M words), and another on 2 billion words of English.

For each language pair, we extracted grammar rules from the same data that were used for word alignment. The development data that were used for discriminative training were: for Chinese-English and Arabic-English, data from the NIST 2004 and NIST 2006 test sets, plus newsgroup data from the

GALE program (LDC2006E92); for Urdu-English, half of the NIST 2008 test set; for Czech-English, a training set of 2051 sentences provided by the WMT10 translation workshop.

The results are shown in the B column of Table 1. We used case-insensitive IBM B (closest reference length) as our metric. Significance testing was carried out using bootstrap resampling with 1000 samples (Koehn, 2004; Zhang et al., 2004).

All of the tests showed significant improvements ( $p < 0.01$ ), ranging from +0.4 B to +1.4 B. For Urdu, even though we didn't have manual alignments to tune hyperparameters, we got significant gains over a good baseline. This is promising for languages that do not have any manually aligned data.

Ideally, one would want to tune  $\alpha$  and  $\beta$  to maximize B. However, this is prohibitively expensive, especially if we must tune them separately in each alignment direction before symmetrization. We ran some contrastive experiments to investigate the impact of hyperparameter tuning on translation quality. For the smaller Arabic-English corpus, we symmetrized all combinations of the two top-scoring alignments (according to F1) in each direction, yielding four sets of alignments. Table 4 shows B scores for translation models learned from these alignments. Unfortunately, we find that optimizing F1 is not optimal for B—using the second-best alignments yields a further improvement of 0.5 B on the NIST 2009 data, which is statistically significant ( $p < 0.05$ ).

## 4 Related Work

Schoenemann (2011a), taking inspiration from Bodrumlu et al. (2009), uses integer linear programming to optimize IBM Model 1–2 and the HMM with the  $\ell_0$ -norm. This method, however, does not outperform GIZA++. In later work, Schoenemann (2011b) used projected gradient descent for the  $\ell_1$ -norm. Here, we have adopted his use of projected gradient descent, but using a smoothed  $\ell_0$ -norm.

Liang et al. (2006) show how to train IBM models in both directions simultaneously by adding a term to the log-likelihood that measures the agreement between the two directions. Graça et al. (2010) explore modifications to the HMM model that encourage bijectivity and symmetry. The modifications

take the form of constraints on the posterior distribution over alignments that is computed during the E-step. Mermer and Saraçlar (2011) explore a Bayesian version of IBM Model 1, applying sparse Dirichlet priors to  $t$ . However, because this method requires the use of Monte Carlo methods, it is not clear how well it can scale to larger datasets.

## 5 Conclusion

We have extended the IBM models and HMM model by the addition of an  $\ell_0$  prior to the word-to-word translation model, which compacts the word-to-word translation table, reducing overfitting, and, in particular, the “garbage collection” effect. We have shown how to perform MAP-EM with this prior efficiently, even for large datasets. The method is implemented as a modification to the open-source toolkit GIZA++, and we have shown that it significantly improves translation quality across four different language pairs. Even though we have used a small set of gold-standard alignments to tune our hyperparameters, we found that performance was fairly robust to variation in the hyperparameters, and translation performance was good even when gold-standard alignments were unavailable. We hope that our method, due to its simplicity, generality, and effectiveness, will find wide application for training better statistical translation systems.

## Acknowledgments

We are indebted to Thomas Schoenemann for initial discussions and pilot experiments that led to this work, and to the anonymous reviewers for their valuable comments. We thank Jason Riesa for providing the Arabic-English and Chinese-English hand-aligned data and the alignment visualization tool, and Chris Dyer for the Czech-English hand-aligned data. This research was supported in part by DARPA under contract DOI-NBC D11AP00244 and a Google Faculty Research Award to L. H.

## Abstract

Writing comments about news articles, blogs, or reviews have become a popular activity in social media. In this paper, we analyze reader comments about reviews. Analyzing review comments is important because reviews only tell the experiences and evaluations of reviewers about the reviewed products or services. Comments, on the other hand, are readers' evaluations of reviews, their questions and concerns. Clearly, the information in comments is valuable for both future readers and brands. This paper proposes two latent variable models to simultaneously model and extract these key pieces of information. The results also enable classification of comments accurately. Experiments using Amazon review comments demonstrate the effectiveness of the proposed models.

## 1. Introduction

Online reviews enable consumers to evaluate the products and services that they have used. These reviews are also used by other consumers and businesses as a valuable source of opinions.

However, reviews only give the evaluations and experiences of the reviewers. Often a reviewer may not be an expert of the product and may misuse the product or make other mistakes. There may also be aspects of the product that the reviewer did not mention but a reader wants to know. Some reviewers may even write fake reviews to promote

some products, which is called *opinion spamming* (Jindal and Liu 2008). To improve the online review system and user experience, some review hosting sites allow readers to write comments about reviews (apart from just providing a feedback by clicking whether the review is helpful or not). Many reviews receive a large number of comments. It is difficult for a reader to read them to get a gist of them. An automated comment analysis would be very helpful. Review comments mainly contain the following information:

**Thumbs-up or thumbs-down:** Some readers may comment on whether they find the review useful in helping them make a buying decision.

**Agreement or disagreement:** Some readers who comment on a review may be users of the product themselves. They often state whether they agree or disagree with the review. Such comments are valuable as they provide a second opinion, which may even identify fake reviews because a genuine user often can easily spot reviewers who have never used the product.

**Question and answer:** A commenter may ask for clarification or about some aspects of the product that are not covered in the review.

In this paper, we use statistical modeling to model review comments. Two new generative models are proposed. The first model is called the Topic and Multi-Expression model (TME). It models topics and different types of expressions, which represent different types of comment posts:

1. *Thumbs-up* (e.g., “review helped me”)
2. *Thumbs-down* (e.g., “poor review”)
3. *Question* (e.g., “how to”)

4. *Answer acknowledgement* (e.g., “thank you for clarifying”). Note that we have no expressions for answers to questions as there are usually no specific phrases indicating that a post answers a question except starting with the name of the person who asked the question. However, there are typical phrases for acknowledging answers, thus *answer acknowledgement* expressions.
5. *Disagreement (contention)* (e.g., “I disagree”)
6. *Agreement* (e.g., “I agree”).

For ease of presentation, we call these expressions the *comment expressions* (or *C-expressions*). TME provides a basic model for extracting these pieces of information and topics. Its generative process separates topics and C-expression types using a switch variable and treats posts as random mixtures over latent topics and C-expression types. The second model, called ME-TME, improves TME by using Maximum-Entropy priors to guide topic/expression switching. In short, the two models provide a principled and integrated approach to simultaneously discover topics and C-expressions, which is the goal of this work. Note that topics are usually product aspects in this work.

The extracted C-expressions and topics from review comments are very useful in practice. First of all, C-expressions enable us to perform more accurate classification of comments, which can give us a good evaluation of the review quality and credibility. For example, a review with many *Disagreeing* and *Thumbs-down* comments is dubious. Second, the extracted C-expressions and topics help identify the key product aspects that people are troubled with in disagreements and in questions. Our experimental results in Section 5 will demonstrate these capabilities of our models.

With these pieces of information, comments for a review can be summarized. The summary may include, but not limited to, the following: (1) percent of people who give the review thumbs-up or thumbs-down; (2) percent of people who agree or disagree (or contend) with the reviewer; (3) contentious (disagreed) aspects (or topics); (4) aspects about which people often have questions.

To the best of our knowledge, there is no reported work on such a fine-grained modeling of review comments. The related works are mainly in sentiment analysis (Pang and Lee, 2008; Liu 2012), e.g., topic and sentiment modeling, review quality prediction and review spam detection. However, our work is different from them. We will compare with them in detail in Section 2.

The proposed models have been evaluated both qualitatively and quantitatively using a large number of review comments from Amazon.com. Experimental results show that both TME and ME-TME are effective in performing their tasks. ME-TME also outperforms TME significantly.

## 2. Related Work

We believe that this work is the first attempt to model review comments for fine-grained analysis. There are, however, several general research areas that are related to our work.

Topic models such as LDA (Latent Dirichlet Allocation) (Blei et al., 2003) have been used to mine topics in large text collections. There have been various extensions to multi-grain (Titov and McDonald, 2008a), labeled (Ramage et al., 2009), partially-labeled (Ramage et al., 2011), constrained (Andrzejewski et al., 2009) models, etc. These models produce only topics but not multiple types of expressions together with topics. Note that in labeled models, each document is labeled with one or multiple labels. For our work, there is no label for each comment. Our labeling is on topical terms and C-expressions with the purpose of obtaining some priors to separate topics and C-expressions.

In sentiment analysis, researchers have jointly modeled topics and sentiment words (Lin and He, 2009; Mei et al., 2007; Lu and Zhai, 2008; Titov and McDonald, 2008b; Lu et al., 2009; Brody and Elhadad, 2010; Wang et al., 2010; Jo and Oh, 2011; Maghaddam and Ester, 2011; Sauper et al., 2011; Mukherjee and Liu, 2012a). Our model is more related to the ME-LDA model in (Zhao et al., 2010), which used a switch variable trained with Maximum-Entropy to separate topic and sentiment words. We also use such a variable. However, unlike sentiments and topics in reviews, which are emitted in the same sentence, C-expressions often interleave with topics across sentences and the same comment post may also have multiple types of C-expressions. Additionally, C-expressions are mostly phrases rather than individual words. Thus, a different model is required to model them.

There have also been works aimed at putting authors in debate into support/oppose camps, e.g., (Galley et al., 2004; Agarwal et al., 2003; Murakami and Raymond, 2010), modeling debate discussions considering reply relations (Mukherjee and Liu, 2012b), and identifying stances in debates (Somasundaran and Wiebe, 2009; Thomas et al.,

2006; Burfoot et al., 2011). (Yano and Smith, 2010) also modeled the relationship of a blog post and the number of comments it receives. These works are different as they do not mine C-expressions or discover the points of contention and questions in comments.

In (Kim et al., 2006; Zhang and Varadarajan, 2006; Ghose and Ipeirotis, 2007; Liu et al., 2007; Liu et al., 2008; O’Mahony and Smyth, 2009; Tsur and Rappoport 2009), various classification and regression approaches were taken to assess the quality of reviews. (Jindal and Liu, 2008; Lim et al., 2010; Li et al. 2011; Ott et al., 2011; Mukherjee et al., 2012) detect fake reviews and reviewers. However, all these works are not concerned with review comments.

### 3. The Basic TME Model

This section discusses TME. The next section discusses ME-TME, which improves TME. These models belong to the family of generative models for text where words and phrases ( $n$ -grams) are viewed as random variables, and a document is viewed as a bag of  $n$ -grams and each  $n$ -gram takes a value from a predefined vocabulary. In this work, we use up to 4-grams, i.e.,  $n = 1, 2, 3, 4$ . For simplicity, we use *terms* to denote both *words* (unigrams or 1-grams) and *phrases* ( $n$ -grams). We denote the entries in our vocabulary by  $v_{1...V}$  where  $V$  is the number of unique terms in the vocabulary. The entire corpus contains  $d_{1...D}$  documents. A document (e.g., comment post)  $d$  is represented as a vector of terms  $\mathbf{w}_d$  with  $N_d$  entries.  $W$  is the set of all observed terms with cardinality,  $|W| = \sum_d N_d$ .

The TME (Topic and Multi-Expression) model is a hierarchical generative model motivated by the joint occurrence of various types of expressions indicating *Thumbs-up*, *Thumbs-down*, *Question*, *Answer acknowledgement*, *Agreement*, and *Disagreement* and topics in comment posts. As before, these expressions are collectively called C-expressions. A typical comment post mentions a few topics (using semantically related topical terms) and expresses some viewpoints with one or more C-expression types (using semantically related expressions). This observation motivates the generative process of our model where documents (posts) are represented as random mixtures of latent topics and C-expression types. Each topic or C-expression type is characterized by a distribution over terms (words/phrases). Assume

Figure 1: Graphical Models in plate notations.

we have  $t_{1...T}$  topics and  $e_{1...E}$  expression types in our corpus. Note that in our case of Amazon review comments, based on reading various posts, we hypothesize that  $E = 6$  as in such review discussions, we mostly find 6 expression types (more details in Section 5.1). Let  $\psi_d$  denote the distribution of topics and C-expressions in a document  $d$  with  $r_{d,j} \in \{\hat{t}, \hat{e}\}$  denoting the binary indicator variable (topic or C-expression) for the  $j^{th}$  term of  $d$ ,  $w_{d,j}$ .  $z_{d,j}$  denotes the appropriate topic or C-expression type index to which  $w_{d,j}$  belongs. We parameterize multinomials over topics using a matrix  $\Theta_{D \times T}^T$  whose elements  $\theta_{d,t}^T$  signify the probability of document  $d$  exhibiting topic  $t$ . For simplicity of notation, we will drop the latter subscript ( $t$  in this case) when convenient and use  $\theta_d^T$  to stand for the  $d^{th}$  row of  $\Theta^T$ . Similarly, we define multinomials over C-expression types using a matrix  $\Theta_{D \times E}^E$ . The multinomials over terms associated with each topic are parameterized by a matrix  $\Phi_{T \times V}^T$ , whose elements  $\phi_{t,v}^T$  denote the probability of generating  $v$  from topic  $t$ . Likewise, multinomials over terms associated with each C-expression type are parameterized by a matrix  $\Phi_{E \times V}^E$ . We now define the generative process of TME (see Figure 1(a)).

- A. For each C-expression type  $e$ , draw  $\varphi_e^E \sim \text{Dir}(\beta_E)$
- B. For each topic  $t$ , draw  $\varphi_t^T \sim \text{Dir}(\beta_T)$
- C. For each comment post  $d \in \{1 \dots D\}$ :
  - i. Draw  $\psi_d \sim \text{Beta}(\gamma \mathbf{u})$
  - ii. Draw  $\theta_d^E \sim \text{Dir}(\alpha_E)$
  - iii. Draw  $\theta_d^T \sim \text{Dir}(\alpha_T)$
  - iv. For each term  $w_{d,j}$ ,  $j \in \{1 \dots N_d\}$ :
    - a. Draw  $r_{d,j} \sim \text{Bernoulli}(\psi_d)$
    - b. if  $(r_{d,j} = \hat{e} // w_{d,j}$  is a C-expression term  
Draw  $z_{d,j} \sim \text{Mult}(\theta_d^E)$   
else  $// r_{d,j} = \hat{t}$ ,  $w_{d,j}$  is a topical term  
Draw  $z_{d,j} \sim \text{Mult}(\theta_d^T)$
    - c. Emit  $w_{d,j} \sim \text{Mult}(\varphi_{z_{d,j}}^{r_{d,j}})$

To learn the TME model from data, as exact inference is not possible, we resort to approximate inference using *collapsed Gibbs sampling* (Griffiths and Steyvers, 2004). Gibbs sampling is a form of Markov Chain Monte Carlo method where a Markov chain is constructed to have a particular stationary distribution. In our case, we want to construct a Markov chain which converges to the posterior distribution over  $R$  and  $Z$  conditioned on the data. We only need to sample  $z$  and  $r$  as we use collapsed Gibbs sampling and the dependencies of  $\theta$  and  $\varphi$  have been integrated out analytically in the joint. Denoting the random variables  $\{w, z, r\}$  by singular subscripts  $\{w_k, z_k, r_k\}$ ,  $k_{1\dots K}$ , where  $K = \sum_d N_d$ , a single iteration consists of performing the following sampling:

$$p(z_k = t, r_k = \hat{t} | W_{-k}, Z_{-k}, R_{-k}, w_k = v) \propto \frac{n_{d,-k}^T + \gamma_a}{n_{d,-k}^T + n_{d,-k}^E + \gamma_a + \gamma_b} \times \frac{n_{d,t,-k}^{DT} + \alpha_T}{n_{d,(\cdot),-k}^{DT} + T\alpha_T} \times \frac{n_{t,v,-k}^{CT} + \beta_T}{n_{t,(\cdot),-k}^{CT} + V\beta_T} \quad (1)$$

$$p(z_k = e, r_k = \hat{e} | W_{-k}, Z_{-k}, R_{-k}, w_k = v) \propto \frac{n_{d,-k}^E + \gamma_b}{n_{d,-k}^T + n_{d,-k}^E + \gamma_a + \gamma_b} \times \frac{n_{d,e,-k}^{DE} + \alpha_E}{n_{d,(\cdot),-k}^{DE} + E\alpha_E} \times \frac{n_{e,v,-k}^{CE} + \beta_E}{n_{e,(\cdot),-k}^{CE} + V\beta_E} \quad (2)$$

where  $k = (d, j)$  denotes the  $j^{\text{th}}$  term of document  $d$  and the subscript  $-k$  denotes assignments excluding the term at  $(d, j)$ . Counts  $n_{t,v}^{CT}$  and  $n_{e,v}^{CE}$  denote the number of times term  $v$  was assigned to topic  $t$  and expression type  $e$  respectively.  $n_{d,t}^{DT}$  and  $n_{d,e}^{DE}$  denote the number of terms in document  $d$  that were assigned to topic  $t$  and C-expression type  $e$  respectively. Lastly,  $n_d^T$  and  $n_d^E$  are the number of terms in  $d$  that were assigned to topics and C-expression types respectively. Omission of the latter index denoted by  $(\cdot)$  represents the marginalized sum over the latter index. We employ a blocked sampler jointly sampling  $r$  and  $z$  as this improves convergence and reduces autocorrelation of the Gibbs sampler (Rosen-Zvi et al., 2004).

**Asymmetric Beta priors:** Based on our initial experiments with TME, we found that properly setting the smoothing hyper-parameter  $\gamma \mathbf{u}$  is crucial as it governs the topic/expression switch.

According to the generative process,  $\psi_d$  is the (success) probability (of the Bernoulli distribution) of emitting a topical/aspect term in a comment post  $d$  and  $1 - \psi_d$ , the probability of emitting a C-expression term in  $d$ . Without loss of generality, we draw  $\psi_d \sim \text{Beta}(\gamma \mathbf{u})$  where  $\gamma$  is the concentration parameter and  $\mathbf{u} = [u_a, u_b]$  is the base measure. Without any prior belief, one resorts

to uniform base measure  $u_a = u_b = 0.5$  (i.e., assumes that both topical and C-expression terms are equally likely to be emitted in a comment post). This results in symmetric Beta priors  $\psi_d \sim \text{Beta}(\gamma_a, \gamma_b)$  where  $\gamma_a = \gamma u_a$ ,  $\gamma_b = \gamma u_b$  and  $\gamma_a = \gamma_b = \gamma/2$ . However, knowing the fact that topics are more likely to be emitted than expressions in a post *a priori* motivates us to take guidance from asymmetric priors (i.e., we now have a non-uniform base measure  $\mathbf{u}$ ). This asymmetric setting of  $\gamma$  ensures that samples of  $\psi_d$  are more close to the actual distribution of topical terms in posts based on some domain knowledge. Symmetric  $\gamma$  cannot utilize any prior knowledge. In (Lin and He, 2009), a method was proposed to incorporate domain knowledge during Gibbs sampling initialization, but its effect becomes weak as the sampling progresses (Jo and Oh, 2011).

For asymmetric priors, we estimate the hyper-parameters from labeled data. Given a labeled set  $D_L$ , where we know the per post probability of C-expression emission ( $1 - \psi_d$ ), we use the method of moments to estimate  $\gamma = [\gamma_a, \gamma_b]$  as follows:

$$\gamma_a = \mu \left( \frac{\mu(1-\mu)}{\sigma} - 1 \right), \gamma_b = \gamma_a \left( \frac{1}{\mu} - 1 \right); \mu = E[\psi_d], \sigma = \text{Var}[\psi_d] \quad (3)$$

#### 4. ME-TME Model

The guidance of Beta priors, although helps, is still relatively coarse and weak. We can do better to produce clearer separation of topical and C-expression terms. An alternative strategy is to employ *Maximum-Entropy* (Max-Ent) priors instead of Beta priors. The Max-Ent parameters can be learned from a small number of labeled topical and C-expression terms (words and phrases) which can serve as good priors. The idea is motivated by the following observation: topical and C-expression terms typically play different syntactic roles in a sentence. Topical terms (e.g. “ipod” “cell phone”, “macro lens”, “kindle”, etc.) tend to be noun and noun phrases while expression terms (“I refute”, “how can you say”, “great review”) usually contain pronouns, verbs, wh-determiners, adjectives, and modals. In order to utilize the part-of-speech (POS) tag information, we move the topic/C-expression distribution  $\psi_d$  (the prior over the indicator variable  $r_{d,j}$ ) from the document plate to the word plate (see Figure 1 (b)) and draw it from a Max-Ent model conditioned on the observed feature vector  $\vec{x}_{d,j}$  associated with  $w_{d,j}$  and the learned Max-Ent parameters  $\lambda$ .  $x_{d,j}$  can

encode arbitrary contextual features for learning. With Max-Ent priors, we have the new model ME-TME. In this work, we encode both lexical and POS features of the previous, current and next POS tags/lexemes of the term  $w_{d,j}$ . More specifically,

$$\vec{x}_{d,j} = [POS_{w_{d,j-1}}, POS_{w_{d,j}}, POS_{w_{d,j+1}}, w_{d,j} - 1, w_{d,j}, w_{d,j} + 1]$$

For phrasal terms (n-grams), all POS tags and lexemes of  $w_{d,j}$  are considered as features. Incorporating Max-Ent priors, the Gibbs sampler of ME-TME is given by:

$$p(z_k = t, r_k = \hat{t} | W_{-k}, Z_{-k}, R_{-k}, w_k = v) \propto \frac{\exp(\sum_{i=1}^n \lambda_i f_i(x_{d,j}, \hat{t}))}{\sum_{y \in \{\hat{e}, \hat{t}\}} \exp(\sum_{i=1}^n \lambda_i f_i(x_{d,j}, y))} \times \frac{n_{d,t}^{DT} + \alpha_T}{n_{d,(c)}^{DT} + T \alpha_T} \times \frac{n_{\hat{t},v}^{CT} + \beta_T}{n_{\hat{t},(c)}^{CT} + V \beta_T} \quad (4)$$

$$p(z_k = e, r_k = \hat{e} | W_{-k}, Z_{-k}, R_{-k}, w_k = v) \propto \frac{\exp(\sum_{i=1}^n \lambda_i f_i(x_{d,j}, \hat{e}))}{\sum_{y \in \{\hat{e}, \hat{t}\}} \exp(\sum_{i=1}^n \lambda_i f_i(x_{d,j}, y))} \times \frac{n_{d,e}^{DE} + \alpha_E}{n_{d,(c)}^{DE} + E \alpha_E} \times \frac{n_{\hat{e},v}^{CE} + \beta_E}{n_{\hat{e},(c)}^{CE} + V \beta_E} \quad (5)$$

where  $\lambda_{1\dots n}$  are the parameters of the learned Max-Ent model corresponding to the  $n$  binary feature functions  $f_{1\dots n}$  from Max-Ent.

## 5. Evaluation

We now evaluate the proposed TME and ME-TME models. Specifically, we evaluate the discovered C-expressions, contentious aspects, and aspects often mentioned in questions.

**5.1 Dataset and Experiment Settings** We crawled comments of reviews in Amazon.com for a variety of products. For each comment we extracted its id, the comment author id, the review id on which it commented, and the review author id. Our database consisted of 21,316 authors, 37,548 reviews, and 88,345 comments with an average of 124 words per comment post.

For all our experiments, the hyper-parameters for TME and ME-TME were set to the heuristic values  $\alpha_T = 50/T$ ,  $\alpha_E = 50/E$ ,  $\beta_T = \beta_E = 0.1$  as suggested in (Griffiths and Steyvers, 2004). For  $\gamma$ , we estimated the asymmetric Beta priors using the method of moments discussed in Section 3. We sampled 1000 random posts and for each post we identified the C-expressions emitted. We thus computed the per-post probability of C-expression emission ( $1 - \psi_d$ ) and used Eq. (3) to get the final estimates,  $\gamma_a = 3.66$ ,  $\gamma_b = 1.21$ . To learn the Max-Ent parameters  $\lambda$ , we randomly sampled 500 terms from our corpus appearing at least 10 times and labeled them as topical (332) or C-expressions (168) and used the corresponding feature vector of

each term (in the context of posts where it occurs) to train the Max-Ent model. We set the number of topics,  $T = 100$  and the number of C-expression types,  $E = 6$  (*Thumbs-up*, *Thumbs-down*, *Question*, *Answer acknowledgement*, *Agreement* and *Disagreement*) as in review comments, we usually find these six dominant expression types. Note that knowing the exact number of topics,  $T$  and expression types,  $E$  in a corpus is difficult. While non-parametric Bayesian approaches (Teh et al., 2006) aim to estimate  $T$  from the corpus, in this work the heuristic values obtained from our initial experiments produced good results. We also tried increasing  $E$  to 7, 8, etc. However, it did not produce any new dominant expression type. Instead, the expression types became less specific as the expression term space became sparser.

## 5.2 C-Expression Evaluation

We now evaluate the discovered C-expressions. We first evaluate them qualitatively in Tables 1 and 2. Table 1 shows the top terms of all expression types using the TME model. We find that TME can discover and cluster many correct C-expressions, e.g., “great review”, “review helped me” in *Thumbs-up*; “poor review”, “very unfair review” in *Thumbs-down*; “how do I”, “help me decide” in *Question*; “good reply”, “thank you for clarifying” in *Answer Acknowledgement*; “I disagree”, “I refute” in *Disagreement*; and “I agree”, “true in fact” in *Agreement*. However, with the guidance of Max-Ent priors, ME-TME did much better (Table 2). For example, we find “level headed review”, “review convinced me” in *Thumbs-up*; “biased review”, “is flawed” in *Thumbs-down*; “any clues”, “I was wondering how” in *Question*; “clears my”, “valid answer” in *Answer-acknowledgement*; “I don’t buy your”, “sheer nonsense” in *Disagreement*; “agree completely”, “well said” in *Agreement*. These newly discovered phrases by ME-TME are marked in *blue* in Table 3. ME-TME also has fewer errors.

Next, we evaluate them quantitatively using the metric *precision @ n*, which gives the precision at different rank positions. This metric is appropriate here because the C-expressions (according to top terms in  $\Phi^E$ ) produced by TME and ME-TME are rankings. Table 3 reports the precisions @ top 25, 50, 75, and 100 rank positions for all six expression types across both models. We evaluated till top 100 positions because it is usually

**Thumbs-up (e<sub>1</sub>):** **review, thanks**, great review, nice review, **time**, best review, **appreciate, you**, your review helped, nice, terrific, review helped me, good critique, **very, assert, wrong**, useful review, **don't, misleading**, thanks a lot, ...

**Thumbs-down (e<sub>2</sub>):** **review, no**, poor review, imprecise, **you, complaint, very**, suspicious, bogus review, **absolutely, credible**, very unfair review, criticisms, **true**, disregard this review, disagree with, **judgment**, without owning, ...

**Question (e<sub>3</sub>):** question, **my, I**, how do I, why isn't, please explain, **good answer**, clarify, don't understand, my doubts, I'm confused, **does not, understand**, help me decide, how to, **yes, answer**, how can I, **can't explain**, ...

**Answer Acknowledgement (e<sub>4</sub>):** **my, informative**, answer, good reply, thank you for clarifying, answer doesn't, good answer, **vague**, helped me choose, useful suggestion, **don't understand, cannot explain**, your answer, **doubts**, answer isn't, ...

**Disagreement (e<sub>5</sub>):** disagree, **I, don't**, I disagree, argument claim, I reject, I refute, I refuse, oppose, debate, **accept**, don't agree, **quote, sense**, would disagree, **assertions**, I doubt, **right**, your, **really**, you, I'd disagree, cannot, nonsense, ...

**Agreement (e<sub>6</sub>):** yes, **do**, correct, indeed, **no**, right, I agree, **you**, agree, I accept, **very**, yes indeed, true in fact, indeed correct, I'd agree, **completely**, true, **but, doesn't, don't**, definitely, **false**, completely agree, agree with your, true, ...

Table 1: Top terms (comma delimited) of six expression types e<sub>1</sub>, e<sub>2</sub>, e<sub>3</sub>, e<sub>4</sub>, e<sub>5</sub>, e<sub>6</sub> ( $\Phi^6$ ) using TME model. **Red (bold)** colored terms denote possible errors

important to see whether a model can discover and rank those major expressions of a type at the top. We believe that top 100 are sufficient for most applications. From Table 3, we observe that ME-TME consistently outperforms TME in precisions across all expression types and all rank positions. This shows that Max-Ent priors are more effective in discovering expressions than Beta priors. Note that we couldn't compare with an existing baseline because there is no reported study on this problem.

### 5.3 Comment Classification

Here we show that the discovered C-expressions can help comment classification. Note that since a comment can belong to one or more types (e.g., a comment can belong to both *Thumbs-up* and *Agreement* types), this task is an instance of multi-label classification, i.e., an instance can have more than one class label. In order to evaluate all the expression types, we follow the binary approach which is an extension of one-against-all method for multi-label classification. Thus, for each label, we build a binary classification problem. Instances associated with that label are in one class and the rest are in the other class. To perform this task, we randomly sampled 2000 comments, and labeled each of them into one or more of the following 8 labels: *Thumbs-up*, *Thumbs-down*, *Disagreement*, *Agreement*, *Question*, *Answer-Acknowledgement*, *Answer*, and *None*, which have 432, 401, 309, 276,

**Thumbs-up (e<sub>1</sub>):** **review, you**, great review, *I'm glad I read*, best review, *review convinced me*, review helped me, good review, *terrific review, job, thoughtful review*, awesome review, *level headed review, good critique*, good job, *video review*, ...

**Thumbs-down (e<sub>2</sub>):** **review, you**, bogus review, con, useless review, *ridiculous, biased review*, very unfair review, *is flawed, completely, skeptical, badmouth, misleading review*, cynical review, wrong, disregard this review, *seemingly honest*, ...

**Question (e<sub>3</sub>):** question, **I**, how do I, why isn't, please explain, clarify, *any clues, answer*, please explain, help me decide, **vague**, how to, how do I, where can I, *how to set, I was wondering how, could you explain*, how can I, *can I use*, ...

**Answer Acknowledgement (e<sub>4</sub>):** **my**, good reply, , answer, reply, helped me choose, *clears my, valid answer*, answer doesn't, *satisfactory answer, can you clarify, informative answer*, useful suggestion, *perfect answer*, thanks for your reply, **doubts**, ...

**Disagreement (e<sub>5</sub>):** disagree, **I, don't**, I disagree, doesn't, *I don't buy your, credible*, I reject, I doubt, I refuse, *I oppose, sheer nonsense, hardly*, don't agree, *can you prove, you have no clue, how do you say, sense, you fail, contradiction*, ...

**Agreement (e<sub>6</sub>):** **I, do**, agree, **point**, yes, **really, would agree, you**, agree, I accept, **claim, agree completely, personally agree**, true in fact, indeed correct, *well said, valid point*, correct, **never meant, might not, definitely agree**, ...

Table 2: Top terms (comma delimited) of six expression types using ME-TME model. **Red (bold)** terms denote possible errors. *Blue (italics)* terms denote those newly discovered by the model; rest (black) were used in Max-Ent training.

305, 201, 228, and 18 comments respectively. We disregard the *None* category due to its small size. This labeling is a fairly easy task as one can almost certainly make out to which type a comment belongs. Thus we didn't use multiple labelers. The distribution reveals that the labels are overlapping. For instance, we found many comments belonging to both *Thumbs-down* and *Disagreement*, *Thumbs-up* with *Acknowledgement* and with *Question*.

For supervised classification, the choice of feature is a key issue. While word and POS n-grams are traditional features, such features may not be the best for our task. We now compare such features with the C-expressions discovered by the proposed models. We used the top 1000 terms from each of the 6 C-expression rankings as features. As comments in *Question* type mostly use the punctuation "?", we added it in our feature set. We use precision, recall and F<sub>1</sub> as our metric to compare classification performance using a trained SVM (linear kernel). All results (Table 4) were computed using 10-fold cross-validation (CV). We also tried Naïve Bayes and Logistic Regression classifiers, but they were poorer than SVM. Hence their results are not reported due to space constraints. As a separate experiment (not shown here also due to space constraints), we analyzed the classification performance by varying the number of top terms from 200, 400, ..., 1000, 1200, etc. and found that the F<sub>1</sub> scores stabilized after top

Table 5 (b)

Table 5: Points of Contention (a), Questioned aspects (b). D1: Ipod, D2: Kindle, D3: Nikon, D4: Garmin. We report the average precision (P), recall (R), and F<sub>1</sub> score over 100 comments for each particular domain.

Statistical significance: Differences between Nearest Noun Phrase and TME for both judges (J<sub>1</sub>, J<sub>2</sub>) across all domains were significant at 97% confidence level ( $p < 0.03$ ). Differences among TME and ME-TME for both judges (J<sub>1</sub>, J<sub>2</sub>) across all domains were significant at 95% confidence level ( $p < 0.05$ ). A paired  $t$ -test was used for testing significance.

1000 terms. From Table 4, we see that F<sub>1</sub> scores dramatically increase with C-expression ( $\Phi^E$ ) features for all expression types. TME and ME-TME progressively improve the classification. Improvements of TME and ME-TME being significant ( $p < 0.001$ ) using a paired  $t$ -test across 10-fold cross validations shows that the discovered C-expressions are of high quality and useful.

We note that the annotation resulted in a new label “Answer” which consists of mostly replies to comments with questions. Since an “answer” to a question usually does not show any specific expression, it does not attain very good F<sub>1</sub> scores. Thus, to improve the performance of the *Answer*

type comments, we added three binary features for each comment  $c$  on top of C-expression features:

- i) Is the author of  $c$  the review author too? The idea here is that most of the times the reviewer answers the questions raised in comments.
- ii) Is there any comment posted before  $c$  by some author  $a$  which has been previously classified as a question post?
- iii) Is there any comment posted after  $c$  by author  $a$  that replies to  $c$  (using @name) and is an *Answer-Acknowledgement* comment (which again has been previously classified as such)?

Using these additional features, we obtained a precision of 0.78 and a recall of 0.73 yielding an F<sub>1</sub>

score of 0.75 which is a dramatic increase beyond 0.64 achieved by ME-TME in Table 4.

#### 5.4 Contention Points and Questioned Aspects

We now turn to the task of discovering points of contention in disagreement comments and aspects (or topics) raised in questions. By “points”, we mean the topical terms on which some contentions or disagreements have been expressed. Topics being the product aspects are also indirectly evaluated in this task. We employ the TME and ME-TME models in the following manner.

We only detail the approach for disagreement comments. The same method is applied to question comments. Given a disagreement comment post  $d$ , we first select the top  $k$  topics that are mentioned in  $d$  according to its topic distribution,  $\theta_d^T$ . Let  $T_d$  be the set of these top  $k$  topics in  $d$ . Then, for each disagreement expression  $w \in d \cap \varphi_{e=Disagreement}^E$ , we emit the topical terms (words/phrases) of topics in  $T_d$  which appear within a word window of  $q$  from  $w$  in  $d$ . More precisely, we emit the set  $A = \{w | w \in d \cap \varphi_t^T, t \in T_d, |posi(w) - posi(v)| \leq q\}$ , where  $posi(\cdot)$  returns the position index of the word or phrase in document  $d$ . To compute the intersection  $w \in d \cap \varphi_t^T$ , we need a threshold. This is so because the Dirichlet distribution has a smoothing effect which assigns some non-zero probability mass to every term in the vocabulary for each topic  $t$ . So for computing the intersection, we considered only terms in  $\varphi_t^T$  which have  $p(v|t) = \varphi_{t,v}^T > 0.001$  as probability masses lower than 0.001 are more due to the smoothing effect of the Dirichlet distribution than true correlation. In an actual application, the values for  $k$  and  $q$  can be set according to the user’s need. In our experiment, we used  $k = 3$  and  $q = 5$ , which are reasonable because a post normally does not talk about many topics ( $k$ ), and the contention points (aspect terms) appear quite close to the disagreement expressions.

For comparison, we also designed a baseline. For each disagreement (or question) expression  $w \in d \cap \varphi_{e=Disagreement}^E (\varphi_{e=Question}^E)$ , we emit the nouns and noun phrases within the same window  $q$  as the points of contention (question) in  $d$ . This baseline is reasonable because topical terms are usually nouns and noun phrases and are near disagreement (question) expressions. We note that this baseline cannot stand alone because it has to rely on our expression models  $\Phi^E$  of ME-TME.

Next, to evaluate the performance of these methods in discovering points of contention, we randomly selected 100 disagreement (contentious) (and 100 question) comment posts on reviews from each of the 4 product domains: Ipod, Kindle, Nikon Cameras, and Garmin GPS in our database and employed the aforementioned methods to discover the points of contention (question) in each post. Then we asked two human judges (graduate students fluent in English) to manually judge the results produced by each method for each post. We asked them to report the precision of the discovered terms for a post by judging them as being indeed valid points of contention and report recall in a post by judging how many of actually contentious points in the post were discovered. In Table 5 (a), we report the average precision and recall for 100 posts in each domain by the two judges  $J_1$  and  $J_2$  for different methods on the task of discovering points (aspects) of contention. In Table 5 (b), similar results are reported for the task of discovering questioned aspects in 100 question comments for each product domain. Since this judging task is subjective, the differences in the results from the two judges are not surprising. Our judges were made to work in isolation to prevent any bias. We observe that across all domains, ME-TME again performs the best consistently. Note that agreement study using Kappa is not used here as our problem is not to label a fixed set of items categorically by the judges.

## 6. Conclusion

This paper proposed the problem of modeling review comments, and presented two models TME and ME-TME to model and to extract topics (aspects) and various comment expressions. These expressions enable us to classify comments more accurately, and to find contentious aspects and questioned aspects. These pieces of information also allow us to produce a simple summary of comments for each review as discussed in Section 1. To our knowledge, this is the first attempt to analyze comments in such details. Our experiments demonstrated the efficacy of the models. ME-TME also outperformed TME significantly.

## Abstract

We describe a joint model for understanding user actions in natural language utterances. Our multi-layer generative approach uses both labeled and unlabeled utterances to jointly learn aspects regarding utterance’s target domain (e.g. movies), intention (e.g., finding a movie) along with other semantic units (e.g., movie name). We inject information extracted from unstructured web search query logs as prior information to enhance the generative process of the natural language utterance understanding model. Using utterances from five domains, our approach shows up to 4.5% improvement on domain and dialog act performance over cascaded approach in which each semantic component is learned sequentially and a supervised joint learning model (which requires fully labeled data).

## 1 Introduction

Virtual personal assistance (VPA) is a human to machine dialog system, which is designed to perform tasks such as making reservations at restaurants, checking flight statuses, or planning weekend activities. A typical spoken language understanding (SLU) module of a VPA (Bangalore, 2006; Tur and Mori, 2011) defines a structured representation for utterances, in which the constituents correspond to meaning representations in terms of slot/value pairs (see Table 1). While target *domain* corresponds to the context of an utterance in a dialog, the dialog act represents overall intent of an utterance. The *slots* are entities, which are semantic constituents at the word or phrase level. Learning each component

### Sample utterances on ‘plan a night out’ scenario

(I) Show me theaters in [Austin] playing [iron man 2].  
(II) I’m in the mood for [indian] food tonight, show me the ones [within 5 miles] that have [patios].

### Extracted Class and Labels

Domain	Dialog Act	Slots=Values
(I) Movie	find theater	Location= <i>Austin</i> Movie-Name= <i>iron man 2</i>
(II) Restaurant	find restaurant	Rest-Cuisine= <i>indian</i> Location= <i>within 5 miles</i> Rest-Amenities= <i>patios</i>

Table 1: Examples of utterances with corresponding semantic components, i.e., domain, dialog act, and slots.

is a challenging task not only because there are no *a priori* constraints on what a user might say, but also systems must generalize from a tractably small amount of labeled training data. In this paper, we argue that each of these components are interdependent and should be modeled simultaneously. We build a joint understanding framework and introduce a multi-layer context model for semantic representation of utterances of multiple domains.

Although different strategies can be applied, typically a cascaded approach is used where each semantic component is modeled separately/sequentially (Begeja et al., 2004), focusing less on interrelated aspects, i.e., dialog’s domain, user’s intentions, and semantic tags that can be shared across domains. Recent work on SLU (Jeong and Lee, 2008; Wang, 2010) presents joint modeling of two components, i.e., the domain and slot or dialog act and slot components together. Furthermore, most of these systems rely on labeled training utterances, focusing little on issues such as information sharing between the discourse and word level components across different domains, or variations in use of language. To deal with de-

pendency and language variability issues, a model that considers dependencies between semantic components and utilizes information from large bodies of unlabeled text can be beneficial for SLU.

In this paper, we present a novel generative Bayesian model that learns domain/dialog-act/slot semantic components as latent aspects of text utterances. Our approach can identify these semantic components simultaneously in a hierarchical framework that enables the learning of dependencies. We incorporate prior knowledge that we observe in web search query logs as constraints on these latent aspects. Our model can discover associations between words within a multi-layered aspect model, in which some words are indicative of higher layer (meta) aspects (domain or dialog act components), while others are indicative of lower layer specific entities.

The contributions of this paper are as follows:

- (i) construction of a novel Bayesian framework for semantic parsing of natural language (NL) utterances in a unifying framework in §4,
- (ii) representation of seed labeled data and information from web queries as informative prior to design a novel utterance understanding model in §3 & §4,
- (iii) comparison of our results to supervised sequential and joint learning methods on NL utterances in §5. We conclude that our generative model achieves noticeable improvement compared to discriminative models when labeled data is scarce.

## 2 Background

Language understanding has been well studied in the context of question/answering (Harabagiu and Hickl, 2006; Liang et al., 2011), entailment (Sammons et al., 2010), summarization (Hovy et al., 2005; Daumé-III and Marcu, 2006), spoken language understanding (Tur and Mori, 2011; Dinarelli et al., 2009), query understanding (Popescu et al., 2010; Li, 2010; Reisinger and Pasca, 2011), etc. However data sources in VPA systems pose new challenges, such as variability and ambiguities in natural language, or short utterances that rarely contain contextual information, etc. Thus, SLU plays an important role in allowing any sophisticated spoken dialog system (e.g., DARPA Calo (Berry et al., 2011), Siri, etc.) to take the correct machine actions.

A common approach to building SLU framework

is to model its semantic components separately, assuming that the context (domain) is given *a priori*. Earlier work takes dialog act identification as a classification task to capture the user’s intentions (Margolis et al., 2010) and slot filling as a sequence learning task specific to a given domain class (Wang et al., 2009; Li, 2010). Since these tasks are considered as a pipeline, the errors of each component are transferred to the next, causing robustness issues. Ideally, these components should be modeled simultaneously considering the dependencies between them. For example, in a local domain application, users may require information about a sub-domain (*movies, hotels, etc.*), and for each sub-domain, they may want to take different actions (*find* a movie, *call* a restaurant or *book* a hotel) using domain specific attributes (e.g., *cuisine type* of a restaurant, *titles* for movies or *star-rating* of a hotel). There’s been little attention in the literature on modeling the dependencies of SLU’s correlated structures.

Only recent research has focused on the joint modeling of SLU (Jeong and Lee, 2008; Wang, 2010) taking into account the dependencies at learning time. In (Jeong and Lee, 2008), a triangular chain conditional random fields (Tri-CRF) approach is presented to model two of the SLU’s components in a single-pass. Their discriminative approach represents semantic slots and discourse-level utterance labels (domain or dialog act) in a single structure to encode dependencies. However, their model requires fully labeled utterances for training, which can be time consuming and expensive to generate for dynamic systems. Also, they can only learn dependencies between two components simultaneously.

Our approach differs from the earlier work in that- we take the utterance understanding as a multi-layered learning problem, and build a hierarchical clustering model. Our joint model can discover domain  $D$ , and user’s act  $A$  as higher layer latent concepts of utterances in relation to lower layer latent semantic topics (slots)  $S$  such as named-entities (“*New York*”) or context bearing non-named entities (“*vegan*”). Our work resembles the earlier work of PAM models (Mimno et al., 2007), i.e., directed acyclic graphs representing mixtures of hierarchical topic structures, where upper level topics are multinomial over lower level topics in a hierarchy. In an analogical way to earlier work, the  $D$  and  $A$  in our

approach represent common co-occurrence patterns (dependencies) between semantic tags  $S$  (Fig. 2). Concretely, correlated topics eliminate assignment of semantic tags to segments in an utterance that belong to other domains, e.g., we can discover that "Show me vegan restaurants in San Francisco" has a low probability of outputting a *movie-actor* slot. Being generative, our model can incorporate unlabeled utterances and encode prior information of concepts.

### 3 Data and Approach Overview

Here we define several abstractions of our joint model as depicted in Fig. 1. Our corpus mainly contains NL utterances ("show me the nearest dinner places") and some keyword queries ("iron man 2 trailers"). We represent each utterance  $u$  as a vector  $w_u$  of  $N_u$  word n-grams (segments),  $w_{uj}$ , each of which are chosen from a vocabulary  $W$  of fixed-size  $V$ . We use entity lists obtained from web sources (explained next) to identify segments in the corpus. Our corpus contains utterances from  $K_D=4$  main **domains**:  $\in \{movies, hotels, restaurants, events\}$ , as well as out-of-domain *other* class. Each utterance has one **dialog act** ( $A$ ) associated with it. We assume a fixed number of possible dialog acts  $K_A$  for each domain. Semantic Tags, **slots** ( $S$ ) are lexical units (segments) of an utterance, which we classify into two types: domain-independent slots that are shared across all domains, (e.g., *location, time, year, etc.*), and domain-dependent slots, (e.g. *movie-name, actor-name, restaurant-name, etc.*). For tractability, we consider a fixed number of latent slot types  $K_S$ . Our algorithm assigns domain/dialog-act/slot labels to each topic at each layer in the hierarchy using labeled data (explained in §4.)

We represent domain and dialog act components as meta-variables of utterances. This is similar to author-topic models (Rosen-Zvi et al., 2004), that capture author-topic relations across documents. In that case, words are generated by first selecting an author uniformly from an observed author list and then selecting a topic from a distribution over words that is specific to that author. In our model, each utterance  $u$  is associated with domain and dialog act topics. A word  $w_{uj}$  in  $u$  is generated by first selecting a domain and an act topic and then slot topic over words of  $u$ . The domain-dependent slots

in utterances are usually not dependent on the dialog act. For instance, while "find [hugo] trailer" and "show me where [hugo] is playing" have both a movie-name slot ("hugo"), they have different dialog acts, i.e., find-trailer and find-movie, respectively. We predict posterior probabilities for domain  $\tilde{P}(d \in D|u)$  dialog act  $\tilde{P}(a \in A|ud)$  and slots  $\tilde{P}(s_j \in S|w_{uj}, d, s_{j-1})$  of words  $w_{uj}$  in sequence.

To handle language variability, and hence discover correlation between hierarchical aspects of utterances<sup>1</sup>, we extract prior information from two web resources as follows:

**Web n-Grams (G).** Large-scale engines such as Bing or Google log more than 100M search queries each day. Each query in the search logs has an associated set of URLs that were clicked after users entered a given query. The click information can be used to infer domain class labels, and therefore, can provide (noisy) supervision in training domain classifiers. For example, two queries ("cheap hotels Las Vegas" and "wine resorts in Napa"), which resulted in clicks on the same base URL (e.g., www.hotels.com) probably belong to the same domain ("hotels" in this case).

Given query logs, we compile sets of in-domain queries based on their base URLs<sup>2</sup>. Then, for each vocabulary item  $w_j \in W$  in our corpus, we calculate frequency of  $w_j$  in each set of in-domain queries and represent each word (e.g., "room") as a discrete normalized probability distribution  $\psi_G^j$  over  $K_D$  domains  $\{\psi_G^{dj}\} \in \psi_G^j$ . We inject them as nonuniform priors over domain and dialog act parameters in §4.

**Entity Lists (E).** We limit our model to a set of *named-entity* slots (e.g., *movie-name, restaurant-name*) and *non-named entity* slots (e.g., *restaurant-cuisine, hotel-rating*). For each entity slot, we extract a large collection of entity lists through the url's on the web that correspond to our domains, such as movie-names listed on IMDB, restaurant-names on OpenTable, or hotel-ratings on tripadvisor.com.

<sup>1</sup>Two utterances can be intrinsically related but contain no common terms, e.g., "has open bar" and "serves free drinks".

<sup>2</sup>We focus on domain specific search engines such as IMDB.com, RottenTomatoes.com for movies, Hotels.com and Expedia.com for hotels, etc.

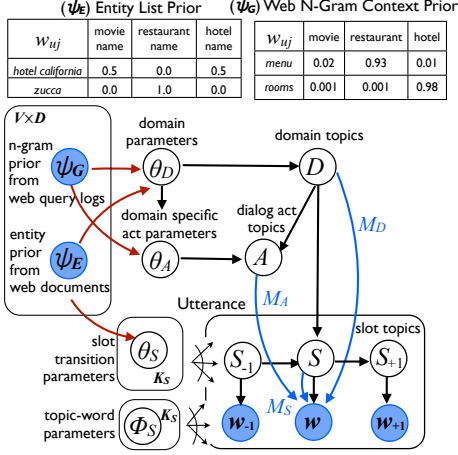

Figure 1: Graphical model depiction of the MCM.  $\mathbf{D}$ ,  $\mathbf{A}$ ,  $\mathbf{S}$  are domain, dialog act and slot in a hierarchy, each consisting of  $K_D, K_A, K_S$  components. Shaded nodes indicate observed variables. Hyper-parameters are omitted. Sample informative priors over latent topics  $\psi_E$  and  $\psi_G$  are shown. Blue arrows indicate frequency of vocabulary terms sampled for each topic.

We represent each entity list as observed nonuniform priors  $\psi_E$  and inject them into our joint learning process as  $V$  sparse multinomial distributions over latent topics  $D$ , and  $S$  to "guide" the generation of utterances (Fig. 1 top-left table), explained in §4.

#### 4 Multi-Layer Context Model - MCM

The generative process of our multi-layer context model (MCM) (Fig. 1) is shown in Algorithm 1. Each utterance  $u$  is associated with  $d = 1..K_D$  multinomial domain-topic distributions  $\theta_D^d$ . Each domain  $d$ , is represented as a distribution over  $a = 1, \dots, K_A$  dialog acts  $\theta_A^{da}$  ( $\theta_D^d \rightarrow \theta_A^{da}$ ). In our MCM model, we assume that each utterance is represented as a hidden Markov model with  $K_S$  slot states. Each state generates n-grams according to a multinomial n-gram distribution. Once domain  $D_u$  and act  $A_{ud}$  topics are sampled for  $u$ , a slot state topic  $S_{ujd}$  is drawn to generate each segment  $w_{uj}$  of  $u$  by considering the word-tag sequence frequencies based on a simple HMM assumption, similar to the content models of (Sauper et al., 2011). Initial and transition probability distributions over the HMM states are sampled from Dirichlet distribution over slots  $\theta_S^{ds}$ . Each slot state  $s$  generates words according to multinomial word distribution  $\phi_S^s$ . We also keep track of the frequency of vocabulary terms  $w_j$ 's in a  $V \times K_D$  matrix  $M_D$ . Every time a  $w_j$  is sampled for a domain  $d$ , we increment its count, a degree of domain bearing

words. Similarly, we keep track of dialog act and slot bearing words in  $V \times K_A$  and  $V \times K_S$  matrices,  $M_A$  and  $M_S$  (shown as red arrows in Fig 1). Being Bayesian, each distribution  $\theta_D^d$ ,  $\theta_A^{da}$ , and  $\theta_S^{ds}$  is sampled from a Dirichlet prior distribution with different parameters, described next.

#### Algorithm 1 Multi-Layer Context Model Generation

- 1: **for** each domain  $d \leftarrow 1, \dots, K_D$
- 2:   draw domain dist.  $\theta_D^d \sim \text{Dir}(\alpha_D^*)^\dagger$ ,
- 3:   **for** each dialog-act  $a \leftarrow 1, \dots, K_A$
- 4:     draw dialog act dist.  $\theta_A^{da} \sim \text{Dir}(\alpha_A^*)$ ,
- 5:     **for** each slot type  $s \leftarrow 1, \dots, K_S$
- 6:       draw slot dist.  $\theta_S^{ds} \sim \text{Dir}(\alpha_S^*)$ .
- 7:   **endfor**
- 8: draw  $\phi_S^s \sim \text{Dir}(\beta)$  for each slot type  $s \leftarrow 1, \dots, K_S$ .
- 9: **for** each utterance  $u \leftarrow 1, \dots, |U|$  **do**
- 10:   Sample a domain  $D_u \sim \text{Multi}(\theta_D^d)$  and,
- 11:   and act topic  $A_{ud} \sim \text{Multi}(\theta_A^{da})$ .
- 12:   **for** words  $w_{uj}, j \leftarrow 1, \dots, N_u$  **do**
- 13:     - Draw  $S_{ujd} \sim \text{Multi}(\theta_S^{D_u, S_{u(j-1)d}})^\ddagger$ .
- 14:     - Sample  $w_{uj} \sim \text{Multi}(\phi_S^{S_{ujd}})$ .
- 15:   **endfor**
- 16: **endfor**

$\dagger \text{Dir}(\alpha_D^*), \text{Dir}(\alpha_A^*), \text{Dir}(\alpha_S^*)$  are parameterized based on prior knowledge.

$\ddagger$  Here HMM assumption over utterance words is used.

In hierarchical topic models (Blei et al., 2003; Mimno et al., 2007), etc., topics are represented as distributions over words, and each document expresses an admixture of these topics, both of which have symmetric Dirichlet ( $\text{Dir}$ ) prior distributions. Symmetric Dirichlet distributions are often used, since there is typically no prior knowledge favoring one component over another. In the topic model literature, such constraints are sometimes used to deterministically allocate topic assignments to known labels (Labeled Topic Modeling (Ramage et al., 2009)) or in terms of pre-learned topics encoded as prior knowledge on topic distributions in documents (Reisinger and Paşca, 2009). Similar to previous work, we define a latent topic per each known semantic component label, e.g., five domain topics for five defined domains. Different from earlier work though, we also inject knowledge that we extract from several resources including entity lists from web search query click logs as well as seed labeled training utterances as prior information. We constrain the generation of the semantic components of our model by encoding prior knowledge in terms of

asymmetric Dirichlet topic priors  $\alpha=(\alpha m_1, \dots, \alpha m_K)$  where each  $k$ th topic has a prior weight  $\alpha_k=\alpha m_k$ , with varying base measure  $\mathbf{m}=(m_1, \dots, m_k)$ <sup>3</sup>.

We update parameter vectors of Dirichlet domain prior  $\alpha_D^{u*}=\{(\alpha_D \cdot \psi_D^{u1}), \dots, (\alpha_D \cdot \psi_D^{uK_D})\}$ , where  $\alpha_D$  is the concentration parameter for domain Dirichlet distribution and  $\psi_D^u=\{\psi_D^{ud}\}_{d=1}^{K_D}$  is the base measure which we obtain from various resources. Because base measure updates are dependent on prior knowledge of corpus words, each utterance  $u$  gets a different base measure. Similarly, we update the parameter vector of the Dirichlet dialog act and slot priors  $\alpha_A^{u*}=\{(\alpha_A \cdot \psi_A^{u1}), \dots, (\alpha_A \cdot \psi_A^{uK_A})\}$  and  $\alpha_S^{u*}=\{(\alpha_S \cdot \psi_S^{u1}), \dots, (\alpha_S \cdot \psi_S^{uK_S})\}$  using base measures  $\psi_A^u=\{\psi_A^{ua}\}_{a=1}^{K_A}$  and  $\psi_S^u=\{\psi_S^{us}\}_{s=1}^{K_S}$  respectively.

Before describing base measure update for domain, act and slot Dirichlet priors, we explain the constraining prior knowledge parameters below:

★ **Entity List Base Measure** ( $\psi_E^j$ ): Entity features are indicative of domain and slots and MCM utilizes these features while sampling topics. For instance, entities *hotel-name* "Hilton" and *location* "New York" are discriminative features in classifying "find nice cheap double room in New York Hilton" into correct domain (*hotel*) and slot (*hotel-name*) clusters. We represent entity lists corresponding to known domains as multinomial distributions  $\psi_E^j$ , where each  $\psi_E^{dj}$  is the probability of entity-word  $w_j$  used in the domain  $d$ . Some entities may belong to more than one domain, e.g., "hotel California" can either be a movie, or song or hotel name.

★ **Web n-Gram Context Base Measure** ( $\psi_G^j$ ): As explained in §3, we use the web n-grams as additional information for calculating the base measures of the Dirichlet topic distributions. Normalized word distributions  $\psi_G^j$  over domains were used as weights for domain and dialog act base measure.

★ **Corpus n-Gram Base Measure** ( $\psi_C^j$ ): Similar to other measures, MCM also encodes n-gram constraints as word-frequency features extracted from labeled utterances. Concretely, we calculate the frequency of vocabulary items given domain-act label pairs from the training labeled utterances and convert there into probability measures over domain-acts. We encode conditional

probabilities  $\{\psi_C^{adj}\} \in \psi_C^j$  as multinomial distributions of words over domain-act pairs, e.g.,  $\psi_C^{adj} = P(d="restaurant", a="make-reservation"|"table")$ .

**Base measure update:** The  $\alpha$ -base measures are used to shape Dirichlet priors  $\alpha_D^{u*}$ ,  $\alpha_A^{u*}$  and  $\alpha_S^{u*}$ . We update the base measures of each sampled domain  $D_u = d$  given each vocabulary  $w_j$  as:

$$\psi_D^{dj} = \begin{cases} \psi_E^{dj}, & \psi_E^{dj} > 0 \\ \psi_G^{dj}, & \text{otherwise} \end{cases} \quad (1)$$

In (1) we assume that entities ( $E$ ) are more indicative of the domain compared to other n-grams ( $G$ ) and should be more dominant in sampling decision for domain topics. Given an utterance  $u$ , we calculate its base measure  $\psi_D^{ud} = (\sum_j^{N_u} \psi_D^{dj}) / N_u$ .

Once the domain is sampled, we update the prior weight of dialog acts  $A_{ud} = a$ :

$$\psi_A^{aj} = \psi_C^{adj} * \psi_G^{dj} \quad (2)$$

and slot components  $S_{ujd} = s$ :

$$\psi_S^{sj} = \psi_E^{dj} \quad (3)$$

Then we update their base measures for a given  $u$  as:  $\psi_A^{ua} = (\sum_j^{N_u} \psi_A^{aj}) / N_u$  and  $\psi_S^{us} = (\sum_j^{N_u} \psi_S^{sj}) / N_u$ .

#### 4.1 Inference and Learning

The goal of inference is to predict the domain, user's act and slot distributions over each segment given an utterance. The MCM has the following set of parameters: domain-topic distributions  $\theta_D^d$  for each  $u$ , the act-topic distributions  $\theta_A^{da}$  for each domain topic  $d$  of  $u$ , local slot-topic distributions for each domain  $\theta^S$ , and  $\phi_S^s$  for slot-word distributions. Previous work (Asuncion et al., 2009; Wallach et al., 2009) shows that the choice of inference method has negligible effect on the probability of testing documents or inferred topics. Thus, we use Markov Chain Monte Carlo (MCMC) method, specifically Gibbs sampling, to model the posterior distribution  $P_{\text{MCM}}(D_u, A_{ud}, S_{ujd} | \alpha_D^{u*}, \alpha_A^{u*}, \alpha_S^{u*}, \beta)$  by obtaining samples  $(D_u, A_{ud}, S_{ujd})$  drawn from this distribution. For each utterance  $u$ , we sample a domain  $D_u$  and act  $A_{ud}$  and hyper-parameters  $\alpha_D$  and  $\alpha_A$  and their base measures  $\psi_D^{ud}$ ,  $\psi_A^{ua}$  (from Eq. 1,2):

$$\theta_D^d = \frac{N_u^d + \alpha_D \psi_D^{ud}}{N_u + \alpha_D^{u*}}; \quad \theta_A^{da} = \frac{N_{a|ud} + \alpha_A \psi_A^{ua}}{N_{ud} + \alpha_A^{u*}} \quad (4)$$

The  $N_u^d$  is the number of occurrences of domain topic  $d$  in utterance  $u$ ,  $N_{a|ud}$  is the number of occurrences of act  $a$  given  $d$  in  $u$ . During sampling of a

<sup>3</sup>See (Wallach, 2008) Chapter 3 for analysis of hyper-priors on topic models.

slot state  $S_{ujd}$ , we assume that utterance is generated by the HMM model associated with the assigned domain. For each segment  $w_{uj}$  in  $u$ , we sample a slot state  $S_{ujd}$  given the remaining slots and hyperparameters  $\alpha_S$ ,  $\beta$  and base measure  $\psi_S^{us}$  (Eq. 3) by:

$$p(S_{ujd} = s | \mathbf{w}, \mathbf{D}_u, \mathbf{S}_{-(ujd)} \alpha_S^{\mathbf{u}^*}, \beta) \propto \frac{N_{ujd}^k + \beta}{N_{(\cdot)}^k + V\beta} * (N_s^{D_u, S_{u(j-1)d}} + \alpha_S \psi_S^{us}) * \frac{N_{S_{u(j+1)d}}^{D_u, s} + \mathbb{I}(S_{uj-1}, s) + \mathbb{I}(S_{uj+1}, s) + \alpha_S \psi_S^{us}}{N_{(\cdot)}^{D_u, s} + \mathbb{I}(S_{uj-1}, s) + K_D \alpha_S^{\mathbf{u}^*}} \quad (5)$$

The  $N_{ujd}^k$  is the number of times segment  $w_{uj}$  is generated from slot state  $s$  in all utterances assigned to domain topic  $d$ ,  $N_{s_2}^{D_u, s_1}$  is the number of transitions from slot state  $s_1$  to  $s_2$ , where  $s_1 \in \{S_{u(j-1)d}, S_{u(j+1)d}\}$ ,  $\mathbb{I}(s_1, s_2) = 1$  if slot  $s_1 = s_2$ .

