We tested the enhanced lexicon on the held out tweets and the review data. The results are presented in Table 5. The improvement of the enhanced lexicon over DuOMan is restricted to the political tweets. In fact, with the additions and shifts applied for the political domain, classification on product reviews performs a lot worse overall. Each polarity class shows a precision-recall trade-off in the results. For classification of the political tweets, the additions and shifts in the lexicon yield a more optimal balance between the two classes, while for classification of the product reviews the balance is upset, incorrectly predicting far more positive labels than DuOMan.

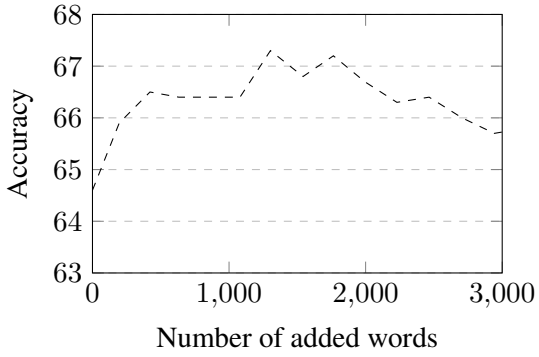

Figure 1: Adding more words from the vocabulary to the enhanced lexicon improves accuracy on the development data initially, but as more neutral words are added, the effect is diminished.

Our interpretation is that for the political domain specifically, the negative sentiment additions contain human traits rather than words that may describe a product. The positive additions seem more general and reusable, which explains the increased tendency of the enhanced lexicon to predict positive labels in the product reviews. When solely using a polarity lexicon to classify documents, the balance between the generality of positive versus negative words is very important.

4.4 Error analysis

Figure 2 shows some of the typical corrections that were made when applying the domain-specific lexicon as opposed to the general purpose lexicon. The first sentence gets the default negative label because none of its words are present in DuOMAn. By expanding the general purpose lexicon with more words, the correct positive label is assigned. This first type of correction accounted for 21 out of 28 total corrections on the test data (75%). The second sentence demonstrates a similar correction in which words were found in DuOMAn but the addition of new words corrected the label. This type of correction was present in 5 out of 28 corrections on the test data (about 18 %). The last type of correction is uncommon, but is caused by a reduction of polarity in the original lexicon where the default label is actually the correct label. This explained the remaining 2 corrections.

We look at errors caused by the adapted lexicon on the out-domain test set because they were far more numerous than the errors on the in-domain data. Our interpretation in section 4.3 is right: in 88 percent of the 656 additional misclassifications the (correct) negative label was flipped because of new positive

polarity word in the review. Similarly, 79 percent of the 268 corrections on the review data was made this way.

There were specific additions to the lexicon that caused many misclassifications, for example *'hoofdstuk'* (chapter), *literatuur* (literature) and *'uitgelezen'* (finished reading; but can also mean excellent) all have positive polarities in the domain-specific lexicon but cause many book reviews to be wrongfully classified as positive. Personal traits such as *'asociale'* (anti-social), *egocentrische* (selfish) and *'houding'* (attitude) caused problems when book or movie plots were described in the review. The same is true for *mannetje* (little man), *goal* and *pass* but for video game reviews.

With regards to domain-specificity these specific word examples show us that there are many (sub)domains within the product review data to be considered. The lexicon adaptation method we propose in this paper can generate a lexicon for use on any level, given there is enough in-domain textual data available. Beyond polarity classification, generated lexicons may be used to study sentiment differences between domains.

5 Conclusion

We have shown that enhancing a lexicon with SentProp for domain-specific use improves its accuracy in an in-domain classification task. Not all induced polarities should be considered when using majority voting for polarity classification. The words with the most extreme polarities make for the best additions to the lexicon (see Figure 1).

When applying polarity shifts, only applying small shifts that average the general-purpose lexicon polarity with the induced polarity had a positive effect on classification accuracy. A large difference between an induced polarity and the general-purpose domain is likely due to some very specific context in the word embeddings. We ignored these large differences and used the general-purpose polarity instead.

We added 1,303 new words to the general-purpose lexicon and applied 1,165 small polarity shifts to its entries. This gave us the best enhanced lexicon for classification on political tweets. We also tested the enhanced lexicon on out-domain product reviews and found that this yielded worse accuracy than the general-purpose domain, showing that the additions and adaptations were domain-specific and do not translate well to other domains.

In future work, we would like to compare lexicons enhanced on different corpora. This should provide more insight into the word additions and shifts that are particular for a domain. We also expect the balance between positive and negative words to shift depending on the domain. Another important addition to the current work would be a comparison of SentProp to other polarity induction methods for domain-specific classification.

SentProp has been shown to accurately reproduce domain-specific lexicon (Hamilton et al., 2016). We have elaborated on the existing body of work by demonstrating its capability to enhance a general-purpose domain for domain-specific classification.

Abstract

Sentence compression condenses a sentence while preserving its most important contents. Delete-based models have the strong ability to delete undesired words, while generate-based models are able to reorder or rephrase the words, which are more coherent to human sentence compression. In this paper, we propose Operation Network, a neural network approach for abstractive sentence compression, which combines the advantages of both delete-based and generate-based sentence compression models. The central idea of Operation Network is to model the sentence compression process as an editing procedure. First, unnecessary words are *deleted* from the source sentence, then new words are either *generated* from a large vocabulary or *copied* directly from the source sentence. A compressed sentence can be obtained by a series of such edit operations (*delete*, *copy* and *generate*). Experiments show that Operation Network outperforms state-of-the-art baselines.

1 Introduction

Sentence compression is the natural language generation (NLG) task of condensing a sentence while preserving its most important contents. It can also be viewed as a sentence-level summarization task. With the rapid growth of the web contents in recent years, summarization techniques such as sentence compression are becoming more and more important since these techniques can greatly reduce the information overload on the web. Sentence compression can benefit a wide range of applications, especially those on mobile devices which have restricted screen spaces. Sentence compression models can be broadly classified into two categories: delete-based models and abstractive models. Delete-based approaches remove unimportant words from the source sentence and generate a shorter sentence by stitching the remaining fragments together. On the contrary, abstractive models consider operations beyond word deletion, such as reordering, substitution and insertion. Abstractive sentence compression models produce a reform of the source sentence from scratch, thus the results produced by abstractive sentence compression models are more expressive. Obviously, abstractive sentence compression is much harder than delete-based sentence compression, since it needs deeper understanding of the source sentence.

Delete-based sentence compression treats the task as a word deletion problem: given an input *source* sentence x $= x_1, x_2, ..., x_n$ (where x_i stands for the ith word in the sentence x), the goal is to produce a *target* sentence by removing any subset of words in the source sentence x (Knight and Marcu, 2002). Delete-based sentence compression has been widely explored across different modeling paradigms, such as noisy-channel model (Knight and Marcu, 2002; Turner and Charniak, 2005), large-margin learning (McDonald, 2006; Cohn and Lapata, 2007), integer linear programming (Clarke and Lapata, 2008) and variational auto-encoder (Miao and Blunsom, 2016). In delete-based sentence compression models, only *delete* operations are allowed, thus the order of the remaining words can not be changed. These constraints make delete-based sentence compression a relatively easier task. However, in spite of the strong ability of deleting undesired words, delete-based models are not able to rephrase the words, which is far

Proceedings of the 27th International Conference on Computational Linguistics, pages 1065–1076
Santa Fe, New Mexico, USA, August 20-26, 2018.

from human sentence compression. For example, in human sentence compression, the word "remove" can replace the phrase "get rid of" under some particular circumstance, but this substitution can not be accomplished by delete-only models.

Abstractive sentence compression has the ability to reorder, substitute words or rephrase, thus it is more coherent to human sentence compression. Due to the difficulty of abstractive sentence compression, there was only a limited number of work on the task (Cohn and Lapata, 2008; Cohn and Lapata, 2013; Galanis and Androutsopoulos, 2011; Coster and Kauchak, 2011a). However, with the recent success of the sequence-to-sequence (Seq2Seq) model, the task of abstractive sentence compression has become viable. Seq2Seq has an encoder-decoder architecture where the encoder encodes the input sequence into hidden states, and the decoder then generates the output sequence from the hidden states. The attention mechanism (Bahdanau et al., 2014), which can align the output sequence with the input sequence automatically, boosts the performance of Seq2Seq significantly. A number of abstractive sentence compression work has been built upon the Seq2Seq architecture with attention mechanism, such as (Chopra et al., 2016; Wubben et al., 2016; Nallapati et al., 2016; See et al., 2017). These abstractive models (which will be termed *generate-based* models hereafter) have the ability to reorder words or rephrase. However, none of these models consider explicit word deletion. As Coster and Kauchak (2011b) pointed out, deletion is a frequently occurring phenomena in sentence compression dataset. Coster and Kauchak (2011a) imposed delete operation on their sentence compression model and improved the performance significantly. Thus, deletion is also very important for abstractive sentence compression task.

Inspired by previous work, we propose an Operation Network for abstractive sentence compression, which combines the advantages of both delete-based and generated-based sentence compression. The central idea is to model the sentence compression process as an editing procedure. We not only enable the model with a strong ability of word deletion inspired from delete-based models, but also endow the model with the ability of word reordering and word rephrasing inspired from generate-based models.

With a series of editing operations, the source text can be transformed into a condensed version of itself. There are three kinds of editing operations in our model: *delete*, *copy* and *generate*. Given a source text as input, first the *delete* operations remove unnecessary words from the source text yet retain the important content. Then, the summary is constructed by the *copy* and *generate* operations. *Copy* operations duplicate words directly from the selected source text, while *generate* operations produce words which are not in the source texts. Our model is built upon the Seq2Seq framework, and can be trained in an end-to-end fashion.

To summarize, the contributions of this paper are as follows:

- We propose Operation Network, a neural framework for abstractive sentence compression, which models the sentence compression task as a series of editing operations.
- Our Operation Network combines the advantages of both delete-based and generate-based sentence compression. The model is equipped with a strong ability of not only word deletion, but also word reordering and word rephrasing. Experiments show that our model outperforms the baselines.

2 Task Definition

We formulate the problem of abstractive sentence compression discussed in this paper as follows: Given a source sentence $X = (x_1, x_2, ..., x_n)$ as input, the goal is to generate a target sentence $Y = (y_1, y_2, ..., y_m)$, $m < n$, which is a condensed version of X with good readability and retains the most important information in X. Essentially, the model estimates the conditional probability as follows:

$$P(\boldsymbol{Y}|\boldsymbol{X}) = \prod_{t=1}^{m} P(y_t|y_{<t}, \boldsymbol{X}). \tag{1}$$

3 Background: Seq2Seq Model

Our model is built upon the general Seq2Seq model (Sutskever et al., 2014), which is also called the encoder-decoder model. The model consists of an encoder and a decoder. The encoder takes as input

a source sequence $\boldsymbol{X} = (x_1, x_2, ..., x_n)$, and outputs a sequence of hidden states $\boldsymbol{h} = (h_1, h_2, ..., h_n)$. The decoder takes $\boldsymbol{h}$ as input and outputs the target sequence $\boldsymbol{Y} = (y_1, y_2, ..., y_m)$.

In both encoder and decoder, we use gated recurrent unit (GRU) (Cho et al., 2014; Chung et al., 2014) as the basic unit. We use a bi-directional RNN (Schuster and Paliwal, 1997) as encoder. A bi-directional RNN contains two distinct RNNs, a forward RNN and a backward RNN. Given the input $\boldsymbol{X} = (x_1, x_2, ..., x_n)$ and the embedding lookup table e, the forward RNN reads the input in the left-to-right direction, resulting a sequence of forward hidden states $\overrightarrow{\boldsymbol{h}} = (\overrightarrow{h}_1, \overrightarrow{h}_2, ..., \overrightarrow{h}_n)$, where $\overrightarrow{h}_t = \text{GRU}(\overrightarrow{h}_{t-1}, e(x_t))$. Similarly, the backward RNN reads the input in the reversed direction and outputs $\overleftarrow{\boldsymbol{h}} = (\overleftarrow{h}_1, \overleftarrow{h}_2, ..., \overleftarrow{h}_n)$. At each time step, we concatenate the hidden states of the corresponding forward and backward RNNs and obtain the encoder hidden states $\boldsymbol{h} = (h_1, h_2, ..., h_n)$, where $h_t = [\overrightarrow{h}_t; \overleftarrow{h}_t]$, $t = 1, ..., n$ and $[A; B]$ denotes vector concatenation.

In the decoder for general Seq2Seq model, another GRU is used for updating the decoder hidden states. Given a context vector c_t and the previously decoded word y_{t-1}, the decoder hidden states are updated as follows:

$$s_t = \text{GRU}(s_{t-1}, [c_t; e(y_{t-1})]) \tag{2}$$

The context vector c_t is designed to dynamically attend on key information of the input sentence during the decoding procedure (Bahdanau et al., 2014). c_t is calculated as a weighted sum of the encoder hidden states:

$$c_t = \sum_{k=1}^{n} \alpha_{tk} h_k \tag{3}$$

$\boldsymbol{\alpha}_t = (\alpha_{t1}, \alpha_{t2}, ..., \alpha_{tn})$ is called the *attention distribution*. It can be viewed as a probability distribution over the source words, which tells the decoder where to attend to produce the next word. The attention distribution is calculated as follows:

$$\alpha_{tk} = \text{softmax}(e_{tk}) = \frac{\exp(e_{tk})}{\sum_{j=1}^{n} \exp(e_{tj})} \tag{4}$$

$$e_{tk} = v_a^\top \tanh(W_a s_{t-1} + U_a h_k + b_a) \tag{5}$$

where v_a, W_a, U_a and b_a are trainable parameters.

The vocabulary distribution P_t^{voc} at time step t is calculated as follows:

$$P_t^{voc} = \text{softmax}(W_o'(W_o[s_t; c_t] + b_o) + b_o') \tag{6}$$

where W_o', W_o, b_o and b_o' are trainable parameters. P_t^{voc} is a probability distribution over all words in the vocabulary V, and the output word y_t at time step t is calculated as follows:

$$y_t = \arg\max_w P_t^{voc}(w), w \in V \tag{7}$$

During training, the loss for time step t is the negative log likelihood of the target word y_t^*: $\text{loss}_t = -\log P_t^{voc}(y_t^*)$. The overall loss function for the whole word sequence is: $\text{loss} = \frac{1}{T_Y} \sum_{t=1}^{T_Y} \text{loss}_t$, where T_Y is the length of the target word sequence $\boldsymbol{Y}$.

4 Operation Network

In this section, we introduce our model, called as the Operation Network, to address the task of abstractive sentence compression. In Operation Network, we consider the transformation from the source sentence to the target sentence as a series of operations. We use three kinds of different operations: delete, copy and generate. To enable the model to perform these three types of edit operations, we use two distinct decoders, one for delete and the other for copy and generate. Specifically, we use the same encoder as in the general Seq2Seq model, but employ a delete decoder and a copy-generate decoder. After the input

sentence is encoded by the encoder, the delete decoder will first delete unnecessary words from the input sentence, then the copy-generate decoder will produce the output sentence either by copying from the choices of the delete decoder, or generating from a fixed vocabulary. The overall architecture of our model is shown in Figure 1.

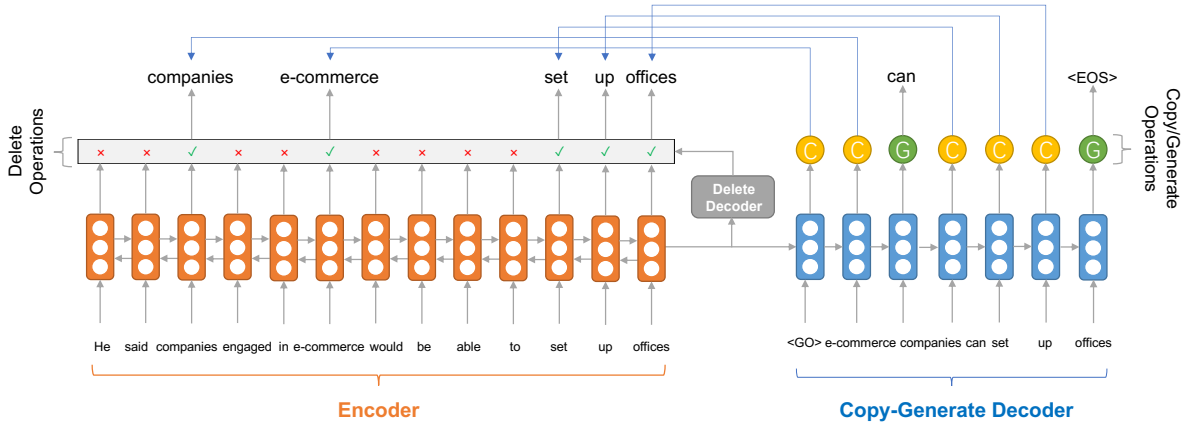

Figure 1: Operation Network, which consists of an encoder, a delete decoder and a copy-generate decoder.

4.1 Delete Decoder

The delete decoder "deletes" all unimportant words from the sentence. It takes as input the sequence of the encoder hidden states $\boldsymbol{h} = (h_1, h_2, ..., h_n)$, the text sequence $\boldsymbol{X} = (x_1, x_2, ..., x_n)$, and outputs a sequence $\boldsymbol{d} = (d_1, d_2, ..., d_n)$, which has the same length n. $d_i \in [0, 1], i \in 1, 2, ..., n$. If d_i is close to 0, then the corresponding word x_i tends to be deleted. Otherwise if d_i is close to 1, then the corresponding word x_i tends to be kept. The output sequence $\boldsymbol{d}$ will be used together with the copy-generate decoder which we will discuss in Section 4.2. The architecture of the delete decoder is shown in Figure 2.

For decoding step t in the delete decoder, we feed the decoder with the embedding of word x_t, the previous decoder output d_{t-1} and the context vector c_t. The delete decoder states are updated as follows:

$$s_t = \text{GRU}(s_{t-1}, [c_t; e(x_t); d_{t-1}]) \tag{8}$$

$$d_t = \sigma(W_d s_t^d + b_d) \tag{9}$$

where σ is the sigmoid function, c_t is the context vector calculated in the same way as Equation 3, e denotes the word embedding table, and W_d and b_d are trainable parameters.

The output of the delete decoder, $\boldsymbol{d} = (d_1, d_2, ..., d_n)$, is fed into the copy-generate decoder for further calculation.

4.2 Copy-Generate Decoder

The Copy-Generate decoder produces output the compressed sentence word by word, and the output words are either copied from the input words which are filtered by the delete decoder, or generated with a fixed vocabulary. In other words, our model integrates copy, generate, delete operations together to produce the output sequence.

We implement the Copy-Generate decoder as a hybrid network between the basic Seq2Seq network and a pointer network (Vinyals et al., 2015). The structure of the Copy-Generate decoder is close to CopyNet (Gu et al., 2016), Pointer Softmax (Gulcehre et al., 2016) and Pointer-Generator (See et al., 2017). However, the Copy-Generate decoder model has some unique characteristic designed for abstractive sentence compression task. The major difference is that our Copy-Generate decoder incorporates the result of the delete decoder, to make sure that unnecessary words will not be copied back by accident. Another difference from the other models is that our model generates explicit operations. During the

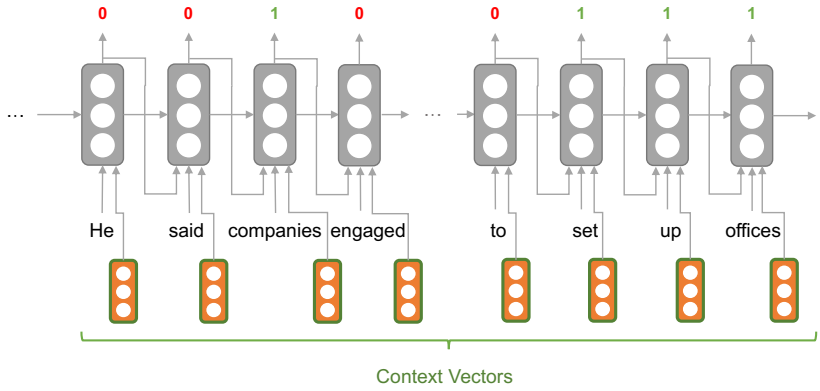

Figure 2: Delete Decoder.

training procedure, we also add supervision on these operations (see Section 4.3). We find that explicit operation supervision can lead to better results. Last, unlike Gu et al. (2016) and Gulcehre et al. (2016), where copy operations are only used for handling UNK tokens (special tokens which stand for out-of-vocabulary words) or named entities, in our model, copy operations are triggered much frequently as long as the output word can be copied from the input sentence. This is useful especially when the training dataset is relatively small.

The Copy-Generate decoder takes as input the encoder hidden states $\boldsymbol{h} = (h_1, h_2, ..., h_n)$ and the attention distributions $\boldsymbol{\alpha} = (\alpha_1, \alpha_2, ..., \alpha_n)$, and outputs the target sentence as a sequence of words $\boldsymbol{Y} = (y_1, y_2, ..., y_m)$. At each step of decoding, a switch network is used to decide whether to use copy mode or generate mode. If copy mode is chosen, the word is copied directly from the source words (filtered by the delete decoder). We use the attention distributions to sample the source words. The output of the delete decoder is used to modify the attention distributions to filter out unwanted words. Otherwise, if generate mode is chosen, the word is generated from the fixed vocabulary. Specifically, for words that are neither in the source sentence nor in the vocabulary, the switch network will choose generate mode and UNK tokens will be produced from the decoder.

The Copy-Generate decoder use another distinct GRU to update its decoder hidden states as follows:

$$s'_t = \text{GRU}(s'_{t-1}, [c_t; e(y_{t-1})]) \tag{10}$$

where s'_t is the decoder hidden state at time step t, c_t is the context vector, e denotes the word embedding table, and y_{t-1} is the previous decoded output.

At each time step t, the switch network calculates *generate probability* as follows:

$$g_t^{gen} = \sigma(W_z[s'_t; c_t] + b_z) \tag{11}$$

g_t^{gen} acts as a soft switch to choose between generate mode and copy mode.

In generate mode, the target word is sampled from the vocabulary distribution P_t^{voc} (see Equation 6).

In copy mode, first we use the outputs of the delete decoder $\boldsymbol{d}$ (see Section 4.1) to mask and re-normalize the attention distribution $\boldsymbol{\alpha_t}$:

$$\boldsymbol{\alpha'_t} = \frac{1}{\sum_{i=1}^{n} d_i \alpha_{ti}} (d_1\alpha_{t1}, d_2\alpha_{t2}, ..., d_n\alpha_{tn}) = (\alpha'_{t1}, \alpha'_{t2}, ..., \alpha'_{tn}). \tag{12}$$

Then the target word is sampled from the modified attention distribution $\boldsymbol{\alpha'_t}$.

For each sentence, let the *extended vocabulary* V' denotes the union of the vocabulary V and all words appearing in the source sentence, then the final probability distribution over the extended vocabulary V' is:

$$P_t(w) = g_t^{gen} P_t^{voc}(w) + (1 - g_t^{gen}) \sum_{k:w=x_k} \alpha'_{tk}, w \in V' \tag{13}$$

where x_k denotes the kth words in the source sequence $\boldsymbol{X}$. The output word y_t at time step t is sampled from the final distribution P_t:

$$y_t = \arg\max_w P_t(w), w \in V' \tag{14}$$

4.3 Loss Function

The total loss consists of two parts: the loss from delete decoder and the loss from copy-generate decoder.

4.3.1 Delete Decoder Loss

The delete decoder loss measures the difference between the target deletion sequence and the actual deletion sequence predicted by the delete decoder. The delete decoder loss is calculated as follows:

$$delete\_loss = \frac{1}{T_X}\sum_{t=1}^{T_X}\Big(-\hat{d}_t \log d_t - (1-\hat{d}_t)\log(1-d_t)\Big) \tag{15}$$

where T_X is the length of the source word sequence X, and $\hat{\boldsymbol{d}}$ is the target deletion sequence, $\hat{d}_t = 0$ if word x_t should be deleted, otherwise, if word x_t should be kept, $\hat{d}_t = 1$.

4.3.2 Copy-Generate Decoder Loss

At each time step t, the copy-generate decoder loss can be divided into three parts: the switch loss, the copy loss and the generate loss. The switch loss measures the difference between the target switch and the predicted switch by the model. The copy loss measures the difference between the target attention distribution and the actual attention distribution predicted by the model. And the generate loss measures the loss between the target vocabulary distribution and the generated vocabulary distribution at that time step. The losses at time step t is calculated as follows:

$$\begin{aligned} switch\_loss_t = &- \hat{g}_t^{gen} \log g_t^{gen} \\ &- (1-\hat{g}_t^{gen}) \log(1-g_t^{gen}) \end{aligned} \tag{16}$$

$$copy\_loss_t = - (1-\hat{g}_t^{gen}) \log \sum_{k:y_t^*=x_k} \alpha'_{tk} \tag{17}$$

$$gen\_loss_t = - \hat{g}_t^{gen} \log P_t^{voc}(y_t^*) \tag{18}$$

where $\hat{g}_t^{gen} = 1$ if target is in *generate mode* at time step t, otherwise, if target is in *copy mode*, $\hat{g}_t^{gen} = 0$. y_t^* denotes the target word at time step t.

The overall copy-generate loss function for the target compressed sentence is as follows:

$$copy\_gen\_loss = \frac{1}{T_Y}\sum_{t=1}^{T_Y}(switch\_loss_t + copy\_loss_t + gen\_loss_t) \tag{19}$$

where T_Y is the length of the target word sequence $\boldsymbol{Y}$.

5 Experiments

In this section, we introduce the experiments for abstractive sentence compression with our proposed Operation Network. First, we present a brief description of the dataset, and the pre-processing procedure in our experiments. Then, we introduce baselines that are compared with our model. Next, we introduce parameters of our models in the experiments. At last we present and analyze the experiment results.

5.1 Dataset

We adopt the dataset provided by Toutanova et al. (2016) for our experiments. It's a manually-created, multi-reference dataset for sentence and short paragraph compression. It contains 6,169 source texts with multiple compressions (26,423 pairs of source and compressed texts), consisting of business letters,

news journals, and technical documents sampled from the Open American National Corpus (OANC[1]). Of all the source texts, 3,769 are single sentences and the rest are 2-sentence short paragraphs. Each pair of the source and compressed text is aligned by the state-of-the-art monolingual aligner Jacana (Yao et al., 2013). The dataset is split into a training set (21,145 pairs), a validation set (1,908 pairs) and a test set (3,370 pairs). The dataset is available online[2].

The alignment information together with the pair of source text and compressed text are used for generating operation sequences for our experiments. Specifically, for each pair of the source and compressed text, a delete operation sequence and a copy/generate sequence are generated. The delete operation sequence is a sequence of *delete*/*retain* tokens which has the same length with the source text. For each word in the source text, if the word exists in the compressed text or is aligned by the aligner, the corresponding token in the delete operation sequence is *retain*. On the other hand, if the word neither exists in the compressed text nor aligned by the aligner, the corresponding token in the delete operation sequence should be *delete*. The copy/generate operation sequence is a sequence of *copy*/*generate* tokens which has the same length with the compressed text. For each word in the compressed text, if the word is aligned by the aligner and is the same as its counterpart, then the corresponding token in the sequence is *copy*, which means this word is copied from the source text. If the word is not aligned or not the same as its counterpart, then the corresponding token in the sequence is set to *generate*, which means this word is generated from the vocabulary. The reason we didn't put *delete*, *copy* and *generate* operations in a single sequence is that *delete* operations are source-text-based operations while *copy* and *generate* operations are target-text-based operations. It is consistent with that the delete operation sequence has the same length as the source text and the copy/generate operation sequence has the same length as the compressed text.

5.2 Baselines

We compared the abstractive sentence compression results generated by our model (Operation Network) with those by two baselines. These baselines consist of a generate-only model (Seq2Seq) and a generate + copy model (Pointer-Generator). The details of the baselines are described as follows:

- **Seq2Seq:** Seq2Seq is an generate-only model similar to the model described by Nallapati et al. (2016). It uses the same bi-directional RNN encoder and attention mechanisms as our model. The decoder of Seq2Seq model can only generate words from the fixed vocabulary.

- **Pointer-Generator:** Pointer-Generator is a model proposed by See et al. (2017). It uses a hybrid pointer-generator network that can copy words from source text or generate words directly from a large vocabulary. This model also use coverage to keep track of what has been summarized, which discourage repetition. Refer to See et al. (2017) for more details.

5.3 Experiment Parameters

For all experiments, we use 300-dimensional word embeddings. We also use the pre-trained *GoogleNews* vectors to initialize the embeddings. For words do not exist in *GoogleNews* vectors, we initialize them randomly. The vocabulary size is set to 20,000. We also use the large vocabulary tricks described by Jean et al. (2014). The sampled vocabulary size is set to 4,096. The hidden state of a single GRU is 256-dimensional. To overcome overfitting, we also imposed dropout on the input, output and state vector of the GRUs. The dropout probability is set to 0.5.

We trained the models on a single Nvidia Titan X GPU with a batch size of 32. During training, we used Stochastic Gradient Descent with an initial learning rate of 0.15, and applied the exponential decay to the learning rate as the training process proceeds. At test time, the output sentences are decoded using beam search with beam size 4.

`https://www.microsoft.com/en-us/research/project/intelligent-editing/`

5.4 Experiment Metric

In the experiments, we compare our model and the baselines with the following metrics.

Compression Ratio: The common assumption in compression research is that the system can make the determination of the optimal compression length. Thus, compression ratios can vary drastically across systems. Different systems can be compared only when they are compressing at similar ratios (Napoles et al., 2011). Compression ratio is defined as:

$$\text{CompRatio} = \frac{\text{\# of tokens in compressed text}}{\text{\# of tokens in source text}} \tag{20}$$

ROUGE: We evaluated our models with the standard ROUGE metric proposed by Lin (2004). ROUGE stands for Recall-Oriented Understudy for Gisting Evaluation. It is commonly used for measuring the quality of the summary by comparing computer-generated summaries to reference summaries generated by humans. The basic idea of ROUGE is to count the number of overlapping units such as n-grams, word sequences, and word pairs between computer-generated summaries and the reference summaries. In our experiments, we considered ROUGE-1, ROUGE-2 and ROUGE-L (which respectively measures the word-overlap, bigram-overlap, and longest common sequence between the reference summary and the summary to be evaluated).

BLEU: We also report BLEU scores of the baseline models and Operation Network on the test dataset. BLEU is proposed by Papineni et al. (2002), and is usually used for automatic evaluation of statistical machine translation systems. However, it can also be used for evaluating sentence compression task (Napoles et al., 2011). We use the multi-bleu script[3] for BLEU score calculation.

5.5 Result Analysis

We present the average ratios of the operations in Operation Network's outputs and the human-written references on the test dataset in Figure 3. Note that the delete ratio is calculated as the number of delete operations divide by the number of tokens in *source* text, and the copy and generate ratio is calculated as the number of copy and generate operations divided by the number of tokens in *compressed* text, respectively. From the figure we can see that Operation Network can utilize the operation information to help accomplish the sentence compression task. The average delete ratio in Operation Network is lower than in human reference, since there are multiple references for one source text in the dataset, and the Operation Network learns to delete a token only it is deleted in most of the references. The average copy ratio is higher in Operation Network than in human reference, this may suggest that Operation Network tends to copy words directly from the source text whenever it is possible.

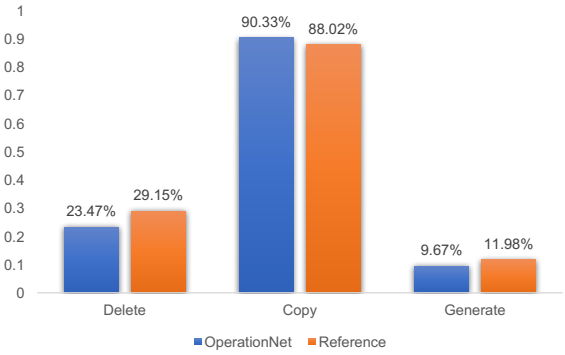

Figure 3: The average ratios of *delete*, *copy* and *generate* operations of Operation Network and human-written references on the test dataset.

Table 1 shows the average compression ratios (%), ROUGE and BLEU scores of the baseline models and Operation Network on the test dataset. The second column shows the average compression ratios.

[3] https://github.com/moses-smt/mosesdecoder/blob/master/scripts/generic/multi-bleu.perl

The average compression ratio is calculated as the average of the compression ratios of all the compressed text outputs in the test dataset. We can see that the average compression ratios of both our model and the other two baselines are similar. Thus, the comparison between our model and the baseline models is fair. Since we have employed the delete decoder in Operation Network, the average compression ratio of our model is lower than the other baselines.

	CompRatio (%)	ROUGE-1	ROUGE-2	ROUGE-L	BLEU
Seq2Seq	69.39	30.05	10.42	26.87	18.32
Pointer-Generator	66.59	35.34	16.57	32.56	25.09
OperationNet	65.53	**36.21**	**17.43**	**33.72**	**26.30**

Table 1: Average compression ratios (%), ROUGE and BLEU scores of the models on the test dataset. Statistically significant improvements ($p < 0.01$) over the baselines are demonstrated by bold fonts.

From Table 1 we can see that the generate-only model (Seq2Seq) performs poorly compared to its counterparts. This is due to the fact that the Seq2Seq model can only generate words from a fixed vocabulary. When the training dataset is relatively small (about 21k pairs of source and compressed text), the model may not be trained adequately. We tried the same models with random-initialized word embeddings and with *GoogleNews*-vector-initialized word embeddings and it turned out that random-initialized word embeddings lead to worse performance. The copy-and-generate model (Pointer-Generator) performs much better than the generate-only model. This is because the copy operations allow to copy words directly from the source texts and the attention distribution is much smaller than the vocabulary distribution and easier to train. With the addition of delete operation, our model (Operation Network) outperforms the other baselines in terms of all three ROUGE metrics and the BLEU metric. Results show that the delete operations can effectively filter out unnecessary words from the source texts and lead to better performance. This can also show that the Operation Network is suitable for the abstractive sentence compression task.

In order to evaluate the quality of the summaries produced by our model and the other baselines, we ask annotators to do a score evaluation on some aspects of the summaries. Specifically, we ask them to score the grammaticality and non-redundancy of the summaries. Annotators are instructed to read the summary carefully and rate each aspect with scores matching the quality of the corresponding aspect. Each aspect is rated with a score from 0 (bad) to 5 (excellent). We randomly sample 100 samples from the test set for evaluation. Each summary generated by our model or baselines is rated by at least 5 annotators. The summaries are randomly reordered and model information is anonymous to the annotators. The evaluation result is shown in Table 2.

	Grammaticality	Non-Redundancy
Seq2Seq	2.53	2.24
Pointer-Generator	**3.46**	3.58
OperationNet	3.23	**3.64**

Table 2: Results of aspect evaluation.

The results in Table 2 show that combined with the delete decoder, our model can effectively delete unimportant contents without losing much grammar quality of the text. This exactly matches what we expect from our model. Pointer-Generator model performs better on grammaticality aspect than our model, however, our model outperforms the other baselines on non-redundancy aspect. The basic Seq2Seq model performs poorly on both grammaticality aspect and non-redundancy aspect.

6 Related Work

Delete-based sentence compression. A large number of work is devoted to delete-based sentence compression. Jing (2000) presented a system that used multiple sources of knowledge to decide which phrases in a sentence can be removed. Knight and Marcu (2000) proposed statistical approaches to mimic the sentence compression process, they used both noisy-channel and decision-tree to solve the problem. McDonald (2006) presented a discriminative large-margin learning framework coupled with a feature set and syntactic representations for sentence compression. Clarke and Lapata (2006) compared different models for sentence compression across domains and assessed a number of automatic evaluation measures. Clarke and Lapata (2008) used integer linear programming to infer globally optimal compression with linguistically motivated constraints. Berg-Kirkpatrick et al. (2011) proposed a joint model of sentence extraction and compression for multi-document summarization. Filippova and Altun (2013) presented a method for automatically building delete-based sentence compression corpus and proposed an compression method which used structured prediction.

Abstractive sentence compression. Abstractive sentence compression extends delete-based compression methods with additional operations, such as substitution, reordering and insertion. Cohn and Lapata (2008) proposed a discriminative tree-to-tree transduction model which incorporated a grammar extraction method and used a language model for coherent output. Galanis and Androutsopoulos (2011) presented a dataset for extractive and abstractive sentence compression and proposed a SVR based abstractive sentence compressor which utilized additional PMI-based and LDA-based features. Shafieibavani et al. (2016) proposed a word graph-based model which can improve both informativeness and grammaticality of the sentence at the same time.

Neural sentence compression. Filippova et al. (2015) proposed a delete-based sentence compression system which took as input a sentence and output a binary sequence corresponding to word deletion decisions in the sentence. The model was trained on a set of 2 millions sentence pairs which was constructed by the same approach used in Filippova and Altun (2013). There are also some neural approaches for abstractive sentence compression. Rush et al. (2015) proposed a fully data-driven approach which utilized neural language models for abstractive sentence compression. They tried different kinds of encoders to encode the input sentence into vector representation of fixed dimensions. Chopra et al. (2016) further improved the model with Recurrent Neural Networks. However, both works used vocabularies of fixed size for target sentence generation. Wubben et al. (2016) used a Seq2Seq model with bi-directional LSTMs for abstractive compression of captions. Toutanova et al. (2016) manually created a multi-reference dataset for sentence and short paragraph compression and studied the correlations between several automatic evaluation metrics and human judgment.

7 Conclusion

In this paper, we propose Operation Network, a neural approach for abstractive sentence compression, which combines the advantages of both delete-based and generate-based abstractive sentence compression. The central idea of Operation Network is to model the sentence compression process as an editing procedure. With 3 kinds of operations (*delete*, *copy* and *generate*), Operation Network can transform the source sentence into the condensed target. Operation Network is implemented based on the neural Seq2Seq network and pointer network, which consists of a delete decoder and a copy-generate decoder. Given a source sentence as input, first the delete decoder *deletes* unnecessary words from the source sentence, then new words are either *generated* from a large vocabulary or *copied* from the source sentence with the copy-generate decoder. The model is equipped with a strong ability of not only word deletion, but also word reordering and word rephrasing. Experiments show that the model outperforms the baselines.

Enhanced Aspect Level Sentiment Classification with Auxiliary Memory

Peisong Zhu, Tieyun Qian *
School of Computer Science, Wuhan University, China
{zhups24, qty}@whu.edu.cn
*Contact author

Abstract

In aspect level sentiment classification, there are two common tasks: to identify the sentiment of an aspect (category) or a term. As specific instances of aspects, terms explicitly occur in sentences. It is beneficial for models to focus on nearby context words. In contrast, as high level semantic concepts of terms, aspects usually have more generalizable representations. However, conventional methods cannot utilize the information of aspects and terms at the same time, because few datasets are annotated with both aspects and terms. In this paper, we propose a novel deep memory network with auxiliary memory to address this problem. In our model, a main memory is used to capture the important context words for sentiment classification. In addition, we build an auxiliary memory to implicitly convert aspects and terms to each other, and feed both of them to the main memory. With the interaction between two memories, the features of aspects and terms can be learnt simultaneously. We compare our model with the state-of-the-art methods on four datasets from different domains. The experimental results demonstrate the effectiveness of our model.

1 Introduction

Sentiment analysis (Pang and Lee, 2008; Liu, 2012) is a fundamental task in the field of natural language processing. As one of the subtasks of sentiment analysis, the goal of aspect level sentiment classification is to infer the sentiment polarity (e.g. positive, negative, neutral) of the aspect (e.g. food, service). Aspect level sentiment classification is arousing more and more researchers' attention, as it can provide more all-round and deeper analysis than document or sentence level sentiment classification.

There are two common scenes in aspect level sentiment classification. The first one aims to identify the sentiment of a predefined aspect, we call it ASC (aspect sentiment classification) for short. The other aims to identify the sentiment of an explicit term which occurs in the sentence, we call it TSC (term sentiment classification). We take the review "*A mix of students and area residents crowd into this narrow, barely there space for its quick, tasty treats at dirt-cheap prices.*" as an example. For ASC task, we need to infer the sentiment polarities for a set of predefined aspects including "*food*", "*price*", and "*ambience*". Here, the sentiment polarities for "*food*" and "*price*" are positive while that for "*ambience*" is negative. For TSC task, we are given three terms "*space*", "*treats*", "*prices*" in the review and need to infer the sentiment polarities for these terms. Here, the sentiment polarities for terms "*treats*" and "*prices*" are positive while that for "*space*" is negative.

In most cases, aspect level sentiment classification works in a supervised manner. Researchers usually extract features and use machine learning algorithms to train the sentiment classifier. Typical methods are usually based on the manually extracted features. Such methods need either laborious feature engineering works or massive linguistic resources. In recent years, neural networks have achieved significant performance in various NLP tasks like question answering (Sukhbaatar et al., 2015), machine translation (Bahdanau et al., 2014), text summarization (Rush et al., 2015), and text classification (Kim, 2014; Kalchbrenner et al., 2014; Yang et al., 2016). The key advantage of these methods is that they

Proceedings of the 27th International Conference on Computational Linguistics, pages 1077–1087
Santa Fe, New Mexico, USA, August 20-26, 2018.

can automatically learn text features or representations from data. There are several pioneering studies introducing neural networks into the field of sentiment classification, including long short term memory (Tang et al., 2016a; Wang et al., 2016) and deep memory network (Tang et al., 2016b; Tay et al., 2017). The main intuition behind these studies is to capture the important context words related to the given aspects.

The terms and aspects in ASC or TSC are closely related to each other. For example, the term "*sandwich*" is surely about the aspect "*food*". However, existing neural network based methods fail to utilize the relevance between the aspects and the terms as very few datasets are annotated with both aspects and terms. On one hand, the number of terms is extremely large and they normally exhibit a long-tailed distribution. For example, in the review "*Not only did they have amazing, sandwiches, soup, pizza etc, but their homemade sorbets are out of this world!*", "*sandwiches*", "*soup*", "*pizza*", and "*sorbets*" are different words though they are all about the aspect of "food", and many of them rarely occur in the corpus. It is hard for neural networks to train high quality embeddings for the terms with low frequency. On the other hand, as the high level semantic concepts of terms, the number of aspects is small and the aspects are usually predefined. This ensures that the embeddings of aspects are of high quality and generalization ability. However, aspects do not explicitly occur in sentences, thus it is hard for a model to capture aspect related context words from the sentence.

In this paper, we propose a novel deep memory network with an auxiliary memory (**DAuM**) to solve the above problems. Specifically, we first adopts a basic memory to capture the important part of context words for sentiment classification. We then present an auxiliary memory to make the connections between aspects and terms. Due to the lack of supervised information, we cannot get term words for each sentence in ASC task, or get aspect words for each sentence in TSC task. Following the idea of (Lau et al., 2017) and (He et al., 2017), we implicitly generate aspects for terms or extract terms for aspects via the auxiliary memory. Finally, the original and generated aspects/terms are fed into the main memory to capture the sentiment words related to the aspects/terms. With the interaction between two memories, the output vectors will combine features of both aspects and terms. We compare our model with the state-of-the-art methods on four datasets. The experimental results show that our model performs well for different domains of data, and consistently outperforms all baselines.

2 Related Work

Aspect level sentiment classification is a challenging task which aims to identify the sentiment polarity of an aspect or a term in the sentence. Recent years have witnessed the boom of deep learning methods in in aspect level sentiment classification tasks. Tang et al. (2016a) proposed target-dependent LSTM to capture the aspect information when modeling sentences. A forward LSTM and a backward LSTM towards term words are used to capture the information before and after the aspect term. Obviously, this method is not suitable to ASC task as aspect words do not always explicitly occur in sentences.

Attention mechanism (Bahdanau et al., 2014) is an effective mechanism which enforces the model to focus on the important part of context words by computing a weight distribution for context words. Wang et al. (2016) proposed an attention-based LSTM method for the ASC task by concentrating on different parts of a sentence to different aspects. In many cases, given terms have multiple words which makes it difficult to build the semantic representations. Ma et al. (2017) proposed an interactive attention network to address this problem.

Tang et al. (2016b) introduced an end-to-end memory network for aspect level sentiment classification, which employs an attention mechanism over an external memory to capture the importance of each context word. Such importance degree and text representation are calculated with multiple computational layers, each of which is a neural attention model over an external memory. Tay et al. (2017) designed a dyadic memory network that models dyadic interactions between aspect and context with neural tensor compositions or holographic compositions for memory selection operation.

We distinguish our work with the memory networks (Tang et al., 2016b; Tay et al., 2017) in that our goal in to capture the relatedness between term and aspect to improve the sentiment classification performance and we design an auxiliary memory to this end. In contrast, existing studies only focus

on the relatedness between context words the aspect/term using a sentiment memory, which is a single component in our model. Our study is inspired by the recent advances in neural networks, including the unsupervised aspect extraction method in (He et al., 2017), the deep multi-task learning framework in (Li and Lam, 2017) for aspect and opinion extraction tasks, the end-to-end deep memory network for attitude identification and polarity classification task in (Li et al., 2017), and the neural attention networks for stance classification task in (Du et al., 2017).

3 Deep Memory Network with Auxiliary Memory

In this section, we describe our proposed **DAuM** model for aspect level sentiment classification. We mainly introduce the model for TSC task, which has similar architecture for ASC task. We first give the overview of the model and then describe the single layer case. Finally, we introduce how to extend model to stack multiple layers.

3.1 An Overview

An illustration of 3-layer model for TSC is given in Figure 1.

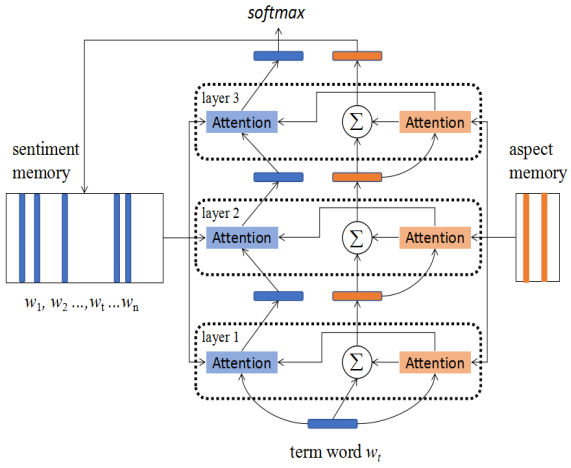

Figure 1: Architecture of **DAuM**

The left part in blue is the main memory for sentiment classification, and we call it sentiment memory. The right part in red is the auxiliary memory. In TSC, auxiliary memory takes a term as input and generates corresponding aspect representation. Therefore we call it aspect memory. Both the original term representation and generated aspect representation, which incorporate term and aspect information at the same time, are fed into sentiment memory to capture the important part of context words. The middle part consists in multiple computational layers. The output vector of a layer is taken as the input of the next layer.

3.2 Single Layer

Input Embedding: To apply deep-learning method to text data, we first map each word into a low-dimensional continuous vector, which is also known as word embedding (Mikolov et al., 2013; Pennington et al., 2014). Specifically, let $\mathbb{L} \in \mathbb{R}^{d \times |V|}$ be an embedding matrix made up of all the word embeddings, where d is the dimensionality of word embedding and $|V|$ is vocabulary size. Given a sentence $s = \{w_1, w_2, ..., w_n\}$ consisting n words, we first use a lookup layer to get the embedding $x_i \in \mathbb{R}^d$ of word w_i, which is a column in the embedding matrix $\mathbb{L}$.

Since terms occur in sentences and a term may contain one single word or multiple words as a phrase, we use word embedding matrix $\mathbb{L}$ to get the representations for terms. In case that a term contains only one word, the term representation will be the embedding of the word. For a phrase-form term, its representation is the average of all constituting word embeddings. We use $v_t \in \mathbb{R}^d$ to denote the term representation.

Aspect Memory: In order to implicitly infer the corresponding aspect for a given term, we define an auxiliary memory to stack the aspect information. The memory takes a term as input, and generates an output representation, which is combined with aspect information. Formally, we define the aspect memory as $M_a \in \mathbb{R}^{k \times d}$, where k is the memory size or the number of defined aspects, and m_i represents the *i*-th piece of the memory.

Taking the term embedding $v_t \in \mathbb{R}^d$ as input, the aspect memory generates a continuous output vector $o_a \in \mathbb{R}^d$. The vector o_a is computed as a weighted sum of each piece of memory m_i via attention mechanism.

$$o_a = \sum_{i=1}^{k} m_i \alpha_i, \tag{1}$$

where α_i is the weight for a piece of memory m_i. The weight α_i is computed based on the semantic relatedness between the term and each aspect.

$$u_i = m_i \cdot W_a \cdot v_t \tag{2}$$

$$\alpha_i = \frac{exp(u_i)}{\sum_{j=1}^{k} exp(u_j)} \tag{3}$$

Eq.2 is a bilinear function used to compute the semantic relatedness. The output of the bilinear function is then fed into a softmax function to generate the final weight α_i in Eq.3.

Sentiment Memory: The goal of TSC is to identify the sentimental polarity of given terms. To this end, we build another external memory, called sentiment memory, to capture the important context words which may be helpful to sentiment classification. Different from the memory network in (Tang et al., 2016b), the sentiment memory in our model takes both term representation and generated aspect representation as the input. Hence our input contains richer information for sentiment classification than that in (Tang et al., 2016b).

We build sentiment memory $M_s \in \mathbb{R}^{n \times d}$ via word embeddings of a sentence , where n is the memory size or the length of the sentence. To differentiate a piece of sentiment memory from that of aspect memory, we use x_i to represent the *i*-th piece in sentiment memory, which is indeed the embedding of the *i*-th word. Similar to aspect memory, the output vector of sentiment memory is also computed as a weighted sum of each piece of memory x_i via attention mechanism. When the term representation $v_t \in \mathbb{R}^d$ is fed into sentiment memory, a feed forward neural network is applied to computing the semantic relatedness between the term and each memory piece.

$$\beta_i^t = softmax(\tanh(W_s^t[x_i; v_t] + b_s^t)), \tag{4}$$

where $W_s^t \in \mathbb{R}^{1 \times 2d}$ and $b_s^t \in \mathbb{R}^{1 \times 1}$ are transformation parameters. To make full use of the information of the term and implicit aspect, sentiment memory further takes the generated aspect representation o_a as input, and generates a weight distribution via attention mechanism.

$$\beta_i^a = softmax(\tanh(W_s^a[x_i; o_a] + b_s^a)), \tag{5}$$

where $W_s^a \in \mathbb{R}^{1 \times 2d}$ and $b_s^a \in \mathbb{R}^{1 \times 1}$ are transformation parameters.

The final weight and output of sentiment memory is computed based on term level weight β^t and aspect level weight β^a. Formally,

$$\beta = (1 - \lambda)\beta^t + \lambda\beta^a, \tag{6}$$

$$o_s = \sum_{i=1}^{n} x_i \beta_i, \tag{7}$$

where β is the final weight combining both term and implicit aspect information, $0 < \lambda < 1$ is the hyperparameter controlling the importance of the aspect or the term, and $o_s \in \mathbb{R}^d$ is the output vector of sentiment memory.

3.3 Multiple Layers

Previous studies (LeCun et al., 2015) show that multiple processing layers can learn higher level representations. Hence we extend our model to stack multiple layers. In the first computational layer, we take the term vector as the input of aspect memory to generate corresponding aspect vector based on

each memory piece in aspect memory through an attention layer. Both the original term vector and the generated aspect vector are then fed into the first layer of sentiment memory to capture the important part of context words through another attention layer. The model is then stacked as follows. In aspect memory, the output of the attention layer and the aspect vector in N_{th} layer are summed as the input of $N+1_{th}$ layer. Then the newly updated aspect vector in $N+1_{th}$ layer of aspect memory and the output of N_{th} attention layer of sentiment memory are taken as the input of $N+1_{th}$ layer of sentiment memory.

3.4 Output and Model Training

After the computation in multiple layers, we get the final output vector o_s^f of sentiment memory and the final output vector o_a^f of aspect memory. Here o_s^f is the sentiment feature, which takes both term and aspect information into consideration. o_a^f is the high level abstraction of a given term. We apply them to different tasks to train the model.

Term Sentiment Classification: Given a term w_t, a sentence s, and the sentiment category set C, the TSC task aims to identify the sentiment polarity of the term in its context. In our model, we regard it as a probability problem, i.e., estimating the conditional probability of w_t in s to a category $c \in C$. We take o_s^f as the final sentiment feature of a sentence, and use a linear layer to transform o_s^f into a real-valued vector which has the same length as the category number $|C|$. We then apply a softmax layer to calculating the conditional probability distribution.

$$P_c(s, w_t) = softmax(W_c o_s^f + b_c), \tag{8}$$

where (s, w_t) denotes a sentence-term pair, and $P_c(s, w_t)$ is the probability of predicting category c given the sentence s and the term w_t. The model is trained in an end-to-end supervised way by minimizing the cross entropy between predicted and real probability distribution. The loss function is written as:

$$L_{cla} = -\sum_{(s,w_t)\in T}\sum_{c\in C} y_c(s, w_t) \cdot log P_c(s, w_t) \tag{9}$$

where T is the set of training data, C is the collection of sentiment categories, and $y_c(s, w_t)$ is the ground truth for (s, w_t) pair.

Term Prediction: o_a^f is the high level aspect representation of a given term. Inspired by (Lau et al., 2017), we believe that the aspect representation generated via a term should be able to predict the term in turn. In other words, the term embedding is more similar to the aspect representation than the embeddings of other words in the sentence. We include this into our objective and define a hinge loss function which maximizes the semantic relatedness between o_a^f and the term while simultaneously minimizing the semantic relatedness between o_a^f and other words in the sentence.

$$L_{pre} = \sum_{(s,w_t)\in T}\sum_{i\in\{1\ldots n\}/\{t\}} max(0, 1 - o_a^f \cdot W_p \cdot v_t + o_a^f \cdot W_p \cdot x_i) \tag{10}$$

Aspect Regularization: We aim to learn the aspect embeddings which can represent different aspects in real-life data. However, the aspect embeddings may suffer from the redundancy problem (He et al., 2017) during the training process. We add a regularization term to ensure the diversity of aspect embeddings.

$$L_{reg} = \|M_a M_a^T - I\|, \tag{11}$$

where I is the identity matrix with the non-diagonal element a_{ij} $(i \neq j)$. $M_a M_a^T$ corresponds to the dot product of two different aspect embeddings, which reflects the relevance between two aspects. L_{reg} reaches its minimum value when the dot product between any two different aspect embeddings is zero. Thus the regularization term encourages orthogonality among the rows of the aspect embedding matrix and penalizes redundant representation. Our final loss function is the linear combination of L_{cla}, L_{pre}, L_{reg}:

$$L_{final} = L_{cla} + \gamma_1 L_{pre} + \gamma_2 L_{reg}, \tag{12}$$

where γ_1, γ_2 are hyperparameters that control the weight of different parts.

3.5 Applied to ASC

The model for ASC task has similar architecture as the model introduced above. With a certain number of aspects, we don't need hyperparameter k for aspect embedding. In addition, auxiliary memory here is used to stack implicit term information, and is initialized with embeddings of words in the sentence. The auxiliary memory takes an aspect as input and generates corresponding term representation with the same method.

4 Experiment

We conduct both the TSC and ASC experiments to check whether our proposed model improve the performance of aspect-level sentiment classification.

4.1 Settings

4.1.1 Dataset

we conduct experiments on four datasets for ASC task and TSC task. In case that the same dataset is used for both tasks, we use a suffix (ASC)/(TSC) to distinguish them.

- **Restaurants(ASC)** is a dataset obtained from SemEval 2014 (Pontiki et al., 2014). This dataset contains customer reviews from the restaurant domain. Each review is annotated a sentiment polarity towards a given aspect. Sentiment polarity set includes "*Positive*", "*Negative*" and "*Neutral*". Predefined aspect set includes "*food*", "*price*", "*service*", "*ambience*" and "*anecdotes/miscellaneous*".
- **Restaurants(TSC)** is the same dataset as Restaurants(ASC) except that terms are given in Restaurants(TSC) while aspects are not annotated.
- **Laptops** is a dataset obtained from SemEval 2014. This dataset contains customer reviews pertaining to the computers and laptops domain. The sentiment polarity set is the same as that in Restaurants(TSC). As terms are given in Laptops, they are used for TSC task.
- **TweetNews** is a dataset obtained from Semeval 2016 Task 6 (Mohammad et al., 2016). It contains English tweets which are annotated for the stance towards one of five topics "*Atheis*", "*Climate Change is a Real Concern*", "*Feminist Movement*", "*Hillary Clinton*", and "*Legalization of Abortio*". The stance set includes "*Favor*", "*Against*" and "*None*" (We treat them as "*Positive*", "*Negative*" and "*Neutral*" for simplification). This dataset is used for ASC task.

We use the official training/testing split in our experiments. To prevent the model from overfitting, we randomly sample one-sixth samples from the training set as the development set. The statistics of four datasets are showed in Table 1.

Table 1: Statistics of four datasets.

Dataset	Set	Total	Pos.	Neg.	Neu.
Restaurants(ASC)	Train	2927	1806	697	424
	Test	973	657	222	94
	Dev	591	372	142	77
Restaurants(TSC)	Train	3017	1806	669	542
	Test	1120	728	196	196
	Dev	591	358	138	95
Laptops	Train	1934	823	730	381
	Test	638	341	128	169
	Dev	394	171	140	63
TweetNews	Train	2416	627	1163	626
	Test	1249	303	716	230
	Dev	498	125	233	140

4.1.2 Metrics

In aspect level sentiment classification task, each dataset has multiple sentiment polarities, and each sample is classified into one of polarities. So we adopt *Accuracy*, *Precision*, *Recall*, as the evaluation

metrics for multi-class classification. We also adopt the macro-averaged *F-score* to show a more thorough result following previous studies (Tay et al., 2017; Tang et al., 2016a).

4.1.3 Experimental Setting

In our experiments, we use 300-dimension word vectors pre-trained by GloVe (Pennington et al., 2014). The dimensionalities of word embedding, aspect embedding are all set to 300, which are same as those in the baselines AE-LSTM and ATAE-LSTM (Wang et al., 2016). λ, γ_1, γ_2 are set to 0.4, 1.0, and 0.5, respectively. We randomize other parameters with uniform distribution $U(-0.01, 0.01)$. We train the model with Stochastic Gradient Descent optimization algorithm and set learning rate as 0.01. We use grid search to get hyper-parameters settings for our method.

4.2 Baselines

In our experiments, we compare our model with the following baseline methods on each dataset.

- **ContextAVG** is a simple baseline which averages the vectors of all context words as the representation of a sentence. The result is then concatenated with the aspect vector and finally fed into softmax function.
- **LSTM** is an implementation of standard LSTM where aspect information cannot be captured in this model.
- **TD-LSTM** (Tang et al., 2016a) takes aspect information into consideration. It uses a forward LSTM and a backward LSTM towards term words to capture the information before and after the term. We run it for only TSC task, as aspect words do not explicitly occur in sentences in ASC task.
- **AE-LSTM** (Wang et al., 2016) takes into account aspect information by embedding aspects into another vector space. The embedding vectors of aspects are learnt during the process of training.
- **ATAE-LSTM** (Wang et al., 2016) is an extension of AE-LSTM. It uses attention mechanism to capture the most important information in response to a given aspect. In addition, ATAE-LSTM can capture the important and different parts of a sentence when different aspects are provides.
- **TAN** (Du et al., 2017) is a model proposed for stance classification which is similar to ASC task. Here we use it as one of baselines to evaluate the effectiveness our model on the task and dataset of other domain.
- **MemNN** (Tang et al., 2016b) is an end-to-end deep memory network which employs an attention mechanism with an external memory to capture the importance of each context word. Such importance degree and text representation are calculated with multiple computational layers.

We re-implemented all baseline methods to make their results as similar as possible to those in the original papers. Each competitor was optimized independently. For the parameters like dimensions, learning rate, and optimization method, we follow their settings in the original paper of the baselines.

4.3 Main Results

In this section, we discuss the experimental results on both ASC task and TSC task. Table 2 reports the results for ASC task on Restaurants (ASC) and TweetNews dataset. Table 3 reports the results for TSC task on Restaurants (TSC) and Laptops dataset.

Table 2: Experimental results for TSC

	Restaurants(TSC)				Laptops			
Method	Accuracy	Precision	Recall	F-score	Accuracy	Precision	Recall	F-score
ContextAVG	75.09	68.93	62.91	63.96	67.24	65.56	60.96	61.86
LSTM	74.28	68.72	61.89	62.21	66.46	65.04	60.54	61.72
TD-LSTM	75.63	69.18	63.05	64.16	68.18	66.86	61.15	62.28
AE-LSTM	76.25	69.76	63.21	64.32	68.97	67.12	61.32	62.50
ATAE-LSTM	77.23	70.83	63.95	64.95	68.65	66.98	61.18	62.45
MemNN	80.09	72.10	65.68	67.82	72.21	70.82	65.03	66.75
DAuM	**82.32**	**74.68**	**70.18**	**71.45**	**74.45**	**72.96**	**69.21**	**70.16**

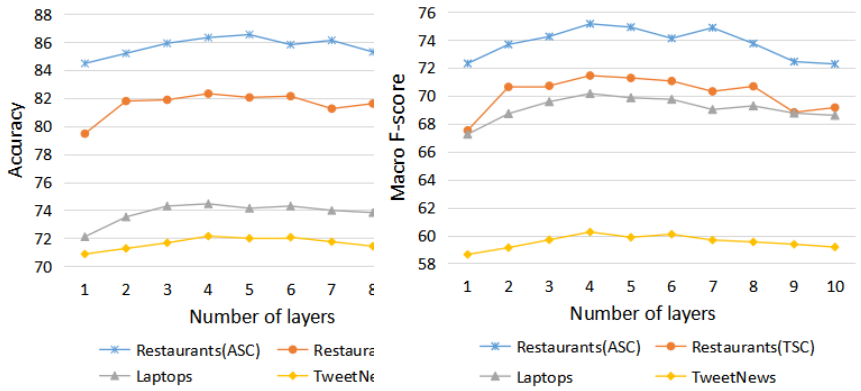
Table 3: Experimental results for ASC

	Restaurants(ASC)				TweetNews			
Method	Accuracy	Precision	Recall	F-score	Accuracy	Precision	Recall	F-score
ContextAVG	80.37	72.86	67.58	68.72	65.25	57.52	51.96	52.88
LSTM	82.01	74.20	69.16	70.20	66.86	58.76	53.12	54.32
AE-LSTM	82.53	74.56	69.36	70.48	69.42	60.96	55.18	56.28
ATAE-LSTM	83.98	75.92	70.88	71.76	69.58	61.10	55.45	56.72
TAN	82.53	74.48	69.50	70.55	68.78	60.42	55.06	56.25
MemNN	84.28	76.06	70.24	72.38	70.14	62.21	57.05	58.62
DAuM	**86.33**	**77.54**	**73.82**	**75.16**	**72.14**	**64.52**	**58.96**	**60.24**

As shown in Table 2 and Table 3, our method consistently outperforms all baselines on four datasets for both ASC task and TSC task. ContextAVG performs poorly. Since averaging context pay equivalent attention to all words, it is unable to capture the sentiment words which are particularly important to sentiment classification. LSTM does not perform well either. The reason may be that it ignores aspect information which plays key role in aspect level sentiment classification. ATAE-LSTM and MemNN perform relatively better as they not only utilize aspect information but also capture important words related to aspect via an attention mechanism. Our model DAuM outperforms ATAE-LSTM and MemNN, as implicit aspect/term representations are generated in our model, which provide more abundant features for sentiment classification. In addition, our model performs better than TAN on TweetNews dataset. This further proves that our model is suitable to some tasks from other domain like stance classification.

4.4 Effects of Multiple Layers

The number of multiple layers has an important effect to the performance of our model. We evaluate our model with 1 to 10 layers with $k = 5$. The results are shown in Figure 2. In general, multiple layers can help compute high level representation and improve the performance. Our model with 4 or 5 layers already works pretty well. However, the performance does not always enhance with the increasing number of layers. It is because too many layers make the training of the model difficult. In addition, the model becomes less generalizable with more parameters introduced.

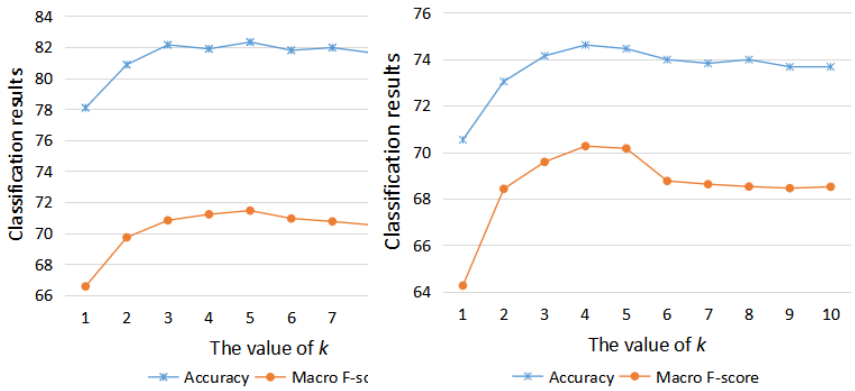


(a) Accuracy (b) Macro F-score

Figure 2: Effects of multiple layers

4.5 Effects of Aspect Number

The aspect number k is a main parameter in our model. To evaluate the effects of aspect number, we fix the number of layers to 4 and change k from 1 to 10. The results are shown in Figure 3. In general, our model performs well in Restaurants(TSC) and Laptops when $k = 5$ and $k = 4$ respectively. When $k < 3$, the result is not as good as when k is large in both datasets. The reason may be that terms are converted into similar aspect representations when k is small. This leads to similar predicted results even



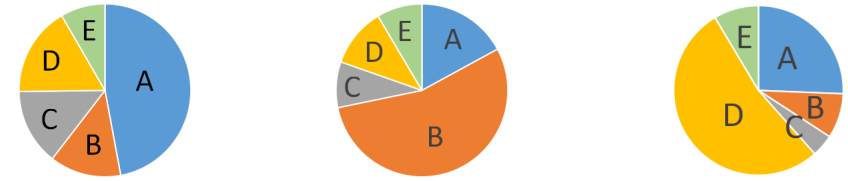
(a) Results on Restaurants(TSC) (b) Results on Laptops

Figure 3: Effects of aspect number k

though different terms are given. It proves that, a limited number of aspects is helpful to our tasks as they have more generalizable representations, but if the number of aspects is too small, it will lose the capability of representing the semantics of different aspects in real-life datasets.

4.6 Case Study

In our model, auxiliary memory takes term/aspect as input and generates corresponding aspect/term representation. To make it more intuitive, we visualize the aspect attention when different terms are fed into aspect memory. The experiment is conducted on Restaurants(TSC) with $k = 5$. "A", "B", "C", "D" and "E" represent the five aspects. Three terms "*pasta*", "*waitress*", "*price*", which belong to aspect "*food*", "*service*", "*price*" respectively, are taken as an example. The pie charts are drawn based on the attention weight for each aspect. The results are shown in Figure 4.



(a) Given "*pasta*" (b) Given "*waitress*" (c) Given "*price*"

Figure 4: Aspect attention weight for different terms

As can be seen, given a term"*pasta*", the aspect memory generates an attention distribution assigning the largest weight to aspect "A". Similarly, the generated attention distribution gives the largest weight to aspect "B" and "D" respectively when other two terms '*waitress*" and "*price*" are fed into aspect memory. To a certain degree, these three cases prove that the aspect memory can effectively compute the semantic relatedness between the given term and each aspect, and consequently generate the most related high level representation.

5 Conclusion

In this paper, we propose a novel deep memory network with auxiliary memory to handle with aspect level sentiment classification tasks. To address the problem that aspect and term information cannot be captured at the same time, we utilize an auxiliary memory to generate aspect or term representation implicitly. The original and generated aspects/terms are all fed into the main memory to capture sentiment words related the aspects/terms. With the interaction between two memories, aspects provide more generalizable representations for terms. And vise versa, terms provide clues for aspects to focus on nearby context words. We demonstrated the effectiveness of our model on four datasets. The results show that

it can significantly outperform the state-of-the-art methods. Besides the improvements of classification performance, our method has a key advantage that it does not need extra annotated aspects or terms. Furthermore, our model can be easily extended to solve other related problems in this domain, or modified with other advanced basic models.

Abstract

The rapid growth of social media in recent years has fed into some highly undesirable phenomena such as proliferation of hateful and offensive language on the Internet. Previous research suggests that such abusive content tends to come from users who share a set of common stereotypes and form communities around them. The current state-of-the-art approaches to abuse detection are oblivious to user and community information and rely entirely on textual (i.e., lexical and semantic) cues. In this paper, we propose a novel approach to this problem that incorporates community-based profiling features of Twitter users. Experimenting with a dataset of $16k$ tweets, we show that our methods significantly outperform the current state of the art in abuse detection. Further, we conduct a qualitative analysis of model characteristics. We release our code, pre-trained models and all the resources used in the public domain.

1 Introduction

Abuse, a term used to collectively refer to offensive language, hate speech, sexist remarks, etc., is omnipresent in social media. Users on social media platforms are at risk of being exposed to content that may not only be degrading but also harmful to their mental health in the long term. *Pew Research Center* highlighted the gravity of the situation via a recently released report (Duggan, 2014). As per the report, 40% of adult Internet users have personally experienced harassment online, and 60% have witnessed the use of offensive names and expletives. Expectedly, the majority (66%) of those who have personally faced harassment have had their most recent incident occur on a social networking website or app. While most of these websites and apps provide ways of flagging offensive and hateful content, only 8.8% of the victims have actually considered using such provisions. These statistics suggest that passive or manual techniques for curbing propagation of abusive content (such as flagging) are neither effective nor easily scalable (Pavlopoulos et al., 2017). Consequently, the efforts to automate the detection and moderation of such content have been gaining popularity in natural language processing (NLP) (Waseem and Hovy, 2016; Wulczyn et al., 2017).