## 4.2 Semantic Structure Extraction with MCM

During Gibbs sampling, we keep track of the frequency of draws of domain, dialog act and slot indicating n-grams  $w_j$ , in  $M_D$ ,  $M_A$  and  $M_S$  matrices, respectively. These n-grams are context bearing words (examples are shown in Fig.1.). For given  $u$  the predicted domain  $d_u^*$  is determined by:

$$d_u^* = \arg \max_d \tilde{P}(d|u) = \arg \max_d [\theta_D^d * \prod_{j=1}^{N_u} \frac{M_D^{jd}}{M_D}]$$

and predicted dialog act by  $\arg \max_a \tilde{P}(a|ud^*)$ :

$$a_u^* = \arg \max_a [\theta_A^{d^* a} * \prod_{j=1}^{N_u} \frac{M_A^{ja}}{M_A}] \quad (6)$$

For each segment  $w_{uj}$  in  $u$ , its predicted slot are determined by  $\arg \max_s P(s_j | w_{uj}, d^*, s_{j-1})$ :

$$s_{uj}^* = \arg \max_s [p(S_{ujd^*} = s | \cdot) * \prod_{j=1}^{N_u} \frac{Z_S^{js}}{Z_S}] \quad (7)$$

## 5 Experiments

We performed several experiments to evaluate our proposed approach. Before presenting our results, we describe our datasets as well as two baselines.

### 5.1 Datasets, Labels and Tags

Our dataset contains utterances obtained from dialogs between human users and our personal assistant system. We use the transcribed text forms of

Domain	Sample Dialog Acts (DAs) & Slots
movie	<b>DAs:</b> find-movie/director/actor, buy-ticket <b>Slots:</b> name, mpaa-rating ( <i>g-rated</i> ), date, director/actor-name, award( <i>oscar winning</i> )...
hotel	<b>DAs:</b> find-hotel, book-hotel, <b>Slots:</b> name, room-type( <i>double</i> ), amenities, smoking, reward-program( <i>platinum elite</i> )...
restaurant	<b>DAs:</b> find-restaurant, make-reservation, <b>Slots:</b> opening-hour, amenities, meal-type,...
event	<b>DAs:</b> find-event/ticket/performers, get-info.. <b>Slots:</b> name, type( <i>concert</i> ), performer...

Table 2: List of domains, dialog acts and semantic slot tags of utterance segments. Examples for some slots values are presented in parenthesis as *italicized*.

the utterances obtained from (acoustic modeling engine) to train our models<sup>4</sup>. Thus, our dataset contains 18084 NL utterances, 5034 of which are used for measuring the performance of our models. The dataset consists of five domain classes, i.e. *movie*, *restaurant*, *hotel*, *event*, *other*, 42 unique dialog acts and 41 slot tags. Each utterance is labeled with a domain, dialog act and a sequence of slot tags corresponding to segments in utterance (see examples in Table 1). Table 2 shows sample dialog act and slot labels. Annotation agreement, Kappa measure (Cohen, 1960), was around 85%.

We pulled a month of web query logs and extracted over 2 million search queries from the movie, hotel, event, and restaurant domains. We also used generic web queries to compile a set of 'other' domain queries. Our vocabulary consists of n-grams and segments (phrases) in utterances that are extracted using web n-grams and entity lists of §3. We extract distributions of n-grams and entities to inject as prior weights for entity list base ( $\psi_{\mathbf{E}}^j$ ) and web n-gram context base measures ( $\psi_{\mathbf{G}}^j$ ) (see §4).

### 5.2 Baselines and Experiment Setup

We evaluated two baselines and two variants of our joint SLU approach as follows:

★ **Sequence-SLU:** A traditional approach to SLU extracts domain, dialog act and slots as semantic components of utterances using three sequential models. Typically, domain and dialog act detection models are taken as query classification, where a given NL query is assigned domain and act labels. Among supervised query classification meth-

<sup>4</sup>We submitted sample utterances used in our models as additional resource. Due to licensing issues, we will reveal the full train/test utterances upon acceptance of our paper.

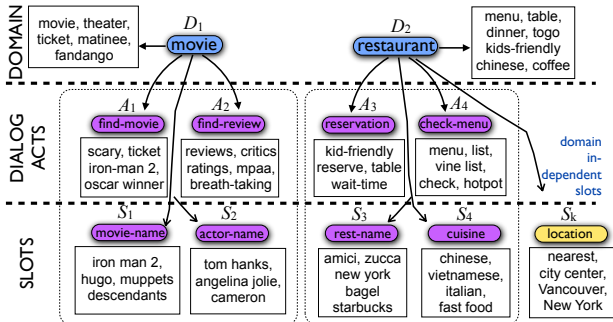

Figure 2: Sample topics discovered by Multi-Layer Context Model (MCM). Given samples of utterances, MCM is able to infer a meaningful set of dialog act ( $A$ ) and slots ( $S$ ), falling into broad categories of domain classes ( $D$ ).

ods, we used the `Adaboost`, utterance classification method that starts from a set of weak classifiers and builds a strong classifier by boosting the weak classifiers. Slot discovery is taken as a sequence labeling task in which *segments* in utterances are labeled (Li, 2010). For segment labeling we use Semi-Markov Conditional Random Fields (`Semi-CRF`) (Sarawagi and Cohen, 2004) method as a benchmark in evaluating semantic tagging performance.

★ **Tri-CRF**: We used Triangular Chain CRF (Jeong and Lee, 2008) as our supervised joint model baseline. It is a state-of-the-art method that learns the sequence labels and utterance class (domain or dialog act) as meta-sequence in a joint framework. It encodes the inter-dependence between the slot sequence  $s$  and meta-sequence label ( $d$  or  $a$ ) using a triangular chain (dual-layer) structure.

★ **Base-MCM**: Our first version injects an informative prior for domain, dialog act and slot topic distributions using information extracted from only labeled training utterances and inject as prior constraints (corpus  $n$ -gram base measure  $\psi_C^j$ ) during topic assignments.

★ **WebPrior-MCM**: Our full model encodes distributions extracted from labeled training data as well as structured web logs as asymmetric Dirichlet priors. We analyze performance gain by the information from web sources ( $\psi_G^j$  and  $\psi_E^j$ ) when injected into our approach compared to `Base-MCM`.

We inject dictionary constraints as features to train supervised discriminative methods, i.e., boosting and `Semi-CRF` in `Sequence-SLU`, and `Tri-CRF` models. For semantic tagging, dictionary constraints apply to the features between individual

segments and their labels, and for utterance classification (to predict domain and dialog acts) they apply to the features between utterance and its label. Given a list of dictionaries, these constraints specify which label is more likely. For discriminative methods, we use several named entities, e.g., `Movie-Name`, `Restaurant-Name`, `Hotel-Name`, etc., non-named entities, e.g., `Genre`, `Cuisine`, etc., and domain independent dictionaries, e.g., `Time`, `Location`, etc.

We train domain and dialog act classifiers via `Icsiboost` (Favre et al., 2007) with 10K iterations using lexical features (up to 3-n-grams) and constraining dictionary features (all dictionaries). For feature templates of sequence learners, i.e., `Semi-CRF` and `Tri-CRF`, we use current word, bi-gram and dictionary features. For `Base-MCM` and `WebPrior-MCM`, we run Gibbs sampler for 2000 iterations with the first 500 samples as burn-in.

### 5.3 Evaluations and Discussions

We evaluate the performance of our joint model on two experiments using two metrics. For domain and dialog act detection performance we present results in accuracy, and for slot detection we use the F1 pairwise measure.

**Experiment 1. Encoding Prior Knowledge:** A common evaluation method in SLU tasks is to measure the performance of each individual semantic model, i.e., domain, dialog act and semantic tagging (slot filling). Here, we not only want to demonstrate the performance of each component of MCM but also their performance under limited amount of labeled data. We randomly select subsets of labeled training data  $U_L^i \subset U_L$  with different samples sizes,  $n_L^i = \{\gamma * n_L\}$ , where  $n_L$  represents the sample size of  $U_L$  and  $\gamma = \{10\%, 25\%, \dots\}$  is the subset percentage. At each random selection, the rest of the utterances are used as unlabeled data to boost the performance of MCM. The supervised baselines do not leverage the unlabeled utterances.

The results reported in Figure 3 reveal both the strengths and some shortcomings of our approach. When the number of labeled data is small ( $n_L^i \leq 25\% * n_L$ ), our `WebPrior-MCM` has a better performance on domain and act predictions compared to the two baselines. Compared to `Sequence-SLU`, we observe 4.5% and 3% performance improvement on the domain and dialog act

Figure 3: Semantic component extraction performance measures for various baselines as well as our approach with different priors.

models, whereas our gain is 2.6% and 1.7% over Tri-CRF models. As the percentage of labeled utterances in training data increase, Tri-CRF performance increases, however WebPrior-MCM is still comparable with Sequence-SLU. This is because we utilize domain priors obtained from the web sources as supervision during generative process as well as unlabeled utterances that enable handling language variability. Adding labeled data improves the performance of all models however supervised models benefit more compared to MCM models.

Although WebPrior-MCM’s domain and dialog act performances are comparable (if not better than) the other baselines, it falls short on the semantic tagging model. This is partially due to the HMM assumption compared to the supervised conditional model’s used in the other baselines, i.e., Semi-CRF in Sequence-SLU and Tri-CRF). Our work can be extended by replacing HMM assumption with CRF based sequence learner to enhance the capability of the sequence tagging component of MCM.

**Experiment 2. Less is More?** Being Bayesian, our model can incorporate unlabeled data at training time. Here, we evaluate the performance gain on domain, act and slot predictions as more unlabeled data is introduced at learning time. We use only 10% of the utterances as labeled data in this experiment and incrementally add unlabeled data (90% of labeled data are treated as unlabeled).

The results are shown in Table 3.  $n\%$  ( $n=10,25,\dots$ ) unlabeled data indicates that the WebPrior-MCM is trained using  $n\%$  of unlabeled utterances along with training utterances. Adding unlabeled data has a positive impact on the performance of all three se-

Table 3: Performance evaluation results of WebPrior-MCM using different sizes of unlabeled utterances at learning time.

Unlabeled %	Domain Accuracy	Dialog Act Accuracy	Slot F-Measure
10%	94.69	84.17	52.61
25%	94.89	84.29	54.22
50%	95.08	84.39	56.58
75%	95.19	84.44	<b>57.45</b>
100%	<b>95.28</b>	84.52	<b>58.18</b>

semantic components when WebPrior-MCM is used. The results show that our joint modeling approach has an advantage over the other joint models (i.e., Tri-CRF) in that it can leverage unlabeled NL utterances. Our approach might be usefully extended into the area of understanding search queries, where an abundance of unlabeled queries is observed.

## 6 Conclusions

In this work, we introduced a joint approach to spoken language understanding that integrates two properties (*i*) identifying user actions in multiple domains in relation to semantic units, (*ii*) utilizing large amounts of unlabeled web search queries that suggest the user’s hidden intentions. We proposed a semi-supervised generative joint learning approach tailored for injecting prior knowledge to enhance the semantic component extraction from utterances as a unifying framework. Experimental results using the new Bayesian model indicate that we can effectively learn and discover meta-aspects in natural language utterances, outperforming the supervised baselines, especially when there are fewer labeled and more unlabeled utterances.

## Abstract

Aspect extraction is a central problem in sentiment analysis. Current methods either extract aspects without categorizing them, or extract and categorize them using unsupervised topic modeling. By categorizing, we mean the synonymous aspects should be clustered into the same category. In this paper, we solve the problem in a different setting where the user provides some seed words for a few aspect categories and the model extracts and clusters aspect terms into categories simultaneously. This setting is important because categorizing aspects is a subjective task. For different application purposes, different categorizations may be needed. Some form of user guidance is desired. In this paper, we propose two statistical models to solve this seeded problem, which aim to discover exactly what the user wants. Our experimental results show that the two proposed models are indeed able to perform the task effectively.

## 1 Introduction

Aspect-based sentiment analysis is one of the main frameworks for sentiment analysis (Hu and Liu, 2004; Pang and Lee, 2008; Liu, 2012). A key task of the framework is to extract aspects of entities that have been commented in opinion documents. The task consists of two sub-tasks. The first sub-task extracts *aspect terms* from an opinion corpus. The second sub-task clusters synonymous aspect terms into categories where each category

represents a single aspect, which we call an *aspect category*. Existing research has proposed many methods for aspect extraction. They largely fall into two main types. The first type only extracts aspect terms without grouping them into categories (although a subsequent step may be used for the grouping, see Section 2). The second type uses statistical topic models to extract aspects and group them at the same time in an unsupervised manner. Both approaches are useful. However, in practice, one also encounters another setting, where grouping is not straightforward because for different applications the user may need different groupings to reflect the application needs. This problem was reported in (Zhai et al., 2010), which gave the following example. In car reviews, internal design and external design can be regarded as two separate aspects, but can also be regarded as one aspect, called “design”, based on the level of details that the user wants to study. It is also possible that the same word may be put in different categories based on different needs. However, (Zhai et al., 2010) did not extract aspect terms. It only categorizes a set of given aspect terms.

In this work, we propose two novel statistical models to extract and categorize aspect terms automatically given some seeds in the user interested categories. It is thus able to best meet the user’s specific needs. Our models also jointly model both aspects and aspect specific sentiments. The first model is called SAS and the second model is called ME-SAS. ME-SAS improves SAS by using Maximum-Entropy (or Max-Ent for short) priors to help separate aspects and sentiment terms. However, to train Max-Ent, we do not need manually labeled training data (see Section 4).

In practical applications, asking users to provide some seeds is easy as they are normally experts in their trades and have a good knowledge what are important in their domains.

Our models are related to topic models in general (Blei et al., 2003) and joint models of aspects and sentiments in sentiment analysis in specific (e.g., Zhao et al., 2010). However, these current models are typically unsupervised. None of them can use seeds. With seeds, our models are thus semi-supervised and need a different formulation. Our models are also related to the DF-LDA model in (Andrzejewski et al., 2009), which allows the user to set must-link and cannot-link constraints. A must-link means that two terms must be in the same topic (aspect category), and a cannot-link means that two terms cannot be in the same topic. Seeds may be expressed with must-links and cannot-links constraints. However, our models are very different from DF-LDA. First of all, we jointly model aspect and sentiment, while DF-LDA is only for topics/aspects. Joint modeling ensures clear separation of aspects from sentiments producing better results. Second, our way of treating seeds is also different from DF-LDA. We discuss these and other related work in Section 2.

The proposed models are evaluated using a large number of hotel reviews. They are also compared with two state-of-the-art baselines. Experimental results show that the proposed models outperform the two baselines by large margins.

## 2 Related Work

There are many existing works on aspect extraction. One approach is to find frequent noun terms and possibly with the help of dependency relations (Hu and Liu, 2004; Popescu and Etzioni, 2005; Zhuang et al., 2006; Blair-Goldensohn et al., 2008; Ku et al., 2006; Wu et al., 2009; Somasundaran and Wiebe, 2009; Qiu et al., 2011). Another approach is to use supervised sequence labeling (Liu, Hu and Cheng 2005; Jin and Ho, 2009; Jakob and Gurevych, 2010; Li et al., 2010; Choi and Cardie, 2010; Kobayashi et al., 2007; Yu et al., 2011). Ma and Wan (2010) also exploited centering theory, and (Yi et al., 2003) used language models. However, all these methods do not group extracted aspect terms into categories. Although there are works on grouping aspect terms (Carenini et al., 2005; Zhai et al., 2010; Zhai et al.,

2011; Guo et al., 2010), they all assume that aspect terms have been extracted beforehand.

In recent years, topic models have been used to perform extraction and grouping at the same time. Existing works are based on two basic models, pLSA (Hofmann, 1999) and LDA (Blei et al., 2003). Some existing works include discovering global and local aspects (Titov and McDonald, 2008), extracting key phrases (Branavan et al., 2008), rating multi-aspects (Wang et al., 2010; Moghaddam and Ester, 2011), summarizing aspects and sentiments (Lu et al., 2009), and modeling attitudes (Sauper et al., 2011). In (Lu and Zhai, 2008), a semi-supervised model was proposed. However, their method is entirely different from ours as they use expert reviews to guide the analysis of user reviews.

Aspect and sentiment extraction using topic modeling come in two flavors: discovering aspect words sentiment wise (i.e., discovering positive and negative aspect words and/or sentiments for each aspect without separating aspect and sentiment terms) (Lin and He, 2009; Brody and Elhadad, 2010; Jo and Oh, 2011) and separately discovering both aspects and sentiments (e.g., Mei et al., 2007; Zhao et al., 2010). Zhao et al. (2010) used Maximum-Entropy to train a switch variable to separate aspect and sentiment words. We adopt this method as well but with no use of manually labeled data in training. One problem with these existing models is that many discovered aspects are not understandable/meaningful to users. Chang et al. (2009) stated that one reason is that the objective function of topic models does not always correlate well with human judgments. Our seeded models are designed to overcome this problem.

Researchers have tried to generate “meaningful” and “specific” topics/aspects. Blei and McAuliffe (2007) and Ramage et al. (2009) used document label information in a supervised setting. Hu et al. (2011) relied on user feedback during Gibbs sampling iterations. Andrzejewski et al. (2011) incorporated first-order logic with Markov Logic Networks. However, it has a practical limitation for reasonably large corpora since the number of non-trivial groundings can grow to  $O(N^2)$  where  $N$  is the number of unique tokens in the corpus. Andrzejewski et al. (2009) used another approach (DF-LDA) by introducing must-link and cannot-link constraints as Dirichlet Forest priors. Zhai et al. (2011) reported that the model does not scale up

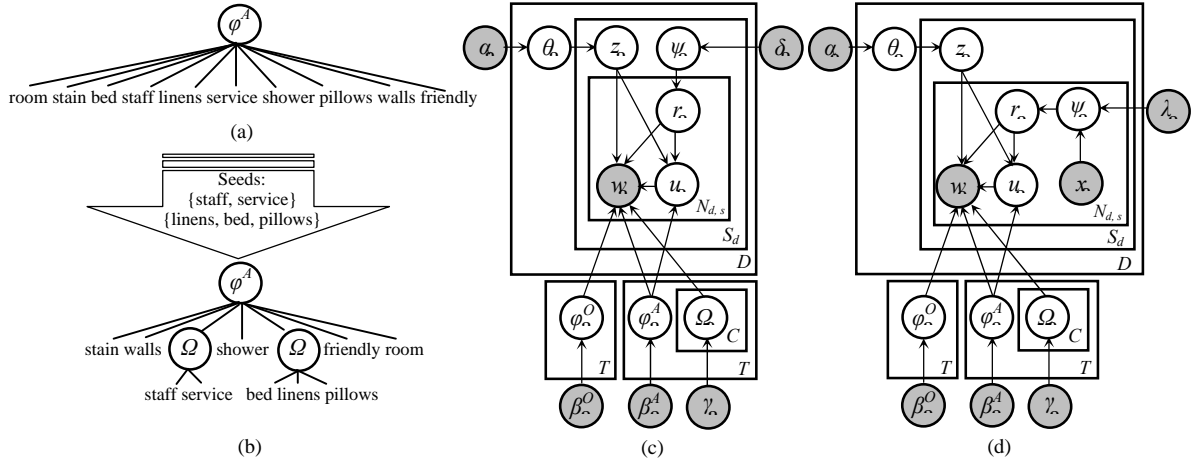

Figure 1: Prior structure: (a) Standard ASMs, (b) Two-level tree structured distribution. Graphical models in plate notation: (c) SAS and (d) ME-SAS.

when the number of cannot-links go beyond 1000 because the number of maximal cliques  $Q^{(r)}$  in a connected component of size  $|r|$  in the cannot-link graph is exponential in  $r$ . Note that we could still experiment with DF-LDA as our problem size is not so large. We will show in Section 4 that the proposed models outperform it by a large margin.

### 3 Proposed Seeded Models

The standard LDA and existing aspect and sentiment models (ASMs) are mostly governed by the phenomenon called “higher-order co-occurrence” (Heinrich, 2009), i.e., based on how often terms co-occur in different contexts<sup>1</sup>. This unfortunately results in many “non-specific” terms being pulled and clustered. We employ seed sets to address this issue by “guiding” the model to group semantically related terms in the same aspect thus making the aspect more specific and related to the seeds (which reflect the user needs). For easy presentation, we will use *aspect* to mean *aspect category* from now on. We replace the multinomial distribution over words for each aspect (as in ASMs) with a special two-level tree structured distribution. The generative process of ASMs assumes that each vocabulary word is independently (i.e., not dependent upon other word-aspect association) and equally probable to be associated with any aspect. Due to higher-order co-occurrences, we find conceptually different terms yet related in contexts (e.g., in hotel domain terms like stain, shower, walls in aspect

*Maintenance*; bed, linens, pillows in aspect *Cleanliness*) equally probable of emission for any aspect. Figure 1(a) shows an example tree. Upon adding the seed sets {bed, linens, pillows} and {staff, service}, the prior structure now changes to the correlated distribution in Figure 1 (b). Thus, each aspect has a top level distribution over non-seed words and seed sets. Each seed set in each aspect further has a second level distribution over seeds in that seed set. The aspect term (word) emission now requires two steps: first sampling at level one to obtain a non-seed word or a seed set. If a non-seed word is sampled we emit it else we further sample at the second seed set level and emit a seed word. This ensures that seed words together have either all high or low aspect associations. Furthermore, seed sets preserve conjugacy between related concepts and also shape more specific aspects by clustering based on higher order co-occurrences with seeds rather than only with standard one level multinomial distribution over words (or terms) alone.

#### 3.1 SAS Model

We now present the proposed Seeded Aspect and Sentiment model (SAS). Let  $v_{1..V}$  denote the entries in our vocabulary where  $V$  is the number of unique non-seed terms. Let there be  $C$  seed sets  $Q_{l=1..C}$  where each seed set  $Q_l$  is a group of semantically related terms. Let  $\varphi_{t=1..T}^A, \varphi_{t=1..T}^O$  denote  $T$  aspect and aspect specific sentiment models. Also let  $\Omega_{t,l}$  denote the aspect specific distribution of seeds in the seed set  $Q_l$ . Following the approach of (Zhao et al., 2010), we too assume that a review sentence usually talks about one

<sup>1</sup>  $w_1$  co-occurring with  $w_2$  which in turn co-occurs with  $w_3$  denotes a second-order co-occurrence between  $w_1$  and  $w_3$ .

aspect. A review document  $d_{1...D}$  comprises of  $S_d$  sentences and each sentence  $s \in S_d$  has  $N_{d,s}$  words. Also, let  $Sent_s^d$  denote the sentence  $s$  of document  $d$ . To distinguish between aspect and sentiment terms, we introduce an indicator (switch) variable  $r_{d,s,j} \in \{\hat{a}, \hat{o}\}$  for the  $j^{th}$  term of  $Sent_s^d, w_{d,s,j}$ . Further, let  $\psi_{d,s}$  denote the distribution of aspects and sentiments in  $Sent_s^d$ . The generative process of the SAS model (see Figure 1(c)) is given by:

1. For each aspect  $t \in \{1, \dots, T\}$ :
  - i. Draw  $\varphi_t^o \sim Dir(\beta^o)$
  - ii. Draw a distribution over terms and seed sets  $\varphi_t^A \sim Dir(\beta^A)$ 
    - a) For each seed set  $l \in \{Q_1, \dots, Q_C\}$   
Draw a distribution over seeds  $\Omega_{t,l} \sim Dir(\gamma)$
2. For each (review) document  $d \in \{1, \dots, D\}$ :
  - i. Draw  $\theta_d \sim Dir(\alpha)$
  - ii. For each sentence  $s \in \{1, \dots, S_d\}$ :
    - a) Draw  $z_{d,s} \sim Mult(\theta_d)$
    - b) Draw  $\psi_{d,s} \sim Beta(\delta)$
    - c) For each term  $w_{d,s,j}$  where  $j \in \{1, \dots, N_{d,s}\}$ :
      - I. Draw  $r_{d,s,j} \sim Bernoulli(\psi_{d,s})$ ,  $r_{d,s,j} \in \{\hat{a}, \hat{o}\}$
      - II. if  $r_{d,s,j} = \hat{o}$  //  $w_{d,s,j}$  is a sentiment  
Emit  $w_{d,s,j} \sim Mult(\varphi_{z_{d,s}}^o)$   
else //  $r_{d,s,j} = \hat{a}$ ,  $w_{d,s,j}$  is an aspect
        - A. Draw  $u_{d,s,j} \sim Mult(\varphi_{z_{d,s}}^A)$
        - B. if  $u_{d,s,j} \in V$  // non-seed term  
Emit  $w_{d,s,j} = u_{d,s,j}$   
else //  $u_{d,s,j}$  is some seed set index say  $l_{d,s,j}$   
Emit  $w_{d,s,j} \sim \Omega_{z_{d,s}, l_{d,s,j}}$

We employ collapsed Gibbs sampling (Griffiths and Steyvers, 2004) for posterior inference. As  $z$  and  $r$  are at different hierarchical levels, we derive their samplers separately as follows:

$$p(z_{d,s} = t | Z_{-d,s}, R_{-d,s}, W_{-d,s}, U_{-d,s}) \propto \frac{B(n_{t,[]-d,s}^o + \beta^o)}{B(n_{t,[]-d,s}^o + \beta^o)} \times \frac{B(n_{t,[]-d,s}^{U,A} + \beta^A)}{B(n_{t,[]-d,s}^{U,A} + \beta^A)} \times \prod_{l=1}^C \frac{B(n_{t,l,[]-d,s}^{S,A} + \gamma)}{B(n_{t,l,[]-d,s}^{S,A} + \gamma)} \times \frac{n_{d,t}^{Sent. -d,s} + \alpha}{n_{d,(.)}^{Sent. -d,s} + T\alpha} \quad (1)$$

$$p(r_{d,s,j} = \hat{o} | Z_{-d,s}, R_{-d,s,j}, W_{-d,s,j}, U_{-d,s,j}, z_{d,s} = t, w_{d,s,j} = w) \propto \frac{n_{t,w-d,s,j}^o + \beta^o}{n_{t,(.)-d,s,j}^o + |V \cup U_l Q_l| \beta^o} \times \frac{n_{d,s-d,s,j}^o + \delta_b}{n_{d,s-d,s,j}^o + \delta_a + n_{d,s-d,s,j}^o + \delta_b} \quad (2)$$

$$p(r_{d,s,j} = \hat{a} | \dots) \propto \begin{cases} \frac{n_{t,l,w-d,s,j}^{S,A} + \gamma}{n_{t,l,(.)-d,s,j}^{S,A} + |Q_l| \gamma} \times \frac{n_{t,l}^o + \beta^A}{n_{t,(.)}^o + (V+C)\beta^A} \times \frac{n_{d,s-d,s,j}^o + \delta_b}{n_{d,s-d,s,j}^o + \delta_a + n_{d,s-d,s,j}^o + \delta_b} ; w \in Q_l \\ \frac{n_{t,w}^{U,A} + \beta^A}{n_{t,(.)}^{U,A} + (V+C)\beta^A} \times \frac{n_{d,s-d,s,j}^o + \delta_b}{n_{d,s-d,s,j}^o + \delta_a + n_{d,s-d,s,j}^o + \delta_b} ; \forall l, w \in Q_l \end{cases} \quad (3)$$

where  $B(\vec{x}) = \frac{\prod_{i=1}^{\dim(\vec{x})} \Gamma(x_i)}{\Gamma(\sum_{i=1}^{\dim(\vec{x})} x_i)}$  is the multinomial Beta function.  $n_{t,v}^o$  is the number of times term  $v$  was

assigned to aspect  $t$  as an opinion/sentiment word.  $n_{t,v}^{U,A}$  is the number of times non-seed term  $v \in V$  was assigned to aspect  $t$  as an aspect.  $n_{t,v}^{S,A}$  is the number of times seed term  $v \in V_l$  was assigned to aspect  $t$  as an aspect.  $n_{d,t}^{Sent.}$  is the number of sentences in document  $d$  that were assigned to aspect  $t$ .  $n_{d,s}^A$  and  $n_{d,s}^o$  denote the number of terms in  $Sent_s^d$  that were assigned to aspects and opinions respectively.  $n_{t,l}^o$  is the number of times any term of seed set  $Q_l$  was assigned to aspect  $t$ . Omission of a latter index denoted by  $[]$  in the above notation represents the corresponding row vector spanning over the latter index. For example,  $n_{t,[]}^{U,A} = [n_{t,v=1}^{U,A}, \dots, n_{t,v=V}^{U,A}]$  and  $(\cdot)$  denotes the marginalized sum over the latter index. The subscript  $-d,s$  denotes the counts excluding assignments of all terms in  $Sent_s^d$ .  $-d,s,j$  denotes counts excluding  $w_{d,s,j}$ . We perform hierarchical sampling. First, an aspect is sampled for each sentence  $z_{d,s}$  using Eq. (1). After sampling the aspect, we sample  $r_{d,s,j}$ . The probability of  $w_{d,s,j}$  being an opinion or sentiment term,  $p(r_{d,s,j} = \hat{o})$  is given by Eq. (2). However, for  $p(r_{d,s,j} = \hat{a})$  we have two cases: (a) the observed term  $w = w_{d,s,j} \in Q_l$  or (b) does not belong to any seed set,  $\forall l, w \in Q_l$ , i.e.,  $w$  is a non-seed term. These cases are dealt in Eq. (3).

**Asymmetric Beta priors:** Hyper-parameters  $\alpha, \beta^o, \beta^A$  are not very sensitive and the heuristic values suggested in (Griffiths and Steyvers, 2004) usually hold well in practice (Wallach et al. 2009). However, the smoothing hyper-parameter  $\delta$  (Figure 1(c)) is crucial as it governs the aspect or sentiment switch. Essentially,  $\psi_{d,s} \sim Beta(\delta \vec{\xi})$  is the probability of emitting an aspect term<sup>2</sup> in  $Sent_s^d$  with concentration parameter  $\delta$  and base measure  $\vec{\xi} = [\xi_a, \xi_b]$ . Without any prior belief, uniform base measures  $\xi_a = \xi_b = 0.5$  are used resulting in symmetric Beta priors. However, aspects are often more probable than sentiments in a sentence (e.g., “The beds, sheets, and bedding were dirty.”). Thus, it is more principled to employ asymmetric priors. Using a labeled set of sentences,  $S_{labeled}$ , where we know the per sentence probability of aspect emission ( $\psi_{d,s}$ ), we can employ the method of moments to estimate the smoothing hyper-parameter  $\delta = [\delta_a, \delta_b]$ :

$$\delta_a = \mu \left( \frac{\mu(1-\mu)}{\sigma} - 1 \right), \delta_b = \delta_a \left( \frac{1}{\mu} - 1 \right); \mu = E[\psi_{d,s}], \sigma = Var[\psi_{d,s}] \quad (4)$$

<sup>2</sup>  $r_{d,s,j} \sim Bernoulli(\psi_{d,s})$ .  $\psi_{d,s}, 1 - \psi_{d,s}$  are the success and failure probability of emitting an aspect/sentiment term.

### 3.2 ME-SAS Model

We can further improve SAS by employing Maximum Entropy (Max-Ent) priors for aspect and sentiment switching. We call this new model ME-SAS. The motivation is that aspect and sentiment terms play different syntactic roles in a sentence. Aspect terms tend to be nouns or noun phrases while sentiment terms tend to be adjectives, adverbs, etc. POS tag information can be elegantly encoded by moving  $\psi_{d,s}$  to the term plate (see Figure 1(d)) and drawing it from a Max-Ent( $x_{d,s,j}; \lambda$ ) model. Let  $\vec{x}_{d,s,j} = [POS_{w_{d,s,j-1}}, POS_{w_{d,s,j}}, POS_{w_{d,s,j+1}}, w_{d,s,j} - 1, w_{d,s,j}, w_{d,s,j} + 1]$  denote the feature vector associated with  $w_{d,s,j}$  encoding lexical and POS features of the previous, current and next term. Using a training data set, we can learn Max-Ent priors. Note that unlike traditional Max-Ent training, we do not need manually labeled data for training (see Section 4 for details). For ME-SAS, only the sampler for the switch variable  $r$  changes as follows:

$$p(r_{d,s,j} = \hat{o} | Z_{-d,s}, R_{-d,s,j}, W_{-d,s,j}, U_{-d,s,j}, Z_{d,s} = t, w_{d,s,j} = w) \propto \frac{n_{t,w_{-d,s,j}}^{\hat{o}} + \beta^{\hat{o}}}{n_{t,(c)-d,s,j}^{\hat{o}} + |V \cup U \cup Q_l| \beta^{\hat{o}}} \times \frac{\exp(\sum_{i=1}^n \lambda_{if_i}(x_{d,s,j}, \hat{o}))}{\sum_{y \in \{\hat{a}, \hat{o}\}} \exp(\sum_{i=1}^n \lambda_{if_i}(x_{d,s,j}, y))} \quad (5)$$

$$p(r_{d,s,j} = \hat{a} | \dots) \propto \begin{cases} \frac{n_{t,w_{-d,s,j}}^{S,A} + \gamma}{n_{t,(c)-d,s,j}^{S,A} + |Q_l| \gamma} \times \frac{n_{t,l}^{\hat{a}} + \beta^{\hat{a}}}{n_{t,(c)}^{\hat{a}} + (V+C)\beta^{\hat{a}}} \times \frac{\exp(\sum_{i=1}^n \lambda_{if_i}(x_{d,s,j}, \hat{a}))}{\sum_{y \in \{\hat{a}, \hat{o}\}} \exp(\sum_{i=1}^n \lambda_{if_i}(x_{d,s,j}, y))} ; w \in Q_l \\ \frac{n_{t,w}^{U,A} + \beta^{\hat{a}}}{n_{t,(c)}^{U,A} + (V+C)\beta^{\hat{a}}} \times \frac{\exp(\sum_{i=1}^n \lambda_{if_i}(x_{d,s,j}, \hat{a}))}{\sum_{y \in \{\hat{a}, \hat{o}\}} \exp(\sum_{i=1}^n \lambda_{if_i}(x_{d,s,j}, y))} ; \hat{a} \in l, w \in Q_l \end{cases} \quad (6)$$

where  $\lambda_{1..n}$  are the parameters of the learned Max-Ent model corresponding to the  $n$  binary feature functions  $f_{1..n}$  of Max-Ent.

## 4 Experiments

This section evaluates the proposed models. Since the focus in this paper is to generate high quality aspects using seeds, we will not evaluate sentiments although both SAS and ME-SAS can also discover sentiments. To compare the performance with our models, we use two existing state-of-the-art models, ME-LDA (Zhao et al. 2010) and DF-LDA (Andrzejewski et al., 2009). As discussed in Section 2, there are two main flavors of aspect and sentiment models. The first flavor does not separate aspect and sentiment, and the second flavor uses a switch to perform the separation. Since our models also perform a

switch, it is natural to compare with the latter flavor, which is also more advanced. ME-LDA is the representative model in this flavor. DF-LDA adds constraints to LDA. We use our seeds to generate constraints for DF-LDA. While ME-LDA cannot consider constraints, DF-LDA does not separate sentiments and aspects. Apart from other modeling differences, our models can do both, which enable them to produce much better results.

**Dataset and Settings:** We used hotel reviews from tripadvisor.com. Our corpus consisted of 101,234 reviews and 692,783 sentences. Punctuations, stop words<sup>3</sup>, and words appearing less than 5 times in the corpus were removed.

For all models, the posterior inference was drawn after 5000 Gibbs iterations with an initial burn-in of 1000 iterations. For SAS and ME-SAS, we set  $\alpha = 50/T$ ,  $\beta^A = \beta^O = 0.1$  as suggested in (Griffiths and Steyvers, 2004). To make the seeds more effective, we set the seed set word-distribution hyper-parameter  $\gamma$  to be much larger than  $\beta^A$ , the hyper-parameter for the distribution over seed sets and aspect terms. This results in higher weights to seeded words which in turn guide the sampler to cluster relevant terms better. A more theoretical approach would involve performing hyper-parameter estimation (Wallach et al., 2009) which may reveal specific properties of the dataset like the estimate of  $\alpha$  (indicating how different documents are in terms of their latent semantics),  $\beta$  (suggesting how large the groups of frequently appearing aspect and sentiment terms are) and  $\gamma$  (giving a sense of which and how large groupings of seeds are good). These are interesting questions and we defer it to our future work. In this work, we found that the setting  $\gamma = 250$ , a larger value compared to  $\beta^A$ , produced good results.

For SAS, the asymmetric Beta priors were estimated using the method of moments (Section 3.1). We sampled 500 random sentences from the corpus and for each sentence identified the aspects. We thus computed the per-sentence probability of aspect emission ( $\psi_{d,s}$ ) and used Eq. (4) to compute the final estimates, which give  $\delta_a = 2.35$ ,  $\delta_b = 3.44$ .

To learn the Max-Ent parameters  $\lambda$  of ME-SAS, we used the sentiment lexicon<sup>4</sup> of (Hu and Liu, 2004) to automatically generate training data (no manual labeling). We randomly sampled 1000 terms from the corpus which have appeared at least

Table 1: Top ranked aspect and sentiment words in three aspects (please see the explanation in Section 4.1).

20 times (to ensure that the training set is reasonably representative of the corpus). Of those 1000 terms if they appeared in the sentiment lexicon, they were treated as sentiment terms, else aspect terms. Clearly, labeling words not in the sentiment lexicon as aspect terms may not always be correct. Even with this noisy automatically-labeled data, the proposed models can produce good results. Since ME-LDA used manually labeled training data for Max-Ent, we again randomly sampled 1000 terms from our corpus appearing at least 20 times and labeled them as aspect terms or sentiment terms, so this labeled data clearly has less noise than our automatically labeled data. For both ME-SAS and ME-LDA we used the corresponding feature vector of each labeled term (in the context of sentences where it occurs) to train the Max-Ent model. As DF-LDA requires must-link and cannot-link constraints, we used our seed sets to generate intra-seed set must-link and inter-seed set cannot-link constraints. For its hyper-parameters, we used the default values in the package<sup>5</sup> (Andrzejewski et al., 2009).

Setting the number of topics/aspects in topic models is often tricky as it is difficult to know the

exact number of topics that a corpus has. While non-parametric Bayesian approaches (Teh et al., 2006) do exist for estimating the number of topics,  $T$ , they strongly depend on the hyper-parameters (Heinrich, 2009). As we use fixed hyper-parameters, we do not learn  $T$  from Bayesian non-parametrics. We used 9 major aspects ( $T = 9$ ) based on commonsense knowledge of what people usually talk about hotels and some experiments. These are *Dining*, *Staff*, *Maintenance*, *Check In*, *Cleanliness*, *Comfort*, *Amenities*, *Location* and *Value for Money* (VFM). However, it is important to note that the proposed models are flexible and do not need to have seeds for every aspect/topic. Our experiments simulate the real-life situation where the user may not know all aspects or have no seeds for some aspects. Thus, we provided seeds only to the first 6 of the 9 aspects/topics. We will see that without seeds for all aspects, our models not only can improve the seeded aspects but also improve the non-seeded aspects.

#### 4.1 Qualitative Results

This section shows some qualitative results to give an intuitive feeling of the results from different models. Table 1 shows the aspect terms and sentiment terms discovered by the 4 models for

<sup>5</sup> [http://pages.cs.wisc.edu/~andrzej/research/df\\_lda.html](http://pages.cs.wisc.edu/~andrzej/research/df_lda.html)

three aspects. Due to space limitations, we are unable to show all 6 aspects for which we have seeds. Since DF-LDA cannot separate aspects and sentiments, we only show its topics (aspects). **Red (bold)** colored words show semantic clustering errors or inappropriate terms for different groups.

It is important to note that we judge the results based on how they are related to the user seeds (which represent the user need). The judgment is to some extent subjective. What we reported here are based on our judgments what are appropriate and what are not for each aspect. For SAS, ME-SAS and ME-LDA, we mark sentiment terms as errors when they are grouped under aspects as these models are supposed to separate sentiments and aspects. For DF-LDA, the situation is different as it is not meant to separate sentiment and aspect terms, we use *red* italic font to indicate those adjectives which are aspect specific adjectives (see more discussion below). Our judgment may be slightly unfair to ME-LDA and DF-LDA as their results may make sense in some other ways. However, that is precisely the purpose of this work, to produce results that suit the user’s need rather than something generic.

We can see from Table 1 that ME-SAS performs the best. Next in order are SAS, ME-LDA, and DF-LDA. We see that only providing a handful of seeds (5) for the aspect *Staff*, ME-SAS can discover highly specific words like manager, attendant, bartender, and janitor. By specific, we mean they are highly related to the given seeds. While SAS also discovers specific words benefiting from seeds, relying on Beta priors for aspect and sentiment switching was less effective. Next in performance is ME-LDA which although produces reasonable results in general, several aspect terms are far from what the user wants based on the seeds, e.g., room, linens, wait, pillow. Finally, we observe that DF-LDA does not perform well either. One reason is that it is unable to separate aspects and sentiments. Although encoding the intra-seed set must-link and inter-seed set cannot-link constraints in DF-LDA discovers some specific words as ME-SAS, they are much lower in the ranked order and hence do not show up in the top 10 words in Table 1. As DF-LDA is not meant to perform extraction and to group both aspect and sentiment terms, we relax the errors of DF-LDA due to correct aspect specific sentiments (e.g., friendly, helpful for *Staff* are correct aspect specific sentiments, but still

regard incorrect sentiments like front, comfortable, large as errors) placed in aspect models. We call this model DF-LDA-Relaxed.

## 4.2 Quantitative Results

Topic models are often evaluated quantitatively using perplexity and likelihood on held-out test data (Blei et al., 2003). However, perplexity does not reflect our purpose since our aim is not to predict whether an unseen document is likely to be a review of some particular aspect. Nor are we trying to evaluate how well the unseen review data fits our seeded models. Instead our focus is to evaluate how well our learned aspects perform in clustering specific terms guided by seeds. So we directly evaluate the discovered aspect terms. Note again we do not evaluate sentiment terms as they are not the focus of this paper<sup>6</sup>. Since aspects produced by the models are rankings and we do not know the number of correct aspect terms, a natural way to evaluate these rankings is to use *precision @ n* (or  $p@n$ ), where  $n$  is a rank position.

**Varying number of seeds:** Instead of a fixed number of seeds, we want to see the effect of the number of seeds on aspect discovery. Table 2 reports the average  $p@n$  vs. the number of seeds. The average is a two-way averaging. The first average was taken over all combinations of actual seeds selected for each aspect, e.g., when the number of seeds is 3, out of the 5 seeds in each aspect, all  $\binom{5}{3}$  combinations of seeds were tried and the results averaged. The results were further averaged over  $p@n$  for 6 aspects with seeds. We start with 2 seeds and progressively increase them to 5. Using only 1 seed per seed set (or per aspect) has practically no effect because the top level distribution  $\varphi^A$  encodes which seed sets (and non-seed words) to include; the lower-level distribution  $\mathcal{Q}$  constrains the probabilities of the seed words to be correlated for each of the seed sets. Thus, having only one seed per seed set will result in sampling that single word whenever that seed set is chosen which will not have the effect of correlating seed words so as to pull other words based on co-occurrence with constrained seed words. From Table 2, we can see that for all models  $p@n$  progressively improves as the number of seeds increases. Again ME-SAS performs the best followed by SAS and DF-LDA.

<sup>6</sup> A qualitative evaluation of sentiment extraction based on Table 1 yields the following order: ME-SAS, SAS, ME-LDA.

No. of Seeds	DF-LDA			DF-LDA-Relaxed			SAS			ME-SAS		
	P@10	P@20	P@30	P@10	P@20	P@30	P@10	P@20	P@30	P@10	P@20	P@30

Avg.	0.67	0.70	0.65	0.52	0.62	0.56	0.70	0.72	0.68	0.72	0.72	0.68	0.88	0.80	0.74

Table 3: Effect of performance on seeded and non-seeded aspects (5 seeds were used for the 6 seeded aspects).

**Effect of seeds on non-seeded aspects:** Here we compare all models aspect wise and see the results of seeded models SAS and ME-SAS on non-seeded aspects (Table 3). Shaded cells in Table 3 give the  $p@n$  values for DF-LDA, DF-LDA-Relaxed, SAS, and ME-SAS on three non-seeded aspects (Amenities, Location, and VFM)<sup>7</sup>.

We see that across all the first 6 aspects with (5) seeds ME-SAS outperforms all other models by large margins in all top 3 ranked buckets  $p@10$ ,  $p@20$  and  $p@30$ . Next in order are SAS, ME-LDA and DF-LDA. For the last three aspects which did not have any seed guidance, we find something interesting. Seeded models SAS and especially ME-SAS result in improvements of non-seeded aspects too. This is because as seeds facilitate clustering specific and appropriate terms in seeded aspects, which in turn improves precision on non-seeded aspects. This phenomenon can be clearly seen in Table 1. In aspect *Staff* of ME-LDA, we find *pillow* and *linens* being clustered. This is not a “flaw” of the model per se, but the point here is *pillow* and *linens* happen to co-occur many times with other words like *maintenance*, *staff*, and *upkeep* because “room-service” generally includes staff members coming and replacing linens and pillow covers. Although *pillow* and *linens* are related to *Staff*, strictly speaking they are semantically incorrect because they do not represent the very concept “Staff” based on the seeds (which reflect the user need). Presence of

seed sets in SAS and ME-SAS result in pulling such words as linens and pillow (due to seeds like beds and cleanliness in the aspect *Cleanliness*) and ranking them higher in the aspect *Cleanliness* (see Table 1) where they make more sense than *Staff*. Lastly, we also note that the improvements in non-seeded aspects are more pronounced for ME-SAS than SAS as SAS encounters more switching errors which counters the improvement gained by seeds.

In summary, the averages over all aspects (Table 3 last row) show that the proposed seeded models SAS and ME-SAS outperform ME-LDA, DF-LDA and even DF-LDA-Relaxed considerably.

## 5 Conclusion

This paper studied the issue of using seeds to discover aspects in an opinion corpus. To our knowledge, no existing work deals with this problem. Yet, it is important because in practice the user often has something in mind to find. The results obtained in a completely unsupervised manner may not suit the user’s need. To solve this problem, we proposed two models SAS and ME-SAS which take seeds reflecting the user needs to discover specific aspects. ME-SAS also does not need any additional help from the user in its Max-Ent training. Our results showed that both models outperformed two state-of-the-art existing models ME-LDA and DF-LDA by large margins.

## Abstract

Most information extraction (IE) systems identify facts that are explicitly stated in text. However, in natural language, some facts are implicit, and identifying them requires “reading between the lines”. Human readers naturally use common sense knowledge to *infer* such implicit information from the explicitly stated facts. We propose an approach that uses Bayesian Logic Programs (BLPs), a statistical relational model combining first-order logic and Bayesian networks, to infer additional implicit information from extracted facts. It involves learning uncertain commonsense knowledge (in the form of probabilistic first-order rules) from natural language text by mining a large corpus of automatically extracted facts. These rules are then used to derive additional facts from extracted information using BLP inference. Experimental evaluation on a benchmark data set for machine reading demonstrates the efficacy of our approach.

## 1 Introduction

The task of information extraction (IE) involves automatic extraction of typed entities and relations from unstructured text. IE systems (Cowie and Lehnert, 1996; Sarawagi, 2008) are trained to extract facts that are stated explicitly in text. However, some facts are implicit, and human readers naturally “read between the lines” and *infer* them from the stated facts using commonsense knowledge. Answering many queries can require inferring such implicitly stated facts. Consider the text “Barack Obama is the

president of the United States of America.” Given the query “Barack Obama is a citizen of what country?”, standard IE systems cannot identify the answer since citizenship is not explicitly stated in the text. However, a human reader possesses the commonsense knowledge that the president of a country is almost always a citizen of that country, and easily infers the correct answer.

The standard approach to inferring implicit information involves using commonsense knowledge in the form of logical rules to deduce additional information from the extracted facts. Since manually developing such a knowledge base is difficult and arduous, an effective alternative is to automatically *learn* such rules by mining a substantial database of facts that an IE system has already automatically extracted from a large corpus of text (Nahm and Mooney, 2000). Most existing rule learners assume that the training data is largely accurate and complete. However, the facts extracted by an IE system are always quite noisy and incomplete. Consequently, a purely logical approach to learning and inference is unlikely to be effective. Consequently, we propose using *statistical relational learning* (SRL) (Getoor and Taskar, 2007), specifically, Bayesian Logic Programs (BLPs) (Kersting and De Raedt, 2007), to learn probabilistic rules in first-order logic from a large corpus of extracted facts and then use the resulting BLP to make effective probabilistic inferences when interpreting new documents.

We have implemented this approach by using an off-the-shelf IE system and developing novel adaptations of existing learning methods to efficiently construct fast and effective BLPs for “reading be-

tween the lines.” We present an experimental evaluation of our resulting system on a realistic test corpus from DARPA’s Machine Reading project, and demonstrate improved performance compared to a purely logical approach based on Inductive Logic Programming (ILP) (Lavrač and Džeroski, 1994), and an alternative SRL approach based on Markov Logic Networks (MLNs) (Domingos and Lowd, 2009).

To the best of our knowledge, this is the first paper that employs BLPs for inferring implicit information from natural language text. We demonstrate that it is possible to learn the structure and the parameters of BLPs automatically using only noisy extractions from natural language text, which we then use to infer additional facts from text.

The rest of the paper is organized as follows. Section 2 discusses related work and highlights key differences between our approach and existing work. Section 3 provides a brief background on BLPs. Section 4 describes our BLP-based approach to learning to infer implicit facts. Section 5 describes our experimental methodology and discusses the results of our evaluation. Finally, Section 6 discusses potential future work and Section 7 presents our final conclusions.

## 2 Related Work

Several previous projects (Nahm and Mooney, 2000; Carlson et al., 2010; Schoenmackers et al., 2010; Doppa et al., 2010; Sorower et al., 2011) have mined inference rules from data automatically extracted from text by an IE system. Similar to our approach, these systems use the learned rules to infer additional information from facts directly extracted from a document. Nahm and Mooney (2000) learn *propositional rules* using C4.5 (Quinlan, 1993) from data extracted from computer-related job-postings, and therefore cannot learn multi-relational rules with quantified variables. Other systems (Carlson et al., 2010; Schoenmackers et al., 2010; Doppa et al., 2010; Sorower et al., 2011) learn *first-order rules* (i.e. Horn clauses in first-order logic).

Carlson et al. (2010) modify an ILP system similar to FOIL (Quinlan, 1990) to learn rules with probabilistic conclusions. They use purely logical deduction (forward-chaining) to infer additional facts.

Unlike BLPs, this approach does not use a well-founded probabilistic graphical model to compute coherent probabilities for inferred facts. Further, Carlson et al. (2010) used a human judge to manually evaluate the quality of the learned rules before using them to infer additional facts. Our approach, on the other hand, is completely automated and learns fully parameterized rules in a well-defined probabilistic logic.

Schoenmackers et al. (2010) develop a system called SHERLOCK that uses statistical relevance to learn first-order rules. Unlike our system and others (Carlson et al., 2010; Doppa et al., 2010; Sorower et al., 2011) that use a pre-defined ontology, they automatically identify a set of entity types and relations using “open IE.” They use HOLMES (Schoenmackers et al., 2008), an inference engine based on MLNs (Domingos and Lowd, 2009) (an SRL approach that combines first-order logic and Markov networks) to infer additional facts. However, MLNs include all possible type-consistent groundings of the rules in the corresponding Markov net, which, for larger datasets, can result in an intractably large graphical model. To overcome this problem, HOLMES uses a specialized model construction process to control the grounding process. Unlike MLNs, BLPs naturally employ a more “focused” approach to grounding by including only those literals that are directly relevant to the query.

Doppa et al. (2010) use FARMER (Nijssen and Kok, 2003), an existing ILP system, to learn first-order rules. They propose several approaches to score the rules, which are used to infer additional facts using purely logical deduction. Sorower et al. (2011) propose a probabilistic approach to modeling implicit information as missing facts and use MLNs to infer these missing facts. They learn first-order rules for the MLN by performing exhaustive search. As mentioned earlier, inference using both these approaches, logical deduction and MLNs, have certain limitations, which BLPs help overcome.

DIRT (Lin and Pantel, 2001) and RESOLVER (Yates and Etzioni, 2007) learn inference rules, also called entailment rules that capture synonymous relations and entities from text. Berant et al. (Berant et al., 2011) propose an approach that uses transitivity constraints for learning entailment rules for typed predicates. Unlike the systems described above,

these systems do not learn complex first-order rules that capture common sense knowledge. Further, most of these systems do not use extractions from an IE system to learn entailment rules, thereby making them less related to our approach.

### 3 Bayesian Logic Programs

Bayesian logic programs (BLPs) (Kersting and De Raedt, 2007; Kersting and Raedt, 2008) can be considered as templates for constructing *directed* graphical models (Bayes nets). Formally, a BLP consists of a set of *Bayesian clauses*, definite clauses of the form  $a|a_1, a_2, a_3, \dots, a_n$ , where  $n \geq 0$  and  $a, a_1, a_2, a_3, \dots, a_n$  are *Bayesian predicates* (defined below), and where  $a$  is called the head of the clause ( $\text{head}(c)$ ) and  $(a_1, a_2, a_3, \dots, a_n)$  is the body ( $\text{body}(c)$ ). When  $n = 0$ , a Bayesian clause is a fact. Each Bayesian clause  $c$  is assumed to be universally quantified and range restricted, i.e.  $\text{variables}\{\text{head}\} \subseteq \text{variables}\{\text{body}\}$ , and has an associated *conditional probability table*  $\text{CPT}(c) = P(\text{head}(c)|\text{body}(c))$ . A *Bayesian predicate* is a predicate with a finite domain, and each ground atom for a Bayesian predicate represents a random variable. Associated with each Bayesian predicate is a combining rule such as *noisy-or* or *noisy-and* that maps a finite set of CPTs into a single CPT.

Given a knowledge base as a BLP, standard logical inference (SLD resolution) is used to automatically construct a Bayes net for a given problem. More specifically, given a set of facts and a query, all possible Horn-clause proofs of the query are constructed and used to build a Bayes net for answering the query. The probability of a joint assignment of truth values to the final set of ground propositions is defined as follows:

$$P(X) = \prod_i P(X_i|Pa(X_i)),$$

where  $X = X_1, X_2, \dots, X_n$  represents the set of random variables in the network and  $Pa(X_i)$  represents the parents of  $X_i$ . Once a ground network is constructed, standard probabilistic inference methods can be used to answer various types of queries as reviewed by Koller and Friedman (2009). The parameters in the BLP model can be learned using the methods described by Kersting and De Raedt (2008).

## 4 Learning BLPs to Infer Implicit Facts

### 4.1 Learning Rules from Extracted Data

The first step involves learning commonsense knowledge in the form of first-order Horn rules from text. We first extract facts that are explicitly stated in the text using SIRE (Florian et al., 2004), an IE system developed by IBM. We then learn first-order rules from these extracted facts using LIME (McCreath and Sharma, 1998), an ILP system designed for noisy training data.

We first identify a set of target relations we want to infer. Typically, an ILP system takes a set of positive and negative instances for a target relation, along with a background knowledge base (in our case, other facts extracted from the same document) from which the positive instances are potentially inferable. In our task, we only have direct access to positive instances of target relations, i.e. the relevant facts extracted from the text. So we artificially generate negative instances using the *closed world assumption*, which states that any instance of a relation that is not extracted can be considered a negative instance. While there are exceptions to this assumption, it typically generates a useful (if noisy) set of negative instances. For each relation, we generate all possible type-consistent instances using all constants in the domain. All instances that are not extracted facts (i.e. positive instances) are labeled as negative. The total number of such closed-world negatives can be intractably large, so we randomly sample a fixed-size subset. The ratio of 1:20 for positive to negative instances worked well in our approach.

Since LIME can learn rules using only positive instances, or both positive and negative instances, we learn rules using both settings. We include all unique rules learned from both settings in the final set, since the goal of this step is to learn a large set of potentially useful rules whose relative strengths will be determined in the next step of parameter learning. Other approaches could also be used to learn candidate rules. We initially tried using the popular ALEPH ILP system (Srinivasan, 2001), but it did not produce useful rules, probably due to the high level of noise in our training data.

## 4.2 Learning BLP Parameters

The parameters of a BLP include the CPT entries associated with the Bayesian clauses and the parameters of combining rules associated with the Bayesian predicates. For simplicity, we use a deterministic logical-and model to encode the CPT entries associated with Bayesian clauses, and use *noisy-or* to combine evidence coming from multiple ground rules that have the same head (Pearl, 1988). The noisy-or model requires just a single parameter for each rule, which can be learned from training data.

We learn the noisy-or parameters using the EM algorithm adapted for BLPs by Kersting and De Raedt (2008). In our task, the supervised training data consists of facts that are extracted from the natural language text. However, we usually do not have evidence for inferred facts as well as noisy-or nodes. As a result, there are a number of variables in the ground networks which are always hidden, and hence EM is appropriate for learning the requisite parameters from the partially observed training data.

## 4.3 Inference of Additional Facts using BLPs

Inference in the BLP framework involves backward chaining (Russell and Norvig, 2003) from a specified query (SLD resolution) to obtain all possible deductive proofs for the query. In our context, each target relation becomes a query on which we backchain. We then construct a ground Bayesian network using the resulting deductive proofs for all target relations and learned parameters using the standard approach described in Section 3. Finally, we perform standard probabilistic inference to estimate the marginal probability of each inferred fact. Our system uses Sample Search (Gogate and Dechter, 2007), an approximate sampling algorithm developed for Bayesian networks with deterministic constraints (0 values in CPTs). We tried several exact and approximate inference algorithms on our data, and this was the method that was both tractable and produced the best results.

# 5 Experimental Evaluation

## 5.1 Data

For evaluation, we used DARPA’s machine-reading intelligence-community (IC) data set, which consists of news articles on terrorist events around the

world. There are 10,000 documents each containing an average of 89.5 facts extracted by SIRE (Floridan et al., 2004). SIRE assigns each extracted fact a confidence score and we used only those with a score of 0.5 or higher for learning and inference. An average of 86.8 extractions per document meet this threshold.

DARPA also provides an ontology describing the entities and relations in the IC domain. It consists of 57 entity types and 79 relations. The entity types include Agent, PhysicalThing, Event, TimeLocation, Gender, and Group, each with several subtypes. The type hierarchy is a DAG rather than a tree, and several types have multiple superclasses. For instance, a GeopoliticalEntity can be a HumanAgent as well as a Location. This can cause some problems for systems that rely on a strict typing system, such as MLNs which rely on types to limit the space of ground literals that are considered. Some sample relations are attended-School, approximateNumberOfMembers, mediatingAgent, employs, hasMember, hasMemberHumanAgent, and hasBirthPlace.

## 5.2 Methodology

We evaluated our approach using 10-fold cross validation. We learned first-order rules for the 13 target relations shown in Table 3 from the facts extracted from the training documents (Section 4.1). These relations were selected because the extractor’s recall for them was low. Since LIME does not scale well to large data sets, we could train it on at most about 2,500 documents. Consequently, we split the 9,000 training documents into four disjoint subsets and learned first-order rules from each subset. The final knowledge base included all unique rules learned from any subset. LIME learned several rules that had only entity types in their bodies. Such rules make many incorrect inferences; hence we eliminated them. We also eliminated rules violating type constraints. We learned an average of 48 rules per fold. Table 1 shows some sample learned rules.

We then learned parameters as described in Section 4.2. We initially set all noisy-or parameters to 0.9 based on the intuition that if exactly one rule for a consequent was satisfied, it could be inferred with a probability of 0.9.

$\text{governmentOrganization}(A) \wedge \text{employs}(A,B) \rightarrow \text{hasMember}(A,B)$ <i>If a government organization A employs person B, then B is a member of A</i>
$\text{eventLocation}(A,B) \wedge \text{bombing}(A) \rightarrow \text{thingPhysicallyDamaged}(A,B)$ <i>If a bombing event A took place in location B, then B is physically damaged</i>
$\text{isLedBy}(A,B) \rightarrow \text{hasMemberPerson}(A,B)$ <i>If a group A is led by person B, then B is a member of A</i>
$\text{nationState}(B) \wedge \text{eventLocationGPE}(A,B) \rightarrow \text{eventLocation}(A,B)$ <i>If an event A occurs in a geopolitical entity B, then the event location for that event is B</i>
$\text{mediatingAgent}(A,B) \wedge \text{humanAgentKillingAPerson}(A) \rightarrow \text{killingHumanAgent}(A,B)$ <i>If A is an event in which a human agent is killing a person and the mediating agent of A is an agent B, then B is the human agent that is killing in event A</i>

Table 1: A sample set of rules learned using LIME

For each test document, we performed BLP inference as described in Section 4.3. We ranked all inferences by their marginal probability, and evaluated the results by either choosing the top  $n$  inferences or accepting inferences whose marginal probability was equal to or exceeded a specified threshold. We evaluated two BLPs with different parameter settings: *BLP-Learned-Weights* used noisy-or parameters learned using EM, *BLP-Manual-Weights* used fixed noisy-or weights of 0.9.

### 5.3 Evaluation Metrics

The lack of ground truth annotation for inferred facts prevents an automated evaluation, so we resorted to a manual evaluation. We randomly sampled 40 documents (4 from each test fold), judged the accuracy of the inferences for those documents, and computed *precision*, the fraction of inferences that were deemed correct. For probabilistic methods like BLPs and MLNs that provide certainties for their inferences, we also computed *precision at top n*, which measures the precision of the  $n$  inferences with the highest marginal probability across the 40 test documents. Measuring recall for making inferences is very difficult since it would require labeling a reasonable-sized corpus of documents with *all* of the correct inferences for a given set of target relations, which would be extremely time consuming. Our evaluation is similar to that used in previous related work (Carlson et al., 2010; Schoenmackers et al., 2010).

SIRE frequently makes incorrect extractions, and therefore inferences made from these extractions are also inaccurate. To account for the mistakes made

by the extractor, we report two different precision scores. The “unadjusted” (UA) score, does not correct for errors made by the extractor. The “adjusted” (AD) score does not count mistakes due to extraction errors. That is, if an inference is incorrect because it was based on incorrect extracted facts, we remove it from the set of inferences and calculate precision for the remaining inferences.

### 5.4 Baselines

Since none of the existing approaches have been evaluated on the IC data, we cannot directly compare our performance to theirs. Therefore, we compared to the following methods:

- *Logical Deduction*: This method forward chains on the extracted facts using the first-order rules learned by LIME to infer additional facts. This approach is unable to provide any confidence or probability for its conclusions.
- *Markov Logic Networks (MLNs)*: We use the rules learned by LIME to define the structure of an MLN. In the first setting, which we call *MLN-Learned-Weights*, we learn the MLN’s parameters using the generative weight learning algorithm (Domingos and Lowd, 2009), which we modified to process training examples in an online manner. In online generative learning, gradients are calculated and weights are estimated after processing each example and the learned weights are used as the starting weights for the next example. The pseudo-likelihood of one round is obtained by multiplying the pseudo-likelihood of all examples.

	UA	AD
Precision	29.73 (443/1490)	35.24 (443/1257)

Table 2: Precision for logical deduction. “UA” and “AD” refer to the unadjusted and adjusted scores respectively

In our approach, the initial weights of clauses are set to 10. The average number of iterations needed to acquire the optimal weights is 131. In the second setting, which we call *MLN-Manual-Weights*, we assign a weight of 10 to all rules and maximum likelihood prior to all predicates. *MLN-Manual-Weights* is similar to *BLP-Manual-Weights* in that all rules are given the same weight. We then use the learned rules and parameters to probabilistically infer additional facts using the MC-SAT algorithm implemented in Alchemy,<sup>1</sup> an open-source MLN package.

## 6 Results and Discussion

### 6.1 Comparison to Baselines

Table 2 gives the unadjusted (UA) and adjusted (AD) precision for logical deduction. Out of 1,490 inferences for the 40 evaluation documents, 443 were judged correct, giving an unadjusted precision of 29.73%. Out of these 1,490 inferences, 233 were determined to be incorrect due to extraction errors, improving the adjusted precision to a modest 35.24%.

MLNs made about 127,000 inferences for the 40 evaluation documents. Since it is not feasible to manually evaluate *all* the inferences made by the MLN, we calculated precision using only the top 1000 inferences. Figure 1 shows both unadjusted and adjusted precision at top- $n$  for various values of  $n$  for different BLP and MLN models. For both BLPs and MLNs, simple manual weights result in superior performance than the learned weights. Despite the fairly large size of the overall training sets (9,000 documents), the amount of data for each target relation is apparently still not sufficient to learn particularly accurate weights for both BLPs and MLNs. However, for BLPs, learned weights do show a substantial improvement initially (i.e.

top 25–50 inferences), with an average of 1 inference per document at 91% adjusted precision as opposed to an average of 5 inferences per document at 85% adjusted precision for *BLP-Manual-Weights*. For MLNs, learned weights show a small improvement initially only with respect to adjusted precision. Between BLPs and MLNs, BLPs perform substantially better than MLNs at most points in the curve. However, *MLN-Manual-Weights* improve marginally over *BLP-Learned-Weights* at later points (top 600 and above) on the curve, where the precision is generally very low. Here, the superior performance of BLPs over MLNs could be possibly due to the focused grounding used in the BLP framework.

For BLPs, as  $n$  increases towards including all of the logically sanctioned inferences, as expected, the precision converges to the results for logical deduction. However, as  $n$  decreases, both adjusted and unadjusted precision increase fairly steadily. This demonstrates that probabilistic BLP inference provides a clear improvement over logical deduction, allowing the system to accurately select the best inferences that are most likely to be correct. Unlike the two BLP models, *MLN-Manual-Weights* has more or less the same performance at most points on the curve, and it is slightly better than that of purely-logical deduction. *MLN-Learned-Weights* is worse than purely-logical deduction at most points on the curve.

### 6.2 Results for Individual Target Relations

Table 3 shows the *adjusted* precision for each relation for instances inferred using logical deduction, *BLP-Manual-Weights* and *BLP-Learned-Weights* with a confidence threshold of 0.95. The probabilities estimated for inferences by MLNs are not directly comparable to those estimated by BLPs. As a result, we do not include results for MLNs here. For this evaluation, using a confidence threshold based cutoff is more appropriate than using top- $n$  inferences made by the BLP models since the estimated probabilities can be directly compared across target relations.

For logical deduction, precision is high for a few relations like *employs*, *hasMember*, and *hasMemberHumanAgent*, indicating that the rules learned for these relations are more accurate than the ones

<sup>1</sup><http://alchemy.cs.washington.edu/>

Figure 1: Unadjusted and adjusted precision at top- $n$  for different BLP and MLN models for various values of  $n$

learned for the remaining relations. Unlike relations like `hasMember` that are easily inferred from relations like `employs` and `isLedBy`, certain relations like `hasBirthPlace` are not easily inferable using the information in the ontology. As a result, it might not be possible to learn accurate rules for such target relations. Other reasons include the lack of a sufficiently large number of target-relation instances during training and lack of strictly defined types in the IC ontology.

Both BLP-Manual-Weights and BLP-Learned-Weights also have high precision for several relations (`eventLocation`, `hasMemberHumanAgent`, `thingPhysicallyDamaged`). However, the actual number of inferences can be fairly low. For instance, 103 instances of `hasMemberHumanAgent` are inferred by logical deduction (i.e. 0 confidence threshold), but only 2 of them are inferred by BLP-Learned-Weights at 0.95 confidence threshold, indicating that the parameters learned for the corresponding rules are not very high. For several relations like `hasMember`, `hasMemberPerson`, and `employs`, no instances were inferred by BLP-Learned-Weights at 0.95 confidence threshold. Lack of sufficient training instances (extracted facts) is possibly the reason for learning low weights for such rules. On the other hand, BLP-Manual-Weights has inferred 26 instances of `hasMemberHumanAgent`, out of which all are correct. These results therefore demonstrate the need for sufficient training examples to learn accurate parameters.

### 6.3 Discussion

We now discuss the potential reasons for BLP's superior performance compared to other approaches. Probabilistic reasoning used in BLPs allows for a principled way of determining the most confident inferences, thereby allowing for improved precision over purely logical deduction. The primary difference between BLPs and MLNs lies in the approaches used to construct the ground network. In BLPs, only propositions that can be logically deduced from the extracted evidence are included in the ground network. On the other hand, MLNs include all possible type-consistent groundings of all rules in the network, introducing many ground literals which cannot be logically deduced from the evidence. This generally results in several incorrect inferences, thereby yielding poor performance.

Even though learned weights in BLPs do not result in a superior performance, learned weights in MLNs are substantially worse. Lack of sufficient training data is one of the reasons for learning less accurate weights by the MLN weight learner. However, a more important issue is due to the use of the closed world assumption during learning, which we believe is adversely impacting the weights learned. As mentioned earlier, for the task considered in the paper, if a fact is not explicitly stated in text, and hence not extracted by the extractor, it does not necessarily imply that it is not true. Since existing weight learning approaches for MLNs do not deal with missing data and open world assumption, developing such approaches is a topic for future work.

Apart from developing novel approaches for

Table 3: Adjusted precision for individual relations (highest values are in bold)

weight learning, additional engineering could potentially improve the performance of MLNs on the IC data set. Due to MLN’s grounding process, several spurious facts like `employs(a,a)` were inferred. These inferences can be prevented by including additional clauses in the MLN that impose integrity constraints that prevent such nonsensical propositions. Further, techniques proposed by Sorower et al. (2011) can be incorporated to explicitly handle missing information in text. Lack of strict typing on the arguments of relations in the IC ontology has also resulted in inferior performance of the MLNs. To overcome this, relations that do not have strictly defined types could be specialized. Finally, we could use the deductive proofs constructed by BLPs to constrain the ground Markov network, similar to the model-construction approach adopted by Singla and Mooney (2011).

However, in contrast to MLNs, BLPs that use first-order rules that are learned by an off-the-shelf ILP system and given simple intuitive hand-coded weights, are able to provide fairly high-precision inferences that augment the output of an IE system and allow it to effectively “read between the lines.”

## 7 Future Work

A primary goal for future research is developing an on-line structure learner for BLPs that can directly learn probabilistic first-order rules from uncertain training data. This will address important limitations of LIME, which cannot accept uncertainty in the extractions used for training, is not specifically

optimized for learning rules for BLPs, and does not scale well to large datasets. Given the relatively poor performance of BLP parameters learned using EM, tests on larger training corpora of extracted facts and the development of improved parameter-learning algorithms are clearly indicated. We also plan to perform a larger-scale evaluation by employing crowdsourcing to evaluate inferred facts for a bigger corpus of test documents. As described above, a number of methods could be used to improve the performance of MLNs on this task. Finally, it would be useful to evaluate our methods on several other diverse domains.

## 8 Conclusions

We have introduced a novel approach using Bayesian Logic Programs to learn to infer implicit information from facts extracted from natural language text. We have demonstrated that it can learn effective rules from a large database of noisy extractions. Our experimental evaluation on the IC data set demonstrates the advantage of BLPs over logical deduction and an approach based on MLNs.

## Acknowledgements

We thank the SIRE team from IBM for providing SIRE extractions on the IC data set. This research was funded by MURI ARO grant W911NF-08-1-0242 and Air Force Contract FA8750-09-C-0172 under the DARPA Machine Reading Program. Experiments were run on the Mastodon Cluster, provided by NSF grant EIA-0303609.

## Abstract

We present a holistic data-driven approach to image description generation, exploiting the vast amount of (noisy) parallel image data and associated natural language descriptions available on the web. More specifically, given a query image, we retrieve existing human-composed phrases used to describe visually similar images, then selectively combine those phrases to generate a novel description for the query image. We cast the generation process as constraint optimization problems, collectively incorporating multiple interconnected aspects of language composition for *content planning*, *surface realization* and *discourse structure*. Evaluation by human annotators indicates that our final system generates more semantically correct and linguistically appealing descriptions than two nontrivial baselines.

## 1 Introduction

Automatically describing images in natural language is an intriguing, but complex AI task, requiring accurate computational visual recognition, comprehensive world knowledge, and natural language generation. Some past research has simplified the general image description goal by assuming that relevant text for an image is provided (e.g., Aker and Gaizauskas (2010), Feng and Lapata (2010)). This allows descriptions to be generated using effective summarization techniques with relatively surface level image understanding. However, such text (e.g., news articles

or encyclopedic text) is often only loosely related to an image's specific content and many natural images do not come with associated text for summarization.

In contrast, other recent work has focused more on the visual recognition aspect by detecting content elements (e.g., scenes, objects, attributes, actions, etc) and then composing descriptions from scratch (e.g., Yao et al. (2010), Kulkarni et al. (2011), Yang et al. (2011), Li et al. (2011)), or by retrieving existing whole descriptions from visually similar images (e.g., Farhadi et al. (2010), Ordonez et al. (2011)). For the latter approaches, it is unrealistic to expect that there will always exist a *single complete description* for retrieval that is pertinent to a given query image. For the former approaches, visual recognition first generates an intermediate representation of image content using a set of English words, then language generation constructs a full description by adding function words and optionally applying simple re-ordering. Because the generation process sticks relatively closely to the recognized content, the resulting descriptions often lack the kind of coverage, creativity, and complexity typically found in human-written text.

In this paper, we propose a holistic data-driven approach that combines and extends the best aspects of these previous approaches – a) using visual recognition to directly predict individual image content elements, and b) using retrieval from existing human-composed descriptions to generate natural, creative, and inter-

esting captions. We also lift the restriction of retrieving existing *whole descriptions* by gathering *visually relevant phrases* which we combine to produce novel and query-image specific descriptions. By judiciously exploiting the correspondence between image content elements and phrases, it is possible to generate natural language descriptions that are substantially richer in content and more linguistically interesting than previous work.

At a high level, our approach can be motivated by linguistic theories about the connection between reading activities and writing skills, i.e., substantial reading enriches writing skills, (e.g., Hafiz and Tudor (1989), Tsang (1996)). Analogously, our generation algorithm attains a higher level of linguistic sophistication by *reading* large amounts of descriptive text available online. Our approach is also motivated by language grounding by visual worlds (e.g., Roy (2002), Dindo and Zambuto (2010), Monner and Reggia (2011)), as in our approach the meaning of a phrase in a description is implicitly grounded by the relevant content of the image.

Another important thrust of this work is collective *image-level content-planning*, integrating saliency, content relations, and discourse structure based on statistics drawn from a large image-text parallel corpus. This contrasts with previous approaches that generate multiple sentences without considering discourse flow or redundancy (e.g., Li et al. (2011)). For example, for an image showing a flock of birds, generating a large number of sentences stating the relative position of each bird is probably not useful.

Content planning and phrase synthesis can be naturally viewed as constraint optimization problems. We employ Integer Linear Programming (ILP) as an optimization framework that has been used successfully in other generation tasks (e.g., Clarke and Lapata (2006), Martins and Smith (2009), Woodsend and Lapata (2010)). Our ILP formulation encodes a rich set of linguistically motivated constraints and weights that incorporate multiple aspects of the generation process. Empirical results demonstrate that our final system generates linguistically more appealing and semantically more cor-

rect descriptions than two nontrivial baselines.

## 1.1 System Overview

Our system consists of two parts. For a query image, we first retrieve candidate descriptive phrases from a large image-caption database using measures of visual similarity (§2). We then generate a coherent description from these candidates using ILP formulations for content planning (§4) and surface realization (§5).

## 2 Vision & Phrase Retrieval

For a query image, we retrieve relevant candidate natural language phrases by visually comparing the query image to database images from the SBU Captioned Photo Collection (Ordonez et al., 2011) (1 million photographs with associated human-composed descriptions). Visual similarity for several kinds of image content are used to compare the query image to images from the database, including: 1) object detections for 89 common object categories (Felzenszwalb et al., 2010), 2) scene classifications for 26 common scene categories (Xiao et al., 2010), and 3) region based detections for *stuff* categories (e.g. grass, road, sky) (Ordonez et al., 2011). All content types are pre-computed on the million database photos, and caption parsing is performed using the Berkeley PCFG parser (Petrov et al., 2006; Petrov and Klein, 2007).

Given a query image, we identify content elements present using the above classifiers and detectors and then retrieve phrases referring to those content elements from the database. For example, if we detect a horse in a query image, then we retrieve phrases referring to visually similar horses in the database by comparing the color, texture (Leung and Malik, 1999), or shape (Dalal and Triggs, 2005; Lowe, 2004) of the detected horse to detected horses in the database images. We collect four types of phrases for each query image as follows:

[1] **NPs** We retrieve noun phrases for each query object detection (e.g., “the brown cow”) from database captions using visual similarity between object detections computed as an equally weighted linear combination of  $L_2$  dis-

tances on histograms of *color*, *texton* (Leung and Malik, 1999), *HoG* (Dalal and Triggs, 2005) and *SIFT* (Lowe, 2004) features.

[2] **VPs** We retrieve verb phrases for each query object detection (e.g. “boy running”) from database captions using the same measure of visual similarity as for NPs, but restricting the search to only those database instances whose captions contain a verb phrase referring to the object category.

[3] **Region/Stuff PPs** We collect prepositional phrases for each query stuff detection (e.g. “in the sky”, “on the road”) by measuring visual similarity of appearance (color, texton, HoG) and geometric configuration (object-stuff relative location and distance) between query and database detections.

[4] **Scene PPs** We also collect prepositional phrases referring to general image scene context (e.g. “at the market”, “on hot summer days”, “in Sweden”) based on global scene similarity computed using  $L_2$  distance between scene classification score vectors (Xiao et al., 2010) computed on the query and database images.

### 3 Overview of ILP Formulation

For each image, we aim to generate multiple sentences, each sentence corresponding to a single distinct object detected in the given image. Each sentence comprises of the NP for the main object, and a *subset* of the corresponding VP, region/stuff PP, and scene PP retrieved in §2. We consider four different types of operations to generate the final description for each image:

- T1.** Selecting the set of objects to describe (one object per sentence).
- T2.** Re-ordering sentences (i.e., re-ordering objects).
- T3.** Selecting the set of phrases for each sentence.
- T4.** Re-ordering phrases within each sentence.

The ILP formulation of §4 addresses T1 & T2, i.e., content-planning, and the ILP of §5 addresses T3 & T4, i.e., surface realization.<sup>1</sup>

<sup>1</sup>It is possible to create one conjoined ILP formulation to address all four operations T1—T4 at once. For com-

## 4 Image-level Content Planning

First we describe image-level content planning, i.e., *abstract generation*. The goals are to (1) select a subset of the objects based on saliency and semantically compatibility, and (2) order the selected objects based on their content relations.

### 4.1 Variables and Objective Function

The following set of indicator variables encodes the selection of objects and ordering:

$$y_{sk} = \begin{cases} 1, & \text{if object } s \text{ is selected} \\ & \text{for position } k \\ 0, & \text{otherwise} \end{cases} \quad (1)$$

where  $k = 1, \dots, S$  encodes the position (order) of the selected objects, and  $s$  indexes one of the objects. In addition, we define a set of variables indicating specific pairs of adjacent objects:

$$y_{skt(k+1)} = \begin{cases} 1, & \text{if } y_{sk} = y_{t(k+1)} = 1 \\ 0, & \text{otherwise} \end{cases} \quad (2)$$

The objective function,  $F$ , that we will maximize is a weighted linear combination of these indicator variables and can be optimized using integer linear programming:

$$F = \sum_s F_s \cdot \sum_{k=1}^S y_{sk} - \sum_{st} F_{st} \cdot \sum_{k=1}^{S-1} y_{skt(k+1)} \quad (3)$$

where  $F_s$  quantifies the salience/confidence of the object  $s$ , and  $F_{st}$  quantifies the semantic compatibility between the objects  $s$  and  $t$ . These coefficients (weights) will be described in §4.3 and §4.4. We use IBM CPLEX to optimize this objective function subject to the constraints introduced next in §4.2.

### 4.2 Constraints

**Consistency Constraints:** We enforce consistency between indicator variables for individual objects (Eq. 1) and consecutive objects (Eq. 2) so that  $y_{skt(k+1)} = 1$  iff  $y_{sk} = 1$  and  $y_{t(k+1)} = 1$ :

$$\forall_{stk}, y_{skt(k+1)} \leq y_{sk} \quad (4)$$

$$y_{skt(k+1)} \leq y_{t(k+1)} \quad (5)$$

$$y_{skt(k+1)} + (1 - y_{sk}) + (1 - y_{t(k+1)}) \geq 1 \quad (6)$$

putational and implementation efficiency however, we opt for the two-step approach.

To avoid empty descriptions, we enforce that the result includes at least one object:

$$\sum_s y_{s1} = 1 \quad (7)$$

To enforce contiguous positions be selected:

$$\forall k = 2, \dots, S-1, \quad \sum_s y_{s(k+1)} \leq \sum_s y_{sk} \quad (8)$$

**Discourse constraints:** To avoid spurious descriptions, we allow at most two objects of the same type, where  $c_s$  is the type of object  $s$ :

$$\forall c \in objTypes, \quad \sum_{\{s: c_s=c\}} \sum_{k=1}^S y_{sk} \leq 2 \quad (9)$$

### 4.3 Weight $F_s$ : Object Detection Confidence

In order to quantify the confidence of the object detector for the object  $s$ , we define  $0 \leq F_s \leq 1$  as the mean of the detector scores for that object type in the image.

### 4.4 Weight $F_{st}$ : Ordering and Compatibility

The weight  $0 \leq F_{st} \leq 1$  quantifies the compatibility of the object pairing  $(s, t)$ . Note that in the objective function, we subtract this quantity from the function to be maximized. This way, we create a competing tension between the single object selection scores and the pairwise compatibility scores, so that variable number of objects can be selected.

**Object Ordering Statistics:** People have biases on the order of topic or content flow. We measure these biases by collecting statistics on ordering of object names from the 1 million image descriptions in the SBU Captioned Dataset (Ordonez et al., 2011). Let  $f_{ord}(w_1, w_2)$  be the number of times  $w_1$  appeared before  $w_2$ . For instance,  $f_{ord}(window, house) = 2895$  and  $f_{ord}(house, window) = 1250$ , suggesting that people are more likely to mention a window before mentioning a house/building<sup>2</sup>. We use these ordering statistics to enhance content flow. We define score for the order of objects using Z-score for normalization as follows:

$$\hat{F}_{st} = \frac{f_{ord}(c_s, c_t) - mean(f_{ord})}{std.dev(f_{ord})} \quad (10)$$

<sup>2</sup>We take into account synonyms.

We then transform  $\hat{F}_{st}$  so that  $\hat{F}_{st} \in [0,1]$ , and then set  $F_{st} = 1 - \hat{F}_{st}$  so that smaller values correspond to better choices.

## 5 Surface Realization

Recall that for each image, the computer vision system identifies phrases from descriptions of images that are similar in a variety of aspects. The result is a set of phrases representing four different types of information (§2). From this assortment of phrases, we aim to select a subset and glue them together to compose a complete sentence that is linguistically plausible and semantically truthful to the content of the image.

### 5.1 Variables and Objective Function

The following set of variables encodes the selection of phrases and their ordering in constructing  $S'$  sentences.

$$x_{sijk} = \begin{cases} 1, & \text{if phrase } i \text{ of type } j \\ & \text{is selected} \\ & \text{for position } k \\ & \text{in sentence } s \\ 0, & \text{otherwise} \end{cases} \quad (11)$$

where  $k = 1, \dots, N$  encodes the ordering of the selected phrases, and  $j$  indexes one of the four phrases types (object-NPs, action-VPs, region-PPs, scene-PPs),  $i = 1, \dots, M$  indexes one of the  $M$  candidate phrases of each phrase type, and  $s = 1, \dots, S'$  encodes the sentence (object). In addition, we define indicator variables for adjacent pairs of phrases:  $x_{sijkpq(k+1)} = 1$  if  $x_{sijk} = x_{spq(k+1)} = 1$  and 0 otherwise. Finally, we define the objective function  $F$  as:

$$F = \sum_{sij} F_{sij} \cdot \sum_{k=1}^N x_{sijk} - \sum_{sijpq} F_{sijpq} \cdot \sum_{k=1}^{N-1} x_{sijkpq(k+1)} \quad (12)$$

where  $F_{sij}$  weights individual phrase goodness and  $F_{sijpq}$  adjacent phrase goodness. All coefficients (weights) will be described in Section 5.3 and 5.4.

We optionally prepend the first sentence in a generated description with a *cognitive phrase*.<sup>3</sup>

<sup>3</sup>We collect most frequent 200 phrases of length 1-7 that start a caption from the SBU Captioned Photo Collection.

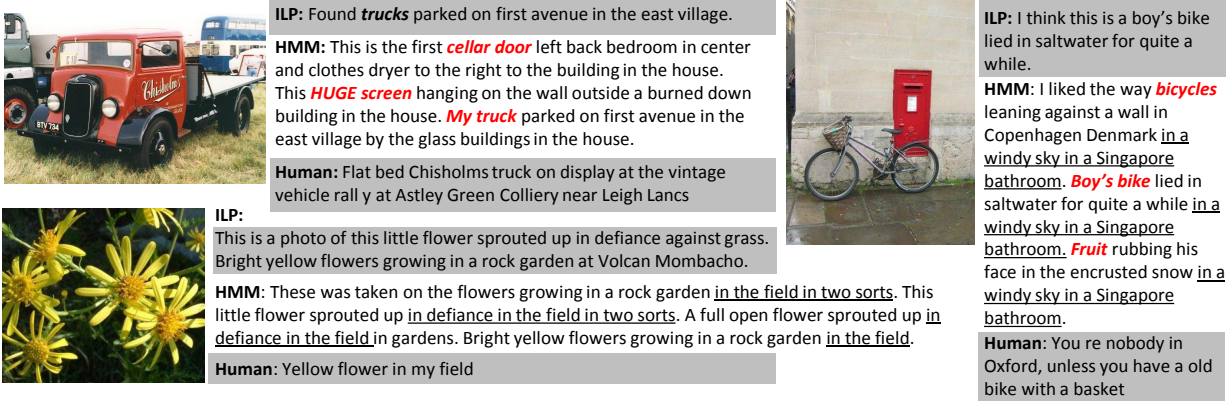

Figure 1: ILP & HMM generated captions. In HMM generated captions, underlined phrases show redundancy across different objects (due to lack of discourse constraints), and phrases in **boldface** show awkward topic flow (due to lack of content planning). Note that in the bicycle image, the visual recognizer detected two separate bicycles and some fruits, as can be seen in the HMM result. Via collective image-level content planning (see §4), some of these erroneous detection can be corrected, as shown in the ILP result. Spurious and redundant phrases can be suppressed via discourse constraints (see §5).

These are generic constructs that are often used to start a description about an image, for instance, “This is an image of...”. We treat these phrases as an additional type, but omit corresponding variables and constraints for brevity.

## 5.2 Constraints

**Consistency Constraints:** First we enforce consistency between the unary variables (Eq. 11) and the pairwise variables so that  $x_{sijkpqm} = 1$  iff  $x_{sijk} = 1$  and  $x_{spqm} = 1$ :

$$\forall ijkpqm, x_{sijkpqm} \leq x_{sijk} \quad (13)$$

$$x_{sijkpqm} \leq x_{spqm} \quad (14)$$

$$x_{sijkpqm} + (1 - x_{sijk}) + (1 - x_{spqm}) \geq 1 \quad (15)$$

Next we include constraints similar to Eq. 8 (contiguous slots are filled), but omit them for brevity. Finally, we add constraints to ensure at least two phrases are selected for each sentence, to promote informative descriptions.

**Linguistic constraints:** We include linguistically motivated constraints to generate syntactically and semantically plausible sentences. First we enforce a noun-phrase to be selected to ensure semantic relevance to the image:

$$\forall s, \sum_{ik} x_{siNpk} = 1 \quad (16)$$

Also, to avoid content redundancy, we allow at most one phrase of each type:

$$\forall sj, \sum_i \sum_{k=1}^N x_{sijk} \leq 1 \quad (17)$$

**Discourse constraints:** We allow at most one prepositional scene phrase for the whole description to avoid redundancy:

$$\text{For } j = PPscene, \sum_{sik} x_{sijk} \leq 1 \quad (18)$$

We add constraints that prevent the inclusion of more than one phrase with identical head words:  $\forall s, ij, pq$  with the same heads,

$$\sum_{k=1}^N x_{sijk} + \sum_{k=1}^N x_{spqk} \leq 1 \quad (19)$$

## 5.3 Unary Phrase Selection

Let  $M_{sij}$  be the confidence score for phrase  $x_{sij}$  given by the image–phrase matching algorithm (§2). To make the scores across different phrase types comparable, we normalize them using Z-score:  $F_{sij} = \text{norm}'(M_{sij}) = (M_{sij} - \text{mean}_j) / \text{dev}_j$ , and then transform the values into the range of [0,1].

## 5.4 Pairwise Phrase Cohesion

In this section, we describe the pairwise phrase cohesion score  $F_{sijpq}$  defined for each  $x_{sijpq}$  in

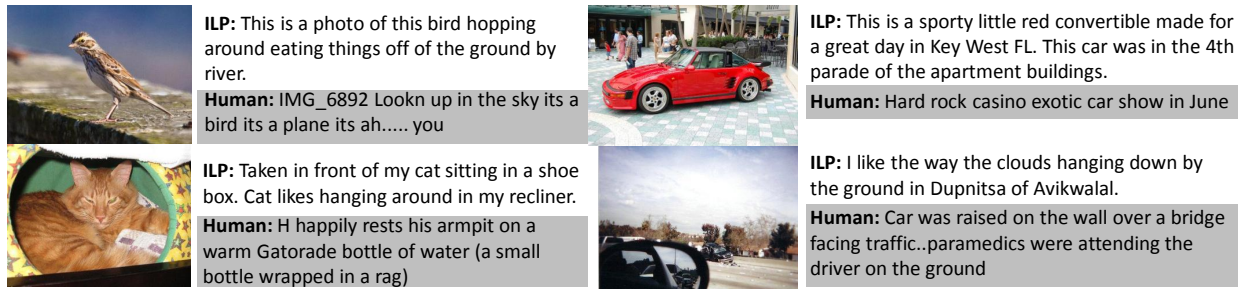

Figure 2: In some cases (16%), ILP generated captions were preferred over human written ones!

the objective function (Eq. 12). Via  $F_{sijpq}$ , we aim to quantify the degree of syntactic and semantic cohesion across two phrases  $x_{sij}$  and  $x_{spq}$ . Note that we subtract this cohesion score from the objective function. This trick helps the ILP solver to generate sentences with varying number of phrases, rather than always selecting the maximum number of phrases allowed.

**N-gram Cohesion Score:** We use n-gram statistics from the Google Web 1-T dataset (Brants and Franz., 2006) Let  $L_{sijpq}$  be the set of all n-grams ( $2 \leq n \leq 5$ ) across  $x_{sij}$  and  $x_{spq}$ . Then the n-gram cohesion score is computed as:

$$F_{sijpq}^{\text{NGRAM}} = 1 - \frac{\sum_{l \in L_{sijpq}} \text{NPMI}(l)}{\text{size}(L_{sijpq})} \quad (20)$$

$$\text{NPMI}(ngr) = \frac{\text{PMI}(ngr) - \text{PMI}_{\min}}{\text{PMI}_{\max} - \text{PMI}_{\min}} \quad (21)$$

Where NPMI is the normalized point-wise mutual information.<sup>4</sup>

**Co-occurrence Cohesion Score:** To capture long-distance cohesion, we introduce a co-occurrence-based score, which measures order-preserved co-occurrence statistics between the head words  $h_{sij}$  and  $h_{spq}$ <sup>5</sup>. Let  $f_{\Sigma}(h_{sij}, h_{spq})$  be the sum frequency of all n-grams that start with  $h_{sij}$ , end with  $h_{spq}$  and contain a preposition  $prep(spq)$  of the phrase  $spq$ . Then the

<sup>4</sup>We include the n-gram cohesion for the sentence boundaries as well, by approximating statistics for sentence boundaries with punctuation marks in the Google Web 1-T data.

<sup>5</sup>For simplicity, we use the last word of a phrase as the head word, except VPs where we take the main verb.

co-occurrence cohesion is computed as:

$$F_{sijpq}^{\text{CO}} = \frac{\max(f_{\Sigma}) - f_{\Sigma}(h_{sij}, h_{spq})}{\max(f_{\Sigma}) - \min(f_{\Sigma})} \quad (22)$$

**Final Cohesion Score:** Finally, the pairwise phrase cohesion score  $F_{ijpq}$  is a weighted sum of n-gram and co-occurrence cohesion scores:

$$F_{sijpq} = \frac{\alpha \cdot F_{sijpq}^{\text{NGRAM}} + \beta \cdot F_{sijpq}^{\text{CO}}}{\alpha + \beta} \quad (23)$$

where  $\alpha$  and  $\beta$  can be tuned via grid search, and  $F_{ijpq}^{\text{NGRAM}}$  and  $F_{ijpq}^{\text{CO}}$  are normalized  $\in [0, 1]$  for comparability. Notice that  $F_{sijpq}$  is in the range  $[0, 1]$  as well.

## 6 Evaluation

**TestSet:** Because computer vision is a challenging and unsolved problem, we restrict our query set to images where we have high confidence that visual recognition algorithms perform well. We collect 1000 test images by running a large number (89) of object detectors on 20,000 images and selecting images that receive confident object detection scores, with some preference for images with multiple object detections to obtain good examples for testing discourse constraints.

**Baselines:** We compare our ILP approaches with two nontrivial baselines: the first is an HMM approach (comparable to Yang et al. (2011)), which takes as input the same set of candidate phrases described in §2, but for decoding, we fix the ordering of phrases as [ NP – VP – Region PP – Scene PP] and find the best combination of phrases using the Viterbi algorithm. We use the same rich set of pairwise

cognitive phrases:	HMM with	HMM w/o	ILP with	ILP w/o
	0.111	0.114	0.114	0.116

Table 1: Automatic Evaluation

	ILP selection rate
ILP V.S. HMM (w/o cogn)	67.2%
ILP V.S. HMM (with cogn)	66.3%

Table 2: Human Evaluation (without images)

	ILP selection rate
ILP V.S. HMM (w/o cogn)	53.17%
ILP V.S. HMM (with cogn)	54.5%
ILP V.S. RETRIEVAL	71.8%
ILP V.S. Human	16%

Table 3: Human Evaluation (with images)

phrase cohesion scores (§5.4) used for the ILP formulation, producing a strong baseline<sup>6</sup>.

The second baseline is a recent RETRIEVAL based description method (Ordonez et al., 2011), that searches the large parallel corpus of images and captions, and transfers a caption from a visually similar database image to the query. This again is a very strong baseline, as it exploits the vast amount of image-caption data, and produces a description high in linguistic quality (since the captions were written by human annotators).

**Automatic Evaluation:** Automatically quantifying the quality of machine generated sentences is known to be difficult. BLEU score (Papineni et al., 2002), despite its simplicity and limitations, has been one of the common choices for automatic evaluation of image descriptions (Farhadi et al., 2010; Kulkarni et al., 2011; Li et al., 2011; Ordonez et al., 2011), as it correlates reasonably well with human evaluation (Belz and Reiter, 2006).

Table 1 shows the the BLEU @1 against the original caption of 1000 images. We see that the ILP improves the score over HMM consistently, with or without the use of cognitive phrases.

<sup>6</sup>Including other long-distance scores in HMM decoding would make the problem NP-hard and require more sophisticated decoding, e.g. ILP.

	Grammar	Cognitive	Relevance
HMM	3.40( $\sigma=.82$ )	3.40( $\sigma=.88$ )	2.25( $\sigma=1.37$ )
ILP	3.56( $\sigma=.90$ )	3.60( $\sigma=.98$ )	2.37( $\sigma=1.49$ )
Hum.	4.36( $\sigma=.79$ )	4.77( $\sigma=.66$ )	3.86( $\sigma=1.60$ )

Table 4: Human Evaluation: Multi-Aspect Rating ( $\sigma$  is a standard deviation)

**Human Evaluation I – Ranking:** We complement the automatic evaluation with Mechanical Turk evaluation. In ranking evaluation, we ask raters to choose a better caption between two choices<sup>7</sup>. We do this rating with and without showing the images, as summarized in Table 2 & 3. When images are shown, raters evaluate content relevance as well as linguistic quality of the captions. Without images, raters evaluate only linguistic quality.

We found that raters generally prefer ILP generated captions over HMM generated ones, twice as much (67.2% ILP V.S. 32.8% HMM), if images are not presented. However the difference is less pronounced when images are shown. There could be two possible reasons. The first is that when images are shown, the Turkers do not try as hard to tell apart the subtle difference between the two imperfect captions. The second is that the relative content relevance of ILP generated captions is negating the superiority in linguistic quality. We explore this question using multi-aspect rating, described below.

Note that ILP generated captions are exceedingly (71.8 %) preferred over the RETRIEVAL baseline (Ordonez et al., 2011), despite the generated captions tendency to be more prone to grammatical and cognitive errors than retrieved ones. This indicates that the generated captions must have substantially better content relevance to the query image, supporting the direction of this research. Finally, notice that as much as 16% of the time, ILP generated captions are preferred over the original human generated ones (examples in Figure 2).

**Human Evaluation II – Multi-Aspect Rating:** Table 4 presents rating in the 1–5 scale (5: perfect, 4: almost perfect, 3: 70~80% good, 2:

<sup>7</sup>We present two captions in a randomized order.

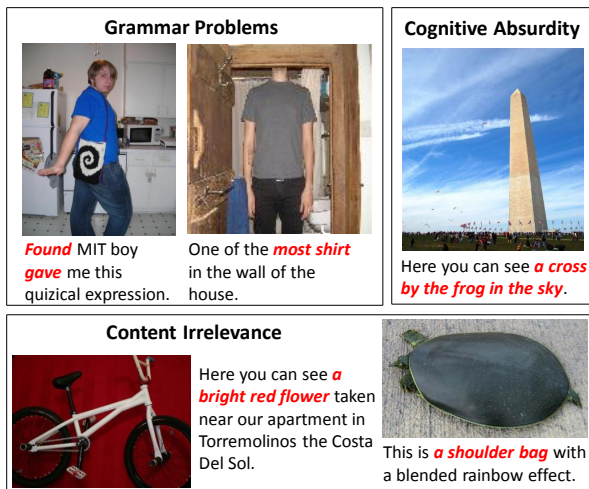

Figure 3: Examples with different aspects of problems in the ILP generated captions.

50~70% good, 1: totally bad) in three different aspects: *grammar*, *cognitive correctness*,<sup>8</sup> and *relevance*. We find that ILP improves over HMM in all aspects, however, the relevance score is noticeably worse than scores of two other criteria. It turns out human raters are generally more critical against the relevance aspect, as can be seen in the ratings given to the original human generated captions.

**Discussion with Examples:** Figure 1 shows contrastive examples of HMM vs ILP generated captions. Notice that HMM captions look *robotic*, containing spurious and redundant phrases due to lack of discourse constraints, and often discussing an awkward set of objects due to lack of image-level content planning. Also notice how image-level content planning underpinned by language statistics helps correct some of the erroneous vision detections. Figure 3 shows some example mistakes in the ILP generated captions.

## 7 Related Work & Discussion

Although not directly focused on image description generation, some previous work in the realm of summarization shares the similar problem of content planning and surface realization. There

<sup>8</sup>E.g., “A desk on top of a cat” is grammatically correct, but cognitively absurd.

are subtle, but important differences however. First, sentence compression is hardly the goal of image description generation, as human written descriptions are not necessarily succinct.<sup>9</sup> Second, unlike summarization, we are not given with a set of coherent text snippet to begin with, and the level of noise coming from the visual recognition errors is much higher than that of starting with clean text. As a result, choosing an additional phrase in the image description is much riskier than it is in summarization.

Some recent research proposed very elegant approaches to summarization using ILP for collective content planning and/or surface realization (e.g., Martins and Smith (2009), Woodsend and Lapata (2010), Woodsend et al. (2010)). Perhaps the most important difference in our approach is the use of *negative* weights in the objective function to create the necessary tension between selection (saliency) and compatibility, which makes it possible for ILP to generate variable length descriptions, effectively correcting some of the erroneous vision detections. In contrast, all previous work operates with a pre-defined upper limit in length, hence the ILP was formulated to include as many textual units as possible modulo constraints.

To conclude, we have presented a collective approach to generating natural image descriptions. Our approach is the first to systematically incorporate state of the art computer vision to retrieve visually relevant candidate phrases, then produce images descriptions that are substantially more complex and human-like than previous attempts.

Choi are partially supported by the Stony Brook University Office of the Vice President for Research. We thank K. Yamaguchi, X. Han, M. Mitchell, H. Daume III, A. Goyal, K. Stratos, A. Mensch, J. Dodge for data pre-processing and useful initial discussions.

<sup>9</sup>On a related note, the notion of saliency also differs in that human written captions often digress on details that might be tangential to the visible content of the image. E.g., “This is a dress *my mom made*.”, where the picture does not show a woman making the dress.

## Abstract

This paper proposes a data-driven method for concept-to-text generation, the task of automatically producing textual output from non-linguistic input. A key insight in our approach is to reduce the tasks of content selection (“what to say”) and surface realization (“how to say”) into a common parsing problem. We define a probabilistic context-free grammar that describes the structure of the input (a corpus of database records and text describing some of them) and represent it compactly as a weighted hypergraph. The hypergraph structure encodes exponentially many derivations, which we rerank discriminatively using local and global features. We propose a novel decoding algorithm for finding the best scoring derivation and generating in this setting. Experimental evaluation on the ATIS domain shows that our model outperforms a competitive discriminative system both using BLEU and in a judgment elicitation study.

## 1 Introduction

Concept-to-text generation broadly refers to the task of automatically producing textual output from non-linguistic input such as databases of records, logical form, and expert system knowledge bases (Reiter and Dale, 2000). A variety of concept-to-text generation systems have been engineered over the years, with considerable success (e.g., Dale et al. (2003), Reiter et al. (2005), Green (2006), Turner et al. (2009)). Unfortunately, it is often difficult to adapt them across different domains as they rely mostly on handcrafted components.

In this paper we present a data-driven approach to concept-to-text generation that is domain-independent, conceptually simple, and flexible. Our generator learns from a set of database records and textual descriptions (for some of them). An example from the air travel domain is shown in Figure 1. Here, the records provide a structured representation of the flight details (e.g., departure and arrival time, location), and the text renders some of this information in natural language. Given such input, our model determines which records to talk about (*content selection*) and which words to use for describing them (*surface realization*). Rather than breaking up the generation process into a sequence of local decisions, we perform both tasks jointly. A key insight in our approach is to reduce content selection and surface realization into a common parsing problem. Specifically, we define a probabilistic context-free grammar (PCFG) that captures the structure of the database and its correspondence to natural language. This grammar represents multiple derivations which we encode compactly using a weighted hypergraph (or packed forest), a data structure that defines a weight for each tree.

Following a generative approach, we could first learn the weights of the PCFG by maximising the joint likelihood of the model and then perform generation by finding the best derivation tree in the hypergraph. The performance of this baseline system could be potentially further improved using discriminative reranking (Collins, 2000). Typically, this method first creates a list of  $n$ -best candidates from a generative model, and then reranks them with arbitrary features (both local and global) that are either not computable or intractable to compute within the

	<b>Flight</b>	<b>Day Number</b>	<b>Month</b>	<b>Condition</b>	<b>Search</b>
Database:	<u>from to</u> denver boston	<u>number dep/ar</u> 9 departure	<u>month dep/ar</u> august departure	<u>arg1 arg2 type</u> arrival_time 1600 <	<u>type what</u> query flight
$\lambda$ -expression:	$\lambda x. flight(x) \wedge from(x, denver) \wedge to(x, boston) \wedge day\_number(x, 9) \wedge month(x, august) \wedge less\_than(arrival\_time(x), 1600)$				
Text:	Give me the flights leaving Denver August ninth coming back to Boston before 4pm.				

Figure 1: Example of non-linguistic input as a structured database and logical form and its corresponding text. We omit record fields that have no value, for the sake of brevity.

baseline system.

An appealing alternative is to rerank the hypergraph *directly* (Huang, 2008). As it compactly encodes exponentially many derivations, we can explore a much larger hypothesis space than would have been possible with an  $n$ -best list. Importantly, in this framework non-local features are computed at all internal hypergraph nodes, allowing the decoder to take advantage of them continuously at all stages of the generation process. We incorporate features that are local with respect to a span of a sub-derivation in the packed forest; we also (approximately) include features that arbitrarily exceed span boundaries, thus capturing more global knowledge. Experimental results on the ATIS domain (Dahl et al., 1994) demonstrate that our model outperforms a baseline based on the best derivation and a state-of-the-art discriminative system (Angeli et al., 2010) by a wide margin.

Our contributions in this paper are threefold: we recast concept-to-text generation in a probabilistic parsing framework that allows to jointly optimize content selection and surface realization; we represent parse derivations compactly using hypergraphs and illustrate the use of an algorithm for *generating* (rather than parsing) in this framework; finally, the application of discriminative reranking to concept-to-text generation is novel to our knowledge and as our experiments show beneficial.

## 2 Related Work

Early discriminative approaches to text generation were introduced in spoken dialogue systems, and usually tackled content selection and surface realization separately. Ratnaparkhi (2002) conceptualized surface realization (from a fixed meaning representation) as a classification task. Local and non-local information (e.g., word  $n$ -grams, long-

range dependencies) was taken into account with the use of features in a maximum entropy probability model. More recently, Wong and Mooney (2007) describe an approach to surface realization based on synchronous context-free grammars. The latter are learned using a log-linear model with minimum error rate training (Och, 2003).

Angeli et al. (2010) were the first to propose a unified approach to content selection and surface realization. Their model operates over automatically induced alignments of words to database records (Liang et al., 2009) and decomposes into a sequence of discriminative local decisions. They first determine which records in the database to talk about, then which fields of those records to mention, and finally which words to use to describe the chosen fields. Each of these decisions is implemented as a log-linear model with features learned from training data. Their surface realization component performs decisions based on templates that are automatically extracted and smoothed with domain-specific knowledge in order to guarantee fluent output.

Discriminative reranking has been employed in many NLP tasks such as syntactic parsing (Charniak and Johnson, 2005; Huang, 2008), machine translation (Shen et al., 2004; Li and Khudanpur, 2009) and semantic parsing (Ge and Mooney, 2006). Our model is closest to Huang (2008) who also performs forest reranking on a hypergraph, using both local and non-local features, whose weights are tuned with the averaged perceptron algorithm (Collins, 2002). We adapt forest reranking to generation and introduce several task-specific features that boost performance. Although conceptually related to Angeli et al. (2010), our model optimizes content selection and surface realization simultaneously, rather than as a sequence. The discriminative aspect of two models is also fundamentally different. We have a single reranking component that applies

throughout, whereas they train different discriminative models for each local decision.

### 3 Problem Formulation

We assume our generator takes as input a set of database records  $\mathbf{d}$  and produces text  $\mathbf{w}$  that verbalizes some of these records. Each record  $r \in \mathbf{d}$  has a type  $r.t$  and a set of fields  $f$  associated with it. Fields have different values  $f.v$  and types  $f.t$  (i.e., integer or categorical). For example, in Figure 1, *flight* is a record type with fields *from* and *to*. The values of these fields are `denver` and `boston` and their type is categorical.

During training, our algorithm is given a corpus consisting of several *scenarios*, i.e., database records paired with texts like those shown in Figure 1. The database (and accompanying texts) are next converted into a PCFG whose weights are learned from training data. PCFG derivations are represented as a weighted directed hypergraph (Gallo et al., 1993). The weights on the hyperarcs are defined by a variety of feature functions, which we learn via a discriminative online update algorithm. During testing, we are given a set of database records without the corresponding text. Using the learned feature weights, we compile a hypergraph specific to this test input and decode it approximately (Huang, 2008). The hypergraph representation allows us to decompose the feature functions and compute them piecemeal at each hyperarc (or sub-derivation), rather than at the root node as in conventional  $n$ -best list reranking. Note that the algorithm does not separate content selection from surface realization, both subtasks are optimized jointly through the probabilistic parsing formulation.

#### 3.1 Grammar Definition

We capture the structure of the database with a number of CFG rewrite rules, in a similar way to how Liang et al. (2009) define Markov chains in their hierarchical model. These rules are purely syntactic (describing the intuitive relationship between records, records and fields, fields and corresponding words), and could apply to any database with similar structure irrespectively of the semantics of the domain.

Our grammar is defined in Table 1 (rules (1)–(9)). Rule weights are governed by an underlying multinomial distribution and are shown in square brackets.

1. $S \rightarrow R(start)$	$[Pr = 1]$
2. $R(r_i.t) \rightarrow FS(r_j, start) R(r_j.t)$	$[P(r_j.t   r_i.t) \cdot \lambda]$
3. $R(r_i.t) \rightarrow FS(r_j, start)$	$[P(r_j.t   r_i.t) \cdot \lambda]$
4. $FS(r, r.f_i) \rightarrow F(r, r.f_j) FS(r, r.f_j)$	$[P(f_j   f_i)]$
5. $FS(r, r.f_i) \rightarrow F(r, r.f_j)$	$[P(f_j   f_i)]$
6. $F(r, r.f) \rightarrow W(r, r.f) F(r, r.f)$	$[P(w   w_{-1}, r, r.f)]$
7. $F(r, r.f) \rightarrow W(r, r.f)$	$[P(w   w_{-1}, r, r.f)]$
8. $W(r, r.f) \rightarrow \alpha$	$[P(\alpha   r, r.f, f.t, f.v)]$
9. $W(r, r.f) \rightarrow g(f.v)$	$[P(g(f.v).mode   r, r.f, f.t = int)]$

Table 1: Grammar rules and their weights shown in square brackets.

ets. Non-terminal symbols are in capitals and denote intermediate states; the terminal symbol  $\alpha$  corresponds to all words seen in the training set, and  $g(f.v)$  is a function for generating integer numbers given the value of a field  $f$ . All non-terminals, save the start symbol  $S$ , have one or more constraints (shown in parentheses), similar to number and gender agreement constraints in augmented syntactic rules.

Rule (1) denotes the expansion from the start symbol  $S$  to record  $R$ , which has the special *start* type (hence the notation  $R(start)$ ). Rule (2) defines a chain between two consecutive records  $r_i$  and  $r_j$ . Here,  $FS(r_j, start)$  represents the set of fields of the target  $r_j$ , following the source record  $R(r_i)$ . For example, the rule  $R(search_1.t) \rightarrow FS(flight_1, start)R(flight_1.t)$  can be interpreted as follows. Given that we have talked about *search*<sub>1</sub>, we will next talk about *flight*<sub>1</sub> and thus emit its corresponding fields.  $R(flight_1.t)$  is a non-terminal place-holder for the continuation of the chain of records, and *start* in  $FS$  is a special boundary field between consecutive records. The weight of this rule is the bigram probability of two records conditioned on their type, multiplied with a normalization factor  $\lambda$ . We have also defined a *null* record type i.e., a record that has no fields and acts as a smoother for words that may not correspond to a particular record. Rule (3) is simply an escape rule, so that the parsing process (on the record level) can finish.

Rule (4) is the equivalent of rule (2) at the field

level, i.e., it describes the chaining of two consecutive fields  $f_i$  and  $f_j$ . Non-terminal  $F(r,r,f)$  refers to field  $f$  of record  $r$ . For example, the rule  $FS(flight_1, from) \rightarrow F(flight_1, to)FS(flight_1, to)$ , specifies that we should talk about the field  $to$  of record  $flight_1$ , after talking about the field  $from$ . Analogously to the record level, we have also included a special *null* field type for the emission of words that do not correspond to a specific record field. Rule (6) defines the expansion of field  $F$  to a sequence of (binarized) words  $W$ , with a weight equal to the bigram probability of the current word given the previous word, the current record, and field.

Rules (8) and (9) define the emission of words and integer numbers from  $W$ , given a field type and its value. Rule (8) emits a single word from the vocabulary of the training set. Its weight defines a multinomial distribution over all seen words, for every value of field  $f$ , given that the field type is categorical or the special *null* field. Rule (9) is identical but for fields whose type is integer. Function  $g(f.v)$  generates an integer number given the field value, using either of the following six ways (Liang et al., 2009): identical to the field value, rounding up or rounding down to a multiple of 5, rounding off to the closest multiple of 5 and finally adding or subtracting some unexplained noise.<sup>1</sup> The weight is a multinomial over the six generation function *modes*, given the record field  $f$ .

The CFG in Table 1 will produce many derivations for a given input (i.e., a set of database records) which we represent compactly using a hypergraph or a packed forest (Klein and Manning, 2001; Huang, 2008). Simplified examples of this representation are shown in Figure 2.

### 3.2 Hypergraph Reranking

For our generation task, we are given a set of database records  $\mathbf{d}$ , and our goal is to find the best corresponding text  $\mathbf{w}$ . This corresponds to the best grammar derivation among a set of candidate derivations represented *implicitly* in the hypergraph structure. As shown in Table 1, the mapping from  $\mathbf{d}$  to  $\mathbf{w}$  is unknown. Therefore, all the intermediate multinomial distributions, described in the previous section, define a hidden correspondence structure  $\mathbf{h}$ , between records, fields, and their values. We find the best

<sup>1</sup>The noise is modeled as a geometric distribution.

5         **if**  $(\mathbf{w}_i^*, \mathbf{h}_i^+) \neq (\hat{\mathbf{w}}_i, \hat{\mathbf{h}}_i)$  **then**  
6              $\alpha \leftarrow \alpha + \Phi(\mathbf{d}_i, \mathbf{w}_i^*, \mathbf{h}_i^+) - \Phi(\mathbf{d}_i, \hat{\mathbf{w}}_i, \hat{\mathbf{h}}_i)$   
7 **return**  $\frac{1}{T} \sum_{t=1}^T \frac{1}{N} \sum_{i=1}^N \alpha_t^i$

---

scoring derivation  $(\hat{\mathbf{w}}, \hat{\mathbf{h}})$  by maximizing over configurations of  $\mathbf{h}$ :

$$(\hat{\mathbf{w}}, \hat{\mathbf{h}}) = \arg \max_{w,h} \alpha \cdot \Phi(\mathbf{d}, \mathbf{w}, \mathbf{h})$$

We define the score of  $(\hat{\mathbf{w}}, \hat{\mathbf{h}})$  as the dot product between a high dimensional feature representation  $\Phi = (\Phi_1, \dots, \Phi_m)$  and a weight vector  $\alpha$ .

We estimate the weights  $\alpha$  using the averaged structured perceptron algorithm (Collins, 2002), which is well known for its speed and good performance in similar large-parameter NLP tasks (Liang et al., 2006; Huang, 2008). As shown in Algorithm 1, the perceptron makes several passes over the training scenarios, and in each iteration it computes the best scoring  $(\hat{\mathbf{w}}, \hat{\mathbf{h}})$  among the candidate derivations, given the current weights  $\alpha$ . In line 6, the algorithm updates  $\alpha$  with the difference (if any) between the feature representations of the best scoring derivation  $(\hat{\mathbf{w}}, \hat{\mathbf{h}})$  and the the *oracle derivation*  $(\mathbf{w}^*, \mathbf{h}^+)$ . Here,  $\hat{\mathbf{w}}$  is the estimated text,  $\mathbf{w}^*$  the gold-standard text,  $\hat{\mathbf{h}}$  is the estimated latent configuration of the model and  $\mathbf{h}^+$  the oracle latent configuration. The final weight vector  $\alpha$  is the average of weight vectors over  $T$  iterations and  $N$  scenarios. This averaging procedure avoids overfitting and produces more stable results (Collins, 2002).

In the following, we first explain how we decode in this framework, i.e., find the best scoring derivation (Section 3.3) and discuss our definition for the oracle derivation  $(\mathbf{w}^*, \mathbf{h}^+)$  (Section 3.4). Our features are described in Section 4.2.

### 3.3 Hypergraph Decoding

Following Huang (2008), we also distinguish features into local, i.e., those that can be computed within the confines of a single hyperedge, and non-local, i.e., those that require the prior visit of nodes other than their antecedents. For example, the

**Alignment** feature in Figure 2(a) is local, and thus can be computed a priori, but the **Word Trigrams** is not; in Figure 2(b) words in parentheses are sub-generations created so far at each word node; their combination gives rise to the trigrams serving as input to the feature. However, this combination may not take place at their immediate ancestors, since these may not be adjacent nodes in the hypergraph. According to the grammar in Table 1, there is no direct hyperedge between nodes representing words (W) and nodes representing the set of fields these correspond to (FS); rather, W and FS are connected implicitly via individual fields (F). Note, that in order to estimate the trigram feature at the FS node, we need to carry word information in the derivations of its antecedents, as we go bottom-up.<sup>2</sup>

Given these two types of features, we can then adapt Huang’s (2008) approximate decoding algorithm to find  $(\hat{\mathbf{w}}, \hat{\mathbf{h}})$ . Essentially, we perform bottom-up Viterbi search, visiting the nodes in reverse topological order, and keeping the  $k$ -best derivations for each. The score of each derivation is a linear combination of local and non-local features weights. In machine translation, a decoder that implements forest rescoring (Huang and Chiang, 2007) uses the language model as an external criterion of the goodness of sub-translations on account of their grammaticality. Analogously here, non-local features influence the selection of the best combinations, by introducing knowledge that exceeds the confines of the node under consideration and thus depend on the sub-derivations generated so far. (e.g., word trigrams spanning a field node rely on evidence from antecedent nodes that may be arbitrarily deeper than the field’s immediate children).

Our treatment of leaf nodes (see rules (8) and (9)) differs from the way these are usually handled in parsing. Since in generation we must emit rather than observe the words, for each leaf node we therefore output the  $k$ -best words according to the learned weights  $\alpha$  of the **Alignment** feature (see Section 4.2), and continue building our sub-generations bottom-up. This generation task is far from trivial: the search space on the word level is the size of the vocabulary and each field of a record can potentially generate all words. Also, note that in decoding it is useful to have a way to score different output

<sup>2</sup>We also store field information to compute structural features, described in Section 4.2.

lengths  $|\mathbf{w}|$ . Rather than setting  $\mathbf{w}$  to a fixed length, we rely on a linear regression predictor that uses the counts of each record type per scenario as features and is able to produce variable length texts.

### 3.4 Oracle Derivation

So far we have remained agnostic with respect to the oracle derivation  $(\mathbf{w}^*, \mathbf{h}^+)$ . In other NLP tasks such as syntactic parsing, there is a gold-standard parse, that can be used as the oracle. In our generation setting, such information is not available. We do not have the gold-standard alignment between the database records and the text that verbalizes them. Instead, we approximate it using the existing decoder to find the best latent configuration  $\mathbf{h}^+$  given the observed words in the training text  $\mathbf{w}^*$ .<sup>3</sup> This is similar in spirit to the generative alignment model of Liang et al. (2009).

## 4 Experimental Design

In this section we present our experimental setup for assessing the performance of our model. We give details on our dataset, model parameters and features, the approaches used for comparison, and explain how system output was evaluated.