Several approaches to abuse detection demonstrate the effectiveness of character-level bag-of-words features in a supervised classification setting (Djuric et al., 2015; Nobata et al., 2016; Davidson et al., 2017). More recent approaches, and currently the best performing ones, utilize recurrent neural networks (RNNs) to transform content into dense low-dimensional semantic representations that are then used for classification (Pavlopoulos et al., 2017; Badjatiya et al., 2017). All of these approaches rely solely on lexical and semantic features of the text they are applied to. Waseem and Hovy (2016) adopted a

more user-centric approach based on the idea that perpetrators of abuse are usually segregated into small demographic groups; they went on to show that gender information of *authors* (i.e., users who have posted content) is a helpful indicator. However, Waseem and Hovy focused only on coarse demographic features of the users, disregarding information about their communication with others. But previous research suggests that users who subscribe to particular stereotypes that promote abuse tend to form communities online. For example, Zook (2012) mapped the locations of racist tweets in response to President Obama's re-election to show that such tweets were not uniformly distributed across the United States but formed clusters instead. In this paper, we present the first approach to abuse detection that leverages author profiling information based on properties of the authors' social network and investigate its effectiveness.

Author profiling has emerged as a powerful tool for NLP applications, leading to substantial performance improvements in several downstream tasks, such as text classification, sentiment analysis and author attribute identification (Hovy, 2015; Eisenstein, 2015; Yang and Eisenstein, 2017). The relevance of information gained from it is best explained by the idea of *homophily*, i.e., the phenomenon that people, both in real life as well as on the Internet, tend to associate more with those who appear similar. Here, similarity can be defined along various axes, e.g., location, age, language, etc. The strength of author profiling lies in that if we have information about members of a community c defined by some similarity criterion, and we know that the person p belongs to c, we can infer information about p. This concept has a straightforward application to our task: knowing that members of a particular community are prone to creating abusive content, and knowing that the author *p* is connected to this community, we can leverage information beyond linguistic cues and more accurately predict the use of abusive/non-abusive language from p. The questions that we seek to address here are: are some authors, and the respective communities that they belong to, more abusive than the others? And can such information be effectively utilized to improve the performance of automated abusive language detection methods?

In this paper, we answer these questions and develop novel methods that take into account community-based profiling features of authors when examining their tweets for abuse. Experimenting with a dataset of $16k$ tweets, we show that the addition of such profiling features to the current state-of-the-art methods for abuse detection significantly enhances their performance. We also release our code (including code that replicates previous work), pre-trained models and the resources we used in the public domain.[1]

2 Related Work

2.1 Abuse detection

Amongst the first ones to apply supervised learning to the task of abuse detection were Yin et al. (2009) who used a linear SVM classifier to identify posts containing harassment based on local (e.g., n-grams), contextual (e.g., similarity of a post to its neighboring posts) and sentiment-based (e.g., presence of expletives) features. Their best results were with all of these features combined.

Djuric et al. (2015) experimented with comments extracted from the Yahoo Finance portal and showed that distributional representations of comments learned using *paragraph2vec* (Le and Mikolov, 2014) outperform simpler bag-of-words (BOW) representations in a supervised classification setting for hate speech detection. Nobata et al. (2016) improved upon the results of Djuric et al. by training their classifier on a combination of features drawn from four different categories: linguistic (e.g., count of insult words), syntactic (e.g., POS tags), distributional semantic (e.g., word and comment embeddings) and BOW-based (word and characters n-grams). They reported that while the best results were obtained with all features combined, character n-grams contributed more to performance than all the other features.

Waseem and Hovy (2016) created and experimented with a dataset of racist, sexist and clean tweets. Utilizing a logistic regression (LR) classifier to distinguish amongst them, they found that character n-grams coupled with gender information of users formed the optimal feature set; on the other hand, geographic and word-length distribution features provided little to no improvement. Working with the same dataset, Badjatiya et al. (2017) improved on their results by training a gradient-boosted decision

[1] https://github.com/pushkarmishra/AuthorProfilingAbuseDetection

tree (GBDT) classifier on averaged word embeddings learnt using a long short-term memory (LSTM) network that they initialized with random embeddings.

Waseem (2016) sampled $7k$ more tweets in the same manner as Waseem and Hovy (2016). They recruited expert and amateur annotators to annotate the tweets as *racism*, *sexism*, *both* or *neither* in order to study the influence of annotator knowledge on the task of hate speech detection. Combining this dataset with that of Waseem and Hovy (2016), Park et al. (2017) explored the merits of a two-step classification process. They first used a LR classifier to separate abusive and non-abusive tweets, followed by another LR classifier to distinguish between racist and sexist ones. They showed that this setup had comparable performance to a one-step classification setup built with convolutional neural networks.

Davidson et al. (2017) created a dataset of about $25k$ tweets wherein each tweet was annotated as being *racist*, *offensive* or *neither of the two*. They tested several multi-class classifiers with the aim of distinguishing clean tweets from racist and offensive tweets while simultaneously being able to separate the racist and offensive ones. Their best model was a LR classifier trained using TF-IDF and POS n-gram features, as well as the count of hash tags and number of words.

Wulczyn et al. (2017) prepared three different datasets of comments collected from the English Wikipedia Talk page; one was annotated for personal attacks, another for toxicity and the third one for aggression. Their best performing model was a multi-layered perceptron (MLP) classifier trained on character n-gram features. Experimenting with the personal attack and toxicity datasets, Pavlopoulos et al. (2017) improved the results of Wulczyn et al. by using a gated recurrent unit (GRU) model to encode the comments into dense low-dimensional representations, followed by a LR layer to classify the comments based on those representations.

2.2 Author profiling

Author profiling has been leveraged in several ways for a variety of purposes in NLP. For instance, many studies have relied on demographic information of the authors. Amongst these are Hovy et al. (2015) and Ebrahimi et al. (2016) who extracted age and gender-related information to achieve superior performance in a text classification task. Pavalanathan and Eisenstein (2015), in their work, further showed the relevance of the same information to automatic text-based geo-location. Researching along the same lines, Johannsen et al. (2015) and Mirkin et al. (2015) utilized demographic factors to improve syntactic parsing and machine translation respectively.

While demographic information has proved to be relevant for a number of tasks, it presents a significant drawback: since this information is not always available for all authors in a social network, it is not particularly reliable. Consequently, of late, a new line of research has focused on creating representations of users in a social network by leveraging the information derived from the connections that they have with other users. In this case, node representations (where nodes represent the authors in the social network) are typically induced using neural architectures. Given the graph representing the social network, such methods create low-dimensional representations for each node, which are optimized to predict the nodes close to it in the network. This approach has the advantage of overcoming the absence of information that the previous approaches face. Among those that implement this idea are Yang et al. (2016), who used representations derived from a social graph to achieve better performance in entity linking tasks, and Chen and Ku (2016), who used them for stance classification.

A considerable amount of literature has also been devoted to sentiment analysis with representations built from demographic factors (Yang and Eisenstein, 2017; Chen et al., 2016). Other tasks that have benefited from social representations are sarcasm detection (Amir et al., 2016) and political opinion prediction (Tălmăcel and Leon, 2017).

3 Dataset

We experiment with the dataset of Waseem and Hovy (2016), containing tweets manually annotated for abuse. The authors retrieved around $136k$ tweets over a period of two months. They bootstrapped their collection process with a search for commonly used slurs and expletives related to religious, sexual, gender and ethnic minorities. From the results, they identified terms and references to entities that

frequently showed up in abusive tweets. Based on this sample, they used a public Twitter API to collect the entire corpus of ca. $136k$ tweets. After having manually annotated a randomly sampled subset of $16,914$ tweets under the categories *racism*, *sexism* or *none* themselves, they asked an expert to review their annotations in order to mitigate against any biases. The inter-annotator agreement was reported at $\kappa = 0.84$, with a further insight that 85% of all the disagreements occurred in the *sexism* class.

The dataset was released as a list of $16,907$ tweet IDs along with their corresponding annotations[2]. Using python's *Tweepy* library, we could only retrieve $16,202$ of the tweets since some of them have now been deleted or their visibility limited. Of the ones retrieved, 1,939 (12%) are labelled as *racism*, 3,148 (19.4%) as *sexism*, and the remaining 11,115 (68.6%) as *none*; this distribution follows the original dataset very closely (11.7%, 20.0%, 68.3%).

We were able to extract community-based information for 1,836 out of the 1,875 unique authors who posted the $16,202$ tweets, covering a cumulative of 16,124 of them; the remaining 39 authors have either deactivated their accounts or are facing suspension. Tweets in the *racism* class are from 5 of the 1,875 authors, while those in the *sexism* class are from 527 of them.

4 Methodology

4.1 Representing authors

In order to leverage community-based information for the authors whose tweets form our dataset, we create an undirected unlabeled community graph wherein nodes are the authors and edges are the connections between them. An edge is instantiated between two authors u and v if u follows v on Twitter or vice versa. There are a total of 1,836 nodes and 7,561 edges. Approximately 400 of the nodes have no edges, indicating *solitary* authors who neither follow any other author nor are followed by any. Other nodes have an average degree[3] of 8, with close to 600 of them having a degree of at least 5. The graph is overall sparse with a density of 0.0075.

From this community graph, we obtain a vector representation, i.e., an embedding that we refer to as *author profile*, for each author using the *node2vec* framework (Grover and Leskovec, 2016). *Node2vec* applies the skip-gram model of Mikolov et al. (2013) to a graph in order to create a representation for each of its nodes based on their positions and their neighbors. Specifically, given a graph with nodes $V = \{v_1, v_2, \ldots, v_n\}$, *node2vec* seeks to maximize the following log probability:

$$\sum_{v \in V} \log Pr\left(N_s(v) \mid v\right)$$

where $N_s(v)$ denotes the *network neighborhood* of node v generated through sampling strategy s.

In doing so, the framework learns low-dimensional embeddings for nodes in the graph. These embeddings can emphasize either their structural role or the local community they are a part of. This depends on the sampling strategies used to generate the neighborhood: if breadth-first sampling (BFS) is adopted, the model focuses on the immediate neighbors of a node; when depth-first sampling (DFS) is used, the model explores farther regions in the network, which results in embeddings that encode more information about the nodes' structural role (e.g., hub in a cluster, or peripheral node). The balance between these two ways of sampling the neighbors is directly controlled by two *node2vec* parameters, namely p and q. The default value for these is 1, which ensures a node representation that gives equal weight to both structural and community-oriented information. In our work, we use the default value for both p and q. Additionally, since *node2vec* does not produce embeddings for *solitary* authors, we map these to a single zero embedding.

Figure 1 shows example snippets from the community graph. Some authors belong to densely-connected communities (left figure), while others are part of more sparse ones (right figure). In either case, *node2vec* generates embeddings that capture the authors' neighborhood.

[2] https://github.com/ZeerakW/hatespeech/blob/master/NAACL_SRW_2016.csv

[3] The degree of a node is equal to the number of its direct connections to other nodes.

(a) Densely-connected authors

(b) Sparsely-connected authors

4.2 Classifying content

We experiment with seven different methods for classifying tweets as one of *racism*, *sexism*, or *none*. We first re-implement three established and currently best-performing abuse detection methods — based on character n-grams and recurrent neural networks — as our baselines. We then test whether incorporating author profiling features improves their performance.

Char n-grams (LR). As our first baseline, we adopt the method used by Waseem and Hovy (2016) wherein they train a logistic regression (LR) classifier on the Twitter dataset using character n-gram counts. We use uni-grams, bi-grams, tri-grams and four-grams, and L_2-normalize their counts. Character n-grams have been shown to be effective for the task of abuse detection (Nobata et al., 2016).

Hidden-state (HS). As our second baseline, we take the "RNN" method of Pavlopoulos et al. (2017) which achieves state-of-the-art results on the Wikipedia datasets released by Wulczyn et al. (2017). The method comprises a 1-layer gated recurrent unit (GRU) that takes a sequence $w_1, \ldots, w_n$ of words represented as d-dimensional embeddings and encodes them into hidden states $h_1, \ldots, h_n$. This is followed by an LR layer that uses the last hidden state h_n to classify the tweet. We make two minor modifications to the authors' original architecture: we deepen the 1-layer GRU to a 2-layer GRU and use softmax instead of sigmoid in the LR layer.[4] Like Pavlopoulos et al., we initialize the word embeddings to GLoVe vectors (Pennington et al., 2014). In all our methods, words not available in the GLoVe set are randomly initialized in the range ± 0.05, indicating the lack of semantic information. By not mapping these words to a single random embedding, we mitigate against the errors that may arise due to their conflation (Madhyastha et al., 2015). A special OOV (out of vocabulary) token is also initialized in the same range. All the embeddings are updated during training, allowing some of the randomly-initialized ones to get task-tuned; the ones that do not get tuned lie closely clustered around the OOV token, to which unseen words in the test set are mapped.

Word-sum (WS). As a third baseline, we adopt the "LSTM+GLoVe+GBDT" method of Badjatiya et al. (2017), which achieves state-of-the-art results on the Twitter dataset we are using. The authors first utilize an LSTM to task-tune GLoVe-initialized word embeddings by propagating the error back from an LR layer. They then train a gradient boosted decision tree (GBDT) classifier to classify texts based on the average of the embeddings of constituent words. We make two minor modifications to this method: we use a 2-layer GRU[5] instead of the LSTM to tune the embeddings, and we train the GBDT classifier on the L_2-normalized sum of the embeddings instead of their average.[6] Although the authors achieved

[4] We also experimented with 1-layer GRU/LSTM and 1/2-layer bi-directional GRUs/LSTMs but performance only worsened or showed no gains; using sigmoid instead of softmax did not have any noteworthy effects on the results either.

[5] We note the deeper 2-layer GRU slightly improves performance.

[6] Although GBDT, as a tree based model, is not affected by the choice of monotonic function, the L_2-normalized sum ensures uniformity of range across the feature set in all our methods.

state-of-the-art results on Twitter by initializing embeddings randomly rather than with GLoVe (which is what we do here), we found the opposite when performing a 10-fold stratified cross-validation (CV). A possible explanation of this lies in the authors' decision to not use stratification, which for such a highly imbalanced dataset can lead to unexpected outcomes (Forman and Scholz, 2010). Furthermore, the authors train their LSTM on the entire dataset (including the test set) without any early stopping criterion, which leads to over-fitting of the randomly-initialized embeddings.

Author profile (AUTH). In order to test whether community-based information of authors is in itself sufficient to correctly classify the content produced by them, we utilize just the author profiles we generated to train a GBDT classifier.

Char n-grams + author profile (LR + AUTH). This method builds upon the LR baseline by appending author profile vectors on to the character n-gram count vectors for training the LR classifier.

Hidden-state + author profile (HS + AUTH) and **Word-sum + author profile (WS + AUTH).** These methods are identical to the *char n-grams + author profile* method except that here we append the author profiling features on to features derived from the *hidden-state* and *word-sum* baselines respectively and feed them to a GBDT classifier.

5 Experiments and Results

5.1 Experimental setup

We normalize the input by lowercasing all words and removing stop words. For the GRU architecture, we use exactly the same hyper-parameters as Pavlopoulos et al. (2017),[7] i.e., 128 hidden units, Glorot initialization, cross-entropy loss, and the Adam optimizer (Kingma and Ba, 2015). Badjatiya et al. (2017) also use the same settings except they have fewer hidden units. In all our models, besides dropout regularization (Srivastava et al., 2014), we hold out a small part of the training set as validation data to prevent over-fitting. We implement the models in *Keras* (Chollet and others, 2015) with *Theano* backend and use 200-dimensional pre-trained GLoVe word embeddings.[8] We employ *Lightgbm* (Ke et al., 2017) as our GDBT classifier and tune its hyper-parameters using 5-fold grid search. For the *node2vec* framework, we use the same parameters as in the original paper (Grover and Leskovec, 2016) except we set the dimensionality of node embeddings to 200 and increase the number of iterations to 25 for better convergence.

5.2 Results

We perform 10-fold stratified cross validation (CV), as suggested by Forman and Scholz (2010), to evaluate all seven methods described in the previous section. Following previous research (Badjatiya et al., 2017; Park and Fung, 2017), we report the average weighted precision, recall, and F_1 scores for all the methods. The average weighted precision is calculated as:

$$\frac{\sum_{i=1}^{10} (w_r \cdot \mathrm{P}_r^i + w_s \cdot \mathrm{P}_s^i + w_n \cdot \mathrm{P}_n^i)}{10}$$

where $\mathrm{P}_r^i, \mathrm{P}_s^i, \mathrm{P}_n^i$ are precision scores on the *racism*, *sexism*, and *none* classes from the i^{th} fold of the CV. The values w_r, w_s, and w_n are the proportions of the *racism*, *sexism*, and *none* classes in the dataset respectively; since we use stratification, these proportions are constant ($w_r = 0.12$, $w_s = 0.19$, $w_n = 0.69$) across all folds. Average weighted recall and F_1 are calculated in the same manner.

The results are presented in Table 1. For all three baseline methods (LR, WS, and HS), the addition of author profiling features significantly improves performance ($p < 0.05$ under 10-fold CV paired t-test). The LR + AUTH method yields the highest performance of $F_1 = 87.57$, exceeding its respective baseline by nearly 4 points. A similar trend can be observed for the other methods as well. These results point to

[7] The authors have not released their models, and we therefore replicate their approach based on the details in their paper.

(b) *Sexism* class

Table 2: Performance of the methods on the *racism* and *sexism* classes separately. All improvements are significant ($p < 0.05$) under 10-fold CV paired t-test.

In Table 2, we further compare the performance of the different methods on the *racism* and *sexism* classes individually. As in the previous experiments, the scores are averaged over 10 folds of CV. Of particular interest are the scores for the *sexism* class where the F_1 increases by over 10 points upon the addition of author profiling features. Upon analysis, we find that such a substantial increase in performance stems from the fact that many of the 527 unique authors of the sexist tweets are closely connected in the community graph. This allows for their penchant for sexism to be expressed in their respective author profiles.

The author profiling features on their own (AUTH) achieve impressive results overall and in particular on the *sexism* class, where their performance is typical of a community-based generalization, i.e., low precision but high recall. For the *racism* class on the other hand, the performance of AUTH on its own is quite poor. This contrast can be explained by the fact that tweets in the *racism* class come from only 5 unique authors who: (i) are isolated in the community graph, or (ii) have also authored several tweets in the *sexism* class, or (iii) are densely connected to authors from the *sexism* and *none* classes which possibly camouflages their racist nature.

We believe that the gains in performance will be more pronounced as the underlying community graph grows since there will be less solitary authors and more edges worth harnessing information from.[9] Even when the data is skewed and there is an imbalance of abusive vs. non-abusive authors, we do expect our approach to still be able to identify clusters of authors with similar views.

6 Analysis and discussion

We conduct a qualitative analysis of system errors and the cases where author profiling leads to the correct classification of previously misclassified examples. Table 3 shows examples of abusive tweets from the dataset that are misclassified by the LR method, but are correctly classified upon the addition of author profiling features, i.e., by the LR + AUTH method. It is worth noting that some of the wins scored by the latter are on tweets that are part of a larger abusive discourse or contain links to abusive

[9]Regarding the scalability of our approach, we quote the authors of *node2vec*: "The major phases of *node2vec* are trivially parallelizable, and it can scale to large networks with millions of nodes in a few hours".

content while not explicitly having textual cues that are indicative of abuse per se. The addition of author profiling features may then be viewed as a proxy for wider discourse information, thus allowing us to correctly resolve the cases where lexical and semantic features alone are insufficient.[10]

Tweet	Predicted label	
	LR	LR + AUTH
@Mich_McConnell Just "her body" right?	*none*	*sexism*
@Starius: #GamerGate https://t.co/xuFwsIgxFK WE WIN! ahahahaha	*none*	*sexism*
#Islam dominates our crime, prison & welfare system & national security. Why are we still importing it? @PeterDutton_MP #amagenda #auspol	*none*	*racism*
@Wateronatrain: @MT8_9 You might like this #patriarchy http://t.co/c9m2pFmFJ3	*none*	*sexism*
It seems that Allah sits around all day obsessing about women's hands and faces showing. I guess idiots need a god on their level. #Islam	*none*	*racism*
@SalemP08: @MT8_9 @LiljaOB @midnitebacon @Superjutah @Transic_nyc her response is pretty terrifying.	*none*	*sexism*
@JosephIsVegan @SumbelinaZ @IronmanL1 @Hatewatch Why would you profile white people. Blacks murder at 6 times the rate as whites.	*none*	*racism*

Table 3: Examples of improved classification upon the addition of author profiling features (AUTH).

However, a number of abusive tweets still remain misclassified despite the addition of author profiling features. According to our analysis, many of these tend to contain URLs to abusive content, e.g., "*@salmonfarmer1: Logic in the world of Islam http://t.co/6nALv2HPc3*" and "*@juliarforster Yes. http://t.co/ixbt0uc7HN*". Since Twitter shortens all URLs into a standard format, there is no indication of what they refer to. One way to deal with this limitation could be to additionally maintain a blacklist of links. Another source of system errors is the deliberate obfuscation of words by authors in order to evade detection, e.g., "*Kat, a massive c*nt. The biggest ever on #mkr #cuntandandre*". Current abuse detection methods, including ours, do not directly attempt to address this issue. While this is a challenge for bag-of-word based methods such as LR, we hypothesize that neural networks operating at the character level may be helpful in recognizing obfuscated words.

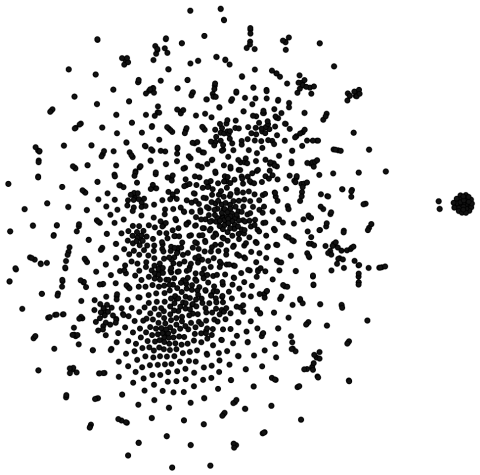

Figure 2: Visualization of author embeddings in 2-dimensional space.

We further conducted an analysis of the author embeddings generated by *node2vec*, in order to validate that they capture the relevant aspects of the community graph. We visualized the author embeddings in

[10]We note that the annotators of the dataset took discourse into account when annotating the tweets. However, the dataset was released as a list of tweet ID and corresponding annotation (racism/sexism/none) pairs; there is no annotation available regarding which tweets are related to which other ones.

(a) *None* class (b) *Sexism* class

Figure 3: Visualization of authors from different classes.

2-dimensional space using *t*-SNE (van der Maaten and Hinton, 2008), as shown in Figure 2. We observe that, as in the community graph, there are a few densely populated regions in the visualization that represent authors in closely knit groups who exhibit similar characteristics. The other regions are largely sparse with smaller clusters. Note that we exclude *solitary* users from this visualization since we have to use a single zero embedding to represent them.

Figure 3 further provides visualizations for authors from the *sexism* and *none* classes separately. While the authors from the *none* class are spread out in the embedding space, the ones from the *sexism* class are more tightly clustered. Note that we do not visualize the 5 authors from the *racism* class since 4 of them are already covered in the *sexism* class.

7 Conclusions

In this paper, we explored the effectiveness of community-based information about authors for the purpose of identifying abuse. Working with a dataset of $16k$ tweets annotated for *racism* and *sexism*, we first comprehensively replicated three established and currently best-performing abuse detection methods based on character n-grams and recurrent neural networks as our baselines. We then constructed a graph of all the authors of tweets in our dataset and extracted community-based information in the form of dense low-dimensional embeddings for each of them using *node2vec*. We showed that the inclusion of author embeddings significantly improves system performance over the baselines and advances the state of the art in this task. Users prone to abuse do tend to form social groups online, and this stresses the importance of utilizing community-based information for automatic abusive language detection.

In the future, we wish to explore the effectiveness of community-based author profiling in other tasks such as stereotype identification and metaphor detection.

Automated Scoring: Beyond Natural Language Processing

Nitin Madnani **Aoife Cahill**

{nmadnani,acahill}@ets.org

Abstract

In this position paper, we argue that building operational automated scoring systems is a task that has disciplinary complexity above and beyond standard competitive shared tasks which usually involve applying the latest machine learning techniques to publicly available data in order to obtain the best accuracy. Automated scoring systems warrant significant cross-discipline collaboration of which natural language processing and machine learning are just two of *many* important components. Such systems have multiple stakeholders with different but valid perspectives that can often times be at odds with each other. Our position is that it is essential for us as NLP researchers to understand and incorporate these perspectives into our research and work towards a mutually satisfactory solution in order to build automated scoring systems that are accurate, fair, unbiased, and useful.

1 What is Automated Scoring?

Automated scoring is an NLP application usually deployed in the educational domain. It involves automatically analyzing a student's response to a question and generating either (a) a score in order to assess the student's knowledge and/or other skills and/or (b) some actionable feedback on how the student can improve the response (Page, 1966; Burstein et al., 1998; Burstein et al., 2004; Zechner et al., 2009; Bernstein et al., 2010). It is considered an NLP application since typically the core technology behind the automated analysis of the student response enlists NLP techniques. The student responses can include essays, short answers, or spoken responses and the two most common kinds of automated scoring are the automated evaluation of writing quality and content knowledge. Both the scores and feedback are usually based on linguistic characteristics of the responses including but not limited to:

(i) Lower-level errors in the response (e.g., pronunciation errors in spoken responses and grammatical/spelling errors in written responses),

(ii) The discourse structure and/or organization of the response,

(iii) Relevance of the response to the question that was asked.

2 Motivation

Over the last few years, there has been a significant increase in the number of NLP conference and workshop publications on the task of automated scoring of student responses (Burrows et al., 2015; Zesch et al., 2015; Sultan et al., 2016). Much of this increase in interest stems from the public availability of fairly large datasets containing scored human responses as part of shared tasks and public contests (the ASAP[1] and ASAP2[2] Kaggle shared tasks, the Powergrading dataset (Basu et al., 2013), and the SemEval

Santa Fe, New Mexico, USA, August 20-26, 2018.

2013 Shared Task (Dzikovska et al., 2013)). Although this increase in interest is well-motivated and has led to useful technical advances, it has also propagated the impression that the task of automated scoring can be a self-contained, moderately simple machine learning task requiring "only" sophisticated feature engineering (Somasundaran et al., 2015; Ghosh et al., 2016) or, more recently, complex neural network architectures (Taghipour and Ng, 2016; Dong et al., 2017; Riordan et al., 2017; Tay et al., 2017). Our motivation for writing this paper is to highlight the differences between automated scoring as a shared task and automated scoring as an area of NLP research that serves the end goal of building and deploying accurate and unbiased scoring models for use in actual assessments or classrooms. For the latter, we argue that it is essential for NLP researchers to interact with and, indeed, collaborate with additional parties who are impacted by and contribute to automated scoring.[3]

To be clear, the issues we highlight are not simply a result of "operationalizing" NLP research. Instead, we claim that in order to make meaningful contributions in the area of automated scoring, these issues must be thought about and discussed as part of the NLP research and development process from the start. Our aim is not to strike a prescriptive tone. We acknowledge that despite the best of intentions, practical and business considerations can sometimes impact the extent to which such desiderata can be incorporated into the research process. However, our position is that these are extremely important problems to solve and even limited engagement with and progress towards solving these problems constitutes an important step. As more and more educational institutions and start-ups opt into automated scoring of educational assessments — which has the potential to impact the lives and livelihoods of members of the public — it is incumbent upon us as NLP researchers to strive towards fair, accountable, and transparent utilization of our research (Barocas et al., 2017).

3 Related Work

Many of the issues we refer to in the previous section are commonly discussed in the related fields of psychometric measurement and educational research. For example, Table 1 lists some of the standards in the 2014 Standards for Educational and Psychological Testing which are relevant for automated scoring. These standards help ensure fair and valid tests and provide guidelines for all aspects of assessment development. In addition, these communities have also been working towards best practices for the use of automated scoring (Clauser et al., 2002; Yang et al., 2002; Williamson et al., 2012; Bridgeman et al., 2012; Bejar et al., 2016). However, since there are limited opportunities for that community to interact with the NLP community, our goal is to bring them to the attention of the mainstream NLP audience as a first step towards the cross-discipline collaboration that we argue for in this paper.

In addition, there have also been efforts in the NLP community itself to highlight how NLP research on automated scoring can be situated in cross-disciplinary contexts (e.g. the workshops on Innovative Use of NLP for Building Educational Applications (BEA) and the workshops on NLP Techniques for Educational Applications (NLPTEA)) (Napoles and Callison-Burch, 2015; Wilson and Martin, 2015; Burstein et al., 2016; Beigman Klebanov et al., 2016; Zalmout et al., 2016; Lugini and Litman, 2017; Pado, 2017; Yaneva et al., 2017). However, the topics of these workshops tend not to always make it into the mainstream NLP conference discussions. Yet, at the same time there has been an increasing interest in automated scoring techniques at main NLP conferences. It is important not to lose the link between developing new and improved NLP techniques for automated scoring and the contexts in which they are generally applied.

4 Perspectives on Automated Scoring

Before we describe our position, we describe the various entities who are likely to be affected by automated scoring systems, and their corresponding perspectives on the use of automated scoring. All of these entities have a stake in making sure that the automated scoring system performs in line with their own expectations and, therefore, we refer to them as "stakeholders" from this point on.

[3]Of course, these kinds of challenges are not unique to the use of automated scoring in the educational domain. Other complex, real-world applications involving NLP also have several stakeholders. For example, in the health care industry, NLP is being used to support clinical decision-making where stakeholders can include patients, medical professionals, caregivers, and healthcare institutions.

Standard 3.8	"When tests require the scoring of constructed responses, test developers and/or users should collect and report evidence of the validity of score interpretations for relevant subgroups in the intended population of test takers for the intended uses of the test scores."
Standard 4.19	"When automated algorithms are to be used to score complex examinee responses, characteristics of responses at each score level should be documented along with the theoretical and empirical basis for the use of the algorithms."
Standard 6.8	"Those responsible for test scoring should establish scoring protocols …When scoring of complex responses is done by computer, the accuracy of the algorithm and processes should be documented."
Standard 6.9	"Those responsible for test scoring should establish and document quality control processes and criteria. Adequate training should be provided. The quality of scoring should be monitored and documented. Any systematic source of scoring errors should be documented and corrected."

Table 1: Some standards in the 2014 Standards for Educational and Psychological Testing that are relevant for automated scoring.

- **Score Users**. The people to whom any assessment is administered (test takers) are important stakeholders since any decisions made about the scoring of the assessment affect them directly. This is particularly true in cases where the assessment is likely to have a significant impact on the test-takers' futures, e.g., by contributing to a decision about whether to admit them into a college or graduate school (IELTS, GRE, TOEFL, SAT, ACT, etc.), or a decision whether to grant them a license to engage in a professional activity such as teaching (PRAXIS). If an automated scoring system is being employed to score their responses to such critically positioned assessments, test-takers want to ensure that such a system measures the same set of characteristics and skills that a well-trained human scorer would[4] and that such measurements are calculated accurately based on their responses. In addition, the test-takers also place emphasis on receiving their scores quickly and on a *score report* providing useful information on why they received the particular scores that they did and what, if anything, they can do to improve their scores if they decide to retake the assessment. Another important consumer of test scores are institutions who use the test scores to make decisions. For example, universities may use test scores to make placement decisions; immigration authorities may use test scores to make visa decisions; school districts and states may use test scores to make funding and policy decisions. Such institutions want to ensure that the scores from the test are valid and reliable and that any automated scoring component does not introduce any biases towards any particular subgroup of test takers.

- **Teachers**. Teachers in classrooms are also likely to be affected by the decision to use automated scoring systems. It is important to them as stakeholders that scores from automated systems are not used inappropriately. For example, if the assessment — and the automated scoring system — are only designed to measure the students' writing proficiency, the scores assigned by the system should not be used for a different purpose, e.g., to assess the teacher's teaching abilities. Teachers are also impacted if automated systems are used directly in the classroom, e.g., to provide feedback to students in the context of *formative* assessments (informal assessments conducted by teachers in the classroom to improve how students learn). For such cases, the teachers want to ensure that the feedback provided by the system is reasonably accurate, does not lead the students astray from the actual learning goal, and encourages engagement with the material being taught.

- **Subject-matter Experts**. Subject-matter experts, also known as assessment developers, write the questions that are included in the assessments. In addition, they also assemble specific questions

[4] An automated system cannot "read" the response in the same way that a human can but it can use features that are reasonable approximations for factors that human scorers consider in their evaluation.

into assessments while taking into account that the chosen questions should cover a wide range of skills that are to be measured by the assessment (usually known as the *construct*) and that different questions try to measure complementary aspects of such skills. As part of the assessment design, they also create what is called a *scoring rubric* - a document that attempts to describe specific and consistent criteria for how human scorers should score responses to each question in the assessment. Rubrics tend to be complex and subjective, particularly for assessments that contain relatively open-ended writing or content-based questions. Such experts would like to ensure that any automated scoring system deployed to score the assessments they have designed pays attention to the scoring rubric and that only construct-relevant information is used by the system during the scoring process. For example, although the length of a response to a question designed to measure the test-taker's writing proficiency might correlate very highly with its score, it is not actually relevant to the mental construct of writing proficiently and, therefore, should not be used as a feature in the automated scoring system (Bejar, 2017).

- **Business Units**. It takes significant resources to develop, administer, and score well-designed assessments. Therefore, the institutions undertaking this process are more likely to be educational technology companies with dedicated staff for assessment development, psychometric analysis, and natural language processing. Therefore, there is a business aspect to educational assessments in addition to research. For example, business units at such companies might comprise of people who try to procure state and federal contracts for developing and scoring K-12 assessments. When it comes to automated scoring systems, such units place emphasis on more practical business aspects of system development, such as building systems that are fast (e.g., with a short turn-around time between the submission of the response and the production of the score), cost-effective to deploy and maintain in an operational setting, and have little to no measurable impact on the overall validity and reliability of the assessment.

- **NLP Researchers & Developers**. NLP researchers and developers such as the authors (and, most likely, the readers) of this paper tend to have a different perspective when it comes to building automated scoring systems. The automated scoring system should perform accurately where accuracy is generally defined as agreement with human scores. Secondly, the system should not only build on top of state-of-the-art ideas and tools from the field but, if possible, should also advance the field forward by sharing and disseminating tools, lessons, and ideas at conferences and workshops. Another important consideration is the modularity of the system that not only allows replacement of NLP components (e.g., taggers and parsers) with newer and better-performing versions but also allows new scoring features to easily be incorporated into the system. Finally, the system should be easy to maintain and well-documented to make it easy for new developers and researchers to become familiar with the system.

Since each set of stakeholders is trying to optimize the automated scoring system for a different set of criteria, it is only natural that many of the above perspectives can be at odds with each other. Below we specifically outline the conflicts between the perspectives of the **NLP researchers** and the other four sets of stakeholders.

(a) **vs. Business Units**. Business units might sometimes place a greater emphasis on getting systems to market faster and with a limited investment depending on the budget available. However, in order to build a system that has a reasonably high agreement with human scores and is more likely to generalize to new and unexpected responses in the field, NLP researchers might require additional time as well as investment. For example, annotation of additional responses may be required for use as training data, or an existing research technique from the literature may need to be adapted for the domain before deployment.

(b) **vs. Score Users**. As described above, one of the most important considerations for test-takers is a reasonably clear explanation of why they received the particular scores that they did. The NLP

researchers optimizing for agreement with human scores might lean towards using more sophisticated machine learning models such as SVMs with non-linear kernels and deep neural networks. However, such models do not really lend themselves to *post-hoc interpretability* (Lipton, 2016). Although interpretability is an active area of research in the machine learning literature (Ribeiro et al., 2016; Koh and Liang, 2017; Doshi-Velez and Kim, 2017), it currently lags far behind the research on machine learning methods. Ensuring that there are no biases in automated scores – important for institutions using test scores to make decisions – is a topic that sees little discussion in the NLP literature. This is partly driven by a lack of demographic data available in publicly available datasets, as well as perhaps a focus on empirical accuracy.

(c) **vs. Subject-matter Experts**. Subject-matter experts or assessment developers want to ensure that all the hard work that has been done on their end to develop a valid (actually measuring what it is supposed to measure) and reliable assessment (scores are comparable across repeated administrations) is not undone by an automated scoring system that is either using construct-irrelevant factors as features or using a set of features that, taken together, have low *construct coverage*, i.e., they only measure part of the skill being assessed. It is difficult for NLP researchers to convert the salient aspects of a complicated – and subjective – document like the scoring rubric into features that are reasonably efficient to compute. Although the conversion can be aided by asking human scorers how they mentally translate the rubric into specific scoring decisions, humans are not as interpretable as one might think (Lipton, 2016).

(d) **vs. Teachers**. To make sure that automated scoring (or feedback) systems behave as expected if deployed for in-classroom use, NLP researchers would like to conduct research studies with such systems in real classrooms in order to collect useful data, e.g., written or spoken responses, student behavior, and indicators of engagement which can then be used to improve the system further (Burstein et al., 2016; Burstein and Sabatini, 2016; Madnani et al., 2016). However, teachers want to ensure that such systems are sufficiently nuanced — and not too primitive — to handle interactions with students and do not lead to students being distracted instead of learning. Furthermore, it takes time to build up a level of trust between the teachers and NLP researchers as a system is being fine-tuned and developed.

It is evident from the above discussion that trying to cater to everyone is akin to solving a difficult constraint satisfaction problem. For example, if NLP researchers want to build a more interpretable automated scoring system that can provide more useful feedback to test-takers, it requires investing more money and time which might need to be negotiated with the business units. Or, if subject-matter experts design an assessment with more intricate, open-ended questions in order to accurately assess the required set of skills, the corresponding automated scoring system would likely require more time and resources to build and potentially be less transparent.

5 Our Position

While NLP and machine learning techniques form a core part of automated scoring systems, there are several other non-NLP considerations that need to be taken into account when designing and developing such techniques. It is important to remember the perspectives of the other stakeholders — as outlined in the previous section — when making decisions during the NLP component development, and not simply focus on having the most accurate, or fastest automated scoring systems. While it is admirable to take advantage of the recent availability of relevant data and develop novel and more sophisticated NLP techniques to advance the field, sometimes it is necessary to take a step back and ensure that the NLP advances are also aligned with the interests of other stakeholders in automated scoring.

For example, the NLP researchers may find through ablation studies that certain computationally complex features are not contributing much to the overall accuracy of the model. They may choose to simplify the processing pipeline and resulting models by excluding those features, at very little cost to overall accuracy (on some held-out evaluation data). However, if those features are measuring important aspects

of the construct, removing them weakens the validity and construct coverage of the system, since now the system omits measuring an important aspect of what is being measured by humans, as defined in the scoring rubric. This is very important for both subject-matter experts (who will assume that any automated system is at least trying to measure the same thing that humans are) and business units (who require a valid test).

6 Case Studies

To explain our position more concretely, we describe three hypothetical case studies involving automated scoring or feedback systems. We focus on some of the stakeholder interactions that we believe are critical for successful deployment of automated scoring systems and provide suggestions for best practices. Note that many of our suggestions are adapted from the best practices that are already recommended by research practitioners in the educational measurement community.

6.1 Adding Automated Scoring to an Existing Assessment

The decision to add automated scoring to an existing assessment can be initiated by the business units as a potential cost-saving measure. It can also be initiated by the NLP researchers who believe they have developed a system that can accurately score a particular type of spoken or written response. In either case, a number of considerations need to be taken into account before automated scoring can be added to an existing assessment.

If a business unit wants to add automated scoring for an existing assessment, they should typically first approach the NLP researchers to estimate the effort involved in developing automated scoring capabilities for the specific question types contained in the assessment (e.g. essays that measure writing quality or free-text responses that measure knowledge of some content area). NLP researchers will assess the feasibility of automated scoring for the requested item types. At this point, it is critical to engage the subject-matter experts in order to fully understand the construct being measured, the scoring rubric and any supplemental scoring guidelines, as well as to get access to any training materials used to train human scorers. Without engaging the subject-matter experts it is all too easy to make assumptions about the assessment based on observations made from a limited amount of scored data. This can lead to automated scoring systems that measure the construct inaccurately or in a limited fashion, that handle aberrant responses incorrectly, and that could ultimately lead to unfairly scored assessments yielding significant consequences for the test-takers.

If NLP researchers initiate the request to add automated scoring to an assessment, they should have already connected with the subject-matter experts to ensure that they have built a system that adequately measures the correct construct. It is important that they also consider other aspects of the assessment and communicate with all relevant stakeholders. For example, if an assessment has a low number of test-takers each year, then the amount of data available to monitor[5] the automated system may be too low. If the number of responses available for monitoring is low, then the risks are that a sample small enough for the monitoring to be cost effective will not provide statistically meaningful monitoring metrics. Conversely, a sample large enough to provide statistically meaningful metrics would effectively offset any potential cost-savings obtained from automated scoring. This consideration would be very important to the business units who have to fund both the setup costs of integrating automated scoring into an existing assessment, as well as the ongoing maintenance costs.

Finally, for any automated scoring system that is proposed, NLP researchers need to take into account ethical considerations regarding fairness and validity and evaluate the system on dimensions other than just the agreement with human scores. For example, it is critical to evaluate whether the system is biased towards certain sub-populations of test-takers. Aggregated metrics of agreement with human scores (such as Pearson correlation or Cohen's kappa) will not be able to capture such biases or fairness issues. Madnani et al. (2017) proposed an open-source tool, RSMTool[6], as an initial step in this direction. In

[5] Monitoring is an important aspect of high-stakes automated scoring systems, wherein a random sample of the responses scored by the automated system are also scored by an expert human scorer to ensure that the system is performing as expected.

[6] https://github.com/EducationalTestingService/rsmtool

addition to the agreement metrics with human scorers, RSMTool also evaluates how well the automated scoring system performs for each sub-population represented in the data. Of course, one key assumption underlying this type of evaluation is that the demographic information about the candidates is available and permitted to be used as part of the evaluation pipeline.

6.2 Creating a New Assessment that Includes Automated Scoring

This particular scenario offers many more opportunities for a collaborative and multi-perspective development process to be adopted right from the start as compared to the previous case study. As a business unit puts together the plans for a new assessment, automated scoring is often a desired component (usually for perceived cost-saving measures). It is important at this juncture for the subject-matter experts and the NLP researchers to collaborate in order to understand the types of questions that will be included in the new assessment, and which ones might actually be suitable for being scored automatically. It is important for the NLP researchers to understand the specific constructs being targeted by the new assessment and advise the subject-matter experts where construct-irrelevant differences might impact automated scoring.

For example, a question might use a passage about a young student with a name that is not likely to be familiar to the population of students taking the test. This means that the test-takers may guess the gender of this student, resulting in a range of pronouns appearing in the sample responses from which automated scoring models might be built. This unnecessarily "dilutes" the vocabulary of the response pool with construct-irrelevant variation. On the other hand, giving the hypothetical student a name that has a widely acknowledged gender associated with it will help limit this kind of variation without any impact on the construct coverage or validity of the question.

At the same time, while subject-matter experts are developing the questions, it is important for the NLP researchers to assess the feasibility of automated scoring for the question types being considered for automated scoring. If a question would require NLP techniques that are in very early stages of research or have not yet been fully tested, this information needs to be shared as quickly as possible with the business units so that they can build contingency plans into their budgets and timetables.

Finally, a comprehensive evaluation of the sort described in the previous case study is still warranted in this scenario since ensuring the accuracy and fairness of an automated scoring system does not depend on whether it is being deployed for a entirely new assessment or for an existing one.

6.3 Including Automated Scoring in a Classroom Setting

It is crucial that NLP researchers engage with both teachers as well as students when developing tools to be deployed in an authentic classroom setting, e.g., tools that can provide feedback on students' writing or content knowledge. An NLP researcher designing and implementing a classroom tool in isolation is not likely to be successful, no matter the accuracy or novelty of the underlying NLP techniques. Before developing any tools, the NLP researchers need to fully understand the problem they are trying to solve by engaging teachers to find out how NLP technology can be integrated in a supportive fashion to their teaching curricula. Ideally, classroom tools should be built in an iterative fashion, by learning what features or techniques improve student engagement and learning and which ones do not. An example study that evaluates the effect of a new tool in an authentic classroom setting has many non-trivial (and non-NLP-specific) components:

- Identify a representative sample of schools/classes/students for the study
- Conduct surveys of teachers and control groups
- Conduct teacher training
- Analyze teachers' daily/weekly logs
- Conduct classroom observations
- Conduct pre- and post-study evaluations

- Analyze tool usage logs

This requires a lot of time and effort both from the teachers as well as the NLP researchers, but at the end of the day is more likely to lead to truly useful tools that can have a positive impact on the classroom learning process and improve students' understanding of the material being taught by the teacher.

7 Conclusion

Our goal in this paper is to bring attention to the inherent complexity of automated scoring of student responses, given the large number of stakeholders, often times with different priorities. We take the position that in order to build fair and accurate automated scoring systems — especially for use in high-stakes assessments where the consequences of being unfair and inaccurate can be severe for the test-takers — NLP researchers must incorporate the perspectives of other stakeholders into the research and development process and avoid working in a bubble surrounded only by scored data and machine learning algorithms. We feel encouraged that our position is increasingly shared by many educational NLP researchers, as is evident by publications in more focused educational NLP workshops, and hope that all NLP researchers will keep this in mind as they develop new and exciting techniques for automated scoring that could be deployed for operational use. We hope to see more and more publications at NLP venues that describe these new advances while at the same time taking into account the perspectives of many of the stakeholders described in this paper.

In closing, we would like to make some concrete suggestions – informed by our position on automated scoring – that can actually apply more broadly to the field:

1. Conference and workshop organizers should strive to include industry tracks with published proceedings so that issues of the sort presented in this paper can be discussed and appropriate best practices can be developed. In addition, this would create a resource that the NLP community at large can go to when considering issues that affect the transition of NLP technology from theory into practice. More panels at conferences with both industry practitioners and academic researchers as panelists will also be helpful.

2. Shared task organizers should provide more context around the data and the specific task. As an example, for automated scoring, additional metadata can be included, if possible, to encourage more comprehensive evaluations of the sort described in §6.1 and §6.2.

3. Companies that have experience with transitioning research into practice should share more of their experiences publicly. Such companies should also offer internship positions for students to help expose them to the challenges that accompany such a transition.

4. Faculty members should encourage students to attend industry panels at conferences and to actively pursue internships in the industry in order to learn about what it takes to for academic research to be deployed in practice. This would likely lead to better dissertations and publications with improved evaluations and nuanced discussions.

Acknowledgments

We would like to thank Jill Burstein, Yoko Futagi, Beata Beigman Klebanov, and the three anonymous reviewers for useful insights and suggestions on how to improve the paper.

Abstract

Review text has been widely studied in traditional tasks such as sentiment analysis and aspect extraction. However, to date, no work is towards the end-to-end abstractive review summarization that is essential for business organizations and individual consumers to make informed decisions. This work takes the lead to study the aspect/sentiment-aware abstractive review summarization in an end-to-end manner without hand-crafted features and templates by exploring the encoder-decoder framework and multi-factor attentions. Specifically, we propose a mutual attention mechanism to interactively learns the representations of context words, sentiment words and aspect words within the reviews, acted as an encoder. The learned sentiment and aspect representations are incorporated into the decoder to generate aspect/sentiment-aware review summaries via an attention fusion network. In addition, the abstractive summarizer is jointly trained with the text categorization task, which helps learn a category-specific text encoder, locating salient aspect information and exploring the variations of style and wording of content with respect to different text categories. The experimental results on a real-life dataset demonstrate that our model achieves impressive results compared to other strong competitors.

1 Introduction

User generated reviews on products are expanding rapidly with the emergence and advancement of e-commerce. These reviews are valuable to business organizations for improving their products and to individual consumers for making informed decisions. Unfortunately, reading though all the product reviews is hard, especially for the reviews that are lengthy and have low readability. It is therefore essential to provide coherent and concise summaries of user generated reviews. In this paper, we focus on generating abstractive summaries of product reviews. Abstractive text summarization is the task of generating a short and concise summary that captures the salient ideas of the source text. The generated summaries potentially contain new phrases and sentences that may not appear in the source text. Inspired by recent success of sequence-to-sequence (seq2seq) model in statistical machine translation, most abstractive summarization systems employ seq2seq framework to generate summaries (Nallapati et al., 2016; See et al., 2017; Paulus et al., 2017). In general, the seq2seq model firstly uses an encoder to convert the input text as a vector representation, and then it feeds this representation into a decoder to generate summary.

Despite the remarkable progress of previous studies, generating aspect/sentiment-aware summaries of product reviews remains a challenge in real-world for two reasons. (i) First, neural sequence-to-sequence models tend to generate trivial and generic summary, often involving high-frequency phrases. These summaries cannot capture the aspect and sentiment information from the product reviews which play a vital role in helping customers to make quick and informed decisions on certain products (Ly et al., 2011). (ii) According to what we observe, summary styles and words in different categories can significantly vary. However, existing methods apply a uniform model to generate text summaries for

Santa Fe, New Mexico, USA, August 20-26, 2018.

the source documents in different categories, which easily miss or under represent salient aspects of the documents.

To alleviate the aforementioned limitations, we design a Multi-factor attention fusion network for aspect/sentiment-aware Abstractive Review Summarization (MARS). Our model exploits the recent success of the encoder-decoder framework to generate aspect/sentiment-aware review summaries. Specifically, a mutual attention mechanism is proposed to capture the correlation of context words, sentiment words and aspect words, which interactively learns attentions in the three kinds of words and generates the representations for contexts, sentiments and aspects separately. The text encoder is regularized with the co-training to perform an additional task of text categorization. The purpose of co-training is not to achieve the best performance on the text categorization (auxiliary task), but rather to compensate for the missing regularization requirement of abstractive summarization in the standard framework, learning a category-specific text encoder and improving the the quality of locating salient aspect information of the review. In addition, we explore three kinds of attentions (i.e., semantic attention, sentiment attention and aspect attention) to selectively attend to the context information when decoding summaries. Finally, we employ a reinforcement learning technique to maximize long-term rewards and address the exposure bias issue (Ranzato et al., 2015).

We summarize our main contributions as follows:

- We leverage text categorization task to learn better category-specific review representation for summarization. The variation of style and wording of summaries with respect to different text categorization are explored.
- We exploit the coordination of context words, sentiment words and aspect words via the mutual attention mechanism to learn aspect/sentiment-aware review representation. With this design, our model can also well represent the collocative sentiment and aspect words, which are helpful to learn sentiment and aspect attentions during decoding.
- We explore three kinds of attentions (i.e., semantic attention, sentiment attention and aspect attention) to selectively attend to the context information when decoding summaries.
- We employ the reinforcement learning technique (i.e., policy gradient) to directly optimize the model with respect to the non-differentiable ROUGE scores, moderating the exposure bias issue.
- The experimental results show that our model outperforms the competitors from both quantitative and qualitative perspectives.

2 Related work

In general, existing text summarization approaches can be categorized as extractive and abstractive. The extractive summarization copies representative sentences from the input (Zhang et al., 2012), while the abstractive summarization generates new phrases, possibly rephrasing or using words that are not in the original text (Rush et al., 2015). In this paper, we focus on abstractive text summarization systems.

Inspired by the recent success of the encoder-decoder framework in statistical machine translation, there has been increasing interest in generalizing the neural language model to the field of abstractive summarization (Rush et al., 2015; Chopra et al., 2016; Chen et al., 2016; Nallapati et al., 2016; See et al., 2017). For example, Rush et al. (2015) were the first to apply attention-based encoder-decoder model to abstractive text summarization, achieving state-of-the-art performance two sentence-level summarization datasets. Nallapati et al. (2016) proposed off-the-shelf attention encoder-decoder RNN that captured hierarchical document structure and identified the key sentences and keywords in the document. See et al. (2017) proposed a hybrid pointer-generator network that allowed both copying words from the source text via pointing, and generating words from a fixed vocabulary.

Several recent studies attempted to integrate the encoder-decoder RNN and reinforcement learning paradigms for abstractive summarization, taking advantages of both (Paulus et al., 2017; Liu et al., 2018). For example, Paulus et al. (2017) combined the maximum-likelihood cross-entropy loss with

rewards from policy gradient reinforcement learning to reduce exposure bias. Liu et al. (2018) proposed an adversarial process for abstractive text summarization, in which the generator is built as an agent of reinforcement learning.

There are also some studies working on summarization of product reviews (Li et al., 2010; Gerani et al., 2014; Di Fabbrizio et al., 2014; Gerani et al., 2016; Yu et al., 2016; Mason et al., 2016). For example, Gerani et al. (2014) proposed an abstractive summarization system to product reviews by applying a template-based NLG framework and taking advantage of the discourse structure of reviews. Yu et al. (2016) proposed a phrase-based approach which leveraged phrase properties to choose a subset of optimal phrases for generating the final summary.

Different from the previous work, this study focuses on generating sentiment/aspect-aware abstractive review summarization that may better fit users' needs by using encoder decoder framework with sentiment/aspect attentions.

3 Methodology

This section defines the key notations and briefly formulates the problem of this study. We suppose that a review x consists of k words $x^c = [w_1^c, w_2^c, ..., w_k^c]$, n aspect words $x^t = [w_1^t, w_2^t, ..., w_n^t]$, and m sentiment words $x^s = [w_1^s, w_2^s, ..., w_m^s]$. To prevent conceptual confusion, we use superscripts "s", "t" and "c" to indicate the variables that are related to sentiment words, aspect words and content, respectively. Each review x in the corpus has a category label y and a corresponding reference summary $Z = [z_1, z_2, \ldots, z_T]$, where T is the length of the reference summary.

Our model MARS consists of two tasks: the abstractive review summarization task and the text categorization task, both working on a shared document encoding layer. In this section, we elaborate the main components of MARS in detail.

3.1 LSTM Encoder

This section introduces our Mutual Attention Network (MAN) to learn better sentiment, aspect and context representation via interactive learning. MAN utilizes the attention mechanism associated with the sentiment and aspect words to capture important information from the input review and learn the sentiment/aspect-aware review representation. Further, MAN makes use of the interactive information from the input review to supervise the modeling of the sentiment and aspect words which are helpful to capture important information in summary generation.

3.1.1 Initial Document Representation

Each word w in the review is mapped to a low-dimensional embedding $e \in \mathbb{R}^d$ through a word embedding layer, where d denotes the embedding dimensionality. Then, we employ three independent LSTM networks to obtain the hidden states of context words, the sentiment words, and the aspect words. Formally, given the input word embedding e_t at time step t, the hidden state h_t can be updated with the previous hidden state h_{t-1}, which is computed by

$$i_t = \sigma(W_i e_t + U_i h_{t-1} + b_i) \tag{1}$$
$$f_t = \sigma(W_f e_t + U_f h_{t-1} + b_f) \tag{2}$$
$$o_t = \sigma(W_o e_t + U_o h_{t-1} + b_o) \tag{3}$$
$$c_t = i_t \odot \tilde{c}_t + f_t \odot c_{t-1} \tag{4}$$
$$\tilde{c} = \tanh(W_c e_t + U_c h_{t-1} + b_c) \tag{5}$$
$$h_t = o_t \odot \tanh(c_t) \tag{6}$$

where i_t, f_t, o_t, c_t are input gate, forget gate, output gate and memory cell, respectively. W and U denote weight matrices to be learned. b represents biases. σ is a sigmoid function and $\odot$ stands for element-wise multiplication. Hence, we can use the LSTM networks to obtain the hidden states $H^c = [h_1^c, h_2^c, ..., h_k^c] \in R^{k \times u}$ for context words, the hidden states $H^s = [h_1^s, h_2^s, ..., h_m^s] \in R^{m \times u}$ for sentiment words in the review, and the hidden states $H^t = [h_1^t, h_2^t, ..., h_n^t] \in R^{n \times u}$ for aspect words in the review, where u is

the size of hidden states for each LSTM unit. Then, we feed these hidden states to a mean-pooling layer to obtain the initial representation of context words, sentiment words, and aspect words in the review, respectively.

$$v^c = \sum_{i=1}^{k} h_i^s/k; \quad v^s = \sum_{i=1}^{m} h_i^c/m; \quad v^t = \sum_{i=1}^{n} h_i^t/n \tag{7}$$

3.1.2 Aspect/sentiment-aware Document Representation

Attention mechanism plays an important role in text modeling. Inspired by (Bahdanau et al., 2014; Ma et al., 2017), this section introduces the proposed mutual attention network (MAN) to learn a better sentiment-aware and aspect-specific document representation. In addition, the MAN model can also well represent the sentiment and aspect word representations. Formally, given the context word representations $[h_1^c, h_2^c, ..., h_k^c]$, the initial representations of sentiment and aspect words (i.e., v^s and v^t, respectively), the mutual attention mechanism generates the attention weight C_i of the context by

$$C_i = \frac{\exp(\rho([h_i^c; v^s; v^t]))}{\sum_{j=1}^{k} \exp(\rho([h_j^c; v^s; v^t]))} \tag{8}$$

where C_i indicates the importance of the i-th word in the context, and ρ is the attention function that calculates the importance of h_i^c in the context:

$$\rho([h_j^c; v^s; v^t]) = {U_c}^T \text{tanh}(W_c[h_j^c; v^s; v^t] + b_c) \tag{9}$$

where U_c and W_c are projection parameters to be learned, and b_c is the bias.

Only using the attention vector C cannot capture the interactive information of the context words and the aspect words (sentiment words), and lacks the ability of discriminating the importance of the words in the context. To make use of the interactive information between the context words and the aspect words (sentiment words), we also use the context words as attention source to attend to the aspect words (sentiment words). Similar to Eq. (8), we can calculate the attention vectors T and S for the aspect words and sentiment words as:

$$T_i = \frac{\exp(\rho([h_i^t; v^c; v^s]))}{\sum_{i=1}^{n} \exp(\rho([h_i^t; v^c; v^s]))} \tag{10}$$

$$S_i = \frac{\exp(\rho([h_i^s; v^c; v^t]))}{\sum_{i=1}^{n} \exp(\rho([h_i^s; v^c; v^t]))} \tag{11}$$

where ρ is the same as in Equation 9.

After computing the mutual attention vectors for the context words, aspect words and sentiment words, we can get the final context, aspect, sentiment representations emb^c, emb^s and emb^t based on the mutual attention vectors C, S and T by:

$$emb_x^c = \sum_{i=1}^{k} (C_i h_i^c), \quad emb_x^s = \sum_{i=1}^{m} (T_i h_i^s), \quad emb_x^t = \sum_{i=1}^{n} (S_i h_i^t) \tag{12}$$

Finally, we concatenate the context, aspect, sentiment representations to form the aspect/sentiment-aware review representation emb_x for review x:

$$emb_x = [emb_x^c, emb_x^t, emb_x^s] \tag{13}$$

3.2 Text Categorization

We feed the final document representation emb_x into a task-specific fully connected layer and a softmax classifier to predict the category distribution of the input document x:

$$\hat{y} = softmax(V_2 \cdot F_x), \; F_x = \text{tanh}(V_1 \cdot emb_x) \tag{14}$$

where V_1 and V_2 are projection parameters to be learned. We train this model by minimizing the cross-entropy between the predicted distribution $\hat{y}$ and the ground truth distribution y for each review in the training data:

$$J_{ML}^{\text{categ.}}(\theta) = -\frac{1}{N}\sum_{i=1}^{N}\sum_{j=1}^{D}\mathbf{I}(y_i = j)\log(\hat{y}_i) \tag{15}$$

where θ is the set of parameters of our model, D is the number of categories, N is the number of reviews in the training set, $\mathbf{I}(\cdot)$ is an indicator such that $\mathbf{I}(\text{true}) = 1$ and $\mathbf{I}(\text{false}) = 0$.

3.3 Abstractive Review Summarization

The abstractive review summarization subtask shares the same review representation module (encoder) with the text categorization subtask. The generation of summary Z is performed by a LSTM decoder.

3.3.1 Category-specific Review Representation

To generate category-specific summaries, the review representation emb_x are transformed to category-specific review embedding which is expected to capture category characteristics. Inspired by (Dong et al., 2014; Cao et al., 2017), we develop a category-specific transformation process to make the transformed review embedding hold the category characteristics information. Formally, our model transforms the review embedding emb_x to a category-specific review embedding $cemb_x$ by

$$cemb_x = \tanh(\mathbf{W}_\mu \times emb_x) \tag{16}$$

where $\mathbf{W}_\mu \in \mathbb{R}^d$ is the transformation matrix, d is the dimensionality of the category-specific document embedding. Note that we define the same dimensionality for both the document embedding and the category-specific document embedding.

To make the transformed embedding capture category-specific information, we develop the category-specific transformation matrix $\mathbf{W}_\mu$ according to the predicted product category. We introduce $|C|$ sub-matrices $(\mathbf{W}_\mu^1, \cdots, \mathbf{W}_\mu^{|C|})$, with each directly corresponding to one product category. Based on the predicted category derived from Eq. 14, the category-specific transformation matrix $\mathbf{W}_\mu$ is computed as the weighted sum of these sub-matrices: $\mathbf{W}_\mu = \sum_{i=1}^{|C|} \hat{y}\mathbf{W}_\mu^i$. In this way, $\mathbf{W}_\mu$ is automatically biased to the sub-matrix of the predicted category.

3.3.2 LSTM Decoder

Inspired by (See et al., 2017), the pointer-generator network is adopted as the decoder to generate summaries. The pointer-generator network allows both copying words from input text via pointing (P_{vocab}), and generating words from a fixed vocabulary (P_{gen}). Thus, the pointer-generator has the ability to produce out-of-vocabulary (OOV) words.

The category-specific review representation $cemb_x$ is used to initialize the hidden states s_0 of LSTM decoder. On each step t of decoding, the decoder receives the word embedding of the previous word w_{t-1} (while training, this is the previous word of the reference summary; at test time it is the previous word emitted by the decoder) and update its hidden state s_t:

$$s_t = \text{LSTM}(s_{t-1}, c_t, w_{t-1}) \tag{17}$$

The attention mechanism is used to calculate the attention weights a_t and context vector c_t. Attention mechaism is expected to take both context-sentiment and context-aspect correlations into consideration. The enhanced context vector c_t is aggregated by the representation of those informative words (see Eq. 21). In this paper, we explore three kinds of attention: semantic attention, sentiment attention and aspect attention. Details of these three kinds of attention are described as follows.

Semantic Attention Semantic attention simply applies the context representation itself as attention source. Following (Shimaoka et al., 2017), we apply a multi-layer perceptron (MLP) to compute semantic attention weights as follows:

$$a_{t,i}^{semantic} = \tanh(W_{a_1} h_i^c + U_{a_1} s_t + b_{a_1}) \tag{18}$$

where W_{a_1} and U_{a_1} are parameter matrices, b_{a_1} is bias parameter. The attention computed for context words are independent of the aspect/sentiment words. Hence, it is difficult for semantic attention to focus on those context words that are highly related to the aspects and sentiments.

Sentiment Attention In order to capture the correlation between sentiment words and the context, we take sentiment word representation emb_x^s as attention source to compute sentiment attention weights:

$$a_{t,i}^{sentiment} = \tanh(emb_x^s W_{a_2} h_i^c + U_{a_2} s_t + b_{a_2}) \tag{19}$$

where W_{a_2} is a bi-linear parameter matrix, U_{a_2} is parameter matrix, b_{a_2} is bias parameter.

Aspect Attention Aspect attention applies aspect word representation emb_x^t as attention query, which is expected to capture the correlations between aspect words and context words.

$$a_{t,i}^{aspect} = \tanh(emb_x^t W_{a_3} h_i^c + U_{a_3} s_t + b_{a_3}) \tag{20}$$

where W_{a_3} is a bi-linear parameter matrix, U_{a_3} is parameter matrix, b_{a_3} is bias parameter.

Attention Fusion We define the attention fusion of the semantic attention, sentiment attention and aspect attention at timestep t as:

$$a_{t,i} = \text{softmax}(\lambda_1 a_{t,i}^{semantic} + \lambda_2 a_{t,i}^{sentiment} + \lambda_3 a_{t,i}^{aspect}), \quad c_t = \sum_{i=1}^{k} a_{t,i} h_i^c \tag{21}$$

where λ_1, λ_2 and λ_3 are hyper-parameters that determines the weights of the three kinds of attentions. We set λ_1 = 0.5, λ_2 = λ_3 = 0.25. Note that for the documents that do not contain sentiment words and aspect words, we use only the semantic attention to distinguish the important information.

The context vector c_t is then concatenated with the decoder state s_t and fed through a linear layer and a *softmax* layer to compute the output probability distribution over a vocabulary of words at the current state:

$$P_{vocab}(w_t) = \text{softmax}(V_{d_2}(V_{d_1}[s_t, c_t] + b_{d_1}) + b_{d_2}) \tag{22}$$

where V_{d_1}, V_{d_2}, b_{d_1} and b_{d_2} are learnable parameters. The number of rows in V_{d_2} represents the number of words in the vocabulary.

On top of the LSTM decoder, we adopt the copy mechanism (See et al., 2017) to integrate the attention attribution into the final vocabulary distribution which is defined as the interpolation between two probability distributions:

$$P(w_t) = p_{gen} P_{vocab}(w_t) + (1 - p_{gen}) \sum_{i:w_i = w_t} a_{t,i} \tag{23}$$

where $p_{gen} \in [0, 1]$ is the switch variable for controlling generating a word from the vocabulary or directly copying it from the original review. If w is an out-of-vocabulary (OOV) word, then $P_{vocab}(w)$ is zero; if w does not appear in the source review, then $\sum_{i:w_i=w} a_{t,i}$ is zero. p_{gen} can be defined as:

$$p_{gen} = \text{sigmoid}(U_{d_1}^T c_t + U_{d_2}^T s_t + U_{d_3}^T w_{t-1} + b_{gen}) \tag{24}$$

where vectors U_{d_1}, U_{d_2}, U_{d_3} and scalar b_{gen} are learnable parameters.

A common way of training a summary generation model is to estimate the parameters by minimizing the negative log-likelihood of the training data:

$$J_{\text{ML}}^{\text{sum}}(\theta) = -\frac{1}{N} \sum_{i=1}^{N} \sum_{t=1}^{T} \log P(w_t) \tag{25}$$

3.4 Training of MARS Model

Overall, MARS consists of two subtasks, each has training objective. To make the document embedding sensitive to the category knowledge, we train these two related task simultaneously. The joint multi-task objective function is minimized by:

$$J_{\text{ML}}(\theta) = \gamma_1 J_{ML}^{\text{categ.}}(\theta) + \gamma_2 J_{\text{ML}}^{\text{sum}}(\theta) \tag{26}$$

where γ_1 and γ_2 are hyper-parameters that determines the weights of L_1 and L_2. Here, we set $\gamma_1 = 0.2$, $\gamma_2 = 0.8$.

3.4.1 Policy Gradient Reinforcement Learning for Summary Generation

However, the maximum likelihood estimation (MLE) method suffers from two main issues. First, the evaluation metric is different from the training loss. For example, in summarization generation systems, the encoder-decoder models are trained using the cross-entropy loss but they are typically evaluated at test time using discrete and non-differentiable metrics such as BLEU (Papineni et al., 2002) and ROUGE (Lin, 2004). Second, the input of the decoder at each time step is often the previous ground-truth word during training. Nevertheless, when generating summaries in the testing phase, the input of the next time step is the previous word generated by the decoder. This exposure bias (Ranzato et al., 2015) leads to error accumulation at the testing phase. Once the model generates a "bad" word, the error will propagate and accumulate with the length of the sequence.

To alleviate the aforementioned issues when generating summaries, we also optimize directly for ROUGE-1 since it achieves best results among the alternatives such as METEOR (Lavie and Agarwal, 2007) and BLEU (Papineni et al., 2002), by using policy gradient algorithm, and minimize the negative expected rewards:

$$J_{\text{RL}}^{\text{sum}}(\theta) = (r(\hat{z}) - r(z^s)) \sum_{t}^{T} \log p(z_t^s | Z_{1:t-1}^s; X) \tag{27}$$

where $r(\hat{z})$ is the reward of a greedy decoding generated sequence $\hat{z}$, and $r(z^s)$ is the reward of sequence z^s generated by sampling among the vocabulary at each step.

After pre-training the proposed model by minimizing the joint ML objective (see Eq. 26), we switch the model to further minimize a mixed training objective, integrating the reinforcement learning objective $J_{\text{RL}}^{\text{sum}}(\theta)$ with the original multi-task loss $J_{\text{ml}}(\theta)$:

$$J_{\text{mixed}}(\theta) = \beta J_{\text{ML}}(\theta) + (1 - \beta) J_{\text{RL}}^{\text{sum}}(\theta) \tag{28}$$

where β is a hyper-parameter, and we set β=0.1.

4 Experimental Setup

4.1 Datasets Description

We evaluate our model on Amazon reviews dataset from Stanford Network Analysis Project (SNAP) (McAuley and Leskovec, 2013). The raw dataset consists of 34,686,770 Amazon reviews from 6,643,669 users spanning different kinds of products such as books, video games, food, music. Each review mainly contains product ID, user information, ratings, a plaintext review and a review summary. There are 82 tokens on average of reviews. Since the dataset is too large to process all at once on our local computer, we randomly choose 50,000 reviews from each of the books, food, electronics, movies, music and clothing categories. For each of the six product categories, we use 80% instances as the training data, 10% instances as the validation data, and the remaining are used for testing.

Sentiment Words Collection The sentiment lexicon used in this paper is the combination of three popular sentiment lexicons: HowNet (Dong and Dong, 2006), MPQA (Wilson et al., 2005) and Liu's Lexicon (Hu and Liu, 2004), which consists of 11,017 words in total.

Aspect Words Collection The aspect dictionary contains about 800 words provided by the experts of each product categories, including product names and the aspect words of the products. Following (Yang et al., 2014), we apply topic model to extend the aspect dictionary by using a minimal set of seed words as prior knowledge to discover a much richer lexicon.