### 4.1 Dataset

We conducted our experiments on the Air Travel Information System (ATIS) dataset (Dahl et al., 1994) which consists of transcriptions of spontaneous utterances of users interacting with a hypothetical on-line flight booking system. The dataset was originally created for the development of spoken language systems and is partitioned in individual user turns (e.g., *flights from orlando to milwaukee, show flights from orlando to milwaukee leaving after six o'clock*) each accompanied with an SQL query to a booking system and the results of this query. These utterances are typically short expressing a specific communicative goal (e.g., a question about the origin of a flight or its time of arrival). This inevitably results in small scenarios with a few words that often unambiguously correspond to a single record. To avoid training our model on a somewhat trivial corpus, we used the dataset introduced in Zettlemoyer

<sup>3</sup>In machine translation, Huang (2008) provides a soft algorithm that finds the forest oracle, i.e., the parse among the reranked candidates with the highest Parseval F-score. However, it still relies on the gold-standard reference translation.

and Collins (2007) instead, which combines the utterances of a single user in one scenario and contains 5,426 scenarios in total; each scenario corresponds to a (manually annotated) formal meaning representation ( $\lambda$ -expression) and its translation in natural language.

Lambda expressions were automatically converted into records, fields and values following the conventions adopted in Liang et al. (2009).<sup>4</sup> Given a lambda expression like the one shown in Figure 1, we first create a record for each variable and constant (e.g.,  $x$ , 9, august). We then assign record types according to the corresponding class types (e.g., variable  $x$  has class type *flight*). Next, fields and values are added from predicates with two arguments with the class type of the first argument matching that of the record type. The name of the predicate denotes the field, and the second argument denotes the value. We also defined special record types, such as *condition* and *search*. The latter is introduced for every lambda operator and assigned the categorical field *what* with the value *flight* which refers to the record type of variable  $x$ .

Contrary to datasets used in previous generation studies (e.g., ROBOCUP (Chen and Mooney, 2008) and WEATHERGOV (Liang et al., 2009)), ATIS has a much richer vocabulary (927 words); each scenario corresponds to a single sentence (average length is 11.2 words) with 2.65 out of 19 record types mentioned on average. Following Zettlemoyer and Collins (2007), we trained on 4,962 scenarios and tested on ATIS NOV93 which contains 448 examples.

## 4.2 Features

Broadly speaking, we defined two types of features, namely lexical and structural ones. In addition, we used a generatively trained PCFG as a baseline feature and an alignment feature based on the co-occurrence of records (or fields) with words.

**Baseline Feature** This is the log score of a generative decoder trained on the PCFG from Table 1. We converted the grammar into a hypergraph, and learned its probability distributions using a dynamic program similar to the inside-outside algorithm (Li and Eisner, 2009). Decoding was performed approx-

<sup>4</sup>The resulting dataset and a technical report describing the mapping procedure in detail are available from <http://homepages.inf.ed.ac.uk/s0793019/index.php?page=resources>

imately via cube pruning (Chiang, 2007), by integrating a trigram language model extracted from the training set (see Konstas and Lapata (2012) for details). Intuitively, the feature refers to the overall goodness of a specific derivation, applied locally in every hyperedge.

**Alignment Features** Instances of this feature family refer to the count of each PCFG rule from Table 1. For example, the number of times rule  $R(\text{search}_1.t) \rightarrow \text{FS}(\text{flight}_1, \text{start})R(\text{flight}_1.t)$  is included in a derivation (see Figure 2(a))

**Lexical Features** These features encourage grammatical coherence and inform lexical selection over and above the limited horizon of the language model captured by Rules (6)–(9). They also tackle anomalies in the generated output, due to the ergodicity of the CFG rules at the record and field level:

*Word Bigrams/Trigrams* This is a group of non-local feature functions that count word  $n$ -grams at every level in the hypergraph (see Figure 2(b)). The integration of words in the sub-derivations is adapted from Chiang (2007).

*Number of Words per Field* This feature function counts the number of words for every field, aiming to capture compound proper nouns and multi-word expressions, e.g., fields *from* and *to* frequently correspond to two or three words such as ‘*new york*’ and ‘*salt lake city*’ (see Figure 2(d)).

*Consecutive Word/Bigram/Trigram* This feature family targets adjacent repetitions of the same word, bigram or trigram, e.g., ‘*show me the show me the flights*’.

**Structural Features** Features in this category target primarily content selection and influence appropriate choice at the field level:

*Field bigrams/trigrams* Analogously to the lexical features mentioned above, we introduce a series of non-local features that capture field  $n$ -grams, given a specific record. For example the record *flight* in the air travel domain typically has the values  $\langle \text{from to} \rangle$  (see Figure 2(c)). The integration of fields in sub-derivations is implemented in fashion similar to the integration of words.

*Number of Fields per Record* This feature family is a coarser version of the *Field bigrams/trigrams*

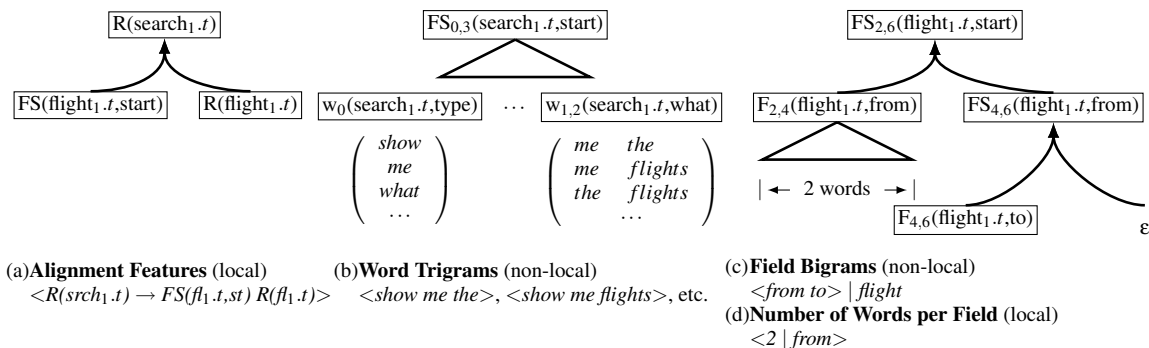

Figure 2: Simplified hypergraph examples with corresponding local and non-local features.

feature, which is deemed to be sparse for rarely-seen records.

*Field with No Value* Although records in the ATIS database schema have many fields, only a few are assigned a value in any given scenario. For example, the *flight* record has 13 fields, of which only 1.7 (on average) have a value. Practically, in a generative model this kind of sparsity would result in very low field recall. We thus include an identity feature function that explicitly counts whether a particular field has a value.

### 4.3 Evaluation

We evaluated three configurations of our model. A system that only uses the top scoring derivation in each sub-generation and incorporates only the baseline and alignment features (1-BEST+BASE+ALIGN). Our second system considers the  $k$ -best derivations and additionally includes lexical features ( $k$ -BEST+BASE+ALIGN+LEX). The number of  $k$ -best derivations was set to 40 and estimated experimentally on held-out data. And finally, our third system includes the full feature set ( $k$ -BEST+BASE+ALIGN+LEX+STR). Note, that the second and third system incorporate non-local features, hence the use of  $k$ -best derivation lists.<sup>5</sup> We compared our model to Angeli et al. (2010) whose approach is closest to ours.<sup>6</sup>

We evaluated system output automatically, using the BLEU-4 modified precision score (Papineni et

<sup>5</sup>Since the addition of these features, essentially incurs reranking, it follows that the systems would exhibit the exact same performance as the baseline system with 1-best lists.

<sup>6</sup>We are grateful to Gabor Angeli for providing us with the code of his system.

al., 2002) with the human-written text as reference. We also report results with the METEOR score (Banerjee and Lavie, 2005), which takes into account word re-ordering and has been shown to correlate better with human judgments at the sentence level. In addition, we evaluated the generated text by eliciting human judgments. Participants were presented with a scenario and its corresponding verbalization (see Figure 3) and were asked to rate the latter along two dimensions: fluency (is the text grammatical and overall understandable?) and semantic correctness (does the meaning conveyed by the text correspond to the database input?). The subjects used a five point rating scale where a high number indicates better performance. We randomly selected 12 documents from the test set and generated output with two of our models (1-BEST+BASE+ALIGN and  $k$ -BEST+BASE+ALIGN+LEX+STR) and Angeli et al.’s (2010) model. We also included the original text (HUMAN) as a gold standard. We thus obtained ratings for 48 ( $12 \times 4$ ) scenario-text pairs. The study was conducted over the Internet, using Amazon Mechanical Turk, and was completed by 51 volunteers, all self reported native English speakers.

## 5 Results

Table 2 summarizes our results. As can be seen, inclusion of lexical features gives our decoder an absolute increase of 6.73% in BLEU over the 1-BEST system. It also outperforms the discriminative system of Angeli et al. (2010). Our lexical features seem more robust compared to their templates. This is especially the case with infrequent records, where their system struggles to learn any meaningful information. Addition of the structural features further boosts performance. Our model increases by 8.69%

System	BLEU	METEOR
1-BEST+BASE+ALIGN	21.93	34.01
<i>k</i> -BEST+BASE+ALIGN+LEX	28.66	45.18
<i>k</i> -BEST+BASE+ALIGN+LEX+STR	30.62	46.07
ANGELI	26.77	42.41

Table 2: BLEU-4 and METEOR results on ATIS.

over the 1-BEST system and 3.85% over ANGELI in terms of BLEU. We observe a similar trend when evaluating system output with METEOR. Differences in magnitude are larger with the latter metric.

The results of our human evaluation study are shown in Table 5. We carried out an Analysis of Variance (ANOVA) to examine the effect of system type (1-BEST, *k*-BEST, ANGELI, and HUMAN) on the fluency and semantic correctness ratings. Means differences were compared using a post-hoc Tukey test. The *k*-BEST system is significantly better than the 1-BEST and ANGELI ( $a < 0.01$ ) both in terms of fluency and semantic correctness. ANGELI is significantly better than 1-BEST with regard to fluency ( $a < 0.05$ ) but not semantic correctness. There is no statistically significant difference between the *k*-BEST output and the original sentences (HUMAN).

Examples of system output are shown in Table 3. They broadly convey similar meaning with the gold-standard; ANGELI exhibits some long-range repetition, probably due to re-iteration of the same record patterns. We tackle this issue with the inclusion of non-local structural features. The 1-BEST system has some grammaticality issues, which we avoid by defining features over lexical *n*-grams and repeated words. It is worth noting that both our system and ANGELI produce output that is semantically compatible with but lexically different from the gold-standard (compare *please list the flights* and *show me the flights* against *give me the flights*). This is expected given the size of the vocabulary, but raises concerns regarding the use of automatic metrics for the evaluation of generation output.

## 6 Conclusions

We presented a discriminative reranking framework for an end-to-end generation system that performs both content selection and surface realization. Central to our approach is the encoding of generation as a parsing problem. We reformulate the input (a set of database records and text describing some of

System	Fluency	SemCor
1-BEST+BASE+ALIGN	2.70	3.05
<i>k</i> -BEST+BASE+ALIGN+LEX+STR	4.02	4.04
ANGELI	3.74	3.17
HUMAN	4.18	4.02

Table 3: Mean ratings for fluency and semantic correctness (SemCor) on system output elicited by humans.

	Flight	Time
	from to	when dep/ar
	phoenix milwaukee	evening departure
	Day	Search
	day dep/ar	type what
	wednesday departure	query flight
HUMAN	give me the flights from phoenix to milwaukee on wednesday evening	
ANGELI	show me the flights from phoenix to milwaukee on wednesday evening flights from phoenix to milwaukee

1-BEST	on wednesday evening from from phoenix to milwaukee on wednesday evening	

Figure 3: Example of scenario input and system output.

them) as a PCFG and convert it to a hypergraph. We find the best scoring derivation via forest reranking using both local and non-local features, that we train using the perceptron algorithm. Experimental evaluation on the ATIS dataset shows that our model attains significantly higher fluency and semantic correctness than any of the comparison systems. The current model can be easily extended to incorporate, additional, more elaborate features. Likewise, it can port to other domains with similar database structure without modification, such as WEATHERGOV and ROBOCUP. Finally, distributed training strategies have been developed for the perceptron algorithm (McDonald et al., 2010), which would allow our generator to scale to even larger datasets.

In the future, we would also like to tackle more challenging domains (e.g., product descriptions) and to enrich our generator with some notion of discourse planning. An interesting question is how to extend the PCFG-based approach advocated here so as to capture discourse-level document structure.

## Abstract

Methods that measure compatibility between mention pairs are currently the dominant approach to coreference. However, they suffer from a number of drawbacks including difficulties scaling to large numbers of mentions and limited representational power. As these drawbacks become increasingly restrictive, the need to replace the pairwise approaches with a more expressive, highly scalable alternative is becoming urgent. In this paper we propose a novel discriminative hierarchical model that recursively partitions entities into trees of latent sub-entities. These trees succinctly summarize the mentions providing a highly compact, information-rich structure for reasoning about entities and coreference uncertainty at massive scales. We demonstrate that the hierarchical model is several orders of magnitude faster than pairwise, allowing us to perform coreference on six million author mentions in under four hours on a single CPU.

## 1 Introduction

Coreference resolution, the task of clustering *mentions* into partitions representing their underlying real-world *entities*, is fundamental for high-level information extraction and data integration, including semantic search, question answering, and knowledge base construction. For example, coreference is vital for determining author publication lists in bibliographic knowledge bases such as CiteSeer and Google Scholar, where the repository must know if the “R. Hamming” who authored “Error detecting and error correcting codes” is the same” “R.

Hamming” who authored “The unreasonable effectiveness of mathematics.” Features of the mentions (e.g., bags-of-words in titles, contextual snippets and co-author lists) provide evidence for resolving such entities.

Over the years, various machine learning techniques have been applied to different variations of the coreference problem. A commonality in many of these approaches is that they model the problem of entity coreference as a collection of decisions between mention pairs (Bagga and Baldwin, 1999; Soon et al., 2001; McCallum and Wellner, 2004; Singla and Domingos, 2005; Bengston and Roth, 2008). That is, coreference is solved by answering a quadratic number of questions of the form “does *mention A* refer to the same entity as *mention B*?” with a compatibility function that indicates how likely A and B are coreferent. While these models have been successful in some domains, they also exhibit several undesirable characteristics. The first is that pairwise models lack the expressivity required to represent aggregate properties of the entities. Recent work has shown that these entity-level properties allow systems to correct coreference errors made from myopic pairwise decisions (Ng, 2005; Culotta et al., 2007; Yang et al., 2008; Rahman and Ng, 2009; Wick et al., 2009), and can even provide a strong signal for unsupervised coreference (Bhattacharya and Getoor, 2006; Haghighi and Klein, 2007; Haghighi and Klein, 2010).

A second problem, that has received significantly less attention in the literature, is that the pairwise coreference models scale poorly to large collections of mentions especially when the expected

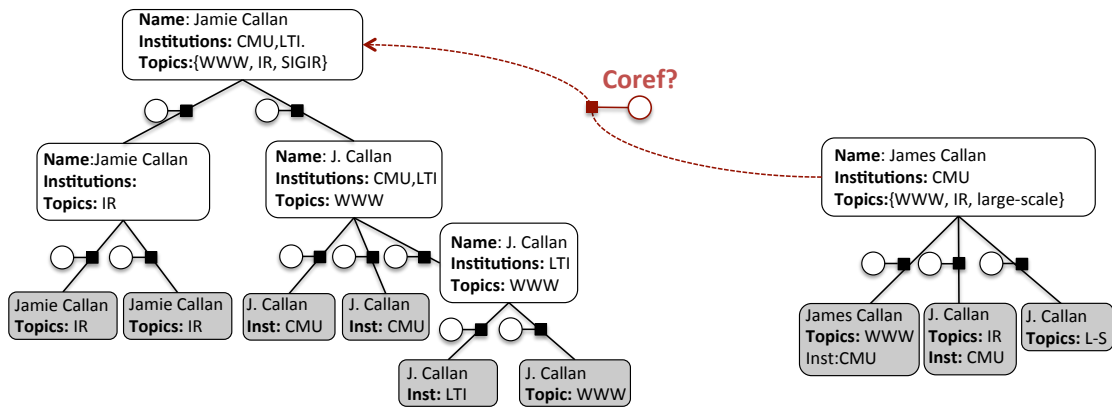

Figure 1: **Discriminative hierarchical factor graph for coreference:** Latent entity nodes (white boxes) summarize subtrees. Pairwise factors (black squares) measure compatibilities between child and parent nodes, avoiding quadratic blow-up. Corresponding decision variables (open circles) indicate whether one node is the child of another. Mentions (gray boxes) are leaves. Deciding whether to merge these two entities requires evaluating just a single factor (red square), corresponding to the new child-parent relationship.

number of mentions in each entity cluster is also large. Current systems cope with this by either dividing the data into blocks to reduce the search space (Hernández and Stolfo, 1995; McCallum et al., 2000; Bilenko et al., 2006), using fixed heuristics to greedily compress the mentions (Ravin and Kazi, 1999; Rao et al., 2010), employing specialized Markov chain Monte Carlo procedures (Milch et al., 2006; Richardson and Domingos, 2006; Singh et al., 2010), or introducing shallow hierarchies of sub-entities for MCMC block moves and super-entities for adaptive distributed inference (Singh et al., 2011). However, while these methods help manage the search space for medium-scale data, evaluating each coreference decision in many of these systems still scales linearly with the number of mentions in an entity, resulting in prohibitive computational costs associated with large datasets. This scaling with the number of mentions per entity seems particularly wasteful because although it is common for an entity to be referenced by a large number of mentions, many of these coreferent mentions are highly similar to each other. For example, in author coreference the two most common strings that refer to Richard Hamming might have the form “R. Hamming” and “Richard Hamming.” In newswire coreference, a prominent entity like Barack Obama may have millions of “Obama” mentions (many occurring in similar semantic contexts). Deciding whether

a mention belongs to this entity need not involve comparisons to all contextually similar “Obama” mentions; rather we prefer a more compact representation in order to efficiently reason about them.

In this paper we propose a novel hierarchical discriminative factor graph for coreference resolution that recursively structures each entity as a tree of latent sub-entities with mentions at the leaves. Our hierarchical model avoids the aforementioned problems of the pairwise approach: not only can it jointly reason about attributes of entire entities (using the power of discriminative conditional random fields), but it is also able to scale to datasets with enormous numbers of mentions because scoring entities does not require computing a quadratic number of compatibility functions. The key insight is that each node in the tree functions as a highly compact information-rich summary of its children. Thus, a small handful of upper-level nodes may summarize millions of mentions (for example, a single node may summarize all contextually similar “R. Hamming” mentions). Although inferring the structure of the entities requires reasoning over a larger state-space, the latent trees are actually beneficial to inference (as shown for shallow trees in Singh et al. (2011)), resulting in rapid progress toward high probability regions, and mirroring known benefits of auxiliary variable methods in statistical physics (such as Swendsen and Wang (1987)). Moreover,

each step of inference is computationally efficient because evaluating the cost of attaching (or detaching) sub-trees requires computing just a single compatibility function (as seen in Figure 1). Further, our hierarchical approach provides a number of additional advantages. First, the recursive nature of the tree (arbitrary depth and width) allows the model to adapt to different types of data and effectively compress entities of different scales (e.g., entities with more mentions may require a deeper hierarchy to compress). Second, the model contains compatibility functions at all levels of the tree enabling it to simultaneously reason at multiple granularities of entity compression. Third, the trees can provide split points for finer-grained entities by placing contextually similar mentions under the same subtree. Finally, if memory is limited, redundant mentions can be pruned by replacing subtrees with their roots.

Empirically, we demonstrate that our model is several orders of magnitude faster than a pairwise model, allowing us to perform efficient coreference on nearly six million author mentions in under four hours using a single CPU.

## 2 Background: Pairwise Coreference

Coreference is the problem of clustering mentions such that mentions in the same set refer to the same real-world entity; it is also known as entity disambiguation, record linkage, and de-duplication. For example, in author coreference, each mention might be represented as a record extracted from the author field of a textual citation or BibTeX record. The mention record may contain attributes for the first, middle, and last name of the author, as well as contextual information occurring in the citation string, co-authors, titles, topics, and institutions. The goal is to cluster these mention records into sets, each containing all the mentions of the author to which they refer; we use this task as a running pedagogical example.

Let  $\mathcal{M}$  be the space of observed mention records; then the traditional pairwise coreference approach scores candidate coreference solutions with a compatibility function  $\psi : \mathcal{M} \times \mathcal{M} \rightarrow \mathfrak{R}$  that measures how likely it is that the two mentions refer to the same entity.<sup>1</sup> In discriminative log-

<sup>1</sup>We can also include an *incompatibility* function for when

linear models, the function  $\psi$  takes the form of weights  $\theta$  on features  $\phi(m_i, m_j)$ , i.e.,  $\psi(m_i, m_j) = \exp(\theta \cdot \phi(m_i, m_j))$ . For example, in author coreference, the feature functions  $\phi$  might test whether the name fields for two author mentions are string identical, or compute cosine similarity between the two mentions' bags-of-words, each representing a mention's context. The corresponding real-valued weights  $\theta$  determine the impact of these features on the overall pairwise score.

Coreference can be solved by introducing a set of binary coreference decision variables for each mention pair and predicting a setting to their values that maximizes the sum of pairwise compatibility functions. While it is possible to independently make pairwise decisions and enforce transitivity *post hoc*, this can lead to poor accuracy because the decisions are tightly coupled. For higher accuracy, a graphical model such as a conditional random field (CRF) is constructed from the compatibility functions to jointly reason about the pairwise decisions (McCallum and Wellner, 2004). We now describe the pairwise CRF for coreference as a factor graph.

### 2.1 Pairwise Conditional Random Field

Each mention  $m_i \in \mathcal{M}$  is an observed variable, and for each mention pair  $(m_i, m_j)$  we have a binary coreference decision variable  $y_{ij}$  whose value determines whether  $m_i$  and  $m_j$  refer to the same entity (i.e., 1 means they are coreferent and 0 means they are not coreferent). The pairwise compatibility functions become the factors in the graphical model. Each factor examines the properties of its mention pair as well as the setting to the coreference decision variable and outputs a score indicating how likely the setting of that coreference variable is. The joint probability distribution over all possible settings to the coreference decision variables ( $\mathbf{y}$ ) is given as a product of all the pairwise compatibility factors:

$$Pr(\mathbf{y}|\mathbf{m}) \propto \prod_{i=1}^n \prod_{j=1}^n \psi(m_i, m_j, y_{ij}) \quad (1)$$

Given the pairwise CRF, the problem of coreference is then solved by searching for the setting of the coreference decision variables that has the highest probability according to Equation 1 subject to the mentions are not coreferent, e.g.,  $\psi : \mathcal{M} \times \mathcal{M} \times \{0, 1\} \rightarrow \mathfrak{R}$

Figure 2: **Pairwise model on six mentions:** Open circles are the binary coreference decision variables, shaded circles are the observed mentions, and the black boxes are the factors of the graphical model that encode the pairwise compatibility functions.

constraint that the setting to the coreference variables obey transitivity;<sup>2</sup> this is the maximum probability estimate (MPE) setting. However, the solution to this problem is intractable, and even approximate inference methods such as loopy belief propagation can be difficult due to the cubic number of deterministic transitivity constraints.

## 2.2 Approximate Inference

An approximate inference framework that has successfully been used for coreference models is Metropolis-Hastings (MH) (Milch et al. (2006), Culotta and McCallum (2006), Poon and Domingos (2007), amongst others), a Markov chain Monte Carlo algorithm traditionally used for marginal inference, but which can also be tuned for MPE inference. MH is a flexible framework for specifying customized local-search transition functions and provides a principled way of deciding which local search moves to accept. A proposal function  $q$  takes the current coreference hypothesis and proposes a new hypothesis by modifying a subset of the decision variables. The proposed change is accepted with probability  $\alpha$ :

$$\alpha = \min \left( 1, \frac{Pr(\mathbf{y}') q(\mathbf{y}|\mathbf{y}')}{Pr(\mathbf{y}) q(\mathbf{y}'|\mathbf{y})} \right) \quad (2)$$

<sup>2</sup>We say that a full assignment to the coreference variables  $\mathbf{y}$  obeys transitivity if  $\forall ijk y_{ij} = 1 \wedge y_{jk} = 1 \implies y_{ik} = 1$

When using MH for MPE inference, the second term  $q(\mathbf{y}|\mathbf{y}')/q(\mathbf{y}'|\mathbf{y})$  is optional, and usually omitted. Moves that reduce model score may be accepted and an optional temperature can be used for annealing. The primary advantages of MH for coreference are (1) only the compatibility functions of the changed decision variables need to be evaluated to accept a move, and (2) the proposal function can enforce the transitivity constraint by exploring only variable settings that result in valid coreference partitionings.

A commonly used proposal distribution for coreference is the following: (1) randomly select two mentions  $(m_i, m_j)$ , (2) if the mentions  $(m_i, m_j)$  are in the same entity cluster according to  $\mathbf{y}$  then move one mention into a singleton cluster (by setting the necessary decision variables to 0), otherwise, move mention  $m_i$  so it is in the same cluster as  $m_j$  (by setting the necessary decision variables). Typically, MH is employed by first initializing to a singleton configuration (all entities have one mention), and then executing the MH for a certain number of steps (or until the predicted coreference hypothesis stops changing).

This proposal distribution always moves a single mention  $m$  from some entity  $e_i$  to another entity  $e_j$  and thus the configuration  $\mathbf{y}$  and  $\mathbf{y}'$  only differ by the setting of decision variables governing to which entity  $m$  refers. In order to guarantee transitivity and a valid coreference equivalence relation, we must properly remove  $m$  from  $e_i$  by untethering  $m$  from each mention in  $e_i$  (this requires computing  $|e_i| - 1$  pairwise factors). Similarly—again, for the sake of transitivity—in order to complete the move into  $e_j$  we must coref  $m$  to each mention in  $e_j$  (this requires computing  $|e_j|$  pairwise factors). Clearly, all the other coreference decision variables are independent and so their corresponding factors cancel because they yield the same scores under  $\mathbf{y}$  and  $\mathbf{y}'$ . Thus, evaluating each proposal for the pairwise model scales linearly with the number of mentions assigned to the entities, requiring the evaluation of  $2(|e_i| + |e_j| - 1)$  compatibility functions (factors).

## 3 Hierarchical Coreference

Instead of only capturing a single coreference clustering between mention pairs, we can imagine multiple levels of coreference decisions over different

granularities. For example, mentions of an author may be further partitioned into semantically similar sets, such that mentions from each set have topically similar papers. This partitioning can be recursive, i.e., each of these sets can be further partitioned, capturing candidate splits for an entity that can facilitate inference. In this section, we describe a model that captures arbitrarily deep hierarchies over such layers of coreference decisions, enabling efficient inference and rich entity representations.

### 3.1 Discriminative Hierarchical Model

In contrast to the pairwise model, where each entity is a flat cluster of mentions, our proposed model structures each entity recursively as a tree. The leaves of the tree are the observed mentions with a set of attribute values. Each internal node of the tree is latent and contains a set of unobserved attributes; recursively, these *node records* summarize the attributes of their child nodes (see Figure 1), for example, they may aggregate the bags of context words of the children. The root of each tree represents the entire entity, with the leaves containing its mentions. Formally, the coreference decision variables in the hierarchical model no longer represent pairwise decisions directly. Instead, a decision variable  $y_{r_i, r_j} = 1$  indicates that node-record  $r_j$  is the parent of node-record  $r_i$ . We say a node-record *exists* if either it is a mention, has a parent, or has at least one child. Let  $R$  be the set of all existing node records, let  $r^p$  denote the parent for node  $r$ , that is  $y_{r, r^p} = 1$ , and  $\forall r' \neq r^p, y_{r, r'} = 0$ . As we describe in more detail later, the structure of the tree and the values of the unobserved attributes are determined during inference.

In order to represent our recursive model of coreference, we include two types of factors: pairwise factors  $\psi_{pw}$  that measure compatibility between a child node-record and its parent, and unit-wise factors  $\psi_{rw}$  that measure compatibilities of the node-records themselves. For efficiency we enforce that parent-child factors only produce a non-zero score when the corresponding decision variable is 1. The unit-wise factors can examine compatibility of settings to the attribute variables for a particular node (for example, the set of topics may be too diverse to represent just a single entity), as well as enforce priors over the tree’s breadth and depth. Our recur-

sive hierarchical model defines the probability of a configuration as:

$$Pr(\mathbf{y}, R | \mathbf{m}) \propto \prod_{r \in R} \psi_{rw}(r) \psi_{pw}(r, r^p) \quad (3)$$

### 3.2 MCMC Inference for Hierarchical models

The state space of our hierarchical model is substantially larger (theoretically infinite) than the pairwise model due to the arbitrarily deep (and wide) latent structure of the cluster trees. Inference must simultaneously determine the structure of the tree, the latent node-record values, as well as the coreference decisions themselves.

While this may seem daunting, the structures being inferred are actually beneficial to inference. Indeed, despite the enlarged state space, inference in the hierarchical model is substantially faster than a pairwise model with a smaller state space. One explanatory intuition comes from the statistical physics community: we can view the latent tree as auxiliary variables in a data-augmentation sampling scheme that guide MCMC through the state space more efficiently. There is a large body of literature in the statistics community describing how these auxiliary variables can lead to faster convergence despite the enlarged state space (classic examples include Swendsen and Wang (1987) and slice samplers (Neal, 2000)).

Further, evaluating each proposal during inference in the hierarchical model is substantially faster than in the pairwise model. Indeed, we can replace the linear number of factor evaluations (as in the pairwise model) with a constant number of factor evaluations for most proposals (for example, adding a subtree requires re-evaluating only a single parent-child factor between the subtree and the attachment point, and a single node-wise factor).

Since inference must determine the structure of the entity trees in addition to coreference, it is advantageous to consider multiple MH proposals per sample. Therefore, we employ a modified variant of MH that is similar to multi-try Metropolis (Liu et al., 2000). Our modified MH algorithm makes  $k$  proposals and samples one according to its model ratio score (the first term in Equation 2) normalized across all  $k$ . More specifically, for each MH step, we first randomly select two subtrees headed by node-

records  $r_i$  and  $r_j$  from the current coreference hypothesis. If  $r_i$  and  $r_j$  are in different clusters, we propose several alternate merge operations: (also in Figure 3):

- **Merge Left** - merges the entire subtree of  $r_j$  into node  $r_i$  by making  $r_j$  a child of  $r_i$
- **Merge Entity Left** - merges  $r_j$  with  $r_i$ 's root
- **Merge Left and Collapse** - merges  $r_j$  into  $r_i$  then performs a collapse on  $r_j$  (see below).
- **Merge Up** - merges node  $r_i$  with node  $r_j$  by creating a new parent node-record variable  $r^p$  with  $r_i$  and  $r_j$  as the children. The attribute fields of  $r^p$  are selected from  $r_i$  and  $r_j$ .

Otherwise  $r_i$  and  $r_j$  are subtrees in the same entity tree, then the following proposals are used instead:

- **Split Right** - Make the subtree  $r_j$  the root of a new entity by detaching it from its parent
- **Collapse** - If  $r_i$  has a parent, then move  $r_i$ 's children to  $r_i$ 's parent and then delete  $r_i$ .
- **Sample attribute** - Pick a new value for an attribute of  $r_i$  from its children.

Computing the model ratio for all of coreference proposals requires only a constant number of compatibility functions. On the other hand, evaluating proposals in the pairwise model requires evaluating a number of compatibility functions equal to the number of mentions in the clusters being modified.

Note that changes to the attribute values of the node-record and collapsing still require evaluating a linear number of factors, but this is only linear in the number of child nodes, not linear in the number of mentions referring to the entity. Further, attribute values rarely change once the entities stabilize. Finally, we incrementally update bags during coreference to reflect the aggregates of their children.

## 4 Experiments: Author Coreference

Author coreference is a tremendously important task, enabling improved search and mining of scientific papers by researchers, funding agencies, and governments. The problem is extremely difficult due to the wide variations of names, limited contextual evidence, misspellings, people with common names, lack of standard citation formats, and large numbers of mentions.

For this task we use a publicly available collection of 4,394 BibTeX files containing 817,193 en-

tries.<sup>3</sup> We extract 1,322,985 author mentions, each containing first, middle, last names, bags-of-words of paper titles, topics in paper titles (by running latent Dirichlet allocation (Blei et al., 2003)), and last names of co-authors. In addition we include 2,833 mentions from the REXA dataset<sup>4</sup> labeled for coreference, in order to assess accuracy. We also include  $\sim 5$  million mentions from DBLP.

### 4.1 Models and Inference

Due to the paucity of labeled training data, we did not estimate parameters from data, but rather set the compatibility functions manually by specifying their log scores. The pairwise compatibility functions punish a string difference in first, middle, and last name, ( $-8$ ); reward a match ( $+2$ ); and reward matching initials ( $+1$ ). Additionally, we use the cosine similarity (shifted and scaled between  $-4$  and  $4$ ) between the bags-of-words containing title tokens, topics, and co-author last names. These compatibility functions define the scores of the factors in the pairwise model and the parent-child factors in the hierarchical model. Additionally, we include priors over the model structure. We encourage each node to have eight children using a per node factor having score  $1/(|\text{number of children}-8|+1)$ , manage tree depth by placing a cost on the creation of intermediate tree nodes  $-8$  and encourage clustering by placing a cost on the creation of root-level entities  $-7$ . These weights were determined by just a few hours of tuning on a development set.

We initialize the MCMC procedures to the singleton configuration (each entity consists of one mention) for each model, and run the MH algorithm described in Section 2.2 for the pairwise model and multi-try MH (described in Section 3.2) for the hierarchical model. We augment these samplers using canopies constructed by concatenating the first initial and last name: that is, mentions are only selected from within the same canopy (or block) to reduce the search space (Bilenko et al., 2006). During the course of MCMC inference, we record the pairwise F1 scores of the labeled subset. The source code for our model is available as part of the FACTORIE package (McCallum et al., 2009, <http://www.iesl.cs.umass.edu/data/bibtex>

<sup>3</sup><http://www.iesl.cs.umass.edu/data/bibtex>

<sup>4</sup><http://www2.selu.edu/Academics/Faculty/aculotta/data/rexa.html>

Figure 3: Example coreference proposals for the case where  $r_i$  and  $r_j$  are initially in different clusters.

//factorie.cs.umass.edu/).

## 4.2 Comparison to Pairwise Model

In Figure 4a we plot the number of samples completed over time for a 145k subset of the data. Recall that we initialized to the singleton configuration and that as the size of the entities grows, the cost of evaluating the entities in MCMC becomes more expensive. The pairwise model struggles with the large cluster sizes while the hierarchical model is hardly affected. Even though the hierarchical model is evaluating up to four proposals for each sample, it is still able to sample much faster than the pairwise model; this is expected because the cost of evaluating a proposal requires evaluating fewer factors. Next, we plot coreference F1 accuracy over time and show in Figure 5a that the prolific sampling rate of the hierarchical model results in faster coreference. Using the plot, we can compare running times for any desired level of accuracy. For example, on the 145k mention dataset, at a 60% accuracy level the hierarchical model is 19 times faster and at 90% accuracy it is 31 times faster. These performance improvements are even more profound on larger datasets: the hierarchical model achieves a 60% level of accuracy 72 times faster than the pairwise model on the 1.3 million mention dataset, reaching 90% in just 2,350 seconds. Note, however, that the hierarchical model requires more samples to reach a similar level of accuracy due to the larger state space (Figure 4b).

## 4.3 Large Scale Experiments

In order to demonstrate the scalability of the hierarchical model, we run it on nearly 5 million author mentions from DBLP. In under two hours (6,700 seconds), we achieve an accuracy of 80%, and in under three hours (10,600 seconds), we achieve an

accuracy of over 90%. Finally, we combine DBLP with BibTeX data to produce a dataset with almost 6 million mentions (5,803,811). Our performance on this dataset is similar to DBLP, taking just 13,500 seconds to reach a 90% accuracy.

## 5 Related Work

Singh et al. (2011) introduce a hierarchical model for coreference that treats entities as a two-tiered structure, by introducing the concept of sub-entities and super-entities. Super-entities reduce the search space in order to propose fruitful jumps. Sub-entities provide a tighter granularity of coreference and can be used to perform larger block moves during MCMC. However, the hierarchy is fixed and shallow. In contrast, our model can be arbitrarily deep and wide. Even more importantly, their model has pairwise factors and suffers from the quadratic curse, which they address by distributing inference.

The work of Rao et al. (2010) uses streaming clustering for large-scale coreference. However, the greedy nature of the approach does not allow errors to be revisited. Further, they compress entities by averaging their mentions' features. We are able to provide richer entity compression, the ability to revisit errors, and scale to larger data.

Our hierarchical model provides the advantages of recently proposed entity-based coreference systems that are known to provide higher accuracy (Haghighi and Klein, 2007; Culotta et al., 2007; Yang et al., 2008; Wick et al., 2009; Haghighi and Klein, 2010). However, these systems reason over a single layer of entities and do not scale well.

Techniques such as lifted inference (Singla and Domingos, 2008) for graphical models exploit redundancy in the data, but typically do not achieve any significant compression on coreference data be-

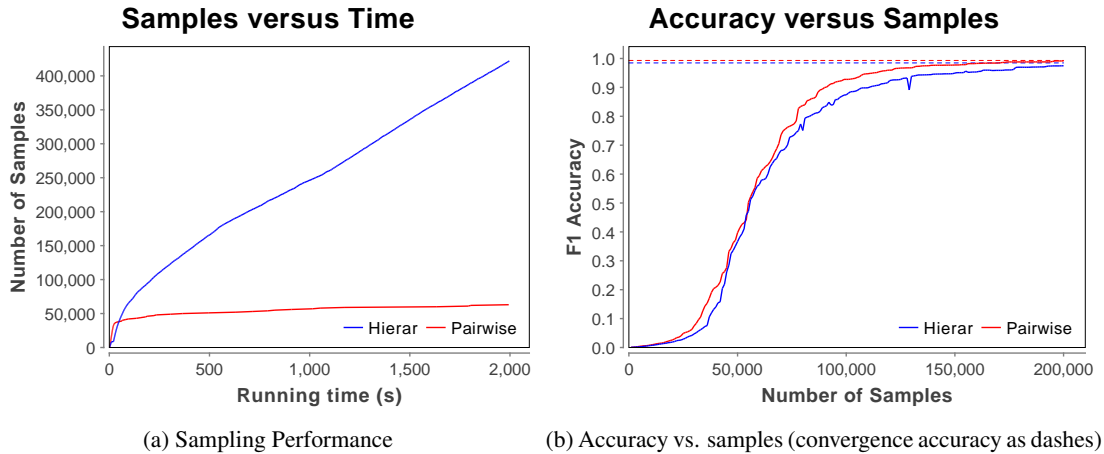

Figure 4: Sampling Performance Plots for 145k mentions

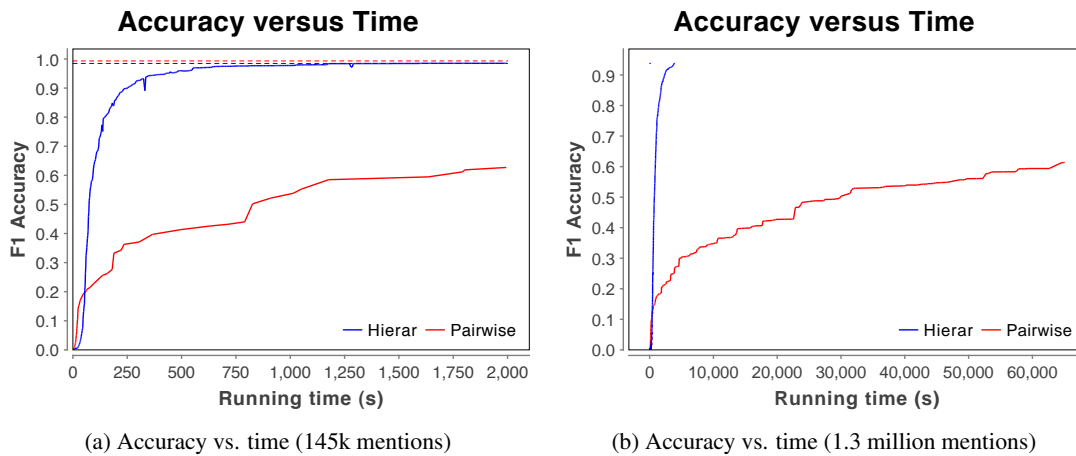

Figure 5: Runtime performance on two datasets

cause the observations usually violate any symmetry assumptions. On the other hand, our model is able to compress similar (but potentially different) observations together in order to make inference fast even in the presence of asymmetric observed data.

## 6 Conclusion

In this paper we present a new hierarchical model for large scale coreference and demonstrate it on the problem of author disambiguation. Our model recursively defines an entity as a summary of its children nodes, allowing succinct representations of millions of mentions. Indeed, inference in the hierarchy is orders of magnitude faster than a pairwise CRF, allowing us to infer accurate coreference on

six million mentions on one CPU in just 4 hours.

# Coreference Semantics from Web Features

Mohit Bansal and Dan Klein

Computer Science Division

University of California, Berkeley

{mbansal, klein}@cs.berkeley.edu

## Abstract

To address semantic ambiguities in coreference resolution, we use Web  $n$ -gram features that capture a range of world knowledge in a diffuse but robust way. Specifically, we exploit short-distance cues to hypernymy, semantic compatibility, and semantic context, as well as general lexical co-occurrence. When added to a state-of-the-art coreference baseline, our Web features give significant gains on multiple datasets (ACE 2004 and ACE 2005) and metrics (MUC and B<sup>3</sup>), resulting in the best results reported to date for the end-to-end task of coreference resolution.

## 1 Introduction

Many of the most difficult ambiguities in coreference resolution are semantic in nature. For instance, consider the following example:

*When Obama met Jobs, the president discussed the economy, technology, and education. His election campaign is expected to [...]*

For resolving coreference in this example, a system would benefit from the world knowledge that *Obama is the president*. Also, to resolve the pronoun *his* to the correct antecedent *Obama*, we can use the knowledge that *Obama* has an *election campaign* while *Jobs* does not. Such ambiguities are difficult to resolve on purely syntactic or configurational grounds.

There have been multiple previous systems that incorporate some form of world knowledge in coreference resolution tasks. Most work (Poesio et al., 2004; Markert and Nissim, 2005; Yang et al., 2005; Bergsma and Lin, 2006) addresses special cases and subtasks such as bridging anaphora,

other anaphora, definite NP reference, and pronoun resolution, computing semantic compatibility via Web-hits and counts from large corpora. There is also work on end-to-end coreference resolution that uses large noun-similarity lists (Daumé III and Marcu, 2005) or structured knowledge bases such as Wikipedia (Yang and Su, 2007; Haghighi and Klein, 2009; Kobdani et al., 2011) and YAGO (Rahman and Ng, 2011). However, such structured knowledge bases are of limited scope, and, while Haghighi and Klein (2010) self-acquires knowledge about coreference, it does so only via reference constructions and on a limited scale.

In this paper, we look to the Web for broader if shallower sources of semantics. In order to harness the information on the Web without presupposing a deep understanding of all Web text, we instead turn to a diverse collection of Web  $n$ -gram counts (Brants and Franz, 2006) which, in aggregate, contain diffuse and indirect, but often robust, cues to reference. For example, we can collect the co-occurrence statistics of an anaphor with various candidate antecedents to judge relative surface affinities (i.e., (*Obama, president*) versus (*Jobs, president*)). We can also count co-occurrence statistics of competing antecedents when placed in the context of an anaphoric pronoun (i.e., *Obama's election campaign* versus *Jobs' election campaign*).

All of our features begin with a pair of headwords from candidate mention pairs and compute statistics derived from various potentially informative queries' counts. We explore five major categories of semantically informative Web features, based on (1) general lexical affinities (via generic co-occurrence statistics), (2) lexical relations (via Hearst-style hypernymy patterns), (3) similarity of entity-based context (e.g., common values of  $y$  for

which *h is a y* is attested), (4) matches of distributional soft cluster ids, and (5) attested substitutions of candidate antecedents in the context of a pronominal anaphor.

We first describe a strong baseline consisting of the mention-pair model of the Reconcile system (Stoyanov et al., 2009; Stoyanov et al., 2010) using a decision tree (DT) as its pairwise classifier. To this baseline system, we add our suite of features in turn, each class of features providing substantial gains. Altogether, our final system produces the best numbers reported to date on end-to-end coreference resolution (with automatically detected system mentions) on multiple data sets (ACE 2004 and ACE 2005) and metrics (MUC and B<sup>3</sup>), achieving significant improvements over the Reconcile DT baseline and over the state-of-the-art results of Haghighi and Klein (2010).

## 2 Baseline System

Before describing our semantic Web features, we first describe our baseline. The core inference and features come from the Reconcile package (Stoyanov et al., 2009; Stoyanov et al., 2010), with modifications described below. Our baseline differs most substantially from Stoyanov et al. (2009) in using a decision tree classifier rather than an averaged linear perceptron.

### 2.1 Reconcile

Reconcile is one of the best implementations of the *mention-pair* model (Soon et al., 2001) of coreference resolution. The mention-pair model relies on a pairwise function to determine whether or not two mentions are coreferent. Pairwise predictions are then consolidated by transitive closure (or some other clustering method) to form the final set of coreference clusters (chains). While our Web features could be adapted to entity-mention systems, their current form was most directly applicable to the mention-pair approach, making Reconcile a particularly well-suited platform for this investigation.

The Reconcile system provides baseline features, learning mechanisms, and resolution procedures that already achieve near state-of-the-art results on multiple popular datasets using multiple standard metrics. It includes over 80 core features that exploit

various automatically generated annotations such as named entity tags, syntactic parses, and WordNet classes, inspired by Soon et al. (2001), Ng and Cardie (2002), and Bengtson and Roth (2008). The Reconcile system also facilitates standardized empirical evaluation to past work.<sup>1</sup>

In this paper, we develop a suite of simple semantic Web features based on pairs of mention headwords which stack with the default Reconcile features to surpass past state-of-the-art results.

### 2.2 Decision Tree Classifier

Among the various learning algorithms that Reconcile supports, we chose the decision tree classifier, available in Weka (Hall et al., 2009) as J48, an open source Java implementation of the C4.5 algorithm of Quinlan (1993).

The C4.5 algorithm builds decision trees by incrementally maximizing information gain. The training data is a set of already classified samples, where each sample is a vector of attributes or features. At each node of the tree, C4.5 splits the data on an attribute that most effectively splits its set of samples into more ordered subsets, and then recurses on these smaller subsets. The decision tree can then be used to classify a new sample by following a path from the root downward based on the attribute values of the sample.

We find the decision tree classifier to work better than the default averaged perceptron (used by Stoyanov et al. (2009)), on multiple datasets using multiple metrics (see Section 4.3). Many advantages have been claimed for decision tree classifiers, including interpretability and robustness. However, we suspect that the aspect most relevant to our case is that decision trees can capture non-linear interactions between features. For example, recency is very important for pronoun reference but much less so for nominal reference.

## 3 Semantics via Web Features

Our Web features for coreference resolution are simple and capture a range of diffuse world knowledge. Given a mention pair, we use the head finder in Reconcile to find the lexical heads of both mentions (for

---

<sup>1</sup>We use the default configuration settings of Reconcile (Stoyanov et al., 2010) unless mentioned otherwise.

example, the head of *the Palestinian territories* is the word *territories*). Next, we take each headword pair ( $h_1, h_2$ ) and compute various Web-count functions on it that can signal whether or not this mention pair is coreferent.

As the source of Web information, we use the Google  $n$ -grams corpus (Brants and Franz, 2006) which contains English  $n$ -grams ( $n = 1$  to 5) and their Web frequency counts, derived from nearly 1 trillion word tokens and 95 billion sentences. Because we have many queries that must be run against this corpus, we apply the trie-based hashing algorithm of Bansal and Klein (2011) to efficiently answer all of them in one pass over it. The features that require word clusters (Section 3.4) use the output of Lin et al. (2010).<sup>2</sup>

We describe our five types of features in turn. The first four types are most intuitive for mention pairs where both members are non-pronominal, but, aside from the general co-occurrence group, helped for all mention pair types. The fifth feature group applies only to pairs in which the anaphor is a pronoun but the antecedent is a non-pronoun. Related work for each feature category is discussed inline.

### 3.1 General co-occurrence

These features capture co-occurrence statistics of the two headwords, i.e., how often  $h_1$  and  $h_2$  are seen adjacent or nearly adjacent on the Web. This count can be a useful coreference signal because, in general, mentions referring to the same entity will co-occur more frequently (in large corpora) than those that do not. Using the  $n$ -grams corpus (for  $n = 1$  to 5), we collect co-occurrence Web-counts by allowing a varying number of wildcards between  $h_1$  and  $h_2$  in the query. The co-occurrence value is:

$$\text{bin} \left( \log_{10} \left( \frac{c_{12}}{c_1 \cdot c_2} \right) \right)$$

<sup>2</sup>These clusters are derived from the V2 Google  $n$ -grams corpus. The V2 corpus itself is not publicly available, but the clusters are available at <http://www.clsp.jhu.edu/~sbergma/PhrasalClusters>

where

$$\begin{aligned} c_{12} &= \text{count}("h_1 \star h_2") \\ &+ \text{count}("h_1 \star \star h_2") \\ &+ \text{count}("h_1 \star \star \star h_2"), \\ c_1 &= \text{count}("h_1"), \text{ and} \\ c_2 &= \text{count}("h_2"). \end{aligned}$$

We normalize the overall co-occurrence count of the headword pair  $c_{12}$  by the unigram counts of the individual headwords  $c_1$  and  $c_2$ , so that high-frequency headwords do not unfairly get a high feature value (this is similar to computing scaled mutual information MI (Church and Hanks, 1989)).<sup>3</sup> This normalized value is quantized by taking its  $\log_{10}$  and binning. The actual feature that fires is an indicator of which quantized bin the query produced. As a real example from our development set, the co-occurrence count  $c_{12}$  for the headword pair (*leader, president*) is 11383, while it is only 95 for the headword pair (*voter, president*); after normalization and  $\log_{10}$ , the values are -10.9 and -12.0, respectively.

These kinds of general Web co-occurrence statistics have been used previously for other supervised NLP tasks such as spelling correction and syntactic parsing (Bergsma et al., 2010; Bansal and Klein, 2011). In coreference, similar word-association scores were used by Kobdani et al. (2011), but from Wikipedia and for self-training.

### 3.2 Hearst co-occurrence

These features capture templated co-occurrence of the two headwords  $h_1$  and  $h_2$  in the Web-corpus. Here, we only collect statistics of the headwords co-occurring with a generalized Hearst pattern (Hearst, 1992) in between. Hearst patterns capture various lexical semantic relations between items. For example, seeing *X is a Y* or *X and other Y* indicates hypernymy and also tends to cue coreference. The specific patterns we use are:

- $h_1 \{is \mid are \mid was \mid were\} \{a \mid an \mid the\} h_2$
- $h_1 \{and \mid or\} \{other \mid the \text{ other} \mid another\} h_2$
- $h_1 \text{ other than } \{a \mid an \mid the\} h_2$

<sup>3</sup>We also tried adding  $\text{count}("h_1 h_2")$  to  $c_{12}$  but this decreases performance, perhaps because truly adjacent occurrences are often not grammatical.

- $h_1$  such as  $\{a \mid an \mid the\}?$   $h_2$
- $h_1$ , including  $\{a \mid an \mid the\}?$   $h_2$
- $h_1$ , especially  $\{a \mid an \mid the\}?$   $h_2$
- $h_1$  of  $\{the \mid all\}?$   $h_2$

For this feature, we again use a quantized normalized count as in Section 3.1, but  $c_{12}$  here is restricted to  $n$ -grams where one of the above patterns occurs in between the headwords. We did not allow wildcards in between the headwords and the Hearst-patterns because this introduced a significant amount of noise. Also, we do not constrain the order of  $h_1$  and  $h_2$  because these patterns can hold for either direction of coreference.<sup>4</sup> As a real example from our development set, the  $c_{12}$  count for the headword pair (*leader*, *president*) is 752, while for (*voter*, *president*), it is 0.

Hypernymic semantic compatibility for coreference is intuitive and has been explored in varying forms by previous work. Poesio et al. (2004) and Markert and Nissim (2005) employ a subset of our Hearst patterns and Web-hits for the subtasks of bridging anaphora, other-anaphora, and definite NP resolution. Others (Haghighi and Klein, 2009; Rahman and Ng, 2011; Daumé III and Marcu, 2005) use similar relations to extract compatibility statistics from Wikipedia, YAGO, and noun-similarity lists. Yang and Su (2007) use Wikipedia to automatically extract semantic patterns, which are then used as features in a learning setup. Instead of extracting patterns from the training data, we use all the above patterns, which helps us generalize to new datasets for end-to-end coreference resolution (see Section 4.3).

### 3.3 Entity-based context

For each headword  $h$ , we first collect context *seeds*  $y$  using the pattern

$$h \{is \mid are \mid was \mid were\} \{a \mid an \mid the\}?$$

taking seeds  $y$  in order of decreasing Web count. The corresponding ordered *seed list*  $Y = \{y\}$  gives us useful information about the headword’s entity type. For example, for  $h = \textit{president}$ , the top

<sup>4</sup>Two minor variants not listed above are  $h_1$  including  $h_2$  and  $h_1$  especially  $h_2$ .

30 seeds (and their parts of speech) include important cues such as *president is elected* (verb), *president is authorized* (verb), *president is responsible* (adjective), *president is the chief* (adjective), *president is above* (preposition), and *president is the head* (noun).

Matches in the seed lists of two headwords can be a strong signal that they are coreferent. For example, in the top 30 seed lists for the headword pair (*leader*, *president*), we get matches including *elected*, *responsible*, and *expected*. To capture this effect, we create a feature that indicates whether there is a match in the top  $k$  seeds of the two headwords (where  $k$  is a hyperparameter to tune).

We create another feature that indicates whether the dominant parts of speech in the seed lists matches for the headword pair. We first collect the POS tags (using length 2 character prefixes to indicate coarse parts of speech) of the seeds matched in the top  $k'$  seed lists of the two headwords, where  $k'$  is another hyperparameter to tune. If the dominant tags match and are in a small list of important tags ( $\{JJ, NN, RB, VB\}$ ), we fire an indicator feature specifying the matched tag, otherwise we fire a *no-match* indicator. To obtain POS tags for the seeds, we use a unigram-based POS tagger trained on the WSJ treebank training set.

### 3.4 Cluster information

The distributional hypothesis of Harris (1954) says that words that occur in similar contexts tend to have a similar linguistic behavior. Here, we design features with the idea that this hypothesis extends to reference: mentions occurring in similar contexts in large document sets such as the Web tend to be compatible for coreference. Instead of collecting the contexts of each mention and creating sparse features from them, we use Web-scale distributional clustering to summarize compatibility.

Specifically, we begin with the phrase-based clusters from Lin et al. (2010), which were created using the Google  $n$ -grams V2 corpus. These clusters come from distributional  $K$ -Means clustering (with  $K = 1000$ ) on phrases, using the  $n$ -gram context as features. The cluster data contains almost 10 million phrases and their *soft* cluster memberships. Up to twenty cluster ids with the highest centroid similarities are included for each phrase in this dataset

(Lin et al., 2010).

Our cluster-based features assume that if the headwords of the two mentions have matches in their cluster id lists, then they are more compatible for coreference. We check the match of not just the top 1 cluster ids, but also farther down in the 20 sized lists because, as discussed in Lin and Wu (2009), the soft cluster assignments often reveal different senses of a word. However, we also assume that higher-ranked matches tend to imply closer meanings. To this end, we fire a feature indicating the value  $\text{bin}(i+j)$ , where  $i$  and  $j$  are the *earliest match* positions in the cluster id lists of  $h_1$  and  $h_2$ . Binning here means that match positions in a close range generally trigger the same feature.

Recent previous work has used clustering information to improve the performance of supervised NLP tasks such as NER and dependency parsing (Koo et al., 2008; Lin and Wu, 2009). However, in coreference, the only related work to our knowledge is from Daumé III and Marcu (2005), who use word class features derived from a Web-scale corpus via a process described in Ravichandran et al. (2005).

### 3.5 Pronoun context

Our last feature category specifically addresses pronoun reference, for cases when the anaphoric mention  $NP_2$  (and hence its headword  $h_2$ ) is a pronoun, while the candidate antecedent mention  $NP_1$  (and hence its headword  $h_1$ ) is not. For such a headword pair ( $h_1, h_2$ ), the idea is to substitute the non-pronoun  $h_1$  into  $h_2$ 's position and see whether the result is attested on the Web.

If the anaphoric pronominal mention is  $h_2$  and its sentential context is  $l' l h_2 r r'$ , then the substituted phrase will be  $l' l h_1 r r'$ .<sup>5</sup> High Web counts of substituted phrases tend to indicate semantic compatibility. Perhaps unsurprisingly for English, only the right context was useful in this capacity. We chose the following three context types, based on performance on a development set:

<sup>5</sup>Possessive pronouns are replaced with an additional apostrophe, i.e.,  $h_1 's$ . We also use features (see R1Gap) that allow wildcards ( $\star$ ) in between the headword and the context when collecting Web-counts, in order to allow for determiners and other filler words.

$$\bullet h_1 r \quad (\text{R1})$$

$$\bullet h_1 r r' \quad (\text{R2})$$

$$\bullet h_1 \star r \quad (\text{R1Gap})$$

As an example of the R1Gap feature, if the anaphor  $h_2$  + context is *his victory* and one candidate antecedent  $h_1$  is *Bush*, then we compute the normalized value

$$\frac{\text{count}(\text{"Bush 's } \star \text{ victory"})}{\text{count}(\text{" } \star \text{ 's } \star \text{ victory"})\text{count}(\text{"Bush"})}$$

In general, we compute

$$\frac{\text{count}(\text{"}h_1 \text{'s } \star \text{ r"})}{\text{count}(\text{" } \star \text{'s } \star \text{ r"})\text{count}(\text{"}h_1 \text{"})}$$

The final feature value is again a normalized count converted to  $\log_{10}$  and then binned.<sup>6</sup> We have three separate features for the R1, R2, and R1Gap context types. We tune a separate bin-size hyperparameter for each of these three features.

These pronoun resolution features are similar to selectional preference work by Yang et al. (2005) and Bergsma and Lin (2006), who compute semantic compatibility for pronouns in specific syntactic relationships such as possessive-noun, subject-verb, etc. In our case, we directly use the general context of any pronominal anaphor to find its most compatible antecedent.

Note that all our above features are designed to be non-sparse by firing indicators of the quantized Web statistics and not the lexical- or class-based identities of the mention pair. This keeps the total number of features small, which is important for the relatively small datasets used for coreference resolution. We go from around 100 features in the Reconcile baseline to around 165 features after adding all our Web features.

<sup>6</sup>Normalization helps us with two kinds of balancing. First, we divide by the count of the antecedent so that when choosing the best antecedent for a fixed anaphor, we are not biased towards more frequently occurring antecedents. Second, we divide by the count of the context so that across anaphora, an anaphor with rarer context does not get smaller values (for all its candidate antecedents) than another anaphor with a more common context.

Dataset	docs	dev	test	ment	chn
ACE04	128	63/27	90/38	3037	1332
ACE05	81	40/17	57/24	1991	775
ACE05-ALL	599	337/145	482/117	9217	3050

Table 1: Dataset characteristics – *docs*: the total number of documents; *dev*: the train/test split during development; *test*: the train/test split during testing; *ment*: the number of gold mentions in the test split; *chn*: the number of coreference chains in the test split.

## 4 Experiments

### 4.1 Data

We show results on three popular and comparatively larger coreference resolution data sets – the ACE04, ACE05, and ACE05-ALL datasets from the ACE Program (NIST, 2004). In ACE04 and ACE05, we have only the newswire portion (of the original ACE 2004 and 2005 training sets) and use the standard train/test splits reported in Stoyanov et al. (2009) and Haghighi and Klein (2010). In ACE05-ALL, we have the full ACE 2005 training set and use the standard train/test splits reported in Rahman and Ng (2009) and Haghighi and Klein (2010). Note that most previous work does not report (or need) a standard development set; hence, for tuning our features and its hyper-parameters, we randomly split the original training data into a training and development set with a 70/30 ratio (and then use the full original training set during testing). Details of the corpora are shown in Table 1.<sup>7</sup>

Details of the Web-scale corpora used for extracting features are discussed in Section 3.