4.2 Baseline Methods

In the experiments, we compare our model with several strong baseline methods:

SummaRuNNer A simple recurrent network based sequence classifier (Nallapati et al., 2017) which facilitates interpretable visualization of its decisions. It is an extractive summarization model.

ABS Attentional encoder decoder recurrent neural networks for abstractive text summarization proposed in (Nallapati et al., 2016).

PGC The pointer-generator coverage networks proposed in (See et al., 2017) which copies words from the source text via pointing, while retaining the ability to produce novel words through the generator.

DeepRL The deep reinforced model (ML+RL version) proposed in (Paulus et al., 2017), which introduce a new objective function by combining the maximum-likelihood cross-entropy loss with rewards from policy gradient reinforcement learning to reduce exposure bias.

GANsum The generative adversarial network for abstractive summarization (Liu et al., 2018).

4.3 Implementation Details

We use 100-dimensional word2vec (Mikolov et al., 2013) vectors pre-trained on English Wikipedia data to initialize the word embeddings, and all out-of-vocabulary words are initialized by sampling from the uniform distribution U(-0.25,0.25) We initialize the recurrent weight matrices of LSTMs as random orthogonal matrices, and all the bias vectors are initialized to zero. The hidden state size of each LSTM is 300. We conduct mini-batch (with size 64) training using Adadelta optimization algorithm. Other hyperparameters include: learning rate 0.01, L2 regularization 0.001, dropout 0.2. For the pointer-generator models, we use a vocabulary of 50k words for both training and text data.

5 Experimental Results

In this section, we compare our model with baseline methods from quantitative and qualitative perspectives.

5.1 Quantitative Evaluation

Following the same evaluation as in (Nallapati et al., 2016), we compare our model with baseline methods in terms of ROUGE-1, ROUGE-2, ROUGE-L and Human evaluation.

ROUGE-N is a widely used evaluation metric for summarization tasks. It measures the consistency between n-gram occurrences in the generated and reference summaries. ROUGE-L compares the longest common sequence between the reference summary and the generated summary. We summarize the ROUGE scores of our model and the baseline methods in Table 1. PGC consistently perform better than ABS. This may be because that the copy mechanism used in PGC can handle the out-of-vocabulary words. DeepRL and GANsum are better than PGC, because they utilize reinforcement learning to alleviate the exposure bias problem and optimize directly the evaluation metrics. **Our model** performs even better than the strong competitors by leveraging text categorization task and aspect/sentiment attentions to improve the summarization results. This verifies the effectiveness of our model for abstractive review summarization.

We also perform human evaluation to evaluate the readability and quality of the generated summaries. We randomly select 200 test examples from the dataset. For each review, three human evaluators are invited to rank each summary generated by all 6 models based on their readability, where 1 indicates the lowest level of readability while 6 indicates the highest level. The experimental results based on human annotations are summarized in Table 1 (fifth column). MARS achieves the best results. Specifically, MARS improves 14.9% on the human evaluation score over the best result of baseline methods (i.e., PGC) on the test data.

Method	ROUGE-1	ROUGE-2	ROUGE-L	Human Evaluation
SummaRuNNer	80.53	62.23	82.64	2.72
ABS	78.53	60.92	79.21	1.68
PGC	81.84	64.15	83.18	2.94
DeepRL	82.12	65.09	84.31	3.22
GANsum	82.64	66.12	84.31	3.42
MARS	**84.13**	**68.28**	**86.15**	**3.93**

Table 1: Quantitative evaluation results. All our ROUGE scores have a 95% confidence interval of at most ± 0.25 as reported by the official ROUGE script.

Method	ROUGE-1	ROUGE-2	ROUGE-L	Human Evaluation
MARS	**84.13**	**68.28**	**86.15**	**3.93**
w/o categorization	81.33	65.25	82.35	2.76
w/o sentiment attention	82.44	66.23	84.14	3.24
w/o aspect attention	83.05	66.09	84.85	3.35
w/o semantic attention	82.12	65.84	83.42	3.06

Table 2: Ablation test results.

5.2 Ablation Study

To investigate the effect of each component of the MARS model, we also perform the ablation test of MARS in terms of discarding text categorization, aspect attention, sentiment attention, and semantic attention. The results are reported in Table 2. For human evaluation, three human evaluators are invited to rank each summary generated by all 5 models based on their readability, where 1 indicates the lowest level of readability while 5 indicates the highest level. Generally, all three factors contribute, and text categorization contribute most. This is within our expectation since the the text categorization helps learn better category-specific review representations. In addition, it also helps the learning of aspect and sentiment representations. The aspect and sentiment attention also makes great contribution to abstractive review summarization, verifying that the aspect and sentiment information plays a vital role in review summaries.

Input summary: Our pup has experienced allergies in forms of hotspots and itching from other dog foods. The cheap 'you can buy it anywhere' food not only have crazy preservatives in them but can cause health problems for your pets. This food works wonders on reducing allergies and our dog loves the food. **Ground-truth summary:** Great allergy sensitive dog food, dogs love it. **Summary by GANsum:** Great foods loves. **Summary by MARS:** Great dog food for reducing allergies.
Input summary: The NOOKColor is awesome- it plays music, is expandable, displays gorgeous color, allows you to surf the internet (not optimally, but the ability is there), and is mostly easy to navigate. From me, it gets a solid 4 stars. The problem is that as an eReader, it's already overpriced, and the Amazon sellers who offer it are asking ridiculous amounts. It's cheaper (and ships free) from Barnes and Noble. Amazon is usually No1 at everything, including price, and I already own two Kindles (I would buy the Kindle in color if it came that way) but the price being charged for the NOOKColor on Amazon is absurd. **Ground-truth summary:** Awesome eReader, Ridiculously Priced from this seller. **Summary by GANsum:** NOOKColor is awesome music gorgeous color Amazon. **Summary by MCARS:** Awesome NOOKColor, absurd Amazon price.

Table 3: Examples summaries.

5.3 Qualitative Evaluation

To evaluate the proposed model qualitatively, we reported some generated summaries by different models. Due to the limitation of space, we randomly choose two generated summaries by GANsum and our model from test data for comparison. The results are reported in Table 3. We observe that MARS tends to generate more specific and meaningful summaries in response to the given reviews. For example, our model successfully catches the sentiment word "Awesome" for the product *eReader* and the sentiment

word "absurd" for the *price* aspect of the eReader. The advantage of our model comes from its capability of integrating category, sentiment and aspect information into the attention encoder-decoder model.

6 Conclusion

We proposed MARS to improve the performance of aspect/sentiment-aware abstractive review summarization. A mutual attention mechanism was employed to integrated the sentiment and aspect information into the encoder-decoder abstractive summarizer. In addition, MARS leveraged text categorization to improve the performance of summarization by learning a category-specific review representation. We also explored three kinds of attentions (i.e., semantic attention, sentiment attention and aspect attention) to selectively attend to the context information when decoding summaries. The experimental results on a real-life dataset showed that our model substantially outperformed the strong competitive methods.

Abstract

Aspect-level sentiment classification aims to determine the sentiment polarity of a review sentence towards an opinion target. A sentence could contain multiple sentiment-target pairs; thus the main challenge of this task is to separate different opinion contexts for different targets. To this end, *attention mechanism* has played an important role in previous state-of-the-art neural models. The mechanism is able to capture the importance of each context word towards a target by modeling their semantic associations. We build upon this line of research and propose two novel approaches for improving the effectiveness of attention. First, we propose a method for target representation that better captures the semantic meaning of the opinion target. Second, we introduce an attention model that incorporates syntactic information into the attention mechanism. We experiment on attention-based LSTM (Long Short-Term Memory) models using the datasets from SemEval 2014, 2015, and 2016. The experimental results show that the conventional attention-based LSTM can be substantially improved by incorporating the two approaches.

1 Introduction

Aspect-level sentiment classification is an important task in fine-grained sentiment analysis (Pang and Lee, 2008). Given a sentence and an opinion target (also called aspect expression) occurring in the sentence, the task aims to determine the sentiment polarity of the sentence towards the opinion target. An opinion target or target for short refers to a word or a phrase (a sequence of words) describing an aspect of an entity. For example, in the sentence "*This little place has a cute interior decor and affordable prices*", the targets are *interior decor* and *prices*, and they belong to the aspects *ambience* and *price* respectively.

Compared to document-level or sentence-level sentiment classification, the main challenge of aspect-level sentiment classification is to differentiate sentiments towards different targets when there are multiple targets in a sentence. For instance, the sentence "*The appetizers are ok, but the service is slow.*" expresses a neutral sentiment on the target *appetizers* and a negative sentiment on the target *service*. To this end, attention mechanism has played an important role in state-of-the-art neural models for this task. It assigns a positive weight att_i for each context word w_i, which can be interpreted as the probability that w_i is the right word to focus on when inferring the sentiment polarity of the given target. The weight att_i is generally computed as a function of the hidden representation $\mathbf{h_i}$ of w_i and the target representation $\mathbf{t}$ as follows:

$$att_i \propto f_{score}(\mathbf{h_i}, \mathbf{t}) \tag{1}$$

It has been shown that adding an attention model substantially improves the accuracy of aspect-level sentiment classification (Tang et al., 2016b; Wang et al., 2016; Liu and Zhang, 2017).

Our work builds upon this line of research. We propose two novel approaches for improving the effectiveness of attention models. The first approach is a new way of encoding a target which better captures the aspect semantics of the target expression. The target representation is crucial since attention weights are computed based on it as shown in Eq. 1. In representing the target, we are mapping a word or

Proceedings of the 27th International Conference on Computational Linguistics, pages 1121–1131
Santa Fe, New Mexico, USA, August 20-26, 2018.

a phrase into a vector in $\mathbb{R}^d$. Ideally, targets that are semantically similar should be mapped to vectors that are close together in $\mathbb{R}^d$. However, previous neural attention models simply map a target by averaging its component word vectors. This may work fine for targets that only contain one word but may fail to capture the semantics of more complex expressions, as also mentioned by Tang et al. (2016b). For example, we cannot obtain a good representation for "*hot dog*" by averaging the word vectors of "*hot*" and "*dog*". Hot would be close to words like warm or cold and dog would be close to animals like cat. The average would not be close to other food like burgers or spaghetti. Another example is "*hong kong style food*". As it consists of many words, the averaged word vector could be far away from "*food*" in vector space.

To address this problem, inspired by He et al. (2017), we instead model each target as a mixture of K aspect embeddings where we would like each embedded aspect to represent a cluster of closely related targets. We use an *autoencoder* structure to learn both the aspect embeddings as well as the representation of the target as a weighted combination of the aspect embeddings. The weight vector represents the probability distribution over aspects for the given target. The autoencoder structure is jointly trained with a neural attention-based sentiment classifier to provide a good target representation as well as a high accuracy on the predicted sentiment. We found the learned embeddings to be semantically meaningful, i.e., embeddings of words that are semantically related appear close to the same aspect embedding. For example, embeddings of the words *service*, *servers*, *staff*, and *courteous* appear close to the same aspect embedding, which we interpret to represent the aspect *service*.

Our second approach exploits syntactic information to construct a syntax-based attention model. The attention models used in previous works give equal importance to all context words. In that case, the computed attention weights rely entirely on the semantic associations between context words and the target. However, this may not be sufficient for differentiating opinions words for different targets. Instead, our syntax-based attention mechanism selectively focuses on a small subset of context words that are close to the target on the syntactic path which is obtained by applying a dependency parser on the review sentence.

We conducted experiments on attention-based LSTM models using the SemEval 2014, 2015, and 2016 datasets. The results show that attention-based LSTM can be substantially improved by incorporating our two proposed methods, and that the resulting model outperforms all baseline methods on aspect-level sentiment classification.

2 Related Work

Under supervised learning conditions, aspect-level sentiment classification is typically considered as a classification problem. Early works (Boiy and Moens, 2009; Jiang et al., 2011; Kiritchenko et al., 2014; Wagner et al., 2014) mainly used manually designed features such as sentiment lexicon, n-grams, and dependency information. However, these methods highly depend on the quality of the designed features, which is labor-intensive. With the advances of deep learning methods, various neural models (Dong et al., 2014; Nguyen and Shirai, 2015; Vo and Zhang, 2015; Tang et al., 2016a; Tang et al., 2016b; Wang et al., 2016; Zhang et al., 2016; Liu and Zhang, 2017; Chen et al., 2017; He et al., 2018) have been proposed for automatically learning target-dependent sentence representations for classification. The main idea behind these works is to develop neural architectures that are capable of learning continuous features without feature engineering and at the same time capturing the intricate relatedness between a target and context words.

Among these works, attention-based neural models have attracted growing interest due to their ability to explicitly capture the importance of context words. Tang et al. (2016b) have shown that a better sentence representation could be obtained by stacking multiple layers of attention. In the work of Wang et al (2016), a variant of attention-based LSTM was proposed. Chen et al. (2017) also adopts multiple layers of attention and aggregates the attention outputs through a recurrent neural network.

As aspect information is very beneficial, in some works (Wang et al., 2016; Cheng et al., 2017; Ma et al., 2018), an aspect embedding is directly used to capture the importance of context words through an attention mechanism, where the authors assume that the aspect label is provided as an input. Unlike them,

we do not assume that the aspects of each sentence are given. Instead, we propose to learn the probability distribution over aspects for the given target, and use the weighted summation of aspect embeddings for target representation. The probability distribution and the aspect embeddings are learned via an unsupervised objective, which is jointly trained with the neural attention-based sentiment classifier.

3 Model Description

We propose two approaches to improve the effectiveness of the attention mechanism. The approaches may be applied more generally but we use them on attention-based LSTM as it has been widely used in previous works for sentiment analysis (Chen et al., 2016; Wang et al., 2016; Chen et al., 2017; Liu and Zhang, 2017; Ma et al., 2018). We first give the task definition in (§3.1). Then, we briefly describe the architecture of attention-based LSTM (§3.2) and introduce the two proposed approaches (§3.3 & §3.4). Finally, we describe the overall architecture of our model for aspect-level sentiment classification and the training objective (§3.5).

3.1 Task Definition and Notation

Given a review sentence $s = (w_1, w_2, ..., w_n)$ consisting of n words, and an opinion target occurring in the sentence $a = (a_1, a_2, ..., a_m)$ consisting of a subsequence of m continuous words from s, aspect-level sentiment classification aims to determine the sentiment polarity of sentence s towards the opinion target a. When dealing with a text corpus, we begin by associating each word w with a continuous feature vector $\mathbf{e}_w \in \mathbb{R}^d$, also known as word embedding (Mikolov et al., 2013), where d denotes the embedding dimension. The vectors associated with the words correspond to the rows of a word embedding matrix $\mathbf{E} \in \mathbb{R}^{V \times d}$, where V is the vocabulary size.

3.2 Attention-based LSTM

We briefly describe a conventional attention-based LSTM in this subsection. Given a sequence of word embeddings $\{\mathbf{e}_{w_1}, \mathbf{e}_{w_2}, ..., \mathbf{e}_{w_n}\}$ of a sentence s, LSTM with trainable parameters θ_{lstm} makes use of three gates to discard or pass the information through time (Hochreiter and Schmidhuber, 1997), and outputs a sequence of hidden vectors $h = \{\mathbf{h}_1, \mathbf{h}_2, ..., \mathbf{h}_n\}$. The sentence representation $\mathbf{z}_s$ used for sentiment classification is then computed as the weighted summation of hidden vectors.

$$\mathbf{z}_s = \sum_{i=1}^{n} p_i \mathbf{h}_i \tag{2}$$

A positive weight p_i is computed for each $\mathbf{h}_i$, which can be interpreted as the probability that w_i is the right word to focus on when inferring the sentiment polarity of the opinion target a. The value p_i is computed by an attention model, which conditions on the hidden vector $\mathbf{h}_i$ as well as the target representation. In previous works (Tang et al., 2016b; Wang et al., 2016; Liu and Zhang, 2017), the attention process is usually described with the following equations:

$$p_i = \frac{\exp(d_i)}{\sum_{j=1}^{n} \exp(d_j)} \tag{3}$$

$$d_i = f_{score}(\mathbf{h}_i, \mathbf{t}_s) \tag{4}$$

$$\mathbf{t}_s = \frac{1}{m} \sum_{i=1}^{m} \mathbf{e}_{a_i} \tag{5}$$

where f_{score} is a function that computes a score for word w_i according to the semantic association between $\mathbf{h}_i$ and $\mathbf{t}_s$, and $\mathbf{t}_s$ is the vector representation of the given target.

3.3 Target Representation

Most previous work (Tang et al., 2016b; Liu and Zhang, 2017; Chen et al., 2017) represent a target by averaging its component word or hidden vectors as shown in Equation 5. Simple averaging may not

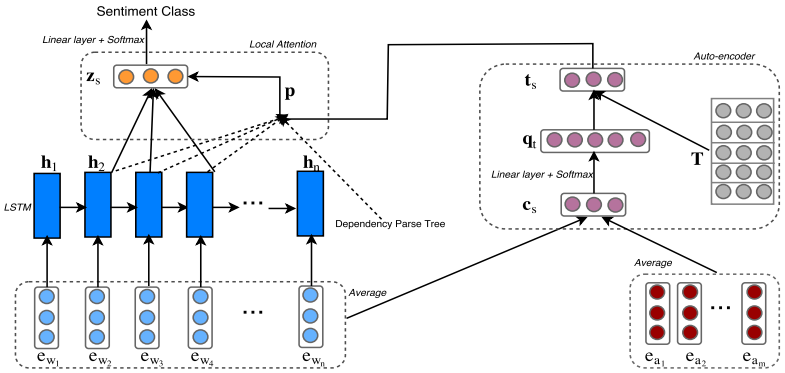

Figure 1: The overall architecture of the integrated model.

capture the real semantics of the target well. Inspired by He et al. (2017), we represent the target as a weighted summation of aspect embeddings, as illustrated in Fig. 1. An aspect embedding matrix is represented by $\mathbf{T} \in \mathbb{R}^{K \times d}$, where K, the number of aspects defined by the user, is much smaller than V. The process is formalized as follows:

$$\mathbf{t}_s = \mathbf{T}^\top \cdot \mathbf{q}_t \tag{6}$$

$$\mathbf{q}_t = \mathit{softmax}(\mathbf{W}_t \cdot \mathbf{c}_s + \mathbf{b}_t) \tag{7}$$

$$\mathbf{c}_s = \mathit{Average}(\frac{1}{m}\sum_{i=1}^{m}\mathbf{e}_{a_i}, \frac{1}{n}\sum_{j=1}^{n}\mathbf{e}_{w_j}) \tag{8}$$

where *Average* returns the mean of the input vectors. $\mathbf{c}_s$ captures both target information and context information. $\mathbf{q}_t$ is the weight vector over K aspect embeddings, where each weight represents the probability that the target belongs to the related aspect. $\mathbf{W}_t$ and $\mathbf{b}_t$ are a weight matrix and a bias vector respectively.

We would like the learned aspect embeddings to be meaningful and semantically coherent. This would allow us to interpret an aspect by looking at its nearby words in vector space. However, the aspect embedding matrix $\mathbf{T}$ is randomly initialized. It is difficult to obtain coherent aspect embeddings if we only rely on the training of the sentiment classifier. Therefore, we add an unsupervised objective function to ensure the quality of the aspect embeddings, which is jointly trained with the attention-based LSTM. Indeed, we can understand the process shown by Eq. (6) (7) (8) as an autoencoder, where we first reduce $\mathbf{c}_s$ from d dimensions to K dimensions with softmax non-linearity. Only the dimensions that are relevant to the aspects are retained in $\mathbf{q}_t$, whereas the other dimensions are removed. Then we reconstruct $\mathbf{c}_s$ from $\mathbf{q}_t$ through linear combination of aspect embeddings. The unsupervised objective is thus to minimize the reconstruction error as shown below:

$$U(\theta) = -\sum_{(s,a)\in D} \log(\min(\epsilon, \mathit{CosSim}(\mathbf{t}_s, \mathbf{c}_s))) \tag{9}$$

where cosine similarity *CosSim()* is used as the similarity measure. ϵ denotes a very small positive number. We set it to 10^{-7} in all experiments. D denotes all training samples, (s, a) denotes a sentence-target pair, and $\theta = \{\mathbf{E}, \mathbf{T}, \mathbf{W}_t, \mathbf{b}_t\}$ is the set of trainable parameters.

The learning process can also be viewed as multi-task learning where the unsupervised objective shown as Eq. 9 is an auxiliary task. Multi-task learning can help to reduce the amount of data required for learning and to improve the model generalization ability.

3.4 Syntax-based Attention Mechanism

The attention mechanism used in previous works (Tang et al., 2016b; Wang et al., 2016; Liu and Zhang, 2017) gives equal importance to all context words, where the attention weight is merely a measure of

semantic association between the target and the context word. But intuitively not all words are equally important for determining the polarity of a target. Words that appear near the target or have a modifier relation to the target, for example, are more important and should receive higher weight. This is particularly true for opinion words that express sentiment and when there are multiple targets and multiple opinion words in one sentence. To address this issue, we propose an attention mechanism that also encodes the syntactic structure of a sentence, where syntactic information is obtained from a dependency parser. Fig. 2 shows the dependency tree of an example sentence. The opinion words that are closer to the target in the dependency tree are more relevant for determining its sentiment. In our model, we define the location l of a context word as its distance to the target[1] along the dependency path. The attention model selectively attends to a small window of context words based on their location. We use ws to denote the attention window size. In our experiment, we ignore context words whose location is larger than ws and for context words within the window, different weights are applied so that words closer to the target receive more attention. The details of the proposed syntax-based attention model are described as follows:

$$p_i = \frac{d_i}{\sum_j d_j} \tag{10}$$

$$d_i = \begin{cases} \frac{1}{2^{(l_i-1)}} \cdot exp(f_{score}(\mathbf{h}_i, \mathbf{t}_s))), & \text{if } l_i \in [1, ws] \\ 0, & \text{otherwise} \end{cases} \tag{11}$$

where t_s is the target representation constructed using the method described in §3.3. We adopt a simple score function as follows:

$$f_{score}(\mathbf{h}_i, \mathbf{t}_s) = tanh(\mathbf{h}_i^T \cdot \mathbf{W}_a \cdot \mathbf{t}_s) \tag{12}$$

where $\mathbf{W}_a \in \mathbb{R}^{d \times d}$ is a trainable weight matrix.

3.5 Overall Architecture and Training Objective

After incorporating the two proposed approaches into the attention-based LSTM, our final model is illustrated in Fig. 1. The attention-based LSTM component is associated with the categorical cross entropy loss of sentiment classification. The loss function is given below:

$$J(\theta) = -\sum_{(s,a) \in D} \sum_{c \in C} P^g_{(s,a)}(c) \log(P_{(s,a)}(c)) \tag{13}$$

where C is the collection of sentiment classes, $P^g_{(s,a)}(c)$ is either 1 or 0, indicating whether the gold label is c for (s, a), and $P_{(s,a)}(c)$ is the predicted probability that (s, a) has sentiment class c. $\theta = \{\mathbf{E}, \mathbf{T}, \mathbf{W}_t, \mathbf{b}_t, \mathbf{W}_a, \theta_{lstm}\}$ is the set of trainable parameters.

The aspect embeddings in $\mathbf{T}$ may become similar to each other during training. To ensure diversity, we employ a regularization term to enforce the uniqueness of each aspect embedding:

$$R(\theta) = \|(\mathbf{T}_{norm} \cdot \mathbf{T}_{norm}^\top - \mathbf{I})^2\| \tag{14}$$

where $\mathbf{I}$ is the identity matrix, $\mathbf{T}_{norm}$ is the L_2 normalization of $\mathbf{T}$, and $\|\|$ denotes the sum of all entries in the matrix. R reaches the minimum when the dot product between any two different aspect embeddings is zero. Thus, the regularization term aims to enforce orthogonality among the rows of $\mathbf{T}$, which punishes redundancy between aspect embeddings.

The final objective function of our model is defined as:

$$L(\theta) = J(\theta) + \lambda_u U(\theta) + \lambda_r R(\theta) \tag{15}$$

where λ_u and λ_r are hyperparameters that control the weights of the unsupervised objective described in §3.3 and the regularization term respectively.

[1]For a target containing multiple words, the distance between a context word and each word in the target is computed, and the minimal value is used to define the location of the context word.

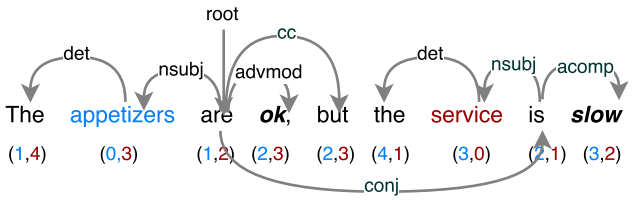

Figure 2: A dependency tree example. The numbers indicate the distances from the word to the two targets respectively along the syntactic path.

	Dataset	Pos	Neg	Neu

Table 1: Dataset description.

4 Experiments

4.1 Datasets

We evaluate our proposed model on four benchmark datasets, taken from SemEval 2014 task 4 (Pontiki et al., 2014), SemEval 2015 task 12 (Pontiki et al., 2015), and SemEval 2016 task 5[2] (Pontiki et al., 2016). Each training and test sample in the 2014 datasets consists of the review sentence, the opinion target, and the sentiment polarity towards the opinion target. Following previous works (Tang et al., 2016b; Wang et al., 2016), we remove samples with *conflicting* polarity in the 2014 datasets – the number of samples in that class is very small and incorporating it will make the training dataset extremely unbalanced. The data format in the 2015 and 2016 datasets is a bit different, where each opinion target is also associated with one or multiple aspects and thus can have multiple sentiment polarities. Below is an example:

The food was delicious but expensive.
(target="food", aspect=food#quality, polarity=Pos)
(target="food", aspect=food#prices, polarity=Neg)

Since our model only takes a sentence and an opinion target as input, without using the aspect information, we remove a sample in both training and test sets if the opinion target has different polarities as the example above. This removes about 5% and 4% of test samples from the 2015 and 2016 datasets respectively. Statistics of the resulting datasets are presented in Table 1.

We initialize word embeddings using the 300-dimension GloVe vectors supplied by Pennington et al. (2014) and we use the dependency parser from spaCy[3] to obtain dependency paths of review sentences. We randomly select 20% of the original training data as the development set and only use the remaining 80% for training. Values for the hyperparameters are obtained empirically on the development set of one task and are fixed for all other experiments. The dimension of the LSTM hidden vectors is set to 300, the objective weights λ_u and λ_r are set to 1 and 0.1 respectively, the attention window size ws is set to 5 and the number of aspects K is set to 8.

We use RMSProp with base learning rate set to 0.001 and decay rate set to 0.9 for network training. The minibatch size is set to 32. As a regularizer, we apply dropout (Srivastava et al., 2014) with probability 0.5 to the LSTM layer and the output layer. We train the network for a fix number of epochs and select the best model according to the performance on the development set, and evaluate it on the test set.

4.2 Model Comparisons

We compare our model with the following baselines:

(1) **Feature-based SVM** (Kiritchenko et al., 2014): We compare with the reported results of a top system in SemEval 2014. We could not directly compare with the reported results from SemEval 2015 and 2016 as their model inputs are different from ours (aspect is also one of their inputs).

(2) **LSTM**: An LSTM network is built on top of word embeddings. The mean over hidden vectors is used as the sentence representation.

[2]Although there is another English dataset in the laptop domain from SemEval 2015 and 2016, it does not contain opinion targets, thus it cannot be used directly in our work.

[3]https://spacy.io

Methods	D1		D2		D3		D4	
	Acc.	Macro-F1	Acc.	Macro-F1	Acc.	Macro-F1	Acc.	Macro-F1
Feature-based SVM	80.16	NA	70.49	NA	NA	NA	NA	NA
LSTM	75.23	64.21	66.79	64.02	75.28	54.10	81.94	58.11
LSTM+ATT	76.83	66.48	68.07	65.27	77.38	60.52	82.73	59.12
TDLSTM	75.37	64.51	68.25	65.96	76.39	58.70	82.16	54.21
TDLSTM+ATT	75.66	65.23	67.82	64.37	77.10	59.46	83.11	57.53
ATAE-LSTM	78.60	67.02	68.88	65.93	78.48	62.84	83.77	61.71
MM	76.87	66.40	68.91	63.95	77.89	59.52	83.04	57.91
RAM	78.48	68.54	72.08	68.43	79.98	60.57	83.88	62.14
Ours: LSTM+ATT+TarRep	78.95	68.67	70.69	66.59	80.05	**68.73**	84.24	**68.62**
Ours: LSTM+SynATT	80.45	71.26	**72.57**	69.13	80.28	65.46	83.39	66.83
Ours: LSTM+SynATT+TarRep	**80.63***	**71.32***	71.94	**69.23**	**81.67***	66.05*	**84.61***	67.45*

Table 2: Average accuracies and Macro-F1 scores over 5 runs with random initializations. The best results are in bold. * indicates that our full model (LSTM+SynATT+TarRep) is significantly better than LSTM, LSTM+ATT, TDLSTM, TDLSTM+ATT, ATAE-LSTM, MM and RAM with $p < 0.05$ based on one-tailed unpaired t-test.

(3) **LSTM+ATT**: The model described in section 3.2.

(4) **TDLSTM** (Tang et al., 2016a): It uses a forward LSTM and a backward LSTM to encode the information before and after the target.

(5) **TDLSTM+ATT**: It extends TDLSTM by incorporating an attention mechanism.

(6) **ATAE-LSTM** (Wang et al., 2016): It is a variant of the attention-based LSTM model.

(7) **MM** (Tang et al., 2016b): It uses multi-hops of attention layers for sentence representation.

(8) **RAM** (Chen et al., 2017): It uses multi-hops of attention layers and combines the multiple attention outputs with a recurrent neural network for sentence representation.

We produce the results of TDLSTM, ATAE-LSTM, and MM with the source codes released by their authors. We re-implement RAM following the instructions in its paper as the code is not available. The comparison results are shown in Table 2. Both accuracy and macro-F1 are used for evaluation as the label distributions are unbalanced. The reported numbers are obtained as the average value over 5 different runs with random initializations for each method. Significant test results are included for testing the robustness of methods under random parameter initializations. We also show the effect of each proposed approach: **LSTM+ATT+TarRep** denotes the model where the proposed target representation is used while the attention model remains the same as LSTM+ATT; **LSTM+SynATT** denotes the model where only the conventional attention is replaced by our syntax-based attention; and **LSTM+SynATT+TarRep** denotes the full model with both approaches integrated as shown in Fig. 1.

We make the following observations: 1) Feature-based SVM is still a strong baseline, our best model achieves competitive results on D1 and D2 without relying on so many manually-designed features and external resources. 2) Compared with all other neural baselines, our full model achieves statistically significant improvements ($p < 0.05$) on both accuracies and macro-F1 scores for D1, D3, D4. 3) Compared with LSTM+ATT, all three settings of our model are able to achieve statistically significant improvements ($p < 0.05$) on all datasets. This demonstrates that both proposed approaches are effective. 4) The integrated full model overall achieves the best performance compared to using only one of the two proposed approaches. This indicates that the two proposed approaches are complementary, thus further improvements could be obtained when combining them. 5) The proposed target representation is more helpful on restaurant domain (D1, D3, and D4) than laptop domain (D2). A plausible reason is that restaurant domain has clearer aspects for opinion targets, while it is much harder to determine the aspects for many opinion targets in the laptop domain. Since our model represents the target as weighted summation of aspect embeddings, domains with clear aspects may benefit more from the model.

4.3 Model Analysis

We conduct more detailed analysis of the proposed approaches quantitatively and qualitatively. By examining the final test outputs of the relevant models, we try to investigate what kind of errors made by the baseline can be more effectively treated by our proposed approaches.

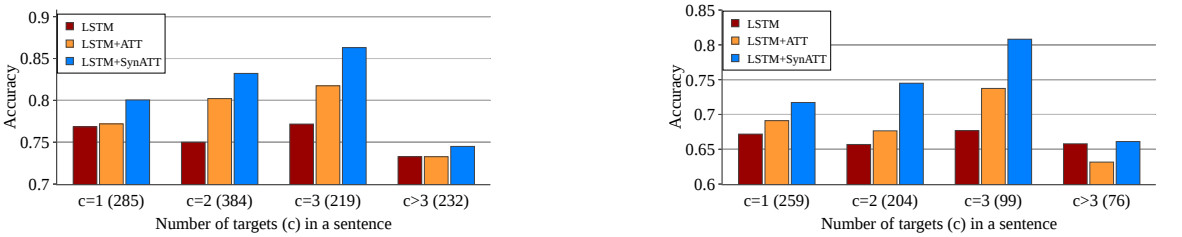

Figure 3: Classification accuracies on groups with different number of opinion targets. The number in brackets indicates the number of test instances in that group. Restaurant14 (left), Laptop14 (right).

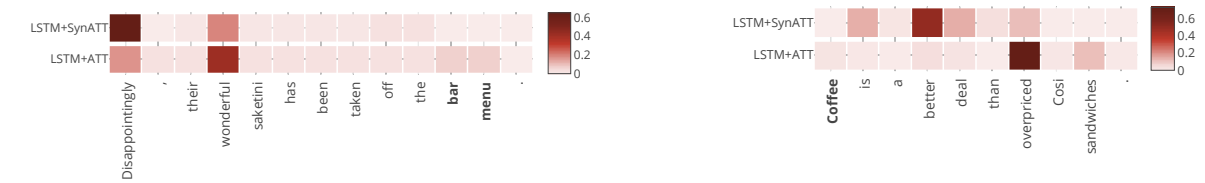
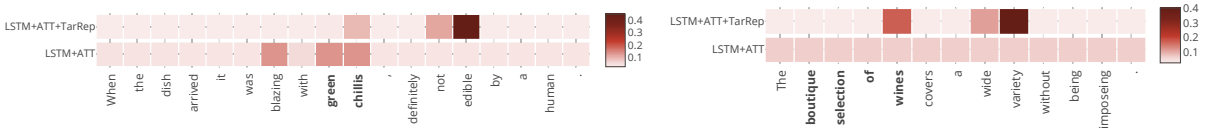


(a) LSTM+ATT vs. LSTM+SynATT



(b) LSTM+ATT vs. LSTM+ATT+TarRep

Figure 4: Attention visualization on example sentence-target pairs. The opinion target is in bold.

Impact of Syntax-based Attention Syntax-based attention is supposed to better differentiate opinion contexts for different targets when there are multiple targets appearing in the sentence. To verify this, we compare LSTM+SynATT with LSTM and LSTM+ATT on sentences grouped by their number of targets. Fig. 3 shows the accuracies on the test sets of Restaurant14 (D1) and Laptop14 (D2).

LSTM+SynATT performs the best on all groups. In particular, it performs substantially better on groups with two or three targets. By analyzing a number of examples from these groups, we find that the proposed syntax-based attention is more effective in capturing the relevant opinion context for a given target when there are multiple targets in the sentence. Two examples are given in Fig. 4a, where our syntax-based attention successfully captures the correct opinion word towards the target of interest, whereas since conventional attention only relies on semantic association between words and the target, it fails by mis-attending to the opinion word towards other target which has similar aspect semantics.

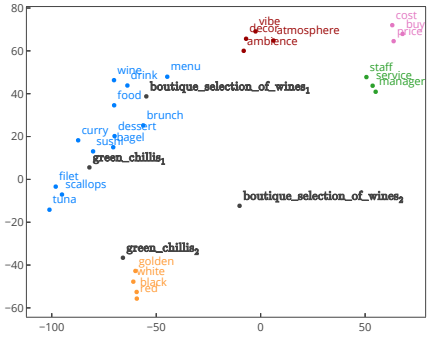


Figure 5: t-SNE visualization of embedding space. Subscripts $_1$ and $_2$ are used to denotes the target representation learned by our method and the method of averaging word vectors used in previous works respectively.

In addition, we observe that all models perform poorly on the group with more than three targets. By analyzing the errors, we find two main causes. First, those sentences are relatively long, involving more complex opinion expressions and sentence structures. Second, the proportion of neutral samples

service	table	atmosphere	price	champagne	curry	bagels	scallops
servers	tables	ambience	prices	wine	thai	bagel	fillet
staff	reservation	ambiance	buy	drink	dumplings	dessert	mignon
courteous	reservations	decor	buying	bottle	sushi	pastries	salmon
waitstaff	waiting	surroundings	cost	wines	samosa	pies	tuna

Table 3: Top 5 representative words of the eight discovered aspects on Restaurant14

contained in this group is much higher than in other groups. Since the number of neutral samples in the training set is small, the trained classifier has difficulties in predicting neutral samples in the test set.

Impact of Target Representation To investigate how the proposed target representation helps to improve performance, we extract test examples from Restaurant14 which are mis-classified by LSTM+ATT but are correctly classified by LSTM+ATT+TarRep. Among these examples, 56% are associated with opinion targets consisting of more than one words. Two examples are shown in Fig. 4b where the targets are "green chillis" and "boutique selection of wines" respectively. Fig. 5 uses t-SNE visualization to show the comparison of the learned target representations between our method and the method of averaging word vectors used in previous works on these two examples. In Fig. 5, we can observe that simply averaging the component word vectors fails to capture the correct semantics of both targets, as the target representations are far away from the food-related words in the embedding space. Due to the inaccurate representation of target, as shown in Fig. 4b, LSTM+ATT fails to attend to the right opinion context in both examples. Our proposed target representation is able to capture the correct aspect semantics for both targets and as a result, the attention mechanism can capture the correct opinion context.

Furthermore, the proposed target representation also outputs aspect embeddings after the training process. Each aspect can be interpreted by its nearby words in vector space. Table 3 presents top representative words of the eight discovered aspects on Restaurant14. The words are ranked based on their cosine similarities with the aspect embedding. As shown, each aspect is semantically coherent and our model is able to discover the typical aspects of a restaurant such as food, ambience, service, and price. Since q_t in Equation (8) represents the probability distribution over aspects for the input target, our model could additionally be used to map the input target to an aspect. We did not conduct further experiments on this since it is not our main focus in this work, but it could be an interesting direction to explore in future.

4.4 Remaining Error Analysis

We additionally conduct a careful analysis of a subset of errors made by our full model, in order to better understand its limitations. To do that, we randomly sample 100 examples with classification errors on the test set of Restaurant14, and classify them into several error categories. Table 4 shows the top three error categories, the corresponding proportions, and some representative examples for each category. The top category is *Neutral*, which denotes examples where the gold sentiment label is neutral. There are two main groups of errors under this category: (1) The polarity of the target is affected by other sentiment words in the sentence. As shown in example 1), the sentence holds a positive sentiment on atmosphere, but expresses no specific opinion on *drinks*. However, affected by the word *perfect*, the predicted sentiment towards *drinks* is positive. Although the proposed attention mechanism aims to address this type of errors, it still fails on complex examples; (2) The sentence is objective, with no opinion expression such as example 2). Since there are many more positive training examples, the predictions on such neutral examples are often biased towards positive sentiment.

The second most common error category is *Complex*, which includes examples with implicit opinion expressions (example 3) or those that require deep comprehension to be understood (example 4). This type of errors is difficult to handle with current techniques, especially when trying to build an end-to-end neural network. The diversity and low frequency of those expressions make it hard for a statistical approach to capture their patterns. For errors made on examples with negation words, we believe this is due to the insufficient training data such that LSTM cannot effectively capture certain sequential patterns.

No.	Category	(%)	Examples
1	Neutral	43	1) *A beautiful atmosphere, perfect for [drinks]$_{neu}$* 2) *We started with the [scallops]$_{neu}$ and [asparagus]$_{neu}$ and also had the [soft shell crab]$_{neu}$.*
2	Complex	28	3) *The [banana pudding]$_{neg}$ they serve has never seen as oven ...* 4) I can understand the [prices]$_{neg}$ if it served better food.
3	Negation words (sentiment shifter)	9	5) *I thought the [food]$_{neg}$ is not cheap at all compared to Chinatown.* 6) *The [dinner]$_{pos}$ here is never disappointing.*

Table 4: Top three error categories.

5 Conclusion

We propose two novel approaches to improve the effectiveness of attention mechanism for aspect-level sentiment classification. In our experiments, we show quantitatively and qualitatively that both methods help to improve the performance of a conventional attention-based LSTM. The integrated model achieves the best results over baseline methods.

As future work, we can consider improving the accuracy on neutral examples. Possible methods include data augmentation on neutral examples and integration of linguistic knowledge to better determine target-relevant opinion expressions.

Bringing replication and reproduction together with generalisability in NLP: Three reproduction studies for Target Dependent Sentiment Analysis

Andrew Moore and Paul Rayson
School of Computing and Communications, Lancaster University, Lancaster, UK
initial.surname@lancaster.ac.uk

Abstract

Lack of repeatability and generalisability are two significant threats to continuing scientific development in Natural Language Processing. Language models and learning methods are so complex that scientific conference papers no longer contain enough space for the technical depth required for replication or reproduction. Taking Target Dependent Sentiment Analysis as a case study, we show how recent work in the field has not consistently released code, or described settings for learning methods in enough detail, and lacks comparability and generalisability in train, test or validation data. To investigate generalisability and to enable state of the art comparative evaluations, we carry out the first reproduction studies of three groups of complementary methods and perform the first large-scale mass evaluation on six different English datasets. Reflecting on our experiences, we recommend that future replication or reproduction experiments should always consider a variety of datasets alongside documenting and releasing their methods and published code in order to minimise the barriers to both repeatability and generalisability. We have released our code with a model zoo on GitHub with Jupyter Notebooks to aid understanding and full documentation, and we recommend that others do the same with their papers at submission time through an anonymised GitHub account.

1 Introduction

Repeatable (replicable and/or reproducible[1]) experimentation is a core tenet of the scientific endeavour. In Natural Language Processing (NLP) research as in other areas, this requires three crucial components: (a) published methods described in sufficient detail (b) a working code base and (c) open dataset(s) to permit training, testing and validation to be reproduced and generalised. In the cognate sub-discipline of corpus linguistics, releasing textual datasets has been a defining feature of the community for many years, enabling multiple comparative experiments to be conducted on a stable basis since the core underlying corpora are community resources. In NLP, with methods becoming increasingly complex with the use of machine learning and deep learning approaches, it is often difficult to describe all settings and configurations in enough detail without releasing code. The work described in this paper emerged from recent efforts at our research centre to reimplement other's work across a number of topics (e.g. text reuse, identity resolution and sentiment analysis) where previously published methods were not easily repeatable because of missing or broken code or dependencies, and/or where methods were not sufficiently well described to enable reproduction. We focus on one sub-area of sentiment analysis to illustrate the extent of these problems, along with our initial recommendations and contributions to address the issues.

The area of Target Dependent Sentiment Analysis (TDSA) and NLP in general has been growing rapidly in the last few years due to new neural network methods that require no feature engineering. However it is difficult to keep track of the state of the art as new models are tested on different datasets, thus preventing true comparative evaluations. This is best shown by table 1 where many approaches

[1]We follow the definitions in Antske Fokkens' guest blog post "replication (obtaining the same results using the same experiment) as well as reproduction (reach the same conclusion through different means)" from http://coling2018.org/slowly-growing-offspring-zigglebottom-anno-2017-guest-post/

Proceedings of the 27th International Conference on Computational Linguistics, pages 1132–1144
Santa Fe, New Mexico, USA, August 20-26, 2018.

are evaluated on the SemEval dataset (Pontiki et al., 2014) but not all. Datasets can vary by domain (e.g. product), type (social media, review), or medium (written or spoken), and to date there has been no comparative evaluation of methods from these multiple classes. Our primary and secondary contributions therefore, are to carry out the first study that reports results across all three different dataset classes, and to release a open source code framework implementing three complementary groups of TDSA methods.

In terms of reproducibility via code release, recent TDSA papers have generally been very good with regards to publishing code alongside their papers (Mitchell et al., 2013; Zhang et al., 2015; Zhang et al., 2016; Liu and Zhang, 2017; Marrese-Taylor et al., 2017; Wang et al., 2017) but other papers have not released code (Wang et al., 2016; Tay et al., 2017). In some cases, the code was initially made available, then removed, and is now back online (Tang et al., 2016a). Unfortunately, in some cases even when code has been published, different results have been obtained relative to the original paper. This can be seen when Chen et al. (2017) used the code and embeddings in Tang et al. (2016b) they observe different results. Similarly, when others (Tay et al., 2017; Chen et al., 2017) attempt to replicate the experiments of Tang et al. (2016a) they also produce different results to the original authors. Our observations within this one sub-field motivates the need to investigate further and understand how such problems can be avoided in the future. In some cases, when code has been released, it is difficult to use which could explain why the results were not reproduced. Of course, we would not expect researchers to produce industrial strength code, or provide continuing free ongoing support for multiple years after publication, but the situation is clearly problematic for the development of the new field in general.

In this paper, we therefore reproduce three papers chosen as they employ widely differing methods: Neural Pooling (NP) (Vo and Zhang, 2015), NP with dependency parsing (Wang et al., 2017), and RNN (Tang et al., 2016a), as well as having been applied largely to different datasets. At the end of the paper, we reflect on bringing together elements of repeatability and generalisability which we find are crucial to NLP and data science based disciplines more widely to enable others to make use of the science created.

Table 1: Methods and Datasets

2 Related work

Reproducibility and replicability have long been key elements of the scientific method, but have been gaining renewed prominence recently across a number of disciplines with attention being given to a 're-producibility crisis'. For example, in pharmaceutical research, as little as 20-25% of papers were found to be replicable (Prinz et al., 2011). The problem has also been recognised in computer science in general (Collberg and Proebsting, 2016). Reproducibility and replicability have been researched for sometime

in Information Retrieval (IR) since the Grid@CLEF pilot track (Ferro and Harman, 2009). The aim was to create a 'grid of points' where a point defined the performance of a particular IR system using certain pre-processing techniques on a defined dataset. Louridas and Gousios (2012) looked at reproducibility in Software Engineering after trying to replicate another authors results and concluded with a list of requirements for papers to be reproducible: (a) All data related to the paper, (b) All code required to reproduce the paper and (c) Documentation for the code and data. Fokkens et al. (2013) looked at reproducibility in WordNet similarity and Named Entity Recognition finding five key aspects that cause experimental variation and therefore need to be clearly stated: (a) pre-processing, (b) experimental setup, (c) versioning, (d) system output, (e) system variation. In Twitter sentiment analysis, Sygkounas et al. (2016) stated the need for using the same library versions and datasets when replicating work.

Different methods of releasing datasets and code have been suggested. Ferro and Harman (2009) defined a framework (CIRCO) that enforces a pre-processing pipeline where data can be extracted at each stage therefore facilitating a validation step. They stated a mechanism for storing results, dataset and pre-processed data[2]. Louridas and Gousios (2012) suggested the use of a virtual machine alongside papers to bundle the data and code together, while most state the advantages of releasing source code (Fokkens et al., 2013; Potthast et al., 2016; Sygkounas et al., 2016). The act of reproducing or replicating results is not just for validating research but to also show how it can be improved. Ferro and Silvello (2016) followed up their initial research and were able to analyse which pre-processing techniques were important on a French monolingual dataset and how the different techniques affected each other given an IR system. Fokkens et al. (2013) showed how changes in the five key aspects affected results.

The closest related work to our reproducibility study is that of Marrese-Taylor and Matsuo (2017) which they replicate three different syntactic based aspect extraction methods. They found that parameter tuning was very important however using different pre-processing pipelines such as Stanford's CoreNLP did not have a consistent effect on the results. They found that the methods stated in the original papers are not detailed enough to replicate the study as evidenced by their large results differential.

Dashtipour et al. (2016) undertook a replication study in sentiment prediction, however this was at the document level and on different datasets and languages to the originals. In other areas of (aspect-based) sentiment analysis, releasing code for published systems has not been a high priority, e.g. in SemEval 2016 task 5 (Pontiki et al., 2016) only 1 out of 21 papers released their source code. In IR, specific reproducible research tracks have been created[3] and we are pleased to see the same happening at COLING 2018[4].

Turning now to the focus of our investigations, Target Dependent sentiment analysis (TDSA) research (Nasukawa and Yi, 2003) arose as an extension to the coarse grained analysis of document level sentiment analysis (Pang et al., 2002; Turney, 2002). Since its inception, papers have applied different methods such as feature based (Kiritchenko et al., 2014), Recursive Neural Networks (RecNN) (Dong et al., 2014), Recurrent Neural Networks (RNN) (Tang et al., 2016a), attention applied to RNN (Wang et al., 2016; Chen et al., 2017; Tay et al., 2017), Neural Pooling (NP) (Vo and Zhang, 2015; Wang et al., 2017), RNN combined with NP (Zhang et al., 2016), and attention based neural networks (Tang et al., 2016b). Others have tackled TDSA as a joint task with target extraction, thus treating it as a sequence labelling problem. Mitchell et al. (2013) carried out this task using Conditional Random Fields (CRF), and this work was then extended using a neural CRF (Zhang et al., 2015). Both approaches found that combining the two tasks did not improve results compared to treating the two tasks separately, apart from when considering POS and NEG when the joint task performs better. Finally, Marrese-Taylor et al. (2017) created an attention RNN for this task which was evaluated on two very different datasets containing written and spoken (video-based) reviews where the domain adaptation between the two shows some promise. Overall, within the field of sentiment analysis there are other granularities such as sentence level (Socher et al., 2013), topic (Augenstein et al., 2018), and aspect (Wang et al., 2016; Tay et al., 2017). Aspect-level sentiment analysis relates to identifying the sentiment of (potentially multiple) topics in the

[2] http://direct.dei.unipd.it/

[3] http://ecir2016.dei.unipd.it/call_for_papers.html

[4] http://coling2018.org/

same text although this can be seen as a similar task to TDSA. However the clear distinction between aspect and TDSA is that TDSA requires the target to be mentioned in the text itself while aspect-level employs a conceptual category with potentially multiple related instantiations in the text.

Tang et al. (2016a) created a Target Dependent LSTM (TDLSTM) which encompassed two LSTMs either side of the target word, then improved the model by concatenating the target vector to the input embeddings to create a Target Connected LSTM (TCLSTM). Adding attention has become very popular recently. Tang et al. (2016b) showed the speed and accuracy improvements of using multiple attention layers only over LSTM based methods, however they found that it could not model complex sentences e.g. negations. Liu and Zhang (2017) showed that adding attention to a Bi-directional LSTM (BLSTM) improves the results as it takes the importance of each word into account with respect to the target. Chen et al. (2017) also combined a BLSTM and attention, however they used multiple attention layers and combined the results using a Gated Recurrent Unit (GRU) which they called Recurrent Attention on Memory (RAM), and they found this method to allow models to better understand more complex sentiment for each comparison. Vo and Zhang (2015) used neural pooling features e.g. max, min, etc of the word embeddings of the left and right context of the target word, the target itself, and the whole Tweet. They inputted the features into a linear SVM, and showed the importance of using the left and right context for the first time. They found in their study that using a combination of Word2Vec embeddings and sentiment embeddings (Tang et al., 2014) performed best alongside using sentiment lexicons to filter the embedding space. Other studies have adopted more linguistic approaches. Wang et al. (2017) extended the work of Vo and Zhang (2015) by using the dependency linked words from the target. Dong et al. (2014) used the dependency tree to create a Recursive Neural Network (RecNN) inspired by Socher et al. (2013) but compared to Socher et al. (2013) they also utilised the dependency tags to create an Adaptive RecNN (ARecNN).

Critically, the methods reported above have not been applied to the same datasets, therefore a true comparative evaluation between the different methods is somewhat difficult. This has serious implications for generalisability of methods. We correct that limitation in our study. There are two papers taking a similar approach to our work in terms of generalisability although they do not combine them with the reproduction issues that we highlight. First, Chen et al. (2017) compared results across SemEval's laptop and restaurant reviews in English (Pontiki et al., 2014), a Twitter dataset (Dong et al., 2014) and their own Chinese news comments dataset. They did perform a comparison across different languages, domains, corpora types, and different methods; SVM with features (Kiritchenko et al., 2014), Rec-NN (Dong et al., 2014), TDLSTM (Tang et al., 2016a), Memory Neural Network (MNet) (Tang et al., 2016b) and their own attention method. However, the Chinese dataset was not released, and the methods were not compared across all datasets. By contrast, we compare all methods across all datasets, using techniques that are not just from the Recurrent Neural Network (RNN) family. A second paper, by Barnes et al. (2017) compares seven approaches to (document and sentence level) sentiment analysis on six benchmark datasets, but does not systematically explore reproduction issues as we do in our paper.

3 Datasets used in our experiments

We are evaluating our models over six different English datasets deliberately chosen to represent a range of domains, types and mediums. As highlighted above, previous papers tend to only carry out evaluations on one or two datasets which limits the generalisability of their results. In this paper, we do not consider the quality or inter-annotator agreement levels of these datasets but it has been noted that some datasets may have issues here. For example, Pavlopoulos and Androutsopoulos (2014) point out that the Hu and Liu (2004) dataset does not state their inter-annotator agreement scores nor do they have aspect terms that express neutral opinion.

We only use a subset of the English datasets available. For two reasons. First, the time it takes to write parsers and run the models. Second, we only used datasets that contain three distinct sentiments (Wilson (2008) only has two). From the datasets we have used, we have only had issue with parsing Wang et al. (2017) where the annotations for the first set of the data contains the target span but the second set does not. Thus making it impossible to use the second set of annotation and forcing us to

only use a subset of the dataset. An as example of this: "Got rid of bureaucrats 'and we put that money, into 9000 more doctors and nurses'... to turn the doctors into bureaucrats#BattleForNumber10" in that Tweet 'bureaucrats' was annotated as negative but it does not state if it was the first or second instance of 'bureaucrats' since it does not use target spans. As we can see from table 2, generally the social media datasets (Twitter and YouTube) contain more targets per sentence with the exception of Dong et al. (2014) and Mitchell et al. (2013). The only dataset that has a small difference between the number of unique sentiments per sentence is the Wang et al. (2017) election dataset.

Lastly we create training and test splits for the YouTuBean (Marrese-Taylor et al., 2017) and Mitchell (Mitchell et al., 2013) datasets as they were both evaluated originally using cross validation. These splits are reproducible using the code that we are open sourcing.

Dataset	DO	T	Size	M	ATS	Uniq	AVG Len	S1	S2	S3

Table 2: Dataset Statistics

4 Reproduction studies

In the following subsections, we present the three different methods that we are reproducing and how their results differ from the original analysis. In all of the experiments below, we lower case all text and tokenise using Twokenizer (Gimpel et al., 2011). This was done as the datasets originate from Twitter and this pre-processing method was to some extent stated in Vo and Zhang (2015) and assumed to be used across the others as they do not explicitly state how they pre-process in the papers.

4.1 Reproduction of Vo and Zhang (2015)

Vo and Zhang (2015) created the first NP method for TDSA. It takes the word vectors of the left, right, target word, and full tweet/sentence/text contexts and performs max, min, average, standard deviation, and product pooling over these contexts to create a feature vector as input to the Support Vector Machine (SVM) classifier. This feature vector is in affect an automatic feature extractor. They created four different methods: 1. **Target-ind** uses only the full tweet context, 2. **Target-dep-** uses left, right, and target contexts, 3. **Target-dep** Uses both features of **Target-ind** and **Target-dep-**, and 4. **Target-dep+** Uses the features of **Target-dep** and adds two additional contexts left and right sentiment (LS & RS) contexts where only the words within a specified lexicon are kept and the rest of the words are zero vectors. All of their experiments are performed on Dong et al. (2014) Twitter data set. For each of the experiments below we used the following configurations unless otherwise stated: we performed 5 fold stratified cross validation, features are scaled using Max Min scaling before inputting into the SVM, and used the respective C-Values for the SVM stated in the paper for each of the models.

One major difficulty with the description of the method in the paper and re-implementation is handling the same target multiple appearances issue as originally raised by Wang et al. (2017). As the method requires context with regards to the target word, if there is more than one appearance of the target word then the method does not specify which to use. We therefore took the approach of Wang et al. (2017) and found all of the features for each appearance and performed median pooling over features. This change could explain the subtle differences between the results we report and those of the original paper.

4.1.1 Sentiment Lexicons

Vo and Zhang (2015) used three different sentiment lexicons: MPQA[5] (Wilson et al., 2005), NRC[6] (Mohammad and Turney, 2010), and HL[7] (Hu and Liu, 2004). We found a small difference in word counts between their reported statistics for the MPQA lexicons and those we performed ourselves, as can be seen in the bold numbers in table 3. Originally, we assumed that a word can only occur in one sentiment class within the same lexicon, and this resulted in differing counts for all lexicons. This distinction is not clearly documented in the paper or code. However, our assumption turned out to be incorrect, giving a further illustration of why detailed descriptions and documentation of all decisions is important. We ran the same experiment as Vo and Zhang (2015) to show the effectiveness of sentiment lexicons the results can be seen in table 4. We can clearly see there are some difference not just with the accuracy scores but the rank of the sentiment lexicons. We found just using HL was best and MPQA does help performance compared to the **Target-dep** baseline which differs to Vo and Zhang (2015) findings. Since we found that using just HL performed best, the rest of the results will apply the **Target-dep+** method using HL and using HL & MPQA to show the affect of using the lexicon that both we and Vo and Zhang (2015) found best.

	Word Counts					
	Original		Reproduction			
Lexicons	Positive	Negative	Positive	Positive Lowered	Negative	Negative Lowered
MPQA	2289	4114	**2298**	**2298**	**4148**	**4148**
HL	2003	4780	2003	2003	4780	4780
NRC	2231	3243	2231	2231	3243	3243
MPQA & HL	2706	5069	**2725**	**2725**	**5080**	**5076**
All three	3940	6490	**4016**	**4016**	**6530**	**6526**

Table 3: Sentiment lexicon statistics comparison

	Results (Accuracy %)	
Sentiment Lexicon	Original	Reproduction
Target-dep	65.72	66.81
Target-dep+: NRC	66.05	67.13
Target-dep+: HL	67.24	**68.61**
Target-dep+: MPQA	65.56	66.81
Target-dep+: MPQA & HL	**67.40**	68.37
Target-dep+: All three	67.30	68.23

Table 4: Effectiveness of Sentiment Lexicons

4.1.2 Using different word vectors

The original authors tested their methods using three different word vectors: 1. Word2Vec trained by Vo and Zhang (2015) on 5 million Tweets containing emoticons (W2V), 2. Sentiment Specific Word

[5] http://mpqa.cs.pitt.edu/lexicons/subj_lexicon/
[6] http://saifmohammad.com/WebPages/NRC-Emotion-Lexicon.htm
[7] https://www.cs.uic.edu/~liub/FBS/sentiment-analysis.html#lexicon

Embedding (SSWE) from Tang et al. (2014), and 3. W2V and SSWE combined. Neither of these word embeddings are available from the original authors as Vo and Zhang (2015) never released the embeddings and the link to Tang et al. (2014) embeddings no longer works[8]. However, the embeddings were released through Wang et al. (2017) code base[9] following requesting of the code from Vo and Zhang (2015). Figure 1 shows the results of the different word embeddings across the different methods. The main finding we see is that SSWE by themselves are not as informative as W2V vectors which is different to the findings of Vo and Zhang (2015). However we agree that combining the two vectors is beneficial and that the rank of methods is the same in our observations.

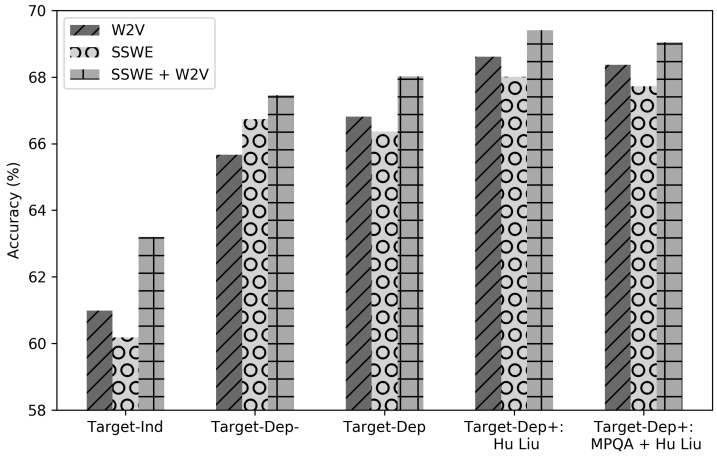

Figure 1: Effectiveness of word embedding

4.1.3 Scaling and Final Model comparison

We test all of the methods on the test data set of Dong et al. (2014) and show the difference between the original and reproduced models in figure 2. Finally, we show the effect of scaling using Max Min and not scaling the data.

As stated before, we have been using Max Min scaling on the NP features, however Vo and Zhang (2015) did not mention scaling in their paper. The library they were using, LibLinear (Fan et al., 2008), suggests in its practical guide (Hsu et al., 2003) to scale each feature to [0, 1] but this was not re-iterated by Vo and Zhang (2015). We are using scikit-learn's (Pedregosa et al., 2011) LinearSVC which is a wrapper of LibLinear, hence making it appropriate to use here. As can be seen in figure 2, not scaling can affect the results by around one-third.

4.2 Reproduction of Wang et al. (2017)

Wang et al. (2017) extended the NP work of Vo and Zhang (2015) and instead of using the full tweet/sentence/text contexts they used the full dependency graph of the target word. Thus, they created three different methods: 1. **TDParse-** uses only the full dependency graph context, 2. **TDParse** the feature of **TDParse-** and the left and right contexts, and 3. **TDParse+** the features of **TDParse** and LS and RS contexts. The experiments are performed on the Dong et al. (2014) and Wang et al. (2017) Twitter datasets where we train and test on the previously specified train and test splits. We also scale our features using Max Min scaling before inputting into the SVM. We used all three sentiment lexicons as in the original paper, and we found the C-Value by performing 5 fold stratified cross validation on the training datasets. The results of these experiments can be seen in figure 3[10]. As found with the results of Vo and Zhang (2015) replication, scaling is very important but is typically overlooked when reporting.

[8] `http://ir.hit.edu.cn/~dytang/`

[9] `https://github.com/bluemonk482/tdparse`

[10] For the Election Twitter dataset TDParse+ result were never reported in the original paper.

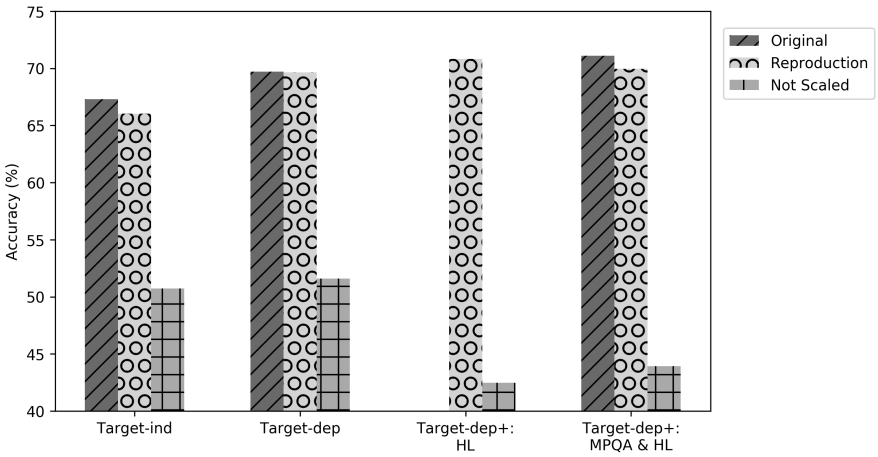

Figure 2: Target Dependent Final Results

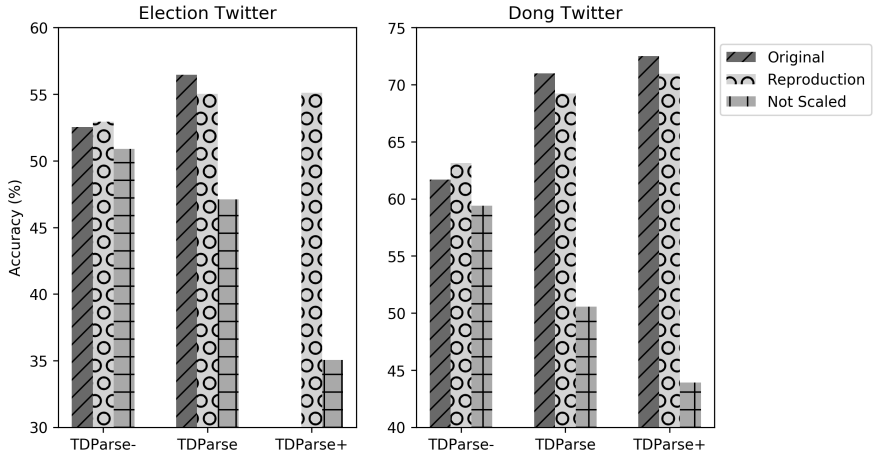

Figure 3: TDParse Final Results

4.3 Reproduction of Tang et al. (2016a)

Tang et al. (2016a) was the first to use LSTMs specifically for TDSA. They created three different models: 1. **LSTM** a standard LSTM that runs over the length of the sentence and takes no target information into account, 2. **TDLSTM** runs two LSTMs, one over the left and the other over the right context of the target word and concatenates the output of the two, and 3. **TCLSTM** same as the **TDLSTM** method but each input word vector is concatenated with vector of the target word. All of the methods outputs are fed into a softmax activation function. The experiments are performed on the Dong et al. (2014) dataset where we train and test on the specified splits. For the LSTMs we initialised the weights using uniform distribution U(0.003, 0.003), used Stochastic Gradient Descent (SGD) a learning rate of 0.01, cross entropy loss, padded and truncated sequence to the length of the maximum sequence in the training dataset as stated in the original paper, and we did not "set the clipping threshold of softmax layer as 200" (Tang et al., 2016a) as we were unsure what this meant. With regards to the number of epochs trained, we used early stopping with a patience of 10 and allowed 300 epochs. Within their experiments they used SSWE (Tang et al., 2014) and Glove Twitter vectors[11] (Pennington et al., 2014).

As the paper being reproduced does not define the number of epochs they trained for, we use early stopping. Thus for early stopping we require to split the training data into train and validation sets to know when to stop. As it has been shown by Reimers and Gurevych (2017) that the random seed statistically significantly changes the results of experiments we ran each model over each word embedding thirty times, using a different seed value but keeping the same stratified train and validation split, and

[11] https://nlp.stanford.edu/projects/glove/

	Macro F1		
Methods	O	R (Max)	R (Mean)
LSTM	64.70	64.34	60.69
TDLSTM	69.00	67.04	65.63
TCLSTM	69.50	67.66	65.23
O=Original, R=Reproduction			

Table 5: LSTM Final Results

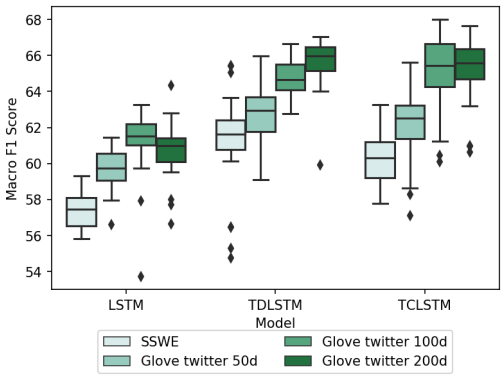

Figure 4: Distribution of the LSTM results

reported the results on the same test data as the original paper. As can be seen in Figure 4, the initial seed value makes a large difference more so for the smaller embeddings. In table 5, we show the difference between our mean and maximum result and the original result for each model using the 200 dimension Glove Twitter vectors. Even though the mean result is quite different from the original the maximum is much closer. Our results generally agree with their results on the ranking of the word vectors and the embeddings.

Overall, we were able to reproduce the results of all three papers. However for the neural network/deep learning approach of Tang et al. (2016a) we agree with Reimers and Gurevych (2017) that reporting multiple runs of the system over different seed values is required as the single performance scores can be misleading, which could explain why previous papers obtained different results to the original for the **TDLSTM** method (Chen et al., 2017; Tay et al., 2017).

5 Mass Evaluation

For all of the methods we pre-processed the text by lower casing and tokenising using Twokenizer (Gimpel et al., 2011), and we used all three sentiment lexicons where applicable. We found the best word vectors from SSWE and the common crawl 42B 300 dimension Glove vectors by five fold stratified cross validation for the NP methods and the highest accuracy on the validation set for the LSTM methods. We chose these word vectors as they have very different sizes (50 and 300), also they have been shown to perform well in different text types; SSWE for social media (Tang et al., 2016a) and Glove for reviews (Chen et al., 2017). To make the experiments quicker and computationally less expensive, we filtered out all words from the word vectors that did not appear in the train and test datasets, and this is equivalent with respect to word coverage as using all words. Finally we only reported results for the LSTM methods with one seed value and not multiple due to time constraints.

The results of the methods using the best found word vectors on the test sets can be seen in table 6. We find that the **TDParse** methods generally perform best but only clearly outperforms the other non-dependency parser methods on the YouTuBean dataset. We hypothesise that this is due to the dataset containing, on average, a deeper constituency tree depth which could be seen as on average more complex sentences. This could be due to it being from the spoken medium compared to the rest of the datasets which are written. Also that using a sentiment lexicon is almost always beneficial, but only by a small amount. Within the LSTM based methods the **TDLSTM** method generally performs the best indicating that the extra target information that the **TCLSTM** method contains is not needed, but we believe this needs further analysis.

We can conclude that the simpler NP models perform well across domain, type and medium and that even without language specific tools and lexicons they are competitive to the more complex LSTM based methods.