### 4.2 Evaluation Metrics

We evaluated our work on both MUC (Vilain et al., 1995) and  $B^3$  (Bagga and Baldwin, 1998). Both scorers are available in the Reconcile infrastructure.<sup>8</sup> MUC measures how many predicted clusters need to be merged to cover the true gold clusters.  $B^3$  computes precision and recall for each mention by computing the intersection of its predicted and gold cluster and dividing by the size of the predicted

<sup>7</sup>Note that the development set is used only for ACE04, because for ACE05, and ACE05-ALL, we directly test using the features tuned on ACE04.

<sup>8</sup>Note that  $B^3$  has two versions which handle twinless (spurious) mentions in different ways (see Stoyanov et al. (2009) for details). We use the  $B^3$ All version, unless mentioned otherwise.

Feature	MUC			$B^3$		
	P	R	F1	P	R	F1
AvgPerc	69.0	63.1	65.9	82.2	69.9	75.5
DecTree	<b>80.9</b>	61.0	69.5	<b>89.5</b>	69.0	77.9
+ Co-occ	79.8	62.1	69.8	88.7	69.8	78.1
+ Hearst	80.0	62.3	70.0	89.1	70.1	78.5
+ Entity	79.4	63.2	70.4	88.1	70.9	78.6
+ Cluster	79.5	63.6	70.7	87.9	71.2	78.6
+ Pronoun	79.9	<b>64.3</b>	<b>71.3</b>	88.0	<b>71.6</b>	<b>79.0</b>

Table 2: Incremental results for the Web features on the ACE04 development set. AvgPerc is the averaged perceptron baseline, DecTree is the decision tree baseline, and the +Feature rows show the effect of adding a particular feature incrementally (not in isolation) to the DecTree baseline. The feature categories correspond to those described in Section 3.

and gold cluster, respectively. It is well known (Recasens and Hovy, 2010; Ng, 2010; Kobdani et al., 2011) that MUC is biased towards large clusters (chains) whereas  $B^3$  is biased towards singleton clusters. Therefore, for a more balanced evaluation, we show improvements on both metrics simultaneously.

### 4.3 Results

We start with the Reconcile baseline but employ the decision tree (DT) classifier, because it has significantly better performance than the default averaged perceptron classifier used in Stoyanov et al. (2009).<sup>9</sup> Table 2 compares the baseline perceptron results to the DT results and then shows the incremental addition of the Web features to the DT baseline (on the ACE04 development set).

The DT classifier, in general, is precision-biased. The Web features somewhat balance this by increasing the recall and decreasing precision to a lesser extent, improving overall F1. Each feature type incrementally increases both MUC and  $B^3$  F1-measures, showing that they are not taking advantage of any bias of either metric. The incremental improvements also show that each Web feature type brings in some additional benefit over the information already present in the Reconcile baseline, which includes alias, animacy, named entity, and WordNet

<sup>9</sup>Moreover, a DT classifier takes roughly the same amount of time and memory as a perceptron on our ACE04 development experiments. It is, however, slower and more memory-intensive ( $\sim 3x$ ) on the bigger ACE05-ALL dataset.

Table 3: Primary test results on the ACE04, ACE05, and ACE05-ALL datasets. All systems reported here use automatically extracted system mentions. B<sup>3</sup> here is the B<sup>3</sup>All version of Stoyanov et al. (2009). We also report statistical significance of the improvements from the Web features on the DT baseline, using the bootstrap test (Noreen, 1989; Efron and Tibshirani, 1993). The perceptron baseline in this work (Reconcile settings: 15 iterations, threshold = 0.45, SIG for ACE04 and AP for ACE05, ACE05-ALL) has different results from Stoyanov et al. (2009) because their current publicly available code is different from that used in their paper (*p.c.*). Also, the B<sup>3</sup> variant used by Rahman and Ng (2009) is slightly different from other systems (they remove all and only the singleton twinless system mentions, so it is neither B<sup>3</sup>All nor B<sup>3</sup>None). For completeness, our (untuned) B<sup>3</sup>None results (DT + Web) on the ACE05-ALL dataset are P=69.9|R=65.9|F1=67.8.

class / sense information.<sup>10</sup>

Table 3 shows our primary *test* results on the ACE04, ACE05, and ACE05-ALL datasets, for the MUC and B<sup>3</sup> metrics. All systems reported use automatically detected mentions. We report our results (the 3 rows marked ‘This Work’) on the perceptron baseline, the DT baseline, and the Web features added to the DT baseline. We also report statistical significance of the improvements from the Web fea-

<sup>10</sup>We also initially experimented with smaller datasets (MUC6 and MUC7) and an averaged perceptron baseline, and we did see similar improvements, arguing that these features are useful independently of the learning algorithm and dataset.

tures on the DT baseline.<sup>11</sup> For significance testing, we use the bootstrap test (Noreen, 1989; Efron and Tibshirani, 1993).

Our main comparison is against Haghighi and Klein (2010), a mostly-unsupervised generative approach that models latent entity types, which generate specific entities that in turn render individual mentions. They learn on large datasets including

<sup>11</sup>All improvements are significant, except on the small ACE05 dataset with the MUC metric (where it is weak, at  $p < 0.12$ ). However, on the larger version of this dataset, ACE05-ALL, we get improvements which are both larger and more significant (at  $p < 0.001$ ).

Wikipedia, and their results are state-of-the-art in coreference resolution. We outperform their system on most datasets and metrics (except on ACE05-ALL for the MUC metric). The other systems we compare to and outperform are the perceptron-based Reconcile system of Stoyanov et al. (2009), the strong deterministic system of Haghighi and Klein (2009), and the cluster-ranking model of Rahman and Ng (2009).

We develop our features and tune their hyperparameter values on the ACE04 development set and then use these on the ACE04 test set.<sup>12</sup> On the ACE05 and ACE05-ALL datasets, we directly transfer our Web features and their hyper-parameter values from the ACE04 dev-set, without any retuning. The test improvements we get on all the datasets (see Table 3) suggest that our features are generally useful across datasets and metrics.<sup>13</sup>

## 5 Analysis

In this section, we briefly discuss errors (in the DT baseline) corrected by our Web features, and analyze the decision tree classifier built during training (based on the ACE04 development experiments).

To study error correction, we begin with the mention pairs that are coreferent according to the gold-standard annotation (after matching the system mentions to the gold ones). We consider the pairs that are wrongly predicted to be non-coreferent by the baseline DT system but correctly predicted to be coreferent when we add our Web features. Some examples of such pairs include:

*Iran ; the country*  
*the EPA ; the agency*  
*athletic director ; Mulcahy*  
*Democrat Al Gore ; the vice president*

---

<sup>12</sup>Note that for the ACE04 dataset only, we use the ‘SmartInstanceGenerator’ (SIG) filter of Reconcile that uses only a filtered set of mention-pairs (based on distance and other properties of the pair) instead of the ‘AllPairs’ (AP) setting that uses all pairs of mentions, and makes training and tuning very slow.

<sup>13</sup>For the ACE05 and ACE05-ALL datasets, we revert to the ‘AllPairs’ (AP) setting of Reconcile because this gives us baselines competitive with Haghighi and Klein (2010). Since we did not need to retune on these datasets, training and tuning speed were not a bottleneck. Moreover, the improvements from our Web features are similar even when tried over the SIG baseline; hence, the filter choice doesn’t affect the performance gain from the Web features.

*Barry Bonds ; the best baseball player*  
*Vojislav Kostunica ; the pro-democracy leader*  
*its closest rival ; the German magazine Das Motorrad*  
*One of those difficult-to-dislodge judges ; John Marshall*

These pairs are cases where our features on Hearst-style co-occurrence and entity-based context-match are informative and help discriminate in favor of the correct antecedents. One advantage of using Web-based features is that the Web has a surprising amount of information on even rare entities such as proper names. Our features also correct coreference for various cases of pronominal anaphora, but these corrections are harder to convey out of context.

Next, we analyze the decision tree built after training the classifier (with all our Web features included). Around 30% of the decision nodes (both non-terminals and leaves) correspond to Web features, and the average error in classification at the Web-feature leaves is only around 2.5%, suggesting that our features are strongly discriminative for pairwise coreference decisions. Some of the most discriminative nodes correspond to the general co-occurrence feature for most (binned) log-count values, the Hearst-style co-occurrence feature for its zero-count value, the cluster-match feature for its zero-match value, and the R2 pronoun context feature for certain (binned) log-count values.

## 6 Conclusion

We have presented a collection of simple Web-count features for coreference resolution that capture a range of world knowledge via statistics of general lexical co-occurrence, hypernymy, semantic compatibility, and semantic context. When added to a strong decision tree baseline, these features give significant improvements and achieve the best results reported to date, across multiple datasets and metrics.

## Acknowledgments

We would like to thank Nathan Gilbert, Adam Pauls, and the anonymous reviewers for their helpful suggestions. This research is supported by Qualcomm via an Innovation Fellowship to the first author and by BBN under DARPA contract HR0011-12-C-0014.

## Abstract

The rapid and continuous growth of social networking sites has led to the emergence of many communities of communicating groups. Many of these groups discuss ideological and political topics. It is not uncommon that the participants in such discussions split into two or more subgroups. The members of each subgroup share the same opinion toward the discussion topic and are more likely to agree with members of the same subgroup and disagree with members from opposing subgroups. In this paper, we propose an unsupervised approach for automatically detecting discussant subgroups in online communities. We analyze the text exchanged between the participants of a discussion to identify the attitude they carry toward each other and towards the various aspects of the discussion topic. We use attitude predictions to construct an attitude vector for each discussant. We use clustering techniques to cluster these vectors and, hence, determine the subgroup membership of each participant. We compare our methods to text clustering and other baselines, and show that our method achieves promising results.

## 1 Introduction

Online forums discussing ideological and political topics are common<sup>1</sup>. When people discuss a disputed topic they usually split into subgroups. The members of each subgroup carry the same opinion

<sup>1</sup>[www.politicalforum.com](http://www.politicalforum.com), [www.createdebate.com](http://www.createdebate.com), [www.forandagainst.com](http://www.forandagainst.com), etc

toward the discussion topic. The member of a subgroup is more likely to show positive attitude to the members of the same subgroup, and negative attitude to the members of opposing subgroups.

For example, let us consider the following two snippets from a debate about the enforcement of a new immigration law in Arizona state in the United States:

(1) *Discussant 1: Arizona immigration law is good. Illegal immigration is bad.*

(2) *Discussant 2: I totally disagree with you. Arizona immigration law is blatant racism, and quite unconstitutional.*

In (1), the writer is expressing positive attitude regarding the immigration law and negative attitude regarding illegal immigration. The writer of (2) is expressing negative attitude towards the writer of (1) and negative attitude regarding the immigration law. It is clear from this short dialog that the writer of (1) and the writer of (2) are members of two opposing subgroups. Discussant 1 is supporting the new law, while Discussant 2 is against it.

In this paper, we present an unsupervised approach for determining the subgroup membership of each participant in a discussion. We use linguistic techniques to identify attitude expressions, their polarities, and their targets. The target of attitude could be another discussant or an entity mentioned in the discussion. We use sentiment analysis techniques to identify opinion expressions. We use named en-

tivity recognition and noun phrase chunking to identify the entities mentioned in the discussion. The opinion-target pairs are identified using a number of syntactic and semantic rules.

For each participant in the discussion, we construct a vector of attitude features. We call this vector the *discussant attitude profile*. The attitude profile of a discussant contains an entry for every other discussant and an entry for every entity mentioned in the discussion. We use clustering techniques to cluster the attitude vector space. We use the clustering results to determine the subgroup structure of the discussion group and the subgroup membership of each participant.

The rest of this paper is organized as follows. Section 2 examines the previous work. We describe the data used in the paper in Section 2.4. Section 3 presents our approach. Experiments, results and analysis are presented in Section 4. We conclude in Section 5

## 2 Related Work

### 2.1 Sentiment Analysis

Our work is related to a huge body of work on sentiment analysis. Previous work has studied sentiment in text at different levels of granularity. The first level is identifying the polarity of individual words. Hatzivassiloglou and McKeown (1997) proposed a method to identify the polarity of adjectives based on conjunctions linking them. Turney and Littman (2003) used pointwise mutual information (PMI) and latent semantic analysis (LSA) to compute the association between a given word and a set of positive/negative seed words. Takamura et al. (2005) proposed using a spin model to predict word polarity. Other studies used WordNet to improve word polarity prediction (Hu and Liu, 2004a; Kamps et al., 2004; Kim and Hovy, 2004; Andreevskaia and Bergler, 2006). Hassan and Radev (2010) used a random walk model built on top of a word relatedness network to predict the semantic orientation of English words. Hassan et al. (2011) proposed a method to extend their random walk model to assist word polarity identification in other languages including Arabic and Hindi.

Other work focused on identifying the subjectivity of words. The goal of this work is to deter-

mine whether a given word is factual or subjective. We use previous work on subjectivity and polarity prediction to identify opinion words in discussions. Some of the work on this problem classifies words as factual or subjective regardless of their context (Wiebe, 2000; Hatzivassiloglou and Wiebe, 2000; Banea et al., 2008). Some other work noticed that the subjectivity of a given word depends on its context. Therefore, several studies proposed using contextual features to determine the subjectivity of a given word within its context (Riloff and Wiebe, 2003; Yu and Hatzivassiloglou, 2003; Nasukawa and Yi, 2003; Popescu and Etzioni, 2005).

The second level of granularity is the sentence level. Hassan et al. (2010) presents a method for identifying sentences that display an attitude from the text writer toward the text recipient. They define attitude as the mental position of one participant with regard to another participant. A very detailed survey that covers techniques and approaches in sentiment analysis and opinion mining could be found in (Pang and Lee, 2008).

### 2.2 Opinion Target Extraction

Several methods have been proposed to identify the target of an opinion expression. Most of the work have been done in the context of product reviews mining (Hu and Liu, 2004b; Kobayashi et al., 2007; Mei et al., 2007; Stoyanov and Cardie, 2008). In this context, opinion targets usually refer to product features (i.e. product components or attributes, as defined by Liu (2009)). In the work of Hu and Liu (2004b), they treat frequent nouns and noun phrases as product feature candidates. In our work, we extract as targets frequent noun phrases and named entities that are used by two or more different discussants. Scaffidi et al. (2007) propose a language model approach to product feature extraction. They assume that product features are mentioned more often in product reviews than they appear in general English text. However, such statistics may not be reliable when the corpus size is small.

In another related work, Jakob and Gurevych (2010) showed that resolving the anaphoric links in the text significantly improves opinion target extraction. In our work, we use anaphora resolution to improve opinion-target

Participant A posted:	I support Arizona because they have every right to do so. They are just upholding well-established federal law. All states should enact such a law.
Participant B commented on A's post:	I support the law because the federal government is either afraid or indifferent to the issue. Arizona has the right and the responsibility to protect the people of the State of Arizona. If this requires a possible slight inconvenience to any citizen so be it.
Participant C commented on B's post:	That is such a sad thing to say. You do realize that under the 14th Amendment, the very interaction of a police officer asking you to prove your citizenship is Unconstitutional? As soon as you start trading Constitutional rights for "security", then you've lost.

Table 1: Example posts from the Arizona Immigration Law thread

pairing as shown in Section 3 below.

### 2.3 Community Mining

Previous work also studied community mining in social media sites. Somasundaran and Wiebe (2009) presents an unsupervised opinion analysis method for debate-side classification. They mine the web to learn associations that are indicative of opinion stances in debates and combine this knowledge with discourse information. Anand et al. (2011) present a supervised method for stance classification. They use a number of linguistic and structural features such as unigrams, bigrams, cue words, repeated punctuation, and opinion dependencies to build a stance classification model. This work is limited to dual sided debates and defines the problem as a classification task where the two debate sides are known beforehand. Our work is characterized by handling multi-side debates and by regarding the problem as a clustering problem where the number of sides is not known by the algorithm. This work also utilizes only discussant-to-topic attitude predictions for debate-side classification. Our work utilizes both discussant-to-topic and discussant-to-discussant attitude predictions.

In another work, Kim and Hovy (2007) predict the results of an election by analyzing discussion threads in online forums that discuss the elections. They use a supervised approach that uses unigrams, bigrams, and trigrams as features. In contrast, our work is unsupervised and uses different types of information. Moreover, although this work is related to ours at the goal level, it does not involve any opinion analysis.

Another related work classifies the speakers side in a corpus of congressional floor debates, using the speakers final vote on the bill as a labeling for side (Thomas et al., 2006; Bansal et al., 2008;

Yessenalina et al., 2010). This work infers agreement between speakers based on cases where one speaker mentions another by name, and a simple algorithm for determining the polarity of the sentence in which the mention occurs. This work shows that even with the resulting sparsely connected agreement structure, the MinCut algorithm can improve over stance classification based on textual information alone. This work also requires that the debate sides be known by the algorithm and it only identifies discussant-to-discussant attitude. In our experiments below we show that identifying both discussant-to-discussant and discussant-to-topic attitudes achieves better results.

### 2.4 Data

In this section, we describe the datasets used in this paper. We use three different datasets. The first dataset (*politicalforum*, henceforth) consists of 5,743 posts collected from a political forum<sup>2</sup>. All the posts are in English. The posts cover 12 disputed political and ideological topics. The discussants of each topic were asked to participate in a poll. The poll asked them to determine their stance on the discussion topic by choosing one item from a list of possible arguments. The list of participants who voted for each argument was published with the poll results. Each poll was accompanied by a discussion thread. The people who participated in the poll were allowed to post text to that thread to justify their choices and to argue with other participants. We collected the votes and the discussion thread of each poll. We used the votes to identify the subgroup membership of each participant.

The second dataset (*createdebate*, henceforth) comes from an online debating site<sup>3</sup>. It consists of

<sup>2</sup><http://www.politicalforum.com>

<sup>3</sup><http://www.createdebate.com>

Source	Topic	Question	#Sides	#Posts	#Participants
Politicalforum	Arizona Immigration Law	Do you support Arizona in its decision to enact their Immigration Enforcement law?	2	738	59
	Airport Security	Should we pick muslims out of the line and give additional scrutiny/screening?	4	735	69
	Vote for Obama	Will you vote for Obama in the 2012 Presidential elections?	2	2599	197
Createdebate	Evolution	Has evolution been scientifically proved?	2	194	98
	Social networking sites	It is easier to maintain good relationships in social networking sites such as Facebook.	2	70	31
	Abortion	Should abortion be banned	3	477	70
Wikipedia	Ireland	Misleading description of Irland island partition	3	40	10
	South Africa Government	Was the current form of South African government born in May 1910?	3	23	5
	Oil Spill	Obama's response to gulf oil spill	3	30	12

Table 2: Example threads from our three datasets

30 debates containing a total of 2,712 posts. Each debate is about one topic. The description of each debate states two or more positions regarding the debate topic. When a new participant enters the discussion, she explicitly picks a position and posts text to support it, support a post written by another participant who took the same position, or to dispute a post written by another participant who took an opposing position. We collected the discussion thread and the participant positions for each debate.

The third dataset (*wikipedia*, henceforth) comes from the Wikipedia<sup>4</sup> discussion section. When a topic on Wikipedia is disputed, the editors of that topic start a discussion about it. We collected 117 Wikipedia discussion threads. The threads contains a total of 1,867 posts.

The *politicalforum* and *createdebate* datasets are self labeled as described above. To annotate the Wikipedia data, we asked an expert annotator (a professor in sociolinguistics who is not one of the authors) to read each of the Wikipedia discussion threads and determine whether the discussants split into subgroups in which case he was asked to determine the subgroup membership of each discussant.

Table 2 lists few example threads from our three datasets. Table 1 shows a portion of discussion thread between three participants about enforcing a new immigration law in Arizona. This thread appeared in the *politicalforum* dataset. The text posted by the three participants indicates that A's position

is with enforcing the law, that B agrees with A, and that C disagrees with both. This means that A and B belong to the same opinion subgroup, while belongs to an opposing subgroup.

We randomly selected 6 threads from our datasets (2 from *politicalforum*, 2 from *createdebate*, and 2 from *Wikipedia*) and used them as development set. This set was used to develop our approach.

### 3 Approach

In this section, we describe a system that takes a discussion thread as input and outputs the subgroup membership of each discussant. Figure 1 illustrates the processing steps performed by our system to detect subgroups. In the following subsections we describe the different stages in the system pipeline.

#### 3.1 Thread Parsing

We start by parsing the thread to identify posts, participants, and the reply structure of the thread (i.e. who replies to whom). In the datasets described in Section 2.4, all this information was explicitly available in the thread. We tokenize the text of each post and split it into sentences using CLAIRLib (Abu-Jbara and Radev, 2011).

#### 3.2 Opinion Word Identification

The next step is to identify the words that express opinion and determine their polarity (positive or negative). Lehrer (1974) defines word polarity as the direction the word deviates to from the norm. We

<sup>4</sup><http://www.wikipedia.com>

use OpinionFinder (Wilson et al., 2005a) to identify polarized words and their polarities.

The polarity of a word is usually affected by the context in which it appears. For example, the word *fine* is positive when used as an adjective and negative when used as a noun. For another example, a positive word that appears in a negated context becomes negative. OpinionFinder uses a large set of features to identify the contextual polarity of a given polarized word given its isolated polarity and the sentence in which it appears (Wilson et al., 2005b). Snippet (3) below shows the result of applying this step to snippet (1) above (*O* means neutral; *POS* means positive; *NEG* means negative).

(3) *Arizona/O Immigration/O law/O good/POS ./O Illegal/O immigration/O bad/NEG ./O*

### 3.3 Target Identification

The goal of this step is to identify the possible targets of opinion. A target could be another discussant or an entity mentioned in the discussion. When the target of opinion is another discussant, either the discussant name is mentioned explicitly or a second person pronoun is used to indicate that the opinion is targeting the recipient of the post. For example, in snippet (2) above the second person pronoun *you* indicates that the opinion word *disagree* is targeting *Discussant 1*, the recipient of the post.

The target of opinion can also be an entity mentioned in the discussion. We use two methods to identify such entities. The first method uses shallow parsing to identify noun groups (NG). We use the Edinburgh Language Technology Text Tokenization Toolkit (LT-TTT) (Grover et al., 2000) for this purpose. We consider as an entity any noun group that is mentioned by at least two different discussants. We replace each identified entity with a unique placeholder ( $ENTITY_{ID}$ ). For example, the noun group *Arizona immigration law* is mentioned by *Discussant 1* and *Discussant 2* in snippets 1 and 2 above respectively. Therefore, we replace it with a placeholder as illustrated in snippets (4) and (5) below.

(4) *Discussant 1: ENTITY<sub>1</sub> is good. Illegal im-*

NER	NP Chunking
Barack Obama	the Republican nominee
Middle East	the maverick economists
Bush	conservative ideologues
Bob McDonell	the Nobel Prize
Iraq	Federal Government

Table 3: Some of the entities identified using NER and NP Chunking in a discussion thread about the US 2012 elections

*migration is bad.*

(5) *Discussant 2: I totally disagree with you. ENTITY<sub>1</sub> is blatant racism, and quite unconstitutional.*

We only consider as entities noun groups that contain two words or more. We impose this requirement because individual nouns are very common and regarding all of them as entities will introduce significant noise.

In addition to this shallow parsing method, we also use named entity recognition (NER) to identify more entities. We use the Stanford Named Entity Recognizer (Finkel et al., 2005) for this purpose. It recognizes three types of entities: person, location, and organization. We impose no restrictions on the entities identified using this method. Again, we replace each distinct entity with a unique placeholder. The final set of entities identified in a thread is the union of the entities identified by the two aforementioned methods. Table 3

Finally, a challenge that always arises when performing text mining tasks at this level of granularity is that entities are usually expressed by anaphorical pronouns. Previous work has shown that for example, the following snippet contains an explicit mention of the entity *Obama* in the first sentence, and then uses a pronoun to refer to the same entity in the second sentence. The opinion word *unbeatable* appears in the second sentence and is syntactically related to the pronoun *He*. In the next subsection, it will become clear why knowing which entity does the pronoun *He* refers to is essential for opinion-target pairing.

(6) *It doesn't matter whether you vote for Obama.*

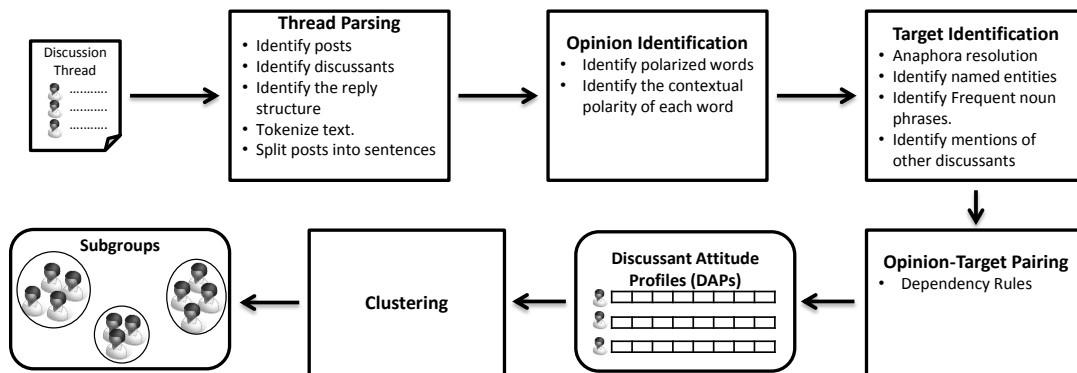

Figure 1: An overview of the subgroups detection system

*He is unbeatable.*

Jakob and Gurevych (2010) showed experimentally that resolving the anaphoric links in the text significantly improves opinion target extraction. We use the Beautiful Anaphora Resolution Toolkit (BART) (Versley et al., 2008) to resolve all the anaphoric links within the text of each post separately. The result of applying this step to snippet (6) is:

(6) *It doesn't matter whether you vote for Obama. Obama is unbeatable.*

Now, both mentions of *Obama* will be recognized by the Stanford NER system and will be identified as one entity.

### 3.4 Opinion-Target Pairing

At this point, we have all the opinion words and the potential targets identified separately. The next step is to determine which opinion word is targeting which target. We propose a rule based approach for opinion-target pairing. Our rules are based on the dependency relations that connect the words in a sentence. We use the Stanford Parser (Klein and Manning, 2003) to generate the dependency parse tree of each sentence in the thread. An opinion word and a target form a pair if they stratify at least one of our dependency rules. Table 4 illustrates some

of these rules <sup>5</sup>. The rules basically examine the types of the dependencies on the shortest path that connect the opinion word and the target in the dependency parse tree. It has been shown in previous work on relation extraction that the shortest dependency path between any two entities captures the information required to assert a relationship between them (Bunescu and Mooney, 2005).

If a sentence  $S$  in a post written by participant  $P_i$  contains an opinion word  $OP_j$  and a target  $TR_k$ , and if the opinion-target pair satisfies one of our dependency rules, we say that  $P_i$  expresses an attitude towards  $TR_k$ . The polarity of the attitude is determined by the polarity of  $OP_j$ . We represent this as  $P_i \xrightarrow{+} TR_k$  if  $OP_j$  is positive and  $P_i \xrightarrow{-} TR_k$  if  $OP_j$  is negative.

It is likely that the same participant  $P_i$  express sentiment toward the same target  $TR_k$  multiple times in different sentences in different posts. We keep track of the counts of all the instances of positive/negative attitude  $P_i$  expresses toward  $TR_k$ . We represent this as  $P_i \xrightarrow[m-]{m+} TR_k$  where  $m$  ( $n$ ) is the number of times  $P_i$  expressed positive (negative) attitude toward  $TR_k$ .

### 3.5 Discussant Attitude Profile

We propose a representation of discussants' attitudes towards the identified targets in the discussion thread. As stated above, a target could be another discussant or an entity mentioned in the discussion.

<sup>5</sup>The code will be made publicly available at the time of publication

ID	Rule	In Words	Example
R1	$OP \rightarrow nsubj \rightarrow TR$	The target $TR$ is the nominal subject of the opinion word $OP$	ENTITY1 $_{TR}$ is good $_{OP}$ .
R2	$OP \rightarrow dobj \rightarrow TR$	The target $T$ is a direct object of the opinion $OP$	I hate $_{OP}$ ENTITY2 $_{TR}$
R3	$OP \rightarrow prep_* \rightarrow TR$	The target $TR$ is the object of a preposition that modifies the opinion word $OP$	I totally disagree $_{OP}$ with you $_{TR}$ .
R4	$TR \rightarrow amod \rightarrow OP$	The opinion is an adjectival modifier of the target	The bad $_{OP}$ ENTITY3 $_{TR}$ is spreading lies
R5	$OP \rightarrow nsubjpass \rightarrow TR$	The target $TR$ is the nominal subject of the passive opinion word $OP$	ENTITY4 $_{TR}$ is hated $_{OP}$ by everybody.
R6	$OP \rightarrow prep_* \rightarrow poss \rightarrow TR$	The opinion word $OP$ connected through a $prep_*$ relation as in $R2$ to something possessed by the target $TR$	The main flaw $_{OP}$ in your $_{TR}$ analysis is that it's based on wrong assumptions.
R7	$OP \rightarrow dobj \rightarrow poss \rightarrow TR$	The target $TR$ possesses something that is the direct object of the opinion word $OP$	I like $_{OP}$ ENTITY5 $_{TR}$ 's brilliant ideas.
R8	$OP \rightarrow csubj \rightarrow nsubj \rightarrow TR$	The opinion word $OP$ is a causal subject of a phrase that has the target $TR$ as its nominal subject	What ENTITY6 $_{TR}$ announced was misleading $_{OP}$ .

Table 4: Examples of the dependency rules used for opinion-target pairing.

Our representation is a vector containing numerical values. The values correspond to the counts of positive/negative attitudes expressed by the discussant toward each of the targets. We call this vector the *discussant attitude profile (DAP)*. We construct a DAP for every discussant. Given a discussion thread with  $d$  discussants and  $e$  entity targets, each attitude profile vector has  $n = (d + e) * 3$  dimensions. In other words, each target (discussant or entity) has three corresponding values in the DAP: 1) the number of times the discussant expressed positive attitude toward the target, 2) the number of times the discussant expressed a negative attitude towards the target, and 3) the number of times the the discussant interacted with or mentioned the target. It has to be noted that these values are not symmetric since the discussions explicitly denote the source and the target of each post.

### 3.6 Clustering

At this point, we have an attitude profile (or vector) constructed for each discussant. Our goal is to use these attitude profiles to determine the subgroup membership of each discussant. We can achieve this goal by noticing that the attitude profiles of discussants who share the same opinion are more likely to be similar to each other than to the attitude profiles of discussants with opposing opinions. This suggests that clustering the attitude vector space will achieve the goal and split the discussants into subgroups according to their opinion.

## 4 Evaluation

In this section, we present several levels of evaluation of our system. First, we compare our system to baseline systems. Second, we study how the choice of the clustering algorithm impacts the results. Third, we study the impact of each component in our system on the performance. All the results reported in this section that show difference in the performance are statistically significant at the 0.05 level (as indicated by a 2-tailed paired t-test). Before describing the experiments and presenting the results, we first describe the evaluation metrics we use.

### 4.0.1 Evaluation Metrics

We use two evaluation metrics to evaluate subgroups detection accuracy: Purity and Entropy. To compute Purity (Manning et al., 2008), each cluster is assigned the class of the majority vote within the cluster, and then the accuracy of this assignment is measured by dividing the number of correctly assigned members by the total number of instances. It can be formally defined as:

$$purity(\Omega, C) = \frac{1}{N} \sum_k \max_j |\omega_k \cap c_j| \quad (1)$$

where  $\Omega = \{\omega_1, \omega_2, \dots, \omega_k\}$  is the set of clusters and  $C = \{c_1, c_2, \dots, c_J\}$  is the set of classes.  $\omega_k$  is interpreted as the set of documents in  $\omega_k$  and  $c_j$  as

the set of documents in  $c_j$ . The purity increases as the quality of clustering improves.

The second metric is Entropy. The Entropy of a cluster reflects how the members of the  $k$  distinct subgroups are distributed within each resulting cluster; the global quality measure is computed by averaging the entropy of all clusters:

$$Entropy = - \sum_j \frac{n_j}{n} \sum_i P(i, j) \times \log_2 P(i, j) \quad (2)$$

where  $P(i, j)$  is the probability of finding an element from the category  $i$  in the cluster  $j$ ,  $n_j$  is the number of items in cluster  $j$ , and  $n$  the total number of items in the distribution. In contrast to purity, the entropy decreases as the quality of clustering improves.

#### 4.1 Comparison to Baseline Systems

We compare our system (DAPC) that was described in Section 3 to two baseline methods. The first baseline (GC) uses graph clustering to partition a network based on the interaction frequency between participants. We build a graph where each node represents a participant. Edges link participants if they exchange posts, and edge weights are based on the number of interactions. We tried two methods for clustering the resulting graph: spectral partitioning (Luxburg, 2007) and a hierarchical agglomeration algorithm which works by greedily optimizing the modularity for graphs (Clauset et al., 2004).

The second baseline (TC) is based on the premise that the member of the same subgroup are more likely to use vocabulary drawn from the same language model. We collect all the text posted by each participant and create a tf-idf representations of the text in a high dimensional vector space. We then cluster the vector space to identify subgroups. We use k-means (MacQueen, 1967) as our clustering algorithm in this experiment (comparison of various clustering algorithms is presented in the next subsection). The distances between vectors are Euclidean distances. Table 5 shows that our system performs significantly better the baselines on the three datasets in terms of both the purity ( $P$ ) and the entropy ( $E$ ) (notice that lower entropy values indicate better clustering). The values reported are the

Method	Createdebate		Politicalforum		Wikipedia	
	P	E	P	E	P	E
GC - Spectral	0.50	0.85	0.50	0.88	0.49	0.89
GC - Hierarchical	0.48	0.86	0.47	0.89	0.49	0.87
TC - kmeans	0.51	0.84	0.49	0.88	0.52	0.85
<b>DAPC - kmeans</b>	<b>0.64</b>	<b>0.68</b>	<b>0.61</b>	<b>0.80</b>	<b>0.66</b>	<b>0.55</b>

DAPC - kmeans	0.64	0.68	0.61	0.80	0.66	0.55

Table 6: Comparison of different clustering algorithms

average results of the threads of each dataset. We believe that the baselines performed poorly because the interaction frequency and the text similarity are not key factors in identifying subgroup structures. Many people would respond to people they disagree with more, while others would mainly respond to people they agree with most of the time. Also, people in opposing subgroups tend to use very similar text when discussing the same topic and hence text clustering does not work as well.

#### 4.2 Choice of the clustering algorithm

We experimented with three different clustering algorithms: expectation maximization (EM), and k-means (MacQueen, 1967), and FarthestFirst (FF) (Hochbaum and Shmoys, 1985; Dasgupta, 2002). As we did in the previous subsection, we use Euclidean distance to measure the distance between vectors. All the system (DAP) components are included as described in Section 3. The purity and entropy values using each algorithm are shown in Table 6. Although k-means seems to be performing slightly better than other algorithms, the differences in the results are not significant. This indicates that the choice of the clustering algorithm does not have a noticeable impact on the results. We also experimented with using Manhattan distance and cosine similarity instead of Euclidean distance to measure the distance between attitude vectors. We noticed that the choice of the distance does not have significant impact on the results as well.

### 4.3 Component Evaluation

In this subsection, we evaluate the impact of the different components in the pipeline on the system performance. We do that by removing each component from the pipeline and measuring the change in performance. We perform the following experiments: 1) We run the full system with all its components included (DAPC). 2) We run the system and include only discussant-to-discussant attitude features in the attitude vectors (DAPC-DD). 3) We include only discussant-to-entity attitude features in the attitude vectors (DAPC-DE). 4) We include only sentiment features in the attitude vector; i.e. we exclude the interaction count features (DAPC-SE). 5) We include only interaction count features to the attitude vector; i.e. we exclude sentiment features (DAPC-INT). 6) We skip the anaphora resolution step in the entity identification component (DAPC-NO\_AR). 7) We only use named entity recognition to identify entity targets; i.e. we exclude the entities identified through noun phrasing chunking (DAPC-NER). 8) Finally, we only noun phrase chunking to identify entity targets (DAPC-NP). In all these experiments k-means is used for clustering and the number of clusters is set as explained in the previous subsection.

The results show that all the components in the system contribute to better performance of the system. We notice from the results that the performance of the system drops significantly if sentiment features are not included. This result corroborates our hypothesis that interaction features are not sufficient factors for detecting rift in discussion groups. Including interaction features improve the performance (although not by a big difference) because they help differentiate between the case where participants A and B never interacted with each other and the case where they interact several time but never posted text that indicate difference in opinion between them. We also notice that the performance drops significantly in DAPC-DD and DAPC-DE which also supports our hypotheses that both the sentiment discussants show toward one another and the sentiment they show toward the aspects of the discussed topic are important for the task. Although using both named entity recognition (NER) and noun phrase chunking achieves better results, it

Method	Createdebate		Politicalforum		Wikipedia	
	P	E	P	E	P	E
DAPC	<b>0.64</b>	<b>0.68</b>	<b>0.61</b>	<b>0.80</b>	<b>0.66</b>	<b>0.55</b>
DAPC-DD	0.59	0.77	0.57	0.86	0.62	0.61
DAPC-DE	0.60	0.69	0.58	0.84	0.58	0.78

DAPC-NP	0.63	0.75	0.59	0.84	0.65	0.62

Table 7: Impact of system components on the performance

can also be noted from the results that NER contributes more to the system performance. Finally, the results support Jakob and Gurevych (2010) findings that anaphora resolution aids opinion mining systems.

## 5 Conclusions

In this paper, we presented an approach for subgroup detection in ideological discussions. Our system uses linguistic analysis techniques to identify the attitude the participants of online discussions carry toward each other and toward the aspects of the discussion topic. Attitude prediction as well as interaction frequency to construct an attitude vector for each participant. The attitude vectors of discussants are then clustered to form subgroups. Our experiments showed that our system outperforms text clustering and interaction graph clustering. We also studied the contribution of each component in our system to the overall performance.

## Abstract

Extracting sentiment and topic lexicons is important for opinion mining. Previous works have showed that supervised learning methods are superior for this task. However, the performance of supervised methods highly relies on manually labeled training data. In this paper, we propose a domain adaptation framework for sentiment- and topic- lexicon co-extraction in a domain of interest where we do not require any labeled data, but have lots of labeled data in another related domain. The framework is twofold. In the first step, we generate a few high-confidence sentiment and topic seeds in the target domain. In the second step, we propose a novel Relational Adaptive bootstraPping (RAP) algorithm to expand the seeds in the target domain by exploiting the labeled source domain data and the relationships between topic and sentiment words. Experimental results show that our domain adaptation framework can extract precise lexicons in the target domain without any annotation.

## 1 Introduction

In the past few years, opinion mining and sentiment analysis have attracted much attention in Natural Language Processing (NLP) and Information Retrieval (IR) (Pang and Lee, 2008; Liu, 2010). Sentiment lexicon construction and topic lexicon extraction are two fundamental subtasks for opinion mining (Qiu et al., 2009). A sentiment lexicon is a list of sentiment expressions, which are used to indicate sentiment polarity (e.g., positive or negative). The sentiment lexicon is domain dependent as users may use different sentiment words to express their opinion in different domains (e.g., different products). A topic lexicon is a list of topic expressions, on which

the sentiment words are expressed. Extracting the topic lexicon from a specific domain is important because users not only care about the overall sentiment polarity of a review but also care about which aspects are mentioned in review. Note that, similar to sentiment lexicons, different domains may have very different topic lexicons.

Recently, Jin and Ho (2009) and Li *et al.* (2010a) showed that supervised learning methods can achieve state-of-the-art results for lexicon extraction. However, the performance of these methods highly relies on manually annotated training data. In most cases, the labeling work may be time-consuming and expensive. It is impossible to annotate each domain of interest to build precise domain-dependent lexicons. It is more desirable to automatically construct precise lexicons in domains of interest by transferring knowledge from other domains.

In this paper, we focus on the co-extraction task of sentiment and topic lexicons in a target domain where we do not have any labeled data, but have plenty of labeled data in a source domain. Our goal is to leverage the knowledge extracted from the source domain to help lexicon co-extraction in the target domain. To address this problem, we propose a two-stage domain adaptation method. In the first step, we build a bridge between the source and target domains by identifying some *common* sentiment words as sentiment seeds in the target domain, such as “good”, “bad”, “nice”, etc. After that, we generate topic seeds in the target domain by mining some *general* syntactic relation patterns between the sentiment and topic words from the source domain. In the second step, we propose a Relational Adaptive bootstraPping (RAP) algorithm to expand the seeds in the target domain. Our proposed method can uti-

lize useful labeled data from the source domain as well as exploit the relationships between the topic and sentiment words to propagate information for lexicon construction in the target domain. Experimental results show that our proposed method is effective for cross-domain lexicon co-extraction.

In summary, we have three main contributions: 1) We give a systematic study on cross-domain sentiment analysis in word level. While, most of previous work focused on document level; 2) A new two-step domain adaptation framework, with a novel RAP algorithm for seed expansion, is proposed. 3) We conduct extensive evaluation, and the experimental results demonstrate the effectiveness of our methods.

## 2 Related Work

### 2.1 Sentiment or Topic Lexicon Extraction

Sentiment or topic lexicon extraction is to identify the sentiment or topic words from text. In the past, many machine learning techniques have been proposed for this task. Hu and Liu *et al.* (2004) proposed an association-rule-based method to extract topic words and a dictionary-based method to identify sentiment words, independently. Wiebe *et al.* (2004) and Rioff *et al.* (2003) proposed to identify subjective adjectives and nouns using word clustering based on their distributional similarity. Popescu and Etzioni (2005) proposed a relaxed labeling approach to utilize linguistic rules for opinion polarity detection. Some researchers also proposed to use topic modeling to identify implicit topics and sentiment words (Mei *et al.*, 2007; Titov and McDonald, 2008; Zhao *et al.*, 2010; Li *et al.*, 2010b), where a topic is a cluster of words, which is different from our fine-grained topic-word extraction.

Jin and Ho (2009) and Li *et al.* (2010a) both proposed to use supervised sequential labeling methods for topic and opinion extraction. Experimental results showed that the supervised learning methods can achieve state-of-the-art performance on lexicon extraction. However, these methods need to manually annotate a lot of training data in each domain. Recently, Qiu *et al.* (2009) proposed a rule-based semi-supervised learning methods for lexicon extraction. However, their method requires to manually define some *general* syntactic rules among sentiment and topic words. In addition, it still requires some annotated words in the target domain. In this paper, we do not assume any predefined rules and

labeled data be available in the target domain.

### 2.2 Domain Adaptation

Domain adaptation aims at transferring knowledge across domains where data distributions may be different (Pan and Yang, 2010). In the past few years, domain adaptation techniques have been widely applied to various NLP tasks, such as part-of-speech tagging (Ando and Zhang, 2005; Jiang and Zhai, 2007; Daumé III, 2007), named-entity recognition and shallow parsing (Daumé III, 2007; Jiang and Zhai, 2007; Wu *et al.*, 2009). There are also lots of studies for cross-domain sentiment analysis (Blitzer *et al.*, 2007; Tan *et al.*, 2007; Li *et al.*, 2009; Pan *et al.*, 2010; Bollegala *et al.*, 2011; He *et al.*, 2011; Glorot *et al.*, 2011). However, most of them focused on coarse-grained document-level sentiment classification, which is different from our fine-grained word-level extraction. Our work is similar to Jakob and Gurevych (2010) which proposed a Conditional Random Field (CRF) for cross-domain topic word extraction. However, the performance of their method highly depends on the manually designed features. In our experiments, we compare our method with theirs, and find that ours can achieve much better results on cross-domain lexicon extraction. Note that our work is also different from a recent work (Du *et al.*, 2010), which focused on identifying the polarity of adjective words by using cross-domain knowledge. While we extract both topic and sentiment words and allow non-adjective sentiment words, which is more practical.

## 3 Cross-Domain Lexicon Co-Extraction

### 3.1 Problem Definition

Recall that, we focus on the setting where we have no labeled data in the target domain, while we have plenty of labeled data in the source domain. Denote  $\mathcal{D}_S = \{(w_{S_i}, y_{S_i})\}_{i=1}^{n_1}$  the source domain data, where  $w_{S_i}$  represents a word in the source domain.  $y_{S_i} \in \mathcal{Y}$  is the corresponding label of  $w_{S_i}$ . Similarly, we denote  $\mathcal{D}_T = \{w_{T_j}\}_{j=1}^{n_2}$  the target domain data, where the input  $w_{T_j}$  is a word in the target domain. In lexicon extraction,  $\mathcal{Y} \in \{1, 2, 3\}$ , where  $y_i = 1$  denotes the corresponding word  $w_i$  a sentiment word,  $y_i = 2$  denotes  $w_i$  a topic word, and  $y_i = 3$  denotes  $w_i$  neither a sentiment nor topic word. Our goal is to predict labels on  $\mathcal{D}_T$  to extract topic and sentiment words for constructing topic and

sentiment lexicons, respectively.

### 3.2 Motivating Examples

In this section, we use some examples to introduce the motivation behind our proposed method. Table 1 shows several reviews from two domains: *movie* and *camera*. From the table, we can observe that there are some common sentiment words across different domains, such as “great”, “excellent” and “amazing”. However, the topic words may be different. For example, in the movie domain, topic words include “movie” and “script”. While in the camera domain, topic words include “camera” and “photos”.

Domain	Review
camera	The <b>camera</b> is <i>great</i> .
	it is a very <i>amazing</i> <b>product</b> .
	i highly <i>recommend</i> this <b>camera</b> .
	takes <i>excellent</i> <b>photos</b> .
	<b>photos</b> had some <i>artifacts</i> and <i>noise</i> .
movie	This <b>movie</b> has <i>good</i> <b>script</b> , <i>great</i> <b>casting</b> , <i>excellent</i> <b>acting</b> .
	I <i>love</i> this <b>movie</b> .
	<b>Godfather</b> was the most <i>amazing</i> <b>movie</b> .
	The <b>movie</b> is <i>excellent</i> .

Table 1: Reviews in *camera* and *movie* domains. Boldfaces are topic words and Italics are sentiment words.

Based on the observations, we can build a connection between the source and target domains by identifying the common sentiment words. Furthermore, intuitively, there are some general syntactic relationships or patterns between topic and sentiment words across different domains. Therefore, if we can mine the patterns from the source and target domain data, then we are able to construct an indirect connection between topic words across domains by using the common sentiment words as a bridge, which makes knowledge transfer across domains possible.

Figure 1 shows two dependency trees for the sentence “the camera is great” in the camera domain and the sentence “the movie is excellent” in the movie domain, respectively. As can be observed, the relationships between the topic and sentiment words in the two sentences are the same. They both share a “TOPIC-nsubj-SENTIMENT” relation. Let the camera domain be the source domain and the movie domain be the target domain. If the word “excellent” is identified as a common sentiment word, and the “TOPIC-nsubj-SENTIMENT” relation extracted from the camera domain is recognized as a common

syntactic pattern, then the word “movie” can be predicted as a topic word in the movie domain with high probability. After new topic words are extracted in the movie domain, we can apply the same syntactic pattern or other syntactic patterns to extract new sentiment and topic words iteratively.

(a) Camera domain.

(b) Movie domain.

Figure 1: Examples of dependency tree structure.

More specifically, we use the shortest path between a topic word and a sentiment word in the corresponding dependency tree to denote the relation between them. To get more general paths, we do not take original words in the path into consideration, but use their POS tags instead, such as “NN”, “VB”, “JJ”, etc. As an example shown in Figure 2, we can extract two paths or relationships between topic and sentiment words from the dependency tree of the sentence “The movie has good script”: “NN-amod-JJ” from “script” and “good”, and “NN-nsubj-VB-dobj-NN-amod-JJ” from “movie” and “good”.

Figure 2: Example of pattern extraction.

In the following sections, we present the proposed two-stage domain adaptation framework: 1) generating some sentiment and topic seeds in the target domain; and 2) expanding the seeds in the target domain to construct sentiment and topic lexicons.

## 4 Seed Generation

Our basic idea is to first identify several *common* sentiment words across domains as sentiment seeds. Meanwhile, we mine some general patterns between sentiment and topic words from the source domain. Finally, we use the sentiment seeds and general patterns to generate topic seeds in the target domain.

#### 4.1 Sentiment Seed Generation

To identify *common* sentiment words across domains, we extract all sentiment words from the source domain as candidates. For each candidate, we calculate its score based on the following metric:

$$S_1(w_i) = (p_S(w_i) + p_T(w_i)) e^{(-|p_S(w_i) - p_T(w_i)|)}, \quad (1)$$

where  $p_S(w_i)$  and  $p_T(w_i)$  are the probabilities of the word  $w_i$  occurring in the source and target domains, respectively. If a word  $w_i$  has high  $S_1$  score, which implies that the word  $w_i$  occurs frequently and similarly in both domains, then it can be considered as a *common* sentiment word (Pan et al., 2010; Blitzer et al., 2007). We select top  $r$  candidates with highest  $S_1$  scores as sentiment seeds.

#### 4.2 Topic Seed Generation

We extract all patterns between sentiment and topic words in the source domain as candidates. For each pattern candidate, we calculate its score based on a metric defined in AutoSlog-TS (Riloff, 1996):

$$S_2(R_j) = Acc(R_j) \times \log_2(Freq(R_j)), \quad (2)$$

where  $Acc(R_j)$  is the accuracy of the pattern  $R_j$  in the source domain, and  $Freq(R_j)$  is the frequency of the pattern  $R_j$  observed in target domain. This metric aims to identify the patterns that are precise in the source domain and observed frequently in the target domain. We also select the top  $r$  patterns with highest  $S_2$  scores. With the patterns and sentiment seeds, we extract topic-word candidates and measure their scores based on a variant metric of quadratic combination (Zhang and Ye, 2008):

$$S_3(w_k) = \sum_{R_j \in A, w_i \in B} (S_2(R_j) \times S_1(w_i)), \quad (3)$$

where  $B$  is a set of sentiment seeds and  $A$  is a set of patterns which the words  $w_i$  and  $w_k$  satisfy. We then select the top  $r$  candidates as topic seeds.

### 5 Seed Expansion

After generating the topic and sentiment seeds, we aim to expand them in the target domain to construct topic and sentiment lexicons. In this section, we propose a new bootstrapping-based method to address this problem.

Bootstrapping is the process of improving the performance of a weak classifier by iteratively adding training data and retraining the classifier. More specifically, bootstrapping starts with a small set of labeled “seeds”, and iteratively adds unlabeled

data that are labeled by the classifier to the training set based on some selection criterion, and retrain the classifier. Many bootstrapping-based algorithms have been proposed to information extraction and other NLP tasks (Blum and Mitchell, 1998; Riloff and Jones, 1999; Jones et al., 1999; Wu et al., 2009).

One important issue in bootstrapping is how to design a criterion to select unlabeled data to be added to the training set iteratively. Our proposed bootstrapping for cross-domain lexicon extraction is based on the following two observations: 1) Although the source and target domains are different, part of source domain labeled data is still useful for lexicon extraction in the target domain after some adaptation; 2) The syntactic relationships among sentiment and topic words can be used to expand the seeds in the target domain for lexicon construction.

Based on the two observations, we propose a new bootstrapping-based method named Relational Adaptive bootstrapping (RAP), as summarized in Algorithm 1, for expanding lexicons across domains. In each iteration, we employ a cross-domain classifier trained on the source domain lexicons and the extracted target domain lexicons to predict the labels of the target unlabeled data, and select top  $k_2$  predicted topic and sentiment words as candidates based on confidence. With the extracted syntactic patterns in the previous iterations, we construct a bipartite graph between sentiment and topic words on the extracted target domain lexicons and candidates. After that, a graph-based score refinement algorithm is performed on the graph, and the top  $k_1$  candidates are added to the extracted lexicons based on the final scores. Accordingly, with the new extracted lexicons, we update the syntactic patterns in each iteration. The details of RAP are presented in the following sections.

#### 5.1 Cross-Domain Classifier

In this paper, we employ *Transfer AdaBoost* (TrAdaBoost) (Dai et al., 2007) as the cross-domain learning algorithm in RAP. In TrAdaBoost, each word  $w_{S_i}$  (or  $w_{T_j}$ ) is represented by a feature vector  $x_{S_i}$  (or  $x_{T_j}$ ). A classifier trained on the source domain data  $\mathcal{D}_S = \{(x_{S_i}, y_{S_i})\}$  may perform poor on  $x_{T_j}$  because of domain difference. The main idea of TrAdaBoost is to re-weight the source domain data based on a few of target domain labeled data, which is referred to as seeds in our task. The re-weighting

aims to reduce the effect of the “bad” source domain data while encourage the “good” ones to get a more precise classifier in target domain. In each iteration of RAP, we train cross-domain classifiers  $f_{\mathcal{O}}^T$  and  $f_{\mathcal{P}}^T$  for sentiment- and topic- word extraction using TrAdaBoost separately (taking sentiment or topic words as positive instances). We use linear Support Vector Machines (SVMs) as the base classifier in TrAdaBoost. For features to represent each word, we use lexicon features, such as the previous, current and next words, and POS tag features, such as the previous, current and next words’ POS tags.

### Algorithm 1 Relational Adaptive bootstrapping

**Require:** Target domain data  $\mathcal{D}_T = \mathcal{D}_T^l \cup \mathcal{D}_T^u$ , where  $\mathcal{D}_T^l$  consists of sentiment seeds  $B$  and topic seeds  $C$  and their initial scores  $S_1(w_i), \forall w_i \in B$  and  $S_3(w_j), \forall w_j \in C$ ,  $\mathcal{D}_T^u$  is the set of unlabeled target domain data; labeled source domain data  $\mathcal{D}_S$ ; a cross-domain classifier; iteration number  $M$  and candidate selection number  $k_1, k_2$ .

**Ensure:** Expand  $C$  and  $B$  in the target domain.

- 1: Initialize a pattern set  $A = \emptyset$ ,  $\tilde{S}_1(w_i) = S_1(w_i)$ ,  $w_i \in B$  and  $\tilde{S}_3(w_j) = S_3(w_j)$ ,  $w_j \in C$ . Consider all patterns observed in the source domain as pattern candidates  $P$ .
- 2: **for**  $m = 1 \dots M$  **do**
- 3: Extract new pattern candidates to  $P$  with  $\mathcal{D}_T^l$  in target domain, update pattern score  $\tilde{S}_2(R_j)$ , where  $R_j \in P$ , based on Eq. (4), and select the top  $k_1$  patterns to the pattern set  $A$ .
- 4: Learn the cross-domain classifiers  $f_{\mathcal{O}}^T$  and  $f_{\mathcal{P}}^T$  for sentiment- and topic- word extraction with  $\mathcal{D}_S \cup \mathcal{D}_T^l$  separately. Predict the sentiment score  $h_{f_{\mathcal{O}}^T}^T(w_{T_j})$  and topic score  $h_{f_{\mathcal{P}}^T}^T(w_{T_j})$  on  $\mathcal{D}_T^u$ , and select  $k_2$  sentiment words and topic words with highest scores as candidates.
- 5: Construct a bipartite graph between sentiment and topic words on  $\mathcal{D}_T^l$  and the  $k_2$  sentiment- and topic- word candidates, and calculate the normalized weights  $\theta_{ij}$ ’s for each edge of the graph.
- 6: Refine the scores  $\tilde{S}_1$  and  $\tilde{S}_3$  of the  $k_2$  sentiment and topic word candidates using Eqs. (5) and (6) iteratively.
- 7: Select  $k_1$  new sentiment words and  $k_1$  new topic words with the final scores, and add them to lexicons  $B$  and  $C$ . Update  $\tilde{S}_1(w_i)$  and  $\tilde{S}_3(w_j)$  accordingly.
- 8: **end for**
- 9: **return** Expanded lexicons  $B$  and  $C$ .

## 5.2 Graph Construction

Based on the cross-domain classifiers  $f_{\mathcal{O}}^T$  and  $f_{\mathcal{P}}^T$ , we can predict the sentiment label score  $h_{f_{\mathcal{O}}^T}^T(w_{T_i})$  and topic label score  $h_{f_{\mathcal{P}}^T}^T(w_{T_i})$  for the target domain data  $w_{T_i}$ . According to all predicted values, we respectively select top  $k_2$  new sentiment- and topic- words as candidates. Together with the extracted sentiment and topic lexicons in the target domain,

we build a bipartite graph among them as shown in Figure 3. In the bipartite graph, one set of nodes represents topic words, including new topic candidates and words in the lexicon  $C$ , and the other set of nodes represents sentiment words, including new sentiment candidates and words in the lexicon  $B$ . For a pair of sentiment and topic words  $w_{T_i}^{\mathcal{O}}$  and  $w_{T_j}^{\mathcal{P}}$ , if there is a pattern  $R_j$  in the pattern set  $A$  that they can satisfy, then there exists an edge  $e_{ij}$  between them. Furthermore, each edge  $e_{ij}$  is associated with a nonnegative weight  $\theta_{ij}$ , which is measured as follows,  $\theta_{ij} = \sum_{R_k \in E} \tilde{S}_2(R_k)$ , where  $\tilde{S}_2$  is the pattern score. Similar to the metric defined in Eq. (3), the pattern score is defined as:

$$\tilde{S}_2(R_j) = \sum_{\{w_i, w_k\} \in E} (\tilde{S}_1(w_i) \times \tilde{S}_3(w_k)), \quad (4)$$

where  $E = \{\{w_i, w_j\} | w_i \in B, w_j \in C \text{ and } w_i, w_j \text{ satisfy } R_j, R_j \in A\}$ . Note that in the beginning of each iteration,  $\tilde{S}_2$  is updated based on the new sentiment score  $\tilde{S}_1$  and topic score  $\tilde{S}_3$ . We further normalize  $\theta_{ij}$  by  $\hat{\theta}_{ij} = \theta_{ij} / (\sum_{ij} \theta_{ij})$ .

Figure 3: Topic and sentiment word graph.

## 5.3 Score Computation

We construct the bipartite graph to exploit the relationships between sentiment and topic words to propagate information for lexicon extraction. We use the following reinforcement formulas to iteratively update the final sentiment score  $\tilde{S}_1(w_{T_j})$  and topic score  $\tilde{S}_3(w_{T_i})$ , respectively:

$$\tilde{S}_1(w_{T_j}) = \mu \sum_i \tilde{S}_3(w_{T_i}) \hat{\theta}_{ij} + (1 - \mu) h_{f_{\mathcal{O}}^T}^T(w_{T_j}), \quad (5)$$

$$\tilde{S}_3(w_{T_i}) = \mu \sum_j \tilde{S}_1(w_{T_j}) \hat{\theta}_{ij} + (1 - \mu) h_{f_{\mathcal{P}}^T}^T(w_{T_i}), \quad (6)$$

where  $\mu$  is a trade-off parameter between the predicted value by cross-domain classifier and the reinforcement scores from other nodes connected by

edge  $e_{ij}$ . Here  $\mu$  is empirically set to be 0.5. With Eqs. (5) and (6), the sentiment scores and topic scores are iteratively refined until the state of the graph trends to be stable. This can be considered as an extension to the HITS algorithm (Kleinberg, 1999). Finally, we select  $k_1 \ll k_2$  sentiment and topic words from the  $k_2$  candidates based on their refined scores, and add them to the target domain lexicons, respectively. We also update the sentiment score  $\tilde{S}_1$  and topic score  $\tilde{S}_3$  for next iteration.

#### 5.4 Special Cases

We now introduce two special cases of the RAP algorithm. In Eqs. (5) and (6), if the parameter  $\mu = 1$ , then RAP only uses the relationships between sentiment and topic words with their patterns to propagate label information in the target domain without using the cross-domain classifier. We call this reduction relational bootstrapping. If  $\mu = 0$ , then RAP only utilizes useful source domain labeled data to assist learning of the target domain classifier without considering the relationships between sentiment and topic words. We call this reduction adaptive bootstrapping, which can be considered as a bootstrapping version of TrAdaBoost. We also empirically study these two special cases in experiments.

## 6 Experiments on Lexicon Evaluation

### 6.1 Data Set and Evaluation Criteria

We use the review dataset from (Li et al., 2010a), which contains 500 movie and 601 product reviews, for evaluation. The sentiment and topic words are manually annotated. In this dataset, all types of sentiment words are annotated instead of adjective words only. For example, the verbs, such as “like”, “recommend”, and nouns, such as “masterpiece”, are also labeled as sentiment words. We construct two cross-domain lexicon extraction tasks: “product vs. movie” and “movie vs. product”, where the word before “vs.” corresponds with the source domain and the word after “vs.” corresponds with the target domain. We evaluate our methods in terms of precision, recall and F-score ( $F1$ ).

### 6.2 Baselines

The results of in-domain classifiers, which are trained on plenty of target domain labeled data, can be treated as upper-bounds. We denote iSVM and iCRF the in-domain SVM and CRF classifiers in experiments, and compare our proposed methods,

RAP, relational bootstrapping, and adaptive bootstrapping, with the following baselines,

**Unsupervised Method (Un)** we implement a rule-based method for lexicon extraction based on (Hu and Liu, 2004), where adjective words that match a rule is recognized as sentiment words, and nouns that match a rule are recognized as topic words.

**Semi-Supervised Method (Semi)** we implement the double propagation model proposed in (Qiu et al., 2009). Since this method requires some target domain labeled data, we manually label 30 sentiment words in the target domain.

**Cross-Domain CRF (Cross-CRF)** we implement a cross-domain CRF algorithm proposed by (Jakob and Gurevych, 2010).

**TrAdaBoost** We apply TrAdaBoost (Dai et al., 2007) on the source domain labeled data and the generated seeds in the target domain to train a lexicon extractor.

### 6.3 Comparison Results

Comparison results on lexicon extraction are shown in Table 2 and Table 3. From Table 2, we can observe that our proposed methods are effective for sentiment lexicon extraction. The relational bootstrapping method performs better than the unsupervised method, TrAdaBoost and the cross-domain CRF algorithm, and achieves comparable results with the semi-supervised method. However, compared to the semi-supervised method, our proposed relational bootstrapping method does not require any labeled data in the target domain. We can also observe that the adaptive bootstrapping method and the RAP method perform much better than other methods in terms of F-score. The reason is that part of the source domain labeled data may be useful for learning the target classifier after reweighting. In addition, we also observe that embedding the TrAdaBoost algorithm into a bootstrapping process can further boost the performance of the classifier for sentiment lexicon extraction.

Table 3 shows the comparison results on topic lexicon extraction. From the table, we can observe that different from the sentiment lexicon extraction task, the relational bootstrapping method performs better than the adaptive bootstrapping method slightly. The reason may be that for the sentiment lexicon extraction task, there exist some common sentiment words

Table 3: Results on topic lexicon extraction. Numbers in boldface denote significant improvement.

across domains, thus part of the labeled source domain data may be useful for the target learning task. However, for the topic lexicon extraction task, the topic words may be totally different, and as a result, we may not be able to find useful source domain labeled data to boost the performance for lexicon extraction in the target domain. In this case, mutual label propagation between sentiment and topic words may be more reasonable for knowledge transfer. RAP absorbs the advantages of the adaptive and relational bootstrapping methods, thus can get the best results in both lexicon extraction tasks.

We also observe that relational bootstrapping can get better recall, but lower precision, compared to adaptive bootstrapping. This is because relational bootstrapping only utilizes the patterns to propagate label information, which may cover more topic and sentiment seeds, but include some *noisy* words. For example, given two phases “like the camera” and “recommend the camera”, we can extract a pattern “VB-dobj-NN”. However, by using this pattern and the topic word “camera”, we may extract “take” as a sentiment word from another phase “take the cam-

era”, which is incorrect. The adaptive bootstrapping method can utilize various features to make predictions more precisely, which may have higher precision, but encounter the lower recall problem. For example, “flash” is not identified as a topic word in the target product domain (camera domain). Our RAP method can exploit both relationships between sentiment and topic words and part of labeled source domain data for cross-domain lexicon extraction. It can correctly identify the above two cases.

### 6.3.1 Parameter Sensitivity Study

In this section, we conduct experiments to study the effect of different parameter settings. There are several parameters in the framework: the number of generated seeds  $r$ , the number of new candidates  $k_2$  and the number of selections  $k$  in each iteration, and the number of iterations  $M$  ( $\mu$  is empirically set to 0.5). For the parameter  $k_2$ , we just set it to a large number ( $k_2 = 100$ ) such that have rich candidates to build the bipartite graph. In the experiments reported in the previous section, we set  $r = 20$ ,  $k_1 = 10$  and  $M = 50$ . Figures 4(a) and 4(b) show the results under varying values of  $r$  in the “product vs. movie” task. Observe that for sentiment word extraction, the results of the proposed methods are not sensitive to the values of  $r$ . While for the topic word extraction, the proposed methods perform well when  $r$  falls in the range from 15 to 20.

(a) Sentiment word extraction (b) Topic word extraction

Figure 4: Results on varying values of  $r$ .

(a) Sentiment word extraction (b) Topic word extraction

Figure 5: Results on varying values of  $M$ .

We also test the sensitivity of the parameter  $k_1$  and find that the proposed methods work well and robust when  $k_1$  falls in the range from 10 to 20.

Figures 5(a) and 5(b) show the results under varying numbers of iterations in the “product vs. movie” task. As we can see, our proposed methods converge well when  $M \geq 40$ .

## 7 Application: Sentiment Classification

To further verify the usefulness of the lexicons extracted by the RAP method, we apply the extracted sentiment lexicon for sentiment classification.

### 7.1 Experiment Setting

Our work is motivated by the work of (Pang and Lee, 2004), which only used subjective sentences for document-level sentiment classification, instead of using all sentences. In this experiment, we only use sentiment related words as features to represent opinion documents for classification, instead of using all words. Our goal is compare the sentiment lexicon constructed by the RAP method with other general lexicons on the impact of for sentiment classification. The general lexicons used for comparison are described in Table 4.

We use the dataset from (Blitzer et al., 2007) for sentiment classification. It contains a collection of product reviews from Amazon.com. The reviews are about four product domains: books, dvds, electronics and kitchen appliance. In each domain, there are 1000 positive and 1000 negative reviews. To construct domain specific sentiment lexicons, we apply RAP on each product domain with the *movie* domain described in Section 6.1 as the source domain. Finally, we use linear SVM as the classifier and the classification accuracy as the evaluate criterion.

Lexicon Name	Size	Description
Senti-WordNet	6957	Words with a subjective score $> 0.6$ (Esuli and Sebastiani, 2006)
HowNet	4619	Eng. translation of subj. Chinese words (Dong and Dong, 2006)
Subj. Clues	6878	Lexicons from (Wilson et al., 2005)

Table 4: Description of different lexicons.

### 7.2 Experimental Results

Experimental results on sentiment classification are shown in Table 5, where we denote “All” using all unigram and bigram features instead of using subjective words. As we can see that a classifier trained with features constructed by our RAP method performance best in all domains. Note that the number of features (sentiment words) constructed by our

method is much smaller than that of all unigram and bigram features, which can reduce the classifier training time dramatically. These promising results imply that our RAP can be applied for sentiment classification effectively and efficiently.

	All	Senti	HowNet	Subj. Clue	Ours
dvd	82.55	79.80	80.57	80.93	<b>84.05</b>
book	80.71	76.22	78.22	79.48	<b>81.65</b>

## 8 Conclusions

In this paper, we propose a two-stage framework for co-extraction of sentiment and topic lexicons across domains where we have no labeled data in the target domain but have plenty of labeled data in another domain. In the first stage, we propose a simple strategy to generate a few high-quality sentiment and topic seeds for the target domain. In the second stage, we propose a novel Relational Adaptive bootstrapping (RAP) method to expand the seeds, which can exploit the relationships between topic and opinion words, and make use of part of useful source domain labeled data for help. Extensive experimental results show our proposed method can extract precise sentiment and topic lexicons from the target domain. Furthermore, the extracted sentiment lexicon can be applied to sentiment classification effectively.

In the future work, besides the heterogeneous relationships between topic and sentiment words, we intend to investigate the homogeneous relationships among topic words and those among sentiment words (Qiu et al., 2009) to further boost the performance of RAP method. Furthermore, in our framework, we do not identify the polarity of the extracted sentiment lexicon. We also plan to embed this component into our unified framework. Finally, it is also interesting to exploit multi-domain knowledge (Li and Zong, 2008; Bollegala et al., 2011) for cross-domain lexicon extraction.

## Abstract

We present a novel approach for building verb subcategorization lexicons using a simple graphical model. In contrast to previous methods, we show how the model can be trained without parsed input or a predefined subcategorization frame inventory. Our method outperforms the state-of-the-art on a verb clustering task, and is easily trained on arbitrary domains. This quantitative evaluation is complemented by a qualitative discussion of verbs and their frames. We discuss the advantages of graphical models for this task, in particular the ease of integrating semantic information about verbs and arguments in a principled fashion. We conclude with future work to augment the approach.

## 1 Introduction

Subcategorization frames (SCFs) give a compact description of a verb’s syntactic preferences. These two sentences have the same sequence of lexical syntactic categories (VP-NP-SCOMP), but the first is a simple transitive (“X understood Y”), while the second is a ditransitive with a sentential complement (“X persuaded Y that Z”):

1. Kim (VP understood (NP the evidence (SCOMP that Sandy was present)))
2. Kim (VP persuaded (NP the judge) (SCOMP that Sandy was present))

An SCF lexicon would indicate that “persuade” is likely to take a direct object and sentential complement (NP-SCOMP), while “understand” is more likely to take just a direct object (NP). A comprehensive lexicon would also include semantic information about selectional preferences (or restrictions) on argument heads of verbs, diathesis alternations (i.e. semantically-motivated alternations between pairs of SCFs) and a mapping from surface frames to the underlying predicate-argument structure. Information about verb subcategorization is useful for tasks like information extraction (Cohen and Hunter, 2006; Rupp et al., 2010), verb clustering (Korhonen et al., 2006b; Merlo and Stevenson, 2001) and parsing (Carroll et al., 1998). In general, tasks that depend on predicate-argument structure can benefit from a high-quality SCF lexicon (Surdeanu et al., 2003).

Large, manually-constructed SCF lexicons mostly target general language (Boguraev and Briscoe, 1987; Grishman et al., 1994). However, in many domains verbs exhibit different syntactic behavior (Roland and Jurafsky, 1998; Lippincott et al., 2010). For example, the verb “develop” has specific usages in newswire, biomedicine and engineering that dramatically change its probability distribution over SCFs. In a few domains like biomedicine, the need for focused SCF lexicons has led to manually-built resources (Bodenreider, 2004). Such resources, however, are costly, prone to human error, and in domains where new lexical and syntactic constructs are frequently coined, quickly become obsolete (Cohen and Hunter, 2006). Data-driven methods for SCF acquisition can alleviate

these problems by building lexicons tailored to new domains with less manual effort, and higher coverage and scalability.

Unfortunately, high quality SCF lexicons are difficult to build automatically. The argument-adjunct distinction is challenging even for humans, many SCFs have no reliable cues in data, and some SCFs (e.g. those involving control such as type raising) rely on semantic distinctions. As SCFs follow a Zipfian distribution (Korhonen et al., 2000), many genuine frames are also low in frequency. State-of-the-art methods for building data-driven SCF lexicons typically rely on parsed input (see section 2). However, the treebanks necessary for training a high-accuracy parsing model are expensive to build for new domains. Moreover, while parsing may aid the detection of some frames, many experiments have also reported SCF errors due to noise from parsing (Korhonen et al., 2006a; Preiss et al., 2007).

Finally, many SCF acquisition methods operate with predefined SCF inventories. This subscribes to a single (often language or domain-specific) interpretation of subcategorization *a priori*, and ignores the ongoing debate on how this interpretation should be tailored to new domains and applications, such as the more prominent role of adjuncts in information extraction (Cohen and Hunter, 2006).

In this paper, we describe and evaluate a novel probabilistic data-driven method for SCF acquisition aimed at addressing some of the problems with current approaches. In our model, a Bayesian network describes how verbs choose their arguments in terms of a small number of frames, which are represented as distributions over syntactic relationships. First, we show that by allowing the inference process to automatically define a probabilistic SCF inventory, we outperform systems with hand-crafted rules and inventories, using identical syntactic features. Second, by replacing the syntactic features with an approximation based on POS tags, we achieve state-of-the-art performance without relying on error-prone unlexicalized or domain-specific lexicalized parsers. Third, we highlight a key advantage of our method compared to previous approaches: the ease of integrating and performing joint inference of additional syntactic and semantic information. We describe how we plan to exploit this in our future research.

## 2 Previous work

Many state-of-the-art SCF acquisition systems take *grammatical relations* (GRs) as input. GRs express binary dependencies between lexical items, and many parsers produce them as output, with some variation in inventory (Briscoe et al., 2006; De Marneffe et al., 2006). For example, a subject-relation like “ncsubj(HEAD, DEPENDENT)” expresses the fact that the lexical item referred to by HEAD (such as a present-tense verb) has the lexical item referred to by DEPENDENT as its subject (such as a singular noun). GR inventories include direct and indirect objects, complements, conjunctions, among other relations. The dependency relationships included in GRs correspond closely to the head-complement structure of SCFs, which is why they are the natural choice for SCF acquisition.

There are several SCF lexicons for general language, such as ANLT (Boguraev and Briscoe, 1987) and COMLEX (Grishman et al., 1994), that depend on manual work. VALEX (Preiss et al., 2007) provides SCF distributions for 6,397 verbs acquired from a parsed general language corpus via a system that relies on hand-crafted rules. There are also resources which provide information about both syntactic and semantic properties of verbs: VerbNet (Kipper et al., 2008) draws on several hand-built and semi-automatic sources to link the syntax and semantics of 5,726 verbs. FrameNet (Baker et al., 1998) provides semantic frames and annotated example sentences for 4,186 verbs. PropBank (Palmer et al., 2005) is a corpus where each verb is annotated for its arguments and their semantic roles, covering a total of 4,592 verbs.

There are many language-specific SCF acquisition systems, e.g. for French (Messiant, 2008), Italian (Lenci et al., 2008), Turkish (Han et al., 2008) and Chinese (Han et al., 2008). These typically rely on language-specific knowledge, either directly through heuristics, or indirectly through parsing models trained on treebanks. Furthermore, some require labeled training instances for supervised (Uzun et al., 2008) or semi-supervised (Han et al., 2008) learning algorithms.

Two state-of-the-art data-driven systems for English verbs are those that produced VALEX, Preiss et al. (2007), and the BioLexicon (Venturi et al., 2009).

The Preiss system extracts a verb instance’s GRs using the Rasp general-language unlexicalized parser (Briscoe et al., 2006) as input, and based on hand-crafted rules, maps verb instances to a predefined inventory of 168 SCFs. Filtering is then performed to remove noisy frames, with methods ranging from a simple single threshold to SCF-specific hypothesis tests based on external verb classes and SCF inventories. The BioLexicon system extracts each verb instance’s GRs using the lexicalized Enju parser tuned to the biomedical domain (Miyao, 2005). Each unique GR-set considered a potential SCF, and an experimentally-determined threshold is used to filter low-frequency SCFs.

Note that both methods require extensive manual work: the Preiss system involves the *a priori* definition of the SCF inventory, careful construction of matching rules, and an unlexicalized parsing model. The BioLexicon system induces its SCF inventory automatically, but requires a lexicalized parsing model, rendering it more sensitive to domain variation. Both rely on a filtering stage that depends on external resources and/or gold standards to select top-performing thresholds. Our method, by contrast, does not use a predefined SCF inventory, and can perform well without parsed input.

Graphical models have been increasingly popular for a variety of tasks such as distributional semantics (Blei et al., 2003) and unsupervised POS tagging (Finkel et al., 2007), and sampling methods allow efficient estimation of full joint distributions (Neal, 1993). The potential for joint inference of complementary information, such as syntactic verb and semantic argument classes, has a clear and interpretable way forward, in contrast to the pipelined methods described above. This was demonstrated in Andrew et al. (2004), where a Bayesian model was used to jointly induce syntactic and semantic classes for verbs, although that study relied on manually annotated data and a predefined SCF inventory and MLE. More recently, Abend and Rappoport (2010) trained ensemble classifiers to perform argument-adjunct disambiguation of PP complements, a task closely related to SCF acquisition. Their study employed unsupervised POS tagging and parsing, and measures of selectional preference and argument structure as complementary features for the classifier.

Finally, our task-based evaluation, verb clustering with Levin (1993)’s alternation classes as the gold standard, was previously conducted by Joanis and Stevenson (2003), Korhonen et al. (2008) and Sun and Korhonen (2009).

### 3 Methodology

In this section we describe the basic components of our study: feature sets, graphical model, inference, and evaluation.

#### 3.1 Input and feature sets

We tested several feature sets either based on, or approximating, the concept of *grammatical relation* described in section 2. Our method is agnostic regarding the exact definition of GR, and for example could use the Stanford inventory (De Marneffe et al., 2006) or even an entirely different lexico-syntactic formalism like CCG supertags (Curran et al., 2007). In this paper, we distinguish “true GRs” (tGRs), produced by a parser, and “pseudo GRs” (pGRs), a POS-based approximation, and employ subscripts to further specify the variations described below. Our input has been parsed into Rasp-style tGRs (Briscoe et al., 2006), which facilitates comparison with previous work based on the same data set.

We’ll use a simple example sentence to illustrate how our feature sets are extracted from CONLL-formatted data (Nivre et al., 2007). The CONLL format is a common language for comparing output from dependency parsers: each lexical item has an index, lemma, POS tag, tGR in which it is the dependent, and index to the corresponding head. Table 1 shows the relevant fields for the sentence “We run training programmes in Romania and other countries”.

We define the feature set for a verb occurrence as the counts of each GR the verb participates in. Table 2 shows the three variations we tested: the simple tGR type, with parameterization for the POS tags of head and dependent, and with closed-class POS tags (determiners, pronouns and prepositions) lexicalized. In addition, we tested the effect of limiting the features to subject, object and complement tGRs, indicated by adding the subscript “lim”, for a total of six tGR-based feature sets.

While ideally tGRs would give full informa-

Index	Lemma	POS	Head	tGR
1	we	PPIS2	2	ncsubj
2	run	VV0	0	-
3	training	NN1	4	ncmod
4	programme	NN2	2	doobj
5	in	II	4	ncmod
6	romania	NP1	7	conj
7	and	CC	5	doobj
8	other	JB	9	ncmod
9	country	NN2	7	conj

Table 1: Simplified CONLL format for example sentence “We run training programmes in Romania and other countries”. Head=0 indicates the token is the root.

Name	Features	
$tGR$	ncsubj	doobj
$tGR_{param}$	ncsubj(VV0,PPIS2)	doobj(VV0,NN2)
$tGR_{param,lex}$	ncsubj(VV0,PPIS2-we)	doobj(VV0,NN2)

Table 2: True-GR features for example sentence: note there are also  $tGR_{*,lim}$  versions of each that only consider subjects, objects and complements and are not shown.

tion about the verb’s syntactic relationship to other words, in practice parsers make (possibly premature) decisions, such as deciding that “in” modifies “programme”, and not “run” in our example sentence. An unlexicalized parser cannot distinguish these based just on POS tags, while a lexicalized parser requires a large treebank. We therefore define *pseudo-GRs* (pGRs), which consider each (distance, POS) pair within a given window of the verb to be a potential tGR. Table 3 shows the pGR features for the test sentence using a window of three. As with tGRs, the closed-class tags can be lexicalized, but there are no corresponding feature sets for *param* (since they are already built from POS tags) or *lim* (since there is no similar rule-based approach).

Name	Features			
$pGR$	-1(PPIS2)	1(NN1)	2(NN2)	3(II)
$pGR_{lex}$	-1(PPIS2-we)	1(NN1)	2(NN2)	3(II-in)

Table 3: Pseudo-GR features for example sentence with window=3

Whichever feature set is used, an instance is sim-

ply the count of each GR’s occurrences. We extract instances for the 385 verbs in the union of our two gold standards from the VALEX lexicon’s data set, which was used in previous studies (Sun and Korhonen, 2009; Preiss et al., 2007) and facilitates comparison with that resource. This data set is drawn from five general-language corpora parsed by Rasp, and provides, on average, 7,000 instances per verb.

### 3.2 SCF extraction

Our graphical modeling approach uses the Bayesian network shown in Figure 1. Its generative story is as follows: when a verb is instantiated, an SCF is chosen according to a verb-specific multinomial. Then, the number and type of syntactic arguments (GRs) are chosen from two SCF-specific multinomials. These three multinomials are modeled with uniform Dirichlet priors and corresponding hyperparameters  $\alpha$ ,  $\beta$  and  $\gamma$ . The model is trained via collapsed Gibbs sampling, where the probability of assigning a particular SCF  $s$  to an instance of verb  $v$  with GRs ( $gr_1 \dots gr_n$ ) is the product

$$\begin{aligned}
 P(s|Verb = v, GRs = gr_1 \dots gr_n) = & \\
 & P(SCF = s|Verb = v) \times \\
 & P(N = n|SCF = s) \times \\
 & \prod_{i=1:n} P(GR = gr_i|SCF = s)
 \end{aligned}$$

The three terms, given the hyper-parameters and conjugate-prior relationship between Dirichlet and Multinomial distributions, can be expressed in terms of current assignments of  $s$  to verb  $v$  ( $c_{sv}$ ),  $s$  to GR-count  $n$  ( $c_{sn}$ ) and  $s$  to GR ( $c_{sg}$ ), the corresponding totals ( $c_v$ ,  $c_s$ ), the dimensionality of the distributions ( $|SCF|$ ,  $|N|$  and  $|G|$ ) and the hyperparameters  $\alpha$ ,  $\beta$  and  $\gamma$ :

$$P(SCF = s|Verb = v) = (c_{sv} + \alpha) / (c_v + |SCF|\alpha)$$

$$P(N = n|SCF = s) = (c_{sn} + \beta) / (c_s + |N|\beta)$$

$$P(GR = gr_i|SCF = s) = (c_{sgr_i} + \gamma) / (c_s + |G|\gamma)$$

Note that  $N$ , the possible GR-count for an instance, is usually constant for pGRs ( $2 \times window$ ), unless the verb is close to the start or end of the sentence.

Figure 1: Our simple graphical model reflecting subcategorization. Double-circles indicate an observed value, arrows indicate conditional dependency. What constitutes a “GR” depends on the feature set being used.

We chose our hyper-parameters  $\alpha = \beta = \gamma = .02$  to reflect the characteristic sparseness of the phenomena (i.e. verbs tend to take a small number of SCFs, which in turn are limited to a small number of realizations). For the pGRs we used a window of 5 tokens: a verb’s arguments will fall within a small window in the majority of cases, so there is diminished return in expanding the window at the cost of increased noise. Finally, we set our SCF count to 40, about twice the size of the strictly syntactic general-language gold standard we describe in section 3.3. This overestimation allows some flexibility for the model to define its inventory based on the data; any supernumerary frames will act as “junk frames” that are rarely assigned and hence will have little influence. We run Gibbs sampling for 1000 iterations, and average the final 100 samples to estimate the posteriors  $P(SCF|Verb)$  and  $P(GR|SCF)$ . Variance between adjacent states’ estimates of  $P(SCF|Verb)$  indicates that the sampling typically converges after about 100-200 iterations.<sup>1</sup>

### 3.3 Evaluation

#### Quantitative: cluster gold standard

Evaluating the output of unsupervised methods is not straightforward: discrete, expert-defined categories (like many SCF inventories) are unlikely to line up perfectly with data-driven, probabilistic output. Even if they do, finding a mapping between them is a problem of its own (Meila, 2003).

<sup>1</sup>Full source code for this work is available at <http://cl.cam.ac.uk/~t1318/files/subcat.tgz>

Our goal is to define a fair quantitative comparison between arbitrary SCF lexicons. An SCF lexicon makes two claims: first, that it defines a reasonable SCF inventory. Second, that for each verb, it has an accurate distribution over that inventory. We therefore compare the lexicons based on their performance on a task that a good SCF lexicon should be useful for: clustering verbs into lexical-semantic classes. Our gold standard is from (Sun and Korhonen, 2009), where 200 verbs were assigned to 17 classes based on their alternation patterns (Levin, 1993). Previous work (Schulte im Walde, 2009; Sun and Korhonen, 2009) has demonstrated that the quality of an SCF lexicon’s inventory and probability estimates corresponds to its predictive power for membership in such alternation classes.

To compare the performance of our feature sets, we chose the simple and familiar K-Means clustering algorithm (Hartigan and Wong, 1979). The instances are the verbs’ SCF distributions, and we select the number of clusters by the Silhouette validation technique (Rousseeuw, 1987). The clusters are then compared to the gold standard clusters with the purity-based F-Score from Sun and Korhonen (2009) and the more familiar Adjusted Rand Index (Hubert and Arabie, 1985). Our main point of comparison is the VALEX lexicon of SCF distributions, whose scores we report alongside ours.

#### Qualitative: manual gold standard

We also want to see how our results line up with a traditional linguistic view of subcategorization, but this requires digging into the unsupervised out-

put and associating anonymous probabilistic objects with established categories. We therefore present sample output in three ways: first, we show the clustering output from our top-performing method. Second, we plot the probability mass over GRs for two anonymous SCFs that correspond to recognizable traditional SCFs, and one that demonstrates unexpected behavior. Third, we compared the output for several verbs to a coarsened version of the manually-annotated gold standard used to evaluate VALEX (Preiss et al., 2007). We collapsed the original inventory of 168 SCFs to 18 purely syntactic SCFs based on their characteristic GRs and removed frames that depend on semantic distinctions, leaving the detection of finer-grained and semantically-based frames for future work.

## 4 Results

### 4.1 Verb clustering

We evaluated SCF lexicons based on the eight feature sets described in section 3.1, as well as the VALEX SCF lexicon described in section 2. Table 4 shows the performance of the lexicons in ascending order.

Method	Pur. F-score	Adj. Rand
<i>tGR</i>	.24	.02
<i>tGR<sub>lim</sub></i>	.27	.02
<i>pGR<sub>lex</sub></i>	.32	.09
<i>tGR<sub>lim,param</sub></i>	.35	.08
<i>pGR</i>	.35	.10
VALEX	.36	.10
<i>tGR<sub>param,lex</sub></i>	.37	.10
<i>tGR<sub>param</sub></i>	.39	.12
<i>tGR<sub>lim,param,lex</sub></i>	.44	.12

Table 4: Task-based evaluation of lexicons acquired with each of the eight feature types, and the state-of-the-art rule-based VALEX lexicon.

These results lead to several conclusions: first, training our model on tGRs outperforms pGRs and VALEX. Since the parser that produced them is known to perform well on general language (Briscoe et al., 2006), the tGRs are of high quality: it makes sense that reverting to the pGRs is unnecessary in this case. The interesting point is the major performance gain over VALEX, which uses the same tGR

features along with expert-developed rules and inventory.

Second, we achieve performance comparable to VALEX using pGRs with a narrow window width. Since POS tagging is more reliable and robust across domains than parsing, retraining on new domains will not suffer the effects of a mismatched parsing model (Lippincott et al., 2010). It is therefore possible to use this method to build large-scale lexicons for any new domain with sufficient data.

Third, lexicalizing the closed-class POS tags introduces semantic information outside the scope of the alternation-based definition of subcategorization. For example, subdividing the indefinite pronoun tag “PN1” into “PN1-anyone” and “PN1-anything” gives information about the animacy of the verb’s arguments. Our results show this degrades performance for both pGR and tGR features, unless the latter are limited to tGRs traditionally thought to be relevant for the task.

### 4.2 Qualitative analysis

Table 5 shows clusters produced by our top-scoring method,  $GR_{param,lex,lim}$ . Some clusters are immediately intelligible at the semantic level and correspond closely to the lexical-semantic classes found in Levin (1993). For example, clusters 1, 6, and 14 include member verbs of Levin’s SAY, PEER and AMUSE classes, respectively. Some clusters are based on broader semantic distinctions (e.g. cluster 2 which groups together verbs related to locations) while others relate semantic classes purely based on their syntactic similarity (e.g. the verbs in cluster 17 share strong preference for ‘to’ preposition). The syntactic-semantic nature of the clusters reflects the multimodal nature of verbs and illustrates why a comprehensive subcategorization lexicon should not be limited to syntactic frames. This phenomenon is also encouraging for future work to tease apart and simultaneously exploit several verbal aspects via additional latent structure in the model.

An SCF’s distribution over features can reveal its place in the traditional definition of subcategorization. Figure 2 shows the high-probability (>.02) tGRs for one SCF: the large mass centered on direct object tGRs indicates this approximates the notion of “transitive”. Looking at the verbs most likely to take this SCF (“stimulate”, “conserve”) confirms

1	exclaim, murmur, mutter, reply, retort, say, sigh, whisper
2	bang, knock, snoop, swim, teeter
3	flicker, multiply, overlap, shine
4	batter, charter, compromise, overwhelm, regard, sway, treat
5	abolish, broaden, conserve, deepen, eradicate, remove, sharpen, shorten, stimulate, strengthen, unify
6	gaze, glance, look, peer, sneer, squint, stare
7	coincide, commiserate, concur, flirt, interact
8	grin, smile, wiggle
9	confuse, diagnose, march
10	mate, melt, swirl
11	frown, jog, stutter
12	chuckle, mumble, shout
13	announce, envisage, mention, report, state
14	frighten, intimidate, scare, shock, upset
15	bash, falter, snarl, wail, weaken
16	cooperate, eject, respond, transmit
17	affiliate, compare, contrast, correlate, forward, mail, ship

Table 5: Clusters (of size  $>2$  and  $<20$ ) produced using  $tGR_{param,lex,lim}$

this. Figure 3 shows a complement-taking SCF, which is far rarer than simple transitive but also clearly induced by our model.

The induced SCF inventory also has some redundancy, such as additional transitive frames beside figure 2, and frames with poor probability estimates. Most of these issues can be traced to our simplifying assumption that each tGR is drawn independently w.r.t. an instance’s other tGRs. For example, if an SCF gives *any* weight to indirect objects, it gives non-zero probability to an instance with *only* indirect objects, an impossible case. This can lead to skewed probability estimates: since some tGRs can occur multiple times in a given instance (e.g. indirect objects and prepositional phrases) the model may find it reasonable to create an SCF with all probability focused on that tGR, ignoring all others, such as in figure 4. We conclude that our independence assumption was too strong, and the model would benefit from defining more structure within

Figure 2: The SCF corresponding to transitive has most probability centered on dobj (e.g. stimulate, conserve, deepen, eradicate, broaden)

Figure 3: The SCF corresponding to verbs taking complements has more probability on xcomp and ccomp (e.g. believe, state, agree, understand, mention)

instances.

The full tables necessary to compare verb SCF distributions from our output with the manual gold standard are prohibited by space, but a few examples reinforce the analysis above. The verbs “load” and “fill” show particularly high usage of ditransitive SCFs in the gold standard. In our inventory, this is reflected in high usage of an SCF with probability centered on indirect objects, but due to the independence assumptions the frame has a corresponding low probability on subjects and direct objects, despite the fact that these necessarily occur *along with* any indirect object. The verbs “acquire” and “buy” demonstrate both a strength of our approach and a weakness of using parsed input: both verbs

Figure 4: This SCF is dominated by indirect objects and complements, catering to verbs that may take several such tGRs, at the expense of subjects

show high probability of simple transitive in our output and the gold standard. However, the Rasp parser often conflates indirect objects and prepositional phrases due to its unlexicalized model. While our system correctly gives high probability to ditransitive for both verbs, it inherits this confusion and over-estimates “acquire”’s probability mass for the frame. This is an example of how bad decisions made by the parser cannot be fixed by the graphical model, and an area where pGR features have an advantage.

## 5 Conclusions and future work

Our study reached two important conclusions: first, given the same data as input, an unsupervised probabilistic model can outperform a hand-crafted rule-based SCF extractor with a predefined inventory. We achieve better results with far less effort than previous approaches by allowing the data to govern the definition of frames while estimating the verb-specific distributions in a fully Bayesian manner. Second, simply treating POS tags within a small window of the verb as pseudo-GRs produces state-of-the-art results without the need for a parsing model. This is particularly encouraging when building resources for new domains, where complex models fail to generalize. In fact, by integrating results from unsupervised POS tagging (Teichert and Daumé III, 2009) we could render this approach fully domain- and language-independent.

We did not dwell on issues related to choosing

our hyper-parameters or latent class count. Both of these can be accomplished with additional sampling methods: hyper-parameters of Dirichlet priors can be estimated via slice sampling (Heinrich, 2009), and their dimensionality via Dirichlet Process priors (Heinrich, 2011). This could help address the redundancy we find in the induced SCF inventory, with the potential SCFs growing to accommodate the data.

Our initial attempt at applying graphical models to subcategorization also suggested several ways to extend and improve the method. First, the independence assumptions between GRs in a given instance turned out to be too strong. To address this, we could give instances internal structure to capture conditional probability between generated GRs. Second, our results showed the conflation of several verbal aspects, most notably the syntactic and semantic. In a sense this is encouraging, as it motivates our most exciting future work: augmenting this simple model to explicitly capture complementary information such as distributional semantics (Blei et al., 2003), diathesis alternations (McCarthy, 2000) and selectional preferences (Ó Séaghdha, 2010). This study targeted high-frequency verbs, but the use of syntactic and semantic classes would also help with data sparsity down the road. These extensions would also call for a more comprehensive evaluation, averaging over several tasks, such as clustering by semantics, syntax, alternations and selectional preferences.

In concrete terms, we plan to introduce latent variables corresponding to syntactic, semantic and alternation classes, that will determine a verb’s syntactic arguments, their semantic realization (i.e. selectional preferences), and possible predicate-argument structures. By combining the syntactic classes with unsupervised POS tagging (Teichert and Daumé III, 2009) and the selectional preferences with distributional semantics (Ó Séaghdha, 2010), we hope to produce more accurate results on these complementary tasks while avoiding the use of any supervised learning. Finally, a fundamental advantage of a data-driven, parse-free method is that it can be easily trained for new domains. We next plan to test our method on a new domain, such as biomedical text, where verbs are known to take on distinct syntactic behavior (Lippincott et al., 2010).

## Abstract

Learning a semantic lexicon is often an important first step in building a system that learns to interpret the meaning of natural language. It is especially important in language grounding where the training data usually consist of language paired with an ambiguous perceptual context. Recent work by Chen and Mooney (2011) introduced a lexicon learning method that deals with ambiguous relational data by taking intersections of graphs. While the algorithm produced good lexicons for the task of learning to interpret navigation instructions, it only works in batch settings and does not scale well to large datasets. In this paper we introduce a new online algorithm that is an order of magnitude faster and surpasses the state-of-the-art results. We show that by changing the grammar of the formal meaning representation language and training on additional data collected from Amazon's Mechanical Turk we can further improve the results. We also include experimental results on a Chinese translation of the training data to demonstrate the generality of our approach.

## 1 Introduction

Learning to understand the semantics of human languages has been one of the ultimate goals of natural language processing (NLP). Traditional learning approaches have relied on access to parallel corpora of natural language sentences paired with their meanings (Mooney, 2007; Zettlemoyer and Collins, 2007; Lu et al., 2008; Kwiatkowski et al., 2010). However, constructing such semantic annotations can be

difficult and time-consuming. More recently, there has been work on learning from ambiguous supervision where a set of potential sentence meanings are given, only one (or a small subset) of which are correct (Chen and Mooney, 2008; Liang et al., 2009; Bordes et al., 2010; Chen and Mooney, 2011). Given the training data, the system needs to infer the correcting meaning for each training sentence.

Building a lexicon of the formal meaning representations of words and phrases, either implicitly or explicitly, is usually an important step in inferring the meanings of entire sentences. In particular, Chen and Mooney (2011) first learned a lexicon to help them resolve ambiguous supervision of relational data in which the number of choices is exponential. They represent the perceptual context as a graph and allow each sentence in the training data to align to any connected subgraph. Their lexicon learning algorithm finds the common connected subgraph that occurs with a word by taking intersections of the graphs that represent the different contexts in which the word appears. While the algorithm produced a good lexicon for their application of learning to interpret navigation instructions, it only works in batch settings and does not scale well to large datasets. In this paper we introduce a novel online algorithm that is an order of magnitude faster and also produces better results on their navigation task.

In addition to the new lexicon learning algorithm, we also look at modifying the meaning representation grammar (MRG) for their formal semantic language. By using a MRG that correlates better to the structure of natural language, we further improve the performance on the navigation task. Since our al-

gorithm can scale to larger datasets, we present results on collecting and training on additional data from Amazon’s Mechanical Turk. Finally, we show the generality of our approach by demonstrating our system’s ability to learn from a Chinese translation of the training data.

## 2 Background

A common way to learn a lexicon across many different contexts is to find the common parts of the formal representations associated with different occurrences of the same words or phrases (Siskind, 1996). For graphical representations, this involves finding the common subgraph between multiple graphs (Thompson and Mooney, 2003; Chen and Mooney, 2011). In this section we review the lexicon learning algorithm introduced by Chen and Mooney (2011) as well as the overall task they designed to test semantic understanding of navigation instructions.

### 2.1 Navigation Task

The goal of the navigation task is to build a system that can understand free-form natural-language instructions and follow them to move to the intended destination (MacMahon et al., 2006; Shimizu and Haas, 2009; Matuszek et al., 2010; Kollar et al., 2010; Vogel and Jurafsky, 2010; Chen and Mooney, 2011). Chen and Mooney (2011) defined a learning task in which the only supervision the system receives is in the form of observing how humans behave when following sample navigation instructions in a virtual world. Formally, the system is given training data in the form:  $\{(e_1, a_1, w_1), (e_2, a_2, w_2), \dots, (e_n, a_n, w_n)\}$ , where  $e_i$  is a written natural language instruction,  $a_i$  is an observed action sequence, and  $w_i$  is a description of the virtual world. The goal is then to build a system that can produce the correct  $a_j$  given a previously unseen  $(e_j, w_j)$  pair.

Since the observed actions  $a_i$  only consists of low-level actions (e.g. turn left, turn right, walk forward) and not high-level concepts (e.g. turn your back against the wall and walk to the couch), Chen and Mooney first use a set of rules to automatically construct the space of reasonable plans using the action trace and knowledge about the world. The space is represented compactly using a graph as shown in

Figure 1: Examples of *landmarks plans* constructed by Chen and Mooney (2011) and how they computed the intersection of two graphs.

Figure 1. This is what they called a *landmarks plan* and consists of the low-level observed actions interleaved with verification steps indicating what objects should be observed after each action.

Given that these *landmarks plans* contain a lot of extraneous details, Chen and Mooney learn a lexicon and use it to identify and remove the irrelevant parts of the plans. They use a greedy method to remove nodes from the graphs that are not associated with any of the words in the instructions. The remaining *refined landmarks plans* are then treated as supervised training data for a semantic-parser learner, KRISP (Kate and Mooney, 2006). Once a semantic parser is trained, it can be used at test time to transform novel instructions into formal navigation plans which are then carried out by a virtual robot (MacMahon et al., 2006).

### 2.2 Lexicon Learning

The central component of the system is the lexicon learning process which associates words and short phrases (n-grams) to their meanings (connected graphs). To learn the meaning of an n-gram  $w$ , Chen and Mooney first collect all navigation plans  $g$  that co-occur with  $w$ . This forms the initial candidate meaning set for  $w$ . They then repeatedly take the intersections between the candidate meanings to generate additional candidate meanings. They use the term intersection to mean a maximal common subgraph (i.e. it is not a subgraph of any other common subgraphs). In general, there are

multiple possible intersections between two graphs. In this case, they bias toward finding large connected components by greedily removing the largest common connected subgraph from both graphs until the two graphs have no overlapping nodes. The output of the intersection process consists of all the removed subgraphs. An example of the intersection operation is shown in Figure 1.

Once the list of candidate meanings are generated, they are ranked by the following scoring metric for an n-gram  $w$  and a graph  $g$ :

$$Score(w, g) = p(g|w) - p(g|\neg w)$$

Intuitively, the score measures how much more likely a graph  $g$  appears when  $w$  is present compared to when it is not. The probabilities are estimated by counting how many examples contain the word  $w$  or graph  $g$ , ignoring multiple occurrences in a single example.

### 3 Online Lexicon Learning Algorithm

While the algorithm presented by Chen and Mooney (2011) produced good lexicons, it only works in batch settings and does not scale well to large datasets. The bottleneck of their algorithm is the intersection process which is time-consuming to perform. Moreover, their algorithm requires taking many intersections between many different graphs. Even though they use beam-search to limit the size of the candidate set, if the initial candidate meaning set for a n-gram is large, it can take a long time to take just one pass through the list of all candidates. Moreover, reducing the beam size could also hurt the quality of the lexicon learned.

In this section, we present another lexicon learning algorithm that is much faster and works in an online setting. The main insight is that most words or short phrases correspond to small graphs. Thus, we concentrate our attention on only candidate meanings that are less than a certain size. Using this constraint, we generate all the potential small connected subgraphs for each navigation plan in the training examples and discard the original graph. Pseudocode for the new algorithm, Subgraph Generation Online Lexicon Learning (SGOLL) algorithm, is shown in Algorithm 1.

As we encounter each new training example which consists of a written navigation instruction

---

#### Algorithm 1 SUBGRAPH GENERATION ONLINE LEXICON LEARNING (SGOLL)

- 15: **end function**
- 16:
- 17:
- 18: **function** OutputLexicon()
- 19:   **for** n-gram  $w$  that has been observed **do**
- 20:     **if** Number of times  $w$  has been observed is less than *minSup* **then**
- 21:       skip  $w$
- 22:     **end if**
- 23:     **for** subgraph  $g$  that has co-occurred with  $w$  **do**
- 24:       **if** score( $w, g$ ) > threshold  $t$  **then**
- 25:         add  $(w, g)$  to *Lexicon*
- 26:       **end if**
- 27:     **end for**
- 28:   **end for**
- 29: **end function**

---

and the corresponding navigation plan, we first segment the instruction into word tokens and construct n-grams from them. From the corresponding navigation plan, we find all connected subgraphs of size less than or equal to  $m$ . We then update the co-occurrence counts between all the n-grams  $w$  and all the connected subgraphs  $g$ . We also update the counts of how many examples we have encountered so far and counts of the n-grams  $w$  and subgraphs  $g$ . At any given time, we can compute a lexicon using these various counts. Specifically, for each n-gram  $w$ , we look at all the subgraphs  $g$  that co-occurred with it, and compute a score for the pair  $(w, g)$ . If the score is higher than the threshold  $t$ , we add the entry  $(w, g)$  to the lexicon. We use the same scoring function as Chen and Mooney, which can be computed efficiently using the counts we keep. In contrast to Chen and Mooney’s algorithm though, we add the constraint of minimum support by not creating lexical entries for any n-gram  $w$  that appeared in less than  $minSup$  training examples. This is to prevent rarely seen n-grams from receiving high scores in our lexicon simply due to their sparsity. Unless otherwise specified, we compute lexical entries for up to 4-grams with threshold  $t = 0.4$ , maximum subgraph size  $m = 3$ , and minimum support  $minSup = 10$ .

It should be noted that SGOLL can also become computationally intractable if the sizes of the navigations plans are large or if we set the maximum subgraph size  $m$  to a large number. Moreover, the memory requirement can be quite high if there are many different subgraphs  $g$  associated with each n-gram  $w$ . To deal with such scalability issues, we could use beam-search and only keep the top  $k$  candidates associated with each  $w$ . Another important step is to define canonical orderings of the nodes in the graphs. This allows us to determine if two graphs are identical in constant time and also lets us use a hash table to quickly update the co-occurrence and subgraph counts. Thus, even given a large number of subgraphs for each training example, each subgraph can be processed very quickly. Finally, this algorithm readily lends itself to being parallelized. Each processor would get a fraction of the training data and compute the counts individually. Then the counts can be merged together at the end to produce the final lexicon.

### 3.1 Changing the Meaning Representation Grammar

In addition to introducing a new lexicon learning algorithm, we also made another modification to the original system proposed by Chen and Mooney (2011). To train a semantic parser using KRISP (Kate and Mooney, 2006), they had to supply a MRG, a context-free grammar, for their formal navigation plan language. KRISP learns string-kernel classifiers that maps natural language substrings to MRG production rules. Consequently, it is important that the production rules in the MRG mirror the structure of natural language (Kate, 2008).

The original MRG used by Chen and Mooney is a compact grammar that contains many recursive rules that can be used to generate an infinite number of actions or arguments. While these rules are quite expressive, they often do not correspond well to any words or phrases in natural language. To alleviate this problem, we designed another MRG by expanding out many of the rules. For example, the original MRG contained the following production rules for generating an infinite number of travel actions from the root symbol  $S$ .

```
*S -> *Action
*Action -> *Action, *Action
*Action -> *Travel
*Travel -> Travel( )
*Travel -> Travel( steps: *Num )
```

We expand out the production rules as shown below to map  $S$  directly to specific travel actions so they correspond better to patterns such as “go forward” or “walk N steps”.

```
*S -> Travel( )
*S -> Travel( steps: *Num )
*S -> Travel( ), *Action
*S -> Travel( steps: *Num ), *Action
*Action -> *Action, *Action
*Action -> Travel( )
*Action -> Travel( steps: *Num )
```

While this process of expanding the production rules resulted in many more rules, these expanded rules usually correspond better with words or phrases in natural language. We still retain some of the recursive rules to ensure that the formal language remains as expressive as before.

## 4 Collecting Additional Data with Mechanical Turk

One of the motivations for studying ambiguous supervision is the potential ease of acquiring large amounts of training data. Without requiring semantic annotations, a human only has to demonstrate how language is used in context which is generally simple to do. We validate this claim by collecting additional training data for the navigation domain using Mechanical Turk (Snow et al., 2008).

There are two types of data we are interested in collecting: natural language navigation instructions and follower data. Thus, we created two tasks on Mechanical Turk. The first one asks the workers to supply instructions for a randomly generated sequence of actions. The second one asks the workers to try to follow a given navigation instruction in our virtual environment. The latter task is used to generate the corresponding action sequences for instructions collected from the first task.

### 4.1 Task Descriptions

To facilitate the data collection, we first recreated the 3D environments used to collect the original data (MacMahon et al., 2006). We built a Java application that allows the user to freely navigate the three virtual worlds constructed by MacMahon et al. (2006) using the discrete controls of turning left, turning right, and moving forward one step.

The follower task is fairly straightforward using our application. The worker is given a navigation instruction and placed at the starting location. They are asked to follow the navigation instruction as best as they could using the three discrete controls. They could also skip the problem if they did not understand the instruction or if the instruction did not describe a viable route. For each Human Intelligence Task (HIT), we asked the worker to complete 5 follower problems. We paid them \$0.05 for each HIT, or 1 cent per follower problem. The instructions used for the follower problems were mainly collected from our Mechanical Turk instructor task with some of the instructions coming from data collected by MacMahon (2007) that was not used by Chen and Mooney (2011).

The instructor task is slightly more involved because we ask the workers to provide new navigation

	Chen & Mooney	MTurk
# instructions	3236	1011
Vocabulary size	629	590
Avg. # words	7.8 (5.1)	7.69 (7.12)
Avg. # actions	2.1 (2.4)	1.84 (1.24)

Table 1: Statistics about the navigation instruction corpora. The average statistics for each instruction are shown with standard deviations in parentheses.

instructions. The worker is shown a 3D simulation of a randomly generated action sequence between length 1 to 4 and asked to write short, free-form instructions that would lead someone to perform those actions. Since this task requires more time to complete, each HIT consists of only 3 instructor problems. Moreover, we pay the workers \$0.10 for each HIT, or about 3 cents for each instruction they write.

To encourage quality contributions, we use a tiered payment structure (Chen and Dolan, 2011) that rewards the good workers. Workers who have been identified to consistently provide good instructions were allowed to do higher-paying version of the same HITs that paid \$0.15 instead of \$0.10.

### 4.2 Data Statistics

Over a 2-month period we accepted 2,884 follower HITs and 810 instructor HITs from 653 workers. This corresponds to over 14,000 follower traces and 2,400 instructions with most of them consisting of single sentences. For instructions with multiple sentences, we merged all the sentences together and treated it as a single sentence. The total cost of the data collection was \$277.92. While there were 2,400 instructions, we filtered them to make sure they were of reasonable quality. First, we discarded any instructions that did not have at least 5 follower traces. Then we looked at all the follower traces and discarded any instruction that did not have majority agreement on what the correct path is.

Using our strict filter, we were left with slightly over 1,000 instructions. Statistics about the new corpus and the one used by Chen and Mooney can be seen in Table 1. Overall, the new corpus has a slightly smaller vocabulary, and each instruction is slightly shorter both in terms of the number of words and the number of actions.

## 5 Experiments

We evaluate our new lexicon learning algorithm as well as the other modifications to the navigation system using the same three tasks as Chen and Mooney (2011). The first task is disambiguating the training data by inferring the correct navigation plans associated with each training sentence. The second task is evaluating the performance of the semantic parsers trained on the disambiguated data. We measure the performance of both of these tasks by comparing to gold-standard data using the same partial correctness metric used by Chen and Mooney which gives credit to a parse for producing the correct action type and additional credit if the arguments were also correct. Finally, the third task is to complete the end-to-end navigation task. There are two versions of this task, the complete task uses the original instructions which are several sentences long and the other version uses instructions that have been manually split into single sentences. Task completion is measured by the percentage of trials in which the system reached the correct destination (and orientation in the single-sentence version).

We follow the same evaluation scheme as Chen and Mooney and perform leave-one-map-out experiments. For the first task, we build a lexicon using ambiguous training data from two maps, and then use the lexicon to produce the best disambiguated semantic meanings for those same data. For the second and third tasks, we train a semantic parser on the automatically disambiguated data, and test on sentences from the third, unseen map.

For all comparisons to the Chen and Mooney results, we use the performance of their *refined landmarks plans* system which performed the best overall. Moreover, it provides the most direct comparison to our approach since both use a lexicon to refine the *landmarks plans*. Other than the modifications discussed, we use the same components as their system including using KRISP to train the semantic parsers and using the execution module from MacMahon et al. (2006) to carry out the navigation plans.

### 5.1 Inferring Navigation Plans

First, we examine the quality of the refined navigation plans produced using SGOLL’s lexicon. The

	Precision	Recall	F1
Chen and Mooney	78.54	78.10	78.32
SGOLL	87.32	72.96	79.49

Table 2: Partial parse accuracy of how well each algorithm can infer the gold-standard navigation plans.

	Precision	Recall	F1
Chen and Mooney	90.22	55.10	68.37
SGOLL	92.22	55.70	69.43
SGOLL with new MRG	88.36	57.03	69.31

Table 3: Partial parse accuracy of the semantic parsers trained on the disambiguated navigation plans.

precision, recall, and F1 (harmonic mean of precision and recall) of these plans are shown in Table 2. Compared to Chen and Mooney, the plans produced by SGOLL has higher precision and lower recall. This is mainly due to the additional minimum support constraint we added which discards many noisy lexical entries from infrequently seen n-grams.

### 5.2 Training Semantic Parsers

Next we look at the performance of the semantic parsers trained on the inferred navigation plans. The results are shown in Table 3. Here SGOLL performs almost the same as Chen and Mooney, with slightly better precision. We also look at the effect of changing the MRG. Using the new MRG for KRISP to train the semantic parser produced slightly lower precision but higher recall, with similar overall F1 score.

### 5.3 Executing Navigation Plans

Finally, we evaluate the system on the end-to-end navigation task. In addition to SGOLL and SGOLL with the new MRG, we also look at augmenting each of the training splits with the data we collected using Mechanical Turk.

Completion rates for both the single-sentence tasks and the complete tasks are shown in Table 4. Here we see the benefit of each of our modifications. SGOLL outperforms Chen and Mooney’s system on both versions of the navigation task. Using the new MRG to train the semantic parsers further improved performance on both tasks. Finally, augmenting the

	Single-sentence	Complete
Chen and Mooney	54.40%	16.18%
SGOLL	57.09%	17.56%
SGOLL with new MRG	57.28%	19.18%
SGOLL with new MRG and MTurk data	57.62%	20.64%

Table 4: End-to-end navigation task completion rates.

	Computation Time
Chen and Mooney (2011)	2,227.63
SGOLL	157.30
SGOLL with MTurk data	233.27

Table 5: The time (in seconds) it took to build the lexicon.

training data with additional instructions and follower traces collected from Mechanical Turk produced the best results.

#### 5.4 Computation Times

Having established the superior performance of our new system compared to Chen and Mooney’s, we next look at the computational efficiency of SGOLL. The average time (in seconds) it takes for each algorithm to build a lexicon is shown in Table 5. All the results are obtained running the algorithms on Dell PowerEdge 1950 servers with 2x Xeon X5440 (quad-core) 2.83GHz processors and 32GB of RAM. Here SGOLL has a decidedly large advantage over the lexicon learning algorithm from Chen and Mooney, requiring an order of magnitude less time to run. Even after incorporating the new Mechanical Turk data into the training set, SGOLL still takes much less time to build a lexicon. This shows how inefficient it is to perform graph intersection operations and how our online algorithm can more realistically scale to large datasets.

#### 5.5 Experimenting with Chinese Data

In addition to evaluating the system on English data, we also translated the corpus used by Chen and Mooney into Mandarin Chinese.<sup>1</sup> To run our sys-

<sup>1</sup>The translation can be downloaded at <http://www.cs.utexas.edu/~ml/clamp/navigation/>

tem, we first segmented the sentences using the Stanford Chinese Word Segmenter (Chang et al., 2008). We evaluated using the same three tasks as before. This resulted in a precision, recall, and F1 of 87.07, 71.67, and 78.61, respectively for the inferred plans. The trained semantic parser’s precision, recall, and F1 were 88.87, 58.76, and 70.74, respectively. Finally, the system completed 58.70% of the single-sentence task and 20.13% of the complete task. All of these numbers are very similar to the English results, showing the generality of the system in its ability to learn other languages.

#### 5.6 Discussion

We have introduced a novel, online lexicon learning algorithm that is much faster than the one proposed by Chen and Mooney and also performs better on the navigation tasks they devised. Having a computationally efficient algorithm is critical for building systems that learn from ambiguous supervision. Compared to systems that train on supervised semantic annotations, a system that only receives weak, ambiguous training data is expected to have to train on much larger datasets to achieve similar performance. Consequently, such system must be able to scale well in order to keep the learning process tractable. Not only is SGOLL much faster in building a lexicon, it can also be easily parallelized. Moreover, the online nature of SGOLL allows the lexicon to be continually updated while the system is in use. A deployed navigation system can gather new instructions from the user and receive feedback about whether it is performing the correct actions. As new training examples are collected, we can update the corresponding n-gram and subgraph counts without rebuilding the entire lexicon.

One thing to note though is that while SGOLL makes the lexicon learning step much faster and scalable, another bottleneck in the overall system is training the semantic parser. Existing semantic-parser learners such as KRISP were not designed to scale to very large datasets and have trouble training on more than a few thousand examples. Thus, designing new scalable algorithms for learning semantic parsers is critical to scaling the entire system.

We have performed a pilot data collection of new training examples using Mechanical Turk. Even though the instructions were collected from very dif-

ferent sources (paid human subjects from a university for the original data versus workers recruited over the Internet), we showed that adding the new data into the training set improved the system's performance on interpreting instructions from the original corpus. It verified that we are indeed collecting useful information and that non-experts are fully capable of training the system by demonstrating how to use natural language in relevant contexts.

## 6 Related Work

The earliest work on cross-situational word learning was by Siskind (1996) who developed a rule-based system to solve the referential ambiguity problem. However, it did not handle noise and was tested only on artificial data. More recently, Fazly et al. (2010) proposed a probabilistic incremental model that can learn online similar to our algorithm and was tested on transcriptions of child-directed speech. However, they generated the semantic representations from the text itself rather than from the environment. Moreover, the referential ambiguity was introduced artificially by including the correct semantic representation of the neighboring sentence.

Our work falls into the larger framework of learning the semantics of language from weak supervision. This problem can be seen as an alignment problem where each sentence in the training data needs to be aligned to one or more records that represent its meaning. Chen and Mooney (2008) previously introduced another task that aligns sportscasting commentaries to events in a simulated soccer game. Using an EM-like retraining method, they alternated between building a semantic parser and estimating the most likely alignment. Liang et al. (2009) developed an unsupervised approach using a generative model to solve the alignment problem. They demonstrated improved results on matching sentences and events on the sportscasting task and also introduced a new task of aligning weather forecasts to weather information. Kim and Mooney (2010) further improved the generative alignment model by incorporating the full semantic parsing model from Lu et al. (2008). This resulted in a joint generative model that outperformed all previous results. In addition to treating the ambiguous supervision problem as an alignment problem, there

have been other approaches such as treating it as a ranking problem (Bordes et al., 2010), or a PCFG learning problem (Borschinger et al., 2011).

Parallel to the work of learning from ambiguous supervision, other recent work has also looked at training semantic parsers from supervision other than logical-form annotations. Clarke et al. (2010) and Liang et al. (2011) trained systems on question and answer pairs by automatically finding semantic interpretations of the questions that would generate the correct answers. Artzi and Zettlemoyer (2011) use conversation logs between a computer system and a human user to learn to interpret the human utterances. Finally, Goldwasser et al. (2011) presented an unsupervised approach of learning a semantic parser by using an EM-like retraining loop. They use confidence estimation as a proxy for the model's prediction quality, preferring models that have high confidence about their parses.

## 7 Conclusion

Learning the semantics of language from the perceptual context in which it is uttered is a useful approach because only minimal human supervision is required. In this paper we presented a novel online algorithm for building a lexicon from ambiguously supervised relational data. In contrast to the previous approach that computed common subgraphs between different contexts in which an n-gram appeared, we instead focus on small, connected subgraphs and introduce an algorithm, SGOLL, that is an order of magnitude faster. In addition to being more scalable, SGOLL also performed better on the task of interpreting navigation instructions. In addition, we showed that changing the MRG and collecting additional training data from Mechanical Turk further improve the performance of the overall navigation system. Finally, we demonstrated the generality of the system by using it to learn Chinese navigation instructions and achieved similar results.

## Acknowledgments

The research in this paper was supported by the National Science Foundation (NSF) under the grants IIS-0712097 and IIS-1016312. We thank Lu Guo for performing the translation of the corpus into Mandarin Chinese.

## Abstract

We propose Symbol-Refined Tree Substitution Grammars (SR-TSGs) for syntactic parsing. An SR-TSG is an extension of the conventional TSG model where each nonterminal symbol can be refined (subcategorized) to fit the training data. We aim to provide a unified model where TSG rules and symbol refinement are learned from training data in a fully automatic and consistent fashion. We present a novel probabilistic SR-TSG model based on the hierarchical Pitman-Yor Process to encode backoff smoothing from a fine-grained SR-TSG to simpler CFG rules, and develop an efficient training method based on Markov Chain Monte Carlo (MCMC) sampling. Our SR-TSG parser achieves an F1 score of 92.4% in the Wall Street Journal (WSJ) English Penn Treebank parsing task, which is a 7.7 point improvement over a conventional Bayesian TSG parser, and better than state-of-the-art discriminative reranking parsers.

## 1 Introduction

Syntactic parsing has played a central role in natural language processing. The resulting syntactic analysis can be used for various applications such as machine translation (Galley et al., 2004; DeNeefe and Knight, 2009), sentence compression (Cohn and Lapata, 2009; Yamangil and Shieber, 2010), and question answering (Wang et al., 2007). Probabilistic context-free grammar (PCFG) underlies many statistical parsers, however, it is well known that the PCFG rules extracted from treebank data via maximum likelihood estimation do not perform well due to unrealistic context freedom assumptions (Klein and Manning, 2003).

In recent years, there has been an increasing interest in tree substitution grammar (TSG) as an alternative to CFG for modeling syntax trees (Post and Gildea, 2009; Tenenbaum et al., 2009; Cohn et al., 2010). TSG is a natural extension of CFG in which nonterminal symbols can be rewritten (substituted) with arbitrarily large tree fragments. These tree fragments have great advantages over tiny CFG rules since they can capture non-local contexts explicitly such as predicate-argument structures, idioms and grammatical agreements (Cohn et al., 2010). Previous work on TSG parsing (Cohn et al., 2010; Post and Gildea, 2009; Bansal and Klein, 2010) has consistently shown that a probabilistic TSG (PTSG) parser is significantly more accurate than a PCFG parser, but is still inferior to state-of-the-art parsers (e.g., the Berkeley parser (Petrov et al., 2006) and the Charniak parser (Charniak and Johnson, 2005)). One major drawback of TSG is that the context freedom assumptions still remain at substitution sites, that is, TSG tree fragments are generated that are conditionally independent of all others given root nonterminal symbols. Furthermore, when a sentence is unparseable with large tree fragments, the PTSG parser usually uses naive CFG rules derived from its backoff model, which diminishes the benefits obtained from large tree fragments.