Dataset	Target-Dep F1	Target-Dep+ F1	TDParse F1	TDParse+ F1	LSTM F1	TDLSTM F1	TCLSTM F1
Dong Twitter	65.70	65.70	66.00	**68.10**	63.60	66.09	67.14

Table 6: Mass Evaluation Results

6 Discussion and conclusion

The fast developing subfield of TDSA has so far lacked a large-scale comparative mass evaluation of approaches using different models and datasets. In this paper, we address this generalisability limitation and perform the first direct comparison and reproduction of three different approaches for TDSA. While carrying out these reproductions, we have noted and described above, the many emerging issues in previous research related to incomplete descriptions of methods and settings, patchy release of code, and lack of comparative evaluations. This is natural in a developing field, but it is crucial for ongoing development within NLP in general that improved repeatability practices are adopted. The practices adopted in our case studies are to reproduce the methods in open source code, adopt only open data, provide format conversion tools to ingest the different data formats, and describe and document all settings via the code and Jupyter Notebooks (released initially in anonymous form at submission time)[12]. We therefore argue that papers should not consider repeatability (replication or reproduction) or generalisability alone, but these two key tenets of scientific practice should be brought together.

In future work, we aim to extend our reproduction framework further, and extend the comparative evaluation to languages other than English. This will necessitate changes in the framework since we expect that dependency parsers and sentiment lexicons will be unavailable for specific languages. Also we will explore through error analysis in which situations different neural network architectures perform best.

Multilevel Heuristics for Rationale-Based Entity Relation Classification in Sentences

Shiou Tian Hsu, Mandar Chaudhary and Nagiza F. Samatova
North Carolina State University
shsu3@ncsu.edu, mschaudh@ncsu.edu, samatova@csc.ncsu.edu

Abstract

Rationale-based models provide a unique way to provide justifiable results for relation classification models by identifying rationales (key words and phrases that a person can use to justify the relation in the sentence) during the process. However, existing generative networks used to extract rationales come with a trade-off between extracting diversified rationales and achieving good classification results. In this paper, we propose a multilevel heuristic approach to regulate rationale extraction to avoid extracting monotonous rationales without compromising classification performance. In our model, rationale selection is regularized by a semi-supervised process and features from different levels: word, syntax, sentence, and corpus. We evaluate our approach on the SemEval 2010 dataset that includes 19 relation classes and the quality of extracted rationales with our manually-labeled rationales. Experiments show a significant improvement in classification performance and a 20% gain in rationale interpretability compared to state-of-the-art approaches.

1 Introduction

The goal of sentence-level entity relation classification is to infer how two target entities are semantically associated in a sentence. It is a core NLP function that supports many high level tasks such as information extraction and knowledge graph population (Hendrickx et al., 2009; Niu et al., 2012). Recent advances in generative models facilitate improved classification performance along with justifiable results which improves model interpretability. A generative model will first extract the most representative fragments in the sentence that expresses the relation first, and augments the classifier with the rationales (Hsu et al., 2018) . These representative fragments are called rationales as per (Zhang et al., 2016; Lei et al., 2016; Hsu et al., 2018), and can be used to justify the results. We illustrate an example of rationale-based models using an example sentence which expresses a Instrument-Agency(e2,e1) relationship between the given target entities e_1 = "attacker" and e_2 = "instrument":

Rationale based models: *She had struggled violently with her [attacker]*e_1*, who* ***killed*** *her* ***with*** *a blunt [instrument]*e_2.
(words marked in bold and the entities are the major sources to infer the relation)

The most commonly used structure in generative models consists of two components: a Generator and a Discriminator. The Generator extracts rationales from an input sentence in an unsupervised fashion; the Discriminator, which is supervised, predicts the relation class utilizing the rationales. However, training a good Generator can be essentially hard due to the mode collapse problem (Chen et al., 2016; Che et al., 2017; Duhyeon and Hyunjung, 2018). Mode collapse is a commonly observed paradox where the Generator attempts to extract varied rationales, but converges to select monotonous rationales because the Discriminator failed to model diversified rationales. A collapsed Generator is not capable of providing

Proceedings of the 27th International Conference on Computational Linguistics, pages 1145–1155
Santa Fe, New Mexico, USA, August 20-26, 2018.

meaningful rationales since it extracts the same rationales repeatedly regardless of the context. However, as shown in Figure 1, a collapsed Generator does not always lead to poor classification performance when compared to a finely converged Generator.

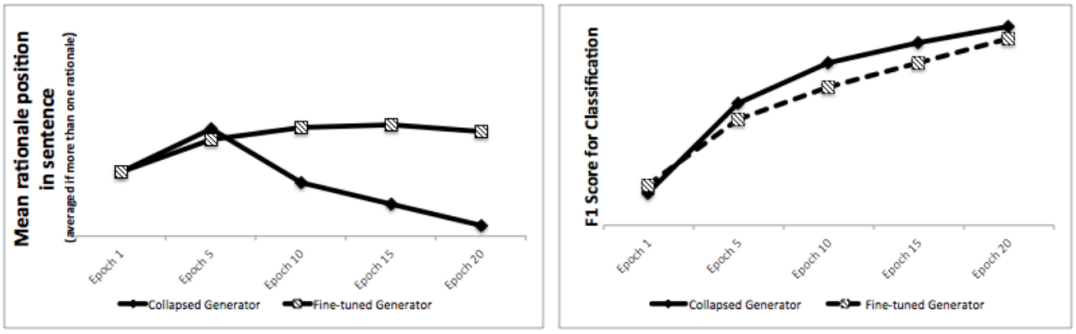

Figure 1: A Generator can converge at collapsed rationales but still lead to good classification results. Figure on the left shows the rationale distribution of a collapsed and a well-converged Generator that uses a recurrent neural net . The well-converged Generator evenly selects rationales from a sentence, while the collapsed Generator selects rationales close to the beginning of the sentence. This is because the best scenario for Discriminator is that some rationales are repetitively selected and optimized in every training iteration, which is difficult for the Generator. Eventually, the Generator learns to exploit position features since it is less diversified than words. Figure on the right shows that a collapsed Generator does not necessarily deteriorate the classification performance.

One of the major causes of mode collapse is the lack of regularizing terms to smooth out the Generator(Chen et al., 2016; Arjovsky and Bottou, 2017; Salimans et al., 2016). In this paper, we aim to improve the rationale-based models for relation classification by introducing semi-supervised capacity and addition regularizing force to the Generator to prevent mode collapsing. In our Generator, we develop a multilevel heuristic to replace the context-focused recurrent neural net used by existing approach(Hsu et al., 2018). Our Generator jointly considers features from different levels of the dataset such as contextual words, target entities, sentence syntax features, rationale-relation closeness, and global word distribution in corpus. The details of our improved Generator are shown in Figure 2.

Our Generator jointly considers several aspects such as contextual words, target entities, word distribution in corpus, sentence grammatical features, and selected rationale-relation closeness to regularize rationale selection.

We evaluate our model on the SemEval 2010 Task 8 dataset which includes 19 relation classes. Specifically, we use F1 score to measure the quality of extracted rationales and the classification performance. Given the absence of ground-truth of rationales in the dataset, we manually label the test set and make it publicly available[1]. We empirically demonstrate an improvement in interpretability of the rationales by 20% compared to Hsu et al. (2018), and also an improvement in the F1 score of 90.7 compared to 89.5 in the state-of-the-art model. We summarize the contributions of our approach as follows:

- We propose a multilevel heuristics approach to avoid mode collapse in rationale-based relation classification models.
- We empirically demonstrate our model produces improved relation classification performance and more interpretable rationales compared to other models
- We provide a labeled set of rationales that can be used for evaluation in future rationale research.

2 Related Work

Research for improving generative neural networks have gained much interest in the research community due to the effectiveness and versatility of these models. These improvements can be divided into two categories: architecture-oriented and divergence-oriented.

[1] https://github.ncsu.edu/shsu3/rationale-improvement

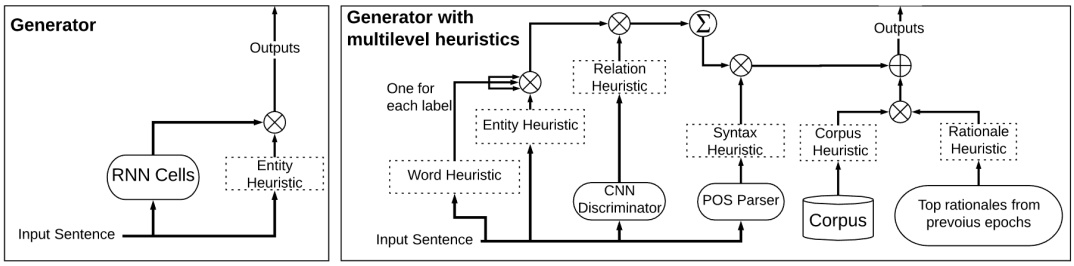

Figure 2: Figure on the left and the right shows the Generator in Hsu et al. (2018) and our proposed multilevel heuristics Generator respectively. The Word heuristic measures the relative closeness of each word in the sentence to every relation class. The Entity heuristic uses the target entities to regulate the Word heuristic. The Relation heuristic contains predictions of the relation from a standalone convolutional neural net model and is also used used to regulate the Word heuristic. The Word heuristic is then summed and weighted by the Syntax heuristic, which considers both, the word distance to entities, and Part-of-Speech labels. The Corpus heuristic is obtained by word-relation distribution in the corpus. The Rationale heuristic is the semi-supervised component which is based on rationales from the previous training iteration.

The Generative Adversarial Network (GAN) (Goodfellow et al., 2014) is the one of most representative model in the architecture-oriented group. Goodfellow et al. (2014) proposed a modified generative model using an adversarial minimax-game formulation. The objective of GAN is to jointly train a Generator and Discriminator, where the loss for Discriminator and the reward for Generator comes from failed attempts to determine ground-truths from the emulated results created by Generator. However, the adversary process in GAN is the major source of mode collapse, hence further extensions of GAN aimed towards addressing this issue. For example, InfoGan (Chen et al., 2016) proposed to maximize the mutual information between a subset of the noise variables with the observations to produce disentangled unsupervised representations. Salimans et al. (2016) proposed to use semi-supervised training and label-smoothing to help GAN converge to Nash Equilibrium between the Generator and the Discriminator. Duhyeon and Hyunjung (2018) proposed RFGAN to implicitly regularize the discriminator using representative features extracted from the data distribution. In VEEGAN (Srivastava et al., 2017), the authors suggested to jointly train an extra Reconstructor with the Generator which is an approximate reverse action of the Generator to encode noise.

Another group of methods have aimed to reduce mode collapse in generative models by modifying the joint loss functions used between the Generator and Discriminator. In Arjovsky et al. (2017), the authors theoretically showed that the KullbackLeibler (KL) divergence often used in GAN was one of the source of instability. Based on this discovery, Arjovsky and Bottou (2017) proposed Wasserstein distance to measure the similarity between the fake and real data to make stabler Generator. Gulrajani et al. (2017) introduce the gradient penalty for regularizing the divergence as an alternative to gradient clipping used in Arjovsky and Bottou (2017) to capture stronger movements in gradients . In DRAGAN (Kodali et al., 2017), they proposed to regulate sharp gradients in the Discriminator, which often happens at some undesired *local equilibria* between Generator and Discriminator. Roth et al. (2017) proposed another type of regularization that breaks down the divergence into different Discriminator output to achieve stability.

We position our work closer to the first category since we can view the multilevel heuristics used in our model close to a combination of models in the first category. The Word and Corpus heuristic are derived from data distribution similar to RFGAN, and the Relation and Rationale heuristic are substantially close to the semi-supervised learning techniques used in Salimans et al. (2016). However, our work is not exclusive to the second category as the Word heuristic included idea close to Roth et al. (2017) where the divergence in the Word heuristic maps to label level in Discriminator instead of treating the Discriminator as a whole.

On a final note, we would like to mention that this work shares some resemblance with (Giuliano et al., 2006) and can be potentially considered as its extension. In Giuliano et al. (2006), the authors utilize several shallow linguistic information for relation classification, such as word-relation frequency or POS to avoid dependent syntactic information. In this work, the fundamental difference is that all token-based computations are replaced by embeddings which are more generalizable when considering words of semantic relatedness. Additionally, the training phase is carried out by the adversarial process.

3 Rationale Generation Framework

We describe the framework for rationale-based approach in the following. Consider an input sentence $\boldsymbol{x} = \{x_t\}_{t=1}^{T}$, where e_1 and e_2 are given target entities of interest and e_1 and $e_2 \subset \{x_1, x_2, ..., x_T\}$. The goal of relation classification is thus to use ($\boldsymbol{x}$,e_1,e_2) to predict the relationship y between e_1 and e_2. We call this prediction process as encoding and denote it as $\boldsymbol{enc}(\boldsymbol{x},e_1,e_2)$.

Following Hsu et al. (2018), we consider this rationale based model as an adversarial problem the goal of the Generator is to generate rationales $\boldsymbol{r}$ that $\boldsymbol{enc}(\boldsymbol{r},\boldsymbol{x},e_1,e_2)$ can outperform all other sets of rationales in $\boldsymbol{enc}(\tilde{\boldsymbol{r}},\boldsymbol{x},e_1,e_2)$. In Hsu et al. (2018), they split the Generator into two steps: the Generator and the Selector. The Generator first generates candidates $\boldsymbol{gen}(\boldsymbol{x},e_1,e_2)$, which samples $\boldsymbol{c} = \{c_t\}_{t=1}^{T}$ from the input where $c_t \in [0, 1]$ and it represents whether x_t should be considered as a rationale ; the Selector then samples rationales $\boldsymbol{r}$ from $\boldsymbol{c}$ and is represented as $\boldsymbol{sel}(\boldsymbol{c},e_1,e_2)$. We illustrate the framework in Figure 3.

A difference against other generative works is worth noting: in Lei et al. (2016), rationales are defined as a sequence of words in a customer review that are directly related to different rating aspects. This is because in Lei et al. (2016), the assumption is that the reviews contain convoluted sentiments, and the goal of a rationale is to disentangle the sentiments. In effect, the goal of $\boldsymbol{r}$ in Lei et al. (2016) is to serve as a proxy of $\boldsymbol{x}$ that makes $\boldsymbol{enc}(\boldsymbol{r})$ approximate to $\boldsymbol{enc}(\boldsymbol{x})$. while our goal is to find $\boldsymbol{r}$ that outperform all possible short enumerations of $\boldsymbol{x}$ in $\boldsymbol{enc}(\boldsymbol{r},\boldsymbol{x},e_1,e_2)$.

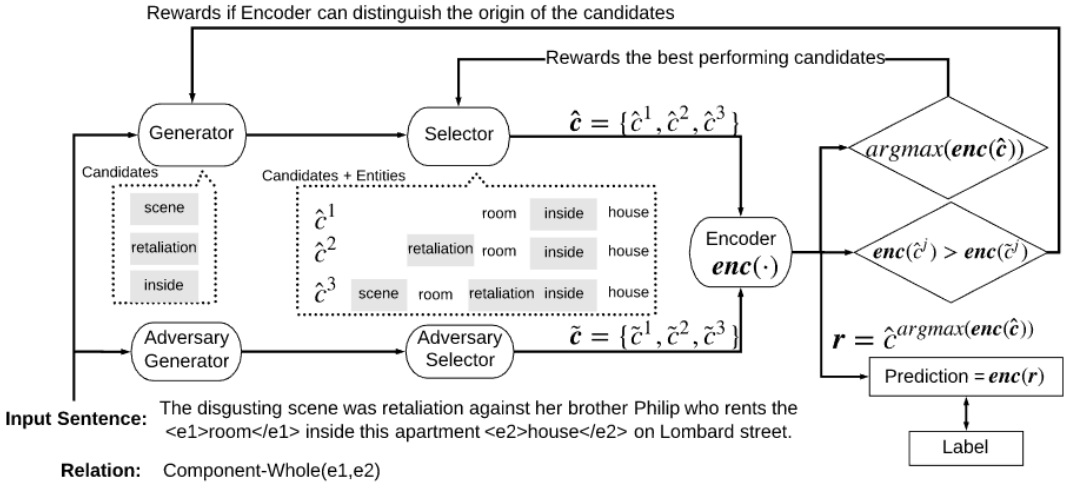

Figure 3: The model structure from Hsu et al. (2018) with a sample input sentence and the given entities. The Generator selects candidate rationales, and the Selector enumerates all possible combinations of candidates with entities and selects one 'best performing candidate set'. An adversary Generator and Selector carry out the same process using a randomized approach. Candidate sets are then transformed into a vector representation by the Encoder and are evaluated against the ground-truth. Rewards are fed back to the Generator if the Encoder is able to identify candidate sets that are generated randomly, while the Selector is rewarded if the best performing rationale candidate set outperforms the one in the adversary. The best performing candidate set from Selector is finally considered as the extracted rationales, and then used in the Encoder to predict entity relation.

4 Model

In this section, we describe each component of the framework. We begin by explaining the Encoder to formalize the goal of relation classification.

4.1 Encoder

Given an input training tuple ($\boldsymbol{x}$,e_1,e_2,y), where $\boldsymbol{x}$ = $\{x_t\}_{t=1}^{T}$, and y is the one-hot L dimensional vector representing the relation class. The goal of the Encoder $\boldsymbol{enc}(\boldsymbol{r},\boldsymbol{x},e_1,e_2)$ is to produce a probability distribution $\hat{y}$ that approximates to y as formulated as follows (N is the size of the training set):

$$loss = \sum_{i=1}^{|N|} -y_i \cdot log(\hat{y}_i) \tag{1}$$

The Encoder produces $\hat{y}$ by encoding ($\boldsymbol{r}$,$\boldsymbol{x}$,e_1,e_2) as a vector representation and then projects it to the y space. This vector representation can further break down to a sentence vector V_x and a rationale vector V_r. We produce V_x through CNN using the same model as Kim (2014) which encodes the sentence through a continuous window approach, where K are the set of sizes for the windows. To produce V_r, we implement a RNN model using GRU cells that reads the rationales and target entities. Since RNN is order sensitive, the rationales and the entities are sorted based on their position in the sentence before applying the RNN model.

$$\begin{aligned} V_x &= CNN(\boldsymbol{x}) & \hat{y} &= \boldsymbol{enc}(\boldsymbol{r}, \boldsymbol{x}, e_1, e_2) \\ V_r &= RNN([\boldsymbol{r}, e_1, e_2]) & &= softmax(W_{enc} \cdot [V_r, V_x, e_1, e_2] + b_{enc}) \end{aligned} \tag{2}$$

4.2 Generator

The goal of the Generator $\boldsymbol{gen}(\boldsymbol{x})$ is to derive a set of binary variables $\boldsymbol{c} = \{c_t\}_{t=1}^{T}$ by sampling from probability scores $\boldsymbol{s} = \{s_t\}_{s=1}^{T}$, where $c_t \in [0, 1]$ indicates whether x_t is chosen as a candidate rationale and s_t is computed by the multilevel heuristics. We represent it as $\boldsymbol{c} \sim \boldsymbol{gen}(\boldsymbol{x})$.

In contrast to Hsu et al. (2018) which uses an RNN model for Generator, we adopted a set of logistic regression models with several feed-forward networks to facilitate the Generator. The reason being, an RNN model can be difficult to train and might be susceptible to mode collapse if not carefully tuned. In the Generator, the number of logistic regression models is equal to L which is the number of classes in y. Each word in the sentence is first moderated by the Entity heuristic he, which is obtained from the target entities and fed through the logistic regression models to obtain the Word heuristic $hw = \{\{hw_t^l\}_{l=1}^{L}\}_{t=1}^{T}$. Each hw_t^l can be considered as a probability of x_t being chosen as a rationale if the given sentence is of relation class l. The second step is to compute the Relation heuristic $hr = \{hr^l\}_{l=1}^{L}$ and the Syntax heuristic hs_t that are applied to the Word heuristic. The Relation heuristic initializes the relation with a random guess using the whole sentence. The heuristic is then trained through a CNN model which similar to the CNN model we used to compute Vx. The Syntax heuristic hs_t is obtained from a feed forward neural network that takes as input (1) word distance to target entities, and (2) Part of Speech (POS) tags. The output, s_t^{local}, is obtained by combining the Word, Entity, Syntax and Relation heuristics, and it represents local sentence information score.

The final score s_t is then computed by applying the Corpus and Rationale heuristics to s_t^{local}. The Corpus heuristic $hc = \{hc^l\}_{l=1}^{L}$ contains binary values computed by sorting and selecting the frequent K words in each relation class in the training set. The Rationale heuristic $hra = \{hra^l\}_{l=1}^{L}$ also contains binary values which are based on taking the top portion of the Word heuristic for each relation class, but the Word heuristic considered here is not moderated by entities when computing the Rationale heuristic. The Corpus and Rationale heuristics capture the association between the words and relations are in the dataset. To leverage this information, we construct a global heuristic, s_t^{global}, by computing an element-wise multiplication of hc and hra. Note that s_t^{global} can be seen as a self-learning resource for semi-supervised learning because the Rationale heuristic is based on the results from previous iterations.

Accordingly, s_t^{global} will not be used in testing and will only be included after several training iterations have completed. Finally, before applying s_t^{global} to the final score s_t we apply a dynamically computed weight factor CR to $s_t^{local}$and s_t^{global}. We formulate all the heuristics in the following equation,

$$
\begin{aligned}
&he = sigmoid(W_{he} \cdot [e1, e2] + b_h e) \\
&hw_t = sigmoid(W_{hw} \cdot (x_t \odot he) + b_h e) \\
&hr = CNN(\boldsymbol{x}) \\
&hs_t = sigmoid(W_{hs} \cdot [POS_t, position_t]) \\
&CR = sigomid(W_{CR} \cdot hr' + b_{CR})
\end{aligned}
\qquad
\begin{aligned}
&s_t^{local} = hw_t \cdot \mathcal{T}(hr) \cdot hs \\
&\quad (\mathcal{T} \text{stands for transpose function}) \\
&s_t^{global} = hc \odot hra \\
&s_t = s_t \cdot (1 - CR) + s_t^{global} CR
\end{aligned}
\tag{3}
$$

In the most simplistic Generator, the probability that x_t is chosen is conditionally independent of all other $\boldsymbol{x}$. In other words, we can sample candidate $\boldsymbol{c}$ from a uniform distribution using the probability scores, $\boldsymbol{s}$. However, we observe that the target rationales in the dataset often consist of few words - for example "*room **inside** apartment*". Therefore, we added the following Equation (4) to limit the number of rationales selected, $\boldsymbol{c}$, to be at most J.

$$
\begin{aligned}
&c_t = \begin{cases} 1, sort(\{(s_t > rand(0,1)) \cdot s_t\}_{t=1}^{T})[1:J] \\ 0, otherwise \end{cases} \\
&\boldsymbol{c} = \{c_t\}_{t=1}^{T}
\end{aligned}
\tag{4}
$$

4.3 Selector

The last component of the model is the Selector $\boldsymbol{sel}(\boldsymbol{c})$, where the goal of the Selector is to decide the number of rationales best suited for the prediction. The Selector is facilitated by a simple feed-forward network that outputs a number from $1 \sim J$ by scoring rationale sets of length ranging from $1 \sim J$ based on the top ranked $s_t * c_t$. During training, all rationale sets will be forwarded to the Encoder, and the training label for Selector will be the size of the set that obtains the least training loss in Encoder. This Selector is identical to the one in Hsu et al. (2018) and is defined as follows:

$$
\begin{aligned}
&\hat{c}_t^j = \begin{cases} 1, sort(\{c_t \cdot s_t\}_{t=1}^{T})[1:j], j \in [1:J] \\ 0, otherwise \end{cases} \\
&\hat{\boldsymbol{c}}^{\boldsymbol{j}} = \{\hat{c}_t^j\}_{t=1}^{T}, \text{where } \hat{c}_t^j = 1 \\
&score(\hat{\boldsymbol{c}}^{\boldsymbol{j}}) = W_c \cdot \boldsymbol{enc}(\hat{\boldsymbol{c}}^{\boldsymbol{j}}, \boldsymbol{x}, e1, e2)
\end{aligned}
\qquad
\begin{aligned}
&scores^j = softmax(\{score(\hat{\boldsymbol{c}}^{\boldsymbol{j}})\}_{j=1}^{J})^j \\
&\hat{scores}^j = \begin{cases} 1 & , j = argmax(scores) \\ 0 & , otherwise \end{cases} \\
&\boldsymbol{r} = \{x_t\}, \text{where } \hat{c}_t^j = 1,\ j = argmax(scores)
\end{aligned}
\tag{5}
$$

4.4 Joint Objective and Adversarial Training

We formulate the joint loss function in the following to bind the components.

As described earlier, the goal of the Generator and the Selector is not to emulate $\boldsymbol{x}$ with $\boldsymbol{r}$ due to the nature of this research. In effect, the Generator and the Selector are not competing against the Encoder, but instead with an adversary Generator, for which we use a randomized approach. The adversary Generator will sample $\tilde{\boldsymbol{c}}$ randomly from $\boldsymbol{x}$. The adversary rationales $\tilde{\boldsymbol{r}}$ will then be selected using $\tilde{\boldsymbol{c}}$ as per Equation (4). $\tilde{\boldsymbol{r}}$ will be passed to the Encoder to generate a projection $\tilde{y}$ onto the target dimension. We compare $\tilde{y}$ with $\hat{y}$ in terms of their similarity to y and is denoted by $\mathcal{D} \in \{0, 1\}$. $\mathcal{D} = 1$ when $\hat{y}$ is closer to y compared to $\tilde{y}$, and is noted as a 'model success case', meanwhile $1 - \mathcal{D} = 1$ for the opposite situation and is noted as an 'adversary success case'. The objective for the Generator and Encoder reacts differently to the two different cases, where the Encoder optimize whichever rationales that performs better, and the Generator rewards the selected rationales in model success case and penalize in the other case. We further split $\hat{y}$, $\tilde{y}$ and $\mathcal{D}$ into $\hat{y}^j$, $\tilde{y}^j$, $\mathcal{D}^j$ and $j \in [1:J]$, where $\mathcal{D}^j$ represents that $\hat{y}^j$ outperforms $\tilde{y}^j$ when using j rationales. Finally, we introduce a penalizing factor P^j when $j \neq argmax(scores)$ to penalize the gradients from poor performing cases. We summarize as follows:

$$
\begin{aligned}
f(s_t^{'jl}) &= -log(s_t^{'jl}) \cdot c_t^j \cdot y_i + \\
&\quad - log(1 - s_t^{'jl}) \cdot c_t^j \cdot (1 - y_i) \\
f(c_t^j) &= -log(s_t) \cdot c_t^j - log(1 - s_t) \cdot (1 - c_t^j) \\
f_y(\hat{y}_i^j) &= -y_i \cdot log(\hat{y}_i^j)
\end{aligned}
$$

$$
\begin{aligned}
\mathcal{L}_{enc} &= \sum_{j=1}^{J} P^j \left[\mathcal{D}^j f_y(\hat{y}^j) + (1 - \mathcal{D}^j) f_y(\tilde{y}^j) \right] \\
\mathcal{L}_{sel} &= \sum_{j=1}^{J} -\mathcal{D}^j * \hat{scores}^j * log(scores^j) \\
\mathcal{L}_{gen} &= \sum_{j=1}^{J} \sum_{t=1}^{T} \left[\mathcal{D}^j f(\hat{c}_t^j) - (1 - \mathcal{D}^j) f(\tilde{c}_t^j) \right] + \\
&\quad \sum_{j=1}^{J} \sum_{t=1}^{T} \sum_{l=1}^{L} \left[\mathcal{D}^j f(\hat{s}_t^{jl}) - (1 - \mathcal{D}^j) f(\tilde{s}_t^{jl}) \right]
\end{aligned}
\tag{6}
$$

The final joint objective and the expected cost is defined as:

$$
\mathcal{L}(\boldsymbol{r}, \boldsymbol{x}, e_1, e_2, y) = \mathcal{L}_{gen} + \mathcal{L}_{sel} + \mathcal{L}_{enc}
$$

$$
\min_{\theta e \theta g \theta s} \sum_{(\boldsymbol{x}, e_1, e_2, y) \in N} \mathbb{E}_{\boldsymbol{r} \sim sel(\boldsymbol{c}), \boldsymbol{c} \sim gen(\boldsymbol{x})} \mathcal{L}(\boldsymbol{r}, \boldsymbol{x}, e_1, e_2, y) \tag{7}
$$

where θe, θg, θs are the parameters used in the Encoder, Generator and Selector respectively.

5 Experiments

5.1 Dataset

We evaluate our approach by performing experiments on the SemEval 2010 Task 8 dataset. A collection of sentences is provided with marked target entities and ground-truth for the relation between the entities.

The dataset contains 10,717 sentences, where 8000 entries are used in training. There are 9 types of relationships plus an "Other" class (Table 1). Relationship types (except for "Other") are expressed bi-directionally, making 19 classes in total. Following SemEval 2010's protocol, we used the macro-F1 metric in the experiment, excluding all cases of the "Other" class.

Besides the original SemEval 2010 Task 8 data, we asked 3 human annotators to label rationales used in the test set. Annotators were asked to choose 0-3 rationales for each test sentence based on their intuition. Each annotator is asked to roughly annotate one-third of the test set. Distribution of rationales are as follows: no-rationales:2%, 1-rationale:57%, 2-rationales:38% and 3-rationales:2%. Note that we did not annotated the training set.

Cause-Effect	Component-Whole	Content-Container
Entity-Destination	Entity-Origin	Instrument-Agency
Member-Collection	Message-Topic	Product-Producer

Table 1: Relation classes in SemEval 2010 task 8

5.2 Experimental Setup

We now describe in detail the parameters used in our experiments. We initialize the word vectors with the GoogleNews[2] corpus. The CNN filter size was initialized to 50. We use at most 3 rationales and set the penalizing factor P_j to 0.1 based on our analysis of the training set. Due to the lack of sufficient samples in certain relation classes, we ignored the relationship directionality while computing the Relation heuristic. Finally, the dimensionality of the POS tag vectors and the position vectors is set to 25, and the Generator is set to ignore nouns, articles and adjectives.

[2]https://code.google.com/p/word2vec

Finally, after training for 10 iterations, the Generator includes the output from the Corpus and Rationale heuristics. The K frequently used words in the Corpus heuristic are computed for each relation class, where the threshold for K_l is 10% of number of sentences of the given l relation class. The Rationale heuristic selects the top 25% of words, hw^l, output by the Word heuristic.

We used the Adagrad optimizer in our experiments and the learning rate is initialized to 0.01, and reduces by 10% after every iteration. During each training iteration, we sample 25 times from the Generator, and re-sample 25 times when training the Selector and the Encoder.

5.3 Results

We present a comparison of relation classification between our model and the state-of-the-art models in Table 2. Dependency tree models are neural network models that work with word dependency tree parsed by a grammar parser. Each model utilizes the dependency tree differently. For instance MVRNN (Socher et al., 2012) uses the whole dependency tree, while SPTree (Miwa and Bansal, 2016) experiments using the entire tree and the nodes on the path that connect the target entities. We refer to the models that do not use a dependency tree as independent models.

Classifier	**F1**
Manually Engineered Models	
SVM(Rink and Harabagiu, 2010)	82.2
Dependency Tree Models	
RNN (Socher et al., 2012)	77.6
MVRNN (Socher et al., 2012)	82.4

6 Discussion and Future Goals

6.1 Logistic Regressions and RNN

The major difference between this work and the previous rationale-based research is that we designed the Generator without a sequential RNN model. Specifically, we developed a layer by layer process that considers different levels of text information for three reasons. First, in relation classification, the excess sequential modeling power from RNN is not required since rationales are often an extremely small span of words. Also, rationales are often strongly-related to POS tags which can be used to replace the sequence information. Second, the purpose of rationales in relation classification is to augment features and illuminate how the model derives the answer. This is different from other tasks like aspect-level sentiment classification in Lei et al. (2016) where the rationales are treated as a compression of the input. Although more empirical experiments are required, we hypothesize that this simpler multilevel heuristic approach suits better for tasks with simpler rationales. Finally, dropping RNN can help the model parallelize and also less prone to mode collapse and gradient vanishing.

6.2 Axillary Information

The improvement in rationale interpretability comes from regularizing the Generator through a wide set of knowledge sources, like the Relation, the Corpus and the Rationale heuristic, and we believe this can be further improved by including more knowledge sources. For example, the Entity heuristic can be improved by annotating entities through a large open source data such Wikipedia, or the Corpus heuristic can be more diverse with distant supervision tricks. However, the amount of axillary information to include and to what degree is a challenge in itself.

Another major difference is that the Generator is directly related to the relation-labels through the Relation and Word heuristics, which is different from Hsu et al. (2018) where the Generator is not aware of the ground-truth. This can be a potential challenge when the diversity of relation vastly increases. To be more specific, the number of relations in some knowledge graph population tasks can be more than a few thousands, which can lead to severe label imbalance issues. Also, we notice several relation classes share the same rationales, like 'of' is commonly seen in Member-Collection and Component-

Whole relations. This can be unfavorable for the Word heuristic since our approach assumes rationales are more heterogeneous than homogeneous between different relations. A potential solution is to cluster or introduce hierarchical structures to the relations thereby reducing diversity.

6.3 Potential Applications: Noise-Reduction in Distant Supervision

A potential application of this work, besides classifying relations and providing interpretable results, is to help reduce noise in distant supervision for relation classification. Distant supervision is a commonly used approach in relation classification where producing ground-truth data is expensive. Distant supervision exploits a simple assumption: if a sentence s contains an entity-relation pair $(e1, relation, e2)$ that exists in a trustworthy knowledge source, then s can be a training data for the $relation$. As a result, distant supervision often contains many noisy false-negative training samples and degrades the result. To reduce the noise, one can penalize sentences that do not contain commonly used rationales for the relation.

7 Conclusion

In this paper, we have proposed an improved rationale-based model for entity relation classification. In our model, besides context word information, we also moderate rationale generation with multiple heuristics computed from different text level features. With multilevel heuristics, we successfully reduce the variability in the Generator to achieve meaningful rationales. Quantitative analysis demonstrates that our model improves both classification performance and the rationale quality. Finally, we provide an annotated test set for rationales, which can be used in future related research to evaluate rationales.

Acknowledgments

We thank the COLING reviewers for their detailed and insightful feedback, and also thank the annotators for their intensive efforts for developing the annotated set. Abstract

Multi-lingual relation extraction aims to find unknown relational facts from text in various languages. Existing models cannot well capture the consistency and diversity of relation patterns in different languages. To address these issues, we propose an adversarial multi-lingual neural relation extraction (AMNRE) model, which builds both consistent and individual representations for each sentence to consider the consistency and diversity among languages. Further, we adopt an adversarial training strategy to ensure those consistent sentence representations could effectively extract the language-consistent relation patterns. The experimental results on real-world datasets demonstrate that our AMNRE model significantly outperforms the state-of-the-art models. The source code of this paper can be obtained from `https://github.com/thunlp/AMNRE`.

1 Introduction

Relation extraction (RE) is a crucial task in NLP, which aims to extract semantic relations between entity pairs from the sentences containing them. For example, given an entity pair (*Bill Gates*, *Microsoft*) and a sentence "*Bill Gates* is the co-founder and CEO of *Microsoft*", we want to figure out the relation `Founder` between the two entities. RE can potentially benefit many applications, such as knowledge base construction (Zhong et al., 2015; Han et al., 2018) and question answering (Xiang et al., 2017).

Recently, neural models have shown their great abilities in RE. Zeng et al. (2014) introduce a convolutional neural network (CNN) to extract relational facts with automatically learning features from text. To address the issue of lack of data, Zeng et al. (2015) incorporate multi-instance learning with a piece-wise convolutional neural network (PCNN) to extract relations in distantly supervised data. Because distant supervision suffer from wrong labeling problems, Lin et al. (2016) further employ a sentence-level selective attention to filter out those noisy sentences in distantly supervised data and achieve state-of-the-art performance. All these neural relation extraction (NRE) models merely focus on extracting relational facts from mono-lingual data, ignoring the rich information in multi-lingual data.

Lin et al. (2017) propose a multi-lingual attention-based neural relation extraction (MNRE) model, which considers the consistency and complementarity in multi-lingual data. MNRE builds a sentence representation for each sentence in various languages and employs a multi-lingual attention to capture the pattern consistency and complementarity among languages.

Although MNRE achieves great success in multi-lingual RE, it still has some problems. MNRE learns a single representation for each sentence in various languages, which cannot well capture both the consistency and diversity of relation patterns in different languages. Moreover, MNRE simply utilizes a multi-lingual attention mechanism and a global relation predictor to capture the consistent relation patterns among multiple languages. From the experimental data, we find that the sentence representations in different languages are still far from each other and linearly separable. Therefore, it is hard for the multi-

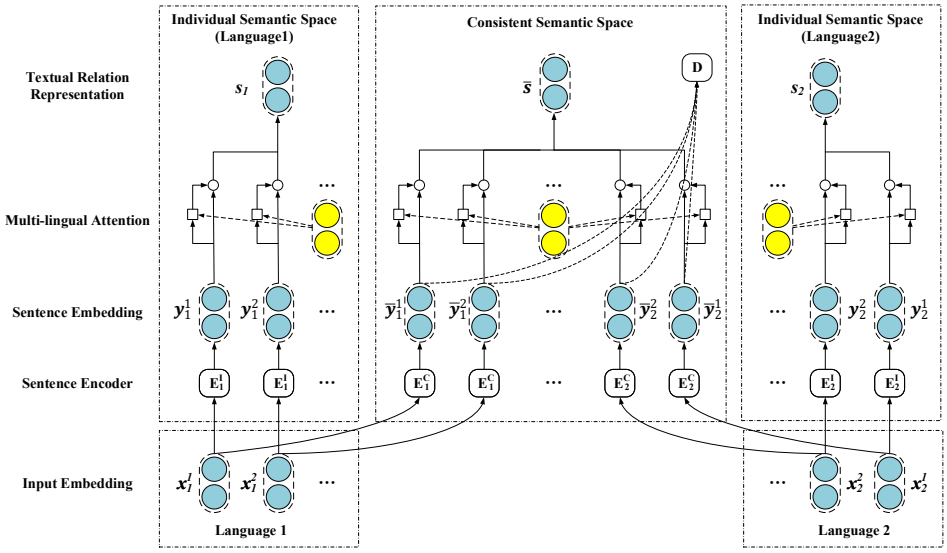

Figure 1: Overall architecture of our adversarial multi-lingual neural relation extraction (AMNRE) which contains two languages.

lingual attention mechanism and global relation predictor to extract relation consistency from distinct sentence representations.

To address these issues, we propose an adversarial multi-lingual NRE (AMNRE) model. As shown in Figure 1, for an entity pair, we encode its corresponding sentences in various languages through neural sentence encoders. For each sentence, we build an individual representation to grasp its individual language features and a consistent representation to encode its substantially consistent features among languages. Further, we adopt an adversarial training strategy to ensure AMNRE can extract the language-consistent relation patterns from the consistent representations. Orthogonality constraints are also adopted to enhance differences between individual representations and consistent representations for each language.

In experiments, we take Chinese and English to show the effectiveness of AMNRE. The experimental results show that AMNRE outperforms all baseline models significantly by explicitly encoding the consistency and diversity among languages. And we further give a case study and an ablation study to demonstrate the adversarial training strategy could help AMNRE to capture language-consistent relation patterns.

2 Related Works

2.1 Relation Extraction

Traditional supervised RE models (Zelenko et al., 2003; Socher et al., 2012; Santos et al., 2015) heavily rely on abundant amounts of high-quality annotated data. Hence, Mintz et al. (2009) propose a distantly supervised model for RE. Distant supervision aligns knowledge bases (KBs) and text to automatically annotate data, and thus distantly supervised models inevitably suffer from wrong labeling problems.

To alleviate the noise issue, Riedel et al. (2010) and Hoffmann et al. (2011) propose multi-instance learning (MIL) mechanisms for single-label and multi-label problems respectively. Then, Zeng et al. (2015) attempt to integrate neural models into distant supervision. Lin et al. (2016) further propose a sentence-level attention to jointly consider all sentences containing same entity pairs for RE. The attention-based neural relation extraction (NRE) model has become a foundation for some recent works (Ji et al., 2017; Zeng et al., 2017; Liu et al., 2017b; Wu et al., 2017; Feng et al., 2018; Zeng et al., 2018).

Most existing RE models are devoted to extracting relations from mono-lingual data and ignore information lying in text of multiple languages. Faruqui and Kumar (2015) and Verga et al. (2016) first attempt to adopt multi-lingual transfer learning for RE. However, both of these works learn predictive

models on a new language for existing KBs, without fully leveraging semantic information in text. Then, Lin et al. (2017) construct a multi-lingual NRE (MNRE) model to jointly represent text of multiple languages to enhance RE. In this paper, we propose a novel multi-lingual NRE framework to explicitly encode language consistency and diversity into different semantic spaces, which can achieve more effective representations for RE.

2.2 Adversarial Training

Goodfellow et al. (2015) propose adversarial training for image classification tasks. Afterwards, Goodfellow et al. (2014) propose a mature adversarial training framework and use the framework to train generative models. Adversarial networks have recently been used as methods to narrow probability distributions and proven effective in some tasks. In domain adaptation, Ganin et al. (2016) and Bousmalis et al. (2016) adopt adverarial training strategies to transfer the features of one source domain to its corresponding target domain.

Inspired by Ganin et al. (2016), adversarial training has also been explored in some typical NLP tasks for multi-feature fusion. Park and Im (2016) propose a multi-modal representation learning model based on adversarial training. Then, Liu et al. (2017a) employ adversarial training to construct a multi-task learning model for text classification by extending the original binary adversarial training to the multi-class version. And a similar adversarial framework is also adapted by Chen et al. (2017) to learn features from different datasets for chinese word segmentation. In this paper, we adopt adversarial training to boost feature fusion to grasp the consistency among different languages.

3 Methodology

In this section, we introduce the overall framework of our proposed AMNRE in detail. As shown in Figure 1, for each entity pair, AMNRE encodes its corresponding sentences in different languages into several semantic spaces to grasp their individual language patterns. Meanwhile, a unified space is also set up to encode consistent features among languages. By explicitly encoding the consistency and diversity among languages, AMNRE can achieve better extraction results in the multi-lingual scenario.

For each given entity pair, we define its corresponding sentences in n different languages as $\mathcal{T} = \{\mathcal{S}_1, \ldots, \mathcal{S}_n\}$, where $\mathcal{S}_j = \{x_j^1, \ldots, x_j^{|\mathcal{S}_j|}\}$ denotes the sentence set in the j-th language. All these sentences are labeled with the relation $r \in \mathcal{R}$ by heuristical labeling algorithms in distant supervision (Mintz et al., 2009). Our model aims to learn a relation extractor by maximizing the conditional probability $p(r|\mathcal{T})$ with the following three components:

Sentence Encoder. Given a sentence and its target entity pair, we employ neural networks to encode the sentence into a embedding. In this paper, we implement the sentence encoder with both convolutional (CNN) and recurrent (RNN) architectures. Specifically, we set the encoders E_j^I and E_j^C to encode each sentence in the j-th language into its individual and consistent embeddings respectively, and expect these embeddings to capture the diversity and consistency among languages.

Multi-lingual Attention. Since not all sentences are labeled correctly in distant supervision, we adopt multi-lingual attention mechanisms to capture those informative sentences. In practice, we apply language-individual and language-consistent attentions to compute local and global textual relation representations respectively for final prediction.

Adversarial Training. Under the framework of AMNRE, we encode the sentences in various languages into a unified consistent semantic space. We further adopt adversarial training to ensure these sentences are well fused in the unified space after encoding so that our model can effectively extract the language-consistent relation patterns.

We will introduce the three components in detail as follows.

3.1 Sentence Encoder

Given a sentence $x = \{w_1, w_2, \ldots\}$ containing two entities, we apply neural architectures including both CNN and RNN to encode the sentence into a continuous low-dimensional space to capture its implicit semantics.

3.1.1 Input Layer

The input layer transforms all input words in the sentence into corresponding input embeddings by concatenating their word embeddings and position embeddings. The word embeddings are pre-trained by Skip-Gram (Mikolov et al., 2013). The position embeddings are a widely-used technique in RE proposed by Zeng et al. (2014), representing each word's relative distances to the two entities into two k_p-dimensional vectors. The input layer represents the input sentence as a k_i-dimensional embedding sequence $\mathbf{x} = \{\mathbf{w}_1, \mathbf{w}_2, \ldots\}$, where $k_i = k_w + k_p \times 2$, k_w and k_p are the dimensions of word embeddings and position embeddings respectively.

3.1.2 Encoding Layer

After representing the input sentence as a k_i-dimensional embedding sequence, we select both CNN (Zeng et al., 2014) and RNN (Zhang and Wang, 2015) to encode the input embedding sequence $\mathbf{x} = \{\mathbf{w}_1, \mathbf{w}_2, \ldots\}$ to its sentence embedding.

CNN slides a convolution kernel with the window size m to extract the k_h-dimensional local features,

$$\mathbf{h}_i = \text{CNN}\big(\mathbf{w}_{i-\frac{m-1}{2}}, \ldots, \mathbf{w}_{i+\frac{m-1}{2}}\big). \tag{1}$$

A max-pooling is then adopted to obtain the final sentence embedding $\mathbf{y}$ as follows,

$$[\mathbf{y}]_j = \max\{[\mathbf{h}_1]_j, \ldots, [\mathbf{h}_n]_j\}. \tag{2}$$

RNN is mainly designed for modeling sequential data. In this paper, we adopt bidirectional RNN (Bi-RNN) to incorporate information from both sides of the sentence sequence as follows,

$$\overrightarrow{\mathbf{h}}_i = \text{RNN}_f(\mathbf{x}_i, \overrightarrow{\mathbf{h}}_{i-1}), \quad \overleftarrow{\mathbf{h}}_i = \text{RNN}_b(\mathbf{x}_i, \overleftarrow{\mathbf{h}}_{i+1}), \tag{3}$$

where $\overrightarrow{\mathbf{h}}_i$ and $\overleftarrow{\mathbf{h}}_i$ are the k_h-dimensional hidden states at the position i of the forward and backward RNN respectively. $\text{RNN}(\cdot)$ is the recurrent unit and we select gated recurrent unit (GRU) (Cho et al., 2014) as the recurrent unit in this paper. We concatenate both the forward and backward hidden states as the sentence embedding $\mathbf{y}$,

$$\mathbf{y} = [\overrightarrow{\mathbf{h}}_n; \overleftarrow{\mathbf{h}}_1]. \tag{4}$$

For simplicity, we denote such a sentence encoding operation as the following equation,

$$\mathbf{y} = \text{E}(x). \tag{5}$$

For each sentence $x_j^i \in \mathcal{S}_j$, we adopt the individual sentence encoder E_j^I and the consistent sentence encoder E_j^C to embed the sentence into its individual and consistent representations respectively,

$$\{\mathbf{y}_j^1, \mathbf{y}_j^2, \ldots\} = \{\text{E}_j^I(x_j^1), \text{E}_j^I(x_j^2), \ldots\}, \quad \{\bar{\mathbf{y}}_j^1, \bar{\mathbf{y}}_j^2, \ldots\} = \{\text{E}_j^C(x_j^1), \text{E}_j^C(x_j^2), \ldots\}. \tag{6}$$

3.2 Multi-lingual Selective Attention

For each given entity pair, AMNRE adopts multi-lingual selective attention mechanisms to exploit informative sentences in $\mathcal{T}$. We explicitly encode languages' consistency and diversity into individual and consistent representations, thus our attentions are more simple than those proposed in Lin et al. (2017).

3.2.1 Language-individual Attention

Since it is intuitive that each language has its own characteristic, we set language-individual attention mechanisms for different languages. In the individual semantic space of the j-th language, we assign a query vector $\mathbf{r}_j$ to each relation $r \in \mathcal{R}$. The attention score for each sentence in $\mathcal{S}_j = \{x_j^1, x_j^2, \ldots\}$ is defined as follows,

$$\alpha_j^i = \frac{\exp(\mathbf{r}_j^\top \mathbf{y}_j^i)}{\sum_{k=1}^{|\mathcal{S}_j|} \exp(\mathbf{r}_j^\top \mathbf{y}_j^k)}. \tag{7}$$

The attention scores can be used to compute language-individual textual relation representations,

$$\mathbf{s}_j = \sum_{k=1}^{|\mathcal{S}_j|} \alpha_j^k \mathbf{y}_j^k. \tag{8}$$

3.2.2 Language-consistent Attention

Besides language-individual attention mechanisms, we also adopt a language-consistent attention to take all sentences in all languages into consideration. In the consistent semantic space, we also assign a query vector $\bar{\mathbf{r}}$ to each relation $r \in \mathcal{R}$ and the attention score for each sentence is defined as follows,

$$\beta_j^i = \frac{\exp(\bar{\mathbf{r}}^\top \bar{\mathbf{y}}_j^i)}{\sum_{l=1}^{n} \sum_{k=1}^{|\mathcal{S}_l|} \exp(\bar{\mathbf{r}}^\top \bar{\mathbf{y}}_l^k)}. \tag{9}$$

The attention scores can be used to compute language-consistent textual relation representations,

$$\bar{\mathbf{s}} = \sum_{l=1}^{n} \sum_{k=1}^{|\mathcal{S}_l|} \beta_l^k \bar{\mathbf{y}}_l^k. \tag{10}$$

3.3 Relation Prediction

With the language-individual textual relation representations $\{\mathbf{s}_1, \mathbf{s}_2, \ldots\}$ and the language-consistent textual relation representation $\bar{\mathbf{s}}$, we can estimate the probability $p(r|\mathcal{T})$ over each relation $r \in \mathcal{R}$,

$$p(r|\mathcal{T}) = p(r|\bar{\mathbf{s}}) \prod_{j=1}^{n} p(r|\mathbf{s}_j). \tag{11}$$

$p(r|\bar{\mathbf{s}})$ and $p(r|\mathbf{s}_j)$ can be defined as follows,

$$p(r|\mathbf{s}_j) = \text{softmax}[\mathbf{R}_j \mathbf{s}_j + \mathbf{d}_j], \quad p(r|\bar{\mathbf{s}}) = \text{softmax}[\bar{\mathbf{R}}\bar{\mathbf{s}} + \bar{\mathbf{d}}], \tag{12}$$

where $\mathbf{d}_j$ and $\bar{\mathbf{d}}$ are bias vectors, $\mathbf{R}_j$ is the specific relation matrix of the j-th language, and $\bar{\mathbf{R}}$ is the consistent relation matrix. We define the objective function to train the relation extractor as follows,

$$\min_{\theta} \mathcal{L}_{nre}(\theta) = -\sum_{l} \log p(r_l|\mathcal{T}_l), \tag{13}$$

where θ is all parameters in the framework. In the training phase, $p(r|\mathcal{T})$ is computed using the labeled relations as the attention queries. In the test phase, we need to use each possible relation as attention queries to compute $p(r|\mathcal{T})$ for relation prediction since the relations are unknown in advance.

3.4 Adversarial Training

In our framework, we encode sentences of various languages into a consistent semantic space to grasp the consistency among languages. One possible situation is that sentences of different languages are aggregated in different places of the space and linearly separable. In this case, our purpose of mining substantially consistent relation patterns in different languages is difficult to be reached. Inspired by Ganin et al. (2016), we adopt adversarial training into our framework to address this problem.

In the adversarial training, we define a discriminator to estimate which kind of languages the sentences from. The probability distributions over these sentences are formalized as follows,

$$\text{D}(\bar{\mathbf{s}}_j^i) = \text{softmax}(\text{MLP}(\bar{\mathbf{s}}_j^i)), \tag{14}$$

where MLP is a two-layer multilayer perceptron network.

Contrary to the discriminator, the consistent sentence encoders are expected to produce sentence embeddings that cannot be reliably predicted by the discriminator. Hence, the adversarial training process is a min-max game and can be formalized as follows,

$$\min_{\theta_{\text{E}}^C} \max_{\theta_{\text{D}}} \sum_{j=1}^{n} \sum_{i=1}^{|\mathcal{S}_j|} \log[\text{D}(\text{E}_j^C(x_j^i))]_j, \tag{15}$$

where $[\cdot]_j$ is the j-th value of the vector.

The formula means that given a sentence of any language, the corresponding sentence encoder of its language generates the sentence embedding to confuse the discriminator. Meanwhile, the discriminator

tries its best to predict the language of the sentence according to the sentence embedding. After sufficient training, the encoders and the discriminator reach a balance, and sentences of different languages containing similar semantic information can be well encoded into adjacent places of the space. In training, we optimize the following loss functions instead of Eq. 15,

$$\min_{\theta_{\mathrm{E}}^C} \mathcal{L}_{adv}^E(\theta_{\mathrm{E}}^C) = \sum_l \sum_{\mathcal{S}_j \in \mathcal{T}_l} \sum_{x_j^i \in \mathcal{S}_j} \log[\mathrm{D}(\mathrm{E}_j^C(x_j^i))]_j, \quad \min_{\theta_{\mathrm{D}}} \mathcal{L}_{adv}^D(\theta_{\mathrm{D}}) = -\sum_l \sum_{\mathcal{S}_j \in \mathcal{T}_l} \sum_{x_j^i \in \mathcal{S}_j} \log[\mathrm{D}(\mathrm{E}_j^C(x_j^i))]_j, \tag{16}$$

where θ_{E}^C and θ_{D} are all parameters of the consistent sentence encoders and the discriminator.

We notice that language-individual semantics could be wrongly encoded into the consistent semantic space, and may have negative effects on extracting language-consistent features. Inspired by Bousmalis et al. (2016), we adopt orthogonality constraints to alleviate this issue. We minimize the following penalty function:

$$\min_{\theta_{\mathrm{E}}} \mathcal{L}_{penalty}(\theta_{\mathrm{E}}) = \sum_{j=1}^{n} \left\| \mathbf{I}_j^T \mathbf{C}_j \right\|_F, \tag{17}$$

where $\mathbf{I}_j$ and $\mathbf{C}_j$ are two matrices whose row vectors are the embeddings of sentences in the j-th language encoded by E_j^I and E_j^C respectively. θ_{E} is parameters of the all encoders. And $\|\cdot\|_F$ is the squared Frobenius norm.

3.5 Implementation Details

During training process, we combine the extraction and adversarial objective functions as follows,

$$\mathcal{L} = \mathcal{L}_{nre}(\theta) + \lambda_1 \mathcal{L}_{adv}^D(\theta_{\mathrm{D}}) + \lambda_2 \mathcal{L}_{adv}^E(\theta_{\mathrm{E}}^C) + \lambda_3 \mathcal{L}_{penalty}(\theta_{\mathrm{E}}), \tag{18}$$

where λ_1, λ_2, and λ_3 are harmonic factors. All models are optimized using stochastic gradient descent (SGD). In practice, we integrate λ_1 and λ_2 into the alternating ratio among the loss functions, and we calibrate a 1:1:5 ratio among $\mathcal{L}_{nre}(\theta) + \lambda_3 \mathcal{L}_{penalty}(\theta_{\mathrm{E}})$, $\mathcal{L}_{adv}^D(\theta_{\mathrm{D}})$ and $\mathcal{L}_{adv}^E(\theta_{\mathrm{E}}^C)$. λ_3 is set as 0.02.

4 Experiments

4.1 Datasets and Evaluation

We evaluate our models on a multi-lingual relation extraction dataset developed by Lin et al. (2017). The dataset consists of English and Chinese data, and has 176 relations including a special relation `NA` indicating that there is no relation between entities. The whole dataset is divided into three parts for training, validation and test. The statistics of the dataset are listed in Table 1.

Dataset		#Rel	#Sent	#Fact	Dataset		#Rel	#Sent	#Fact
English	Training	176	1,022,239	47,638	Chinese	Training	176	940,595	42,536
	Validation	176	80,191	2,192		Validation	176	82,699	2,192
	Test	176	162,018	4,326		Test	176	167,224	4,326

Table 1: Statistics of the dataset

We evaluate all models by the held-out evaluation following previous works (Mintz et al., 2009; Lin et al., 2017). In experiments, we report precision-recall curves of recall under 0.3 since we focus more on the performance of those top-ranked results. To give a complete view of the performance, we also report the area under the curve (AUC).

4.2 Experiment Settings

Following the settings of previous works, we use the pre-trained word embeddings learned by Skip-Gram as the initial word embeddings. We implement the MNRE framework proposed by Lin et al. (2017) by ourselves. For fair comparision, we set most of the hyperparameters following Lin et al. (2017). We list the best setting of hyperparameters in Table 2.

Batch Size B	160	Convolution Kernel Size m	3
Learning Rate α	0.002	Dropout Probability p for CNN and RNN	0.5
Hidden Layer Dimension k_h for CNN	230	Dropout Probability p_d for the Discriminator	0.1
Hidden Layer Dimension k_h for RNN	200	Word Dimension k_w	50
Hidden Layer Dimension k_d for the Discriminator	2048	Position Dimension k_p	5

Table 2: Parameter settings.

4.3 Overall Evaluation Results

To evaluate the effectiveness of our proposed models **AMNRE-CNN** and **AMNRE-RNN**, we compare the proposed models with various neural methods: **MNRE-CNN** and **MNRE-RNN** are multi-lingual attention-based NRE models with CNN and RNN sentence encoders respectively (Lin et al., 2017); **CNN-EN** and **RNN-EN** are vanilla selective-attention NRE models trained with English data, which are the state-of-the-art models in mono-lingual RE (Lin et al., 2016); **CNN-CN** and **RNN-CN** are trained with Chinese data; **CNN-Joint** and **RNN-Joint** are naive joint models which predict relations by directly summing up ranking scores of both English and Chinese; **CNN-Share** and **RNN-Share** are another naive joint models which train English and Chinese models with shared relation embeddings. The results of precision-recall curves are shown in Figure 2 and the results of AUC are shown in Table 3.

From the results, we have the following observations:

(1) Both for CNN and RNN, the models jointly utilizing English and Chinese sentences outperform the models only using mono-lingual sentences. This demonstrates that the rich information in multi-lingual data is useful and can significantly enhance existing NRE models.

(2) The **-Joint** models achieve similar performance with the **-Share** models, and both of them underperform the **MNRE** and **AMNRE** models. They all benefit from the multi-lingual information, but the models with multi-lingual attentions can better take advantage of multi-lingual data. It indicates that designing targeted schemes to extract rich multi-lingual information is crucial.

(3) **AMNRE** achieves the best results among all the baseline models over the entire range of recall in Figure 2, even as compared with **MNRE**. **AMNRE** also outperforms **MNRE** with 3 percentage points increasing in the AUC results. It indicates our proposed framework which explicitly encodes language-consistent and language-individual semantics better extract multi-lingual information, and therefore lead to the significant improvement in RE performance.

Models	CNN-EN	CNN-CN	CNN-Joint	CNN-Share	MNRE-CNN	AMNRE-CNN
AUC	36.6	33.2	37.1	37.0	43.4	**46.2**
Models	RNN-EN	RNN-CN	RNN-Joint	RNN-Share	MNRE-RNN	AMNRE-RNN
AUC	34.5	34.4	36.5	37.6	44.2	**47.3**

Table 3: The AUC results of different models (%).

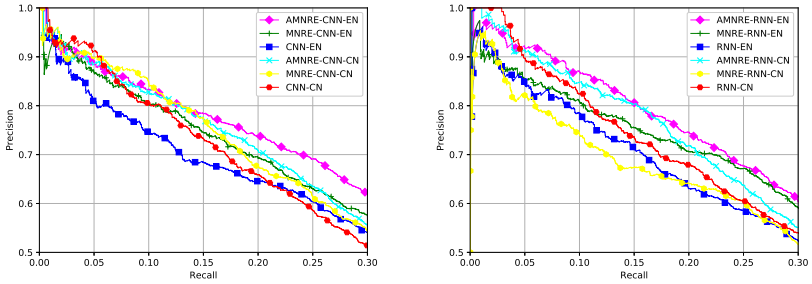

Figure 3: The aggregated precision-recall curves for proposed models and various baseline models in the mono-lingual scenario. Left: models with CNN as sentence encoders. Right: models with RNN as sentence encoders.

Models	CNN-EN	MNRE-EN	AMNRE-EN	RNN-EN	MNRE-EN	AMNRE-EN
AUC	36.6	39.6	**42.7**	34.5	42.2	**43.2**
Models	CNN-CN	MNRE-CN	AMNRE-CN	RNN-CN	MNRE-CN	AMNRE-CN
AUC	33.2	34.6	**37.9**	33.5	34.8	**36.4**

Table 4: The AUC results of different models in the mono-lingual scenario (%).

4.4 Mono-lingual Evaluation Results

To further verify that every mono-lingual RE models can benefit from our proposed framework, which explicitly consider language-consistent relation patterns, we train models with multi-lingual data and evaluate the performance of these models in the mono-lingual RE scenario. To show the results clearly, we report the precision-recall curves in Figure 3 and the AUC results in Table 4.

From the results, we can observe that:

(1) As compared with the models directly learned with the mono-lingual data, the models exploiting the multi-lingual information perform better in the mono-lingual scenario. This demonstrates that there is latent consistency among languages, and grasping this consistency from multi-lingual data can provide additional information for models in each language to enhance their results in the mono-lingual scenario.

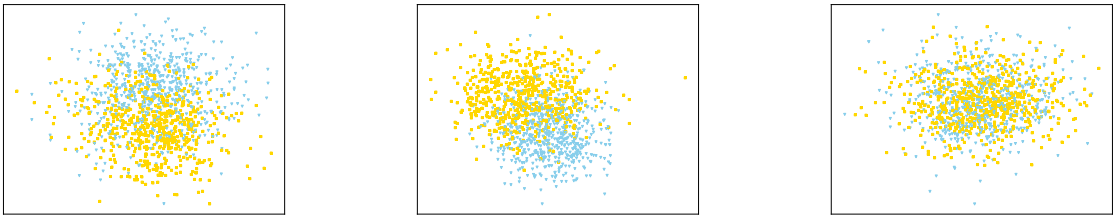
(2) Our proposed models achieve the best precision over the entire range of recall and also significantly improve the AUC results as compared with both MNRE and mono-lingual RE models. It indicates that due to the consistent semantic space in our framework, language-consistent information lying in the multi-lingual data is better mined and serve the mono-lingual scenario.

4.5 Effectiveness of Adversarial Training and Orthogonality Constraints

We adopt an adversarial training strategy to fuse the features from different languages to extract consistent relation patterns. Orthogonality constraints are also adopted to separate the consistent and individual feature spaces. To measure the effectiveness of them, we conduct an ablation study which compares the proposed models with the similar models but without adversarial training strategy (**AMNRE-noA**), without orthogonality constraints (**AMNRE-noO**), and without both of them (**AMNRE-noBoth**). The AUC results are shown in Table 5.

We can observe that both the adversarial training strategy and orthogonality constraints have significant influence on the performance of our proposed model. This demonstrates the effectiveness of adversarial training strategy and orthogonality constraints for multi-lingual RE. To give a more intuitive picture of the effect of these two mechanisms, we visualize the distribution of sentence feature embeddings encoded by the individual and consistent encoders using t-SNE (Maaten and Hinton, 2008). The results are shown in Figure 4.

Figure 4(a) shows that there are obvious differences between the feature embeddings encoded from the same sentences by individual and consistent encoders. It indicates the orthogonality constraints are effective to separate the individual and consistent latent spaces. From the comparison between Figure



(a) The same English sentences encoded by the consistent encoder (yellow) and individual encoder (blue).

(b) The English sentences (yellow) and the Chinese sentences (blue) encoded by their own consistent encoders without adversarial training.

(c) The English sentences (yellow) and the Chinese sentences (blue) encoded by their own consistent encoders with adversarial training.

Figure 4: The visualization of sentence feature embeddings with different mechanisms.

Models	AMNRE-CNN	AMNRE-CNN-noA	AMNRE-CNN-noO	AMNRE-CNN-noBoth
AUC	**46.2**	44.1	43.9	41.3
Models	AMNRE-RNN	AMNRE-RNN-noA	AMNRE-RNN-noO	AMNRE-RNN-noBoth
AUC	**47.3**	43.5	43.5	42.2

Table 5: The AUC results of the proposed models and ablated models.(%)

4(b) and Figure 4(c), we can observe that the feature embeddings from different languages are well-mixed due to the adversarial training strategy. We can more easily to grasp latent consistency among languages after multi-feature fusion.

5 Case Study

To further show the effectiveness of our proposed model to extract the language-consistent semantic information, we give an example in Table 6. We adopt the cosine similarity to measure the similarity between sentence embeddings encoded by consistent encoders. The first sentence in the middle column is the standard Chinese translation of the left sentence, thus they share the same semantic information. We observe that in our proposed model, the feature embedding similarity between these two sentences are significantly higher than the other English sentences sharing entity pair and relational fact but differing in semantics. It indicates that sentences in different languages containing similar semantics can be indeed encoded into adjacent places of the consistent space in our framework.

Relation : `Located in`		Cosine Similarity

6 Conclusion and Future Work

In this paper, we introduce a novel adversarial multi-lingual neural relation extraction model (AMNRE). AMNRE builds both individual and consistent representations for each sentence to consider the consistency and diversity of relation patterns among languages. It also employs an adversarial training strategy and orthogonality constraints to ensure the consistent representations could extract the language-consistent features to extract relations. The experimental results on real-world datasets demonstrate that

our AMNRE could effectively encode the consistency and diversity among languages, and achieves state-of-the-art performance in relation extraction.

We will explore the following directions as our future work: (1) AMNRE can be also implemented in the scenario of multiple languages, and this paper shows the effectiveness of AMNRE on the dataset with two languages (English and Chinese). In the future, we will explore AMNRE in much more other languages such as French, Spanish, and so on. (2) AMNRE simply aligns the sentences with similar semantics in different languages with an adversarial training strategy. In fact, machine translation is a typical approach to align sentences in various languages. In the future, we will combine machine translation with our model to further improve the extraction performance.

Abstract

Relation classification is an important task in natural language processing fields. State-of-the-art methods usually concentrate on building deep neural networks based classification models on the training data in which the relations of the labeled entity pairs are given. However, these methods usually suffer from the data sparsity issue greatly. On the other hand, we notice that it is very easy to obtain some concise text descriptions for almost all of the entities in a relation classification task. The text descriptions can provide helpful supplementary information for relation classification. But they are ignored by most of existing methods. In this paper, we propose DesRC, a new neural relation classification method which integrates entities text descriptions into deep neural networks models. We design a two-level attention mechanism to select the most useful information from the *"intra-sentence"* aspect and the *"cross-sentence"* aspect. Besides, the adversarial training method is also used to further improve the classification performance. Finally, we evaluate the proposed method on the SemEval 2010 dataset. Extensive experiments show that our method achieves much better experimental results than other state-of-the-art relation classification methods.

1 Introduction

The aim of relation classification is that given a sentence in which two target entities are labeled, to select a proper relation for these two entities from a predefined relation set. For example, given a sentence "*The system as described above has its greatest application in an arrayed <e1>configuration </e1> of antenna <e2>elements</e2>*", a relation classification system aims to identify that there is a "*Component-Whole*" relation from *e2* to *e1*. Obviously, accurate relation classification results would benefit lots of natural language processing tasks, such as sentence interpretations, Q&A, knowledge graph construction, ontology learning, and so on. Thus, lots of researchers have devoted to this research field.

For relation classification, deep neural networks (DNN) based methods have been widely explored and have achieved state-of-the-art experimental results. However, when evaluating state-of-the-art relation classification methods on some standard datasets, experimental results show that there are usually huge performance gaps between different relations. Besides, when using the trained relation classification models to predict relations on new data, the prediction performance is usually far lower than expected. This is mainly because of the data sparsity issue: first, there are always some relations that have far less training data than others; second, the available training data is not sufficient enough to train a robust relation classification model.

On the other hand, we notice that for almost all of the entities in a relation classification task, there are usually available text descriptions for them on some Encyclopedia websites like Wikipedia, DBpedia, Wikidata, etc. For example, from the Wikipedia website, we can extract the following text descriptions as shown in Figure 1, where the example sentence is taken from the SemEval 2010 dataset.

Proceedings of the 27th International Conference on Computational Linguistics, pages 1167–1177
Santa Fe, New Mexico, USA, August 20-26, 2018.

2 Related Work

Up to now, lots of novel relation classification methods have been proposed. Early research mainly focuses on features based methods. Usually, these methods firstly select some syntactic and semantic features from the given sentences. Then the selected features are fed into some classification models like support vector machines, maximum entropy, etc.

Recently, DNN based methods have been widely explored and have achieved state-of-the-art experimental results. The core of these methods is to embed features into real-valued vectors, and then feed these vectors into some DNN based learning frameworks. Generally, there are three widely used DNN frameworks for relation classification: convolutional neural networks (CNN), recurrent neural networks (RNN), and their combination. In most recent years, inspired by both the success of DNN methods and the broad consensus that syntactic tree structures are of great help for relation classification, more and more research attention is being paid to the methods that integrate syntactic tree features into DNN based learning frameworks. Among the syntactic tree features, the *Shortest Dependent Path* (SDP) is one of the most frequently used. In Table 1, we summarize some representative state-of-the-art DNN based relation classification methods.

Table1: A summarization of representative state-of-the-art relation classification methods.

From Table 1 we can see that there are many similarities among the state-of-the-art relation classification methods. For example, most of them use a cross entropy loss function, use WordNet, and use the stochastic gradient descent (SGD) method for optimization, etc. The main differences among them mainly lie in the learning frameworks.

CNN is a very popular learning framework for relation classification and lots of methods are based on it. For example, Zeng et al. (2014) proposed a CNN based approach for relation classification. In their method, sentence level features are learned through a CNN model that takes word embedding features and position embedding features as input. In parallel, lexical level features are extracted from some context windows that are around the labeled entities. Then the sentence level features and the lexical level features are concatenated into a single vector. This vector is then fed into a *softmax* classifier for relation prediction. Another representative CNN based relation classification method is CR-CNN

(Dos Santos et al., 2015), which tackles the relation classification task with a CNN model that performs classification by ranking. They proposed a new pairwise ranking loss function that is easy to reduce the impact of the artificial relation "*Other*". Their method is also the unique one that takes a specific processing strategy for the "*Other*" relation.