On the other hand, current state-of-the-art parsers use *symbol refinement* techniques (Johnson, 1998; Collins, 2003; Matsuzaki et al., 2005). Symbol refinement is a successful approach for weakening context freedom assumptions by dividing coarse treebank symbols (e.g. NP and VP) into subcategories, rather than extracting large tree fragments. As shown in several studies on TSG parsing (Zuidema, 2007; Bansal and Klein, 2010), large

tree fragments and symbol refinement work complementarily for syntactic parsing. For example, Bansal and Klein (2010) have reported that deterministic symbol refinement with heuristics helps improve the accuracy of a TSG parser.

In this paper, we propose Symbol-Refined Tree Substitution Grammars (SR-TSGs) for syntactic parsing. SR-TSG is an extension of the conventional TSG model where each nonterminal symbol can be refined (subcategorized) to fit the training data. Our work differs from previous studies in that we focus on a unified model where TSG rules and symbol refinement are learned from training data in a fully automatic and consistent fashion. We also propose a novel probabilistic SR-TSG model with the hierarchical Pitman-Yor Process (Pitman and Yor, 1997), namely a sort of nonparametric Bayesian model, to encode backoff smoothing from a fine-grained SR-TSG to simpler CFG rules, and develop an efficient training method based on blocked MCMC sampling.

Our SR-TSG parser achieves an F1 score of 92.4% in the WSJ English Penn Treebank parsing task, which is a 7.7 point improvement over a conventional Bayesian TSG parser, and superior to state-of-the-art discriminative reranking parsers.

## 2 Background and Related Work

Our SR-TSG work is built upon recent work on Bayesian TSG induction from parse trees (Post and Gildea, 2009; Cohn et al., 2010). We firstly review the Bayesian TSG model used in that work, and then present related work on TSGs and symbol refinement.

A TSG consists of a 4-tuple,  $G = (T, N, S, R)$ , where  $T$  is a set of *terminal symbols*,  $N$  is a set of *nonterminal symbols*,  $S \in N$  is the distinguished *start nonterminal symbol* and  $R$  is a set of productions (a.k.a. rules). The productions take the form of *elementary trees* i.e., tree fragments of height  $\geq 1$ . The root and internal nodes of the elementary trees are labeled with nonterminal symbols, and leaf nodes are labeled with either terminal or nonterminal symbols. Nonterminal leaves are referred to as *frontier nonterminals*, and form the substitution sites to be combined with other elementary trees.

A *derivation* is a process of forming a parse tree. It starts with a root symbol and rewrites (substi-

tutes) nonterminal symbols with elementary trees until there are no remaining frontier nonterminals. Figure 1a shows an example parse tree and Figure 1b shows its example TSG derivation. Since different derivations may produce the same parse tree, recent work on TSG induction (Post and Gildea, 2009; Cohn et al., 2010) employs a probabilistic model of a TSG and predicts derivations from observed parse trees in an unsupervised way.

A Probabilistic Tree Substitution Grammar (PTSG) assigns a probability to each rule in the grammar. The probability of a derivation is defined as the product of the probabilities of its component elementary trees as follows.

$$p(\mathbf{e}) = \prod_{x \rightarrow e \in \mathbf{e}} p(e|x),$$

where  $\mathbf{e} = (e_1, e_2, \dots)$  is a sequence of elementary trees used for the derivation,  $x = \text{root}(e)$  is the root symbol of  $e$ , and  $p(e|x)$  is the probability of generating  $e$  given its root symbol  $x$ . As in a PCFG,  $e$  is generated conditionally independent of all others given  $x$ .

The posterior distribution over elementary trees given a parse tree  $t$  can be computed by using the Bayes' rule:

$$p(\mathbf{e}|t) \propto p(t|\mathbf{e})p(\mathbf{e}).$$

where  $p(t|\mathbf{e})$  is either equal to 1 (when  $t$  and  $\mathbf{e}$  are consistent) or 0 (otherwise). Therefore, the task of TSG induction from parse trees turns out to consist of modeling the prior distribution  $p(\mathbf{e})$ . Recent work on TSG induction defines  $p(\mathbf{e})$  as a nonparametric Bayesian model such as the Dirichlet Process (Ferguson, 1973) or the Pitman-Yor Process to encourage sparse and compact grammars.

Several studies have combined TSG induction and symbol refinement. An adaptor grammar (Johnson et al., 2007a) is a sort of nonparametric Bayesian TSG model with symbol refinement, and is thus closely related to our SR-TSG model. However, an adaptor grammar differs from ours in that all its rules are *complete*: all leaf nodes must be terminal symbols, while our model permits nonterminal symbols as leaf nodes. Furthermore, adaptor grammars have largely been applied to the task of unsupervised structural induction from raw texts such as

Figure 1: (a) Example parse tree. (b) Example TSG derivation of (a). (c) Example SR-TSG derivation of (a). The refinement annotation is hyphenated with a nonterminal symbol.

morphology analysis, word segmentation (Johnson and Goldwater, 2009), and dependency grammar induction (Cohen et al., 2010), rather than constituent syntax parsing.

An all-fragments grammar (Bansal and Klein, 2010) is another variant of TSG that aims to utilize all possible subtrees as rules. It maps a TSG to an implicit representation to make the grammar tractable and practical for large-scale parsing. The manual symbol refinement described in (Klein and Manning, 2003) was applied to an all-fragments grammar and this improved accuracy in the English WSJ parsing task. As mentioned in the introduction, our model focuses on the automatic learning of a TSG and symbol refinement without heuristics.

### 3 Symbol-Refined Tree Substitution Grammars

In this section, we propose Symbol-Refined Tree Substitution Grammars (SR-TSGs) for syntactic parsing. Our SR-TSG model is an extension of the conventional TSG model where every symbol of the elementary trees can be refined to fit the training data. Figure 1c shows an example of SR-TSG derivation. As with previous work on TSG induction, our task is the induction of SR-TSG derivations from a corpus of parse trees in an unsupervised fashion. That is, we wish to infer the symbol subcategories of every node and substitution site (i.e., nodes where substitution occurs) from parse trees. Extracted rules and their probabilities can be used to parse new raw sentences.

#### 3.1 Probabilistic Model

We define a probabilistic model of an SR-TSG based on the Pitman-Yor Process (PYP) (Pitman and Yor, 1997), namely a sort of nonparametric Bayesian model. The PYP produces power-law distributions, which have been shown to be well-suited for such uses as language modeling (Teh, 2006b), and TSG induction (Cohn et al., 2010). One major issue as regards modeling an SR-TSG is that the space of the grammar rules will be very sparse since SR-TSG allows for arbitrarily large tree fragments and also an arbitrarily large set of symbol subcategories. To address the sparseness problem, we employ a hierarchical PYP to encode a backoff scheme from the SR-TSG rules to simpler CFG rules, inspired by recent work on dependency parsing (Blunsom and Cohn, 2010).

Our model consists of a three-level hierarchy. Table 1 shows an example of the SR-TSG rule and its backoff tree fragments as an illustration of this three-level hierarchy. The topmost level of our model is a distribution over the SR-TSG rules as follows.

$$\begin{aligned}
 e | x_k &\sim G_{x_k} \\
 G_{x_k} &\sim \text{PYP}(d_{x_k}, \theta_{x_k}, P^{\text{sr-tsg}}(\cdot | x_k)),
 \end{aligned}$$

where  $x_k$  is a refined root symbol of an elementary tree  $e$ , while  $x$  is a raw nonterminal symbol in the corpus and  $k = 0, 1, \dots$  is an index of the symbol subcategory. Suppose  $x$  is NP and its symbol subcategory is 0, then  $x_k$  is NP<sub>0</sub>. The PYP has three parameters:  $(d_{x_k}, \theta_{x_k}, P^{\text{sr-tsg}}(\cdot | x_k))$ .

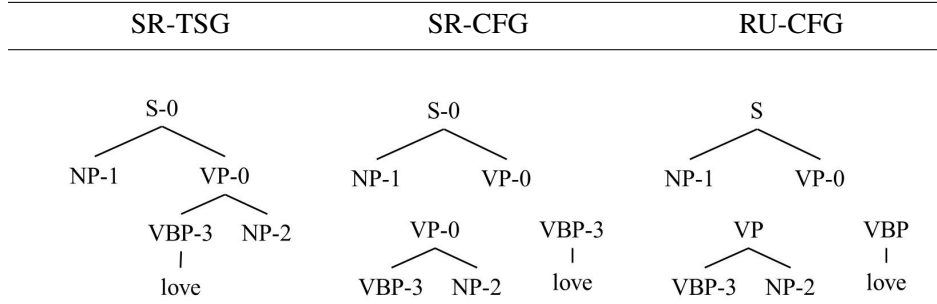

Table 1: Example three-level backoff.

is a *base distribution* over infinite space of symbol-refined elementary trees rooted with  $x_k$ , which provides the backoff probability of  $e$ . The remaining parameters  $d_{x_k}$  and  $\theta_{x_k}$  control the strength of the base distribution.

The backoff probability  $P^{\text{sr-tsg}}(e|x_k)$  is given by the product of *symbol-refined CFG (SR-CFG)* rules that  $e$  contains as follows.

$$\begin{aligned}
 P^{\text{sr-tsg}}(e|x_k) &= \prod_{f \in F(e)} s_{c_f} \times \prod_{i \in I(e)} (1 - s_{c_i}) \\
 &\times H(\text{cfg-rules}(e|x_k)) \\
 \alpha|x_k &\sim H_{x_k} \\
 H_{x_k} &\sim \text{PYP}(d_x, \theta_x, P^{\text{sr-cfg}}(\cdot|x_k)),
 \end{aligned}$$

where  $F(e)$  is a set of frontier nonterminal nodes and  $I(e)$  is a set of internal nodes in  $e$ .  $c_f$  and  $c_i$  are nonterminal symbols of nodes  $f$  and  $i$ , respectively.  $s_c$  is the probability of stopping the expansion of a node labeled with  $c$ . SR-CFG rules are CFG rules where every symbol is refined, as shown in Table 1. The function  $\text{cfg-rules}(e|x_k)$  returns the SR-CFG rules that  $e$  contains, which take the form of  $x_k \rightarrow \alpha$ . Each SR-CFG rule  $\alpha$  rooted with  $x_k$  is drawn from the backoff distribution  $H_{x_k}$ , and  $H_{x_k}$  is produced by the PYP with parameters:  $(d_x, \theta_x, P^{\text{sr-cfg}})$ . This distribution over the SR-CFG rules forms the second level hierarchy of our model.

The backoff probability of the SR-CFG rule,  $P^{\text{sr-cfg}}(\alpha|x_k)$ , is given by the *root-unrefined CFG (RU-CFG)* rule as follows,

$$\begin{aligned}
 P^{\text{sr-cfg}}(\alpha|x_k) &= I(\text{root-unrefine}(\alpha|x_k)) \\
 \alpha|x &\sim I_x \\
 I_x &\sim \text{PYP}(d'_x, \theta'_x, P^{\text{ru-cfg}}(\cdot|x)),
 \end{aligned}$$

where the function  $\text{root-unrefine}(\alpha|x_k)$  returns the RU-CFG rule of  $\alpha$ , which takes the form of  $x \rightarrow \alpha$ . The RU-CFG rule is a CFG rule where the root symbol is unrefined and all leaf nonterminal symbols are refined, as shown in Table 1. Each RU-CFG rule  $\alpha$  rooted with  $x$  is drawn from the backoff distribution  $I_x$ , and  $I_x$  is produced by a PYP. This distribution over the RU-CFG rules forms the third level hierarchy of our model. Finally, we set the backoff probability of the RU-CFG rule,  $P^{\text{ru-cfg}}(\alpha|x)$ , so that it is uniform as follows.

$$P^{\text{ru-cfg}}(\alpha|x) = \frac{1}{|x \rightarrow \cdot|}.$$

where  $|x \rightarrow \cdot|$  is the number of RU-CFG rules rooted with  $x$ . Overall, our hierarchical model encodes backoff smoothing consistently from the SR-TSG rules to the SR-CFG rules, and from the SR-CFG rules to the RU-CFG rules. As shown in (Blunsom and Cohn, 2010; Cohen et al., 2010), the parsing accuracy of the TSG model is strongly affected by its backoff model. The effects of our hierarchical backoff model on parsing performance are evaluated in Section 5.

## 4 Inference

We use Markov Chain Monte Carlo (MCMC) sampling to infer the SR-TSG derivations from parse trees. MCMC sampling is a widely used approach for obtaining random samples from a probability distribution. In our case, we wish to obtain derivation samples of an SR-TSG from the posterior distribution,  $p(\mathbf{e}|\mathbf{t}, \mathbf{d}, \boldsymbol{\theta}, \mathbf{s})$ .

The inference of the SR-TSG derivations corresponds to inferring two kinds of latent variables: latent symbol subcategories and latent substitution

sites. We first infer latent symbol subcategories for every symbol in the parse trees, and then infer latent substitution sites stepwise. During the inference of symbol subcategories, every internal node is fixed as a substitution site. After that, we unfix that assumption and infer latent substitution sites given symbol-refined parse trees. This stepwise learning is simple and efficient in practice, but we believe that the joint learning of both latent variables is possible, and we will deal with this in future work. Here we describe each inference algorithm in detail.

#### 4.1 Inference of Symbol Subcategories

For the inference of latent symbol subcategories, we adopt split and merge training (Petrov et al., 2006) as follows. In each split-merge step, each symbol is split into at most two subcategories. For example, every NP symbol in the training data is split into either  $NP_0$  or  $NP_1$  to maximize the posterior probability. After convergence, we measure the loss of each split symbol in terms of the likelihood incurred when removing it, then the smallest 50% of the newly split symbols as regards that loss are merged to avoid overfitting. The split-merge algorithm terminates when the total number of steps reaches the user-specified value.

In each splitting step, we use two types of blocked MCMC algorithm: the *sentence-level* blocked Metropolis-Hastings (MH) sampler and the *tree-level* blocked Gibbs sampler, while (Petrov et al., 2006) use a different MLE-based model and the EM algorithm. Our sampler iterates sentence-level sampling and tree-level sampling alternately.

The sentence-level MH sampler is a recently proposed algorithm for grammar induction (Johnson et al., 2007b; Cohn et al., 2010). In this work, we apply it to the training of symbol splitting. The MH sampler consists of the following three steps: for each sentence, 1) calculate the inside probability (Lari and Young, 1991) in a bottom-up manner, 2) sample a derivation tree in a top-down manner, and 3) accept or reject the derivation sample by using the MH test. See (Cohn et al., 2010) for details. This sampler simultaneously updates blocks of latent variables associated with a sentence, thus it can find MAP solutions efficiently.

The tree-level blocked Gibbs sampler focuses on the type of SR-TSG rules and simultaneously up-

dates all root and child nodes that are annotated with the same SR-TSG rule. For example, the sampler collects all nodes that are annotated with  $S_0 \rightarrow NP_1VP_2$ , then updates those nodes to another subcategory such as  $S_0 \rightarrow NP_2VP_0$  according to the posterior distribution. This sampler is similar to table label resampling (Johnson and Goldwater, 2009), but differs in that our sampler can update multiple table labels simultaneously when multiple tables are labeled with the same elementary tree. The tree-level sampler also simultaneously updates blocks of latent variables associated with the type of SR-TSG rules, thus it can find MAP solutions efficiently.

#### 4.2 Inference of Substitution Sites

After the inference of symbol subcategories, we use Gibbs sampling to infer the substitution sites of parse trees as described in (Cohn and Lapata, 2009; Post and Gildea, 2009). We assign a binary variable to each internal node in the training data, which indicates whether that node is a substitution site or not. For each iteration, the Gibbs sampler works by sampling the value of each binary variable in random order. See (Cohn et al., 2010) for details.

During the inference, our sampler ignores the symbol subcategories of internal nodes of elementary trees since they do not affect the derivation of the SR-TSG. For example, the elementary trees “ $(S_0 (NP_0 NNP_0) VP_0)$ ” and “ $(S_0 (NP_1 NNP_0) VP_0)$ ” are regarded as being the same when we calculate the generation probabilities according to our model. This heuristic is helpful for finding large tree fragments and learning compact grammars.

#### 4.3 Hyperparameter Estimation

We treat hyperparameters  $\{\mathbf{d}, \boldsymbol{\theta}\}$  as random variables and update their values for every MCMC iteration. We place a prior on the hyperparameters as follows:  $d \sim \text{Beta}(1, 1)$ ,  $\theta \sim \text{Gamma}(1, 1)$ . The values of  $d$  and  $\theta$  are optimized with the auxiliary variable technique (Teh, 2006a).

## 5 Experiment

### 5.1 Settings

#### 5.1.1 Data Preparation

We ran experiments on the Wall Street Journal (WSJ) portion of the English Penn Treebank data set (Marcus et al., 1993), using a standard data split (sections 2–21 for training, 22 for development and 23 for testing). We also used section 2 as a *small* training set for evaluating the performance of our model under low-resource conditions. Henceforth, we distinguish the small training set (section 2) from the full training set (sections 2-21). The treebank data is right-binarized (Matsuzaki et al., 2005) to construct grammars with only unary and binary productions. We replace lexical words with count  $\leq 5$  in the training data with one of 50 unknown words using lexical features, following (Petrov et al., 2006). We also split off all the function tags and eliminated empty nodes from the data set, following (Johnson, 1998).

#### 5.1.2 Training and Parsing

For the inference of symbol subcategories, we trained our model with the MCMC sampler by using 6 split-merge steps for the full training set and 3 split-merge steps for the small training set. Therefore, each symbol can be subdivided into a maximum of  $2^6 = 64$  and  $2^3 = 8$  subcategories, respectively. In each split-merge step, we initialized the sampler by randomly splitting every symbol in two subcategories and ran the MCMC sampler for 1000 iterations. After that, to infer the substitution sites, we initialized the model with the final sample from a run on the small training set, and used the Gibbs sampler for 2000 iterations. We estimated the optimal values of the stopping probabilities  $s$  by using the development set.

We obtained the parsing results with the MAX-RULE-PRODUCT algorithm (Petrov et al., 2006) by using the SR-TSG rules extracted from our model. We evaluated the accuracy of our parser by bracketing F1 score of predicted parse trees. We used EVALB<sup>1</sup> to compute the F1 score. In all our experiments, we conducted ten independent runs to train our model, and selected the one that performed best on the development set in terms of parsing accuracy.

## 5.2 Results and Discussion

### 5.2.1 Comparison of SR-TSG with TSG

We compared the SR-TSG model with the CFG and TSG models as regards parsing accuracy. We also tested our model with three backoff hierarchy settings to evaluate the effects of backoff smoothing on parsing accuracy. Table 2 shows the F1 scores of the CFG, TSG and SR-TSG parsers for small and full training sets. In Table 2, SR-TSG ( $P^{sr-tsg}$ ) denotes that we used only the topmost level of the hierarchy. Similarly, SR-TSG ( $P^{sr-tsg}, P^{sr-cfg}$ ) denotes that we used only the  $P^{sr-tsg}$  and  $P^{sr-cfg}$  backoff models.

Our best model, SR-TSG ( $P^{sr-tsg}, P^{sr-cfg}, P^{ru-cfg}$ ), outperformed both the CFG and TSG models on both the small and large training sets. This result suggests that the conventional TSG model trained from the vanilla treebank is insufficient to resolve

structural ambiguities caused by coarse symbol annotations in a training corpus. As we expected, symbol refinement can be helpful with the TSG model for further fitting the training set and improving the parsing accuracy.

The performance of the SR-TSG parser was strongly affected by its backoff models. For example, the simplest model,  $P^{SR-TSG}$ , performed poorly compared with our best model. This result suggests that the SR-TSG rules extracted from the training set are very sparse and cannot cover the space of unknown syntax patterns in the testing set. Therefore, sophisticated backoff modeling is essential for the SR-TSG parser. Our hierarchical PYP modeling technique is a successful way to achieve backoff smoothing from sparse SR-TSG rules to simpler CFG rules, and offers the advantage of automatically estimating the optimal backoff probabilities from the training set.

We compared the rule sizes and frequencies of SR-TSG with those of TSG. The rule sizes of SR-

TSG and TSG are defined as the number of CFG rules that the elementary tree contains. Figure 2 shows a histogram of the SR-TSG and TSG rule sizes (by *unrefined* token) on the small training set. For example, SR-TSG rules:  $S_1 \rightarrow NP_0VP_1$  and  $S_0 \rightarrow NP_1VP_2$  were considered to be the same token. In Figure 2, we can see that there are almost the same number of SR-TSG rules and TSG rules with size = 1. However, there are more SR-TSG rules than TSG rules with size  $\geq 2$ . This shows that an SR-TSG can use various large tree fragments depending on the context, which is specified by the symbol subcategories.

### 5.2.2 Comparison of SR-TSG with Other Models

We compared the accuracy of the SR-TSG parser with that of conventional high-performance parsers. Table 3 shows the F1 scores of an SR-TSG and conventional parsers with the full training set. In Table 3, SR-TSG (single) is a standard SR-TSG parser,

and SR-TSG (multiple) is a combination of sixteen independently trained SR-TSG models, following the work of (Petrov, 2010).

Our SR-TSG (single) parser achieved an F1 score of 91.1%, which is a 6.4 point improvement over the conventional Bayesian TSG parser reported by (Cohn et al., 2010). Our model can be viewed as an extension of Cohn’s work by the incorporation of symbol refinement. Therefore, this result confirms that a TSG and symbol refinement work complementarily in improving parsing accuracy. Compared with a symbol-refined CFG model such as the Berkeley parser (Petrov et al., 2006), the SR-TSG model can use large tree fragments, which strengthens the probability of frequent syntax patterns in the training set. Indeed, the few very large rules of our model memorized full parse trees of sentences, which were repeated in the training set.

The SR-TSG (single) is a pure generative model of syntax trees but it achieved results comparable to those of discriminative parsers. It should be noted that discriminative reranking parsers such as (Charniak and Johnson, 2005) and (Huang, 2008) are constructed on a generative parser. The reranking parser takes the k-best lists of candidate trees or a packed forest produced by a baseline parser (usually a generative model), and then reranks the candidates using arbitrary features. Hence, we can expect that combining our SR-TSG model with a discriminative reranking parser would provide better performance than SR-TSG alone.

Recently, (Petrov, 2010) has reported that combining multiple grammars trained independently gives significantly improved performance over a single grammar alone. We applied his method (referred to as a TREE-LEVEL inference) to the SR-TSG model as follows. We first trained sixteen SR-TSG models independently and produced a 100-best list of the derivations for each model. Then, we erased the subcategory information of parse trees and selected the best tree that achieved the highest likelihood under the product of sixteen models. The combination model, SR-TSG (multiple), achieved an F1 score of 92.4%, which is a state-of-the-art result for the WSJ parsing task. Compared with discriminative reranking parsers, combining multiple grammars by using the product model provides the advantage that it does not require any additional training. Several

studies (Fossum and Knight, 2009; Zhang et al., 2009) have proposed different approaches that involve combining k-best lists of candidate trees. We will deal with those methods in future work.

Let us note the relation between SR-CFG, TSG and SR-TSG. TSG is weakly equivalent to CFG and generates the same set of strings. For example, the TSG rule “ $S \rightarrow (NP\ NNP)\ VP$ ” with probability  $p$  can be converted to the equivalent CFG rules as follows: “ $S \rightarrow NP^{NNP}\ VP$ ” with probability  $p$  and “ $NP^{NNP} \rightarrow NNP$ ” with probability 1. From this viewpoint, TSG utilizes surrounding symbols (NNP of  $NP^{NNP}$  in the above example) as latent variables with which to capture context information. The search space of learning a TSG given a parse tree is  $\mathcal{O}(2^n)$  where  $n$  is the number of internal nodes of the parse tree. On the other hand, an SR-CFG utilizes an arbitrary index such as  $0, 1, \dots$  as latent variables and the search space is larger than that of a TSG when the symbol refinement model allows for more than two subcategories for each symbol. Our experimental results confirm that jointly modeling both latent variables using our SR-TSG assists accurate parsing.

## 6 Conclusion

We have presented an SR-TSG, which is an extension of the conventional TSG model where each symbol of tree fragments can be automatically subcategorized to address the problem of the conditional independence assumptions of a TSG. We proposed a novel backoff modeling of an SR-TSG based on the hierarchical Pitman-Yor Process and sentence-level and tree-level blocked MCMC sampling for training our model. Our best model significantly outperformed the conventional TSG and achieved state-of-the-art result in a WSJ parsing task. Future work will involve examining the SR-TSG model for different languages and for unsupervised grammar induction.

## Abstract

Learning for sentence re-writing is a fundamental task in natural language processing and information retrieval. In this paper, we propose a new class of kernel functions, referred to as string re-writing kernel, to address the problem. A string re-writing kernel measures the similarity between *two pairs of strings*, each pair representing re-writing of a string. It can capture the lexical and structural similarity between two pairs of sentences without the need of constructing syntactic trees. We further propose an instance of string re-writing kernel which can be computed efficiently. Experimental results on benchmark datasets show that our method can achieve better results than state-of-the-art methods on two sentence re-writing learning tasks: paraphrase identification and recognizing textual entailment.

## 1 Introduction

Learning for sentence re-writing is a fundamental task in natural language processing and information retrieval, which includes paraphrasing, textual entailment and transformation between query and document title in search.

The key question here is how to represent the re-writing of sentences. In previous research on sentence re-writing learning such as paraphrase identification and recognizing textual entailment, most representations are based on the lexicons (Zhang and Patrick, 2005; Lintean and Rus, 2011; de Marneffe et al., 2006) or the syntactic trees (Das and Smith,

Figure 1: Example of re-writing. (A) is a re-writing rule and (B) is a re-writing of sentence.

2009; Heilman and Smith, 2010) of the sentence pairs.

In (Lin and Pantel, 2001; Barzilay and Lee, 2003), re-writing rules serve as underlying representations for paraphrase generation/discovery. Motivated by the work, we represent re-writing of sentences by all possible re-writing rules that can be applied into it. For example, in Fig. 1, (A) is one re-writing rule that can be applied into the sentence re-writing (B). Specifically, we propose a new class of kernel functions (Schölkopf and Smola, 2002), called string re-writing kernel (SRK), which defines the similarity between two re-writings (pairs) of strings as the inner product between them in the feature space induced by all the re-writing rules. SRK is different from existing kernels in that it is for re-writing and defined on *two pairs of strings*. SRK can capture the lexical and structural similarity between re-writings of sentences and does not need to parse the sentences and create the syntactic trees of them.

One challenge for using SRK lies in the high computational cost of straightforwardly computing the kernel, because it involves two re-writings of strings (i.e., four strings) and a large number of re-writing rules. We are able to develop an instance of SRK, referred to as kb-SRK, which directly computes the number of common rewriting rules without explic-

itly calculating the inner product between feature vectors, and thus drastically reduce the time complexity.

Experimental results on benchmark datasets show that SRK achieves better results than the state-of-the-art methods in paraphrase identification and recognizing textual entailment. Note that SRK is very flexible to the formulations of sentences. For example, informally written sentences such as long queries in search can also be effectively handled.

## 2 Related Work

The string kernel function, first proposed by Lodhi et al. (2002), measures the similarity between two strings by their shared substrings. Leslie et al. (2002) proposed the  $k$ -spectrum kernel which represents strings by their contiguous substrings of length  $k$ . Leslie et al. (2004) further proposed a number of string kernels including the wildcard kernel to facilitate inexact matching between the strings. The string kernels defined on two pairs of objects (including strings) were also developed, which decompose the similarity into product of similarities between individual objects using tensor product (Basilico and Hofmann, 2004; Ben-Hur and Noble, 2005) or Cartesian product (Kashima et al., 2009).

The task of paraphrasing usually consists of paraphrase pattern generation and paraphrase identification. Paraphrase pattern generation is to automatically extract semantically equivalent patterns (Lin and Pantel, 2001; Bhagat and Ravichandran, 2008) or sentences (Barzilay and Lee, 2003). Paraphrase identification is to identify whether two given sentences are a paraphrase of each other. The methods proposed so far formalized the problem as classification and used various types of features such as bag-of-words feature, edit distance (Zhang and Patrick, 2005), dissimilarity kernel (Linteau and Rus, 2011) predicate-argument structure (Qiu et al., 2006), and tree edit model (which is based on a tree kernel) (Heilman and Smith, 2010) in the classification task. Among the most successful methods, Wan et al. (2006) enriched the feature set by the BLEU metric and dependency relations. Das and Smith (2009) used the quasi-synchronous grammar formalism to incorporate features from WordNet, named entity recognizer, POS tagger, and dependency la-

bels from aligned trees.

The task of recognizing textual entailment is to decide whether the hypothesis sentence can be entailed by the premise sentence (Giampiccolo et al., 2007). In recognizing textual entailment, de Marneffe et al. (2006) classified sentences pairs on the basis of word alignments. MacCartney and Manning (2008) used an inference procedure based on natural logic and combined it with the methods by de Marneffe et al. (2006). Harmeling (2007) and Heilman and Smith (2010) classified sequence pairs based on transformation on syntactic trees. Zanzotto et al. (2007) used a kernel method on syntactic tree pairs (Moschitti and Zanzotto, 2007).

## 3 Kernel Approach to Sentence Re-Writing Learning

We formalize sentence re-writing learning as a kernel method. Following the literature of string kernel, we use the terms “string” and “character” instead of “sentence” and “word”.

Suppose that we are given training data consisting of re-writings of strings and their responses

$$((s_1, t_1), y_1), \dots, ((s_n, t_n), y_n) \in (\Sigma^* \times \Sigma^*) \times Y$$

where  $\Sigma$  denotes the character set,  $\Sigma^* = \bigcup_{i=0}^{\infty} \Sigma^i$  denotes the string set, which is the Kleene closure of set  $\Sigma$ ,  $Y$  denotes the set of responses, and  $n$  is the number of instances.  $(s_i, t_i)$  is a re-writing consisting of the source string  $s_i$  and the target string  $t_i$ .  $y_i$  is the response which can be a category, ordinal number, or real number. In this paper, for simplicity we assume that  $Y = \{\pm 1\}$  (e.g. paraphrase/non-paraphrase). Given a new string re-writing  $(s, t) \in \Sigma^* \times \Sigma^*$ , our goal is to predict its response  $y$ . That is, the training data consists of binary classes of string re-writings, and the prediction is made for the new re-writing based on learning from the training data.

We take the kernel approach to address the learning task. The kernel on re-writings of strings is defined as

$$K : (\Sigma^* \times \Sigma^*) \times (\Sigma^* \times \Sigma^*) \rightarrow \mathbb{R}$$

satisfying for all  $(s_i, t_i), (s_j, t_j) \in \Sigma^* \times \Sigma^*$ ,

$$K((s_i, t_i), (s_j, t_j)) = \langle \Phi(s_i, t_i), \Phi(s_j, t_j) \rangle$$

where  $\Phi$  maps each re-writing (pair) of strings into a high dimensional Hilbert space  $\mathcal{H}$ , referred to as

feature space. By the representer theorem (Kimeldorf and Wahba, 1971; Schölkopf and Smola, 2002), it can be shown that the response  $y$  of a new string re-writing  $(s, t)$  can always be represented as

$$y = \text{sign}\left(\sum_{i=1}^n \alpha_i y_i K((s_i, t_i), (s, t))\right)$$

where  $\alpha_i \geq 0$ ,  $(i = 1, \dots, n)$  are parameters. That is, it is determined by a linear combination of the similarities between the new instance and the instances in training set. It is also known that by employing a learning model such as SVM (Vapnik, 2000), such a linear combination can be automatically learned by solving a quadratic optimization problem. The question then becomes how to design the kernel function for the task.

#### 4 String Re-writing Kernel

Let  $\Sigma$  be the set of characters and  $\Sigma^*$  be the set of strings. Let wildcard domain  $D \subseteq \Sigma^*$  be the set of strings which can be replaced by wildcards.

The string re-writing kernel measures the similarity between two string re-writings through the re-writing rules that can be applied into them. Formally, given re-writing rule set  $R$  and wildcard domain  $D$ , the *string re-writing kernel (SRK)* is defined as

$$K((s_1, t_1), (s_2, t_2)) = \langle \Phi(s_1, t_1), \Phi(s_2, t_2) \rangle \quad (1)$$

where  $\Phi(s, t) = (\phi_r(s, t))_{r \in R}$  and

$$\phi_r(s, t) = n\lambda^i \quad (2)$$

where  $n$  is the number of contiguous substring pairs of  $(s, t)$  that re-writing rule  $r$  matches,  $i$  is the number of wildcards in  $r$ , and  $\lambda \in (0, 1]$  is a factor punishing each occurrence of wildcard.

A *re-writing rule* is defined as a triple  $r = (\beta_s, \beta_t, \tau)$  where  $\beta_s, \beta_t \in (\Sigma \cup \{*\})^*$  denote source and target string patterns and  $\tau \subseteq \text{ind}_*(\beta_s) \times \text{ind}_*(\beta_t)$  denotes the alignments between the wildcards in the two string patterns. Here  $\text{ind}_*(\beta)$  denotes the set of indexes of wildcards in  $\beta$ .

We say that a re-writing rule  $(\beta_s, \beta_t, \tau)$  *matches* a string pair  $(s, t)$ , if and only if string patterns  $\beta_s$  and  $\beta_t$  can be changed into  $s$  and  $t$  respectively by substituting each wildcard in the string patterns with an element in the strings, where the elements are defined in the wildcard domain  $D$  and the wildcards

$\beta_s[i]$  and  $\beta_t[j]$  are substituted by the same elements, when there is an alignment  $(i, j) \in \tau$ .

For example, the re-writing rule in Fig. 1 (A) can be formally written as  $r = (\beta_s, \beta_t, \tau)$  where  $\beta_s = (*, \text{wrote}, *)$ ,  $\beta_t = (*, \text{was}, \text{written}, \text{by}, *)$  and  $\tau = \{(1, 5), (3, 1)\}$ . It matches with the string pair in Fig. 1 (B).

String re-writing kernel is a class of kernels which depends on re-writing rule set  $R$  and wildcard domain  $D$ . Here we provide some examples. Obviously, the effectiveness and efficiency of SRK depend on the choice of  $R$  and  $D$ .

**Example 1.** We define the pairwise  $k$ -spectrum kernel (*ps-SRK*)  $K_k^{ps}$  as the re-writing rule kernel under  $R = \{(\beta_s, \beta_t, \tau) \mid \beta_s, \beta_t \in \Sigma^k, \tau = \emptyset\}$  and any  $D$ . It can be shown that  $K_k^{ps}((s_1, t_1), (s_2, t_2)) = K_k^{spec}(s_1, s_2)K_k^{spec}(t_1, t_2)$  where  $K_k^{spec}(x, y)$  is equivalent to the  $k$ -spectrum kernel proposed by Leslie et al. (2002).

**Example 2.** The pairwise  $k$ -wildcard kernel (*pw-SRK*)  $K_k^{pw}$  is defined as the re-writing rule kernel under  $R = \{(\beta_s, \beta_t, \tau) \mid \beta_s, \beta_t \in (\Sigma \cup \{*\})^k, \tau = \emptyset\}$  and  $D = \Sigma$ . It can be shown that  $K_k^{pw}((s_1, t_1), (s_2, t_2)) = K_{(k,k)}^{wc}(s_1, s_2)K_{(k,k)}^{wc}(t_1, t_2)$  where  $K_{(k,k)}^{wc}(x, y)$  is a special case ( $m=k$ ) of the  $(k, m)$ -wildcard kernel proposed by Leslie et al. (2004).

Both kernels shown above are represented as the product of two kernels defined separately on strings  $s_1, s_2$  and  $t_1, t_2$ , and that is to say that they do not consider the alignment relations between the strings.

#### 5 K-gram Bijective String Re-writing Kernel

Next we propose another instance of string re-writing kernel, called the  $k$ -gram bijective string re-writing kernel (*kb-SRK*). As will be seen, kb-SRK can be computed efficiently, although it is defined on two pairs of strings and is not decomposed (note that ps-SRK and pw-SRK are decomposed).

##### 5.1 Definition

The kb-SRK has the following properties: (1) A wildcard can only substitute a single character, denoted as “?”. (2) The two string patterns in a re-writing rule are of length  $k$ . (3) The alignment relation in a re-writing rule is bijective, i.e., there is a one-to-one mapping between the wildcards in

the string patterns. Formally, the  $k$ -gram *bijective string re-writing kernel*  $\mathbb{K}_k$  is defined as a string re-writing kernel under the re-writing rule set  $\mathbf{R} = \{(\beta_s, \beta_t, \tau) \mid \beta_s, \beta_t \in (\Sigma \cup \{?\})^k, \tau \text{ is bijective}\}$  and the wildcard domain  $\mathbf{D} = \Sigma$ .

Since each re-writing rule contains two string patterns of length  $k$  and each wildcard can only substitute one character, a re-writing rule can only match  $k$ -gram pairs in  $(s, t)$ . We can rewrite Eq. (2) as

$$\phi_r(s, t) = \sum_{\alpha_s \in \text{k-grams}(s)} \sum_{\alpha_t \in \text{k-grams}(t)} \bar{\phi}_r(\alpha_s, \alpha_t) \quad (3)$$

where  $\bar{\phi}_r(\alpha_s, \alpha_t) = \lambda^i$  if  $r$  (with  $i$  wildcards) matches  $(\alpha_s, \alpha_t)$ , otherwise  $\bar{\phi}_r(\alpha_s, \alpha_t) = 0$ .

For ease of computation, we re-write kb-SRK as

$$\begin{aligned} & \mathbb{K}_k((s_1, t_1), (s_2, t_2)) \\ = & \sum_{\substack{\alpha_{s_1} \in \text{k-grams}(s_1) \\ \alpha_{t_1} \in \text{k-grams}(t_1)}} \sum_{\substack{\alpha_{s_2} \in \text{k-grams}(s_2) \\ \alpha_{t_2} \in \text{k-grams}(t_2)}} \bar{\mathbb{K}}_k((\alpha_{s_1}, \alpha_{t_1}), (\alpha_{s_2}, \alpha_{t_2})) \end{aligned} \quad (4)$$

where

$$\bar{\mathbb{K}}_k = \sum_{r \in \mathbf{R}} \bar{\phi}_r(\alpha_{s_1}, \alpha_{t_1}) \bar{\phi}_r(\alpha_{s_2}, \alpha_{t_2}) \quad (5)$$

## 5.2 Algorithm for Computing Kernel

A straightforward computation of kb-SRK would be intractable. The computation of  $\mathbb{K}_k$  in Eq. (4) needs computations of  $\bar{\mathbb{K}}_k$  conducted  $O((n - k + 1)^4)$  times, where  $n$  denotes the maximum length of strings. Furthermore, the computation of  $\bar{\mathbb{K}}_k$  in Eq. (5) needs to perform matching of all the re-writing rules with the two  $k$ -gram pairs  $(\alpha_{s_1}, \alpha_{t_1})$ ,  $(\alpha_{s_2}, \alpha_{t_2})$ , which has time complexity  $O(k!)$ .

In this section, we will introduce an efficient algorithm, which can compute  $\bar{\mathbb{K}}_k$  and  $\mathbb{K}_k$  with the time complexities of  $O(k)$  and  $O(kn^2)$ , respectively. The latter is verified empirically.

### 5.2.1 Transformation of Problem

For ease of manipulation, our method transforms the computation of kernel on  $k$ -grams into the computation on a new data structure called lists of doubles. We first explain how to make the transformation.

Suppose that  $\alpha_1, \alpha_2 \in \Sigma^k$  are  $k$ -grams, we use  $\alpha_1[i]$  and  $\alpha_2[i]$  to represent the  $i$ -th characters of them. We call a pair of characters a double. Thus  $\Sigma \times \Sigma$  denotes the set of doubles and  $\alpha_s^D, \alpha_t^D \in (\Sigma \times$

$$\begin{aligned} \alpha_{s_1} &= \text{abbccbb} ; & \alpha_{s_2} &= \text{abccdd} ; \\ \alpha_{t_1} &= \text{cbcbbcb} ; & \alpha_{t_2} &= \text{cbccdc} ; \end{aligned}$$

Figure 2: Example of two  $k$ -gram pairs.

$$\begin{aligned} \alpha_s^D &= (\text{a, a}), (\text{b, b}), (\mathbf{b, c}), (\text{c, c}), (\text{c, c}), (\mathbf{b, d}), (\mathbf{b, d}) \\ \alpha_t^D &= (\text{c, c}), (\text{b, b}), (\text{c, c}), (\mathbf{b, c}), (\mathbf{b, d}), (\text{c, c}), (\mathbf{b, d}) \end{aligned}$$

Figure 3: Example of the pair of double lists combined from the two  $k$ -gram pairs in Fig. 2. Non-identical doubles are in bold.

$\Sigma)^k$  denote lists of doubles. The following operation combines two  $k$ -grams into a list of doubles.

$$\alpha_1 \otimes \alpha_2 = ((\alpha_1[1], \alpha_2[1]), \dots, (\alpha_1[k], \alpha_2[k])).$$

We denote  $\alpha_1 \otimes \alpha_2[i]$  as the  $i$ -th element of the list. Fig. 3 shows example lists of doubles combined from  $k$ -grams.

We introduce the set of *identical doubles*  $\mathbf{I} = \{(c, c) \mid c \in \Sigma\}$  and the set of *non-identical doubles*  $\mathbf{N} = \{(c, c') \mid c, c' \in \Sigma \text{ and } c \neq c'\}$ . Obviously,  $\mathbf{I} \cup \mathbf{N} = \Sigma \times \Sigma$  and  $\mathbf{I} \cap \mathbf{N} = \emptyset$ .

We define the set of *re-writing rules for double lists*  $\mathbf{R}^D = \{r^D = (\beta_s^D, \beta_t^D, \tau) \mid \beta_s^D, \beta_t^D \in (\mathbf{I} \cup \{?\})^k, \tau \text{ is a bijective alignment}\}$  where  $\beta_s^D$  and  $\beta_t^D$  are lists of identical doubles including wildcards and with length  $k$ . We say rule  $r^D$  matches a pair of double lists  $(\alpha_s^D, \alpha_t^D)$  iff.  $\beta_s^D, \beta_t^D$  can be changed into  $\alpha_s^D$  and  $\alpha_t^D$  by substituting each wildcard pair to a double in  $\Sigma \times \Sigma$ , and the double substituting the wildcard pair  $\beta_s^D[i]$  and  $\beta_t^D[j]$  must be an identical double when there is an alignment  $(i, j) \in \tau$ . The rule set defined here and the rule set in Sec. 4 only differ on the elements where re-writing occurs. Fig. 4 (B) shows an example of re-writing rule for double lists. The pair of double lists in Fig. 3 can match with the re-writing rule.

### 5.2.2 Computing $\bar{\mathbb{K}}_k$

We consider how to compute  $\bar{\mathbb{K}}_k$  by extending the computation from  $k$ -grams to double lists.

The following lemma shows that computing the weighted sum of re-writing rules matching  $k$ -gram pairs  $(\alpha_{s_1}, \alpha_{t_1})$  and  $(\alpha_{s_2}, \alpha_{t_2})$  is equivalent to computing the weighted sum of re-writing rules for double lists matching  $(\alpha_{s_1} \otimes \alpha_{s_2}, \alpha_{t_1} \otimes \alpha_{t_2})$ .

Figure 4: For re-writing rule (A) matching both  $k$ -gram pairs shown in Fig. 2, there is a corresponding re-writing rule for double lists (B) matching the pair of double lists shown in Fig. 3.

$$\begin{aligned} \#_{\Sigma \times \Sigma}(\alpha_s^D) &= \{(a, a): 1, (b, b): 1, (\mathbf{b}, \mathbf{c}): 1, (\mathbf{b}, \mathbf{d}): 2, (c, c): 2\} \\ \#_{\Sigma \times \Sigma}(\alpha_t^D) &= \{(a, a): 0, (b, b): 1, (\mathbf{b}, \mathbf{c}): 1, (\mathbf{b}, \mathbf{d}): 2, (c, c): 3\} \end{aligned}$$

Figure 5: Example of  $\#_{\Sigma \times \Sigma}(\cdot)$  for the two double lists shown in Fig. 3. Doubles not appearing in both  $\alpha_s^D$  and  $\alpha_t^D$  are not shown.

**Lemma 1.** *For any two  $k$ -gram pairs  $(\alpha_{s_1}, \alpha_{t_1})$  and  $(\alpha_{s_2}, \alpha_{t_2})$ , there exists a one-to-one mapping from the set of re-writing rules matching them to the set of re-writing rules matching the corresponding double lists  $(\alpha_{s_1} \otimes \alpha_{s_2}, \alpha_{t_1} \otimes \alpha_{t_2})$ .*

The re-writing rule in Fig. 4 (A) matches the  $k$ -gram pairs in Fig. 2. Equivalently, the re-writing rule for double lists in Fig. 4 (B) matches the pair of double lists in Fig. 3. By lemma 1 and Eq. 5, we have

$$\bar{K}_k = \sum_{r^D \in R^D} \bar{\phi}_{r^D}(\alpha_{s_1} \otimes \alpha_{s_2}, \alpha_{t_1} \otimes \alpha_{t_2}) \quad (6)$$

where  $\bar{\phi}_{r^D}(\alpha_s^D, \alpha_t^D) = \lambda^{2i}$  if the rewriting rule for double lists  $r^D$  with  $i$  wildcards matches  $(\alpha_s^D, \alpha_t^D)$ , otherwise  $\bar{\phi}_{r^D}(\alpha_s^D, \alpha_t^D) = 0$ . To get  $\bar{K}_k$ , we just need to compute the weighted sum of re-writing rules for double lists matching  $(\alpha_{s_1} \otimes \alpha_{s_2}, \alpha_{t_1} \otimes \alpha_{t_2})$ . Thus, we can work on the ‘‘combined’’ pair of double lists instead of two pairs of  $k$ -grams.

Instead of enumerating all possible re-writing rules and checking whether they can match the given pair of double lists, we only calculate the number of possibilities of ‘‘generating’’ from the pair of double lists to the re-writing rules matching it, which can be carried out efficiently. We say that a re-writing rule of double lists can be generated from a pair of double lists  $(\alpha_s^D, \alpha_t^D)$ , if they match with each other. From the definition of  $R^D$ , in each generation, the identical doubles in  $\alpha_s^D$  and  $\alpha_t^D$  can be either or not substituted by an aligned wildcard pair in the re-writing

---

### Algorithm 1: Computing $\bar{K}_k$

---

**Input:**  $k$ -gram pair  $(\alpha_{s_1}, \alpha_{t_1})$  and  $(\alpha_{s_2}, \alpha_{t_2})$

**Output:**  $\bar{K}_k((\alpha_{s_1}, \alpha_{t_1}), (\alpha_{s_2}, \alpha_{t_2}))$

- 1 Set  $(\alpha_s^D, \alpha_t^D) = (\alpha_{s_1} \otimes \alpha_{s_2}, \alpha_{t_1} \otimes \alpha_{t_2})$ ;
  - 2 Compute  $\#_{\Sigma \times \Sigma}(\alpha_s^D)$  and  $\#_{\Sigma \times \Sigma}(\alpha_t^D)$ ;
  - 3  $result = 1$ ;
  - 4 **for** each  $e \in \Sigma \times \Sigma$  satisfies  $\#_e(\alpha_s^D) + \#_e(\alpha_t^D) \neq 0$  **do**
  - 5      $g_e = 0, n_e = \min\{\#_e(\alpha_s^D), \#_e(\alpha_t^D)\}$ ;
  - 6     **for**  $0 \leq i \leq n_e$  **do**
  - 7          $g_e = g_e + a_i^{(e)} \lambda^{2i}$ ;
  - 8      $result = result * g$ ;
  - 9 **return**  $result$ ;
- 

rule, and all the non-identical doubles in  $\alpha_s^D$  and  $\alpha_t^D$  must be substituted by aligned wildcard pairs. From this observation and Eq. 6,  $\bar{K}_k$  only depends on the number of times each double occurs in the double lists.

Let  $e$  be a double. We denote  $\#_e(\alpha^D)$  as the number of times  $e$  occurs in the list of doubles  $\alpha^D$ . Also, for a set of doubles  $S \subseteq \Sigma \times \Sigma$ , we denote  $\#_S(\alpha^D)$  as a vector in which each element represents  $\#_e(\alpha^D)$  of each double  $e \in S$ . We can find a function  $g$  such that

$$\bar{K}_k = g(\#_{\Sigma \times \Sigma}(\alpha_{s_1} \otimes \alpha_{s_2}), \#_{\Sigma \times \Sigma}(\alpha_{t_1} \otimes \alpha_{t_2})) \quad (7)$$

Alg. 1 shows how to compute  $\bar{K}_k$ .  $\#_{\Sigma \times \Sigma}(\cdot)$  is computed from the two pairs of  $k$ -grams in line 1-2. The final score is made through the iterative calculation on the two lists (lines 4-8).

The key of Alg. 1 is the calculation of  $g_e$  based on  $a_i^{(e)}$  (line 7). Here we use  $a_i^{(e)}$  to denote the number of possibilities for which  $i$  pairs of aligned wildcards can be generated from  $e$  in both  $\alpha_s^D$  and  $\alpha_t^D$ .  $a_i^{(e)}$  can be computed as follows.

(1) If  $e \in N$  and  $\#_e(\alpha_s^D) \neq \#_e(\alpha_t^D)$ , then  $a_i^{(e)} = 0$  for any  $i$ .

(2) If  $e \in N$  and  $\#_e(\alpha_s^D) = \#_e(\alpha_t^D) = j$ , then  $a_j^{(e)} = j!$  and  $a_i^{(e)} = 0$  for any  $i \neq j$ .

(3) If  $e \in I$ , then  $a_i^{(e)} = \binom{\#_e(\alpha_s^D)}{i} \binom{\#_e(\alpha_t^D)}{i} i!$ .

We next explain the rationale behind the above computations. In (1), since  $\#_e(\alpha_s^D) \neq \#_e(\alpha_t^D)$ , it is impossible to generate a re-writing rule in which all

the occurrences of non-identical double  $e$  are substituted by pairs of aligned wildcards. In (2),  $j$  pairs of aligned wildcards can be generated from all the occurrences of non-identical double  $e$  in both  $\alpha_s^D$  and  $\alpha_t^D$ . The number of combinations thus is  $j!$ . In (3), a pair of aligned wildcards can either be generated or not from a pair of identical doubles in  $\alpha_s^D$  and  $\alpha_t^D$ . We can select  $i$  occurrences of identical double  $e$  from  $\alpha_s^D$ ,  $i$  occurrences from  $\alpha_t^D$ , and generate all possible aligned wildcards from them.

In the loop of lines 4-8, we only need to consider  $a_i^{(e)}$  for  $0 \leq i \leq \min\{\#_e(\alpha_s^D), \#_e(\alpha_t^D)\}$ , because  $a_i^{(e)} = 0$  for the rest of  $i$ .

To sum up, Eq. 7 can be computed as below, which is exactly the computation at lines 3-8.

$$g(\#_{\Sigma \times \Sigma}(\alpha_s^D), \#_{\Sigma \times \Sigma}(\alpha_t^D)) = \prod_{e \in \Sigma \times \Sigma} \left( \sum_{i=0}^{n_e} a_i^{(e)} \lambda^{2i} \right) \quad (8)$$

For the  $k$ -gram pairs in Fig. 2, we first create lists of doubles in Fig. 3 and compute  $\#_{\Sigma \times \Sigma}(\cdot)$  for them (lines 1-2 of Alg. 1), as shown in Fig. 5. We next compute  $K_k$  from  $\#_{\Sigma \times \Sigma}(\alpha_s^D)$  and  $\#_{\Sigma \times \Sigma}(\alpha_t^D)$  in Fig. 5 (lines 3-8 of Alg. 1) and obtain  $K_k = (1)(1 + \lambda^2)(\lambda^2)(2\lambda^4)(1 + 6\lambda^2 + 6\lambda^4) = 12\lambda^{12} + 24\lambda^{10} + 14\lambda^8 + 2\lambda^6$ .

### 5.2.3 Computing $K_k$

Algorithm 2 shows how to compute  $K_k$ . It prepares two maps  $m_s$  and  $m_t$  and two vectors of counters  $c_s$  and  $c_t$ . In  $m_s$  and  $m_t$ , each key  $\#_N(\cdot)$  maps a set of values  $\#_{\Sigma \times \Sigma}(\cdot)$ . Counters  $c_s$  and  $c_t$  count the frequency of each  $\#_{\Sigma \times \Sigma}(\cdot)$ . Recall that  $\#_N(\alpha_{s_1} \otimes \alpha_{s_2})$  denotes a vector whose element is  $\#_e(\alpha_{s_1} \otimes \alpha_{s_2})$  for  $e \in N$ .  $\#_{\Sigma \times \Sigma}(\alpha_{s_1} \otimes \alpha_{s_2})$  denotes a vector whose element is  $\#_e(\alpha_{s_1} \otimes \alpha_{s_2})$  where  $e$  is any possible double.

One can easily verify the output of the algorithm is exactly the value of  $K_k$ . First,  $\bar{K}_k((\alpha_{s_1}, \alpha_{t_1}), (\alpha_{s_2}, \alpha_{t_2})) = 0$  if  $\#_N(\alpha_{s_1} \otimes \alpha_{s_2}) \neq \#_N(\alpha_{t_1} \otimes \alpha_{t_2})$ . Therefore, we only need to consider those  $\alpha_{s_1} \otimes \alpha_{s_2}$  and  $\alpha_{t_1} \otimes \alpha_{t_2}$  which have the same key (lines 10-13). We group the  $k$ -gram pairs by their key in lines 2-5 and lines 6-9.

Moreover, the following relation holds

$$\bar{K}_k((\alpha_{s_1}, \alpha_{t_1}), (\alpha_{s_2}, \alpha_{t_2})) = \bar{K}_k((\alpha'_{s_1}, \alpha'_{t_1}), (\alpha'_{s_2}, \alpha'_{t_2}))$$

if  $\#_{\Sigma \times \Sigma}(\alpha_{s_1} \otimes \alpha_{s_2}) = \#_{\Sigma \times \Sigma}(\alpha'_{s_1} \otimes \alpha'_{s_2})$  and  $\#_{\Sigma \times \Sigma}(\alpha_{t_1} \otimes \alpha_{t_2}) = \#_{\Sigma \times \Sigma}(\alpha'_{t_1} \otimes \alpha'_{t_2})$ , where  $\alpha'_{s_1}, \alpha'_{s_2}, \alpha'_{t_1}, \alpha'_{t_2}$  are

---

### Algorithm 2: Computing $K_k$

---

**Input:** string pair  $(s_1, t_1)$  and  $(s_2, t_2)$ , window size  $k$

**Output:**  $K_k((s_1, t_1), (s_2, t_2))$

```

1 Initialize two maps  $m_s$  and  $m_t$  and two counters  $c_s$  and  $c_t$ ;
2 for each  $k$ -gram  $\alpha_{s_1}$  in  $s_1$  do
3   for each  $k$ -gram  $\alpha_{s_2}$  in  $s_2$  do
4     Update  $m_s$  with key-value pair  $(\#_N(\alpha_{s_1} \otimes \alpha_{s_2}), \#_{\Sigma \times \Sigma}(\alpha_{s_1} \otimes \alpha_{s_2}))$ ;
5      $c_s[\#_{\Sigma \times \Sigma}(\alpha_{s_1} \otimes \alpha_{s_2})]++$ ;
6 for each  $k$ -gram  $\alpha_{t_1}$  in  $t_1$  do
7   for each  $k$ -gram  $\alpha_{t_2}$  in  $t_2$  do
8     Update  $m_t$  with key-value pair  $(\#_N(\alpha_{t_1} \otimes \alpha_{t_2}), \#_{\Sigma \times \Sigma}(\alpha_{t_1} \otimes \alpha_{t_2}))$ ;
9      $c_t[\#_{\Sigma \times \Sigma}(\alpha_{t_1} \otimes \alpha_{t_2})]++$ ;
10 for each key  $\in m_s.keys \cap m_t.keys$  do
11   for each  $v_s \in m_s[key]$  do
12     for each  $v_t \in m_t[key]$  do
13       result +=  $c_s[v_s]c_t[v_t]g(v_s, v_t)$ ;
14 return result;
```

---

other  $k$ -grams. Therefore, we only need to take  $\#_{\Sigma \times \Sigma}(\alpha_{s_1} \otimes \alpha_{s_2})$  and  $\#_{\Sigma \times \Sigma}(\alpha_{t_1} \otimes \alpha_{t_2})$  as the value under each key and count its frequency. That is to say,  $\#_{\Sigma \times \Sigma}$  provides sufficient statistics for computing  $\bar{K}_k$ .

The quantity  $g(v_s, v_t)$  in line 13 is computed by Alg. 1 (lines 3-8).

### 5.3 Time Complexity

The time complexities of Alg. 1 and Alg. 2 are shown below.

For Alg. 1, lines 1-2 can be executed in  $O(k)$ . The time for executing line 7 is less than  $\#_e(\alpha_s^D) + \#_e(\alpha_t^D) + 1$  for each  $e$  satisfying  $\#_e(\alpha_s^D) \neq 0$  or  $\#_e(\alpha_t^D) \neq 0$ . Since  $\sum_{e \in \Sigma \times \Sigma} \#_e(\alpha_s^D) = \sum_{e \in \Sigma \times \Sigma} \#_e(\alpha_t^D) = k$ , the time for executing lines 3-8 is less than  $4k$ , which results in the  $O(k)$  time complexity of Alg. 1.

For Alg. 2, we denote  $n = \max\{|s_1|, |s_2|, |t_1|, |t_2|\}$ . It is easy to see that if the maps and counters in the algorithm are implemented by hash maps, the time complexities of lines 2-5 and lines 6-9 are  $O(kn^2)$ . However, analyzing the time complexity of lines 10-

Figure 6: Relation between ratio  $\mathcal{C}/n_{avg}^2$  and window size  $k$  when running Alg. 2 on MSR Paraphrases Corpus.

13 is quite difficult.

Lemma 2 and Theorem 1 provide an upper bound of the number of times computing  $g(v_s, v_t)$  in line 13, denoted as  $\mathcal{C}$ .

**Lemma 2.** For  $\alpha_{s_1} \in k\text{-grams}(s_1)$  and  $\alpha_{s_2}, \alpha'_{s_2} \in k\text{-grams}(s_2)$ , we have  $\#\Sigma \times \Sigma(\alpha_{s_1} \otimes \alpha_{s_2}) = \#\Sigma \times \Sigma(\alpha_{s_1} \otimes \alpha'_{s_2})$  if  $\#_N(\alpha_{s_1} \otimes \alpha_{s_2}) = \#_N(\alpha_{s_1} \otimes \alpha'_{s_2})$ .

**Theorem 1.**  $\mathcal{C}$  is  $O(n^3)$ .

By Lemma 2, each  $m_s[key]$  contains at most  $n - k + 1$  elements. Together with the fact that  $\sum_{key} m_s[key] = (n - k + 1)^2$ , Theorem 1 is proved. It can be also proved that  $\mathcal{C}$  is  $O(n^2)$  when  $k = 1$ .

Empirical study shows that  $O(n^3)$  is a loose upper bound for  $\mathcal{C}$ . Let  $n_{avg}$  denote the average length of  $s_1, t_1, s_2$  and  $t_2$ . Our experiment on all pairs of sentences on MSR Paraphrase (Fig. 6) shows that  $\mathcal{C}$  is in the same order of  $n_{avg}^2$  in the worst case and  $\mathcal{C}/n_{avg}^2$  decreases with increasing  $k$  in both average case and worst case, which indicates that  $\mathcal{C}$  is  $O(n^2)$  and the overall time complexity of Alg. 2 is  $O(kn^2)$ .

## 6 Experiments

We evaluated the performances of the three types of string re-writing kernels on paraphrase identification and recognizing textual entailment: pairwise  $k$ -spectrum kernel (ps-SRK), pairwise  $k$ -wildcard kernel (pw-SRK), and  $k$ -gram bijective string re-writing kernel (kb-SRK). We set  $\lambda = 1$  for all kernels. The performances were measured by accuracy (e.g. percentage of correct classifications).

In both experiments, we used LIBSVM with default parameters (Chang et al., 2011) as the classifier. All the sentences in the training and test sets were segmented into words by the tokenizer at OpenNLP (Baldrige et al., ). We further conducted stemming on the words with IVEONIK English Stemmer (<http://www.iveonik.com/>).