Xu et al. (2016) pointed out that compared with a raw word sequence or a whole parse tree, the SDP between two entities has two main advantages. First, it reduces irrelevant information; second, grammatical relations between words focus on the action and agents in a sentence and are naturally suitable for a relation classification task. Thus many researchers integrate SDP into DNN based learning frameworks for relation classification. For example, based on SDP, Xu et al. (2016) proposed deep recurrent neural networks (DRNNs) for relation classification. Their method can be roughly regarded as a "*RNN + SDP*" relation classification method. Xu et al. (2015a) proposed a neural relation classification architecture that picks up heterogeneous information along the left and right sub-path of the *SDP* respectively, leveraging RNN with multichannel *long short term memory* (LSTM) units. And their method can be roughly regarded as a "*LSTM + SDP*" relation classification method. Other similar work, Xu et al. (2015b) proposed to learn more robust relation representations from SDP through a CNN model; Liu et al. (2015) proposed augmented dependency path (ADP), which is a variant of SDP. Both of these two methods can be roughly regarded as a "*CNN + SDP*" relation classification method.

Some researchers combine CNN and RNN together for relation classification. For example, Vu et al. (2016) investigated CNN and RNN as well as their combination for relation classification. They proposed extended middle context, a new context representation for the CNN architecture. The extended middle context uses all parts of the sentence (the relation arguments, left/right and between of the relation arguments) and pays special attention to the middle part. Meanwhile, they proposed a connectionist bidirectional RNN model and introduced a ranking loss function for the RNN model. Finally, CNN and RNN are combined with a simple voting scheme. Cai et al. (2016) proposed a bidirectional neural network BRCNN, which consists of two RCNNs that can learn features along SDP inversely at the same time. Specifically, information of words and dependency relations is extracted by a two-channel RNN model with LSTM units. The features of dependency units in a SDP are extracted by a convolution layer. Liu et al. (2015) used a RNN model to learn the features of the sub-trees, and used a CNN model to capture the most important features on a SDP.

Recently, the attention method is achieving more and more research attention. Some researchers also add the attention method in their relation classification models. For example, Wang et al. (2016) proposed a multi-level attention CNN model for relation classification. In their method, two levels of attentions are used in order to better discern patterns in heterogeneous contexts. Zhou et al. (2016) proposed an attention-based bidirectional LSTM model for relation classification.

Another research line explores a kind of end-to-end method for relation classification. For example, Miwa et al. (2016) proposed a novel end-to-end neural model to extract entities and the relations between them. Their model captures both word sequence and dependency tree substructure information by stacking bidirectional tree-structured LSTM-RNNs on bidirectional sequential LSTM-RNNs, which allows the model to jointly represent both entities and relations with shared parameters in a single model.

3 Our Model

Figure2 demonstrates the architecture of our method. For each original training/test sentence S_i, it will be augmented to a new triplet format like $<S_i$, $Des_i(e_1)$, $Des_i(e_2)>$, where $Des_i(e_1)$ and $Des_i(e_2)$ are the text descriptions of the labeled entities e_1 and e_2 in S_i. Our model takes the augmented training/test sentences as input.

From Figure2 we can see that in our model, there are three parallel DNN-based encoders that are used to learn the real-valued vector representations for S_i, $Des_i(e_1)$, and $Des_i(e_2)$ respectively. Then with a "*cross-sentence*" attention method, the three learned vector representations are combined into one global real-valued vector representation. Finally, the classification decision is made based on the global vector representation.

For the description representation learning, we use a CNN-based method. And for the original training/test sentence representation learning, we use two methods: one is the CNN-based method that is the

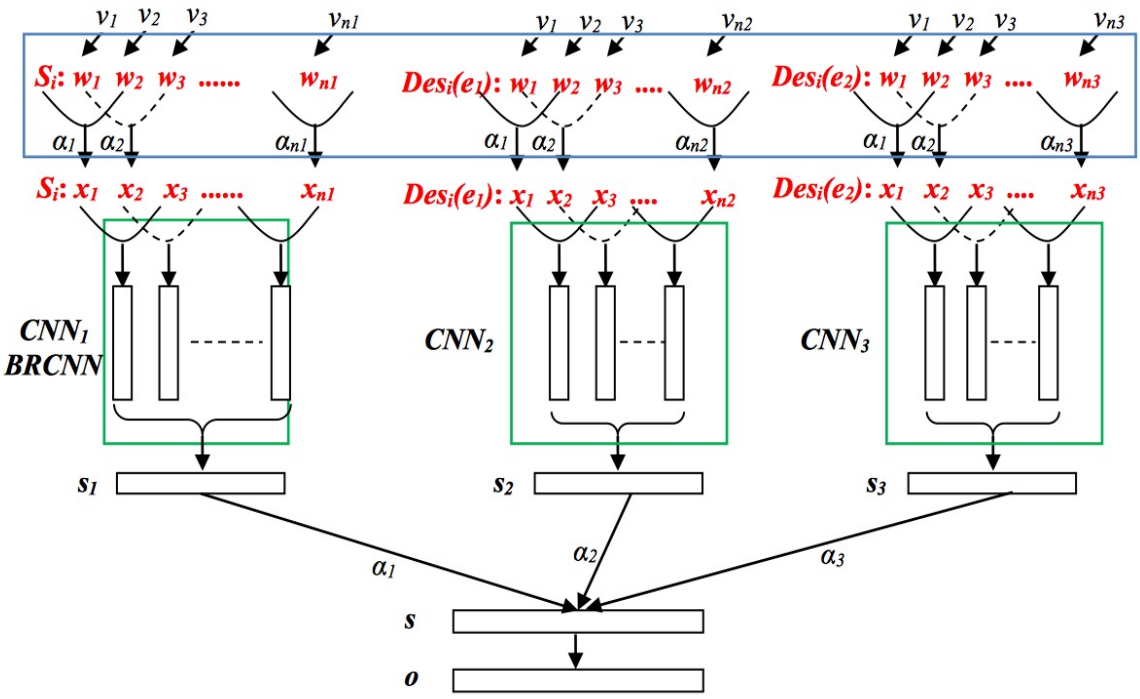

Figure 2: Architecture of DesRC

same as the one used in the description representation learning, and the other is a BRCNN-based method that is similar to the one proposed by Cai et al. (2016). In the three representation learning encoders, an "*intra-sentence*" attention method is used to select the most useful word information inside an input sentence. Besides, the adversarial training technique is also used on the word embedding level during training (in Figure2, v_i denotes the adversarial perturbation w.r.t. a word embedding w_i).

3.1 CNN-Based Encoder

Given a sentence, this encoder aims to transform it into a distributed representation via a CNN model. There is a same encoding process for both S_i and its two text descriptions $Des_i(e_1)$ and $Des_i(e_2)$. Here we take S_i as an example to demonstrate the whole CNN-based endoding process. First, each word in S_i is transformed into a real-valued vector representation. Then, a convolutional operation, a max-pooling operation, and a non-linear transformation operation are performed in turn. Finally, the encoder outputs a distributed representation for S_i.

Word Representation Given a sentence $S_i = (w_1, w_2, ..., w_n)$, we transform each of its word w_i into the concatenation of two kinds of embedding representations: 1) a word embedding that captures syntactic and semantic meaning of this word; and 2) a position embedding that specifies which input words are the labeled entities (or entity) or how close an input word to the labeled entities (or entity). Finally, the sentence S_i can be represented as a vector sequence $\boldsymbol{S}_i = (\boldsymbol{w}_1, \boldsymbol{w}_2, ..., \boldsymbol{w}_n)$, where $\boldsymbol{w}_i \in R^d$ and $d = d_a + 2*d_b$ (for original training/test sentences) or $d = d_a + d_b$ (for descriptions). d_a and d_b are the dimension of word embeddings and position embeddings respectively.

***Intra-sentence* Attention** In a sentence, not all of its words are equally useful for the final classification decision. Some of them may be important, some of them may not. Thus, we design an "*intra-sentence*" attention method to automatically identify which words in a sentence are more important for the final classification decision. Following Feng et al. (2017), for each word $\boldsymbol{w}_i$ in $\boldsymbol{S}_i$, we take the embedding of its m context words and the corresponding entities' embeddings as input, the "*intra-sentence*" attention model outputs a new representation $\boldsymbol{x}_i$ for $\boldsymbol{w}_i$ with the following formula.

$$x_i = \sum_{l=1}^{w} \alpha_l * \boldsymbol{m}_l \tag{1}$$

where $\boldsymbol{m}_l \in R^d$ is the embedding of a considered context word, and the attention score α_l is defined as:

$$\alpha_l = \frac{exp(f_i)}{\sum_{j=1}^{n} exp(f_j)} \tag{2}$$

f_i is a function to evaluate the semantic relatedness of a text fragment with the given entity (for text descriptions) or the given entity pair (for the original training/test sentences) and the linked relation. It is calculated with the following formulas.

$$f_i = tanh(\boldsymbol{M} * [\boldsymbol{m_i}; \boldsymbol{w_{e1}}; \boldsymbol{w_{e2}}] + U * \boldsymbol{r}) \tag{3}$$

$$or \quad f_i = tanh(\boldsymbol{M_{1/2}} * [\boldsymbol{m_i}; \boldsymbol{w_{e1}/w_{e2}}] + U * \boldsymbol{r}) \tag{3'}$$

where $\boldsymbol{M} \in R^{d*3}$, $\boldsymbol{M}_{1/2} \in R^{d*2}$, $\boldsymbol{U} \in R^{dr}$, d_r is the dimension of relation, and $\boldsymbol{w}_{e1/e2}$ and $\boldsymbol{r}$ are the word embeddings of the labeled entities and the relation linked with them. The "[]" symbol denotes the concatenation operation. Similar to Lin et al. (2017), in the testing phase, since $\boldsymbol{r}$ is not known, we will take each possible relation into consideration. Finally, the "*intra-sentence*" attention model outputs a new representation for $\boldsymbol{S}_i$ that can be denoted as $\boldsymbol{S}_i = (\boldsymbol{x}_1, \boldsymbol{x}_2, ..., \boldsymbol{x}_n)$.

Convolution Transformation After the above operation, a convolutional layer is used to extract the local features of an input sentence. This layer slides a word window of length *w* over the input sentence and performs a convolution operation within each sliding window. Its output for the *i-th* window is computed with the following formula.

$$\boldsymbol{C_i} = \boldsymbol{M_3} * \boldsymbol{cx_i} + \boldsymbol{b_1} \tag{4}$$

where $\boldsymbol{M}_3 \in R^{h1 * (d*w)}$, h_1 (a hyper-parameter) is the size of hidden units in the convolutional layer, $\boldsymbol{cx}_i$ is the embedding concatenation of the *w* word within the *i-th* window, and $\boldsymbol{b}_1$ is a bias term.

Max-pooling After the convolutional transformation, a max-pooling operation is applied to capture the most useful local features produced by the convolutional operation. This process can be written as the following formula.

$$\boldsymbol{p_i} = max_n \boldsymbol{C(i, n)}; \qquad 0 \leq i \leq h_1 \tag{5}$$

The result of max-pooling is an h_1-element real-valued vector whose size is no longer related to the length of the input sentence.

Non-linear Operation After the max-pooling operation, its output vectors $\boldsymbol{p}$ is fed into a non-linear transformation layer to generate the final representation for S_i with the following formula.

$$\boldsymbol{s_i} = tanh(\boldsymbol{M_4} * \boldsymbol{p} + \boldsymbol{b_2}) \tag{6}$$

where $\boldsymbol{M}_4 \in R^{h2*h1}$, h_2 (a hyper-parameter) is the size of hidden units in this layer, and $\boldsymbol{b}_2$ is a bias term.

3.2 BRCNN-Based Encoder

BRCNN is a relation classification model that is first proposed by Cai et al. (2016). It builds a relation classification model based on SDP, and can take full advantages of both the CNN model and the RNN model. Specifically, given a sentence and its dependency tree, the BRCNN model first extracts a SDP from the dependency tree. Then, along the SDP, two RNN models with LSTM units are used to learn hidden representations of words and dependency relations respectively. A convolution layer is applied to capture local features from hidden representations of every two neighbor words and the dependency relations between them. A max-pooling layer thereafter gathers information from local features of the SDP and the inverse SDP. Finally, a linear operation is performed to generate the final representation of the given sentence. More detail information can be referred to the work of Cai et al. (2016).

Here we take the BRCNN model as a new encoder to learn the representations of the original training/test sentences mainly for the following two reasons. First, BRCNN is one of the current-best relation classification models, and we want to explore the maximal potential of our method. Second, we want to explore the effectiveness of text descriptions in different relation classification frameworks.

However, it should be noted that the BRCNN-based encoder cannot be used in the description representation learning. This is because that the BRCNN model is based on SDP, which is extracted from the shorted dependency path between the **TWO** labeled entities, but a text description only focuses on **ONE** single entity. Thus it is impossible to extract a SDP from an entity's text description. Accordingly, the BRCNN based encoder cannot be utilized.

3.3 Representation Combination

After the CNN/BRCNN based representation learning, there will be three generated representations that are for the original training/test sentence and its two text descriptions respectively. We use a "*cross-sentence*" attention method to combine them into **ONE** global real-valued representation. With this attention method, we can capture the most useful information among different representations. The global representation $\boldsymbol{s}$ is computed as a weighted sum of the single representation vectors.

$$\boldsymbol{s} = \sum_i \alpha_i * \boldsymbol{s}_i \tag{7}$$

The attention score α_i is defined as:

$$\alpha_i = \frac{exp(g_i)}{\sum_{j=1}^{k} exp(g_j)} \tag{8}$$

g_i is a function to evaluate how well a representation vector reflects its corresponding entities (or entity) and the relation linked by the two labeled entities. It is calculated with the following formula.

$$g_i = \boldsymbol{s_i} * \boldsymbol{r} \tag{9}$$

where $\boldsymbol{r}$ is the embedding of the corresponding relation. In the testing phase, we will also take each possible relation into consideration

3.4 Classification Prediction

After the representation combination, the generated representation $\boldsymbol{s}$ is fed into a linear output layer to compute the confidence score for each possible relation. A *softmax* classifier is further used to get the probability distribution $\boldsymbol{y}$ over all relations. This process is written as formula10.

$$\boldsymbol{y} = softmax(\boldsymbol{M_5} * \boldsymbol{s} + \boldsymbol{b_3}) \tag{10}$$

where $\boldsymbol{M}_5 \in R^{h3*h2}$ and h_3 is the number of all possible relations.

3.5 Dropout Operation

Over-fitting is an issue that cannot be ignored in DNN models. Hinton et al. (2012) proposed the dropout method that has been proved to be effective for alleviating this issue. This method randomly sets a proportion (called drop rate, a hyper-parameter) of features to zero during training. It is expected to obtain less interdependent network units, thus the over-fitting issue is expected to be alleviated. In our method, we take dropout operations on $\boldsymbol{w}_i$ (see the word representation section) and $\boldsymbol{s}$ (see formula 7). The drop rates for them are denoted as $dp_{1\sim2}$ respectively.

3.6 Training Procedure

All the parameters in our method can be denoted as θ=($\boldsymbol{E}^w$,$\boldsymbol{E}^p$,$\boldsymbol{M}$,$\boldsymbol{M}_1$,$\boldsymbol{M}_2$,$\boldsymbol{M}_3$,$\boldsymbol{M}_4$,$\boldsymbol{M}_5$,$\boldsymbol{U}$,$\boldsymbol{b}_1$,$\boldsymbol{b}_2$,$\boldsymbol{b}_3$,$\boldsymbol{r}$),where $\boldsymbol{E}^w$ and $\boldsymbol{E}^p$ represent the embedding matrices of word and position respectively. In this paper, we use the *word2vecc* toolkit (Mikolov et al., 2013) to train the word embedding matrix $\boldsymbol{E}^w$ on the English Wikipedia data from May 2014, which is similar to Vu et al. (2016). $\boldsymbol{E}^p$, other transformation matrices, and the bias terms are randomly initialized. All the parameters are tuned using the back propagation method. SGD optimization technique is used for training. Formally, we try to maximize the following loss function.

$$L(\theta) = \sum_{i=1}^{N} log(y_i) \tag{11}$$

where N is the total number of training samples. During training, each input sample is considered independently. And each parameter is updated by applying the following update rule, where η is the learning rate.

$$\theta = \theta + \eta * \partial log y_i / \partial \theta \tag{12}$$

3.7 Adversarial Training

Adversarial training (Goodfellow et al., 2014) is a method that adds some random perturbations to the training data, whose aim is to improve the robustness of a classifier. Researchers (Wu et al., 2017, Miyato et al., 2016, etc) show that when some adversarial noise is added at the level of word embedding by computing the gradient direction of a loss function w.r.t. the data, better experimental results are obtained. Following these previous methods, we also add adversarial noise at the word embedding level during training. This process is written as the following formulas.

$$\boldsymbol{w_i} = \boldsymbol{w_i} + \boldsymbol{v_i} \tag{13}$$

$$\boldsymbol{v_i} = \epsilon * g/||g|| \qquad where \quad g = \partial L/\partial w_i \tag{14}$$

where L is the loss function, and $||g||$ is the norm of gradients over all the words in a given training sentence (or the text descriptions).

4 Experimental Results and Analysis

Dataset The SemEval-2010 Task 8 dataset is used to evaluate our method. In this dataset, there are 8000 training sentences and 2717 test sentences. For each training/test sentence, two entities that are expected to be predicted a relation are labeled. In this dataset, there are 9 relations whose directions need to be considered and an extra artificial relation "*Other*" that does not need to consider the direction. Thus totally there are 19 relations in this dataset. Some statistics of this dataset are reported in Table 2. In this paper, macro-averaged *F1* score (excluding "*Other*"), the official evaluation metric, is used. And the direction of a relation is considered. In experiments, we download the needed text descriptions for all the labeled entities from *Wikipedia*[1]. All the dependency parsing trees used in the BRCNN model are generated by the Stanford Parser (Klein and Manning, 2003).

Table 2: Statistics for the Experimental Dataset

In experiments, we apply a cross-validation procedure on the training data to select suitable hyper-parameters. Finally, the best configurations are: the dimensions of word embeddings (d_a) and relation embeddings (d_r) are both set to 300, the dimension of position embeddings (d_b) is set to 15, learning rate η is set to 0.001, $h_{1\sim2}$ are set to 200 and 300, $dp_{1\sim2}$ are set to 0.35 and 0.3, both m (see formula 1) and w (see formula 4) are set to 3, the adversarial training parameter ϵ (see formula 14) is set to 0.01.

[1]https://www.wikipedia.org/

Effectiveness of Different Model Components In the first part of our experiments, we conduct experiments to evaluate: (1) the effectiveness of text descriptions; (2) the contributions of two proposed attention methods; and (3) the contribution of the adversarial training. To this end, we implement two classification models: one is a "*CNN-CNN-CNN*" model that uses the CNN based method for the original training/test sentence representation learning; and the other is a "*BRCNN-CNN-CNN*" model that uses the BRCNN based method for the original training/test sentence representation learning. They are denoted as *DesRC*(CNN) and *DesRC*(BRCNN) respectively. In experiments, we first implement a basic CNN model and a basic BRCNN model. Based on them, we incrementally add text descriptions, attention methods and the adversarial training. The experimental results are reported in Table 3.

Table 3: Performance of *DesRC*(CNN)/*DesRC*(BRCNN) with different features, WN means WordNet.

From Table 3 we can draw the following conclusions.

First, there is substantial performance improvement for both the basic CNN model and the basic BRCNN model when text descriptions are added. With the "*intra-sentence*" and "*cross-sentence*" attention methods, the F1 score for the basic CNN model increases about 2, and the F1 score for the basic BRCNN increases about 1.8. The experimental results indicate that text descriptions could provide much useful decision information for relation classification. Accordingly, the data sparsity issue is alleviated greatly when text descriptions are utilized. It is worth noting that when only part of the descriptions used (for example, only the descriptions of *e1* or *e2* are used), the F1 score still improves for both the basic CNN model and the basic BRCNN model. This is in line with our original hypothesis: as long as the text description could provide some property information for a given entity, the possible relations linked by this entity will be limited into a small candidate set. Thus, the classification decisions are more easy to be made. Accordingly, the F1 score increases.

Second, a well-designed attention method can improve the performance of relation classification greatly. For example, when using only *des(e1)* or *des(e2)* with an "*cross-sentence*" attention method, the maximal F1 improvement for the basic CNN model and the basic BRCNN model are about 1 and 0.6 respectively. We notice that the "*intra-sentence*" attention contributes much more performance improvement for the basic CNN model (F1 increases 1.1) than for the basic BRCNN model (F1 increases only 0.2). This is because that the basic BRCNN model is based on SDP whose average word number is very small (about 4, Cai et al., 2016). Thus as long as a word is in SDP, it must be much important. In other words, the role of SDP and the attention method overlaps to a certain extent. As a result, the role of the

"*intra-sentence*" attention for a basic BRCNN model is not as obvious as for a basic CNN model.

Third, the adversarial training method can further improve the performance of relation classification. When adding the adversarial training method in the basic CNN model and the basic BRCNN model, their F1 scores increase about 0.3 and 0.2 respectively. When both the description information and two attention methods are used, the F1 contributions of the adversarial training method are 0.5 and 0.4 for the basic CNN model and the basic BRCNN model respectively.

Fourth, when WordNet is added, the F1 scores for both *DesRC*(CNN) and *DesRC*(BRCNN) further increase about 0.5 and 0.7, which is a little less than the results reported in other state-of-the-art DNN based methods. In their methods, the F1 score often increases about 1 when WordNet is used. We think this is because that part of the information provided by WordNet can also be provided by text descriptions. Thus, the role of WordNet decreases when text descriptions are used. In other words, in a relation classification task, text descriptions can replace WordNet to a certain extent.

Comparisons with other State-of-the-art Relation Classification Methods In the second part of our experiments, we compare our method with several state-of-the-art DNN based relation classification methods. The comparison results are shown in Table 4. From Table 4 we can see that even without

Methods	Extra resources used	F1
CNN(Zeng et al., 2014)	WordNet	82.7
CRCNN(Dos Santos et al., 2015)	No	84.1
RNN + SDP(Xu et al., 2016)	WordNet	86.1
LSTM + SDP(Xu et al., 2015a)	WordNet	83.7
CNN + SDP(Xu et al., 2015b)	WordNet	85.6
CNN + RNN + SDP(Cai et al., 2016)	WordNet	**86.3**
CNN + SDP(Liu et al., 2015)	WordNet	83.6
CNN + RNN(Vu et al., 2016)	No	84.9
LSTM + Attention(Zhou et al., 2016)	No	84
End-to-End(Miwa et al., 2016)	WordNet	85.5
DesRC(CNN)	Text descriptions	***86.1***
DesRC(BRCNN)	Text descriptions	***86.7***
DesRC(CNN)	Text descriptions + WordNet	***86.6***
DesRC(BRCNN)	Text descriptions + WordNet	***87.4***

Table 4: Comparisons with other state-of-the-art DNN based methods.

WordNet, our method still achieves much better results than the baselines. For *DesRC*(CNN), its F1 score is close to the current-best F1 score very much. And for *DesRC*(BRCNN), it achieves the best F1 score. When WordNet is used, both *DesRC*(CNN) and *DesRC*(BRCNN) outperform the current-best method. These experimental results indicate that text descriptions are of great adaptive. They can benefit both the CNN based learning framework and the RNN based learning frameworks (BRCNN can be seen as a combination of CNN and RNN). What's more, compared with WordNet, text descriptions are more easily obtained. Thus, our method is easier to be transplanted to a new language's relation classification task.

Detailed Results In the third part of our experiments, we compare the classification performance of different relations. Here the used model is *DesRC*(BRCNN) and WordNet is used. The comparison results are reported in Table 5.

From Table 5 we can see that there are still huge performance gaps between different relations in our method. For example, the best F1 score (for example, "*cause-effect*" and "*entity-destination*") is almost 10 higher than the worst F1 score (for example, "*product-producer*" and "*content-container*"). But compared with the huge imbalance among the number of their training samples, the performance gaps are far smaller. These experimental results also show the effectiveness of text descriptions for alleviating the data sparsity issue.

5 Conclusions and Future Work

In this paper, we propose a new relation classification method that uses text descriptions as a kind of supplement information. The main contributions of our method are listed as follows.

First, to the best of our knowledge, this is the first relation classification method that uses description information. In our method, two well-designed attention methods are used to combine the classification features that come from the original input sentences and their corresponding descriptions. Besides, the adversarial training method is also used to further improve the performance of our method.

Second, we conduct extensive experiments to evaluate the proposed method. Experimental results show that our method is much effective for relation classification, and it outperforms all the compared state-of-the-art baselines.

In the future, we will further explore the following two research directions. First, we will explore more kinds of descriptions that come from different websites, even to explore multi-lingual descriptions, as Lin et al. (2017) do in their work. Second, we will explore whether there are more effective learning framework that can take personalized classification strategies for different relations.

Abstract

Generating an abstract from a collection of documents is a desirable capability for many real-world applications. However, abstractive approaches to multi-document summarization have not been thoroughly investigated. This paper studies the feasibility of using Abstract Meaning Representation (AMR), a semantic representation of natural language grounded in linguistic theory, as a form of content representation. Our approach condenses source documents to a set of summary graphs following the AMR formalism. The summary graphs are then transformed to a set of summary sentences in a surface realization step. The framework is fully data-driven and flexible. Each component can be optimized independently using small-scale, in-domain training data. We perform experiments on benchmark summarization datasets and report promising results. We also describe opportunities and challenges for advancing this line of research.

1 Introduction

Abstractive summarization seeks to generate concise and grammatical summaries that preserve the meaning of the original; further, they shall abstract away from the source syntactic forms. The task often involves high-level text transformations such as sentence fusion, generalization, and paraphrasing (Jing and McKeown, 1999). Recent neural abstractive summarization studies focus primarily on single-document summarization (Paulus et al., 2017; See et al., 2017). These approaches are limited by the availability of training data, and large datasets for multi-document summarization can be costly to obtain. Generating abstractive summaries for sets of source documents thus remains a challenging task.

Traditional approaches to abstractive summarization often condense the source documents to a set of "semantic units," then reconstruct abstractive summaries from these semantic units. Previous work has investigated various forms of content representation. Examples include noun/verb phrases (Genest and Lapalme, 2011; Bing et al., 2015), word-occurrence graphs (Ganesan et al., 2010), syntactic parse trees (Cheung and Penn, 2014; Gerani et al., 2014), and domain-specific templates (Pighin et al., 2014). Nonetheless, generating summary text from these heuristic forms of representation can be difficult. There is an increasing need to exploit a semantic formalism so that condensing source documents to this form and generating summary sentences from it can both be carried out in a principled way.

This paper explores Abstract Meaning Representation (AMR, Banarescu et al., 2013) as a form of content representation. AMR is a semantic formalism based on propositional logic and the neo-Davidsonian event representation (Parsons, 1990; Schein, 1993). It represents the meaning of a sentence using a rooted, directed, and acyclic graph, where nodes are concepts and edges are semantic relations. Figure 1 shows an example AMR graph. A concept node can be a PropBank frameset ("state-01"), an English word ("warhead"), a special keyword ("date-entity"), or a string literal ("Japan"). A relation can be either a core argument ("ARG0," "ARG1") or a modification relationship ("mod," "time"). The AMR representation abstracts away from surface word strings and syntactic structure, producing a language-neutral representation of meaning. The graph representation is flexible and not specifically designed for a particular domain. It is thus conceptually appealing to explore AMR for abstractive summarization.

Proceedings of the 27th International Conference on Computational Linguistics, pages 1178–1190

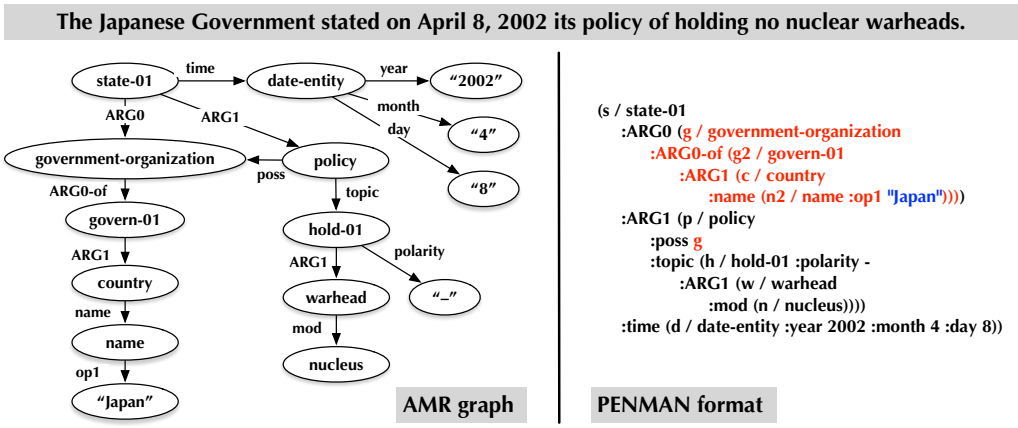

Figure 1: A example sentence, its goldstandard AMR graph, and the corresponding PENMAN format.

Our goal in this work is to generate a text abstract containing multiple sentences from a cluster of news articles discussing a given topic. The system framework includes three major components: *source sentence selection* takes a set of news articles as input and selects sets of similar sentences covering different aspects of the topic; *content planning* consumes a set of similar sentences and derives a summary graph from them; *surface realization* transforms a summary graph to a natural language sentence. This framework allows each component (source sentence selection, content planning, surface realization) to be individually optimized using small-scale, in-domain training data, reducing the need for large-scale parallel training data. Our research contributions are summarized as follows:

- we investigate AMR, a linguistically-grounded semantic formalism, as a new form of content representation for multi-document summarization. Liu et al. (2015) conducted a pilot study using AMR for single-document summarization. This paper exploits the structured prediction framework but presents a full pipeline for generating abstractive summaries from multiple source documents;
- we study to what extent the AMR parser and generator, used for mapping text to and from AMR, can impact the summarization performance. We also compare multiple source sentence selection strategies to group source sentences into clusters covering various aspects of the topic;
- we conduct extensive experiments on benchmark summarization datasets, and contrast our work with state-of-the-art baselines, including the pointer-generator networks (See et al., 2017). Results show that leveraging the AMR representation for summarization is promising. Our framework is flexible, allowing different components to be optimized independently using small-scale, in-domain datasets. We finally describe opportunities and challenges for advancing this line of research.

2 Related Work

Neural abstractive summarization has sparked great interest in recent years. These approaches focus primarily on short text summarization and single-document summarization (Rush et al., 2015; Nallapati et al., 2016). Variants of the neural encoder-decoder architecture have been exploited to reduce out-of-vocabulary tokens and word repetitions (See et al., 2017; Suzuki and Nagata, 2017), improve the attention mechanism (Chen et al., 2016; Zhou et al., 2017; Tan et al., 2017), control the summary length (Kikuchi et al., 2016), improve the learning objective and search (Ranzato et al., 2016; Huang et al., 2017), and generate summaries that are true to the original inputs (Cao et al., 2018; Song et al., 2018). Training neural models requires large amounts of data; they are often acquired by pairing news articles with titles or human-written highlights. Nonetheless, obtaining parallel data for multi-document summarization is often costly. There is thus a need to investigate alternative approaches that are less data-thirsty.

Abstractive summarization via natural language generation (NLG, Reiter and Dale, 2000; Gatt and Krahmer, 2018) is a promising line of work. The approaches often identify salient text units from source documents, arrange them in a compact form, such as domain-specific templates, and subsequently synthesize them into natural language texts (Barzilay et al., 1999; Genest and Lapalme, 2011; Oya et al., 2014; Gerani et al., 2014; Fabbrizio et al., 2014). A challenge faced by these approaches is that there

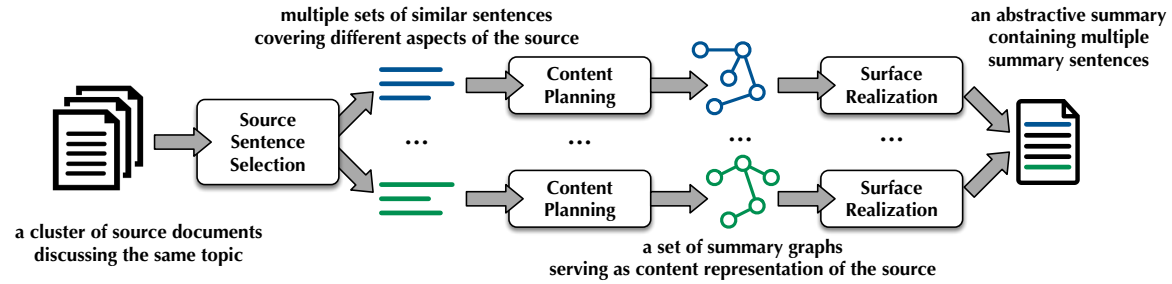

Figure 2: Our system framework, consisting of three major components.

lacks a principled means of content representation. This paper studies the feasibility of using AMR, a semantic formalism grounded in linguistic theory, for content representation. Within this framework, condensing source documents to summary AMR graphs and generating natural language sentences from summary graphs are both data-driven and not specifically designed for any domain.

The AMR formalism has demonstrated great potential on a number of downstream applications, including machine translation (Tamchyna et al., 2015), entity linking (Pan et al., 2015), summarization (Liu et al., 2015; Takase et al., 2016), question answering (Jurczyk and Choi, 2015), and machine comprehension (Sachan and Xing, 2016). Moreover, significant research efforts are dedicated to map English sentences to AMR graphs (Flanigan et al., 2014; Wang et al., 2015a; Wang et al., 2015b; Ballesteros and Al-Onaizan, 2017; Buys and Blunsom, 2017; Damonte et al., 2017; Szubert et al., 2018), and generating sentences from AMR (Flanigan et al., 2016; Song et al., 2016; Pourdamghani et al., 2016; Song et al., 2017; Konstas et al., 2017). These studies pave the way for further research exploiting AMR for multi-document summarization.

3 Our Approach

We describe our major system components in this section. In particular, content planning (§3.1) takes as input a set of similar sentences. It maps each sentence to an AMR graph, merges all AMR graphs to a connected *source graph*, then extracts a *summary graph* from the source graph via structured prediction. Surface realization (§3.2) converts a summary graph to its PENMAN representation (Banarescu et al., 2013) and generates a natural language sentence from it. Source sentence extraction (§3.3) selects sets of similar sentences from source documents discussing different aspects of the topic. The three components form a pipeline to generate an abstractive summary from a collection of documents. Figure 2 illustrates the system framework. In the following sections we describe details of the components.

3.1 Content Planning

The meaning of a source sentence is represented by a rooted, directed, and acyclic AMR graph (Banarescu et al., 2013), where nodes are concepts and edges are semantic relations. A sentence AMR graph can be obtained by applying an AMR parser to a natural language sentence. In this work we investigate two AMR parsers to understand to what extent the performance of AMR parsing may impact the summarization task. JAMR (Flanigan et al., 2014) presents the first open-source AMR parser. It introduces a two-part algorithm that first identifies concepts from the sentence and then determines the relations between them by searching for the maximum spanning connected subgraph (MSCG) from a complete graph representing all possible relations between the identified concepts. CAMR (Wang et al., 2015b) approaches AMR parsing from a different perspective. It describes a transition-based AMR parsing algorithm that transforms from a dependency parse tree to an AMR graph. We choose JAMR and CAMR because these parsers have been made open-source and both of them reported encouraging results in the recent SemEval evaluations (May, 2016; May and Priyadarshi, 2017).

Source Graph Construction. Given a set of source sentences and their AMR graphs, source graph construction attempts to consolidate all sentence AMR graphs to a connected *source graph*. This is accomplished by performing *concept merging*. Graph nodes representing the same concept, determined by the surface word form, are merged to a single node in the source graph. Importantly, we perform

coreference resolution on the source documents to identify clusters of mentions of the same entity or event. Graph nodes representing these mentions are also merged. A special treatment to date entity (see "date-entity" in Figure 1) and named entity ("country") includes collapsing the subtree to a "mega-node" whose surface form is the concatenation of the consisting concepts and relations (e.g., "date-entity_:year_2002_:month_1_:day_5"). These mega-nodes can then only be merged with other identical fragments. Finally, a 'ROOT' node is introduced; it is connected to the root of each sentence AMR graph, yielding a connected source graph.

Summary Graph Extraction. We hypothesize that a summary graph, containing the salient content of source texts, can be identified from the source graph via a trainable, feature-rich structured prediction framework. The framework iteratively performs *graph decoding* and *parameter update*. The former identifies an optimal summary graph using integer linear programming, while the latter performs parameter update by minimizing a loss function that measures the difference between the system-decoded summary graph and the goldstandard summary graph.

We use $G = (V, E)$ to represent the source graph. Let v_i and $e_{i,j}$ be a set of binary variables where $v_i = 1$ (or $e_{i,j} = 1$) indicates the corresponding source graph node (or edge) is selected to be included in the summary graph. The node and edge saliency are characterized by a set of features, represented using $\mathbf{f}(i)$ and $\mathbf{g}(i, j)$, respectively. $\boldsymbol{\theta}$ and $\boldsymbol{\phi}$ are the feature weights. Eq. (1) presents a scoring function for any graph G. It can be factorized into a sum of scores for selected nodes and edges. In particular, $[\boldsymbol{\theta}^\top \mathbf{f}(i)]_{v_i=1}$ denotes the node score (if v_i is selected) and $[\boldsymbol{\phi}^\top \mathbf{g}(i, j)]_{e_{i,j}=1}$ denotes the edge score.

$$score(G; \boldsymbol{\theta}, \boldsymbol{\phi}) = \sum_{i=1}^{N} v_i \underbrace{[\boldsymbol{\theta}^\top \mathbf{f}(i)]_{v_i}}_{\text{node score}} + \sum_{(i,j)\in E} e_{i,j} \underbrace{[\boldsymbol{\phi}^\top \mathbf{g}(i, j)]_{e_{i,j}}}_{\text{edge score}} \quad (1)$$

Features characterizing the graph nodes and edges are adopted from (Liu et al., 2015). They include concept/relation labels and their frequencies in the documents, average depth of the concept in sentence AMR graphs, position of sentences containing the concept/relation, whether the concept is a named entity/date entity, and the average length of concept word spans. We additionally include the concept TF-IDF score and if the concept occurs in a major news event (Wiki, 2018). All features are binarized.

The *graph decoding* process searches for the summary graph that maximizes the scoring function: $\hat{G} = \arg\max_G score(G)$. We can formulate graph decoding as an integer linear programming problem. Each summary graph corresponds to a set of values assigned to the binary variables v_i and $e_{i,j}$. We implement a set of linear constraints to ensure the decoded graph is connected, forms a tree structure, and limits to L graph nodes (Liu et al., 2015).

The *parameter update* process adjusts $\boldsymbol{\theta}$ and $\boldsymbol{\phi}$ to minimize a loss function capturing the difference between the system-decoded summary graph ($\hat{G}$) and the goldstandard summary graph (G^*). Eq. (2) presents the structured perceptron loss. Minimizing this loss function with respect to $\boldsymbol{\theta}$ and $\boldsymbol{\phi}$ is straightforward. However, the structured perceptron loss has problems when the goldstandard summary graph G^* is unreachable via the graph decoding process. In that case, there remains a gap between $score(\hat{G})$ and $score(G^*)$ and the loss cannot be further minimized. The structured ramp loss (Eq. (3)) addresses this problem by performing cost-augmented decoding. It introduces a cost function $cost(G; G^*)$ that can also be factored over graph nodes and edges. A cost of 1 is incurred if the system graph and the goldstandard graph disagree on whether a node (or edge) should be included. As a result, the first component of the loss function $\max_G(score(G) + cost(G; G^*))$ yields a decoded system graph that is slightly *worse* than $\hat{G} = \arg\max_G score(G)$; and the second component $\max_G(score(G) - cost(G; G^*))$ yields a graph that is slightly *better* than $\hat{G}$. The scoring difference between the two system graphs becomes the structured ramp loss we wish to minimize. This formulation is similar to the objective of the structured support vector machines (SSVMs, Tsochantaridis et al., 2005). Becase decent results have been reported by (Liu et al., 2015), we adopt structured ramp loss in all experiments.

$$\mathcal{L}_{\text{perc}}(\boldsymbol{\theta}, \boldsymbol{\phi}) = \max_G score(G) - score(G^*) = score(\hat{G}) - score(G^*) \quad (2)$$

$$\mathcal{L}_{\text{ramp}}(\boldsymbol{\theta}, \boldsymbol{\phi}) = \max_G(score(G) + cost(G; G^*)) - \max_G(score(G) - cost(G; G^*)) \quad (3)$$

3.2 Surface Realization

The surface realization component converts each summary graph to a natural language sentence. This is a nontrivial task, because AMR abstracts away from the source syntactic forms and an AMR graph may correspond to a number of valid sentence realizations. In this section we perform two subtasks that have not been investigated in previous studies. We first convert the summary AMR graphs to the PENMAN format (Figure 1), which is a representation that can be understood by humans. It is also the required input form for an AMR-to-text generator. We then leverage the AMR-to-text generator to generate English sentences from summary graphs.

Algorithm 1 presents our algorithm for transforming a summary graph to the PENMAN format. Because the summary graph is rooted and acyclic, we can extract all paths from the ROOT node to all leaves. These paths are sorted by the concept indices on the path, and the paths sharing the same ancestors will be processed in order. The core of Algorithm 1 is the *while* loop (line 9–35); it writes out one concept per line. An AMR concept can have three forms: a regular form ("c / country"), string literal ("Japan"), or a re-entrance ("g"). The last two are treated as "special forms." In these cases, a relation is first written out, followed by the special concept ($\mathcal{R}_{m',n'}$::$\mathcal{C}_{n'}$). "::" denotes a whitespace. A regular concept will be wrapped by a left bracket ($\mathcal{R}_{m',n'}$::"("::$\mathcal{C}_{n'}$, line 23/25) and a right bracket (($k-k'$)*")"::EOS, line 41). Finally, a proper number of closing brackets is postpended to each path (line 37–42).

To transform the PENMAN string to a summary sentence we employ the JAMR AMR-to-text generator (Flanigan et al., 2016). JAMR is the first full-fledged AMR-to-text generator. It is trained on approximately 10K sentences and achieves about 22% BLEU score on the test set. The system first transforms the input graph to a spanning tree, and then decodes it into a string using a tree-to-string transducer and a language model. The final output sentence is the highest-scoring sentence according to a feature-rich discriminatively trained linear model. We choose the JAMR AMR-to-text generator because of its competitive performance in the recent SemiEval evaluations (May and Priyadarshi, 2017).

Algorithm 1 An algorithm for transforming a summary graph to the PENMAN format.

Input: Triples: (src_concept, relation, tgt_concept).

1: $r \leftarrow$ index of the ROOT concept
2: $\mathcal{P} \leftarrow$ all paths from ROOT to leaves, sorted by the concept indices on the paths
3: ▶ Set all concepts and relations as unvisited
4: $visited[\mathcal{C}_m] \leftarrow$ FALSE, $\forall m$
5: $visited[\mathcal{R}_{m,n}] \leftarrow$ FALSE, $\forall m, n$
6: **for** $i = 1, \ldots, |\mathcal{P}|$ **do**
7: $flag\_special\_concept \leftarrow$ FALSE.
8: $k \leftarrow 0$
9: **while** $k < |p_i|$ **do**
10: $k \leftarrow k + 1$
11: $n' \leftarrow$ index of the k-th concept on the path
12: $m' \leftarrow$ index of the previous concept
13: **if** $visited[\mathcal{C}_{n'}]$ = FALSE **then**
14: ▶ Concept unvisited
15: $visited[\mathcal{C}_{n'}] \leftarrow$ TRUE
16: $visited[\mathcal{R}_{m',n'}] \leftarrow$ TRUE
17: $output$ += $(k-1)$*TAB
18: **if** $\mathcal{C}_{n'}$ is a string literal **then**
19: $output$ += $\mathcal{R}_{m',n'}$::$\mathcal{C}_{n'}$
20: $flag\_special\_concept \leftarrow$ TRUE
21: BREAK
22: **else if** $k < |p_i|$ **then**
23: $output$ += $\mathcal{R}_{m',n'}$::"("::$\mathcal{C}_{n'}$::EOS
24: **else**
25: $output$ += $\mathcal{R}_{m',n'}$::"("::$\mathcal{C}_{n'}$
26: **end if**
27: **else if** $visited[\mathcal{R}_{m',n'}]$ = FALSE **then**
28: ▶ Concept reentrance
29: $visited[\mathcal{R}_{m',n'}] \leftarrow$ TRUE
30: $output$ += $(k-1)$*TAB
31: $output$ += $\mathcal{R}_{m',n'}$::$\mathcal{C}_{n'}$
32: $flag\_special\_concept \leftarrow$ TRUE
33: BREAK
34: **end if**
35: **end while**
36: ▶ Output path ending brackets and EOS.
37: $k' \leftarrow$ tracing the path backwards to find position of the closest ancestor who has an unvisited child; if none exists, $k' \leftarrow 0$
38: **if** $flag\_special\_concept$ = TRUE **then**
39: $output$ += $(k-k'-1)$*")"::EOS
40: **else**
41: $output$ += $(k-k')$*")"::EOS
42: **end if**
43: **end for**

3.3 Source Sentence Selection

We seek to generate an abstractive summary containing multiple sentences from a cluster of documents discussing a single topic (e.g., health and safety). Each summary sentence will cover a topic aspect; it is generated by fusing a set of relevant source sentences. We thus perform clustering on all source sentences to find salient topic aspects and their corresponding sets of similar sentences. Spectral clustering has been shown to perform strongly on different clustering problems (Ng et al., 2002; Yogatama and Tanaka-Ishii, 2009). The approach constructs an affinity matrix by applying a pairwise similarity function to all source sentences. It then calculates the eigenvalues of the matrix and performs clustering in the low-dimensional space spanned by the largest eigenvectors. A large cluster indicates a salient topic aspect. We focus on the M largest clusters and extract N sentences from each cluster.[1] These sentences have the highest similarity scores with other sentences in the cluster. The selected sets of relevant sentences are later fed to the content planning component to generate summary AMR graphs.

Training the content planning component, however, requires sets of source sentences paired with their goldstandard summary graphs. Manually selecting sets of sentences and annotating summary graphs is costly and time-consuming. Instead, we leverage human reference summaries to create training instances. We obtain summary graphs by AMR-parsing sentences of human reference summaries. For every reference sentence, we further extract a set of source sentences. They are judged similar to the reference sentence via a similarity metric. The summary AMR graphs and sets of source sentences thus form the training data for content planning. We gauge how best to select source sentences by exploring different similarity metrics. In particular, (i) **LCS** calculates the longest common subsequence between a candidate source sentence and the reference sentence; (ii) **VSM** represents sentences using the vector space model and calculates the cosine similarity between the two sentence vectors; (iii) **Smatch** (Cai and Knight, 2013) calculates the F-score of AMR concepts between the candidate and reference sentences; (iv) **Concept Coverage** selects source sentences to maximize the coverage of AMR concepts of the reference sentence. We experiment with these source sentence selection strategies and compare their effectiveness in Section §5.1.

4 Datasets and Baselines

We perform experiments on standard multi-document summarization datasets[2], prepared by the NIST researchers for DUC/TAC competitions and later exploited by various summarization studies (Nenkova and McKeown, 2011; Hong et al., 2014; Yogatama et al., 2015). A summarization instance includes generating a text summary containing 100 words or less from a cluster of 10 source documents discussing a single topic. 4 human reference summaries are provided for each cluster of documents; they are created by NIST assessors. We use the datasets from DUC-03, DUC-04, TAC-09, TAC-10, and TAC-11 in this study, containing 30/50/44/46/44 clusters of documents respectively.

We compare our AMR summarization framework with a number of extractive (*ext*-$*$) and abstractive (*abs*-$*$) summarization systems, including the most recent neural encoder-decoder architecture (See et al., 2017). They are described as follows.

- *ext*-**LexRank** (Erkan and Radev, 2004) is a graph-based approach that computes sentence importance based on the concept of eigenvector centrality in a graph representation of source sentences;
- *ext*-**SumBasic** (Vanderwende et al., 2007) is an extractive approach that assumes words occurring frequently in a document cluster have a higher chance of being included in the summary;
- *ext*-**KL-Sum** (Haghighi and Vanderwende, 2009) describes a method that greedily adds sentences to the summary so long as it decreases the KL divergence;
- *abs*-**Opinosis** (Ganesan et al., 2010) generates abstractive summaries by searching for salient paths on a word co-occurrence graph created from source documents;

[1] We use N=M=5 in our experiments. This setting fuses 5 source sentences to a summary sentence. It then produces 5 summary sentences for each topic, corresponding to the average number of sentences in human summaries.

[2] https://duc.nist.gov/data.html https://tac.nist.gov/data/index.html

Approach	Nodes			(Oracle) Nodes			Edges			(Oracle) Edges		
	P	**R**	**F**	**P**	**R**	**F**	**P**	**R**	**F**	**P**	**R**	**F**
LCS	16.7	26.7	19.9	31.5	49.5	37.6	6.7	8.0	6.9	16.1	18.7	16.6
Smatch	20.9	33.2	24.9	33.2	52.0	39.6	9.3	10.7	9.4	17.2	20.1	17.8
Concept Cov.	**25.0**	**40.3**	**30.1**	**48.8**	**77.5**	**58.7**	7.3	10.0	8.0	18.9	**25.3**	20.8
VSM	24.0	38.6	28.8	40.8	64.3	48.9	**9.6**	**11.3**	**9.8**	**21.1**	25.1	**22.1**

Table 1: Summary graph prediction results on the DUC-04 dataset. The scores measure how well the predicted summary graphs match reference summary graphs on nodes and edges. Reference summary graphs are created by parsing reference summary sentences using the CAMR parser. "Oracle" results are obtained by performing only cost-based decoding. They establish an upper bound for the respective approaches.

- *abs*-**Pointer-Generator** (See et al., 2017) describes a neural encoder-decoder architecture. It encourages the system to copy words from the source text via pointing, while retaining the ability to produce novel words through the generator. It also includes a coverage mechanism to keep track of what has been summarized, thus reducing word repetition. The pointer-generator networks have not been tested for multi-document summarization. In this study we evaluate their performance on the DUC/TAC datasets.

5 Experimental Results

In this section we evaluate our AMR summarization framework. We are interested in knowing how well the system performs on predicting summary graphs from sets of relevant source sentences (§5.1). We also investigate the system's performance on generating abstractive summaries and its comparison with various baselines (§5.2). Finally, we provide an analysis on system summaries and outline challenges and opportunities for advancing this line of work (§5.3).

5.1 Results on Summary Graph Prediction

Graph prediction results on the DUC-04 dataset (trained on DUC-03) are presented in Table 1. We report how well the decoded summary graphs match goldstandard summary graphs on nodes (concepts) and edges (relations). We compare several strategies to select sets of source sentences. The goldstandard summary graphs are created by parsing the reference summary sentences via the CAMR parser (Wang et al., 2015b). Note that we cannot obtain goldstandard summary graphs for sets of source sentences selected by spectral clustering. This approach therefore is not evaluated for graph prediction. The system-decoded summary graphs are limited to 15 graph nodes, corresponding to the average number of words in reference summary sentences (stopwords excluded). We additionally report "Oracle" decoding results, obtained by performing only cost-based decoding $\hat{G} = \arg\max_G(-cost(G; G^*))$ on the source graph, where G^* is the goldstandard summary graph. The oracle results establish an upper bound for the respective approaches.

We observe that node prediction generates better results than edge prediction. Using 'Concept Cov,' the system-decoded summary graphs successfully preserve 40.3% of the goldstandard summary concepts, and this number increases to 77.5% when using oracle decoding, indicating the content planning component is effective at identifying important source concepts and preserving them in summary graphs. 'VSM' performs best on edge prediction. It achieves an F-score of 9.8% and the oracle decoding further boosts the performance to 22.1%. We observe that only 42% of goldstandard summary bigrams appear in the source documents, serving as a cap for edge prediction. The results suggest that 'VSM' is effective at selecting sets of source sentences containing salient source relations. The high performance on summary node prediction but low on edge prediction suggests that future work may consider increasing the source graph connectivity by introducing edges between concepts so that salient summary edges can be effectively preserved.

5.2 Results on Summarization

In Table 2 we report the summarization results evaluated by ROUGE (Lin, 2004). In particular, R-1, R-2, and R-SU4 respectively measure the overlap of unigrams, bigrams, and skip bigrams (up to 4 words)

	System	ROUGE-1			ROUGE-2			ROUGE-SU4		
		P	R	F	P	R	F	P	R	F
DUC 2004	*ext*-SumBasic	37.5	24.9	29.5	5.3	3.6	4.3	11.1	7.3	8.6
	ext-KL-Sum	31.1	31.1	31.0	6.0	6.1	6.0	10.2	10.3	10.2
	ext-LexRank	34.3	34.6	34.4	7.1	7.2	7.1	11.1	11.2	11.2
	abs-Opinosis	36.5	23.7	27.5	7.2	4.3	5.1	11.7	7.4	8.6
	abs-Pointer-Gen-all	37.5	20.9	26.5	8.0	4.4	**5.6**	12.3	6.7	8.5
	abs-Pointer-Gen	33.2	21.5	25.6	5.8	3.8	4.5	10.3	6.6	7.9
	abs-AMRSumm-Clst	29.9	30.5	**30.2**	4.1	4.2	4.1	8.7	8.9	**8.8**
	abs-AMRSumm-VSM	36.7	39.0	**37.8**	6.5	6.9	**6.6**	11.4	12.2	**11.8**
TAC 2011	*ext*-SumBasic	37.3	28.2	31.6	6.9	5.5	6.1	11.8	9.0	10.1
	ext-KL-Sum	31.2	31.4	31.2	7.1	7.1	7.1	10.5	10.6	10.6
	ext-LexRank	32.9	33.3	33.1	7.4	7.6	7.5	11.1	11.2	11.1
	abs-Opinosis	38.0	20.4	25.2	8.6	4.0	5.1	12.9	6.5	8.1
	abs-Pointer-Gen-all	37.3	22.2	27.6	7.8	4.6	**5.8**	12.2	7.1	8.9
	abs-Pointer-Gen	34.4	21.6	26.2	6.9	4.4	5.3	10.9	6.8	8.2
	abs-AMRSumm-Clst	32.2	31.7	**31.9**	4.7	4.7	4.7	9.8	9.7	**9.7**
	abs-AMRSumm-VSM	40.1	42.3	**41.1**	8.1	**8.5**	**8.3**	13.1	13.9	**13.5**

Table 2: Summarization results on DUC-04 and TAC-11 datasets. We compare the AMR summarization framework (AMRSumm-*) with both extractive (*ext*-*) and abstractive (*abs*-*) summarization systems.

between system and reference summaries. Our AMR summarization framework outperforms all other abstractive systems with respect to R-1 and R-SU4 F-scores on both DUC-04 (trained on DUC-03) and TAC-11 (trained on TAC-09,10) datasets. "AMRSumm-VSM" further produces the highest R-2 F-scores. We conjecture that the R-2 scores of AMRSumm-* are related to the performance of the AMR-to-text generator (Flanigan et al., 2016). When it transforms a summary graph to text, there can be multiple acceptable realizations (e.g., "I hit my hand on the table" or "My hand hit the table") and the one chosen by the AMR generator may not always be the same as the source text. Because abstractive systems are expected to produce novel words, they may yield slightly inferior results to the best extractive system (LexRank). Similar findings are also reported by Nallapati et al. (2017) and See et al. (See et al., 2017).

We experiment with two variants of the pointer-generator networks: "Pointer-Generator-all" uses all source sentences of the document set and "Pointer-Generator" uses the source sentences selected by spectral clustering, hence the same input as "AMRSumm-Clst." We observe that "AMRSumm-Clst" performs stronger than "Pointer-Generator" at preserving salient summary concepts, yielding R-1 F-scores of 30.2% vs. 25.6% and 31.9% vs. 26.2% on DUC-04 and TAC-11 datasets. Further, we found that the summaries produced by the pointer-generator networks are more extractive than abstractive. We report the percentages of summary n-grams contained in the source documents in Figure 3. "Pointer-Generator-all" has 99.6% of unigrams, 95.2% bigrams, and 87.2% trigrams contained in the source documents (DUC-04). In contrast, the ratios for human summaries are 85.2%, 41.6% and 17.1%, and for "AMRSumm-Clst" the ratios are 84.6%, 31.3% and 8.4% respectively. Both human summaries and "AMRSumm-Clst" summaries tend to be more abstractive, with fewer bigrams/trigrams appeared in the source. These results suggest that future abstractive systems for multi-document summarization may need to carefully balance between copying words from the source text with producing new words/phrases in order to generate summaries that resemble human abstracts.

5.3 Result Analysis

Table 3 shows results of the AMR-Summ framework with different system configurations. We use CAMR (Wang et al., 2015b) to parse source sentences into AMR graphs during training, and apply either JAMR (Flanigan et al., 2014) or CAMR to parse sentences at test time. We observe that the quality of AMR parsers has an impact on summarization performance. In particular, JAMR reports 58% F-score and CAMR reports 63% F-score for parsing sentences. The inter-annotator agreement places

	Approach	JAMR P	JAMR R	JAMR F	CAMR P	CAMR R	CAMR F	(Oracle) CAMR P	(Oracle) CAMR R	(Oracle) CAMR F
ROUGE-1	AMRSumm-Clst	29.0	29.8	29.4	29.9	30.5	30.2	36.4	37.8	37.1
	AMRSumm-Concept Cov	36.3	37.8	**36.9**	36.9	39.3	**38.1**	46.9	49.8	**48.3**
	AMRSumm-VSM	35.9	37.2	36.5	36.7	39.0	37.8	43.3	46.1	44.6
ROUGE-2	AMRSumm-Clst	3.2	3.3	3.2	4.1	4.2	4.1	6.0	6.3	6.1
	AMRSumm-Concept Cov	4.8	5.0	**4.9**	5.7	6.0	5.8	9.8	10.4	**10.1**
	AMRSumm-VSM	4.6	4.8	4.7	6.5	6.9	**6.6**	9.7	10.3	10.0

Table 3: Summarization results of the AMR-Summ framework on the DUC-04 dataset. "JAMR" uses the JAMR parser (Flanigan et al., 2014) to produce AMR graphs for source sentences, while "CAMR" uses the CAMR parser (Wang et al., 2015b). "Oracle" results are obtained by performing only cost-based decoding.

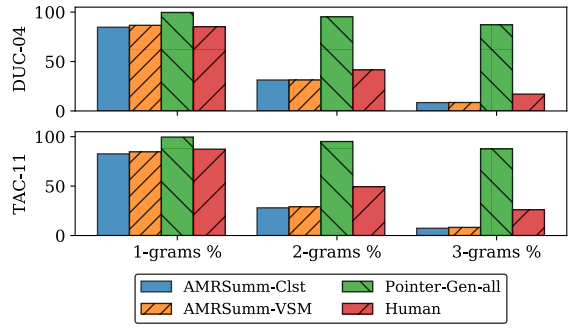

Figure 3: Percentages of summary n-grams contained in the source documents. Both human summaries and AMRSumm summaries are highly abstractive, with few bigrams and trigrams contained in the source. Pointer-Generator summaries appear be more extractive than abstractive.

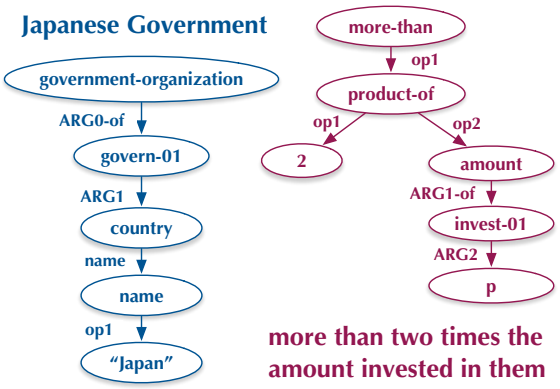

Figure 4: Example AMR for text segments.

an upper bound of 83% F-score on expected parser performance (Wang et al., 2015b). There remains a significant gap between the current parser performance and the best it can achieve. Consequently, we notice that there is a gap of 1∼2 points in terms of ROUGE scores when comparing summaries produced using the two parsers. We notice that source sentence selection strategies making use of reference summary sentences produces better results than 'AMRSumm-Clst.' Using oracle decoding further boosts the summarization performance by 7-10% for R-1 F-score and 2-5% for R-2 F-score.

When examining the source and summary graphs, we notice that a simplified AMR representation could be helpful to summarization. As a meaning representation grounded in linguistic theory, AMR strives to be comprehensive and accurate. However, a summarization system may benefit from a reduced graph representation to increase the algorithm robustness. For example, the large 'semantic content units' could be collapsed to "mega-nodes" in some cases. Figure 4 shows two examples. In the first example ("Japanese Government"), the human annotator chooses to decompose derivational morphology given that a relative clause paraphrase is possible (Schneider et al., 2015). It produces 5 concept nodes, representing "government organization that governs the country of Japan." In the second example, "more than two times the amount invested in them" also has fine-grained annotation. For the purpose of summarization, these graph fragments could potentially be collapsed to "mega-nodes" and future AMR parsers may consider working on reduced AMR graphs.

6 Conclusion

In this paper we investigated the feasibility of utilizing the AMR formalism for multi-document summarization. We described a full-fledged approach for generating abstractive summaries from multiple source documents. We further conducted experiments on benchmark summarization datasets and showed that the AMR summarization framework performs competitively with state-of-the-art abstractive approaches. Our findings suggest that the abstract meaning representation is a powerful semantic formalism that holds potential for the task of abstractive summarization.

Abstract

In this work, we aim at developing an unsupervised abstractive summarization system in the multi-document setting. We design a paraphrastic sentence fusion model which jointly performs sentence fusion and paraphrasing using skip-gram word embedding model at the sentence level. Our model improves the information coverage and at the same time abstractiveness of the generated sentences. We conduct our experiments on the human-generated multi-sentence compression datasets and evaluate our system on several newly proposed Machine Translation (**MT**) evaluation metrics. Furthermore, we apply our sentence level model to implement an abstractive multi-document summarization system where documents usually contain a related set of sentences. We also propose an optimal solution for the classical summary length limit problem which was not addressed in the past research. For the document level summary, we conduct experiments on the datasets of two different domains (e.g., news article and user reviews) which are well suited for multi-document abstractive summarization. Our experiments demonstrate that the methods bring significant improvements over the state-of-the-art methods.

1 Introduction

The task of automatic document summarization aims at finding the most relevant informations in a text and presenting them in a condensed form. A good summary should retain the most important contents of the original document or a cluster of related documents, while being coherent, non-redundant and grammatically readable. There are two types of summarizations: abstractive summarization and extractive summarization. Abstractive methods need extensive natural language generation to rewrite the sentences (Chali et al., 2017). Therefore, research community is focusing more on extractive summaries, which selects salient (important) sentences from the source document without any modification to create a summary. The abstractive techniques which are traditionally used are sentence compression, syntactic reorganization and lexical paraphrasing. Summarization is classified as single-document or multi-document based upon the number of source document. The information overlap between the documents from the same topic makes the multi-document summarization more challenging than the task of summarizing single documents. However, in case of multi-document summarization where source documents usually contain similar information, the extractive methods would produce redundant summary or biased towards specific source document (Nayeem and Chali, 2017a).

Multi-sentence compression (**MSC**) can be a useful solution for the above problem. It usually takes a group of related sentences and produces an output sentence through merging the sentences about the same topic, retaining the most important information and still maintain the grammaticality of the generated sentence. MSC is a text-to-text generation process in which a novel sentence is produced as a result of summarizing a set of similar sentences originally called sentence fusion (Barzilay and McKeown, 2005). On the other hand, lexical paraphrasing aims at replacing some selected words with other similar words while preserving the meaning of the original text. A good lexical substitution for a target word needs to be semantically similar to the target word and compatible with the given context (Melamud et al., 2015).

Proceedings of the 27th International Conference on Computational Linguistics, pages 1191–1204
Santa Fe, New Mexico, USA, August 20-26, 2018.

For example, the sentence "Jack composed these verses in 1995" could be lexically paraphrased into "Jack wrote these lines in 1995" without altering the sense of the initial sentence. The contributions of this paper are as follows:

- We design a novel abstractive sentence generation model which jointly performs sentence fusion and paraphrasing using skipgram word embedding model.
- We apply our sentence level model to design a full abstractive multi-document summarization system and achieved the state-of-the-art results on two different datasets. Different from the recent neural abstractive models, our model is completely unsupervised, full abstractive (not limited to deletion based compressions) and applied to multi-document summarization.
- We also propose an optimal solution for the classical summary length limit problem in multi-document setting.

2 Related Work

Abstractive summarization is generally much more difficult which involves sophisticated techniques for meaning representation, content organization, sentence compression, sentence fusion, paraphrasing etc. There has been a huge interest on compressive document summarization that tries to compress original sentences to form a summary (Clarke and Lapata, 2006; Clarke and Lapata, 2008; Filippova, 2010) as a first intermediate step towards abstractive summarization. Compressive summarization techniques include sentences which are compressed from original sentences without further modifications other than word deletion. Sentence compression involving two or more sentences is called **MSC** (Multi-Sentence Compression). Most of the previous MSC approaches rely on the syntactic parsing to build the dependency tree for each related sentence in a cluster for producing grammatical compressions (Filippova and Strube, 2008). Unfortunately, syntactic parsers are not available for all the languages. As an alternative, word graph-based approaches that only require a POS tagger and a list of stopwords have been proposed first by (Filippova, 2010). A directed word graph is constructed in which nodes represent words and edges represent the adjacency between words in a sentence. Hence, compressed sentences are generated by finding k-shortest paths in the word graph. (Boudin and Morin, 2013) improved Filippova's approach by re-ranking the fusion candidate paths according to keyphrases to generate more informative sentences. However, grammaticality is sacrificed to improve informativity in these works (Nayeem and Chali, 2017b).

(Banerjee et al., 2015) proposed an abstractive multi-document summarization system using sentence fusion approach of (Filippova, 2010) combined with Integer Linear Programming (**ILP**) sentence selection. Following (Banerjee et al., 2015) work, several recent approaches have been proposed with slight modifications. Multiword Expressions (**MWE**) was exploited in (ShafieiBavani et al., 2016) to produce more informative compressions. Recently, (Tuan et al., 2017) include syntax factor along with (Banerjee et al., 2015) to improve performance. However, all the above mentioned systems try to produce compressions by copying the source sentence words, no paraphrasing is involved in the process.

Recently end-to-end training with encoder-decoder neural networks have achieved huge success in case of abstractive summarization. These systems have adopted techniques such as encoder-decoder with attention (Bahdanau et al., 2015; Luong et al., 2015) neural network models from the field of machine translation to model the sentence summarization task. (Rush et al., 2015) was the first to use neural sequence-to-sequence learning in headline generation task from a single document. Unfortunately, this line of research under the term sentence summarization (Rush et al., 2015), which can generate only a single sentence, somewhat misleadingly called text summarization in some follow-up research works (Nallapati et al., 2016; Chopra et al., 2016; Suzuki and Nagata, 2017; Zhou et al., 2017; Ma et al., 2017). There are some limitations to the above mentioned models, one is that the the produced output is also very short (about 75 characters). Same as the headlines, their model produces ungrammatical sentences during generation. However, there are some recent attempts which uses **CNN/DailyMail** corpus (Hermann et al., 2015) as a supervised training data to generate multi-sentence summary from a single document (See

et al., 2017; Li et al., 2017b; Paulus et al., 2017; Narayan et al., 2018a; Narayan et al., 2018b). The recent abstractive summarization models actually produce compressive summaries by deleting the words form a single source document, no direct paraphrasing was involved in the process. Hence, no new words were generated which are different form the source document words (other than morphological variation), which is pointed out by their own experimental results. Very recently, some researchers employ neural network based framework to tackle the summarization problem in multi-document setting (Yasunaga et al., 2017; Li et al., 2017a). (Yasunaga et al., 2017) is limited to extractive summmarization. On the other hand, (Li et al., 2017a) is limited to compressive summary generation using an ILP based model, and there is no explicit redundancy control in the summary side. Unfortunately, full abstractive summarization in multi-document setting still lacks satisfactory solutions due to the lack of large multi-document summarization datasets needed to train the computationally expensive sequence-to-sequence models. In this paper, we tackle this issue in an unsupervised way using deep representation learning.

3 Paraphrastic Sentence Fusion Model

Most of the previous works rely only on deletion based compressions, either sentence compression or fusion for abstracting sentences. Instead, in this paper we take the first step towards finding a joint representation for sentence abstraction using sentence fusion and lexical paraphrase rather than treating these two independently.

3.1 Word Graph Construction for Sentence Fusion

Given a cluster of related sentences we construct a word-graph following (Filippova, 2010; Boudin and Morin, 2013). Let $S = \{s_1, s_2, ..., s_n\}$ be a set of related sentences, we construct a graph $G = (V, E)$ by iteratively adding sentences to it. The vertices are the words along with the parts-of-speech (POS) tags and directed edges are formed by simply connecting the adjacent words in the sentences. Once the first sentence is added, words from the other related sentences are mapped onto a node in the graph provided that they have exactly the same lower cased word form and the same POS tag. Each sentence is connected to dummy start and end nodes to mark the beginning and ending of the sentences. Figure 1 illustrates an example word-graph for the following two sentences,

S1: In Asia Japan Nikkei lost 9.6% while Hong Kongs Hang Seng index fell 8.3%.

S2: Elsewhere in Asia Hong Kongs Hang Seng index fell 8.3% to 12,618.

As we can see, the two input sentences contain similar information, but differs in sentence length, syntax, and the detail of information. The solid directed arrows connect the words in the first sentence S1, while the dotted arrows join the words in the second sentence S2. After constructing the word-graph using (Filippova, 2010; Boudin and Morin, 2013) as described above, we can generate K-shortest paths from dummy start node to end node in the word graph (see Figure 1). For example, we can generate these paths:

Ex1: In Asia Hong Kongs Hang Seng index fell 8.3%.

Ex2: Elsewhere in Asia Hong Kongs Hang Seng index fell 8.3%.

Ex3: Elsewhere in Asia Japan Nikkei lost 9.6% while Hong Kongs Hang Seng index fell 8.3%.

The above examples are sampled from the K-shortest paths generated from the word-graph G (K is usually ranges from 50 to 200 according to the literature (Filippova, 2010; Boudin and Morin, 2013)). The main challenge is to rank these K fused sentences according to the information they contain. Hence, we design a candidate ranking strategy to sort the generated K-shortest paths based on the information coverage.

3.2 Candidate Ranking

We rank the fused candidates by applying **TextRank** algorithm (Mihalcea and Tarau, 2004) which involves constructing an undirected graph where candidates are vertices, and weighted edges are formed by connecting candidate sentences by a similarity metric. Original TextRank algorithm determines the similarity based on the lexical overlap. However, this algorithm has a serious drawback: If two sentences

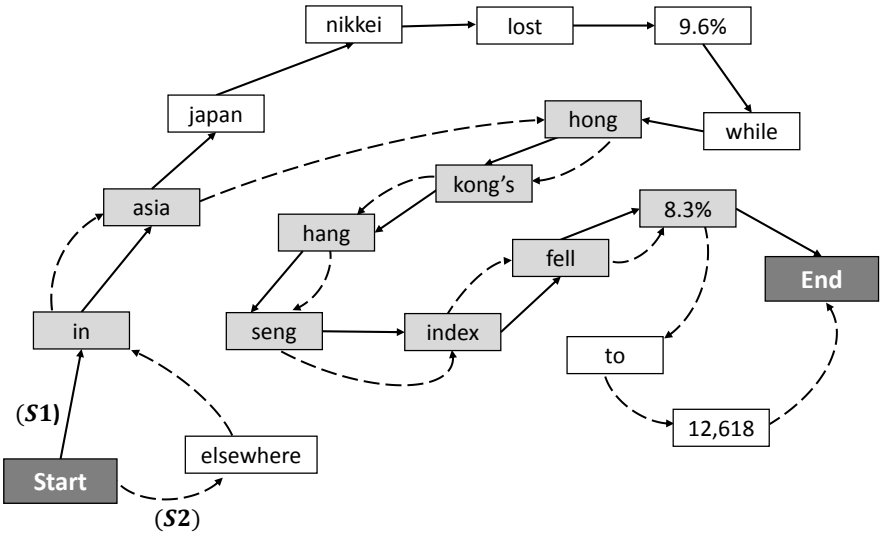

Figure 1: Constructed Word graph and a possible compression path (light gray nodes)

are talking about the same topic without using any overlapped words, there will be no edge between them. Instead, we apply the following representation of a sentence to capture the semantic information.

3.2.1 Sentence Embedding

A sentence is a sequence of words $\mathbf{S} = (w_1, w_2, ..., w_L)$, where L is the length of the sentence. We encode a sentence using bi-directional GRUs (Cho et al., 2014). In the simplest uni-directional case, while reading input symbols from left to right, a GRU learns the hidden annotations h_t at time t with

$$h_t = \mathbf{GRU}(h_{t-1}, e(w_t)) \tag{1}$$

where, the $h_t \in \mathbb{R}^n$ encodes all content seen so far at time t which is computed from h_{t-1} and $e(w_t)$, where $e(w_t) \in \mathbb{R}^m$ is the m-dimensional embedding of the current word w_t. We use 300-dimensional pre-trained word2vec embeddings[1](Mikolov et al., 2013) for each word as input to GRU.

As shown in Figure 2, **Bi-GRU** processes the input sentence in both forward and backward direction with two separate hidden layers calculated with GRUs, obtains the forward hidden states $(\overrightarrow{h_1}, \ldots, \overrightarrow{h_L})$ and the backward hidden states $(\overleftarrow{h_1}, \ldots, \overleftarrow{h_L})$. For each position t, we simply concatenate both forward and backward states into the final hidden state:

$$h_t = \overrightarrow{h_t} \oplus \overleftarrow{h_t} \tag{2}$$

in which operator $\oplus$ indicates concatenation. $\overrightarrow{h_t}$ is calculated using Eq. (1) and $\overleftarrow{h_t}$ is calculated using the following equation.

$$\overleftarrow{h_t} = \mathbf{GRU}(\overleftarrow{h_{t+1}}, e(w_t)) \tag{3}$$

$\overrightarrow{h_0}$ is initialized as zero vector, and the output sentence embedding x_i for the sentence S_i is the last hidden state:

$$x_i = h_L \tag{4}$$

We start by constructing an undirected graph where fused sentence candidates are vertices, and weighted edges are formed by measuring the cosine distance between the candidate sentence embeddings obtained from equation (4). After we have our graph, we run the TextRank (Mihalcea and Tarau,

[1]https://code.google.com/archive/p/word2vec/

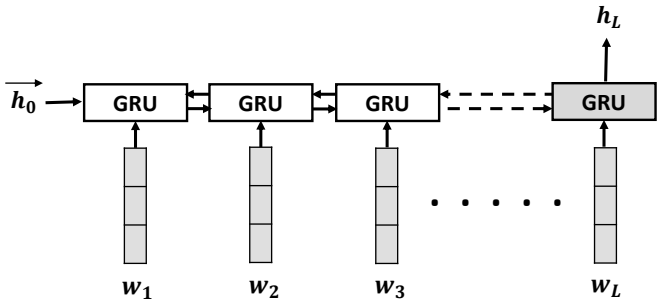

Figure 2: Sentence Embedding

2004) algorithm on it. This involves initializing a score of 1 for each vertex, and repeatedly applying the TextRank update rule until convergence. After reaching convergence, we extract the fused candidate sentences along with TextRank scores. For instance, $Rank(S_i)$ indicates the importance score assigned to sentence S_i.

3.3 Context Sensitive Lexical Substitution

3.3.1 Target Word Identification for Substitution

After constructing the word-graph as presented in section 3.1, we take only the nouns and verbs for possible substitution candidates from the word-graph G. We didn't consider the named entities, where, $NE \in \{PER; LOC; ORG; MISC\}$ for the substitution.

3.3.2 Substitution Selection

The **PPDB 2.0** (Pavlick et al., 2015) provides millions of lexical, phrasal and syntactic paraphrases which come into packages of different sizes (going from S to XXXL). For our model, we use the lexical XXL. For instance, we can gather lexical substitution set S = {*gliding, sailing, diving, travelling*} for the target word ($t = flying$) from PPDB 2.0. We hardcoded the model to select substitutes with the same POS tag and that are not a morphological variant (*e.g., fly, flew, flown*).

3.3.3 Substitution Ranking

Word embeddings are low-dimensional vector representations of words such as **word2vec** (Mikolov et al., 2013) that recently gained much attention in various semantic tasks. **Word2vecf** (Levy and Goldberg, 2014) is an extension of word2vec to produce syntax-based word embeddings. They show that these embeddings tend to capture functional word similarity (as in *manage* $\rightarrow$ *supervise*) rather than topical similarity (as in *manage* $\rightarrow$ *manager*). We use the word and context vectors released by (Melamud et al., 2015) which was shown to perform strongly on lexical substitution task. These embeddings contain 600d (600 dimension) vectors for 173k words and about 1M syntactic contexts processed using the dependency based word2vecf model (Levy and Goldberg, 2014). Their measure $addCos$ for estimating the appropriateness of a substitute s from the substitution set S, for the target word t in the set of the target word's context elements $C = \{c_1, c_2, ..., c_n\}$, which is defined as follows,

$$addCos(s|t, C) = \frac{cos(s, t) + \sum_{c \in C} cos(s, c)}{|C| + 1}$$

Finally, we select the best substitution $\mathbf{s}$ according to maximum $\mathbf{addCos}$ scores over $\mathbf{0.7}$ and attach it with the target word vertex $\mathbf{t}$ in the word-graph G along with the $\mathbf{addCos}$ score. For the other vertices which don't have substitution alternatives, we assign an $\mathbf{addCos}$ score of zero in the word-graph G.

3.3.4 Confidence Score

Once the substitutions are placed into the word-graph G, in order to maintain the grammaticality and the reliability of the final generated sentences, we use a 3-gram language model, which assigns probabilities to sequence of words in a generated candidate. Suppose that a candidate contains a sequence of m

words $\{w_1, w_2, w_3, \ldots, w_m\}$. The score **CS** (Confidence Score) assigned to each candidate is defined as follows:

$$CS(w_1, ..., w_m) = \frac{1}{1 - Score_{LM}(w_1, ..., w_m)}$$

In our experiment, we used a language model that is trained on the English Gigaword corpus[2]. In the word-graph G, for each substitution candidate we calculate the confidence score with the adjacent vertices (in our case words) and calculate their average. We also assign this confidence score with the substitution vertex in the word-graph G.

Finally, we rank the K candidate fusions and find the N-best paraphrastic sentence fusion which balances the information coverage and the abstractiveness. The score of a candidate sentence fusion c is given by the following linear combination between the candidate rank score and the abstractiveness score (where, we set $\alpha = 0.5$ to give equal importance and scaling the score to [0,1]).

$$score(c) = \alpha \cdot Rank(c) + (1 - \alpha) \cdot \sum_{V_i = V_{start}}^{V_{end}} addCos(\mathbf{V_i}) + CS(\mathbf{N}(\mathbf{V_i})) \quad (5)$$

where, $addCos(\mathbf{V_i})$ is the *addCos* score of the vertex V_i and $N(V_i)$ is the neighbours of the vertex V_i from the word-graph G.

4 Multi-Document Abstractive Summarization

In this section, we apply our sentence level paraphrastic fusion model to generate multi-document level abstractive summary under a certain length limit (L). Our system takes a set of related documents as input and preprocesses them which includes tokenization, Part-Of-Speech (POS) tagging, removal of stopwords, filtering punctuation marks and Lemmatization. We use **NLTK** toolkit[3] to preprocess each sentence to obtain a more accurate representation of the information. In the following, we successively describe each of the steps involved in the document summarization process.

4.1 Sentence Clustering

The sentence clustering step allows us to group similar sentences. We use a hierarchical agglomerative clustering (Murtagh and Legendre, 2014) with a complete linkage criteria. This method proceeds incrementally, starting with each sentence considered as a cluster, and merging the pair of similar clusters after each step using bottom up approach. The complete linkage criteria determines the metric used for the merge strategy, which means largest distance between a sentence in one cluster and a sentence in the other candidate cluster. In building the clusters, we use the cosine similarity between the sentence embeddings obtained from equation (5). We set a similarity threshold ($\tau = 0.5$) to stop the clustering process by using a hold out dataset **SICK**[4] of SemEval-2014 (Marelli et al., 2014) for getting optimal performance. If we cannot find any cluster pair with a similarity above the threshold ($\tau = 0.5$), the process stops, and the clusters are released. The clusters may be small, but are highly coherent as each sentence they contain must be similar to every other sentence in the same cluster. This sentence clustering step is very important due to two main reasons,

- Selecting at most one sentence from each cluster of related sentences will decrease redundancy from the summary side.
- Selecting sentences from the diverse set of clusters will increase the information coverage from the document side as well.

[2]Available : http://www.keithv.com/software/giga/ (We used the 64K NVP vocabulary version)
[3]http://www.nltk.org/
[4]http://clic.cimec.unitn.it/composes/sick.html

For each cluster of related sentences, we generate 10-best (N = 10) abstractive fused sentences using our model described in section 3, the generated sentences differ in lengths as well as information. However, for the clusters containing only one sentence, we use our context sensitive lexical substitution model presented in section 3.3 to generate just the abstractive version of the source sentence.

4.2 Abstractive Sentence Selection

In our work, we use the concept-based ILP framework introduced in (Gillick and Favre, 2009) with some suitable changes to select the best subset of sentences. This approach aims to extract sentences that cover as many important concepts as possible, while ensuring the summary length is within a given budgeted constraint. Unlike (Gillick and Favre, 2009) which uses bigrams as concepts, we use keyphrases as concepts. Keyphrases are the words or phrases that represent the main topics of a document. Sentences containing the most relevant keyphrases are important for the summary generation. We extract the keyphrases from the document cluster using **RAKE**[5] (Rose et al., 2010). We assign a weight to each keyphrase using the score returned by RAKE.

Let $\bar{w}_i$ be the weight of keyphrase i and k_i a binary variable that indicates the presence of keyphrase i in the selected parafused sentences. Let l_j be the number of words or characters in sentence j, s_j a binary variable that indicates the presence of sentence j in the selected parafused sentence set and L the length limit for the set. Let Occ_{ij} indicate the occurrence of keyphrase i in sentence j, the ILP formulation is,

$$max : (\sum_i \bar{w}_i k_i + \sum_j (score(s_j) + \frac{l_j}{L}) \cdot s_j) \tag{6}$$

$$Subject\ to : \sum_j l_j s_j \leq L \tag{7}$$

$$s_j Occ_{ij} \leq k_i, \quad \forall i, j \tag{8}$$

$$\sum_j s_j Occ_{ij} \geq k_i, \quad \forall i \tag{9}$$

$$\sum_{j \in g_c} s_j \leq 1, \quad \forall g_c \tag{10}$$

$$k_i \in \{0, 1\} \quad \forall i \tag{11}$$

$$s_j \in \{0, 1\} \quad \forall j \tag{12}$$

We try to maximize the weight of the keyphrases and our **ParaFuse** model's score (6), while avoiding repetition of those keyphrases (8, 9) and staying under the maximum number of words or characters allowed for the selected parafused sentences (7). In order to ensure at most one sentence per parafused cluster in the summary, we add an extra constraint (10), this will ensure non-redundancy from the summary side. In this process, we select the optimal combination of abstractive sentences that maximize information coverage while minimizing redundancy.

[5]https://github.com/aneesha/RAKE

4.3 Summary Length Limit Problem

One of the essential properties of the text summarization systems is the ability to generate a summary with a fixed length (**DUC 2004**, Task-2 (Multi-Document): Length limit = 100 Words). According to (Hong et al., 2014) all the multi-document summarizer from the previous research either truncated the summary to 100^{th} word, or removed the last sentence from the summary set. However, the first option produces a certain ungrammatical sentence, the later one can lose a lot of information in the worst case, if the sentences are long. Recently, (Kikuchi et al., 2016) propose four methods in order to tackle this issue, two of them are based on different decoding procedures without model architecture modification and the other two are learning-based, i.e., the models take the desired length information as input and encode it into the model architecture. However, their model is limited to headline generation task, where models generate a single sentence headline of a document. In this work, we tackle this issue in multi-document setting by generating N-best paraphrastic fusion length variations of a cluster of related sentences. Our model can effectively produce different length variations because of the shortest path strategy from start node to end node (see section 3.1 for the examples). In our ILP formulation for the document level summary generation, we try to maximize the total summary length in the objective function (equation (6)) to optimally solve the length limit problem. Under any circumstances, our model can choose a shorter variation of a sentence automatically to be included in the summary.

4.4 Experiments

In this section, we present our experimental details for assessing the performance of the sentence level paraphrastic fusion model and multi-document level abstractive summarization system as described above. We give details on the datasets we used, evaluation metrics, and the baseline systems used for comparison with our approach.

4.4.1 Sentence Level Experiments

We generate 50 shortest paths from start to end node for each cluster of related sentences using our paraphrastic sentence fusion model. The paths shorter than eight words or that do not contain a verb are filtered. To ensure pure abstractive compression generation, we remove the paths that have $cosineSimilarity \geq 0.9$ to any of the original sentence in the cluster. We then select 3-best candidates from K paths using the scoring function in equation (5). For fair evaluation, we also select the 3-best candidates for the baseline systems that we compare with our model.

Dataset: We conduct experiments on the human generated sentence fusion dataset released by (McKeown et al., 2010). This dataset consists of 300 English sentence pairs taken from newswire clusters accompanied by human-produced sentence fusions rewrites collected via Amazon's Mechanical Turk service[6]. We filtered the sentences which have no main verbs. The resulting set contains 296 pairs of sentences.

Evaluation Metric: We evaluate our system automatically using various automatic metrics. **BLEU** (Papineni et al., 2002) is the most commonly used metric for Machine Translation evaluation. BLEU relies on exact matching of n-grams and has no concept of synonymy or paraphrasing. **SARI** (Xu et al., 2016) a recently proposed metric which compares **S**ystem output **A**gainst **R**eferences and against the **I**nput sentence. SARI computes the arithmetic average of n-gram precision and recall of three rewrite operations: addition, copying, and deletion which correlates well with human references. **METEOR-E**[7] (Servan et al., 2016) is an augmented version of METEOR (Denkowski and Lavie, 2014) using distributed representations which can easily measure the abstractiveness. **Compression Ratio** is a measure of how terse a compression. A compression ratio of zero implies that the source sentence is fully uncompressed. We define **Copy Rate** as how many tokens are copied to the abstract sentence from the source sentence without paraphrasing in the following equation (13). Lower copy rate score means more paraphrasing is involved in the abstract sentence. Copy rate of 100% means no paraphrasing.

Input Sentences	Bush, who initially nominated Roberts to replace retiring Justice Sandra Day O'Connor, tapped him to lead the court the day after Rehnquist's death. President Bush initially nominated Roberts in July to succeed retiring Justice Sandra Day O'Connor.
(Filippova, 2010)	president bush initially nominated roberts to replace retiring justice sandra day o'connor .
(Boudin and Morin, 2013)	bush , who initially nominated roberts in july to succeed retiring justice sandra day o'connor , tapped him to lead the court the day after rehnquist 's death .
(Banerjee et al., 2015)	bush , who initially nominated roberts to replace retiring justice sandra day o'connor , tapped him to lead the court the day after rehnquist 's death .
Paraphrastic Fusion (*ours*)	president bush initially **recommended** roberts in july to **substitute** retiring justice sandra day o'connor , tapped him to **run** the court the day after rehnquist 's death .

Table 1: The output generated by the baseline and our system (the paraphrased words are marked bold)

Model	BLEU	SARI	METEOR-E	Compression Ratio	Copy Rate
(Filippova, 2010)	40.6	34.6	0.31	**0.57**	99.8
(Boudin and Morin, 2013)	**44.0**	37.2	0.36	0.42	99.9
(Banerjee et al., 2015)	42.3	36.5	0.34	0.45	99.8
Paraphrastic Fusion (*ours*)	42.5	**37.4**	**0.43**	0.41	**76.2**

Table 2: Comparison with baselines and our **Paraphrastic Fusion** model across different automatic evaluation metrics (the scores are averaged)

$$Copy\ Rate = \frac{|S_{orig} \cap S_{abs}|}{|S_{abs}|} \tag{13}$$

4.5 Baseline Systems and Results

We compare our system with (Filippova, 2010), (Boudin and Morin, 2013)[8] and (Banerjee et al., 2015)[9]. Table 1 shows the output generated by the baseline and our system. We report our system's performance compared with the baselines in terms of different evaluation metrics in Table 2. Our model balances the information coverage (**BLUE**, **SARI**) and complete abstractiveness (**METEOR-E**, **Copy Rate**) instead of over compressing the generated sentences (**Compression Ratio**). We get slightly higher score in **SARI** because of the multiple human abstractive rewrites along with input sentence. The **Copy Rate** score of other baseline systems clearly indicates the fact that they are doing completely deletion based compression, no paraphrasing is involved. Moreover, we also get higher score in **METEOR-E** metric because of the lexical substitution operation. As expected, we get little lower **BLEU** score compared to (Boudin and Morin, 2013) for two main reasons (1) We tried to balance between information coverage and abstractiveness (2) **BLEU** works well on surface level lexical overlap.

4.5.1 Multi-Document Level Experiments

Dataset: We consider the generic multi-document summarization dataset provided at Document Understanding Conference (**DUC 2004**)[10] which is one of the main benchmark dataset in the multi-document summarization field. It contains 50 document clusters and each is composed of 10 news wire articles about a given topic from the Associated Press and The New York Times that are published between 1998 to 2000. The dataset also contains multiple human-written summaries which are used for the evaluation of system-generated summaries. The **Opinosis** (Ganesan et al., 2010) is another dataset consists of short user reviews in 51 different topics collected from TripAdvisor, Amazon, and Edmunds. The dataset is well suited for multi-document summarization which includes 5 different golden summaries for each topic created by human authors.

Dataset	Models	R-1	R-2	R-WE-1	R-WE-2
DUC 2004	LexRank (Erkan and Radev, 2004)	35.95	7.47	36.91	7.91
	Submodular (Lin and Bilmes, 2011)	39.18	9.35	40.03	9.92
	RegSum (Hong and Nenkova, 2014)	38.57	9.75	39.12	10.33
	ILPSumm (Banerjee et al., 2015)	39.24	11.99	40.21	12.08
	PDG* (Yasunaga et al., 2017)	38.45	9.48	39.07	10.24
	ParaFuse_doc (*ours*)	**40.07**	**12.04**	**42.31**	**12.96**
Opinosis 1.0	TextRank (Mihalcea and Tarau, 2004)	27.56	6.12	28.20	6.45
	Opinosis (Ganesan et al., 2010)	32.35	9.13	33.54	9.41
	Biclique (Muhammad et al., 2016)	33.03	8.96	33.91	9.25
	ParaFuse_doc (*ours*)	**33.86**	**9.74**	**34.46**	**10.09**

Table 3: Results on DUC 2004 (Task-2) and Opinosis 1.0

Evaluation Metric: We evaluate our summarization system using **ROUGE**[11] (Lin, 2004) on **DUC 2004** (Task-2, Length limit (L) = 100 Words) and **Opinosis 1.0** (L = 15 Words). However, ROUGE scores are unfairly biased towards lexical overlap at surface level. Taking this into account, we also evaluate our system using **ROUGE-WE** (Ng and Abrecht, 2015), which considers word embeddings to compute the semantic similarity of the words. We report limited length recall performance for both the metrics, as our system generated summaries are forced to be concise through some constraints (such as length limit constraint). Therefore, we consider using just the recall score since precision is of less concern in this scenario.

4.5.2 Baseline Systems & Results

The summaries generated by the baseline **LexRank** (Erkan and Radev, 2004) and the state-of-the-art summarizers (**Submodular** (Lin and Bilmes, 2011) and **RegSum** (Hong and Nenkova, 2014)) on the DUC 2004 dataset were collected from (Hong et al., 2014). In case of **ILPSumm**[12] (Banerjee et al., 2015) and **PDG*** (Yasunaga et al., 2017), we use the author provided implementation to generate summary from their model. For Opinosis 1.0 dataset, we use an open source implementation of **TextRank** (Mihalcea and Tarau, 2004)[13]. Moreover, we use the author provided implementation for the **Opinosis** (Ganesan et al., 2010) and **Biclique** (Muhammad et al., 2016) to generate summaries. According to the Table 3, our multi-document level model **ParaFuse_doc** achieves the best summarization performance on all the ROUGE metrics for both the datasets. The slight increase in terms of **R-WE** metric clearly justifies the fact of abstractiveness proposed in this work which highly correlates with human references.

5 Conclusion

In this paper, we designed a new abstractive fusion generation model at the sentence level which jointly performs sentence fusion and paraphrasing. Our sentence level model is very well suited for full abstractive multi-document summarization which was justified by the experimental results on two benchmark datasets of different domains. Furthermore, we designed an optimal solution for the classical summary length limit problem in multi-document setting.

Abstract

Domain Adaptation arises when we aim at learning from source domain a model that can perform acceptably well on a different target domain. It is especially crucial for Natural Language Generation (NLG) in Spoken Dialogue Systems when there are sufficient annotated data in the source domain, but there is a limited labeled data in the target domain. How to effectively utilize as much of existing abilities from source domains is a crucial issue in domain adaptation. In this paper, we propose an adversarial training procedure to train a Variational encoder-decoder based language generator via multiple adaptation steps. In this procedure, a model is first trained on a source domain data and then fine-tuned on a small set of target domain utterances under the guidance of two proposed critics. Experimental results show that the proposed method can effectively leverage the existing knowledge in the source domain to adapt to another related domain by using only a small amount of in-domain data.

1 Introduction

Traditionally, Spoken Dialogue Systems are typically developed for various specific domains, including: finding a hotel, searching a restaurant (Wen et al., 2015a), or buying a tv, laptop (Wen et al., 2015b), flight reservations (Levin et al., 2000), etc. Such system are often requiring a well-defined ontology, which is essentially a data structured representation that the dialogue system can converse about. Statistical approaches to multi-domain in SDS system have shown promising results in how to reuse data in a domain-scalable framework efficiently (Young et al., 2013). Mrkšić et al. (2015) addressed the question of multi-domain in the SDS belief tracking by training a general model and adapting it to each domain.

Recently, Recurrent Neural Networks (RNNs) based methods have shown improving results in tackling the domain adaptation issue (Chen et al., 2015; Shi et al., 2015; Wen et al., 2016a; Wen et al., 2016b). Such generators have also achieved promising results when providing such adequate annotated datasets (Wen et al., 2015b; Wen et al., 2015a; Tran et al., 2017; Tran and Nguyen, 2017a; Tran and Nguyen, 2017b). More recently, the development of the variational autoencoder (VAE) framework (Kingma and Welling, 2013; Rezende and Mohamed, 2015) has paved the way for learning large-scale, directed latent variable models. This has brought considerable benefits to significant progress in natural language processing (Bowman et al., 2015; Miao et al., 2016; Purushotham et al., 2017; Mnih and Gregor, 2014), dialogue system (Wen et al., 2017; Serban et al., 2017).

This paper presents an adversarial training procedure to train a variational neural language generator via multiple adaptation steps, which enables the generator to learn more efficiently when in-domain data is in short supply. In summary, we make the following contributions: (1) We propose a variational approach for an NLG problem which benefits the generator to adapt faster to new, unseen domain irrespective of scarce target resources; (2) We propose two critics in an adversarial training procedure, which can guide the generator to generate outputs that resemble the sentences drawn from the target domain; (3) We propose a unifying variational domain adaptation architecture which performs acceptably well

Proceedings of the 27th International Conference on Computational Linguistics, pages 1205–1217
Santa Fe, New Mexico, USA, August 20-26, 2018.

in a new, unseen domain by using a limited amount of in-domain data; (4) We investigate the effectiveness of the proposed method in different scenarios, including ablation, domain adaptation, scratch, and unsupervised training with various amount of data.

2 Related Work

Generally, Domain Adaptation involves two different types of datasets, one from a source domain and the other from a target domain. The source domain typically contains a sufficient amount of annotated data such that a model can be efficiently built, while there is often little or no labeled data in the target domain. Domain adaptation for NLG have been less studied despite its important role in developing multi-domain SDS. Walker et al. (2001) proposed a SPoT-based generator to address domain adaptation problems. Subsequently, a system focused on tailoring user preferences (Walker et al., 2007), and controlling user perceptions of linguistic style (Mairesse and Walker, 2011). Moreover, a phrase-based statistical generator (Mairesse et al., 2010) using graphical models and active learning, and a multi-domain procedure (Wen et al., 2016a) via data counterfeiting and discriminative training.

Neural variational framework for generative models of text have been studied longitudinally. Chung et al. (2015) proposed a recurrent latent variable model VRNN for sequential data by integrating latent random variables into hidden state of a RNN model. A hierarchical multi scale recurrent neural networks was proposed to learn both hierarchical and temporal representation (Chung et al., 2016). Zhang et al. (2016) introduced a variational neural machine translation that incorporated a continuous latent variable to model underlying semantics of sentence pairs. Bowman et al. (2015) presented a variational autoencoder for unsupervised generative language model.

Adversarial adaptation methods have shown promising improvement in many machine learning applications despite the presence of domain shift or dataset bias, which reduce the difference between the training and test domain distributions, and thus improve generalization performance. Tzeng et al. (2017) proposed an improved unsupervised domain adaptation method to learn a discriminative mapping of target images to the source feature space by fooling a domain discriminator that tries to differentiate the encoded target images from source examples. We borrowed the idea of (Ganin et al., 2016), where a domain-adversarial neural network are proposed to learn features that are discriminative for the main learning task on the source domain, and indiscriminate with respect to the shift between domains.

3 Variational Domain-Adaptation Neural Language Generator

Drawing inspiration from Variational autoencoder (Kingma and Welling, 2013) with assumption that there exists a continuous latent variable z from a underlying semantic space of Dialogue Act (DA) and utterance pairs $(\mathbf{d}, \mathbf{y})$, we explicitly model the space together with variable $\mathbf{d}$ to guide the generation process, *i.e.*, $p(\mathbf{y}|z, \mathbf{d})$. With this assumption, the original conditional probability evolves to reformulate as follows:

$$p(\mathbf{y}|\mathbf{d}) = \int_z p(\mathbf{y}, z|\mathbf{d})\mathbf{d}_z = \int_z p(\mathbf{y}|z, \mathbf{d})p(z|\mathbf{d})\mathbf{d}_z \tag{1}$$

This latent variable enables us to model the underlying semantic space as a global signal for generation, in which the variational lower bound of variational generator can be formulated as follows:

$$\mathcal{L}_{VAE}(\theta, \phi, \mathbf{d}, \mathbf{y}) = -KL(q_\phi(z|\mathbf{d}, \mathbf{y})||p_\theta(z|\mathbf{d})) + \mathbb{E}_{q_\phi(z|\mathbf{d},\mathbf{y})}[\log p_\theta(\mathbf{y}|z, \mathbf{d})] \tag{2}$$

where: $p_\theta(z|\mathbf{d})$ is the prior model, $q_\phi(z|\mathbf{d}, \mathbf{y})$ is the posterior approximator, and $p_\theta(\mathbf{y}|z, \mathbf{d})$ is the decoder with the guidance from global signal z, $KL(Q||P)$ is the Kullback-Leibler divergence between Q and P.

3.1 Variational Neural Encoder

The variational neural encoder aims at encoding a given input sequence $w_1, w_2, .., w_L$ into continuous vectors. In this work, we use a 1-layer, Bidirectional LSTM (BiLSTM) to encode the sequence embedding. The BiLSTM consists of forward and backward LSTMs, which read the sequence from left-to-right and right-to-left to produce both forward and backward sequence of hidden states $(\overrightarrow{\mathbf{h}_1}, .., \overrightarrow{\mathbf{h}_L})$, and

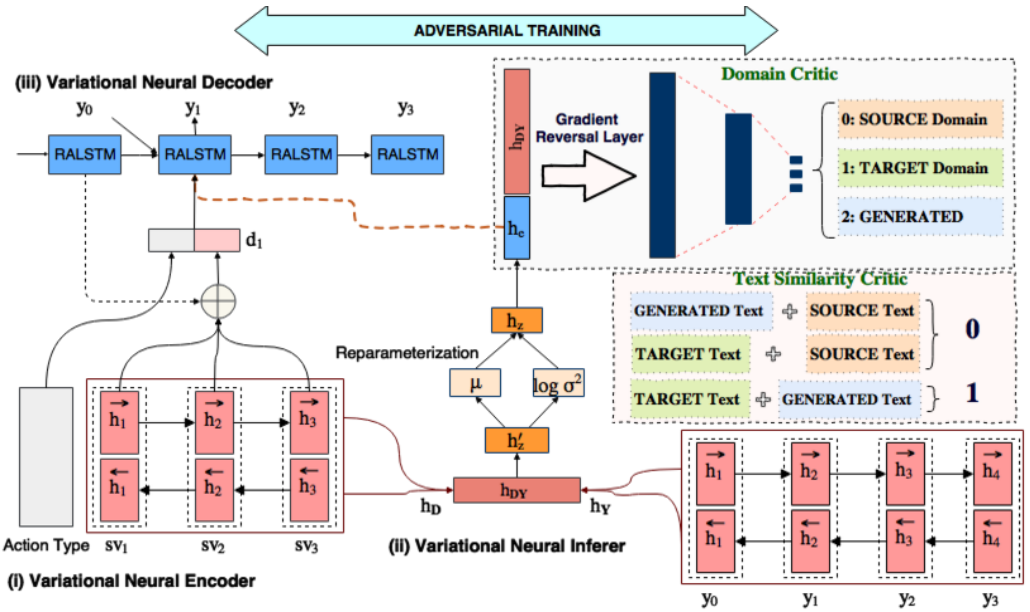

Figure 1: The VDANLG architecture which consists of two main components: the VRALSTM to generate the sentence and two Critics with an adversarial training procedure to guide the model in domain adaptation.

$(\overleftarrow{\mathbf{h}}_1, .., \overleftarrow{\mathbf{h}}_L)$, respectively. We then obtain the sequence of encoded hidden states $\mathbf{h_E} = (\mathbf{h}_1, \mathbf{h}_2, .., \mathbf{h}_L)$ where: $\mathbf{h}_i = \overrightarrow{\mathbf{h}_i} + \overleftarrow{\mathbf{h}_i}$. We utilize this encoder to represent both the sequence of slot-value pairs $\{\mathbf{sv}_i\}_{i=1}^{T_{DA}}$ in a given Dialogue Act, and the corresponding utterance $\{\mathbf{y}_i\}_{i=1}^{T_Y}$ (see the red parts in Figure 1). We finally operate the mean-pooling over the BiLSTM hidden vectors to obtain the representation: $\mathbf{h}_D = \frac{1}{T_{DA}} \sum_i^{T_{DA}} \mathbf{h}_i, \mathbf{h}_Y = \frac{1}{T_Y} \sum_i^{T_Y} \mathbf{h}'_i$. The encoder, accordingly, produces both the DA representation vector which flows into the inferer and decoder, and the utterance representation which streams to the posterior approximator.

3.2 Variational Neural Inferer

In this section, we describe our approach to model both the prior $p_\theta(z|\mathbf{d})$ and the posterior $q_\phi(z|\mathbf{d}, \mathbf{y})$ by utilizing neural networks.

Neural Posterior Approximator

Modeling the true posterior $p(z|\mathbf{d}, \mathbf{y})$ is usually intractable. Traditional approach fails to capture the true posterior distribution of z due to its oversimplified assumption when using the mean-field approaches. Following the work of (Kingma and Welling, 2013), in this paper we employ neural network to approximate the posterior distribution of z to simplify the posterior inference. We assume the approximation has the following form:

$$q_\phi(z|\mathbf{d}, \mathbf{y}) = \mathcal{N}(z; \mu(f(\mathbf{h}_D, \mathbf{h}_Y)), \sigma^2(f(\mathbf{h}_D, \mathbf{h}_Y))\boldsymbol{I}) \tag{3}$$

where: the mean μ and standard variance σ are the outputs of the neural network based on the representations of $\mathbf{h}_D$ and $\mathbf{h}_Y$. The function f is a non-linear transformation that project the both DA and utterance representations onto the latent space:

$$\mathbf{h}'_z = f(\mathbf{h}_D, \mathbf{h}_Y) = g(\mathbf{W}_z[\mathbf{h}_D; \mathbf{h}_Y] + b_z) \tag{4}$$

where: $\mathbf{W}_z \in \mathbb{R}^{d_z \times (d_{\mathbf{h}_D} + d_{\mathbf{h}_Y})}$, $b_z \in \mathbb{R}^{d_z}$ are matrix and bias parameters respectively, d_z is the dimensionality of the latent space, $g(.)$ is an elements-wise activation function which we set to be $Relu$ in our experiments. In this latent space, we obtain the diagonal Gaussian distribution parameter μ and $\log \sigma^2$ through linear regression:

$$\mu = \mathbf{W}_\mu \mathbf{h}'_z + b_\mu, \log \sigma^2 = \mathbf{W}_\sigma \mathbf{h}'_z + b_\sigma \tag{5}$$

where: μ, $\log \sigma^2$ are both d_z dimension vectors.

Neural Prior Model

We model the prior as follows:

$$p_\theta(z|\mathbf{d}) = \mathcal{N}(z; \mu'(\mathbf{d}), \sigma'(\mathbf{d})^2 \boldsymbol{I}) \tag{6}$$

where: μ' and σ' of the prior are neural models based on DA representation only, which are the same as those of the posterior $q_\phi(z|\mathbf{d}, \mathbf{y})$ in Eq. 4 and Eq. 5, except for the absence of $\mathbf{h}_Y$. To acquire a representation of the latent variable z, we utilize the same technique as proposed in VAE (Kingma and Welling, 2013) and re-parameterize it as follows:

$$\mathbf{h}_z = \mu + \sigma \odot \epsilon, \epsilon \sim \mathcal{N}(0, \boldsymbol{I}) \tag{7}$$

In addition, we set $\mathbf{h}_z$ to be the mean of the prior $p_\theta(z|\mathbf{d})$, *i.e.*, μ', during decoding due to the absence of the utterance y. Intuitively, by parameterizing the hidden distribution this way, we can back-propagate the gradient to the parameters of the encoder and train the whole network with stochastic gradient descent. Note that the parameters for the prior and the posterior are independent of each other.

In order to integrate the latent variable $\mathbf{h}_z$ into the decoder, we use a non-linear transformation to project it onto the output space for generation:

$$\mathbf{h}_e = g(\mathbf{W}_e \mathbf{h}_z + b_e) \tag{8}$$

where: $\mathbf{h}_e \in \mathbb{R}^{d_e}$. It is important to notice that due to the sample noise ϵ, the representation of $\mathbf{h}_e$ is not fixed for the same input DA and model parameters. This benefits the model to learn to quickly adapt to a new domain (see Table 1-(a) and Table 3, *sec.* 3).

3.3 Variational Neural Decoder

Given a DA $\mathbf{d}$ and the latent variable z, the decoder calculates the probability over the generation $\mathbf{y}$ as a joint probability of ordered conditionals:

$$p(\mathbf{y}|z, \mathbf{d}) = \prod_{j=1}^{T_Y} p(\mathbf{y}_t|\mathbf{y}_{<t}, z, \mathbf{d}) \tag{9}$$

where: $p(\mathbf{y}_t|\mathbf{y}_{<t}, z, \mathbf{d}) = g'(RNN(\mathbf{y}_t, \mathbf{h}_{t-1}, \mathbf{d}_t)$ In this paper, we borrow the $\mathbf{d}_t$ calculation and the computational RNN cell from (Tran and Nguyen, 2017a) where RNN(.)=RALSTM(.) with a slightly modification in order to integrate the representation of latent variable, *i.e.*, $\mathbf{h}_e$, into the RALSTM cell, which is denoted by the bold dashed orange arrow in Figure 1-(iii). We modify the cell calculation as follows:

$$\begin{pmatrix} \mathbf{i}_t \\ \mathbf{f}_t \\ \mathbf{o}_t \\ \hat{\mathbf{c}}_t \end{pmatrix} = \begin{pmatrix} \sigma \\ \sigma \\ \sigma \\ \tanh \end{pmatrix} \mathbf{W}_{4d_h, 4d_h} \begin{pmatrix} \mathbf{h}_e \\ \mathbf{d}_t \\ \mathbf{h}_{t-1} \\ \mathbf{y}_t \end{pmatrix} \tag{10}$$

where: $\mathbf{i}_i$, $\mathbf{f}_t$, $\mathbf{o}_t$ are input, forget and output gates respectively, d_h is hidden layer size, $\mathbf{W}_{4d_h, 4d_h}$ is model parameter.

The resulting Variational RALSTM (VRALSTM) model is demonstrated in Figure 1-(i), (ii), (iii), in which the latent variable can affect the hidden representation through the gates. This allows the model can indirectly take advantage of the underlying semantic information from the latent variable z. In addition, when the model learns to adapt to a new domain with unseen dialogue act, the semantic representation $\mathbf{h}_e$ can help to guide the generation process (see *sec.* 6.3 for details).

3.4 Critics

In this section, we introduce a *text-similarity critic* and a *domain critic* to guarantee, as much as possible, that the generated sentences resemble the sentences drawn from the target domain.

Text similarity critic

To check the relevance between sentence pair in two domains and to encourage the model generating sentences in the style which is highly *similar* to those in the target domain, we propose a Text Similarity Critic (SC) to classify $(\mathbf{y}_{(1)}, \mathbf{y}_{(2)})$ as 1-similar or 0-unsimilar text style. The model SC consists of two parts: a shared BiLSTM $\mathbf{h}_Y$ with the Variational Neural Encoder to represent the $\mathbf{y}_{(1)}$ sentence, and a second BiLSTM to encode the $\mathbf{y}_{(2)}$ sentence. The SC model takes input as a pair $(\mathbf{y}_{(1)}, \mathbf{y}_{(2)})$ of ([*target*], *source*), ([*target*], *generated*), and ([*generated*], *source*). Note that we give priority to encoding the $\mathbf{y}_{(1)}$ sentence in [.] using the shared BiLSTM, which guides the model to learn the sentence style from the target domain, and also contributes the target domain information into the global latent variables. We further utilize Siamese recurrent architectures (Neculoiu et al., 2016) for learning sentence similarity, in which the architecture allows us to learn useful representations with limited supervision.

Domain critic

In consideration of the shift between domains, we introduce a Domain Critic (DC) to classify sentence as *source*, *target*, or *generated* domain, respectively. Drawing inspiration from work of (Ganin et al., 2016), we model DC with a gradient reversal layer and two standard feed-forward layers. It is important to notice that our DC model shares parameters with the Variational Neural Encoder and the Variational Neural Inferer. The DC model takes input as a pair of given DA and corresponding utterance to produce a concatenation of both its representation and its latent variable in the output space, which is then passed through a feed-forward layer and a 3-labels classifier. In addition, the gradient reversal layer, which multiplies the gradient by a specific negative value during back-propagation training, ensures that the feature distributions over the two domains are made similar, as indistinguishable as possible for the domain critic, hence resulting in the domain-invariant features.

4 Training Domain Adaptation Model

Given a training instance represented by a pair of DA and sentence $(\mathbf{d}^{(i)}, \mathbf{y}^{(i)})$ from the rich source domain $\mathcal{S}$ and the limited target domain $\mathcal{T}$, the task aims at finding a set of parameters $\Theta_{\mathcal{T}}$ that can perform acceptably well on the target domain.

4.1 Training Critics

We provide as following the training objective of SC and DC. For SC, the goal is to classify a sentence pair into 1-*similar* or 0-*unsimilar* textual style. This procedure can be formulated as a supervised classification training objective function:

$$\mathcal{L}_s(\psi) = -\sum_{n=1}^{N} \log C_s(l_s^n | \mathbf{y}_{(1)}^n, \mathbf{y}_{(2)}^n, \psi), l_s^n = \begin{cases} 1 - similar & \text{if } (\mathbf{y}_{(1)}^n, \mathbf{y}_{(2)}^n) \in \mathcal{P}_{sim}, \\ 0 - unsimilar & \text{if } (\mathbf{y}_{(1)}^n, \mathbf{y}_{(2)}^n) \in \mathcal{P}_{unsim}, \end{cases} \quad (11)$$
$$\mathcal{Y}_{\mathcal{G}} = \{\mathbf{y} | \mathbf{y} \sim \mathcal{G}(.|\mathbf{d}_{\mathcal{T}}, .)\}, \mathcal{P}_{sim} = \{\mathbf{y}_{\mathcal{T}}^n, \mathbf{y}_{\mathcal{Y}_{\mathcal{G}}}^n\}, \mathcal{P}_{unsim} = (\{\mathbf{y}_{\mathcal{T}}^n, \mathbf{y}_{\mathcal{S}}^n\}, \{\mathbf{y}_{\mathcal{Y}_{\mathcal{G}}}^n, \mathbf{y}_{\mathcal{S}}^n\})$$

where: N is number of sentences, ψ is the model parameters of SC, $\mathcal{Y}_{\mathcal{G}}$ denotes sentences generated from the current generator $\mathcal{G}$ given target domain dialogue act $\mathbf{d}_{\mathcal{T}}$. The scalar probability $C_s(1|\mathbf{y}_{\mathcal{T}}^n, \mathbf{y}_{\mathcal{Y}_{\mathcal{G}}}^n)$ indicates how a generated sentence $\mathbf{y}_{\mathcal{Y}_{\mathcal{G}}}^n$ is relevant to a target sentence $\mathbf{y}_{\mathcal{T}}^n$.

The DC critic aims at classifying a pair of DA-utterance into *source*, *target*, or *generated* domain. This can also be formulated as a supervised classification training objective as follows:

$$\mathcal{L}_d(\varphi) = -\sum_{n=1}^{N} \log C_d(l_d^n | \mathbf{d}^n, \mathbf{y}^n, \varphi), l_d^n = \begin{cases} source & \text{if } (\mathbf{d}^n, \mathbf{y}^n) \in (\mathcal{D}_{\mathcal{S}}, \mathcal{Y}_{\mathcal{S}}), \\ target & \text{if } (\mathbf{d}^n, \mathbf{y}^n) \in (\mathcal{D}_{\mathcal{T}}, \mathcal{Y}_{\mathcal{T}}), \\ generated & \text{if } (\mathbf{d}^n, \mathbf{y}^n) \in (\mathcal{D}_{\mathcal{T}}, \mathcal{Y}_{\mathcal{G}}), \end{cases} \quad (12)$$

where: φ is the model parameters of DC, $(\mathcal{D}_S, \mathcal{Y}_S)$, $(\mathcal{D}_T, \mathcal{Y}_T)$ are the DA-utterance pairs from source, target domain, respectively. Note also that the scalar probability $C_d(target|\mathbf{d}^n, \mathbf{y}^n)$ indicates how likely the DA-utterance pair $(\mathbf{d}^n, \mathbf{y}^n)$ is from the target domain.

4.2 Training Variational Generator

We utilize the Monte Carlo method to approximate the expectation over the posterior in Eq. 2, *i.e.*, $\mathbb{E}_{q_\phi(z|\mathbf{d},\mathbf{y})}[.] \simeq \frac{1}{M}\sum_{m=1}^{M} \log p_\theta(\mathbf{y}|\mathbf{d}, \mathbf{h}_z^{(m)})$ where: M is the number of samples. In this study, the joint training objective for a training instance $(\mathbf{d}, \mathbf{y})$ is formulated as follows:

$$\mathcal{L}(\theta, \phi) \simeq -KL(q_\phi(z|\mathbf{d}, \mathbf{y})||p_\theta(z|\mathbf{d})) + \frac{1}{M}\sum_{m=1}^{M}\sum_{t=1}^{T_y} \log p_\theta(\mathbf{y}_t|\mathbf{y}_{<t}, \mathbf{d}, \mathbf{h}_z^{(m)}) \tag{13}$$

where: $\mathbf{h}_z^{(m)} = \mu + \sigma \odot \epsilon^{(m)}$, and $\epsilon^{(m)} \sim \mathcal{N}(0, \mathbf{I})$. The first term is the KL divergence between two Gaussian distribution, and the second term is the approximation expectation. We simply set $M = 1$ which degenerates the second term to the objective of conventional generator. Since the objective function in Eq. 13 is differentiable, we can jointly optimize the parameter θ and variational parameter ϕ using standard gradient ascent techniques.

4.3 Adversarial Training

Our domain adaptation architecture is demonstrated in Figure 1, in which both generator $\mathcal{G}$ and critics C_s, and C_d jointly train by pursuing competing goals as follows. Given a dialogue act $\mathbf{d}_\mathcal{T}$ in the target domain, the generator generates K sentences $\mathbf{y}$'s. It would prefer a "*good*" generated sentence $\mathbf{y}$ if the values of $C_d(target|\mathbf{d}_\mathcal{T}, \mathbf{y})$ and $C_s(1|\mathbf{y}_\mathcal{T}, \mathbf{y})$ are large. In contrast, the critics would prefer large values of $C_d(generated|\mathbf{d}_\mathcal{T}, \mathbf{y})$ and $C_s(1|\mathbf{y}, \mathbf{y}_\mathcal{S})$, which imply the small values of $C_d(target|\mathbf{d}_\mathcal{T}, \mathbf{y})$ and $C_s(1|\mathbf{y}_\mathcal{T}, \mathbf{y})$. We propose a domain-adversarial training procedure in order to iteratively updating the generator and critics as described in Algorithm 1. While the parameters of generator are optimized to minimize their loss in the training set, the parameters of the critics are optimized to minimize the error of text similarity, and to maximize the loss of domain classifier.

Algorithm 1: Adversarial Training Procedure

Require: generator $\mathcal{G}$, domain critic C_d, text similarity critic C_s, generated sentence $\mathcal{Y}_\mathcal{G} = \emptyset$;
Input: DA-utterance pairs of source $(\mathcal{D}_\mathcal{S}, \mathcal{Y}_\mathcal{S})$, target $(\mathcal{D}_\mathcal{T}, \mathcal{Y}_\mathcal{T})$;
1 Pretrain $\mathcal{G}$ on $(\mathcal{D}_\mathcal{S}, \mathcal{Y}_\mathcal{S})$ using VRALSTM;
2 **while** Θ *has not converged* **do**
3 **for** *i = 0, .., $N_\mathcal{T}$* **do**
4 Sample $(\mathbf{d}_\mathcal{S}, \mathbf{y}_\mathcal{S})$ from source domain;
5 (D_1)-Compute $g_d = \nabla_\varphi \mathcal{L}_d(\varphi)$ using Eq. 12 for $(\mathbf{d}_\mathcal{S}, \mathbf{y}_\mathcal{S})$ and $(\mathbf{d}_\mathcal{T}, \mathbf{y}_\mathcal{T})$;
6 (D_2)-Adam update of φ for C_d using g_d;
7 (G_1)-Compute $g_\mathcal{G} = \{\nabla_\theta \mathcal{L}(\theta, \phi), \nabla_\phi \mathcal{L}(\theta, \phi)\}$ using Eq. 13
8 (G_2)-Adam update of θ, ϕ for $\mathcal{G}$ using $g_\mathcal{G}$
9 (S_1)-Compute $g_s = \nabla_\psi \mathcal{L}_s(\psi)$ using Eq. 11 for $(\mathbf{y}_\mathcal{T}, \mathbf{y}_\mathcal{S})$;
10 (S_2)-Adam update of ψ for C_s using g_s;
11 $\mathcal{Y}_\mathcal{G} \leftarrow \{\mathbf{y}_{\bar{k}}\}_{\bar{k}=1}^{K}$, where $\mathbf{y}_{\bar{k}} \sim \mathcal{G}(.|\mathbf{d}_\mathcal{T}^{(i)}, .)$;
12 Choose top ***k*** best sentences of $\mathcal{Y}_\mathcal{G}$;
13 **for** *j = 1,..,**k*** **do**
14 (D_1), (D_2) steps for C_d with $(\mathbf{d}_\mathcal{T}, \mathbf{y}_\mathcal{G}^{(j)})$;
15 (S_1), (S_2) steps for C_s with $(\mathbf{y}_\mathcal{G}^{(j)}, \mathbf{y}_\mathcal{S})$ and $(\mathbf{y}_\mathcal{T}, \mathbf{y}_\mathcal{G}^{(j)})$;
16 **end**
17 **end**
18 **end**

Generally, the current generator $\mathcal{G}$ for each training iteration i takes a *target* dialogue act $\mathbf{d}_\mathcal{T}^{(i)}$ as input to over-generate a set $\mathcal{Y}_\mathcal{G}$ of K candidate sentences (step 11). We then choose top **k** best sentences in the $\mathcal{Y}_\mathcal{G}$ set (step 12) after re-ranking to measure how "*good*" the generated sentences are by using the critics (steps 14-15). These "*good*" signals from the critics can guide the generator step by step to generate the outputs which resemble the sentences drawn from the target domain. Note that the re-ranking step is important for separating the "*correct*" sentences from the current generated outputs $\mathcal{Y}_\mathcal{G}$ by penalizing the generated sentences which have redundant or missing slots.

5 Experiments

We conducted experiments on the proposed models in different scenarios: ***Adaptation***, ***Scratch***, and ***All*** using several model architectures, evaluation metrics, datasets (Wen et al., 2016a), and configurations (see Appendix A).

KL cost annealing strategy (Bowman et al., 2015) encourages the model to encode meaningful representations into the latent vector z, in which we gradually anneal the KL term from 0 to 1. This helps our model to achieve solutions with non-zero KL term.

Gradient reversal layer (Ganin et al., 2016) leaves the input unchanged during forward propagation and reverses the gradient by multiplying it with a negative scalar $-\lambda_p$ during the backpropagation-based training. We set the domain adaptation parameter λ_p which gradually increases, starting from 0 to 1, by using the following schedule for each training step i: $p = float(i)/num\_steps$, and $\lambda_p = \frac{2}{1+exp(-10*p)} - 1$ where: num_steps is a constant which is set to be 8600, p is training progress. This strategy allows the Domain critic to be less sensitive to noisy signal at the early training stages.

6 Results and Analysis

6.1 Integrating Variational Inference

We compare the original model RALSTM with its modification by integrating Variational Inference (VRALSTM) as demonstrated in Table 2 and Table 1-(a). It clearly shows that the VRALSTM not only preserves the power of the original RALSTM on generation task since its performances are very competitive to those of RALSTM, but also provides a compelling evidence on adapting to a new, unseen domain when the target domain data is scarce, *i.e.*, from 1% to 7%. Table 3, *sec.* 3 further shows the necessity of the integrating in which the VRALSTM achieved a significant improvement over the RALSTM in ***Scratch*** scenario, and of the adversarial domain adaptation algorithm in which although both the RALSTM and VRALSTM model can perform well when providing sufficient in-domain training data (Table 2), the performances are extremely impaired when training from ***Scratch*** with only a limited data. These indicate that the proposed variational method can learn the underlying semantic of DA-utterance pairs in the source domain via the representation of the latent variable z, from which when adapting to another domain, the models can leverage the existing knowledge to guide the generation process.

6.2 Ablation Studies

The ablation studies (Table 3, *sec.* 1, 2) demonstrate the contribution of two Critics, in which the models were assessed with either no Critics or both or only one. It clearly sees that combining both Critics makes a substantial contribution to increasing the BLEU score and decreasing the slot error rate by a large margin in every dataset pairs. A comparison of model adapting from source Laptop domain between VRALSTM without Critics (Laptop$^\flat$) and VDANLG (Laptop$^\sharp$) evaluated on the target **Hotel** domain shows that the VDANLG not only has better performance with much higher the BLEU score, 82.18 in comparison to 78.70, but also significantly reduce the ERR, from 15.17% down to 2.89%. The trend is consistent across all the other domain pairs. These stipulate the necessary Critics in effective learning to adapt to a new domain.

Table 3, *sec.* 4 further demonstrates that using DC only (*sec.* 4) brings a benefit of effectively utilizing similar slot-value pairs seen in the training data to *closer* domain pairs such as: Hotel→Restaurant (68.23 BLEU, 4.97 ERR), Restaurant→Hotel (80.31 BLEU, 6.71 ERR), Laptop→Tv (51.14 BLEU, 10.07 ERR), and Tv→Laptop (50.01 BLEU, 15.40 ERR) pairs. Whereas it is inefficient for the *longer* domain pairs since their performances are worse than those without Critics, or in some cases even worse than the VRALSTM in ***scr10*** scenario, such as Restaurant→Tv (41.69 BLEU, 34.74 ERR), and the cases where Laptop to be a Target domain. On the other hand, using only SC (*sec.* 5) helps the models achieve better results since it is aware of the sentence style when adapting to the target domain.

6.3 Distance of Dataset Pairs

To better understand the effectiveness of the methods, we analyze the learning behavior of the proposed model between different dataset pairs. The datasets' order of difficulty was, from easiest to hardest:

Hotel↔Restaurant↔Tv↔Laptop. On the one hand, it might be said that the *longer* datasets' distance is, the more difficult of domain adaptation task becomes. This clearly shows in Table 3, *sec.* 1, at **Hotel** column where the adaptation ability gets worse regarding decreasing the BLEU score and increasing the ERR score alongside the order of Restaurant→Tv→Laptop datasets. On the other hand, the *closer* the dataset pair is, the faster model can adapt. It can be expected that the model can better adapt to the target **Tv/Laptop** domain from source Laptop/Tv than those from source Restaurant, Hotel, and vice versa, the model can easier adapt to the target **Restaurant/Hotel** domain from source Hotel/Restaurant than those from Laptop, Tv. However, the above-mentioned is not always true that the proposed method can perform acceptably well from *easy* source domains (Hotel, Restaurant) to the more *difficult* target domains (Tv, Laptop) and vice versa (Table 3, *sec.* 1, 2).

Table 3, *sec.* 2 further shows that the proposed method is able to leverage the out of domain knowledge since the adaptation models trained on union source dataset, such as [R+H] or [L+T], show better performances than those trained on individual source domain data. A specific example in Table 3, *sec.* 2 shows that the adaptation VDANLG model trained on the source union dataset of Laptop and Tv ([L+T]$^\sharp$) has better performance, at 82.52 BLEU and 2.87 ERR, than those models trained on the individual source dataset, such as Laptop$^\sharp$ (82.18 BLEU, 2.89 ERR), and Tv$^\sharp$ (82.51 BLEU, 4.89 ERR). Another example in Table 3, *sec.* 2 also shows that the adaptation VDANLG model trained on the source union dataset of Restaurant and Hotel ([R+H]$^\sharp$) has better results, at 51.97 BLEU and 2.58 ERR, than those models trained on the separate source dataset, such as Restaurant$^\sharp$ (50.43 BLEU, 2.99 ERR), and Hotel$^\sharp$ (51.64 BLEU, 3.25 ERR). The trend is mostly consistent across all other domain comparisons in different training scenarios. All these demonstrate that the proposed model can learn global semantics that can be efficiently transferred into new domains.

6.4 *Adaptation* vs. *All* Training Scenario

It is interesting to compare ***Adaptation*** (Table 3, *sec.* 2) with ***All*** training scenario (Table 2). The VDANLG model shows its considerable ability to shift to another domain with a limited of in-domain labels whose results are competitive to or in some cases better than the previous models trained on full labels of the **Target** domain. A specific comparison evaluated on the **Tv** domain where the VDANLG model trained on the source Laptop$^\sharp$ achieved better performance, at 52.43 BLEU and 1.52 ERR, than HLSTM (52.40, 2.65), SCLSTM (52.35, 2.41), and Enc-Dec (51.42, 3.38). The VDANLG models, in many cases, also have lower of slot error rate ERR scores than the Enc-Dec model. These indicate the stable strength of the VDANLG models in adapting to a new domain when the target domain data is scarce.

6.5 Unsupervised Domain Adaptation

We further examine the effectiveness of the proposed methods by training the VDANLG models on target ***Counterfeit*** datasets (Wen et al., 2016a). The promising results are shown in Table 1-(b), despite the fact that the models were instead adaptation trained on the **Counterfeit** datasets, or in other words, were indirectly trained on the (*Test*) domains. However, the proposed models still showed positive signs in remarkably reducing the slot error rate ERR in the cases of *Hotel* and *Tv* be the (*Test*) domains. Surprisingly, even the source domains (Hotel$^\sharp$/Restaurant$^\sharp$) are far from the (*Test*) domain *Tv*, and the **Target** domain **Counterfeit L2T** is also very different to the source domains, the model can still acceptably adapt well since its BLEU scores on (*Test*) Tv domain reached to (41.83/42.11), and it also produced a very low of ERR scores (2.38/2.74). This phenomenon will be further investigated in the unsupervised scenario in the future work.

6.6 Comparison on Generated Outputs

On the one hand, the VRALSTM models (trained from ***Scratch*** or trained adapting model from Source domains) produce the outputs with a diverse range of error types, including missing, misplaced, redundant, wrong slots, or even spelling mistake information, leading to a very high of the slot error rate ERR score. Specifically, the VRALSTM from ***Scratch*** tends to make repeated slots and also many of the missing slots in the generated outputs since the training data may inadequate for the model to generally

Table 4: Comparison of top **Laptop** responses generated for different scenarios by adaptation training VRALSTM (denoted by ♭) and VDANLG (denoted by ♯) models from Source domains, and by training VRALSTM from ***Scratch***. Errors are marked in colors ([missing], misplaced, redundant, wrong, spelling mistake information). [OK] denotes successful generation. VDANLG$^{\sharp}$ = VRALSTM$^{\flat}$+SC+DC.

Model	Generated Responses from Laptop Domain

VRALSTM	which would be the *tecra erebus 20 is a business computing* laptop with *4 gb* of memory and is the SLOT_NAME , and is not for business computing . [satellite heracles 45][2 gb]
Hotel$^{\flat}$	*the tecra erebus 20 is used for business computing* . the *satellite heracles 45* has 4 gb of memory and a SLOT_BATTERY battery life for business computing . which one do you want
Restaurant$^{\flat}$	the *tecra erebus 20 is for business computing* . the *satellite heracles 45* which has 4 gb of memory and *is not for business computing* . which one do you want [2 gb]
Tv$^{\flat}$	*the tecra erebus 20* has *4 gb* of memory and is not for business computing . which one do you prefer [is for business computing][satellite heracles 45][2 gb]
[R+H]$^{\flat}$	the *tecra erebus 20* is not for business computing . which one do you want a business computing . which one do you prefer [4 gb][is for business computing][satellite heracles 45][2 gb]
Hotel$^{\sharp}$	the *tecra erebus 20* has a *4 gb* memory , that *is for business computing* . the *satellite heracles 45* with *2 gb* of memory and *is not for business computing* . which one do you want [OK]
Restaurant$^{\sharp}$	the *tecra erebus 20* has a *4 gb* memory , and *is for business computing* . the *satellite heracles 45 is not for business computing* . which one do you want to know more [2 gb]
Tv$^{\sharp}$	the *tecra erebus 20 is a business computing* . the *satellite heracles 45* has a 4 gb memory and *is not for business computing* . which one do you prefer [2 gb]
[R+H]$^{\sharp}$	the *tecra erebus 20 is for business computing* , has a 2 gb of memory. the *satellite heracles 45* has 4 gb of memory , *is not for business computing*. which one do you want

handle the unseen dialog acts. Whereas the VRALSTM models without Critics adapting trained from Source domains (denoted by ♭ in Table 4 and Appendix B. Table 5) tend to generate the outputs with fewer error types than the model from ***Scratch*** because the VRALSTM$^{\flat}$ models may capture the overlap slots of both source and target domain during adaptation training.

On the other hand, under the guidance of the Critics (SC and DC) in an adversarial training procedure, the VDANLG model (denoted by ♯) can effectively leverage the existing knowledge of the source domains to better adapt to the target domains. The VDANLG models can generate the outputs in style of the target domain with much fewer the error types compared with the two above models. Moreover, the VDANLG models seem to produce satisfactory utterances with more correct generated slots. For example, a sample outputted by the [R+H]$^{\sharp}$ in Table 4-example 1 contains all the required slots with only a misplaced information of two slots *2 gb* and *4 gb*, while the generated output produced by Hotel$^{\sharp}$ is a successful generation. Another samples in Appendix B. Table 5 generated by the Hotel$^{\sharp}$, Tv$^{\sharp}$, [R+H]$^{\sharp}$ (in DA 2) and Laptop$^{\sharp}$ (DA 3) models are all fulfilled responses. An analysis of the generated responses in Table 5-example 2 illustrates that the VDANLG models seem to generate a concise response since the models show a tendency to form some potential slots into a concise phrase, *i.e.*, "SLOT_NAME SLOT_TYPE". For example, the VDANLG models tend to concisely response as "the *portege phosphorus 43 laptop* ..." instead of "the *portege phosphorus 43* is a *laptop* ...". All these above demonstrate that the VDANLG models have ability to produce better results with a much lower of the slot error rate ERR score.

7 Conclusion and Future Work

We have presented an integrating of a variational generator and two Critics in an adversarial training algorithm to examine the model ability in domain adaptation task. Experiments show that the proposed models can perform acceptably well in a new, unseen domain by using a limited amount of in-domain data. The ablation studies also demonstrate that the variational generator contributes to effectively learn the underlying semantic of DA-utterance pairs, while the Critics show its important role of guiding the model to adapt to a new domain. The proposed models further show a positive sign in unsupervised domain adaptation, which would be a worthwhile study in the future.

Appendix A. Experimental Setups

We followed the configurations for the RALSTM model from work of (Tran and Nguyen, 2017a), in which the hidden layer size and beam width were set to be 80 and 10, respectively, and the generators were trained with a 70% of keep dropout rate. We performed 5 runs with different random initialization of the network, and the training process is terminated by using early stopping. We then selected a model that yields the highest BLEU score (Papineni et al., 2002) on the validation set. For the variational inference, we set the latent variable size to be 16. We used Adam optimizer with the learning rate is initially set to be 0.001, and after 3 epochs for the Union dataset and 5 epochs for the single dataset the learning rate is decayed every epoch using an exponential rate of 0.95. The decoding phase is mostly similar to those in work of (Tran and Nguyen, 2017a).

Appendix B. Generated Utterances

Abstract

Our goal is to explore how the abilities brought in by a dialogue manager can be included in end-to-end visually grounded conversational agents. We make initial steps towards this general goal by augmenting a task-oriented visual dialogue model with a decision-making component that decides whether to ask a follow-up question to identify a target referent in an image, or to stop the conversation to make a guess. Our analyses show that adding a decision making component produces dialogues that are less repetitive and that include fewer unnecessary questions, thus potentially leading to more efficient and less unnatural interactions.

1 Introduction

The field of interactive conversational agents, also called dialogue systems, is receiving renewed attention not only within Computational Linguistics (CL) and Natural Language Processing (NLP) – its original and probably most natural locus – but also within the Machine Learning (ML) and the Computer Vision (CV) communities. The overarching challenge, in line with the long-term aims of Artificial Intelligence, is to develop data-driven agents that are capable of perceiving (and possibly acting upon) the external world and that we can collaborate with through natural language dialogue to achieve common goals.

Within the ML and CV communities, recent research on conversational agents combined with Deep Learning techniques has yielded interesting results on visually grounded tasks (Das et al., 2017a; de Vries et al., 2017; Mostafazadeh et al., 2017). In this line of research, the focus is mostly on improving model performance by investigating new machine learning paradigms (like reinforcement learning or adversarial learning) in end-to-end settings, where the model learns directly from raw data without symbolic annotations (Strub et al., 2017; Lu et al., 2017; Wu et al., 2017). Task accuracy, however, is not the only criterion by which a conversational agent should be judged. Crucially, the dialogue should be coherent, with no unnatural repetitions nor unnecessary questions — unlike the 5-turn dialogue shown in Figure 1. To achieve this, a conversational agent needs to learn a strategy to decide how to respond given the current context and the task at hand. These abilities are typically considered part of *dialogue management* and have been the focus of attention in dialogue systems research within the CL/NLP community (Larsson and Traum, 2000; Williams et al., 2008; Bohus and Rudnicky, 2009; Young et al., 2013).

Questioner	**Answerer**

Santa Fe, New Mexico, USA, August 20-26, 2018.

logue manager can be included in end-to-end conversational agents within the Deep Learning paradigm mostly put forward by the ML and CV communities. We make initial steps towards this general goal by augmenting the task-oriented visual dialogue model proposed by de Vries et al. (2017), not yet with a full-fledged dialogue manager, but with a decision-making component that decides whether to ask a follow-up question to identify a target referent in an image, or to stop the conversation to make a guess (see Figure 1). Our focus is on providing a thorough analysis of the resulting dialogues. Our results show that the presence of a decision making component leads to dialogues that are less repetitive and that include fewer unnecessary questions.

2 Related Work

Our system operates on both linguistic and visual information. Visually-grounded dialogue has experienced a boost in recent years, in part thanks to the construction of large visual human-human dialogue datasets built by the Computer Vision community (Mostafazadeh et al., 2017; Das et al., 2017a; de Vries et al., 2017). These datasets include two participants, a Questioner and an Answerer, who ask and answer questions about an image. For example, in the *GuessWhat?!* dataset developed by de Vries et al. (2017), which we exploit in the present work, a Questioner agent needs to guess a target object in a visual scene by asking yes-no questions (more details are provided in the next section).

Research on visually-grounded dialogue within the Computer Vision community exploits encoder-decoder architectures (Sutskever et al., 2014) — which have shown some promise for modelling chatbot-style dialogue (Vinyals and Le, 2015; Sordoni et al., 2015; Serban et al., 2016; Li et al., 2016a; Li et al., 2016b) — augmented with visual features. This community has mostly focused on model learning paradigms. Initial models, proposed by de Vries et al. (2017) and Das et al. (2017a), use supervised learning (SL): the Questioner and the Answerer are trained to generate utterances (by word sampling) that are similar to the human gold standard. To account for the intuition that dialogues require some form of planning, subsequent work by Das et al. (2017b) and Strub et al. (2017) makes use of reinforcement learning (RL). In all these approaches but Strub et al. (2017), however, the Questioner performs a non-linguistic action (i.e., selects an image or object within an image) after a fixed number of question-answer rounds. Thus, there is no decision making on whether further questions are or are not needed to identify a visual target. To address this limitation, Strub et al. (2017) put forward a more flexible approach: They let the Questioner ask at most 8 questions, but introduce an extra token (`stop`) within the vocabulary, which the question generation model has to learn. This strategy, however, is suboptimal: The question generator needs to generate probabilities for items that do not lie on the same distribution (the distribution of natural language words vs. the distribution of binary decisions *ask*/*guess*).[1] Our work addresses this limitation in a more principled way, by including a new decision-making module within the encoder-decoder architecture and analysing its impact on the resulting dialogues.

We build on work by the dialogue systems community. In traditional dialogue systems, the basic system architecture includes several components – mainly, a language interpreter, a dialogue manager, and a response generator – as discrete modules that operate in a pipeline (Jurafsky and Martin, 2009; Jokinen and McTear, 2009) or in a cascading incremental manner (Schlangen and Skantze, 2009; Dethlefs et al., 2012). The *dialogue manager* is the core component of a dialogue agent: it integrates the semantic content produced by the interpretation module into the agent's representation of the context (the *dialogue state*) and determines the next action to be performed by the agent, which is transformed into linguistic output by the generation module. Conceptually, a dialogue manager thus includes both (i) a *dialogue state tracker*, which acts as a context model that ideally keeps track of aspects such as current goals, commitments made in the dialogue, entities mentioned, and the level of shared understanding among the participants (Clark, 1996); and (ii) an *action selection policy*, which makes decisions on how to act next, given the current dialogue state. In the present work, we focus on incorporating a *decision-making module* akin to an action selection policy into a visually-grounded encoder-decoder architecture and leave

[1] We also note that on the *GuessWhat?!* GitHub page at `https://github.com/GuessWhatGame/guesswhat` it is mentioned that in the updated version of the system by Strub et al. (2017) "qgen [the question generator] stop learning to stop" (GitHub accessed on 16/03/2018).

the integration of other more advanced dialogue management aspects for future work.