We normalized each kernel by  $\tilde{K}(x, y) = \frac{K(x, y)}{\sqrt{K(x, x)K(y, y)}}$  and then tried them under different window sizes  $k$ . We also tried to combine the kernels with two lexical features “unigram precision and recall” proposed in (Wan et al., 2006), referred to as PR. For each kernel  $K$ , we tested the window size settings of  $K_1 + \dots + K_{k_{max}}$  ( $k_{max} \in \{1, 2, 3, 4\}$ ) together with the combination with PR and we report the best accuracies of them in Tab 1 and Tab 2.

### 6.1 Paraphrase Identification

The task of paraphrase identification is to examine whether two sentences have the same meaning. We trained and tested all the methods on the MSR Paraphrase Corpus (Dolan and Brockett, 2005; Quirk et al., 2004) consisting of 4,076 sentence pairs for training and 1,725 sentence pairs for testing.

The experimental results on different SRKs are shown in Table 1. It can be seen that kb-SRK outperforms ps-SRK and pw-SRK. The results by the state-of-the-art methods reported in previous work are also included in Table 1. kb-SRK outperforms the existing lexical approach (Zhang and Patrick, 2005) and kernel approach (Lintean and Rus, 2011). It also works better than the other approaches listed in the table, which use syntactic trees or dependency relations.

Fig. 7 gives detailed results of the kernels under different maximum  $k$ -gram lengths  $k_{max}$  with and without PR. The results of ps-SRK and pw-SRK without combining PR under different  $k$  are all below 71%, therefore they are not shown for clar-

ity. By comparing the results of kb-SRK and pw-SRK we can see that the bijective property in kb-SRK is really helpful for improving the performance (note that both methods use wildcards). Furthermore, the performances of kb-SRK with and without combining PR increase dramatically with increasing  $k_{max}$  and reach the peaks (better than state-of-the-art) when  $k_{max}$  is four, which shows the power of the lexical and structural similarity captured by kb-SRK.

## 6.2 Recognizing Textual Entailment

Recognizing textual entailment is to determine whether a sentence (sometimes a short paragraph) can entail the other sentence (Giampiccolo et al., 2007). RTE-3 is a widely used benchmark dataset. Following the common practice, we combined the development set of RTE-3 and the whole datasets of RTE-1 and RTE-2 as training data and took the test set of RTE-3 as test data. The train and test sets contain 3,767 and 800 sentence pairs.

The results are shown in Table 2. Again, kb-SRK outperforms ps-SRK and pw-SRK. As indicated in (Heilman and Smith, 2010), the top-performing RTE systems are often built with significant engi-

Figure 8: Performances of different kernels under different maximum window size  $k_{max}$  on RTE-3.

neering efforts. Therefore, we only compare with the six systems which involves less engineering. kb-SRK still outperforms most of those state-of-the-art methods even if it does not exploit any other lexical semantic sources and syntactic analysis tools.

Fig. 8 shows the results of the kernels under different parameter settings. Again, the results of ps-SRK and pw-SRK without combining PR are too low to be shown (all below 55%). We can see that PR is an effective method for this dataset and the overall performances are substantially improved after combining it with the kernels. The performance of kb-SRK reaches the peak when window size becomes two.

## 7 Conclusion

In this paper, we have proposed a novel class of kernel functions for sentence re-writing, called string re-writing kernel (SRK). SRK measures the lexical and structural similarity between two pairs of sentences without using syntactic trees. The approach is theoretically sound and is flexible to formulations of sentences. A specific instance of SRK, referred to as kb-SRK, has been developed which can balance the effectiveness and efficiency for sentence re-writing. Experimental results show that kb-SRK achieve better results than state-of-the-art methods on paraphrase identification and recognizing textual entailment.

## Abstract

To adapt a translation model trained from the data in one domain to another, previous works paid more attention to the studies of parallel corpus while ignoring the in-domain monolingual corpora which can be obtained more easily. In this paper, we propose a novel approach for translation model adaptation by utilizing in-domain monolingual topic information instead of the in-domain bilingual corpora, which incorporates the topic information into translation probability estimation. Our method establishes the relationship between the out-of-domain bilingual corpus and the in-domain monolingual corpora via a topic mapping and phrase-topic distribution probability estimation from in-domain monolingual corpora. Experimental result on the NIST Chinese-English translation task shows that our approach significantly outperforms the baseline system.

## 1 Introduction

In recent years, statistical machine translation(SMT) has been rapidly developing with more and more novel translation models being proposed and put into practice (Koehn et al., 2003; Och and Ney, 2004; Galley et al., 2006; Liu et al., 2006; Chiang, 2007; Chiang, 2010). However, similar to other natural language processing(NLP) tasks, SMT systems often suffer from domain adaptation problem during practical applications. The simple reason is that the underlying statistical models always tend to closely

approximate the empirical distributions of the training data, which typically consist of bilingual sentences and monolingual target language sentences. When the translated texts and the training data come from the same domain, SMT systems can achieve good performance, otherwise the translation quality degrades dramatically. Therefore, it is of significant importance to develop translation systems which can be effectively transferred from one domain to another, for example, from *newswire* to *weblog*.

According to adaptation emphases, domain adaptation in SMT can be classified into translation model adaptation and language model adaptation. Here we focus on how to adapt a translation model, which is trained from the large-scale out-of-domain bilingual corpus, for domain-specific translation task, leaving others for future work. In this aspect, previous methods can be divided into two categories: one paid attention to collecting more sentence pairs by information retrieval technology (Hildebrand et al., 2005) or synthesized parallel sentences (Ueffing et al., 2008; Wu et al., 2008; Bertoldi and Federico, 2009; Schwenk and Senellart, 2009), and the other exploited the full potential of existing parallel corpus in a *mixture-modeling* (Foster and Kuhn, 2007; Civera and Juan, 2007; Lv et al., 2007) framework. However, these approaches focused on the studies of bilingual corpus synthesis and exploitation while ignoring the monolingual corpora, therefore limiting the potential of further translation quality improvement.

In this paper, we propose a novel adaptation method to adapt the translation model for domain-specific translation task by utilizing in-domain

\*Part of this work was done during the first author's internship at Baidu.

monolingual corpora. Our approach is inspired by the recent studies (Zhao and Xing, 2006; Zhao and Xing, 2007; Tam et al., 2007; Gong and Zhou, 2010; Ruiz and Federico, 2011) which have shown that a particular translation always appears in some specific topical contexts, and the topical context information has a great effect on translation selection. For example, “*bank*” often occurs in the sentences related to the *economy* topic when translated into “*yínháng*”, and occurs in the sentences related to the *geography* topic when translated to “*hén*”. Therefore, the co-occurrence frequency of the phrases in some specific context can be used to constrain the translation candidates of phrases. In a monolingual corpus, if “*bank*” occurs more often in the sentences related to the *economy* topic than the ones related to the *geography* topic, it is more likely that “*bank*” is translated to “*yínháng*” than to “*hén*”. With the out-of-domain bilingual corpus, we first incorporate the topic information into translation probability estimation, aiming to quantify the effect of the topical context information on translation selection. Then, we rescore all phrase pairs according to the phrase-topic and the word-topic posterior distributions of the additional in-domain monolingual corpora. As compared to the previous works, our method takes advantage of both the in-domain monolingual corpora and the out-of-domain bilingual corpus to incorporate the topic information into our translation model, thus breaking down the corpus barrier for translation quality improvement. The experimental results on the NIST data set demonstrate the effectiveness of our method.

The reminder of this paper is organized as follows: Section 2 provides a brief description of translation probability estimation. Section 3 introduces the adaptation method which incorporates the topic information into the translation model; Section 4 describes and discusses the experimental results; Section 5 briefly summarizes the recent related work about translation model adaptation. Finally, we end with a conclusion and the future work in Section 6.

## 2 Background

The statistical translation model, which contains phrase pairs with bi-directional *phrase probabilities* and bi-directional *lexical probabilities*, has a great

effect on the performance of SMT system. Phrase probability measures the co-occurrence frequency of a phrase pair, and lexical probability is used to validate the quality of the phrase pair by checking how well its words are translated to each other.

According to the definition proposed by (Koehn et al., 2003), given a source sentence  $\mathbf{f} = f_1^J = f_1, \dots, f_j, \dots, f_J$ , a target sentence  $\mathbf{e} = e_1^I = e_1, \dots, e_i, \dots, e_I$ , and its word alignment  $\mathbf{a}$  which is a subset of the Cartesian product of word positions:  $\mathbf{a} \subseteq (j, i) : j = 1, \dots, J; i = 1, \dots, I$ , the phrase pair  $(\tilde{f}, \tilde{e})$  is said to be *consistent* (Och and Ney, 2004) with the alignment if and only if: (1) there must be at least one word inside one phrase aligned to a word inside the other phrase and (2) no words inside one phrase can be aligned to a word outside the other phrase. After all consistent phrase pairs are extracted from training corpus, the phrase probabilities are estimated as *relative frequencies* (Och and Ney, 2004):

$$\phi(\tilde{e}|\tilde{f}) = \frac{\text{count}(\tilde{f}, \tilde{e})}{\sum_{\tilde{e}'} \text{count}(\tilde{f}, \tilde{e}')} \quad (1)$$

Here  $\text{count}(\tilde{f}, \tilde{e})$  indicates how often the phrase pair  $(\tilde{f}, \tilde{e})$  occurs in the training corpus.

To obtain the corresponding lexical weight, we first estimate a lexical translation probability distribution  $w(e|f)$  by *relative frequency* from the training corpus:

$$w(e|f) = \frac{\text{count}(f, e)}{\sum_{e'} \text{count}(f, e')} \quad (2)$$

Retaining the alignment  $\tilde{a}$  between the phrase pair  $(\tilde{f}, \tilde{e})$ , the corresponding lexical weight is calculated as

$$p_w(\tilde{e}|\tilde{f}, \tilde{a}) = \prod_{i=1}^{|\tilde{e}|} \frac{1}{|\{j|(j, i) \in \tilde{a}\}|} \sum_{\forall (j, i) \in \tilde{a}} w(e_i|f_j) \quad (3)$$

However, the above-mentioned method only counts the co-occurrence frequency of bilingual phrases, assuming that the translation probability is independent of the context information. Thus, the statistical model estimated from the training data is not suitable for text translation in different domains, resulting in a significant drop in translation quality.

### 3 Translation Model Adaptation via Monolingual Topic Information

In this section, we first briefly review the principle of Hidden Topic Markov Model (HTMM) which is the basis of our method, then describe our approach to translation model adaptation in detail.

#### 3.1 Hidden Topic Markov Model

During the last couple of years, topic models such as Probabilistic Latent Semantic Analysis (Hofmann, 1999) and Latent Dirichlet Allocation model (Blei, 2003), have drawn more and more attention and been applied successfully in NLP community. Based on the “bag-of-words” assumption that the order of words can be ignored, these methods model the text corpus by using a co-occurrence matrix of words and documents, and build generative models to infer the latent aspects or topics. Using these models, the words can be clustered into the derived topics with a probability distribution, and the correlation between words can be automatically captured via topics.

However, the “bag-of-words” assumption is an unrealistic oversimplification because it ignores the order of words. To remedy this problem, Gruber et al. (2007) propose HTMM, which models the topics of words in the document as a Markov chain. Based on the assumption that all words in the same sentence have the same topic and the successive sentences are more likely to have the same topic, HTMM incorporates the local dependency between words by Hidden Markov Model for better topic estimation.

HTMM can also be viewed as a soft clustering tool for words in training corpus. That is, HTMM can estimate the probability distribution of a topic over words, i.e. the topic-word distribution  $P(\text{word}|\text{topic})$  during training. Besides, HTMM derives inherent topics in sentences rather than in documents, so we can easily obtain the sentence-topic distribution  $P(\text{topic}|\text{sentence})$  in training corpus. Adopting maximum likelihood estimation (MLE), this posterior distribution makes it possible to effectively calculate the word-topic distribution  $P(\text{topic}|\text{word})$  and the phrase-topic distribution  $P(\text{topic}|\text{phrase})$  both of which are very important in our method.

#### 3.2 Adapted Phrase Probability Estimation

We utilize the additional in-domain monolingual corpora to adapt the out-of-domain translation model for domain-specific translation task. In detail, we build an adapted translation model in the following steps:

- Build a topic-specific translation model to quantify the effect of the topic information on the translation probability estimation.
- Estimate the topic posterior distributions of phrases in the in-domain monolingual corpora.
- Score the phrase pairs according to the predefined topic-specific translation model and the topic posterior distribution of phrases.

Formally, we incorporate monolingual topic information into translation probability estimation, and decompose the phrase probability  $\phi(\tilde{e}|\tilde{f})$ <sup>1</sup> as follows:

$$\begin{aligned}\phi(\tilde{e}|\tilde{f}) &= \sum_{t_f} \phi(\tilde{e}, t_f|\tilde{f}) \\ &= \sum_{t_f} \phi(\tilde{e}|\tilde{f}, t_f) \cdot P(t_f|\tilde{f})\end{aligned}\quad (4)$$

where  $\phi(\tilde{e}|\tilde{f}, t_f)$  indicates the probability of translating  $\tilde{f}$  into  $\tilde{e}$  given the source-side topic  $t_f$ ,  $P(t_f|\tilde{f})$  denotes the phrase-topic distribution of  $\tilde{f}$ .

To compute  $\phi(\tilde{e}|\tilde{f})$ , we first apply HTMM to respectively train two monolingual topic models with the following corpora: one is the source part of the out-of-domain bilingual corpus  $C_{f.out}$ , the other is the in-domain monolingual corpus  $C_{f.in}$  in the source language. Then, we respectively estimate  $\phi(\tilde{e}|\tilde{f}, t_f)$  and  $P(t_f|\tilde{f})$  from these two corpora. To avoid confusion, we further refine  $\phi(\tilde{e}|\tilde{f}, t_f)$  and  $P(t_f|\tilde{f})$  with  $\phi(\tilde{e}|\tilde{f}, t_{f.out})$  and  $P(t_{f.in}|\tilde{f})$ , respectively. Here,  $t_{f.out}$  is the topic clustered from the corpus  $C_{f.out}$ , and  $t_{f.in}$  represents the topic derived from the corpus  $C_{f.in}$ .

However, the two above-mentioned probabilities can not be directly multiplied in formula (4) because they are related to different topic spaces from

<sup>1</sup>Due to the limit of space, we omit the description of the calculation method of the phrase probability  $\phi(\tilde{f}|\tilde{e})$ , which can be adjusted in a similar way to  $\phi(\tilde{e}|\tilde{f})$  with the help of in-domain monolingual corpus in the target language.

different corpora. Besides, their topic dimensions are not assured to be the same. To solve this problem, we introduce the topic mapping probability  $P(t_{f\_out}|t_{f\_in})$  to map the in-domain phrase-topic distribution into the one in the out-domain topic space. To be specific, we obtain the out-of-domain phrase-topic distribution  $P(t_{f\_out}|\tilde{f})$  as follows:

$$P(t_{f\_out}|\tilde{f}) = \sum_{t_{f\_in}} P(t_{f\_out}|t_{f\_in}) \cdot P(t_{f\_in}|\tilde{f}) \quad (5)$$

Thus formula (4) can be further refined as the following formula:

$$\begin{aligned} \phi(\tilde{e}|\tilde{f}) &= \sum_{t_{f\_out}} \sum_{t_{f\_in}} \phi(\tilde{e}|\tilde{f}, t_{f\_out}) \\ &\quad \cdot P(t_{f\_out}|t_{f\_in}) \cdot P(t_{f\_in}|\tilde{f}) \quad (6) \end{aligned}$$

Next we will give detailed descriptions of the calculation methods for the three probability distributions mentioned in formula (6).

### 3.2.1 Topic-Specific Phrase Translation

**Probability**  $\phi(\tilde{e}|\tilde{f}, t_{f\_out})$

We follow the common practice (Koehn et al., 2003) to calculate the topic-specific phrase translation probability, and the only difference is that our method takes the topical context information into account when collecting the fractional counts of phrase pairs. With the sentence-topic distribution  $P(t_{f\_out}|\mathbf{f})$  from the relevant topic model of  $C_{f\_out}$ , the conditional probability  $\phi(\tilde{e}|\tilde{f}, t_{f\_out})$  can be easily obtained by MLE method:

$$\begin{aligned} &\phi(\tilde{e}|\tilde{f}, t_{f\_out}) \\ &= \frac{\sum_{\langle \mathbf{f}, \mathbf{e} \rangle \in C_{out}} count_{\langle \mathbf{f}, \mathbf{e} \rangle}(\tilde{f}, \tilde{e}) \cdot P(t_{f\_out}|\mathbf{f})}{\sum_{\tilde{e}'} \sum_{\langle \mathbf{f}, \mathbf{e} \rangle \in C_{out}} count_{\langle \mathbf{f}, \mathbf{e} \rangle}(\tilde{f}, \tilde{e}') \cdot P(t_{f\_out}|\mathbf{f})} \quad (7) \end{aligned}$$

where  $C_{out}$  is the out-of-domain bilingual training corpus, and  $count_{\langle \mathbf{f}, \mathbf{e} \rangle}(\tilde{f}, \tilde{e})$  denotes the number of the phrase pair  $(\tilde{f}, \tilde{e})$  in sentence pair  $\langle \mathbf{f}, \mathbf{e} \rangle$ .

### 3.2.2 Topic Mapping Probability $P(t_{f\_out}|t_{f\_in})$

Based on the two monolingual topic models respectively trained from  $C_{f\_in}$  and  $C_{f\_out}$ , we compute the topic mapping probability by using source word  $f$  as the pivot variable. Noticing that there

are some words occurring in one corpus only, we use the words belonging to both corpora during the mapping procedure. Specifically, we decompose  $P(t_{f\_out}|t_{f\_in})$  as follows:

$$\begin{aligned} &P(t_{f\_out}|t_{f\_in}) \\ &= \sum_{f \in C_{f\_out} \cap C_{f\_in}} P(t_{f\_out}|f) \cdot P(f|t_{f\_in}) \quad (8) \end{aligned}$$

Here we first get  $P(f|t_{f\_in})$  directly from the topic model related to  $C_{f\_in}$ . Then, considering the sentence-topic distribution  $P(t_{f\_out}|\mathbf{f})$  from the relevant topic model of  $C_{f\_out}$ , we define the word-topic distribution  $P(t_{f\_out}|f)$  as:

$$\begin{aligned} &P(t_{f\_out}|f) \\ &= \frac{P(t_{f\_out}|f) \sum_{\mathbf{f} \in C_{f\_out}} count_{\mathbf{f}}(f) \cdot P(t_{f\_out}|\mathbf{f})}{\sum_{t_{f\_out}} \sum_{\mathbf{f} \in C_{f\_out}} count_{\mathbf{f}}(f) \cdot P(t_{f\_out}|\mathbf{f})} \quad (9) \end{aligned}$$

where  $count_{\mathbf{f}}(f)$  denotes the number of the word  $f$  in sentence  $\mathbf{f}$ .

### 3.2.3 Phrase-Topic Distribution $P(t_{f\_in}|\tilde{f})$

A simple way to compute the phrase-topic distribution is to take the fractional counts from  $C_{f\_in}$  and then adopt MLE to obtain relative probability. However, it is infeasible in our model because some phrases occur in  $C_{f\_out}$  while being absent in  $C_{f\_in}$ . To solve this problem, we further compute this posterior distribution by the interpolation of two models:

$$\begin{aligned} P(t_{f\_in}|\tilde{f}) &= \theta \cdot P_{mle}(t_{f\_in}|\tilde{f}) + \\ &\quad (1 - \theta) \cdot P_{word}(t_{f\_in}|\tilde{f}) \quad (10) \end{aligned}$$

where  $P_{mle}(t_{f\_in}|\tilde{f})$  indicates the phrase-topic distribution by MLE,  $P_{word}(t_{f\_in}|\tilde{f})$  denotes the phrase-topic distribution which is decomposed into the topic posterior distribution at the word level, and  $\theta$  is the interpolation weight that can be optimized over the development data.

Given the number of the phrase  $\tilde{f}$  in sentence  $\mathbf{f}$  denoted as  $count_{\mathbf{f}}(\tilde{f})$ , we compute the in-domain phrase-topic distribution in the following way:

$$\begin{aligned} &P_{mle}(t_{f\_in}|\tilde{f}) \\ &= \frac{\sum_{\mathbf{f} \in C_{f\_in}} count_{\mathbf{f}}(\tilde{f}) \cdot P(t_{f\_in}|\mathbf{f})}{\sum_{t_{f\_in}} \sum_{\mathbf{f} \in C_{f\_in}} count_{\mathbf{f}}(\tilde{f}) \cdot P(t_{f\_in}|\mathbf{f})} \quad (11) \end{aligned}$$

Under the assumption that the topics of all words in the same phrase are independent, we consider two methods to calculate  $P_{word}(t_{f.in}|\tilde{f})$ . One is a “Noisy-OR” combination method (Zens and Ney, 2004) which has shown good performance in calculating similarities between bags-of-words in different languages. Using this method,  $P_{word}(t_{f.in}|\tilde{f})$  is defined as:

$$\begin{aligned} & P_{word}(t_{f.in}|\tilde{f}) \\ = & 1 - P_{word}(\bar{t}_{f.in}|\tilde{f}) \\ \approx & 1 - \prod_{f_j \in \tilde{f}} P(\bar{t}_{f.in}|f_j) \\ = & 1 - \prod_{f_j \in \tilde{f}} (1 - P(t_{f.in}|f_j)) \end{aligned} \quad (12)$$

where  $P_{word}(\bar{t}_{f.in}|\tilde{f})$  represents the probability that  $t_{f.in}$  is not the topic of the phrase  $\tilde{f}$ . Similarly,  $P(\bar{t}_{f.in}|f_j)$  indicates the probability that  $t_{f.in}$  is not the topic of the word  $f_j$ .

The other method is an “Averaging” combination one. With the assumption that  $t_{f.in}$  is the topic of  $\tilde{f}$  if at least one of the words in  $\tilde{f}$  belongs to this topic, we derive  $P_{word}(t_{f.in}|\tilde{f})$  as follows:

$$P_{word}(t_{f.in}|\tilde{f}) \approx \sum_{f_j \in \tilde{f}} P(t_{f.in}|f_j)/|\tilde{f}| \quad (13)$$

where  $|\tilde{f}|$  denotes the number of words in phrase  $\tilde{f}$ .

### 3.3 Adapted Lexical Probability Estimation

Now we briefly describe how to estimate the adapted lexical weight for phrase pairs, which can be adjusted in a similar way to the phrase probability.

Specifically, adopting our method, each word is considered as one phrase consisting of only one word, so

$$\begin{aligned} w(e|f) = & \sum_{t_{f.out}} \sum_{t_{f.in}} w(e|f, t_{f.out}) \\ & \cdot P(t_{f.out}|t_{f.in}) \cdot P(t_{f.in}|f) \end{aligned} \quad (14)$$

Here we obtain  $w(e|f, t_{f.out})$  with a similar approach to  $\phi(\tilde{e}|f, t_{f.out})$ , and calculate  $P(t_{f.out}|t_{f.in})$  and  $P(t_{f.in}|f)$  by resorting to formulas (8) and (9).

With the adjusted lexical translation probability, we resort to formula (4) to update the lexical weight for the phrase pair  $(f, \tilde{e})$ .

## 4 Experiment

We evaluate our method on the Chinese-to-English translation task for the *weblog* text. After a brief description of the experimental setup, we investigate the effects of various factors on the translation system performance.

### 4.1 Experimental setup

In our experiments, the out-of-domain training corpus comes from the FBIS corpus and the Hansards part of LDC2004T07 corpus (54.6K documents with 1M parallel sentences, 25.2M Chinese words and 29M English words). We use the Chinese Sohu weblog in 2009<sup>1</sup> and the English Blog Authorship corpus<sup>2</sup> (Schler et al., 2006) as the in-domain monolingual corpora in the source language and target language, respectively. To obtain more accurate topic information by HTMM, we firstly filter the noisy blog documents and the ones consisting of short sentences. After filtering, there are totally 85K Chinese blog documents with 2.1M sentences and 277K English blog documents with 4.3M sentences used in our experiments. Then, we sample equal numbers of documents from the in-domain monolingual corpora in the source language and the target language to respectively train two in-domain topic models. The web part of the 2006 NIST MT evaluation test data, consisting of 27 documents with 1048 sentences, is used as the development set, and the weblog part of the 2008 NIST MT test data, including 33 documents with 666 sentences, is our test set.

To obtain various topic distributions for the out-of-domain training corpus and the in-domain monolingual corpora in the source language and the target language respectively, we use HTMM tool developed by Gruber et al.(2007) to conduct topic model training. During this process, we empirically set the same parameter values for the HTMM training of different corpora:  $topics = 50$ ,  $\alpha = 1.5$ ,  $\beta = 1.01$ ,  $iters = 100$ . See (Gruber et al., 2007) for the meanings of these parameters. Besides, we set the interpolation weight  $\theta$  in formula (10) to 0.5 by observing the results on development set in the additional experiments.

We choose MOSES, a famous open-source

<sup>1</sup><http://blog.sohu.com/>

<sup>2</sup><http://u.cs.biu.ac.il/~koppel/BlogCorpus.html>

phrase-based machine translation system (Koehn et al., 2007), as the experimental decoder. GIZA++ (Och and Ney, 2003) and the heuristics “grow-diag-final-and” are used to generate a word-aligned corpus, from which we extract bilingual phrases with maximum length 7. We use SRILM Toolkits (Stolcke, 2002) to train two 4-gram language models on the filtered English Blog Authorship corpus and the Xinhua portion of Gigaword corpus, respectively. During decoding, we set the ttable-limit as 20, the stack-size as 100, and perform minimum-error-rate training (Och and Ney, 2003) to tune the feature weights for the log-linear model. The translation quality is evaluated by case-insensitive BLEU-4 metric (Papineni et al., 2002). Finally, we conduct paired bootstrap sampling (Koehn, 2004) to test the significance in BLEU score differences.

## 4.2 Result and Analysis

### 4.2.1 Effect of Different Smoothing Methods

Our first experiments investigate the effect of different smoothing methods for the in-domain phrase-topic distribution: “Noisy-OR” and “Averaging”. We build adapted phrase tables with these two methods, and then respectively use them in place of the out-of-domain phrase table to test the system performance. For the purpose of studying the generality of our approach, we carry out comparative experiments on two sizes of in-domain monolingual corpora: 5K and 40K.

Adaptation Method	(Dev) MT06 Web	(Tst) MT08 Weblog
Baseline	30.98	20.22
Noisy-OR (5K)	31.16	20.45
Averaging (5K)	31.51	20.54
Noisy-OR (40K)	31.87	20.76
Averaging (40K)	31.89	21.11

Table 1: Experimental results using different smoothing methods.

Table 1 reports the BLEU scores of the translation system under various conditions. Using the out-of-domain phrase table, the baseline system achieves a BLEU score of 20.22. In the experiments with the small-scale in-domain monolingual corpora, the

BLEU scores acquired by two methods are 20.45 and 20.54, achieving absolute improvements of 0.23 and 0.32 on the test set, respectively. In the experiments with the large-scale monolingual in-domain corpora, similar results are obtained, with absolute improvements of 0.54 and 0.89 over the baseline system.

From the above experimental results, we know that both “Noisy-OR” and “Averaging” combination methods improve the performance over the baseline, and “Averaging” method seems to be slightly better. This finding fails to echo the promising results in the previous study (Zens and Ney, 2004). This is because the “Noisy-OR” method involves the multiplication of the word-topic distribution (shown in formula (12)), which leads to much sharper phrase-topic distribution than “Averaging” method, and is more likely to introduce bias to the translation probability estimation. Due to this reason, all the following experiments only consider the “Averaging” method.

### 4.2.2 Effect of Combining Two Phrase Tables

In the above experiments, we replace the out-of-domain phrase table with the adapted phrase table. Here we combine these two phrase tables in a log-linear framework to see if we could obtain further improvement. To offer a clear description, we represent the out-of-domain phrase table and the adapted phrase table with “OutBP” and “AdapBP”, respectively.

Used Phrase Table	(Dev) MT06 Web	(Tst) MT08 Weblog
Baseline	30.98	20.22
AdapBp (5K)	31.51	20.54
+ OutBp	31.84	20.70
AdapBp (40K)	31.89	21.11
+ OutBp	32.05	21.20

Table 2: Experimental results using different phrase tables. OutBp: the out-of-domain phrase table. AdapBp: the adapted phrase table.

Table 2 shows the results of experiments using different phrase tables. Applying our adaptation approach, both “AdapBP” and “OutBP + AdapBP” consistently outperform the baseline, and the lat-

Figure 1: Effect of in-domain monolingual corpus size on translation quality.

ter produces further improvements over the former. Specifically, the BLEU scores of the “OutBP + AdapBP” method are 20.70 and 21.20, which obtain 0.48 and 0.98 points higher than the baseline method, and 0.16 and 0.09 points higher than the ‘AdapBP’ method. The underlying reason is that the probability distribution of each in-domain sentence often converges on some topics in the “AdapBP” method and some translation probabilities are over-estimated, which leads to negative effects on the translation quality. By using two tables together, our approach reduces the bias introduced by “AdapBP”, therefore further improving the translation quality.

#### 4.2.3 Effect of In-domain Monolingual Corpus Size

Finally, we investigate the effect of in-domain monolingual corpus size on translation quality. In the experiment, we try different sizes of in-domain documents to train different monolingual topic models: from 5K to 80K with an increment of 5K each time. Note that here we only focus on the experiments using the “OutBP + AdapBP” method, because this method performs better in the previous experiments.

Figure 1 shows the BLEU scores of the translation system on the test set. It can be seen that the more data, the better translation quality when the corpus size is less than 30K. The overall BLEU scores corresponding to the range of great  $N$  values are generally higher than the ones corresponding to the range of small  $N$  values. For example, the BLEU scores under the condition within the range [25K, 80K] are all higher than the ones within the range [5K, 20K]. When  $N$  is set to 55K, the BLEU

score of our system is **21.40**, with **1.18** gains on the baseline system. This difference is statistically significant at  $P < 0.01$  using the significance test tool developed by Zhang et al.(2004). For this experimental result, we speculate that with the increment of in-domain monolingual data, the corresponding topic models provide more accurate topic information to improve the translation system. However, this effect weakens when the monolingual corpora continue to increase.

## 5 Related work

Most previous researches about translation model adaptation focused on *parallel data collection*. For example, Hildebrand et al.(2005) employed information retrieval technology to gather the bilingual sentences, which are similar to the test set, from available in-domain and out-of-domain training data to build an adaptive translation model. With the same motivation, Munteanu and Marcu (2005) extracted in-domain bilingual sentence pairs from comparable corpora. Since large-scale monolingual corpus is easier to obtain than parallel corpus, there have been some studies on how to generate parallel sentences with monolingual sentences. In this respect, Ueffing et al. (2008) explored semi-supervised learning to obtain synthetic parallel sentences, and Wu et al. (2008) used an in-domain translation dictionary and monolingual corpora to adapt an out-of-domain translation model for the in-domain text.

Differing from the above-mentioned works on the acquirement of bilingual resource, several studies (Foster and Kuhn, 2007; Civera and Juan, 2007; Lv et al., 2007) adopted *mixture modeling* framework to exploit the full potential of the existing parallel corpus. Under this framework, the training corpus is first divided into different parts, each of which is used to train a sub translation model, then these sub models are used together with different weights during decoding. In addition, discriminative weighting methods were proposed to assign appropriate weights to the sentences from training corpus (Matsoukas et al., 2009) or the phrase pairs of phrase table (Foster et al., 2010). Final experimental results show that without using any additional resources, these approaches all improve SMT performance sig-

nificantly.

Our method deals with translation model adaptation by making use of the topical context, so let us take a look at the recent research development on the application of topic models in SMT. Assuming each bilingual sentence constitutes a mixture of hidden topics and each word pair follows a topic-specific bilingual translation model, Zhao and Xing (2006,2007) presented a bilingual topical admixture formalism to improve word alignment by capturing topic sharing at different levels of linguistic granularity. Tam et al.(2007) proposed a bilingual LSA, which enforces one-to-one topic correspondence and enables latent topic distributions to be efficiently transferred across languages, to cross-lingual language modeling and translation lexicon adaptation. Recently, Gong and Zhou (2010) also applied topic modeling into domain adaptation in SMT. Their method employed one additional feature function to capture the topic inherent in the source phrase and help the decoder dynamically choose related target phrases according to the specific topic of the source phrase.

Besides, our approach is also related to context-dependent translation. Recent studies have shown that SMT systems can benefit from the utilization of context information. For example, *trigger-based lexicon model* (Hasan et al., 2008; Mauser et al., 2009) and *context-dependent translation selection* (Chan et al., 2007; Carpuat and Wu, 2007; He et al., 2008; Liu et al., 2008). The former generated triplets to capture long-distance dependencies that go beyond the local context of phrases, and the latter built the classifiers which combine rich context information to better select translation during decoding. With the consideration of various local context features, these approaches all yielded stable improvements on different translation tasks.

As compared to the above-mentioned works, our work has the following differences.

- We focus on how to adapt a translation model for domain-specific translation task with the help of additional in-domain monolingual corpora, which are far from full exploitation in the *parallel data collection* and *mixture modeling* framework.
- In addition to the utilization of in-domain

monolingual corpora, our method is different from the previous works (Zhao and Xing, 2006; Zhao and Xing, 2007; Tam et al., 2007; Gong and Zhou, 2010) in the following aspects: (1) we use a different topic model — HTMM which has different assumption from PLSA and LDA; (2) rather than modeling topic-dependent translation lexicons in the training process, we estimate topic-specific lexical probability by taking account of topical context when extracting word pairs, so our method can also be directly applied to topic-dependent phrase probability modeling. (3) Instead of rescoring phrase pairs online, our approach calculate the translation probabilities offline, which brings no additional burden to translation systems and is suitable to translate the texts without the topic distribution information.

- Different from *trigger-based lexicon model* and *context-dependent translation selection* both of which put emphasis on solving the translation ambiguity by the exploitation of the context information at the sentence level, we adopt the topical context information in our method for the following reasons: (1) the topic information captures the context information beyond the scope of sentence; (2) the topical context information is integrated into the posterior probability distribution, avoiding the sparseness of word or POS features; (3) the topical context information allows for more fine-grained distinction of different translations than the genre information of corpus.

## 6 Conclusion and future work

This paper presents a novel method for SMT system adaptation by making use of the monolingual corpora in new domains. Our approach first estimates the translation probabilities from the out-of-domain bilingual corpus given the topic information, and then rescoring the phrase pairs via topic mapping and phrase-topic distribution probability estimation from in-domain monolingual corpora. Experimental results show that our method achieves better performance than the baseline system, without increasing the burden of the translation system.

In the future, we will verify our method on oth-

er language pairs, for example, Chinese to Japanese. Furthermore, since the in-domain phrase-topic distribution is currently estimated with simple smoothing interpolations, we expect that the translation system could benefit from other sophisticated smoothing methods. Finally, the reasonable estimation of topic number for better translation model adaptation will also become our study emphasis.

## Abstract

We propose a novel model to automatically extract transliteration pairs from parallel corpora. Our model is efficient, language pair independent and mines transliteration pairs in a consistent fashion in both unsupervised and semi-supervised settings. We model transliteration mining as an interpolation of transliteration and non-transliteration sub-models. We evaluate on NEWS 2010 shared task data and on parallel corpora with competitive results.

## 1 Introduction

Transliteration mining is the extraction of transliteration pairs from unlabelled data. Most transliteration mining systems are built using labelled training data or using heuristics to extract transliteration pairs. These systems are language pair dependent or require labelled information for training. Our system extracts transliteration pairs in an unsupervised fashion. It is also able to utilize labelled information if available, obtaining improved performance.

We present a novel model of transliteration mining defined as a mixture of a transliteration model and a non-transliteration model. The transliteration model is a joint source channel model (Li et al., 2004). The non-transliteration model assumes no correlation between source and target word characters, and independently generates a source and a target word using two fixed unigram character models. We use Expectation Maximization (EM) to learn parameters maximizing the likelihood of the interpolation of both sub-models. At test time, we label word

pairs as transliterations if they have a higher probability assigned by the transliteration sub-model than by the non-transliteration sub-model.

We extend the unsupervised system to a semi-supervised system by adding a new S-step to the EM algorithm. The S-step takes the probability estimates from unlabelled data (computed in the M-step) and uses them as a backoff distribution to smooth probabilities which were estimated from labelled data. The smoothed probabilities are then used in the next E-step. In this way, the parameters learned by EM are constrained to values which are close to those estimated from the labelled data.

We evaluate our unsupervised and semi-supervised transliteration mining system on the datasets available from the NEWS 2010 shared task on transliteration mining (Kumaran et al., 2010b). We call this task *NEWS10* later on. Compared with a baseline unsupervised system our unsupervised system achieves up to 5% better F-measure. On the NEWS10 dataset, our unsupervised system achieves an F-measure of up to 95.7%, and on three language pairs, it performs better than all systems which participated in NEWS10. We also evaluate our semi-supervised system which additionally uses the NEWS10 labelled data for training. It achieves an improvement of up to 3.7% F-measure over our unsupervised system. Additional experiments on parallel corpora show that we are able to effectively mine transliteration pairs from very noisy data.

The paper is organized as follows. Section 2 describes previous work. Sections 3 and 4 define our unsupervised and semi-supervised models. Section 5 presents the evaluation. Section 6 concludes.

## 2 Previous Work

We first discuss the literature on semi-supervised and supervised techniques for transliteration mining and then describe a previously defined unsupervised system. Supervised and semi-supervised systems use a manually labelled set of training data to learn character mappings between source and target strings. The labelled training data either consists of a few hundred transliteration pairs or of just a few carefully selected transliteration pairs. The NEWS 2010 shared task on transliteration mining (NEWS10) (Kumaran et al., 2010b) is a semi-supervised task conducted on Wikipedia InterLanguage Links (WIL) data. The NEWS10 dataset contains 1000 labelled examples (called the “seed data”) for initial training. All systems which participated in the NEWS10 shared task are either supervised or semi-supervised. They are described in (Kumaran et al., 2010a). Our transliteration mining model can mine transliterations without using any labelled data. However, if there is some labelled data available, our system is able to use it effectively.

The transliteration mining systems evaluated on the NEWS10 dataset generally used heuristic methods, discriminative models or generative models for transliteration mining (Kumaran et al., 2010a).

The heuristic-based system of Jiampojarn et al. (2010) is based on the edit distance method which scores the similarity between source and target words. They presented two discriminative methods – an SVM-based classifier and alignment-based string similarity for transliteration mining. These methods model the conditional probability distribution and require supervised/semi-supervised information for learning. We propose a flexible generative model for transliteration mining usable for both unsupervised and semi-supervised learning.

Previous work on generative approaches uses Hidden Markov Models (Nabende, 2010; Darwish, 2010; Jiampojarn et al., 2010), Finite State Automata (Noeman and Madkour, 2010) and Bayesian learning (Kahki et al., 2011) to learn transliteration pairs from labelled data. Our method is different from theirs as our generative story explains the unlabelled data using a combination of a transliteration and a non-transliteration sub-model. The transliteration model jointly generates source and target

strings, whereas the non-transliteration system generates them independently of each other.

Sajjad et al. (2011) proposed a heuristic-based unsupervised transliteration mining system. We later call it *Sajjad11*. It is the only unsupervised mining system that was evaluated on the NEWS10 dataset up until now, as far as we know. That system is computationally expensive. We show in Section 5 that its runtime is much higher than that of our system.

In this paper, we propose a novel model-based approach to transliteration mining. Our approach is language pair independent – at least for alphabetic languages – and efficient. Unlike the previous unsupervised system, and unlike the supervised and semi-supervised systems we mentioned, our model can be used for both unsupervised and semi-supervised mining in a consistent way.

## 3 Unsupervised Transliteration Mining Model

A source word and its corresponding target word can be character-aligned in many ways. We refer to a possible alignment sequence which aligns a source word  $e$  and a target word  $f$  as “ $a$ ”. The function  $Align(e, f)$  returns the set of all valid alignment sequences  $a$  of a word pair  $(e, f)$ . The joint transliteration probability  $p_1(e, f)$  of a word pair is the sum of the probabilities of all alignment sequences:

$$p_1(e, f) = \sum_{a \in Align(e, f)} p(a) \quad (1)$$

Transliteration systems are trained on a list of transliteration pairs. The alignment between the transliteration pairs is learned with Expectation Maximization (EM). We use a simple unigram model, so an alignment sequence from function  $Align(e, f)$  is a combination of 0–1, 1–1, and 1–0 character alignments between a source word  $e$  and its transliteration  $f$ . We refer to a character alignment unit as “*multigram*” later on and represent it by the symbol “ $q$ ”. A sequence of multigrams forms an alignment of a source and target word. The probability of a sequence of multigrams  $a$  is the product of the probabilities of the multigrams it contains.

$$p(a) = p(q_1, q_2, \dots, q_{|a|}) = \prod_{j=1}^{|a|} p(q_j) \quad (2)$$

While transliteration systems are trained on a clean list of transliteration pairs, our transliteration mining system has to learn from data containing both transliterations and non-transliterations. The transliteration model  $p_1(e, f)$  handles only the transliteration pairs. We propose a second model  $p_2(e, f)$  to deal with non-transliteration pairs (the “*non-transliteration model*”). Interpolation with the non-transliteration model allows the transliteration model to concentrate on modelling transliterations during EM training. After EM training, transliteration word pairs are assigned a high probability by the transliteration submodel and a low probability by the non-transliteration submodel, and vice versa for non-transliteration pairs. This property is exploited to identify transliterations.

In a non-transliteration word pair, the characters of the source and target words are unrelated. We model them as randomly seeing a source word and a target word together. The non-transliteration model uses random generation of characters from two unigram models. It is defined as follows:

$$p_2(e, f) = p_E(e) p_F(f) \quad (3)$$

$$p_E(e) = \prod_{i=1}^{|e|} p_E(e_i) \text{ and } p_F(f) = \prod_{i=1}^{|f|} p_F(f_i).$$

The transliteration mining model is an interpolation of the transliteration model  $p_1(e, f)$  and the non-transliteration model  $p_2(e, f)$ :

$$p(e, f) = (1 - \lambda)p_1(e, f) + \lambda p_2(e, f) \quad (4)$$

$\lambda$  is the prior probability of non-transliteration.

### 3.1 Model Estimation

In this section, we discuss the estimation of the parameters of the transliteration model  $p_1(e, f)$  and the non-transliteration model  $p_2(e, f)$ .

The non-transliteration model consists of two unigram character models. Their parameters are estimated from the source and target words of the training data, respectively, and the parameters do not change during EM training.

For the transliteration model, we implement a simplified form of the grapheme-to-phoneme converter, g2p (Bisani and Ney, 2008). In the following, we use notations from Bisani and Ney (2008). g2p learns m-to-n character alignments between a source and a target word. We restrict ourselves to 0–1, 1–1, 1–0 character alignments and to a unigram

model.<sup>1</sup> The Expectation Maximization (EM) algorithm is used to train the model. It maximizes the likelihood of the training data. In the E-step the EM algorithm computes expected counts for the multigrams and in the M-step the multigram probabilities are reestimated from these counts. These two steps are iterated. For the first EM iteration, the multigram probabilities are initialized with a uniform distribution and  $\lambda$  is set to 0.5.

The expected count of a multigram  $q$  (E-step) is computed by multiplying the posterior probability of each alignment  $a$  with the frequency of  $q$  in  $a$  and summing these weighted frequencies over all alignments of all word pairs.

$$c(q) = \sum_{i=1}^N \sum_{a \in \text{Align}(e_i, f_i)} \frac{(1 - \lambda)p_1(a, e_i, f_i)}{p(e_i, f_i)} n_q(a)$$

$n_q(a)$  is here the number of times the multigram  $q$  occurs in the sequence  $a$  and  $p(e_i, f_i)$  is defined in Equation 4. The new estimate of the probability of a multigram is given by:

$$p(q) = \frac{c(q)}{\sum_{q'} c(q')} \quad (5)$$

Likewise, we calculate the expected count of non-transliterations by summing the posterior probabilities of non-transliteration given each word pair:

$$c_{ntr} = \sum_{i=1}^N p_{ntr}(e_i, f_i) = \sum_{i=1}^N \frac{\lambda p_2(e_i, f_i)}{p(e_i, f_i)} \quad (6)$$

$\lambda$  is then reestimated by dividing the expected count of non-transliterations by  $N$ .

### 3.2 Implementation Details

We use the Forward-Backward algorithm to estimate the counts of multigrams. The algorithm has a forward variable  $\alpha$  and a backward variable  $\beta$  which are calculated in the standard way (Deligne and Bimbot, 1995). Consider a node  $r$  which is connected with a node  $s$  via an arc labelled with the multigram  $q$ . The expected count of a transition between  $r$  and  $s$  is calculated using the forward and backward probabilities as follows:

$$\gamma'_{rs} = \frac{\alpha(r) p(q) \beta(s)}{\alpha(E)} \quad (7)$$

<sup>1</sup>In preliminary experiments, using an n-gram order of greater than one or more than one character on the source side or the target side or both sides of the multigram caused the transliteration model to incorrectly learn non-transliteration information from the training data.

where  $E$  is the final node of the graph.

We multiply the expected count of a transition by the posterior probability of transliteration ( $1 - p_{ntr}(e, f)$ ) which indicates how likely the string pair is to be a transliteration. The counts  $\gamma_{rs}$  are then summed for all multigram types  $q$  over all training pairs to obtain the frequencies  $c(q)$  which are used to reestimate the multigram probabilities according to Equation 5.

## 4 Semi-supervised Transliteration Mining Model

Our unsupervised transliteration mining system can be applied to language pairs for which no labelled data is available. However, the unsupervised system is focused on high recall and also mines close transliterations (see Section 5 for details). In a task dependent scenario, it is difficult for the unsupervised system to mine transliteration pairs according to the details of a particular definition of what is considered a transliteration (which may vary somewhat with the task). In this section, we propose an extension of our unsupervised model which overcomes this shortcoming by using labelled data. The idea is to rely on probabilities from labelled data where they can be estimated reliably and to use probabilities from unlabelled data where the labelled data is sparse. This is achieved by smoothing the labelled data probabilities using the unlabelled data probabilities as a backoff.

### 4.1 Model Estimation

We calculate the unlabelled data probabilities in the E-step using Equation 4. For labelled data (containing only transliterations) we set  $\lambda = 0$  and get:

$$p(e, f) = \sum_{a \in \text{Align}(e, f)} p_1(e, f, a) \quad (8)$$

In every EM iteration, we smooth the probability distribution in such a way that the estimates of the multigrams of the unlabelled data that do not occur in the labelled data would be penalized. We obtain this effect by smoothing the probability distribution of unlabelled and labelled data using a technique similar to Witten-Bell smoothing (Witten and Bell, 1991), as we describe below.

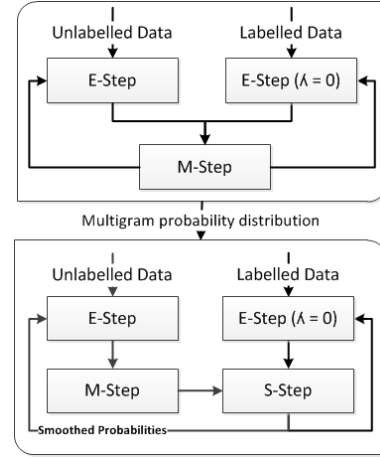

Figure 1: Semi-supervised training

### 4.2 Implementation Details

We divide the training process of semi-supervised mining in two steps as shown in Figure 1. The first step creates a reasonable alignment of the labelled data from the unlabelled data from which multigram counts can be obtained. The labelled data is a small list of transliteration pairs. Therefore we use the unlabelled data to help correctly align it and train our unsupervised mining system on the combined labelled and unlabelled training data. In the expectation step, the prior probability of non-transliteration  $\lambda$  is set to zero on the labelled data since it contains only transliterations. The first step passes the resulting multigram probability distribution to the second step.

We start the second step with the probability estimates from the first step and run the E-step separately on labelled and unlabelled data. The E-step on the labelled data is done using Equation 8, which forces the posterior probability of non-transliteration to zero, while the E-step on the unlabelled data uses Equation 4. After the two E-steps, we estimate a probability distribution from the counts obtained from the unlabelled data (M-step) and use it as a backoff distribution in computing smoothed probabilities from the labelled data counts (S-step).

The smoothed probability estimate  $\hat{p}(q)$  is:

$$\hat{p}(q) = \frac{c_s(q) + \eta_s p(q)}{N_s + \eta_s} \quad (9)$$

where  $c_s(q)$  is the labelled data count of the multigram  $q$ ,  $p(q)$  is the unlabelled data probability estimate, and  $N_s = \sum_q c_s(q)$ , and  $\eta_s$  is the number of different multigram types observed in the Viterbi alignment of the labelled data.

## 5 Evaluation

We evaluate our unsupervised system and semi-supervised system on two tasks, NEWS10 and parallel corpora. NEWS10 is a standard task on transliteration mining from WIL. On NEWS10, we compare our results with the unsupervised mining system of Sajjad et al. (2011), the best supervised and semi-supervised systems presented at NEWS10 (Kumaran et al., 2010b) and the best supervised and semi-supervised results reported in the literature for the NEWS10 task. For the challenging task of mining from parallel corpora, we use the English/Hindi and English/Arabic gold standard provided by Sajjad et al. (2011) to evaluate our results.

### 5.1 Experiments using the NEWS10 Dataset

We conduct experiments on four language pairs: English/Arabic, English/Hindi, English/Tamil and English/Russian using data provided at NEWS10. Every dataset contains training data, seed data and reference data. The NEWS10 data consists of pairs of titles of the same Wikipedia pages written in different languages, which may be transliterations or translations. The seed data is a list of 1000 transliteration pairs provided to semi-supervised systems for initial training. We use the seed data only in our semi-supervised system, and not in the unsupervised system. The reference data is a small subset of the training data which is manually annotated with positive and negative examples.

#### 5.1.1 Training

We word-aligned the parallel phrases of the training data using GIZA++ (Och and Ney, 2003), and symmetrized the alignments using the grow-diag-final-and heuristic (Koehn et al., 2003). We extract all word pairs which occur as 1-to-1 alignments (like Sajjad et al. (2011)) and later refer to them as the *word-aligned list*. We compared the word-aligned list with the NEWS10 reference data and found that the word-aligned list is missing some transliteration pairs because of word-alignment errors. We built another list by adding a word pair for every source word that cooccurs with a target word in a parallel phrase/sentence and call it the *cross-product list* later on. The cross-product list is noisier but contains almost all transliteration pairs in the corpus.

	Word-aligned			Cross-product		
	P	R	F	P	R	F
<b>EA</b>	27.8	97.1	43.3	14.3	98.0	25.0
<b>EH</b>	42.5	98.7	59.4	20.5	99.6	34.1
<b>ET</b>	32.0	98.1	48.3	17.2	99.6	29.3
<b>ER</b>	25.5	95.6	40.3	12.8	99.0	22.7

Table 1: Statistics of word-aligned and cross-product list calculated from the NEWS10 dataset, before mining. *EA* is English/Arabic, *EH* is English/Hindi, *ET* is English/Tamil and *ER* is English/Russian

Table 1 shows the statistics of the word-aligned list and the cross-product list calculated using the NEWS10 reference data.<sup>2</sup> The word-aligned list calculated from the NEWS10 dataset is used to compare our unsupervised system with the unsupervised system of Sajjad et al. (2011) on the same training data. All the other experiments on NEWS10 use cross-product lists. We remove numbers from both lists as they are defined as non-transliterations (Kumaran et al., 2010b).

#### 5.1.2 Unsupervised Transliteration Mining

We run our unsupervised transliteration mining system on the word-aligned list and the cross-product list. The word pairs with a posterior probability of transliteration  $1 - p_{ntr}(e, f) = 1 - \lambda p_2(e_i, f_i) / p(e_i, f_i)$  greater than 0.5 are selected as transliteration pairs.

We compare our unsupervised system with the unsupervised system of Sajjad11. Our unsupervised system trained on the word-aligned list shows F-measures of 91.7%, 95.5%, 92.9% and 77.7% which is 4.3%, 3.3%, 2.8% and 1.7% better than the system of Sajjad11 on English/Arabic, English/Hindi, English/Tamil and English/Russian respectively.

Sajjad11 is computationally expensive. For instance, a phrase-based statistical MT system is built once in every iteration of the heuristic procedure. We ran Sajjad11 on the English/Russian word-aligned list using a 2.4 GHz Dual-Core AMD machine, which took almost 10 days. On the same machine, our transliteration mining system only takes 1.5 hours to finish the same experiment.

<sup>2</sup>Due to inconsistent word definition used in the reference data, we did not achieve 100% recall in our cross-product list. For example, the underscore is defined as a word boundary for English WIL phrases. This assumption is not followed for certain phrases like "New\_York" and "New\_Mexico".

	Unsupervised		Semi-supervised/Supervised			
	<i>SJD</i>	<i>O<sub>U</sub></i>	<i>O<sub>S</sub></i>	<i>S<sub>Best</sub></i>	<i>GR</i>	<i>DBN</i>
<b>EA</b>	87.4	92.4	92.7	91.5	94.1	-
<b>EH</b>	92.2	95.7	96.3	94.4	93.2	95.5
<b>ET</b>	90.1	93.2	94.6	91.4	95.5	93.9
<b>ER</b>	76.0	79.4	83.1	87.5	92.3	82.5

Table 2: F-measure results on NEWS10 datasets where *SJD* is the unsupervised system of Sajjad11, *O<sub>U</sub>* is our unsupervised system built on the cross-product list, *O<sub>S</sub>* is our semi-supervised system, *S<sub>Best</sub>* is the best NEWS10 system, *GR* is the supervised system of Kahki et al. (2011) and *DBN* is the semi-supervised system of Nabende (2011)

Our unsupervised mining system built on the cross-product list consistently outperforms the one built on the word-aligned list. Later, we consider only the system built on the cross-product list. Table 2 shows the results of our unsupervised system *O<sub>U</sub>* in comparison with the unsupervised system of Sajjad11 (*SJD*), the best semi-supervised systems presented at NEWS10 (*S<sub>BEST</sub>*) and the best semi-supervised results reported on the NEWS10 dataset (*GR*, *DBN*). On three language pairs, our unsupervised system performs better than all semi-supervised systems which participated in NEWS10. It has competitive results with the best supervised results reported on NEWS10 datasets. On English/Hindi, our unsupervised system outperforms the state-of-the-art supervised and semi-supervised systems. Kahki et al. (2011) (*GR*) achieved the best results on English/Arabic, English/Tamil and English/Russian. For the English/Arabic task, they normalized the data using language dependent heuristics<sup>3</sup> and also used a non-standard evaluation method (discussed in Section 5.1.4).

On the English/Russian dataset, our unsupervised system faces the problem that it extracts cognates as transliterations. The same problem was reported in Sajjad et al. (2011). Cognates are close transliterations which differ by only one or two characters from an exact transliteration pair. The unsupervised system learns to delete the additional one or two characters with a high probability and incorrectly mines such word pairs as transliterations.

<sup>3</sup>They applied an Arabic word segmenter which uses language dependent information. Arabic long vowels which have identical sound but are written differently were merged to one form. English characters were normalized by dropping accents.

	Unsupervised			Semi-supervised		
	P	R	F	P	R	F
<b>EA</b>	89.2	95.7	92.4	92.9	92.4	92.7
<b>EH</b>	92.6	99.0	95.7	95.5	97.0	96.3
<b>ET</b>	88.3	98.6	93.2	93.4	95.8	94.6
<b>ER</b>	67.2	97.1	79.4	74.0	94.9	83.1

Table 3: Precision(P), Recall(R) and F-measure(F) of our unsupervised and semi-supervised transliteration mining systems on NEWS10 datasets

### 5.1.3 Semi-supervised Transliteration Mining

Our semi-supervised system uses similar initialization of the parameters as used for unsupervised system. Table 2 shows on three language pairs, our semi-supervised system *O<sub>S</sub>* only achieves a small gain in F-measure over our unsupervised system *O<sub>U</sub>*. This shows that the unlabelled training data is already providing most of the transliteration information. The seed data is used to help the transliteration mining system to learn the right definition of transliteration. On the English/Russian dataset, our semi-supervised system achieves almost 7% increase in precision with a 2.2% drop in recall compared to our unsupervised system. This provides a 3.7% gain on F-measure. The increase in precision shows that the seed data is helping the system in disambiguating transliteration pairs from cognates.

### 5.1.4 Discussion

The unsupervised system produces lists with high recall. The semi-supervised system tends to better balance out precision and recall. Table 3 compares the precision, recall and F-measure of our unsupervised and semi-supervised mining systems.

The errors made by our semi-supervised system can be classified into the following categories:

**Pronunciation differences:** English proper names may be pronounced differently in other languages. Sometimes, English short vowels are converted to long vowels in Hindi such as the English word “Lanthanum” which is pronounced “Laanthanum” in Hindi. Our transliteration mining system wrongly extracts such pairs as transliterations.

In some cases, different vowels are used in two languages. The English word “January” is pronounced as “Janvary” in Hindi. Such word pairs are non-transliterations according to the gold standard but our system extracts them as transliterations. Ta-

English	Hindi	English	Hindi
Lanthanum	लाञ्छनम्/Laanthanum	Sailendra	शैलेन्द्र/Shalendra
January	जनवरी/Janvary	August	अगस्त/Aagast

Table 4: Word pairs with pronunciation differences

English	Arabic	English	Arabic
Basrah	البصرة/Albasrah	Nasr	النصر/Alnasr
Kuwait	الكويت/Alkuwait	Riyadh	الرياض/Alriyadh

Table 5: Examples of word pairs which are wrongly annotated as transliterations in the gold standard

ble 4 shows a few examples of such word pairs.

**Inconsistencies in the gold standard:** There are several inconsistencies in the gold standard where our transliteration system correctly identifies a word pair as a transliteration but it is marked as a non-transliteration or vice versa. Consider the example of the English word “George” which is pronounced as “Jaarj” in Hindi. Our semi-supervised system learns this as a non-transliteration but it is wrongly annotated as a transliteration in the gold standard.

Arabic nouns have an article “al” attached to them which is translated in English as “the”. There are various cases in the training data where an English noun such as “Quran” is matched with an Arabic noun “alQuran”. Our mining system classifies such cases as non-transliterations, but 24 of them are incorrectly annotated as transliterations in the gold standard. We did not correct this, and are therefore penalized. Kahki et al. (2011) preprocessed such Arabic words and separated “al” from the noun “Quran” before mining. They report a match if the version of the Arabic word with “al” appears with the corresponding English word in the gold standard. Table 5 shows examples of word pairs which are wrongly annotated as transliterations.

**Cognates:** Sometimes a word pair differs by only one or two ending characters from a true transliteration. For example in the English/Russian training data, the Russian nouns are marked with cases whereas their English counterparts do not mark the case or translate it as a separate word. Often the Russian word differs only by the last character from a correct transliteration of the English word. Due to the large amount of such word pairs in the English/Russian data, our mining system learns to delete the final case marking characters from the Russian words. It assigns a high transliteration prob-

English	Russian	English	Russian
Studio	Студия/Studiya	Catalonia	Каталонии/Katalonii
Estonia	Эстонии/Estonii	Geography	География/Geografiya

Table 6: A few examples of English/Russian cognates

ability to these word pairs and extracts them as transliterations. Table 6 shows some examples.

There are two English/Russian supervised systems which are better than our semi-supervised system. The Kahki et al. (2011) system is built on seed data only. Jiampojarn et al. (2010)’s best system on English/Russian is based on the edit distance method. Both of these systems are focused on high precision. Our semi-supervised system is focused on high recall at the cost of lower precision.<sup>4</sup>

## 5.2 Transliteration Mining using Parallel Corpora

The percentage of transliteration pairs in the NEWS10 datasets is high. We further check the effectiveness of our unsupervised and semi-supervised mining systems by evaluating them on parallel corpora with as few as 2% transliteration pairs.

We conduct experiments using two language pairs, English/Hindi and English/Arabic. The English/Hindi corpus is from the shared task on word alignment organized as part of the ACL 2005 Workshop on Building and Using Parallel Texts (WA05) (Martin et al., 2005). For English/Arabic, we use 200,000 parallel sentences from the United Nations (UN) corpus (Eisele and Chen, 2010). The English/Hindi and English/Arabic transliteration gold standards were provided by Sajjad et al. (2011).

### 5.2.1 Experiments