In particular, work on incremental dialogue processing, where a system needs to decide not only *what* to respond but also *when* to act (Rieser and Schlangen, 2011), has some similarities with the problem we address in the present paper, namely, when to stop asking questions to guess a target.[2] Researchers within the dialogue systems community have applied different approaches to design incremental dialogue policies for how and when to act. Two common approaches are the use of rules parametrised by thresholds that are optimised with human-human data (Buß et al., 2010; Ghigi et al., 2014; Paetzel et al., 2015; Kennington and Schlangen, 2016) and the use of reinforcement learning (Kim et al., 2014; Khouzaimi et al., 2015; Manuvinakurike et al., 2017). For example, Paetzel et al. (2015) implement an agent that aims to identify a target image out of a set of images given descriptive content by its dialogue partner. Decision making is handled by means of a parametrised rule-based policy: the agent keeps waiting for additional descriptive input until either her confidence on a possible referent exceeds a given threshold or a maximum-time threshold is reached (in which case the agent gives up). The thresholds are set up by optimising points per second on a corpus of human-human dialogues (pairs of participants score a point for each correct guess). In a follow-up paper by Manuvinakurike et al. (2017), the agent's policy is learned with reinforcement learning, achieving higher performance.

We develop a decision-making module that determines, after each question-answer pair in the visually grounded dialogue, whether to ask a further question or to pick a referent in a visual scene. We are interested in investigating the impact of such a module in an architecture that can be trained end-to-end directly from raw data, without specific annotations commonly used in dialogue systems, such as dialogue acts (Paetzel et al., 2015; Manuvinakurike et al., 2017; Kennington and Schlangen, 2016), segment labels (Manuvinakurike et al., 2016), dialogue state features (Williams et al., 2013; Young et al., 2013; Kim et al., 2014), or logical formulas (Yu et al., 2016).

3 Dataset

To develop our model and perform our analyses, we use the *GuessWhat?!* dataset,[3] a dataset of approximately 155k human-human dialogues created via Amazon Mechanical Turk (de Vries et al., 2017). *GuessWhat?!* is a cooperative two-player game: both players see an image with several objects; one player (the Oracle) is assigned a target object in the image and the other player (the Questioner) has to guess it. To do so, the Questioner has to ask Yes/No questions to the Oracle. When the Questioner thinks he/she can guess the object, the list of objects is provided and if the Questioner picks the right one the game is considered successful. No time limit is given, but the Questioner can leave the game incomplete (viz. not try to guess). The set of images and target objects has been built from the training and validation sections of the MS-COCO dataset (Lin et al., 2014) by only keeping images that contain at least three and at most twenty objects and by only considering target objects whose area is big enough to be located well by humans ($area > 500px^2$). Further details are provided in Appendix A.

4 Models

de Vries et al. (2017) develop models of the Questioner and Oracle roles in *GuessWhat?!*. We first describe their models, which we consider as our baseline, and then describe our modified Questioner model. As explained below, de Vries et al. (2017) model the Questioner role by means of two disconnected modules: a Question Generator (QGen) and a Guesser, that are trained independently. After a fixed number of questions by QGen, the Guesser selects a candidate object. We propose and evaluate a model of the Questioner role that incorporates a decision-making component that connects the tasks of asking and guessing (which we take to be part of the planning capabilities of a single agent) and offers more flexibility regarding the number of questions asked to solve the game.

[2] Our system is not word-by-word incremental at this point, but given the incremental nature of encoder-decoder architectures, an extension in this direction should be possible. We leave this for future work.

[3] Available at: `https://guesswhat.ai/`

4.1 Baseline Models

We provide a brief description of the models by de Vries et al. (2017), which we re-implement for our study. Further details on the implementation of each module are available in Appendix A.

Question Generator (QGen) This module is implemented as a Recurrent Neural Network (RNN) with a transition function handled with Long-Short-Term Memory (LSTM), on which a probabilistic sequence model is built with a Softmax classifier. Given the overall image (encoded by extracting its VGG features) and the current dialogue history (i.e. the previous sequence of questions and answers), QGen produces a representation of the visually grounded dialogue (the RNN's hidden state QH_{t-1} at time $t-1$ in the dialogue) that encodes information useful to generate the next question q_t. See the sketch on the top-right part of Figure 2.

Guesser The best performing model of the Guesser module by de Vries et al. (2017) represents candidate objects by their object category and spatial coordinates. These features are passed through a Multi-Layer Perceptron (MLP) to get an embedding for each object. The Guesser also takes as input the dialogue history processed by an LSTM, whose hidden state GH_{t-1} is of the same size as the MLP output. A dot product between both returns a score for each candidate object in the image. A diagram of the architecture is given on the bottom-right section of Figure 2.

Oracle The Oracle is aware of the target object and answers each question by QGen with Yes, No, or Not Applicable. The best performing model of the Oracle module by de Vries et al. (2017) takes as input embeddings of the target object category, its spatial coordinates, and the current question. These embeddings are concatenated into a single vector and fed to an MLP that outputs the answer, as illustrated in Figure 2, righthand side.

4.2 Our Questioner Model

We extend the Questioner model of de Vries et al. (2017) with a third module, a decision making component (DM) that determines, after each question/answer pair, whether QGen should *ask* another question or whether the Guesser should *guess* the target object. We treat this decision problem as a binary classification task, for which we use an MLP followed by a Softmax function that outputs probabilities for the two classes of interest: *ask* and *guess*. The Argmax function then determines the class of the next action.

With this approach, we bypass the need to specify any decision thresholds and instead let the model learn whether enough evidence has been accumulated during the dialogue so far to let the Guesser pick up a referent.[4]

We experimented with two versions of the DM component, DM1 and DM2, which differ with respect to the encoding of the linguistic input they have access to. Both decision makers have access to the image and implicitly to the linguistic dialogue history: DM1 exploits the dialogue encoding learned by QGen's LSTM, which is trained to record information relevant for generating a follow-up question. In contrast, DM2 leverages the dialogue encoding learned by the Guesser's LSTM, which is trained to capture the properties of the linguistic input that are relevant to make a guess. The two versions are illustrated in Figure 3. The DM takes as input the concatenation (s_t) of the visual features and of the dialogue history representation it gets either via QGen's hidden state QH_{t-1} (DM1) or the Guesser's hidden state GH_{t-1} (DM2). The resulting vector is passed through a MLP. The output is then scaled between 0 and 1 by the Softmax function and treated as a probability distribution.

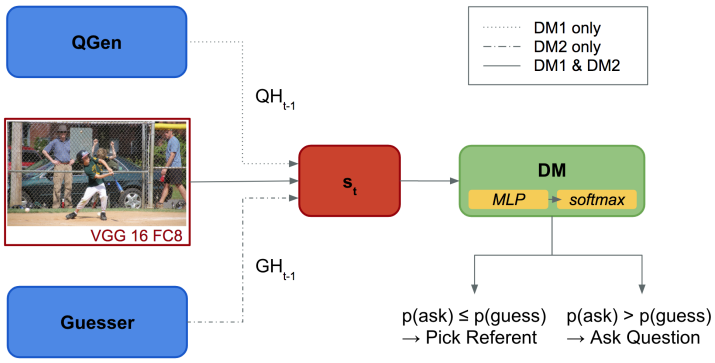

Figure 3: Our Questioner Model with two versions of the Decision Making module, DM1 and DM2.

We also implemented a hybrid DM module that receives as input both QH_{t-1} and GH_{t-1}, but we obtained worse performance. Instead of insisting on the hybrid architecture (left for future work), we maintain the two versions, DM1 and DM2, separated here so that we can focus on investigating their differences and their complementary contributions.[5]

5 Experiments and Results

Next, we present our experimental setup and accuracy results. In Section 6 we then provide an in-depth analysis of the games and dialogues.

5.1 Experimental setup

The modules in the system by de Vries et al. (2017) (QGen, Guesser, and Oracle) are trained independently with supervised learning. To allow for direct comparison with their model, we follow the same setup for training the three original modules and also our new decision making module. Details on hyperparameter settings are provided in Appendix A. We use the same train, validation, and test sets as de Vries et al. (2017).

Both DM1 and DM2 are trained with Cross Entropy loss in a supervised manner, which requires decision labels for the dialogue state after each question/answer pair. We use two different approaches to obtain decision labels from the *GuessWhat?!* ground truth dialogues. In the first approach, the question/answer pairs are labelled based on the human decision to *ask* or *guess*, obtained by checking whether there is a follow-up question in the human-human dialogues. We refer to this paradigm as *gt-label* (*gt* for *ground truth*). In the second approach, we label the question/answer pairs based on whether the Guesser module is able to correctly predict the target object given the current dialogue fragment. If the Guesser

[4]Note also that, since we have separate states for *ask* and *guess* decisions, we could potentially extend the approach to decide among multiple action types beyond the binary case.

[5]In principle, a decision-making module could also leverage the entropy of the scores for each candidate object produced by the Guesser. However, given the setup of the baseline Guesser (which we keep untouched for comparability), this would lead to implicitly using the symbolic object categories and spatial coordinates of each candidate object. This information, however, is not available to the humans at the time of deciding whether to guess or to continue asking: the list of candidate targets only becomes available once a participant decides to guess. Our DM modules only use the raw visual features, and thus are in a similar position to humans performing the task.

MaxQ	5	8	10	12	20	25	30
Baseline	41.18	40.7	39.8	38.96	36.02	35.918	35.88
DM1	40.45 (4.62)	40.12 (6.17)	40.02 (6.70)	40.00 (6.97)	39.87 (7.14)	39.68 (7.14)	39.68 (7.14)
DM2	42.19 (4.53)	41.30 (7.22)	41.12 (8.71)	39.73 (10.72)	37.75 (13.39)	36.86 (13.47)	36.83(13.51)

Table 1: Accuracy on the entire test set (all games, viz. including successful, unsuccessful, decided and undecided ones) for task success by varying the maximum number of questions allowed (MaxQ). Within brackets, the average number of questions asked for each setting. The baseline model always asks the maximum number of questions allowed.

module is able to make a correct prediction after a given question/answer pair, we label that dialogue state with *guess* and otherwise with *ask*. This is referred to as *guess-label*. DM1 can only be trained with *gt-label* (since it does not have access to information coming from the Guesser). For DM2, we treat the choice between these two labelling approaches as a hyperparameter to be tuned on the validation set. DM2 achieves better results when trained with *guess-label*. Experiments on the test set are then conducted with the optimal settings.

5.2 Accuracy Results

We first report results on task accuracy, i.e., the percentage of games where the task is successfully accomplished. Human accuracy is 90.8%. Humans can ask as many questions as they like and, on average, they guess after having asked 5.12 questions. Table 1 gives an overview of the accuracy results obtained by the baseline model, which always asks a fixed number of questions, and by our extended model with the two different versions of the DM, which decides when to ask or guess. We report the accuracy of our re-implementation of the baseline system, which is slightly better than the one reported by de Vries et al. (2017) for 5 questions.[6] To highlight the impact of including a DM module, we report the accuracies the models achieve when changing the maximum number of questions allowed (MaxQ). When MaxQ = 5, the accuracies of the model enriched with a DM module are very similar to the baseline model (slightly lower for DM1: 40.45%, and slightly higher for DM2: 42.19%), and the average number of questions asked by the DM models is also comparable to the 5 questions asked by the baseline, namely 4.62 (DM1) and 4.53 (DM2). However, if we observe how the model accuracy varies when increasing MaxQ, we see that the models equipped with a DM module tend to perform better than the baseline model and that they do so by asking fewer questions than the baseline on average. Furthermore, of the two models enriched with a decision maker, DM1 is more stable across the various settings both in terms of accuracy and of number of questions asked.

In the following analysis, unless indicated otherwise, we consider the baseline model with 5 questions, because it yields the highest baseline accuracy, and the DM models with MaxQ = 10, because more than 90% of the games solved by humans contain up to 10 questions.

6 Analysis

To better understand the results reported above and to gain insight on how the inclusion of a decision making component affects the resulting dialogues, we carry out an analysis of the behaviour of our models. We first examine how the complexity of the game (as determined by visual properties of the image) affects performance, and then analyse the quality of the linguistic interaction from the perspective of the Questioner role.

6.1 Complexity of the Game

Intuitively, the more complex the image involved in a round of the game, the harder it is to guess the target object. As a proxy for image complexity, we consider the following measures: (i) the number of objects in the image, (ii) the number of objects with the same category as the target object, and (iii) the

[6] de Vries et al. (2017) report an accuracy of 34% with a fixed number of 5 questions, while 40.8% is reported on the first author's GitHub page. Our re-implementation of the Oracle and Guesser obtain an accuracy of 78.47% (78.5) and 61.26% (61.3), respectively (in brackets, the original accuracies reported by de Vries et al. (2017)).

	successful vs. *unsuccessful*					*decided* vs. *undecided*	
	all games			decided games		all games	
	Baseline	DM1	DM2	DM1	DM2	DM1	DM2
# objects	-0.213094	-0.212920	-0.217468	-0.220929	-0.23967	-0.05292	0.144233
# objects same cat. as target	-0.150294	-0.144740	-0.150090	-0.148251	-0.165415	-0.058392	0.087068
% target object's area	4.88720	4.254	3.82114	4.15606	7.0496	1.59634	-2.38053

Table 2: Estimated regression coefficients for the logistic regression models distinguishing between *successful* vs. *unsuccessful* and *decided* vs. *undecided* games. A positive/negative coefficient indicates a positive/negative correlation between a predictor and the probability of the *successful* or *decided* class. The contribution of all predictors is statistically significant in all models ($p < 0.0001$).

size of the target object, which we compute in terms of the proportion of the cropped target object area with respect to the whole image. The distribution of games in the whole dataset is fairly balanced across these factors. See Appendix B for full details.

We fit a linear logistic regression model for the task of predicting whether a game will be successful or unsuccessful (i.e., whether the right target object will be selected), using the three measures above as independent predictor variables. It should be noted that in some cases our Questioner model may reach the maximum number of 10 questions without ever taking the action to guess. We refer to these games as *undecided*, whereas we call *decided* games those games where the DM lets the Guesser pick a referent within the maximum number of questions allowed. Out of the whole test set, the amount of decided games is 77.67% and 15.58% for DM1 and DM2, respectively.[7] It is critical to take this into account, since cases where the model is simply forced to make a guess are less informative about the performance of the DM module. Therefore, we fit two additional logistic regression models using the same three predictors: one where we consider only decided games and predict whether they are *successful* or *unsuccessful*, and one where the dependent variable to be predicted are the *decided* vs. *undecided* status of a game.

In Table 2, we report the regression coefficients for the different logistic regression models, estimated with iteratively reweighted least squares.[8] Plots of the predictor variables are available in Appendix B. Regarding the distinction between successful and unsuccessful games, we observe that the three image complexity measures we consider play a significant role. The three models (baseline, DM1, and DM2) are more likely to succeed in games that are intuitively easier — i.e., when the image contains fewer objects overall and fewer objects of the same category as the target (negative coefficients), and when the relative size of the target object is larger (positive coefficients). Interestingly, when we look into the distinction between decided and undecided games, we observe different behaviour for the two versions of the DM module. While DM1 tends to make a decision to stop asking questions and guess in easier games, surprisingly DM2 is more likely to make a guessing decision when the image complexity is higher (note the contrasting tendency of the coefficients in the last column of Table 2 for DM2). However, similarly to DM1, once DM2 decides to guess (decided games in Table 2), the simpler the image the more likely the model is to succeed in picking up the right target object.

6.2 Quality of the Dialogues

As stated in the introduction, we believe that a good visual dialogue model should not only be measured in terms of its task success but also with respect to the quality of its dialogues. In particular unnatural repetitions and unnecessary questions should be avoided. Hence, here we look into the dialogues produced by the different Questioner models comparing them with respect to these two criteria.

[7] To understand the rather big difference between the number of decided games in DM1 and DM2, we also evaluated the models using ground truth data for the QGen and Oracle modules. When human-human dialogues are used as input, the percentage of decided games is high and virtually identical for the two versions of the DM module (81.31% for DM1 and 81.30 for DM2.) This shows that DM2 is affected much more than DM1 by the errors produced by other modules. We leave an analysis of this aspect to future work. Throughout the present paper, all results and analyses reported are not based on ground truth data, but on the representations automatically generated by other modules.

[8] We use the R implementation of the logistic regression algorithm.

	All games						Decided games			
	Overall			Objects			Overall		Objects	
	Baseline	DM1	DM2	Baseline	DM1	DM2	DM1	DM2	DM1	DM2
across-games	98.07%	74.66%	84.05%	44.88%	32.94%	40.10%	69.18%	7.90%	67.05%	7.79%
within-game	45.74%	23.34%	39.27%	18.38%	11.61%	16.42%	31.28%	12.52%	30.06%	12.36%

Table 3: Percentages of repeated questions in all games and in decided games. Overall: all types of questions; Objects: only questions mentioning a candidate target object. All differences between the baseline and our models are statistically significant (Welch t-test with $p < 0.0001$).

Repeated questions Qualitative examination of the dialogues shows that the Questioner models often ask the same question over and over again. This results in unnatural linguistic interactions that come across as incoherent — see, for example, the dialogue in Figure 4 (bottom part). We analyse the dialogues produced by the models in terms of the amount of repetitions they contain. For the sake of simplicity, we only consider repeated questions that are exact string matchings (i.e., verbatim repetitions of entire questions). In this case, we consider the baseline model that asks 10 questions, as this makes for a fairer comparison with our models, where MaxQ = 10 (see end of Section 5).

Table 3 reports the percentage of dialogues that contain at least one repeated question (across-games) and the percentage of repeated questions within a dialogue averaged across games (within-game). We check the percentages with respect to both all the games and only decided games. When considering all games, we find that the baseline model produces many more dialogues with repeated questions (98.07% vs. 74.66% for DM1 and 84.05% for DM2) and many more repeated questions per dialogue (45.74% vs. 23.34% for DM1 and 39.27% for DM2) than our DM models. Among our models, the dialogues by DM1 are less repetitive than those by DM2. However, the difference between the two DM models is reversed when zooming into the decided games.

Our method for quantifying repeated questions is clearly simplistic: questions that have an identical surface form may not count as mere repetitions if they contain pronouns that have different antecedents. For example, a question such as "Is it the one on the left?" could be asked twice within the same dialogue with different antecedents for the anaphoric phrase "the one". In contrast, several instances of a question that includes a noun referring to a candidate object (such as "Is it a dog?") most probably are true repetitions that should be avoided. Therefore, as a sanity check, we perform our analysis taking into account only questions that mention a candidate object.[9] As shown in Table 3, this yields the same patterns observed when considering all types of questions.

Unnecessary questions Another feature of the dialogues revealed by qualitative examination is the presence of questions that are not repetitions of earlier questions but that, in principle, are not needed to successfully solve the game given the information gathered so far. For example, the last three questions in the dialogue in Figure 1 in the Introduction are not necessary to solve the game, given the evidence provided by the first two questions. By including a decision making component, our models may be able to alleviate this problem. In this analysis, we compare the baseline system that asks 5 questions to our models with MaxQ = 10 and look into cases where our models ask either fewer or more questions than the baseline.

Table 4 provides an overview of the results. When considering all the games, we see that the DM models ask many more questions (64.43% DM1 and 85.14% DM2) than the baseline. This is not surprising, since many games are undecided (see Section 6.1) and hence contain more questions than the baseline (10 vs. 5). Zooming into decided games thus allows for a more appropriate comparison. Table 4 also includes information on whether asking fewer or more questions helps (+ Change), hurts (– Change) or does not have an impact on task success (No Change) with respect to the baseline results. We observe that DM2 dramatically decreases the number of questions: in 95.17% of decided games, it asks fewer questions than the baseline; interestingly, in only 13.98% of cases where it asks fewer questions its performance is worse than the baseline — in all the other cases, either it achieves the same success

[9] A list of objects is provided in Appendix C.

DM	Decided games								All games	
	+ Change		– Change		No Change		Total		Total	
	Fewer	More	Fewer	More	Fewer	More	Fewer	More	Fewer	More

Figure 4: Examples where our model achieves task success by asking fewer or more questions than the baseline. Answers in red highlight Oracle errors. QGen often produces repeated or incoherent questions.

(56.18%) or even improves on the baseline results (25.01%). The latter shows that DM2 is able to reduce the number of unnecessary questions, as illustrated in Figure 1. On the other hand, DM1 does not seem to reduce the number of unnecessary questions in a significant way.

6.3 Discussion

Our analyses show that using a decision making component produces dialogues with fewer repeated questions and can reduce the number of unnecessary questions, thus potentially leading to more efficient and less unnatural interactions. Indeed, for some games not correctly resolved by the baseline system, our model is able to guess the right target object by asking fewer questions. DM2 is substantially better at this than DM1 (25.01% vs. 1.77% of decided games; see Table 4). By being restricted to a fixed number of questions, the baseline system often introduces noise or apparently forgets about important information that was obtained with the initial questions. Thanks to the DM component, our model can decide to stop the dialogue once there is enough information and make a guess at an earlier time, thus avoiding possible noise introduced by Oracle errors, as illustrated in Figure 4 (left). Qualitative error analysis, however, also shows cases where the DM makes a premature decision to stop asking questions before obtaining enough information. Yet in other occasions, the DM seems to have made a sensible decision, but the inaccuracy of the Oracle or the Guesser components lead to task failure. Further examples are available in Appendix D.

In some games with complex images, the information obtained with 5 questions (as asked by the baseline) is not enough to resolve the target. The flexibility introduced by the DM allows our model to reach task success by asking additional questions. Figure 4 (right) gives an example. Furthermore, if noise has been introduced at earlier stages of the dialogue, asking further questions can increase the chance to recover relevant information. However, we also observe that in some games correctly guessed

by the baseline system, asking more questions leads to failure since it opens the door to getting wrong information from the Oracle.

In the current analyses, we have not studied the behaviour of our DM models when using ground truth data instead of the noisy automatic output produced by the other modules. In part, this is motivated by our long-term goal of developing fully data-driven multimodal conversational agents that can be trained end-to-end. We leave for future work carrying out a proper ablation study that analyses the impact of using ground truth vs. automatic data on the DM component.

7 Conclusion

Research on dialogue systems within the Computational Linguistics community has shown the importance of equipping such systems with dialogue management capabilities. Computer Vision researchers have launched the intriguing Visual Dialogue challenge mostly focusing on comparing strong machine learning paradigms on task accuracy, and largely ignoring the aforementioned line of research on dialogue systems. Our goal is to explore how data-driven conversational agents, modelled by neural networks without additional annotations usually exploited by traditional dialogue systems, can profit from a dialogue management module. The present work is a first step towards this long-standing goal. We have taken the *GuessWhat?!* task as our testbed, since it provides a simple setting with elementary question-answer sequences and is task-oriented, which opens the door to using an unsupervised approach in the future. We have focused on augmenting the Questioner agent of the *GuessWhat?!* baseline, which consists of a Question Generator and a Guesser module, with a decision making component (DM) that determines after each question-answer pair whether the Question Generator should ask another question or whether the Guesser should guess the target object. The solution we propose is technically simple, and we believe promising and more cognitive principled than, for example, including a `stop` token as Strub et al. (2017). We show that incorporating a decision making component does lead to less unnatural dialogues. It remains to be seen whether a hybrid DM module that exploits the dialogue encodings of both the Question Generator and the Guesser modules could bring further qualitative and quantitative improvements.

Appendix A: Details of *GuessWhat?!* Dataset and Experimental Setup

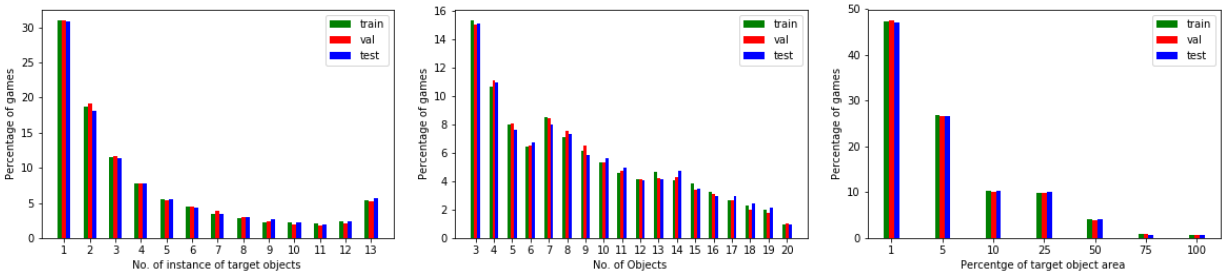
Dataset. The GuessWhat?! dataset contains 77,973 images with 609,543 objects and around 155K human-human dialogues. The dialogues contain around 821K question/answer pairs composed out of 4900 words (counting only words that occur at least 3) on 66,537 unique images and 134,073 target objects. Answers are Yes (52.2%), No (45.6%) and NA (not applicable, 2.2%); dialogues contain on average 5.2 questions and there are on average 2.3 dialogues per image. There are successful (84.6%), unsuccessful (8.4%) and not completed (7.0%) dialogues.

Games and Experimental Setting. In the baseline model, games consist of 5 turns each consisting of question/answer pairs asked by QGen and answered by the Oracle. The QGen module stops asking questions after having received the answer to the 5th question. It is then the turn of the Guesser.

All the modules are trained independently using Ground Truth data. For the visual features, 'fc8' of the VGG-16 network is used. Before visual feature calculation, all images are resized to 224X224. For each object, the module receives the representation of the object category, viz., a dense category embedding obtained from its one-hot class vector using a learned look-up table, and its spatial representation, viz., an 8-dimensional vector. The dialogue is encoded using variable length LSTM with 512 hidden size for Guesser and Oracle and 1024 hidden size for QGen. The LSTM, object category/word look-up tables and MLP parameters are optimized while training by minimizing the negative log-likelihood of the correct answer using ADAM optimizer with learning rate 0.001 for Guesser and Oracle. For QGen, the conditional log-likelihood is maximized based on the next question given the image and dialogue history. All the parameters are tuned on the validation set, training is stopped when there is no improvement in the validation loss for 5 consecutive epochs and best epoch is taken.

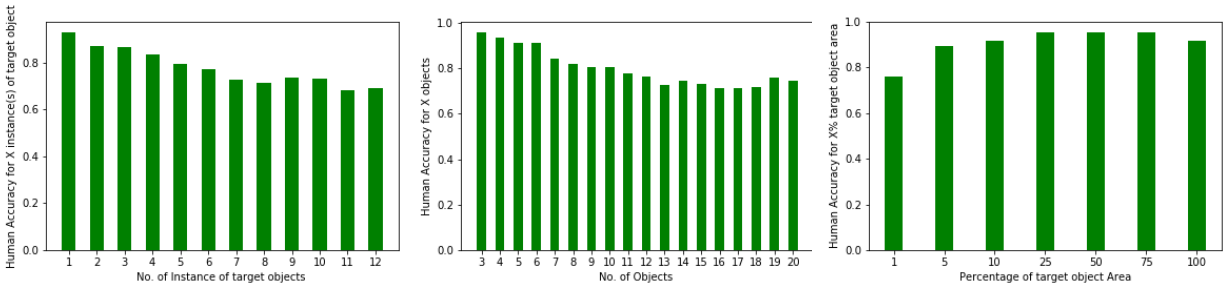
Appendix B: Analysis Regarding Image Complexity

Distribution of image complexity measures. Figure 5 shows the image distribution across the train, validation and test sets with respect to the image complexity measures, namely (a) the number of instances of the target object, (b) the number of objects, and (c) the percentage of target object area with respect to the overall image. We can see that the distribution with respect to these measures is very similar in the three sets. Figure 6 provides human performance based on the different image complexity measures. Human performance is similar to the model performance. While human accuracy is comparatively high, it also decreases when the image complexity increases.



(a) # instances of target object. (b) # of objects. (c) % area covered by target object.

Figure 5: Image distribution with respect to the image complexity measures in the different dataset splits.

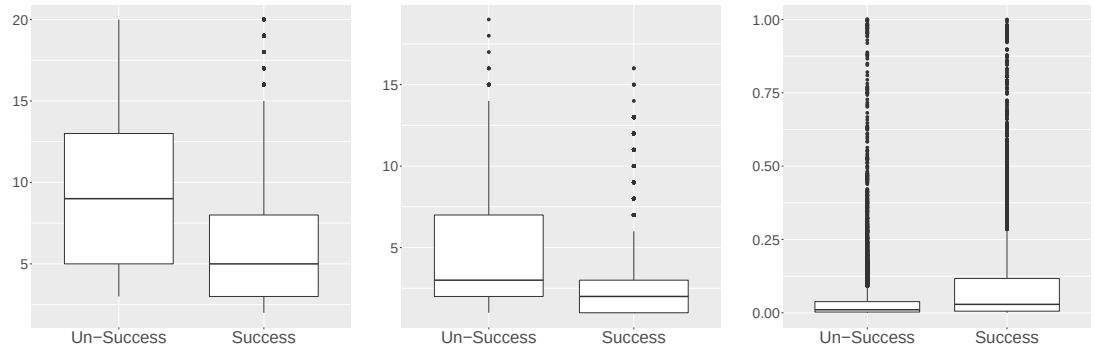


(a) no. of instances of target object. (b) no. of objects. (c) % area covered by target object.

Figure 6: Human accuracy distribution with respect to the image complexity features.

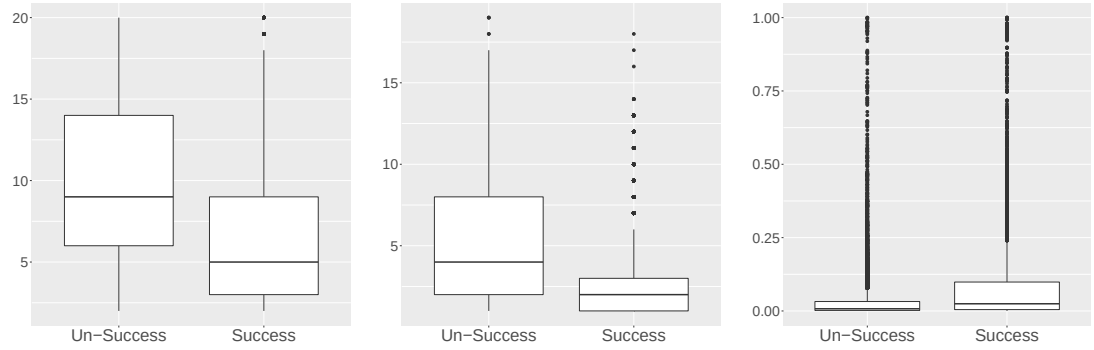
Image complexity measures as predictors in the logistic regression models. Figures 7 and 8 show plots of the image complexity measures in successful vs. unsuccessful games, for all games played by DM1 and DM2. As already noted in Section 6.1, fewer instances of the target object, fewer objects, and larger area of the target object correspond to higher chance of the game being successful, similarly to what we had noticed for humans. We observe the same trend when we restrict the analysis to decided games only, as shown in Figures 9 and 10 for DM1 and DM2, respectively

Figures 11 and 12 compare decided vs. undecided games played by the two DMs. In this case, we observe a difference: DM1 seems to exploit the image complexity measures in a way similar to humans, as noted earlier. DM2, however, decides more often when there are more instances of the target object and when the number of objects in the image is higher. Why this is the case remains unclear.



(a) no. of instances of target object. (b) no. of objects. (c) % area covered by target object.

Figure 7: Effect of image complexity measures on successful vs. unsuccessful games played by DM1.



(a) # of instances of target object. (b) # of objects. (c) % area covered by target object.

Appendix C: Repeated Questions

To automatically find the repeated questions in a generated game (see Section 6.2), we have used full string matching, i.e., a question is considered a repetition only when there is another question in the same game having exactly the same words. We have considered repetitions for three types of questions, namely, questions about Object type, Attributes, and Spatial location. Keyword matching is used to decide the type of question that is repetition. For instance, a repeated question is of Object type if it contains keywords such as 'dog', 'cat', etc. These keywords are created using MS-COCO object categories and super-categories, plus the following manually curated list: [man, woman, girl, boy, table, meter, bear, cell, phone, wine, glass, racket, baseball, glove, hydrant, drier, kite].

Appendix D: Example Dialogues

We provide some more examples of successful and unsuccessful games.

(1.) Is it a person? Yes
(2.) Is it the girl? Yes (DM2) (Success)
(3.) Is she in the background? No
(4.) Is she in the background? No
(5.) Is she wearing a white shirt? No (Baseline)(Fail)

(1.) Is it a bike? No
(2.) Is it a car? No
(3.) Is it a bike? No
(4.) Is it a person? Yes
(5.) Is it in the background? Yes (Baseline) (Fail)
(6.) Is it in the left side? Yes (DM1) (Success)

(1.) Is it a person? Yes
(2.) Is it in the foreground? No
(3.) the road? No
(4.) Is it in the foreground? No
(5.) Is it in the background? Yes (Baseline) (Fail)
(6.) the left side? Yes (DM2) (Success)

Figure 13: Successful games where the DM decides to ask more/fewer questions compared to the Baseline. Some of the target objects are very small and by allowing to agent to ask extra questions about the spatial location, the Guesser manages to correctly guess the target object.

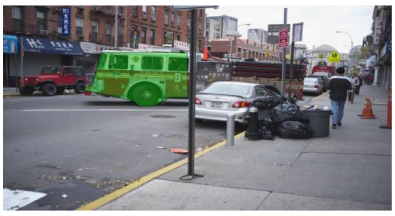
(1.) is it a person? Yes
(2.) in the foreground ? Yes (Oracle Error)
(3.) is it the person in the foreground? No (DM1) (Fail)
(4.) is it the person in the foreground? No
(Repetitive Question)
(5.) is it the person in the background? Yes (Success)

(1.) is it a person? Yes
(2.) is it a male? Yes
(3.) is he wearing a blue shirt? Yes (Oracle Error)
(4.) is he wearing a blue shirt? Yes DM1 (Fail)
(Oracle Error)(Repetitive Question)
(5.) is he wearing a black shirt? Yes (Baseline)
(Success)

(1.) is it a person? No
(2.) is it on the table? Yes
(3.) is it on the table? Yes (DM1) (Fail)
(Repetitive Question)
(4.) Is it the cake? Yes
(5.) Is it the cake? No (Baseline) (Success)
(Repetitive Question)

Figure 14: Unsuccessful games played by DM1, where the system decides to stop asking earlier than the baseline. These failures seem to occur due to the problems by QGen (which generates repeated questions) or the Oracle (which provides a wrong answer).

(1.) is it a person? Yes
(2.) in the foreground? Yes
(3.) the picture? Yes (DM2) (Fail)
(Oracle Error)
(4.) is it the left? No
(5.) Is it the right? Yes (Baseline) (Success)



(1.) is it a person? No
(2.) is it a vehicle? Yes
(3.) on the right? Yes (DM2) (Fail)
(Oracle Error)
(4.) is it the bus? Yes
(5.) is it the fire truck? No (Baseline) (Success)

Figure 15: Unsuccessful games played by DM2, where the system decides to stop asking earlier than the baseline. DM2 seems to be overconfident. Again, failures are often affected by Oracle errors.

Sequence-to-Sequence Data Augmentation for Dialogue Language Understanding

Yutai Hou, Yijia Liu, Wanxiang Che*, Ting Liu
Research Center for Social Computing and Information Retrieval
Harbin Institute of Technology, China
{ythou, yjliu, car, tliu}@ir.hit.edu.cn

Abstract

In this paper, we study the problem of data augmentation for language understanding in task-oriented dialogue system. In contrast to previous work which augments an utterance without considering its relation with other utterances, we propose a sequence-to-sequence generation based data augmentation framework that leverages one utterance's same semantic alternatives in the training data. A novel diversity rank is incorporated into the utterance representation to make the model produce diverse utterances and these diversely augmented utterances help to improve the language understanding module. Experimental results on the Airline Travel Information System dataset and a newly created semantic frame annotation on Stanford Multi-turn, Multi-domain Dialogue Dataset show that our framework achieves significant improvements of 6.38 and 10.04 F-scores respectively when only a training set of hundreds utterances is represented. Case studies also confirm that our method generates diverse utterances.

Title and Abstract in Chinese

对话语义理解的序列到序列数据增强

在本文中，我们研究了面向任务的对话系统中语言理解模块的数据增强问题。相比之前的工作在生成新语句时不考虑语句间关系，我们利用训练数据中与一个语句具有相同语义的其他句子，提出了基于序列到序列生成的数据增强框架。我们创新地将多样性等级结合到话语表示中以使模型产生多样化的语句数据，而这些多样化的新语句有助于改善语言理解模块。在航空旅行信息系统数据集以及一个新标注的斯坦福多轮多域对话数据集上的实验结果表明，当训练集仅包含数百句语料时，我们的框架在F值上分别实现了6.38和10.04的显着提升。案例研究也证实我们的方法能够产生多样化的话语。

1 Introduction

Language understanding (LU) is the initial and essential component in the task-oriented dialogue system pipeline (Young et al., 2013). One challenge in building robust LU is to handle myriad ways in which users express demands. This challenge becomes more serious when switching to a new domain whose large-scale labeled data is usually unreachable. Insufficiency in training data makes LU vulnerable to unseen utterances which are syntactically different but semantically related to the existing training data, and further harms the whole task-oriented dialogue system pipeline.

Data augmentation, which enlarges the size of training data in machine learning systems, is an effective solution to the data insufficiency problem. Success has been achieved with data augmentation on a wide range of problems including computer vision (Krizhevsky et al., 2012), speech recognition (Hannun et al., 2014), text classification (Zhang et al., 2015), and question answering (Fader et al., 2013). However, its application in the task-oriented dialogue system is less studied. Kurata et al. (2016a) presented the only work we know that tried to augment data for LU. In their paper, an encoder-decoder is

* Email corresponding.

Proceedings of the 27th International Conference on Computational Linguistics, pages 1234–1245
Santa Fe, New Mexico, USA, August 20-26, 2018.

learned to reconstruct the utterances in the training data. During the augmenting process, the encoder's output hidden states are randomly perturbed to yield different utterances.

The work of Kurata et al. (2016a) augments one single utterance by adding noise without considering its relation with other utterances. Besides theirs, there are also works which explicitly consider the paraphrasing relations between instances that share the same output. These works achieve improvements on tasks like text classification and question answering. Paraphrasing techniques including word-level substitution (Zhang et al., 2015; Wang and Yang, 2015), hand-crafted rules generation (Fader et al., 2013; Jia and Liang, 2016), and grammar-tree generation (Narayan et al., 2016) have been explored. Compared with these work, Kurata et al. (2016a) has the advantage of fully data-driven method and can easily switch to new domain without too much domain-specific knowledge, but doesn't make use of the relations between instances within the training data.

In this paper, we study the problem of data augmentation for LU and propose a novel data-driven framework that models relations between utterances of the same semantic frame in the training data. A sequence-to-sequence (seq2seq, Sutskever et al. 2014) model lies in the core of our framework which takes a delexicalised utterance and generates its lexical and syntactical alternatives. To further encourage diverse generation, we incorporate a novel *diversity rank* into the utterance representation. When training the seq2seq model, the diversity rank is also used to filter the over-alike pairs of alternatives. These approaches lead to diversely augmented data that significantly improves the LU performance in the domains that labeled data is scarce.

We conduct experiments on the Airline Travel Information System dataset (ATIS, Price 1990) along with a newly annotated layer of slot filling over the Stanford Multi-turn, Multi-domain Dialogue Dataset (Eric and Manning, 2017).[1] On the small proportion of ATIS which contains 129 utterances, our method outperforms the baseline by a 6.38 F-score on slot filling. On the medium proportion, this improvement is 2.87. Similar trends are witnessed on our LU annotation over Stanford dialogue dataset which the average improvement on three new domains is 10.04 on 100 utterances and 0.47 on 500 utterances.

The major contributions of this paper include:

- We propose a data augmentation framework for LU (§2) using the seq2seq model. A novel diversity rank (§3) is used to encourage our seq2seq model to generate diverse utterances both in the augmentation and training (§4).

- We conduct experiments on the ATIS and Stanford dialogue dataset (§5). Experimental results show our augmentation can effectively enlarge the training data and improve LU performance by a large margin when only a small size of training data is presented. Case studies also confirm that our method generates diverse utterances compared to the results from previous work.

We release our code at:
`https://github.com/AtmaHou/Seq2SeqDataAugmentationForLU`.

2 Overview of the Approach

Notion and Problem Description. In this paper, we study the data augmentation for language understanding (LU), which maps a natural language utterance into its semantic frames. We focus on *slot filling* and follow previous works (Pieraccini et al., 1992) by treating it as a sequence classification in which semantic class labels (*slot types*) are assigned to contiguous sequences of words indicating these sequences are corresponding *slot values*. In this paper, we use the bidirectional long short term memory (BiLSTM) for slot labeling (tagging) as previous works did (Mesnil et al., 2013; Yao et al., 2014; Kurata et al., 2016b).

We formalize the data augmentation for LU as given a natural language utterance $\mathbf{u}$ and its semantic frame $\mathbf{s}$, we generate a set of new utterances with corresponding semantic frames. During the augmenting process, we go through the whole training data $D = \{(\mathbf{u}_i, \mathbf{s}_i)\}_{i=1}^{N}$. For each training instance $(\mathbf{u}_i, \mathbf{s}_i)$,

[1] abbreviated as *Stanford dialogue dataset* henceforth.

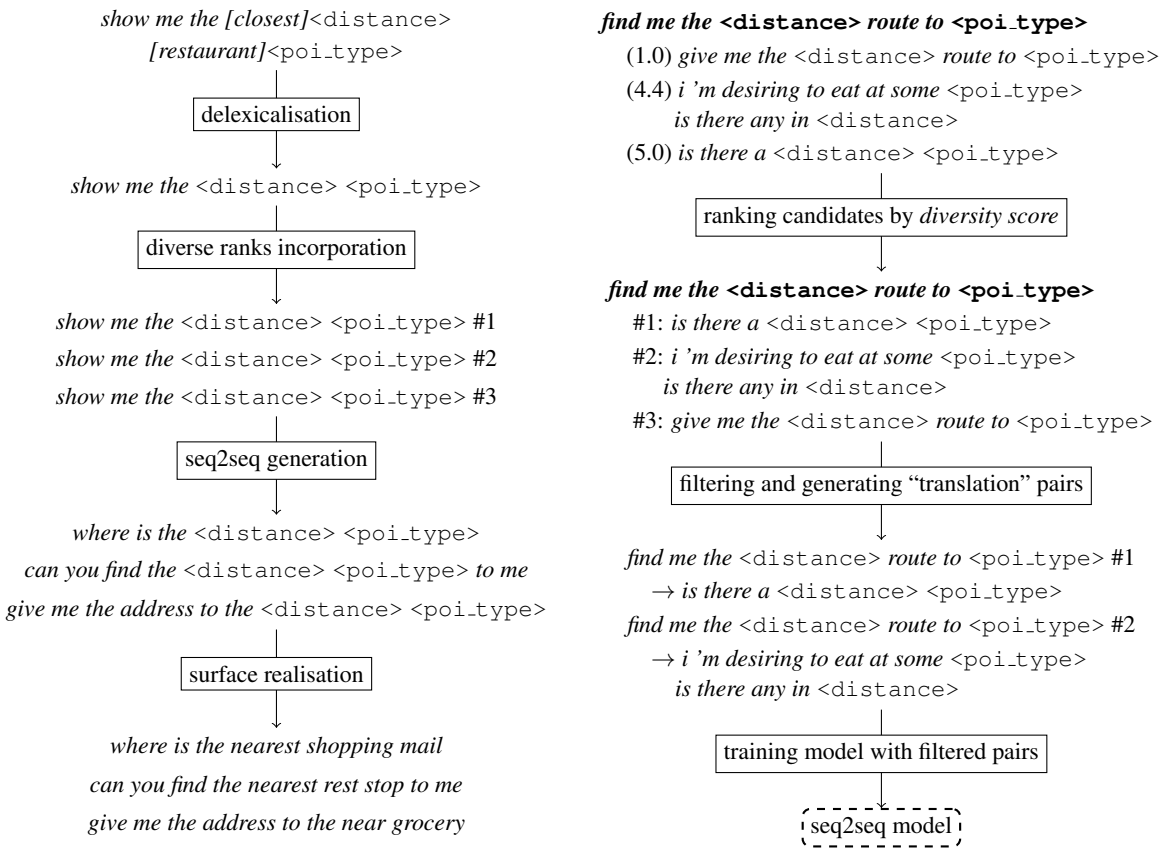


Figure 1: The workflow of our framework. The left part shows the augmenting process and the right part shows the training instance generation process for our seq2seq model. $\mathbf{u} \rightarrow \mathbf{u}'$ marks that $\mathbf{u}$ can be augmented into $\mathbf{u}'$.

we expand it to a set of instances $\{(\mathbf{u}_i^k, \mathbf{s}_i^k)\}_k$ and use the union of the expanded instances as new data to train the LU module.

In the training phase, we define the cluster of semantic frame $\mathbf{s}$ as $C_\mathbf{s} = \{(\mathbf{u}', \mathbf{s}') \mid (\mathbf{u}', \mathbf{s}') \in D \wedge \mathbf{s}' = \mathbf{s}\}$. For one utterance $\mathbf{u}$ and its semantic frame $\mathbf{s}$, each utterance $\mathbf{u}' \in C_\mathbf{s}/\{(\mathbf{u}, \mathbf{s})\}$ is considered as the alternative expression and augmentation of $\mathbf{u}$. We use $\mathbf{u} \rightarrow \mathbf{u}'$ to mark this relation.

To achieve the goal of generating variant utterances under the same semantic frames, We break down the problem into first converting the input utterance $\mathbf{u}$ into its delexicalised form $\mathbf{d}$, and then generating the delexicalised variances of $\mathbf{d}$ with a seq2seq model. Finally, surface realization is carried out to convert the delexicalised form into the raw utterance. The left part of Figure 1 shows the workflow of our augmenting process.

Delexicalisation. When given the raw utterance and its semantic frames associated with certain segments of the utterance, we can easily delexicalise the utterance by replacing the corresponding segments with the semantic frame label. For example, when given the 4th word in "*show me the closest restaurant*" as a `<distance>` slot type and 5th word as `<poi_type>` slot type, its delexicalized form "*show me the* `<distance>` `<poi_type>`" is straight-forward to achieve.

In the task-oriented dialogue system, slot values usually consist of various entity names and are very sparse. Delexicalisation reduces the size of vocabulary and makes the model focus more on generating variant ways of expressing demands. What's more, the semantic frames can be directly derived from the delexicalised generation and used for training the LU module.

Incorporating Diversity Ranks into Utterance Representations. Considering the example in the right part of Figure 1, "*is there a* `<distance>` `<poi_type>`" is more diverse than "*give me the* `<distance>` *route to* `<poi_type>`" when compared with "*find me the* `<distance>` *route to*

<poi_type>". This example shows that for utterance $\mathbf{u}$ with semantic frame $\mathbf{s}$, its alternatives expressions can have different ranks in diversity. To consider the ranking information, we compile the *diversity rank* as an additional information into the utterance representation. By setting it to a higher rank, we aim to generate input utterance's diverse augmentation, and by setting it to lower, a similar utterance should be generated. We will discuss the details of how to compute the ranks during training and how to decide the effective numbers of ranks during testing in Section 3.

Data Augmentation as Seq2Seq Generation. When given the delexicalised input utterance $\mathbf{d}$ and the specified diverse rank k, we use the standard seq2seq model to generate the alternative delexicalised utterance $\mathbf{d}'$. In our seq2seq model, we append $\#k$ to the end of the input utterances and the model is formalized as

$$p(\mathbf{d}' \mid \mathbf{d}, k) = \prod_t p(d'_t \mid d_1, ..., d_n, \#k, d'_1, ..., d'_{t-1})$$

where n is the number of words for the input utterance $\mathbf{d}$.

In this paper, we follow the seq2seq model for neural machine translation and use the *input-feeding* network in (Luong et al., 2015) with attention as our seq2seq model. During testing, we use beam search with beam size of 10 to yield more than one translation following Gimpel et al. (2013) and Vijayakumar et al. (2016).

To train the seq2seq model, our basic assumption is that if $\mathbf{d}$ and $\mathbf{d}'$ contain the same semantic frames, they can be generated from each other. Generally, we assume each pair of delexicalised utterances in the cluster $C_\mathbf{s}$ makes a pair of generation. However, it's nontrivial to assign *diverse ranks* to training data. What's more, to prevent the model from just producing produce lexical paraphrases (like "*show me*" to "*give me*"), we propose to also consider the diversities when generating training translations for the seq2seq model. We will talk about the details in Section 4.

Surface Realisation. Till now, we have achieved the lexically and syntactically different utterances in their delexicalized forms. We would like to bridge these utterances to their lexicalized forms and surface realisation is employed as the final step of our approach.

In this paper, the surface realisation is performed by replacing the slot type in the delexicalised form with its slot value. The mapping from slot type to its set of slot values (e.g. from <poi_type> to {*hospital*, *restaurant*}) is collected on the training data. Somehow, it's nontrivial to just do the replacement because one slot value doesn't fit its slot type in any context. Taking the utterance in Figure 1 for example, in the delexicalised utterance "*i 'm desiring to eat at some* <poi_type> *is there any in* <distance>", 'hospital' doesn't fit in the <poi_type> because 'hospital' isn't the place intended for a meal. To make the surface realisation more reasonable, we build the mapping with consideration of the context and use slot type along with its surrounding 5 words as the key in the mapping.

During surface realisation for an utterance, we first extract the slot type and its context. Then we use this to get all its slot values. If the slot type under certain context is not presented in the mapping, we use the one with the most similar context in the sense of *edit distance*. If more than one slot values present, we randomly pick a slot value.

3 *Diversity Ranks* in Utterance Representations

The major motivation of this paper is to encourage diverse generation. To accomplish this motivation, we propose a criterion named *diversity rank* to model the diversities. During augmenting the data, for an instance $(\mathbf{u}, \mathbf{s})$ we generate the delexicalised utterance at rank from 1 to $N_\mathbf{s}$, where $N_\mathbf{s}$ is a number governed by the semantic frame $\mathbf{s}$ and calculated as $||C_\mathbf{s}||/2$, which is the half size of the instances in D that have the semantic frame $\mathbf{s}$.

During training the seq2seq model with diversity rank, for one instance $(\mathbf{u}, \mathbf{s})$, we first collect $C_\mathbf{s}$, then rank each instance $(\mathbf{u}', \mathbf{s}) \in C_\mathbf{s}/\{(\mathbf{u}, \mathbf{s})\}$ by its *diversity score* against $\mathbf{u}$. In this paper, the diversity score of an utterance pair $(\mathbf{u}, \mathbf{u}')$ is calculated by both considering the *edit distance* and a *length difference penalty* (LDP) as:

$$\text{SCORE}(\mathbf{u}, \mathbf{u}') = \text{EDITDISTANCE}(\mathbf{u}, \mathbf{u}') \times \text{LDP}(\mathbf{u}, \mathbf{u}') \quad (1)$$

	Navigation	Scheduling	Weather
# of training utterances	500	500	500
# of devel. utterances	321	201	262
# of test utterances	337	212	271
Kappa	0.68	0.92	0.90
Agreement	85.05	90.75	95.99

Table 1: Statistics for our annotation.

where LDP is defined as $\text{LDP}(\mathbf{u}, \mathbf{u}') = e^{-\frac{|||\mathbf{u}||-||\mathbf{u}'|||}{||\mathbf{u}||}}$. After obtaining the ranks over the utterances $\mathbf{u}'$, we directly incorporate the rank value as an additional last token for the seq2seq model.

We note that using the LDP reduces the impact of differences in length and makes the score paying more attention to the lexical and syntactical difference. For example, the first block of right part of Figure 1 shows the diversity scores of three different utterances. Although the utterance "*i 'm desiring to eat at some* <poi_type> *is there any in* <distance>" presents larger *edit distance* (12 in this case) than that of "*is there a* <distance> <poi_type>" (5 in this case), the final score is penalized to 4.4 because the length difference.

In our method, the diversity rank can be treated as an utterance-independent controller for the diversity of target generation.

4 Filtering the Alike Instances

To learn the seq2seq model, it's straight-forward to use each pair of utterances in $C_{\mathbf{s}}$ as training data for the model. However, the goal of our paper is to generate diverse augmented data and the usefulness of less diverse pair (like *give me the* <distance> *route to* <poi_type> and *find me the* <distance> *route to* <poi_type> in Figure 1) is arguable.

In this paper, we propose to filter the less diverse pairs when training the seq2seq model. Again, we make use of the ranks derived by the diversity scores and for an utterance $\mathbf{u}$ only the most diverse half of the translations $\mathbf{u} \rightarrow \mathbf{u}'$ are used to train the seq2seq model and the training data can be formalized as

$$D_{\text{seq2seq}} = \bigcup_{(\mathbf{u},\mathbf{s}) \in D} \{\mathbf{u}, \textsc{Rank}(\mathbf{u}, \mathbf{u}') \rightarrow \mathbf{u}' \mid \mathbf{u}' \in C_{\mathbf{s}}, \textsc{Rank}(\mathbf{u}, \mathbf{u}') \geq ||C_{\mathbf{s}}||/2\}$$

After filtering the less diverse pairs, we use D_{seq2seq} to train the seq2seq model.

In this section, we revisit the role of our diversity ranks in the learning perspective. Since we consider the utterance in cluster $C_{\mathbf{s}}$ as translation to each other, without the RANK value, one utterance can simultaneously translate to different utterances in the training data. It increases the ambiguities in learning the seq2seq model and even makes it intractable. With the RANK value, such ambiguities are resolved because each pair of the training data is expanded with a unique value.

5 Experiments

5.1 Settings

Dataset. In this paper, we conduct our experiments on the ATIS dataset which is extensively used for LU (Mesnil et al., 2013; Mesnil et al., 2015; Chen et al., 2016a). The ATIS dataset contains 4978 training utterances from Class A training data in the ATIS-2 and ATIS-3 corpus, while the test contains 893 utterances from the ATIS-3 Nov93 and Dec94 datasets. The size of the training data is relatively large for LU in a single domain. To simulate the data insufficient situations, we follow Chen et al. (2016a), and also evaluate our model on two small proportions of the training data which is *small* (1/40 of the original training set with 129 instances) proportion and *medium* (1/10 of the original training set with 515 instances). In all the experiments, a development set of 500 instances is used.

To test our model on new domains beyond ATIS, we also create a new LU annotation over the Stanford dialogue dataset (Eric and Manning, 2017). We use the same data split as Eric and Manning (2017) and

Model	small	medium	full
	129	515	4,478
Baseline	67.33**	85.85**	94.93*
Ours	73.71	88.72	94.82
Re-implementation of Kurata et al. (2016a)	67.93**	87.34**	94.61**
Model-1 Additive (Kurata et al., 2016a)	-	-	95.08
K-SAN syntax (Chen et al., 2016a)	74.35	88.40	95.00
Model-III (Zhai et al., 2017)	-	-	95.86

Table 2: The results on the ATIS dataset. The first block shows the results from our implementation and the second block is drawn from the papers of previous works. Here we use * to indicate that the difference between the model and Ours is statistically significant under t-test (** for p-value threshold as 0.05 and * for threshold as 0.1) .

annotate the full test sets for the three domains (*navigation*, *scheduling*, and *weather*) along with a small training set of 500 utterances. The Stanford dialogue dataset provides semantic frames (*slot*) for each utterance but doesn't associate the semantic class of the slot with corresponding segment in the utterance. Our annotation focus on assigning the slot to its corresponding segment. During the annotation, each dialogue was processed by two annotators. Data statistics, Kappa value (Snow et al., 2008), and inner annotator agreement measured by F-score on the three domains are shown in Table 1.

Evaluation. We evaluate our data augmentation's effect on LU with F-score. `conlleval` is used in the same way with previous works (Mesnil et al., 2013; Mesnil et al., 2015; Chen et al., 2016a).

Implementation. We use OpenNMT (Klein et al., 2017) as the implementation of our seq2seq model. We set the number of layers in LSTM as 2 and the size of hidden states as 500. Utterances that are longer than 50 are truncated. We adopt the same training setting as Luong et al. (2015) and use Adam (Kingma and Ba, 2014) to train the seq2seq model. Learning rate is halved when perplexity on the development set doesn't decrease. During generation, we replace the model-yielded unknown token (*unk*) with the source word that has the highest attention score.

For the slot tagging model, we set both the dimension for word embedding and the size of hidden state to 100. We also vary dropout rate in $\{0, 0.1, 0.2\}$ considering its regularization power on small size of data. The batch size is set to 16 in all the experiments. Best hyperparameter settings are determined on the development set. GloVe embedding (Pennington et al., 2014) is used to initialize the word embedding in the model. Adam with the suggested settings in Kingma and Ba (2014) is used to train the parameters.

Reimers and Gurevych (2017) pointed out that neural network training is nondeterministic and depends on the seed for the random number generator. We witness dramatic changes of the slot tagging performance using different random seeds. To control for this effect, we take their suggestions and report the average of 5 differently-seeded runs.

5.2 Results on ATIS

Table 2 shows the slot tagging results on the ATIS dataset. Our baseline model is the vanilla BiLSTM slot tagger and our augmented slot tagger use the same architecture but is trained with the augmented data generated by our method. Compared with the vanilla tagger baseline, our augmentation method significantly improves the LU performance by a 6.38 F-score on the *small* proportion and a 2.02 F-score on the *medium* proportion. The improvements show the effectiveness of our augmentation method in the data-insufficient scenario. On the full data, our augmentation slightly lags the baseline. We address this to the fact that full ATIS is large enough for LU on a single domain and our augmentation introduce some noise.

To compare with the previous augmentation work from Kurata et al. (2016a), we re-implemented their *model-1 additive* model using the suggested settings in their paper. The results on the *small*, *medium*, and *full* proportions are shown in the third row of Table 2. On all the proportions, our augmentation

# utterances	Model	Navigation	Scheduling	Weather
100	Baseline	59.93	68.29	82.43
	Ours	72.91	77.30	90.55
500	Baseline	78.99	86.05	93.68
	Ours	78.46	87.67	94.01

Table 3: The results on Stanford dialogue dataset.

Model	F-score	# new	max. ED
Ours	88.72	301	3.18
- seq2seq generation	-0.84**	0	0
- diversity ranks	-0.40*	163	2.42
- filtering	-0.38	870	2.86

Table 4: The result of the ablation test. *# new* marks the number of newly generated delexicalised utterances. *max. ED* marks the averaged maximum edit distances. Here we use * to indicate that the result is statistically significant under t-test (** for p-value threshold as 0.05 and * for threshold as 0.1) By removing the seq2seq generation from our method, no delexicalised utterance will be generated so the *max. ED* cell is 0.

method outperforms theirs and the differences are significant on *small* and *medium*. Since their model relies on learning a seq2seq model to reconstruct the input utterances, it's usually difficult to train a reasonable model on very small data due to sparsity. Our method mitigates this by both generating on the delexicalised utterances and learning the generation model from pairs of utterances that share same semantic frame which enlarge the size of data for us to train the model. We also compare our model with the syntax version of K-SAN (Chen et al., 2016a) without joint training from intent annotation. We see that our augmented tagger lags their syntax-parsing-enhanced model by a 0.64 F-score on small proportion and outperforms theirs by a 0.32 F-score on medium proportion. But considering the training data is sampled with different random seeds between our work and theirs, these results are not directly comparable. At last, we show the (Zhai et al., 2017) as state-of-art results on ATIS dataset, which views slot filling task as sequence chunking problem. As we focus data augmentation for sequence labeling task rather than chunking, this result is not directly comparable to ours. Besides, K-SAN (Chen et al., 2016a) and (Zhai et al., 2017) are not data augmentation methods, we included their results to show that our augmentation method is reasonably good The basic trend shows that our augmentation can be used as an alternative to the LU model leveraging rich syntactic information.

5.3 Results on Stanford Dialogue Dataset

The results for Stanford dialogue dataset are shown in Table 3. Similar trend as the ATIS experiments is witnessed in which the augmentation improves the LU performance. The average improvement on the training data with 100 utterances is 10.04, and the number is 0.47 for that with 500 utterances. Considering that only fewer than 350 utterances present in the test set in all these domains, these improvements are reasonable. Besides, similar to the ATIS results, the margin of improvements is larger for the smaller training set.

An advantage of our method is that it's purely data-driven. Only a mapping from slot type context to slot values is required and it can be constructed from the training data. It's easy for our method to switch to new domains and our results on the Stanford dialogue dataset confirms this.

5.4 Analysis

Ablation. To get further understanding of each component in our method, we conduct ablation on the *medium* proportion, Each of the three parts of our method is removed respectively, including the *seq2seq generation*, *diversity ranks*, and *filtering*. In addition to evaluate the model's performance with F-score, we also examine the augmented data by the number of newly generated delexicalised utterances and the

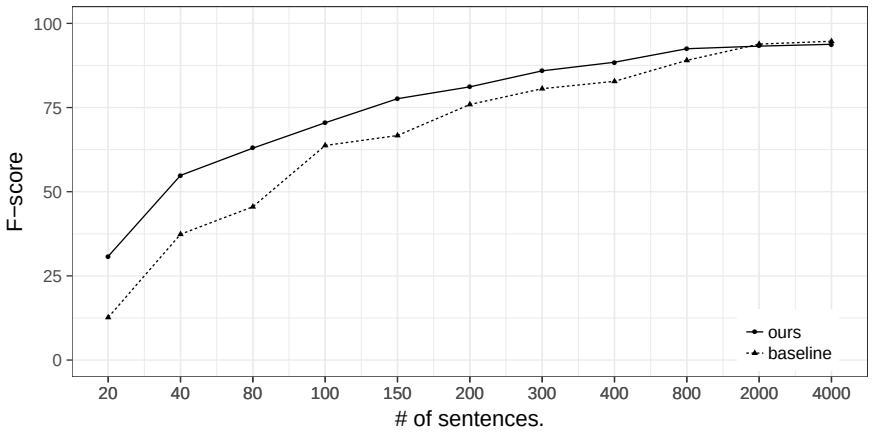

Figure 2: Our method's performances on the ATIS training data of different sizes.

maximum edit distances against the rest of instances.[2] The results are shown in Table 4.

For our method without *seq2seq generation*, we only conduct surface realisation on the delexicalised utterance and a 0.84 F-score drop is witnessed. Since surface realisation only substitutes slot type with different slot values without changing the utterances syntactically, this ablation shows it's more beneficial to generate syntactic alternatives using our seq2seq model.

For our method without *diversity ranks*, we remove diversity ranks from the utterance representation and this lead a drop of 0.40 F-score. We address the drop of performance to the fact that removing either these components will lead to less diverse generation. The second and third column in Table 4 confirm this by showing less newly and diversely generated delexicalised utterances.

If we don't filter the alike instances when training the seq2seq model, the drop of performance is a 0.65 F-score. However, larger number of new utterances with smaller edit distances are yielded which indicates that more noise is introduced when the training data of the seq2seq model is not properly filtered.

This ablation also shows correlation between the maximum edit distance and the final F-score, which indicates generating diverse augmentation helps the performance.

Effect of Training Data Size. The results on ATIS and Stanford dialogue dataset witness the trend that smaller training data benefits more from our augmentation method. A natural question that arises is what's boundary of our augmentation in the sense of improving the baseline. In this section, we study this by varying training data size on the ATIS data. Figure 2 shows the results. For the ATIS data, improvements can be achieved in all our settings with training size smaller than one thousand. These results indicate that our augmentation is applicable when we only access to a LU training data of hundreds instances.

Case Study. In this paragraph, we perform case study on our method to verify its capability of generating diversely augmented data. Table 5 shows two cases of our augmentation. Each case includes the original sentence and its delexicalised form (in *italic* font), the diversity rank (starts with # mark), the training utterance under this rank, our augmentation along with surface realization, and the augmentation produced by Kurata et al. (2016a).

By comparing our augmentation with the delexicalised form of source utterance, two observations can be drawn: 1) our method yields syntactically different alternatives meanwhile keeps the original semantic frame as the source utterance; 2) the lengths of the generated utterances are in the same scale with the source utterance thanks to the effect of length penalty in Equation 1.

By comparing our augmentation with the target training utterance under the same rank, our seq2seq model yields different utterance instead of repeating the training utterance. We address this diversity

[2]This number is normalized by the total number of utterances.

(2016a) (marked as Kurata16). *train* marks the target utterance in the training data. **(delex.)** marks the delexicalised form of the input utterance. **(realized)** marks the utterance after surface realisation.

to the fact that our diversity rank has some universal effect on modeling the diversity degree across different instances. When contrasting to the augmentation of Kurata et al. (2016a), our method clearly shows diverse augmentation against the source utterance while theirs are basically repeating the source utterances. In the sense of generating diverse alternatives for expressing the same semantics, our method has the advantage.

6 Related work

Data augmentation is an effective way of improving the model's performance and it has been extensively explored on the computer vision community. Single transformation approaches like randomly copying, flipping, and changing the intensity of RGB are the common practice in the top-performed vision systems (Krizhevsky et al., 2012). Beyond these classic approaches, adding noise to the image, randomly interpolating a pair of images (Zhang et al., 2018) are also proposed in previous works. However, these signal transformation approaches are not directly applicable to language because order of words in language may form rigorous syntactic and semantic meaning (Zhang et al., 2015). Therefore, the best way of data augmentation in language usually involves generating the alternative expressions.

Paraphrasing is the most studied techniques in natural language processing for generating alternative expressions (Barzilay and McKeown, 2001; Bannard and Callison-Burch, 2005; Callison-Burch, 2008). However, generic paraphrasing technique has been reported not helpful for specific problem (Narayan et al., 2016). Most of the successful work that applying paraphrasing for data augmentation requires special tailored paraphrasing techniques. For example, Wang and Yang (2015) performed word-level paraphrasing to extend their corpus on twitter that contains annoying behaviors. Fader et al. (2013) derived question templates from seed paraphrases and bootstrap the templates to achieve the enlarged open-domain QA dataset. Narayan et al. (2016) constructed latent variable PCFG for questions and augment the training data by sampling from the grammar. All these works assume the same output (i.e.

class in text classification, answer in question answering) for input paraphrases. Our method resembles theirs in the assumption for input paraphrases, but differs on using the seq2seq generation which is purely data-driven and doesn't rely on special tailored domain knowledge. Besides these methods, works that introduce errors to language understanding have also been proposed (Schatzmann et al., 2007b; Sagae et al., 2012).

Language understanding, as an important component in the task-oriented dialogue system pipeline, has drawn a lot of research attention in recent year, especially when enhanced by the rich representation power of the neural network, like recurrent neural network, LSTM (Yao et al., 2013; Yao et al., 2014; Mesnil et al., 2013; Mesnil et al., 2015) and memory network (Chen et al., 2016b). Rich linguistic features (Chen et al., 2016a) and representation in broader scope on sentence-level (Kurata et al., 2016c) and dialogue history-level (Chen et al., 2016b) have also been studied. Our augmentation method is orthogonal to these works and it's hopeful to achieve more improvements with their works.

Dialogue management is also a key component of task-oriented dialogue system, which mainly focuses on dialogue policy. However, optimal dialogue policy is hard to obtain from a static corpus due to the vast space of conversation process. A solution is to transform the static corpus into user simulator (Kreyssig et al., 2018), and most user simulators work on user semantics level. (Eckert et al., ; Schatzmann et al., 2007a; Asri et al., 2016; Scheffler and Young, 2000; Scheffler and Young, 2001; Pietquin and Dutoit, 2006; Georgila et al., 2005; Cuayáhuitl et al., 2005). Recent work starts to generate user utterance directly to reduce data annotation(Kreyssig et al., 2018).

In recent years, Generative Adversarial Network (GAN, Goodfellow et al. 2014) draws a lot of research attention. Its ability of generating adversarial examples is attractive for data augmentation. However, it hasn't been tried in data augmentation beyond computer vision (Antoniou et al., 2018). How to apply GAN to language understanding is still an open question.

7 Conclusion

In this paper, we study the problem of data augmentation for LU. We propose a data-driven framework to augment training data. In our framework, one utterance's alternative expressions of the same semantic are leveraged to train seq2seq model. We also propose a novel diversity rank to encourage diverse generation and filter alike instances. In the experiments, our model achieves significant improvements of 6.38 and 10.04 F-scores respectively when only a training set of hundreds utterances is represented. Careful case study also shows the capability of our framework to generate diverse alternative expressions.

Abstract

The utility of additional semantic information for the task of next utterance selection in an automated dialogue system is the focus of study in this paper. In particular, we show that additional information available in the form of dialogue acts –when used along with context given in the form of dialogue history– improves the performance irrespective of the underlying model being generative or discriminative. In order to show the model agnostic behavior of dialogue acts, we experiment with several well-known models such as sequence-to-sequence encoder-decoder model, hierarchical encoder-decoder model, and Siamese-based models with and without hierarchy; and show that in all models, incorporating dialogue acts improves the performance by a significant margin. We, furthermore, propose a novel way of encoding dialogue act information, and use it along with hierarchical encoder to build a model that can use the *sequential* dialogue act information in a natural way. Our proposed model achieves an MRR of about 84.8% for the task of next utterance selection on a newly introduced DailyDialog dataset, and outperform the baseline models. We also provide a detailed analysis of results including key insights that explain the improvement in MRR because of dialogue act information.

1 Introduction

In the last decade, natural language processing and machine learning –in particular deep learning– have come a long way towards building an automated dialogue system. In a fully automated dialogue system, the goal is to predict an appropriate response given the dialogue history. This problem of response prediction can be formulated in two ways. One is purely generative, where the task is to *generate* a text response, i.e. generating a sentence or utterance from scratch, whereas the other is Next Utterance Selection, where the task is to *select* an appropriate response from a set of given candidates. Despite significant research in text generation, a pure generative model capable of generating syntactically and semantically correct text still remains a distant reality. There have been several efforts such as (Vinyals and Le, 2015; Serban et al., 2016a; Serban et al., 2016b; Serban et al., 2017b) for the task of dialogue generation, however these models still do not seem to work in practice (Liu et al., 2016). This is particularly true for open domain dialogue systems. Dialogue generation in a task-oriented oriented dialogue system, such as flight-booking and troubleshooting, is much easier than in a non-task oriented dialogue system. This level of difficulty arises because a non-task-oriented dialogue system has no predefined goal (or domain), and the vocabulary and possibilities of the dialogues could be endless. Given these challenges, researchers have defined a simpler problem for conversation modeling based on retrieval, i.e. next utterance selection. In this paper we use this second formulation of the problem, and show that using additional information available in the form of dialogue acts help in improving the performance of the underlying model.

Dialogue acts (DA) are higher level semantic abstractions assigned to utterances in a conversation. An example of a dialogue act for an utterance *i'll give you a call tonight* is *Inform* since speaker is providing information. In a traditional dialogue system, where dialogues are formulated by first sentence planning

Proceedings of the 27th International Conference on Computational Linguistics, pages 1246–1256
Santa Fe, New Mexico, USA, August 20-26, 2018.

and then by surface realization, the first step is to understand the dialogue act of the utterance that needs to be generated, and then plan and realize the dialogue accordingly. To better understand the importance of dialogue acts, consider an example of a simple conversation, where if the previous utterance is of type *Question* then the next utterance is most likely going to be of the type, i.e. *Inform*, providing information to that question. Knowing that the next utterance is of type *Inform*, a conversation system with support of dialogue act information can filter a set of candidate responses, and select the most appropriate one. Driven by this intuition, we hypothesize that understanding dialogue acts and using them in the task of next utterance selection should improve the performance irrespective of the underlying model.

Driven by this intuition, we hypothesize that understanding dialogue acts and using them in the task of next utterance selection should improve the performance irrespective of the underlying model.

Most of the existing literature for the task of next utterance selection can be classified into two categories. First is based on Sequence-to-sequence models (generative models) (Serban et al., 2016a; Serban et al., 2017a; Vinyals and Le, 2015), where a model is trained to *generate* a response given context; and the other is Siamese models (discriminative models) (Lowe et al., 2017), where a model is trained to *discriminate* between positive and negative responses for a similar context. In both types of models, at test time, a set of candidate responses is provided consisting of one correct response and several incorrect responses, and the model is evaluated on its ability to assign a higher rank to the true response.

In this paper, through the experimentation with both generative and discriminative types of models, we validate the hypothesis that additional information available in the form of dialogue act significantly improves the performance irrespective of the underlying model. In addition to showing the utility of dialogue acts, we propose a novel model that can use the sequential dialogue act information in a natural way. More specifically, we propose a dialogue-act-driven hierarchical Siamese model. Hierarchical models have shown to perform better than non-hierarchical models for the task of dialogue generation, whereas Siamese models have been shown to outperform the encoder-decoder based models for the task of next utterance selection. In this paper, we combine both of these models, and further enhance them with a dialogue act encoder. The proposed model has a hierarchical encoder which encodes the past utterances, and combine them with the representation of additional contextual information, obtained from the dialogue acts associated with the past utterances, to discriminate the correct response from the incorrect ones. Our proposed model provides us the best of both worlds and outperforms the baseline models by a significant margin. Among others, a key contribution of this paper is that we do a deeper analysis of the reasons for the performance improvement due to inclusion of dialogue act and draw several important key insights such as, dialogue acts induce uniformity in the data, they aid in learning the right patterns. We believe that these insights would inspire new research in this field and push the boundary even further. The main contributions of this paper are as follows:

1. For the task of next utterance selection, we validate the hypothesis that additional information available in the form of dialogue acts improves the performance irrespective of the underlying models.

2. We propose a novel model that combines the strength of Siamese network with strengths of hierarchical structure inherent in the conversations and dialogue act information. The model gives us the best of all, and outperforms the baseline models by a significant margin on the DailyDialog Dataset.

3. We perform a deeper analysis of the utility of the dialogue act information and draw three key insights: models learn dominant dialogue act patterns; dialogue acts induce uniformity; dialogue acts reinforce correct dialogue act patterns.

4. We modify the DailyDialog (Li et al., 2017b) dataset for the task of next utterance selection, and release it publicly along with the code-base of the proposed model[1]. We believe that this dataset will work as a benchmark dataset for further research on this problem. Similar benchmark datasets have been released earlier(Lowe et al., 2015; Serban et al., 2015), however they do not come with dialogue act information.

2 Approach

In this section, we provide details of several existing models that we will use to validate our hypothesis. These models include generative models (such as encoder-decoder model and its hierarchical version i.e., hierarchical encoder-decoder) and discriminative model (Siamese-based model). Next, we provide details of the proposed model that adds the hierarchical structure to the Siamese model along with the dialogue act information. To set the notations, we are given a set $\mathcal{D}$ of N conversations, i.e. $\mathcal{D} = (C^1, C^2, \ldots C^N)$, with each conversation C^i being a sequence of R_i utterances, $C^i = (u_1, u_2, \ldots u_{R_i})$. Each utterance u_j in turn is itself a sequence of S_j words, i.e. $u_j = (w_1, w_2, \ldots w_{S_j})$.

2.1 Generative Model

Generative models are the most widely used models for conversation modeling. These models include encoder-decoder model and hierarchical encoder-decoder model.

2.1.1 Encoder-decoder Model

An encoder-decoder is a *generative* model that works on the idea of obtaining a representation of an input and use it for generating an output. It has two main components, encoder and decoder. The encoder encodes the first K utterances, and the decoder uses that encoding to generate the next $K + 1^{th}$ utterance. In a conversation, all words in first K utterances can be stringed together to form a single long chain and passed to an RNN encoder as following:

$$\begin{aligned} e_k &= f^1_{embed}(w_k) \quad \forall k \in 1, 2, \ldots \\ h^e_k &= f^1_{rnn}(h^e_{k-1}, e_k) \quad \forall k \in 1, 2, \ldots \end{aligned} \tag{1}$$

where, f^1_{embed} represents the embedding layer, whereas f^1_{rnn} is the encoder (RNN). Let v be the final output of the encoder which is considered as a representation of the entire context, and used to initialize the decoder (another RNN). Mathematically, the sequence of operations at the decoder are as follows:

$$\begin{aligned} h^d_0 &= v \\ h^d_k &= f^2_{rnn}(h^d_{k-1}, f^2_{embed}(w_k)) \quad \forall k \in 1, 2, \ldots n-1 \\ P_k &= Logistic(h^d_k). \end{aligned} \tag{2}$$

Here, f^2_{embed} represents the embedding layer. $Logistic$ is the final layer, which outputs the probability distribution over the vocabulary. Encoder-decoder models are trained to maximize the likelihood of generating the next utterance, however, for the task of next utterance selection, they are tested based on the probability of generating the candidate utterances.

2.1.2 Hierarchical Encoder-decoder Model

A simple encoder-decoder treats the first K utterances as a single long chain of words, and therefore fails to leverage the hierarchical structure, which is an inherent part of a conversation. Hierarchy is important for conversation modeling since it captures the natural dependency among utterances. Several researchers (Sordoni et al., 2015; Serban et al., 2016b; Serban et al., 2017b; Dehghani et al., 2017; Kumar et al., 2017) have shown that hierarchical models outperform standard non-hierarchical models. Hierarchical models use two encoders to capture the hierarchical structure. The first encoder, referred as utterance encoder, operates at the utterance level, encoding each word in each utterance. The second encoder, referred as conversation encoder, operates at the conversation level, encoding each utterance in the conversation, based on the representations of the previous encoder. These two encoders make sure that the output of the conversation encoder captures the dependencies among utterances. For a given conversation, each word w_k of each utterance u_j is processed by an embedding layer, followed by an RNN which serves as the utterance encoder. Similar to the encoder in equation (1), an utterance encoder gives us a sequence of representations $v_1, v_2, \ldots v_K$, corresponding to the first K utterances $u_1, u_2, \ldots u_K$ in a conversation. These representations are passed on to the conversation encoder, another RNN, which transforms v_j to another representation g_j. The representation obtained from the last time-step of the

conversation-level encoder i.e. g_K is considered as the representation of the entire conversation and used to initialize the decoder which works in the same way as Equation 2.

2.2 Discriminative Model

A decoder in the encoder-decoder model generates the next word given the context, and though it has several valid and reasonable choices, it is burdened with the task of generating exactly a particular choice that matches the ground truth. For example, for a context *I am enjoying the day, it is warm and sunny*, if decoder generates *yes, it is.* and the ground truth dictates *yes, indeed, it is a lovely day*, the decoder has failed, though it is a valid response. Due to these challenges with generative models, discriminative models are trained directly to discriminate between positive and negative utterances. A typical discriminative model, or in particular Siamese model, consists of two encoders, one encoder encoding the context, while another encoding the candidate utterance, i.e utterance $K+1$. These two representations are passed to a final layer that computes the probability of candidate being a valid response given the context. Let $h^{(1)}$ and $h^{(2)}$ be the representations obtained from the first encoder and second encoder, respectively, then the probability of their association can be computed using the following expression.

$$p(s|h^{(1)}, h^{(2)}) = \sigma\big({h^{(1)}}^T A h^{(2)} + b\big) \tag{3}$$

where, the bias b and matrix A are learned model parameters.

2.3 Dialog-act-driven Models

Dialogue acts are higher level abstractions assigned to utterances. In our problem setting, we are given a list of dialogue acts $da_1, da_2, \ldots da_K$, corresponding to first K utterances in the conversation. These dialogue acts are treated as an additional sequence of signals that can aid in the learning process, and are passed through an encoder, denoted as Dialog-Act encoder (DA-encoder). The DA-encoder works on the same principle as the utterance encoder. It builds a dialogue act vocabulary and uses that to learn dialogue act embeddings. Similar to the utterance encoder, the input to the DA-encoder are one hot encodings of the dialogue acts, which are then passed through an embedding layer to learn DA embeddings. These DA embeddings are sent to an RNN to learn dialogue act representations. The sequence of operations for the DA-encoder are as follows:

$$\begin{aligned} e_{da_k} &= f^3_{embed}(da_k) \quad \forall k \in 1, 2, \ldots K \\ h_{da_k} &= f^4_{rnn}(h_{da_{k-1}}, e_{da_k}) \quad \forall k \in 1, 2, \ldots K. \\ q_K &= h_{da_K} \end{aligned} \tag{4}$$

The output of the DA-encoder at the last time step (q_K) gives us the representation of the entire DA sequence which is then used in the further modeling process in generative and discriminative models. In generative models, it is used in the decoder by concatenating g_K and q_K, whereas in discriminative models, it is used along with encoder's output by combining g_K with q_K through a linear combination.

2.4 Dialog-act-driven Hierarchical Siamese - Proposed Model

Our proposed model, i.e. Dialog-act-driven Hierarchical Siamese Model (HSiamese-DA), uses the following three components: a hierarchical encoder to obtain a representation that captures the dependencies among K utterances; an utterance encoder to obtain a representation of the candidate response, $(K+1)^{th}$ utterance; a DA-encoder (Equation 4) that captures the dependencies among the dialogue acts of the first K utterances. Let the representation obtained from the hierarchical encoder, DA-encoder and utterance encoder be g_K, q_K and v_{K+1}, respectively. The two representations, g_K and q_K, are linearly combined to obtained a compositional representation of the context, which is then used along with candidate representation to compute the probability of associating the candidate response with the context using following expression:

$$\begin{aligned} d_K &= \alpha * g_K + (1-\alpha) * q_K \\ p(s|d_K, v_{K+1}) &= \sigma(d_K^T \cdot A \cdot v_{K+1} + b) \end{aligned} \tag{5}$$

The model is trained by minimizing the cross-entropy of all labeled conversations including positive and negative examples. At the test time, each conversation has K utterances followed by a set of 10 candidates responses. The system is tested in its ability to assign a higher rank to the true response.

3 Experiments

In this section, we describe the details of the experiments, i.e. dataset and its preparation, baseline models, experimental setup, and analysis of results.

3.1 Dataset

In our problem setting, we require a dataset that is of reasonable size[2] and has utterances annotated with the corresponding dialogue acts. Although there are several available datasets(Serban et al., 2015), such as SwDA (Switchboard Dialogue Act Corpus (Jurafsky, 1997)), MRDA (Meeting Recorder Dialogue Act corpus (Janin et al., 2003)), Ubuntu(Lowe et al., 2015), OpenSubtitles(Tiedemann, 2009), etc., they are not really suitable for our problem setting. Most of these datasets do not come with dialogue acts, and the ones which do (i.e. SWDA and MRDA) are small in size. Note that the SwDA and MRDA datasets contain 1003 and 51 conversations, respectively. To the best of our knowledge, a recently released dataset, DailyDialog(Li et al., 2017b), is the only dataset that has utterances annotated with dialogue acts and is large enough for conversation modeling methods to work. Furthermore, in this dataset, conversations are non-task oriented, and each conversation focuses on one topic. Each utterance is annotated with four dialogue acts as described in Table 1. The dataset has train, validation, and test splits of 11118, 1000, and 1000 conversations, respectively. We evaluate and report our results on the DailyDialog dataset.

In this paper, we hypothesize that dialogue acts improve conversation modeling. However, it is not always possible that such dialogue acts are available in practice, and it would be ideal to predict dialogue acts first (Kumar et al., 2017), and then use them for next utterance generation/retrieval; having a model where both tasks, i.e. prediction and generation, are performed simultaneously may not be ideal for validating the hypothesis. Note that the error from the dialogue act prediction may propagate to the next utterance generation/retrieval. Therefore, we intentionally did not use the predicted dialogue acts (rather used the available dialogue acts) to make sure that the insights about the usefulness of the dialogue acts are not corrupted due to the error in the upstream prediction model.

Dialogue Act	Description
Inform	A speaker is providing information by means of a question or statement
Question	A speaker intends to obtain information by asking a question
Directive	A speaker is requesting, accept/reject offer, or making a suggestion
Comissive	A speaker accept/reject a request or suggestion

Table 1: Dialogue Acts and their description available in the DailyDialog Dataset.

3.1.1 Dataset Preparation for Next Utterance Selection Task

The DailyDialog dataset in its original form is not directly useful for the task of next utterance selection, and hence requires preparation. The dataset has the dialogues from both the speakers. Owing to the different conversational style of human and conversation agent, our objective is to build a model that is specific to the agent, i.e. bot. Therefore, we need to modify the dataset in such a way that we only consider those turns where we need to predict the bot's utterance. To clarify further, consider the example conversation given in Table 2. The conversation has 8 utterances, and each utterances is marked with the speaker, i.e. human (H) and bot (B). Since we are only interested in building bot-specific model, we only pick those subsequences from this conversation where the last utterance is "B". This gives us three subsequences: 1,2,3,4; 3,4,5,6; 5,6,7,8 for a context of size 3. In each of these sub-conversations,

[2]Generative models such as sequence-to-sequence or discriminative models such as Siamese only perform better when there is large amount of data for training.

the first three utterances constitute the context, while the last utterance is the true response. Our training data consists of such subsequences made up of 4 utterances. In the test data, each subsequence, in addition to these 4 utterances, has 9 more utterances selected randomly from the test pool, therefore a total of 13 utterances. These 9 utterances along with the 4^{th} response (i.e., true response) utterance constitute the candidate pool. With this data preparation exercise, the total number of conversations in train, test, and valid are 30515, 2849, and 2695, respectively. This version of dataset is used for training and testing generative models. For discriminative models, data required is a bit different. The training of discriminative models require positive examples and an equal number of negative examples. Note that training data of the generative models did not have any negative examples. In-order to prepare negative examples, we replicate each conversation by replacing the last utterance with a random utterance from the test data. The test and valid dataset remain as in the generative models. Thus, with this data preparation exercise, the total number of conversations in train, test, and valid are 61030, 2849, and 2695, respectively.

Id		Utterance	DA
1	H	Hello, this is Mike, Kara .	I
2	B	Mike! Good to hear from you. How are you?	Q
3	H	Everything is fine, and how are you?	Q
4	B	Things are going well with me.	I
5	H	Kara, I had fun the other night at the movies and was wondering if you would like to go out again this Friday.	D
6	B	Mike, I don't think that it's a good idea to go out again.	C
7	H	Maybe we could just meet for coffee or something.	D
8	B	I can't really deal with any distractions right now, but I appreciate the nice evening we spent together.	C

Table 2: A snippet of a conversation showing few dialogues between a Human (H) and Bot (B).

3.2 Baseline models and Proposed Model

Here we list the baseline models, their modified version enhanced with dialogue act information, and the proposed model.

Generative Models:

- **ED** - It is a vanilla sequence to sequence model that uses an utterance encoder to obtain a representation of first K utterances which is then used in a decoder to generate next utterance.
- **HRED** - An extension of sequence to sequence model that uses a hierarchical encoder to obtain a representation of first K utterances, which is then used in decoder to generate next utterance.
- **ED-DA** - An extension of the ED model which uses dialogue act information. It has a conditional decoder, that conditions the generation of each word on the dialogue acts representation.
- **HRED-DA** - An extension of the HRED model which uses dialogue act information. Similar to ED-DA, it also has a conditional decoder that conditions the generation of each word on the dialogue acts representation.

Discriminative Models

- **Siamese** - Also known as Dual-Encoder, it uses two encoders (both utterance encoders) with shared weights, to produce the representation for the K utterances and the $(K+1)$ utterance.
- **HSiamese** - A Hierarchical version of the Siamese model that uses a hierarchical encoder to produce a representation for the K utterances, and a plain encoder (utterance encoder) to produce a representation for the $(K+1)$ utterance.

- **Siamese-DA** - An extension of Siamese model that uses the additional dialogue act information obtained through DA-encoder. The representation obtained from the DA-encoder is linearly combined with the representation of the K utterances obtained from an utterance encoder.
- **HSiamese-DA** - The proposed model uses a Hierarchical Encoder and a DA-Encoder. The representation obtained from the DA-Encoder is linearly combined with the representation obtained from the hierarchical encoder.

3.3 Hyper-parameter Tuning

In our experiments, the parameters are tuned on validation set while the results are reported on test set. Each utterance in a mini-batch was padded to the maximum length for that batch. The maximum batch size allowed was 32. The word vectors were initialized with the 300-dimensional Glove embeddings (Pennington et al., 2014), and were also updated during training. For the generative models, the utterance encoder, conversation encoder, DA-Encoder and decoder are all GRUs with rnn_size set to 1000 (optimized over 100 to 1200 in steps of 100). For the discriminative model, the utterance encoder, conversation encoder, and DA-Encoder are all GRUs with rnn_size set to 300 (optimized over 100 to 500 in steps of 100). Dropout of 0.1 (optimized over 0.0 to 0.7 in steps of 0.1) was applied to embeddings obtained from the output of conversation encoder. Note that, dropout was not used in the discriminative model and its variations. Models were trained to minimize cross entropy using Adam optimizer with learning rate of 0.0003 (optimized over 0.0001, 0.0003, 0.0005, 0.0007, 0.001). We found that a higher learning rate up-to 0.0005 helps the model to learn quickly, whereas learning rate greater than 0.0005 leads to oscillations.

3.4 Results and Discussion

In this section, we present results of our experimental study, followed by its analysis.

3.4.1 Performance Evaluation

Since our problem formulation is retrieval based, we use standard IR metrics such as Mean Reciprocal Rank (MRR) and Recall@k as our evaluation metrics. MRR is calculated as the mean of the reciprocal rank of the true candidate response among other candidate responses. Recall@k measures whether the true candidate response appears in a ranked list of k responses.

In this work, our hypothesis is that additional information about utterances available in the form of dialogue acts helps irrespective of the underlying model, i.e. generative or discriminative. Results in Table 3 support our hypothesis. These results clearly indicate that the MRR of the true candidate response improves when dialogue acts of previous utterances are provided. From these tables we see that for all underlying models, the dialogue act version performs better than non dialogue act version. These results furthermore indicate that hierarchical version performs better than non-hierarchical version for both generative and discriminative models. In the generative case, the plain ED has an MRR of 0.474, whereas the same model, when conditioned with DA-Encoder, has an MRR of 0.54, an improvement of 13.9%. The hierarchical encoder-decoder HRED and HRED-DA has an MRR of 0.523 and 0.583, respectively, an improvement of 11.4%. Generative models are sequence-to-sequence models and rather complex in nature, so it is interesting to note that even a much simpler discriminative model, i.e. plain Siamese model, without any dialogue act information, has an MRR of 0.8 compared to 0.58 of the best performing generative model, i.e. HRED-DA. This observation demonstrates the strength of the discriminative models, and therefore is a motivation behind the proposed model. The proposed model improves these baseline numbers by incorporating hierarchy and dialogue act information, and pushes the MRR to 0.848.

3.4.2 Performance Analysis

While we have shown that using dialogue act information does help in the next utterance selection task, in this section, we dig deeper and understand reasons for it. In order to do that, we analyze the dialogue act distribution of the test data and model outputs. Although all K dialogue acts corresponding to K utterances in the context might play a role in ranking candidate utterances, the following analysis only

	MRR	R@1	R@2	R@5
ED	0.474	0.327	0.405	0.639
ED-DA	0.54	0.407	0.478	0.690
HRED	0.523	0.384	0.471	0.676
HRED-DA	0.583	0.448	0.542	0.742

(a) Generative Models

	MRR	R@1	R@2	R@5
Siamese	0.800	0.711	0.785	**0.949**
Siamese-DA	0.844	0.784	**0.824**	0.944
HSiamese	0.817	0.743	0.792	0.948
HSiamese-DA	**0.848**	**0.795**	0.821	0.932

(b) Discriminative Models

Table 3: Comparison of different models with and without dialogue acts

uses the pairs of dialogue acts, i.e. dialogue acts of K^{th} and $(K+1)^{th}$ utterances. Tables 4(a), 4(b) and 4(c) show the distribution of such dialogue act pairs for test data, HSiamese, and HSiamese-DA models respectively. Here, rows indicate the dialogue act of K^{th} utterance, whereas columns indicate the dialogue act of $(K+1)^{th}$ utterance. A cell value indicates the count of utterance pairs with the respective dialogue act combinations where $(K+1)^{th}$ utterance was ranked 1. Note that in the test data, $(K+1)^{th}$ utterance is the true candidate response and always have the rank 1. For instance, there are 742 utterance pairs in the test data, where K^{th} and $(K+1)^{th}$ utterances have dialogue acts Q and I, respectively, however, out of those 742 instances, HSiamese ranked only 605 as 1 while HSiamese-DA ranked 638 as 1. From these tables, we draw following observations.

	I	Q	D	C
I	600	336	176	16
Q	742	73	87	2
D	26	75	56	305
C	69	50	76	6

(a) Ground-truth test data

	I	Q	D	C	R@1
I	403	208	115	9	0.65
Q	605	34	64	2	0.78
D	16	41	42	192	0.63
C	48	33	56	4	0.70

(b) HSiamese

	I	Q	D	C	R@1
I	446	253	121	12	0.74
Q	638	43	61	2	0.82
D	17	58	42	243	0.78
C	52	39	68	5	0.82

(c) HSiamese-DA

Table 4: Number of rank-1 conversations and theie DAs for K^{th} and $(K+1)^{th}$ utterances.

Models Learn Dominant Patterns: The first is that there are certain dominant communication patterns that we observe in both, test data and model outputs (See Table 4), suggesting that models are able to learn these patterns and retain them in their outputs . We observe that a *Question* is often followed by an *Information*, whereas an *Information* can be followed by another *Information* or a *Question*. A *Directive* tends to be followed by *Commissive*. These communication patterns not only make sense intuitively but they are also in agreement with previous studies (Li et al., 2017b; Ribeiro et al., 2015).

Dialogue Acts Bring Uniformity: The second and a rather more important observation is that dialogue acts help the most for the dialogue act class (DA-class) when the utterances belonging to that class are non-uniform in their linguistic construct. In order to better exlpain this, we first compute the break-up of recall@1 according to the dialogue act classes. A DA-class of a conversation in the test data is defined based on the dialogue act of the last utterance (K^{th} utterance) in the context. These numbers are shown in the last column of Tables 4(b) and 4(c) for the respective models. In Table 4(b), first row in recall@1 column is 0.65, which indicates that out of the total number of test conversations where dialogue act of the last utterance of context was I, 65% of true candidate responses were ranked 1 by the HSiamese model. Such a DA-class wise breakup of the recall@1 numbers helps us do an analysis with respect to individual DA-classes. From this break-up, it is clear that for the HSiamese model, *Question* DA-class has the best performance of 78% whereas *Directive* has the worst performance of 63%. This difference can be attributed to the fact that all utterances with dialogue act as *Question* have rather uniform construct. Some examples of *Question* utterances are, '*Q: Do you have a fever?*' and '*Q: Why do you want to work for our company?*', while the examples of *Directive* utterances are, '*D:when we have the final results, we will call you.*' and '*D:we will take the trip. could you give us a pamphlet?*'. From these examples, we observe that utterances belonging to DA-class *Question* have rather uniform construct in terms of linguistic features, whereas utterances belonging to DA-class *Directive* are ambiguous –some of the utterances of type *Directive* can be easily confused for *Question*. This uniformity makes the learning task easier for *Question* class, and thereby giving us better results in the next utterance selection

task, even for the model that does not use the dialogue act information. This performance difference reduces when we provide the dialogue act information along with the textual content (See Table 4(c)). Inclusion of dialogue act information within a non-uniform class such as *Directive* brings in uniformity, and therefore, results in significant performance improvement. In the case of *Directive*, we see as much as 15 percentage point improvement. Similar improvement pattern has been observed for DA-class *Information* and *Comissive*. Similar to *Directive*, utterances belonging to *Comissive* have rather non-uniform construct, and with the availability of dialogue acts, this DA-class is able to gain much more than the *Information* DA-class.

	I	Q	D	C	Total
I	43	45	6	3	97
Q	33	9	-3	0	39
D	1	17	0	51	69
C	4	6	12	1	23
Total	81	77	15	55	228

Table 5: Difference of number of rank-1 conversations between HSiamese-DA and HSiamese.

Dialogue Acts Help Model Learn the Right Patterns: In Table 5, we show the relative improvement of HSiamese-DA model over HSiamese. From this table, we observe that there are a total of 228 conversations where the proposed model was able to improve the ranking of true candidate response to 1. We further observe that the biggest improvement is in $I \rightarrow I$, $I \rightarrow Q$, $Q \rightarrow I$, and $D \rightarrow C$, which make sense intuitively. These are dominant patterns observed in the training data which should be preserved in the model output as well, however these patterns will only be preserved when model is able to capture the *correct* dialogue act information. Since in many cases D and Q have similar construct, without explicit dialogue act information, a model may get confused and may learn patterns not observed in the training data. For example, $Q \rightarrow I$ and $D \rightarrow C$ are the dominant and right patterns in the training data, however in the absence of explicit dialogue act information, the model may get confused between D and Q and may learn $D \rightarrow I$ and $Q \rightarrow C$ instead of the dominant patterns i.e. $Q \rightarrow I$ and $D \rightarrow C$. With the explicit dialogue act information, this ambiguity is alleviated and model learns the right patterns as demonstrated by Table 5. Similar observations are true for other two constructs, i.e. *Information* and *Commisive*. Both are rather similar in construct, '*I: No, thank you*', '*I: It doesn't matter. it happens to everyone .*' and '*C: I knew you'd see it my way .*', '*C: Ok , i am ready to think of other things .*', and there is no obvious distinguishing factor. However, providing explicit DA information helps in disambiguation, and learn the patterns that are observed in the training data such as $I \rightarrow I$, $I \rightarrow Q$.

4 Related Work

In conversation modeling, the most basic problem is to generate a response given a context. Several efforts have been made towards solving the problem of dialogue generation(Vinyals and Le, 2015; Liu et al., 2016; Li et al., 2015), however, due to the inherent difficulty of the problem, these efforts have only had limited success and are known to have issues like generating repetitive and generalized responses such as *I don't know* or *Ok*.

For the task of Next Utterance Selection, which is a relatively simpler problem than generation, though existing generative models can be easily adopted, their counterpart discriminative models have shown to have better performance. In generative models, the most notable work is from (Vinyals and Le, 2015), however this work considers the context as a flat long string of words and ignores the hierarchical structure. Researchers have proposed hierarchical model (Serban et al., 2016b) and their variations (Serban et al., 2017b; Serban et al., 2017a; Li et al., 2017a) but none of these models take into account the dialogue act information. In Discriminative models, such as Siamese, a very notable work by (Kannan et al., 2016), *smart reply*, retrieves the most likely response from a set of candidate response clusters. (Lowe et al., 2017) has used a retrieval based Siamese model and shown its results on the Ubuntu corpus. Our

proposed model builds upon the strengths of generative and discriminative models, and uses hierarchy along with the dialogue act information to achieve the best performance. A recent work by (Zhao et al., 2017) has used dialogue acts for the task of dialogue generation. Our work complements their findings, and further show that dialogue acts improve the model performance across the board irrespective of underlying model (i.e. generative or discriminative models) and for the task of next utterance selection.

5 Conclusion

For the task of next utterance selection, we show that dialogue acts helps achieve better performance irrespective of the underlying model, be it generative or discriminative. We also propose a novel discriminative model that leverages the hierarchical structure in a conversation and dialogue act information to produce much improved results, an MRR of 0.848. Our results not only show the improvement in performance, but we also present key reasons for it by doing a detailed analysis and drawing key insights that the inclusion of dialogue act information induces uniformity and removes ambiguity.

Abstract

Recently, deep reinforcement learning (DRL) has been used for dialogue policy optimization. However, many DRL-based policies are not sample-efficient. Most recent advances focus on improving DRL optimization algorithms to address this issue. Here, we take an *alternative* route of designing neural network structure that is better suited for DRL-based dialogue management. The proposed *structured deep reinforcement learning* is based on graph neural networks (GNN), which consists of some sub-networks, each one for a node on a directed graph. The graph is defined according to the domain ontology and each node can be considered as a sub-agent. During decision making, these sub-agents have internal message exchange between neighbors on the graph. We also propose an approach to jointly optimize the graph structure as well as the parameters of GNN. Experiments show that structured DRL significantly outperforms previous state-of-the-art approaches in almost all of the 18 tasks of the PyDial benchmark.

1 Introduction

A task-oriented spoken dialogue system (SDS) is a system that can continuously interact with a human to accomplish a predefined task, e.g. finding a restaurant or booking a flight. Dialogue management (DM) is the core of an SDS. It has two missions: one is to maintain the dialogue state, and another is to decide how to respond according to a dialogue policy. In this paper, we focus on the dialogue policy.

A dialogue policy can be viewed simply as a set of hand-crafted mapping rules from dialogue states to dialogue actions. This is referred to as a rule-based policy. However, in real-world scenarios, unpredictable user behavior, inevitable automatic speech recognition, and spoken language understanding errors make it difficult to maintain the true dialogue state and make the decision. Hence, in recent years, there is a research trend towards statistical dialogue management. A well-founded theory for this is the partially observable Markov decision process (POMDP) (Kaelbling et al., 1998).

Under the POMDP-based framework, a distribution of possible states – belief state $\mathbf{b}$ is maintained in every dialogue turn. Then reinforcement learning (RL) methods automatically optimize the policy π, i.e. a mapping function from belief state $\mathbf{b}$ to dialogue action $a = \pi(\mathbf{b})$ (Young et al., 2013). Initially, linear RL-based models are adopted, e.g. least-squares policy iteration (LSPI) and natural actor-critic (NAC). However, these linear models have a poor ability of expression and suffer from slow training. Recently, nonparametric algorithms, e.g. Gaussian process reinforcement learning (GPRL), which can optimize policies from a minimal number of dialogues have been proposed. However, the computation cost of GPRL increases with the increase of the number of data. It is therefore questionable as to whether GPRL can scale to support commercial wide-domain SDS.

More recently, deep reinforcement learning (DRL) methods are adopted for dialogue policies (Cuayáhuitl et al., 2015; Fatemi et al., 2016; Zhao and Eskenazi, 2016; Williams et al., 2017; Chen et al., 2017b; Chang et al., 2017). These policies are often represented by fully connected deep neural networks including deep Q-networks and actor-critic networks. DRL-based models are often more

* Both authors contributed equally to this work.

Proceedings of the 27th International Conference on Computational Linguistics, pages 1257–1268
Santa Fe, New Mexico, USA, August 20-26, 2018.

expressive and computational effective. However, these deep models are not sample-efficient and not robust to errors from input modules of SDS. So the focus of these recent advances has been on designing improved RL algorithms to improve the sample-efficiency, e.g. eNAC (Su et al., 2017), BBQ (Lipton et al., 2018).

In this paper, we take an *alternative* but *complementary* approach of focusing primarily on innovating a *structured* neural network architecture that is better suited for dialogue policy. This approach has the benefit that the new network can be easily combined with most existing methods for DRL, which results in *structured deep reinforcement learning*.

The proposed structured DRL is based on graph neural networks (GNN) (Scarselli et al., 2009), which consists of some sub-networks, each one corresponding to a node in the directed graph. The graph has two types of nodes: *slot-dependent* node and *slot-independent* node. The same types of nodes partially share parameters. This can speed up the learning process. In order to model the interaction between sub-networks, they have internal message exchanges between neighbors when doing forward computation.

The main contribution of this paper is three-fold: (1) We proposed a unified *structured* dialogue policy based on GNN. To the best of our knowledge, this is the first work to introduce the graph-based approach for dialogue policy optimization. (2) We introduced a novel method to optimize the graph structure along with the parameters of GNN. (3) Our proposed framework achieves state of the art in PyDial benchmark.

2 Related Work

Recent mainstream studies on statistical dialogue management have been modeling dialogue as a partially observable Markov decision process (POMDP), where reinforcement learning (RL) can be applied to realize automatic dialogue policy optimization (Young et al., 2013).

To achieve efficient policy learning, (Gašić et al., 2010) proposed Gaussian process reinforcement learning (GPRL), where the prior correlations of the objective function given different belief states are defined by the kernel function (Gašić et al., 2010; Gašić and Young, 2014). Recently, deep reinforcement learning (DRL) (Mnih et al., 2015) has been applied in dialogue policy optimization, including value function approximation methods, like deep Q-network (DQN) (Cuayáhuitl et al., 2015; Zhao and Eskenazi, 2016; Fatemi et al., 2016; Chen et al., 2017a; Chang et al., 2017; Peng et al., 2017), and policy gradient methods, e.g. REINFORCE (Williams et al., 2017), advantage actor-critic (A2C) (Fatemi et al., 2016). However, compared with GPRL, most of these models are not sample-efficient. More recently, some methods are proposed to speed up the learning process based on improved DRL algorithms, e.g. eNAC (Su et al., 2017), BBQ (Lipton et al., 2018). In contrast, our proposed method is based on a structured neural architecture, which is complementary to various DRL algorithms.

The most related work is the recently proposed multi-agent dialogue policy (MADP) (Chen et al., 2018). In MADP, the dialogue policy is decomposed into some *slot-dependent* sub-policies and a *slot-independent* sub-policy. While MADP is proposed under the view of multi-agent reinforcement learning, it's can be interpreted as the special instance of our proposed graph-based policy with a fully connected graph structure. That is, our proposed framework is more general. Moreover, the graph structure can be jointly optimized with the parameters of neural networks in our methods.

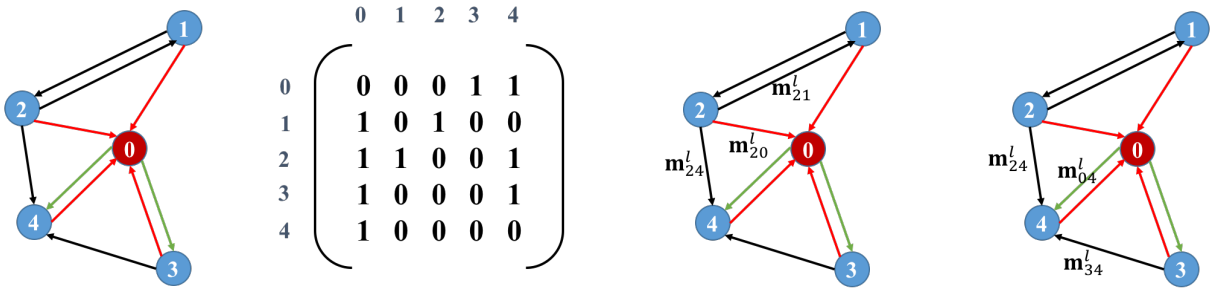
Graph-based approaches are previously adopted for dialogue state tracking, such as the Bayesian update of dialogue state (BUDS) model (Thomson and Young, 2010), structured discriminative model (Lee, 2013). However, they have not been explored for dialogue policy optimization.

3 Proposed Framework

3.1 DRL-based Dialogue Policy

Task-oriented dialogue systems are typically designed according to a structured *ontology* which consists of some concepts (or slots) that a user might wish to use to frame a query. Each slot possesses two attributes: whether it is *requestable* and *informable*. A slot is requestable if the user can request the value of it. An informable slot is one that the user can provide a value for to use as a constraint on their search.

At each dialogue turn, the dialogue state tracker maintains a belief state for each informable slot. Generally, the belief state is a distribution of candidate values for the slot. After the update of belief state,



(a) (b) (c) (d)

Figure 1: (a) An example of directed graph G with 5 nodes and 10 edges. There are two types of nodes: nodes 1∼4 (blue) are *slot-dependent* nodes (S-nodes) and node 0 (red) (I-node) is *slot-independent* node. Accordingly, there are 3 type of edges. (b) The adjacency matrix of G. (c) An example of sending messages. S-node 2 sends messages to its out-going neighbors, i.e. S-nodes 1, 4 and I-node 0. (d) An example of aggregating messages. S-node 4 aggregates messages from its in-coming neighbors, i.e. S-nodes 2, 3 and I-node 0.

the values with the largest belief for each informable slot are used as a constraint to search the database. The matched entities in the database as well as the belief state for slots are concatenated as whole belief dialogue state, which is the input of dialogue policy. Therefore, the dialogue state $\mathbf{b}$ usually can be decomposed into some *slot-dependent* states and a *slot-independent* state, i.e. $\mathbf{b} = \mathbf{b}_1 \oplus \cdots \oplus \mathbf{b}_n \oplus \mathbf{b}_0$. $\mathbf{b}_j (1 \leq j \leq n)$ is the belief state corresponding to j-th informable slot, and $\mathbf{b}_0$ represents the slot-independent state, e.g. database search results.

The output of dialogue policy is a summary action. Similarly, the summary actions can be divided into $n+1$ sets including n slot-dependent action sets $\mathbb{A}_j (1 \leq j \leq n)$, e.g. *request_slot*$_j$, *confirm_slot*$_j$, *select_slot*$_j$, and one slot-independent action set $\mathbb{A}_0$, e.g. *repeat, inform, reqmore, bye, restart*.

Most of previous DRL-based policies don't take advantage of the structure of belief dialogue state and summary actions. The focus in these recent advances has been on designing improved RL algorithms, e.g. eNAC, BBQ. Here, we take an *alternative* but *complementary* approach of focusing primarily on innovating a *structured* neural network architecture that is better suited for dialogue policy. This approach has the benefit that the new network can be easily combined with existing and future algorithms for RL. That is, this paper advances a new network, but uses already published algorithms. In this paper, we adopt deep-Q-networks (DQN). In the next two sections, we will first give the background of DQN and then introduce the proposed structured policy based on graph neural networks (GNN).

3.2 Deep-Q-Networks (DQN)

A Deep Q-Network (DQN) is a multi-layer neural network which maps a belief state $\mathbf{b}$ to the values of the possible actions a at that state, $Q(\mathbf{b}, a; \theta)$, where θ is the weight vector of the neural network. Neural networks for the approximation of value functions have long been investigated (Lin, 1993). However, these methods were previously quite unstable (Mnih et al., 2013). In DQN, two techniques were proposed to overcome this instability, namely experience replay and the use of a target network (Mnih et al., 2013; Mnih et al., 2015).

At every turn, the transition τ including the previous state $\mathbf{b}$, previous action a, corresponding reward r and current state $\mathbf{b}'$ is put in a finite pool $\mathcal{D}$. Once the pool has reached its maximum size, the oldest transition will be deleted. During training, a mini-batch of transitions is uniformly sampled from the pool, i.e. $\tau \sim \mathrm{U}(D)$. This method removes the instability arising from strong correlation between the subsequent transitions of a dialogue. Additionally, a target network with weight vector $\hat{\theta}$ is used. This target network is similar to the Q-network except that its weights are only copied every K steps from the Q-network, and remain fixed during all the other steps. The loss function for the Q-network at each iteration takes the following form:

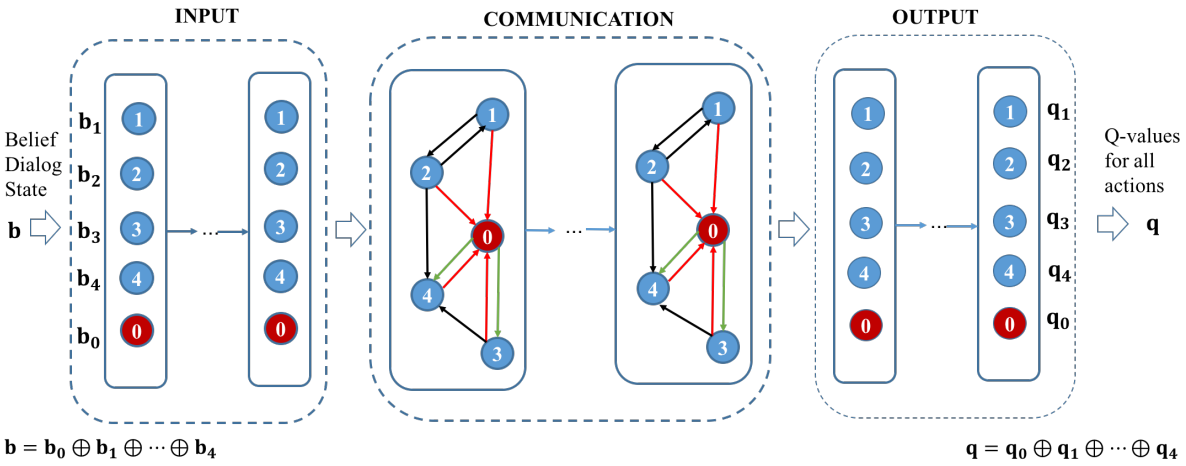


Figure 2: A Q-network with graph neural network (GNN). GNN consists of three modules: input, communication, and output. $\oplus$ denotes concatenation of vectors.

$$\mathcal{L}_{TD}(\theta) = \mathbb{E}_{\tau \sim \mathrm{U}(\mathcal{D})} \left[\left(y - Q_\theta(\mathbf{b}, a) \right)^2 \right], \tag{1}$$

where $y = r + \gamma \max_{a'} Q_{\hat{\theta}}(\mathbf{b}', a')$ and $\gamma \in [0, 1]$ is the discount factor.

Most of the previous work adopts *fully* connected deep neural networks for Q-networks. Here we propose a new network architecture for Q-networks based on *structured* graph neural networks.

3.3 Graph Neural Networks (GNN)

Before delving into details of GNN, we first introduce our notation. We denote the graph structure as $G = (V, E)$ with nodes $v_i (0 \le i \le n) \in V$ and directed edges $e_{ij} \in E$. $\mathcal{N}_{in}(v_i)$ denotes the in-coming neighbors of node v_i, and $\mathcal{N}_{out}(v_i)$ denotes the out-going neighbors of node v_i. $\mathbf{Z}$ is the adjacency matrix of G. The element z_{ij} of $\mathbf{Z}$ is 1 only and only if there is a directed edge from i-th node v_i to j-th node v_j, otherwise z_{ij} is 0. Each node v_i has an associated node type c_i. Similarly, each edge e_{ij} has an edge type u_e, which is determined by node type c_i and node type c_j, i.e. two edges have the same type if and only if their starting node type and their ending node type both are the same.

For dialogue policy, it has two types of nodes: a *slot-independent* node (I-node) and n *slot-dependent* nodes (S-nodes). Accordingly, there are 3 types of edges. Each S-node corresponds to an informable slot in the ontology, while I-node is responsible for slot-independent aspects. Fig.1(a) shows an example of directed graph G with 5 nodes and 10 edges. Nodes 1$\sim$4 (blue) are S-nodes for 4 slots and node 0 (red) is I-node. Fig.1(b) is the corresponding adjacency matrix.

GNN is a deep neural network defined on the graph G. As shown in Fig.3, it consists of three modules: input module, communication module, and output module.

3.3.1 Input Module

At each dialogue turn, each node $v_i (0 \le i \le n)$ will receive the belief dialogue state $\mathbf{b}_i$, which goes through an input module to obtain a state vector $\mathbf{h}_i^0$ as follows:

$$\mathbf{h}_i^0 = f_{c_i}(\mathbf{b}_i), \tag{2}$$

where f_{c_i} is a function for node type c_i, which may be a multilayer perceptron (MLP).

Usually, different slots have different number of candidate values, therefore the dimensions of the inputs of two S-nodes are different. However, in practice, for dialogue policy the probabilities of top K values of each slot play a more important role. Therefore, the whole belief state of each slot is often approximated by the probabilities of *sorted* top K values (Gašić and Young, 2014), which can be implemented by sorted K-max pooling (Kalchbrenner et al., 2014).

3.3.2 Communication Module

The communication module takes $\mathbf{h}_i^0$ as the initial state for node v_i, then update state from one step to the next with following operations.

Sending Messages At l-th step, each node v_i will send messages $\mathbf{m}_{ij}^l$ to node v_j if there is a directed edge from v_i to v_j,

$$\mathbf{m}_{ij}^l = m_{u_e}^l(\mathbf{h}_i^{l-1}), \tag{3}$$

where $m_{u_e}^l$ is a function for edge type u_e at l-th step. For simplicity, we only consider $m_{u_e}^l$ in the form of a linear embedding: $m_{u_e}^l(\mathbf{h}_i^{l-1}) = \mathbf{W}_{u_e}^l \mathbf{h}_i^{l-1}$, where $\mathbf{W}_{u_e}^l$ is a weight matrix to be learned. Fig.1(c) is an example of sending messages for S-node 2. It sends messages to its out-going neighbors, i.e. S-nodes 1, 4 and I-node 0.

Aggregating Messages After sending messages, each node v_j will aggregate messages from its in-coming neighbors,

$$\mathbf{a}_j^l = \sum_{v_i \in \mathcal{N}_{in}(v_j)} \hat{k}_{u_e}^l(\mathbf{h}_i^{l-1}, \mathbf{h}_j^{l-1}) \mathbf{m}_{ij}^l = \sum_{1 \le i \le n} z_{ij} \hat{k}_{u_e}^l(\mathbf{h}_i^{l-1}, \mathbf{h}_j^{l-1}) \mathbf{m}_{ij}^l, \tag{4}$$

where the function $\hat{k}_{u_e}^l$ computes a normalized scalar representing relationship between node v_i and node v_j. There are various versions of $\hat{k}_{u_e}^l$. Here we introduce two instantiations:

- **Mean-Comm**: All messages from in-coming neighbors are treated equally, i.e. $\hat{k}_{u_e}^l(\mathbf{h}_i^{l-1}, \mathbf{h}_j^{l-1}) = \frac{1}{|\mathcal{N}_{in}(v_j)|}$.
- **Attention-Comm**: In practice, some messages are more important than others. Inspired by *self-attention* model for machine translation (Vaswani et al., 2017), here we first compute the similarity of two states in an unified space, i.e.

  $$k_{u_e}^l(\mathbf{h}_i^{l-1}, \mathbf{h}_j^{l-1}) = (\mathbf{W}_{1u_e}^l \mathbf{h}_i^{l-1})^\mathsf{T} (\mathbf{W}_{2u_e}^l \mathbf{h}_j^{l-1}), \tag{5}$$

  then normalize it with softmax:

  $$\hat{k}_{u_e}^l(\mathbf{h}_i^{l-1}, \mathbf{h}_j^{l-1}) = \frac{e^{(\mathbf{W}_{1u_e}^l \mathbf{h}_i^{l-1})^\mathsf{T} (\mathbf{W}_{2u_e}^l \mathbf{h}_j^{l-1})}}{\sum_i e^{(\mathbf{W}_{1u_e}^l \mathbf{h}_i^{l-1})^\mathsf{T} (\mathbf{W}_{2u_e}^l \mathbf{h}_j^{l-1})}}. \tag{6}$$

Fig.1(d) is an example of aggregating messages for S-node 4. It aggregates messages from its in-coming neighbors, i.e. S-nodes 2, 3 and I-node 0.

Updating State After aggregating messages from neighbors, every node v_i will update its state from $\mathbf{h}_i^{l-1}$ to $\mathbf{h}_i^l$,

$$\mathbf{h}_i^l = g_{c_i}^l(\mathbf{h}_i^{l-1}, \mathbf{a}_i^l), \tag{7}$$

where $g_{c_i}^l$ is the update function for node type c_i at l-th step, which may be a non-linear layer in practice, i.e.

$$\mathbf{h}_i^l = \sigma(\mathbf{W}_{c_i}^l \mathbf{h}_i^{l-1} + \mathbf{a}_i^l), \tag{8}$$

where σ is an activation function, e.g. RELU, and $\mathbf{W}_{c_i}^l$ is the transition matrix.

3.3.3 Output Module

After updating state L steps, based on the last state $\mathbf{h}_i^L$ each node v_i will compute the Q-values $\mathbf{q}_i$ for the actions corresponding to v_i:

$$\mathbf{q}_i = o_i(\mathbf{h}_i^L), \tag{9}$$

where o_i is a function for node i, which may be a MLP in practice. Note that, in input module and communication module, the same types of nodes share parameters, which may speed up the learning

process. However, in output module, in oder to capture the *specific characteristics* of each node, they don't share parameters.

When making decision, the outputs of all nodes are first concatenated, i.e. $\mathbf{q} = \mathbf{q}_0 \oplus \mathbf{q}_1 \oplus \cdots \oplus \mathbf{q}_n$, then the action is chosen according to $\mathbf{q}$ as done in vanilla DQN.

3.4 Inference of Graph Structure

In the previous section, we assume that the structure of graph G, i.e. the adjacency matrix $\mathbf{Z}$, is known. However, usually the graph is not known in practice, and the hypothetical structure is not guaranteed to be optimal. Therefore, it's better to optimize the structure along with the parameters of GNN. We assume that $\mathbf{Z}$ is a *latent* variable, and follows a factorized Bernoulli distribution, i.e. each element $z_{ij} \sim \mathrm{Bern}(\phi_{ij})$. The exact posterior distribution of $\mathbf{Z}$ is hard to inference and we can obtain the approximate posterior $q_\phi(\mathbf{Z})$ via variational inference. The loss function in equation (1) will be reformulated as follows:

$$\begin{aligned}\mathcal{L}(\theta, \phi) =& \mathbb{E}_{\tau \sim \mathrm{U}(\mathcal{D}), \mathbf{Z} \sim q_\phi(\mathbf{Z})} \left[\left(y - Q_\theta(\mathbf{b}, a; \mathbf{Z}) \right)^2 \right] + \lambda \mathrm{KL}(q_\phi(\mathbf{Z}) || p(\mathbf{Z})) \\ =& \mathcal{L}_E(\theta, \phi) + \lambda \mathcal{L}_C(\phi),\end{aligned} \tag{10}$$

where $p(\mathbf{Z})$ is the prior, and also follows a factorized Bernoulli distribution.

As shown in the equation, the loss function $\mathcal{L}(\theta, \phi)$ consists of two terms $\mathcal{L}_E(\theta, \phi)$ and $\mathcal{L}_C(\phi)$. $\mathcal{L}_E(\theta, \phi)$ corresponds to the error loss that measures how well the model is fitting the current dataset, whereas $\mathcal{L}_C(\phi)$ refers to the complexity loss that measures the flexibility of the model. For a uniform Bernoulli prior distribution, $\mathcal{L}_C(\phi)$ can be written following:

$$\mathcal{L}_C(\phi) = \sum_{i,j} \mathrm{KL}(q_{\phi_{ij}}(z_{ij}) || p(z_{ij}))) = \sum_{i,j} \left[-\mathrm{log}0.5 + \phi_{ij} \mathrm{log} \phi_{ij} + (1 - \phi_{ij}) \mathrm{log}(1 - \phi_{ij}) \right]. \tag{11}$$

Minimising the KL divergence between $q_{\phi_{ij}}(z_{ij})$ and the prior is equivalent to maximising the entropy of the Bernoulli random variable with probability ϕ_{ij}. This pushes the probability towards 0.5.

While $\mathcal{L}_C(\phi)$ is straightforward to minimize, $\mathcal{L}_E(\theta, \phi)$ does not allow for efficient gradient based optimization due to the discrete nature of $\mathbf{Z}$. To obtain the Q-values $Q_\theta(\mathbf{b}, a; \mathbf{Z})$, we need first to sample the discrete graph structure $\mathbf{Z}$ according to the factorized Bernoulli distribution with parameters ϕ. Therefore, the loss function $\mathcal{L}_E(\theta, \phi)$ is non-differential w.r.t. ϕ. While in principle a score function estimator such as the REINFORCE (Williams, 1992) could be employed, it suffers from high variance in practice. An alternative is to replace the discrete Bernoulli distribution with its continuous relaxation, i.e. the Concrete distribution as done at Concrete dropout (Gal et al., 2017). Instead of sampling the random variable from the discrete Bernoulli distribution we sample realisations from the following Concrete distribution with some temperature t:

$$\tilde{z}_{ij} = \mathrm{sigmoid} \left(\frac{1}{t} \left(\mathrm{log} \phi_{ij} - \mathrm{log}(1 - \phi_{ij}) + \mathrm{log} \epsilon_{ij} - \mathrm{log}(1 - \epsilon_{ij}) \right) \right), \tag{12}$$

where ϵ_{ij} is the noise sampled from a uniform distribution, i.e. $\epsilon_{ij} \sim \mathrm{U}(0, 1)$. The Concrete distribution concentrates most mass on the boundaries of the interval 0 and 1. With the continue relaxation $\tilde{z}_{ij}$ of the Bernoulli random variable z_{ij}, the loss function will be reparameterized as follows:

$$\mathcal{L}(\theta, \phi) = \mathbb{E}_{\tau \sim \mathrm{U}(\mathcal{D}), \epsilon \sim \mathrm{U}(0,1)} \left[\left(y - Q_\theta(\mathbf{b}, a; \tilde{\mathbf{Z}}) \right)^2 \right] + \lambda KL(q_\phi(\mathbf{Z}) || p(\mathbf{Z})), \tag{13}$$

where $\epsilon \sim \mathrm{U}(0, 1)$ denotes that every ϵ_{ij} is sampled from the uniform distribution independently. Every element z_{ij} of $\tilde{\mathbf{Z}}$ is calculated with equation (12). Note that whereas the sampling still exists, the sampled noise ϵ is independent of the parameters ϕ. Therefore the loss function $\mathcal{L}(\theta, \phi)$ is differential w.r.t. ϕ and it can be straightforward to minimize.

Note that the procedure of sampling according to equation (12) is approximately equivalent to sampling the neighbors of every node v_i according to the probability ϕ_{ij}. It is a variant of dropout and adopted in self-attention models (Tan et al., 2018) and graph convolutional networks (Kipf and Welling, 2017).

4 Experiments

4.1 PyDial Benchmark

Dialogue management research is typically evaluated on a small set of environments. Fortunately, a set of extensive simulated dialogue management environments is published in (Casanueva et al., 2017), which can test the capability of models in different environments. These environments are implemented in an open domain toolkit: PyDial. With providing domain-independent implementations of all the dialogue system modules, simulated users and simulated error models, PyDial has the potential to create a set of benchmark environments to compare different models in the same conditions. In this paper, we evaluate our proposed approaches on these environments, which will be briefly introduced next and are summarized in Table 1.

Firstly, there are three different **domains**: information seeking tasks for restaurants in Cambridge (CR) and San Francisco (SFR) and a generic shopping task for laptops (LAP). They are slot-based, which means the dialogue state is factorized into slots.

The second different dimension of variability is the **semantic error rate (SER)**, which simulates different noise levels in the speech understanding input channel.

In addition, env.5's **user model** is defined to be an *Unfriendly* distribution, where the users barely provide any extra information to the system, while others' are all *Standard*.

Finally, in order to test the learning capability of the models, the action **masking mechanism** is disabled in two of the tasks: env2 and env4.

The metrics in the next section has presented the average success rate and average reward for each applied model. The success rate is defined as the percentage of dialogues which are completed successfully.The reward is defined as $20 \times \mathbb{1}(\mathcal{D}) - T$, here $\mathbb{1}(\mathcal{D})$ is the success indicator and T is the dialogue length in turns.

4.2 Results

We evaluate four variants of our proposed structured DRL-based dialogue policy:

- **GNN-M**: GNN-based dialogue policy with *fully* connected graph. The communication method between nodes is *Mean-Comm* described in section 3.3.2.
- **GNN-M-C**: It is similar to GNN-M except that the graph structure is jointly optimized with the parameters of GNN as described in section 3.4. The hyperparameter λ in equation (13) is 4×10^{-4}.
- **GNN-A**: GNN-based dialogue policy with *fully* connected graph. The communication method between nodes is *Attention-Comm* described in section 3.3.2.
- **GNN-A-C**: It is similar to GNN-A except that the graph structure is jointly optimized with the parameters of GNN as described in section 3.4. The hyperparameter λ in equation (13) is 4×10^{-4}.

These models are compared with three baselines[1] presented in (Casanueva et al., 2017): GP-Sarsa, DQN, and eNAC. The results in the 18 tasks after 1000/4000 training dialogues are shown in Table 2. For each task, the result is the mean over 10 different random seeds.

[1]Due to the limitation of space, the results of A2C is omitted. The performance of A2C is worst among these baselines.

Table 2: Reward and success rates after 1000/4000 training dialogues. The results in bold blue are the best success rates, and the results in bold black are the best rewards.

We can find that our models can achieve the best performance in almost all of the tasks. In the two larger domains (SFR, LAP), the performance boost is more clear. For our four models, there is no significant difference in their performance, which indicates our proposed framework is not sensitive to these variants. However, through further analysis of these results, some interesting phenomena are observed.

After 1000 training dialogues, on average, two models (GNN-A and GNN-A-C) with *Attention-Comm* achieve the best reward and the best success rate respectively. It shows that *Attention-Comm* may benefit the sample-efficiency in the early learning stage. The potential reason is that models with *Attention-Comm* can quickly adjust their parameters to pay more attention on most important messages.

It is interesting to observe that two models with optimization of graph structure obtain better success rate than the other two (GNN-M-C vs. GNN-M, GNN-A-C vs. GNN-A). As described in section 3.4,

our proposed approach for structure optimization is a variant of dropout, i.e dropout neighbors. Dropout introduces some noise in the neural networks and can improve exploration in DRL (Gal and Ghahramani, 2016; Gal et al., 2017). Here, GNN-A-C and GNN-M-C also do more exploration, resulting in long dialogues which have more potential for success.

4.3 Analysis and Discussion

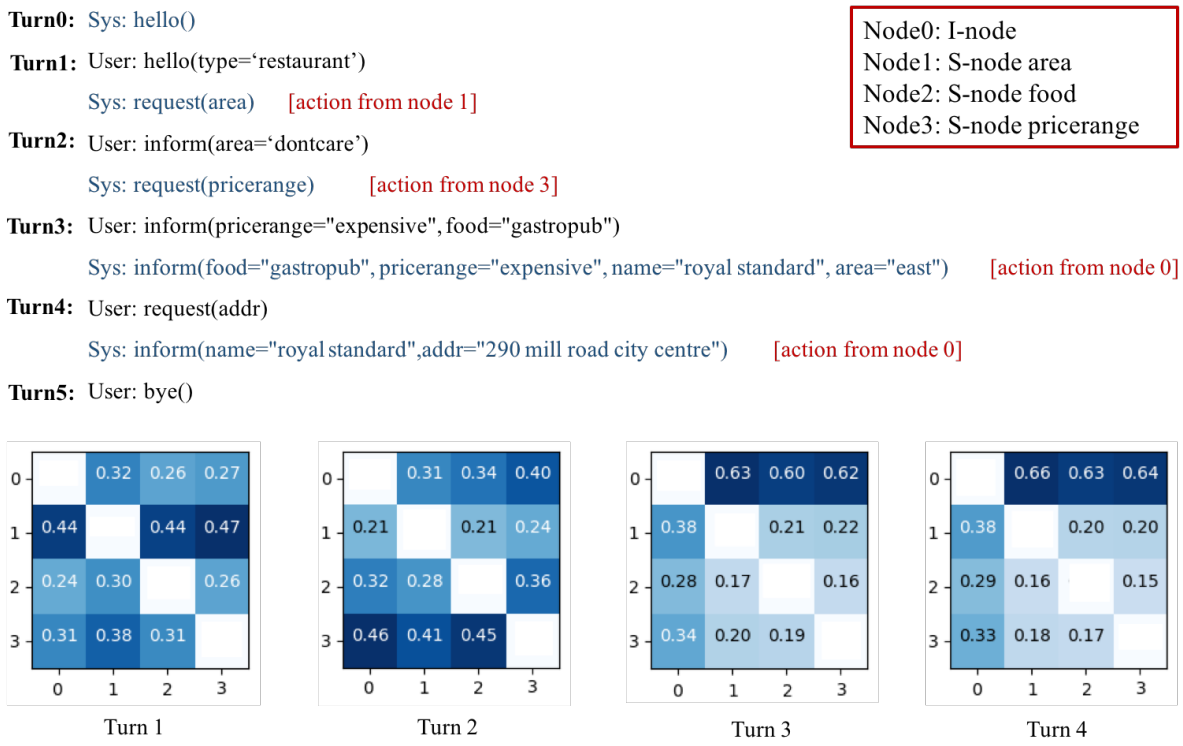

Figure 3: An example of dialogue on semantic level with a policy of GNN-A in CR domain (Env.1).

Fig.3 is an example of dialogue with a policy of GNN-A in CR domain (Env.1). The confusion matrices show the attention weights in the first communication step computed by equation (6). The elements in the i-th row represent the weights node v_i sending messages to other nodes. And each column is normalized by *softmax*. We can find that if the final action comes from the action sets $\mathbb{A}_i$, which is corresponding to node v_i, then the weights in the i-th row will be larger, as if to say:*" Hey, it's my duty to making decision at this turn, and you should make the Q-values for your action sets smaller!"*.

The confusion matrix in Fig.4 in Appendix A is the optimized graph structure in LAP domain (Env.3), i.e. the parameter ϕ_{ij} represents the probability of the existence of edge from node v_i to node v_j. We can find that all probabilities are in the range [0.7,0.9]. However, the probabilities associated with I-node is much larger than others, which means the communication between I-node and S-node is more important than the communication between S-node and S-node.

5 Conclusion

In this paper, we propose a structured dialogue policy, which is represented by a graph neural network (GNN). It consists of some sub-networks, each one for a node in a directed graph. The graph has two types of nodes: a *slot-independent* (I-node) node and n *slot-dependent* nodes (S-nodes). Each S-node corresponds to a slot. The same types of nodes partially share parameters. In order to model the interaction between sub-networks, they have internal message exchanges between neighbors in the graph when doing forward computation. We evaluate our framework on PyDial benchmark. Our models achieve state of the art in almost all of 18 tasks.

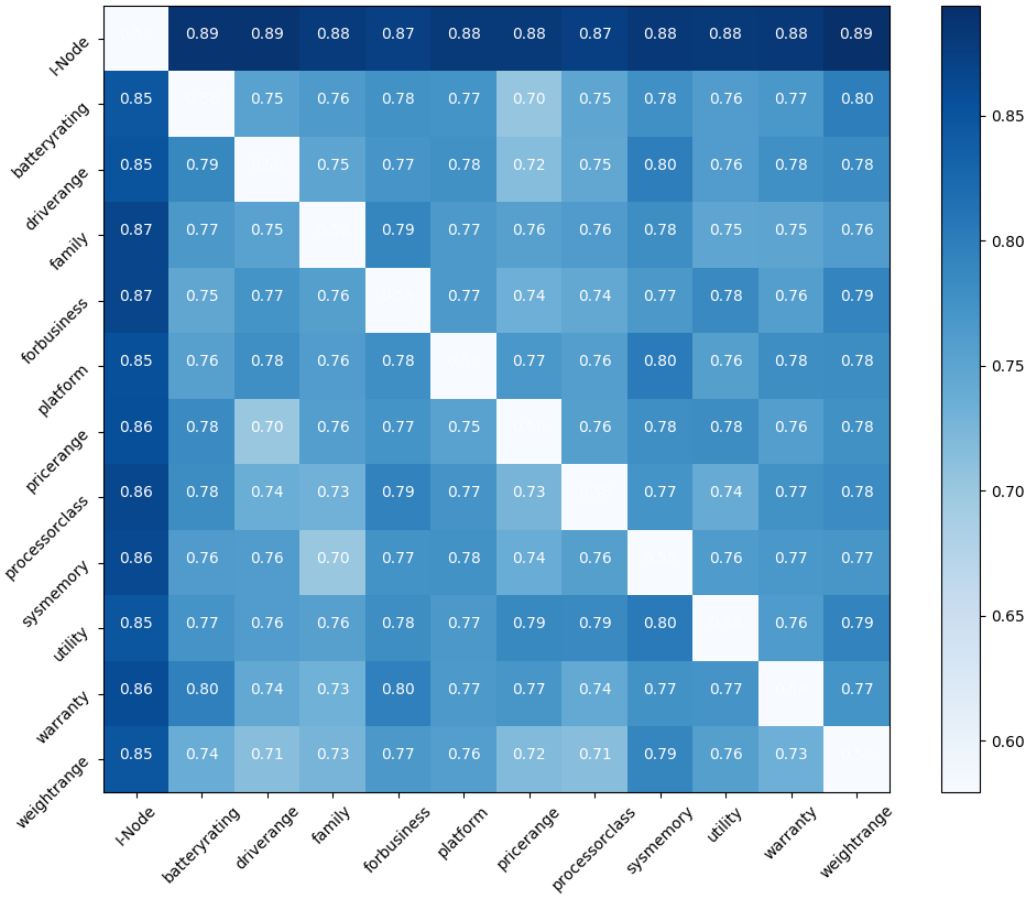

Figure 4: The confusion matrix of graph structure in LAP domain (Env.3). Each element denotes the probability that there is a edge from node v_i to v_j.

Abstract

Learning social media content is the basis of many real-world applications, including information retrieval and recommendation systems, among others. In contrast with previous works that focus mainly on single modal or bi-modal learning, we propose to learn social media content by fusing jointly textual, acoustic, and visual information (JTAV). Effective strategies are proposed to extract fine-grained features of each modality, that is, attBiGRU and DCRNN. We also introduce cross-modal fusion and attentive pooling techniques to integrate multi-modal information comprehensively. Extensive experimental evaluation conducted on real-world datasets demonstrates our proposed model outperforms the state-of-the-art approaches by a large margin.

1 Introduction

The popularity of the social media (e.g., Twitter, Weibo) over the last two decades has led to increasing demands for learning the content of social media, which may be beneficial to many real-world applications, such as sentiment analysis (Wang et al., 2015), information retrieval (Li et al., 2017), and recommendation systems (Wu et al., 2017). However, the task is non-trivial and challenging, because social media content is commonly multi-modal and involves several types of data, including text, audio, and image (an example is illustrated in Fig. 1). Each representation of the individual modality encodes specific knowledge and complementary, which can be explored to facilitate understanding of the entire meaning of the content. Therefore, gaining comprehensive knowledge from learning arising out of social media requires deliberate exploration of single-modal information and joint learning of the intrinsic correlation among various-modalities.

Santa Fe, New Mexico, USA, August 20-26, 2018.

Previous works on learning social media content have focused mainly on single modality, e.g., textual information (Wu et al., 2017) and image information (Garimella et al., 2016). To our best knowledge, no studies have focused on mere acoustic information analysis for social media. These previous works cope with data in the early stage of social media, because users are limited to posting single-modal content. In contrast, today's social media content usually includes textual, acoustic, and visual ingredients simultaneously, and requires multi-modal learning strategies to integrate rich information from all modalities.

Many researchers have studied the bi-modal utilization to address the issue of incomplete information exploration. This utilization can be classified into two kinds of approaches. The first is bi-modal retrieval, which utilizes one modality to find similar content in the other modality, such as finding the most relevant texts to a given image (Li et al., 2017). This kind of approach is similar to machine translation tasks to some extent, for instance, the input is fine-grained features of one modality, the objective of which is to minimize the distance between the output vectors with fine-grained features of the target modality. The second is bi-modal unification (Park and Im, 2016), which seeks to integrate individual information of the two modalities together. The process of this kind of approach can be divided into two stages: (a) feature extraction, in which the two modalities are encoded into their corresponding vectors or matrices via embedding approaches; and (b) bi-modal feature aggregation, in which the extracted features are mapped into a shared latent space through multilayer perceptrons or directly into the target spaces of tasks through classifiers (Chen et al., 2017).

Learning representations of multi-modal data, which contains features of more than two modalities, is a more challenging task. The main reason is that the fine-grained features of the modalities can be difficult to obtain because of the lack of annotated labels for every modality. Previous studies lack the appropriate strategies to aggregate various kinds of information effectively. It's easy to imagine that bi-modal aggregation models might be extended to multi-modal learning with linear operations, e.g., the concatenation operation. However, this technique may generate inappropriate integral representation of the multiple features and lacks further exploration in the previous work.

We address the abovementioned issues by introducing effective strategies to represent the individual features for the three modalities. A general unified framework is proposed to integrate multi-modalities seamlessly. Specifically, we begin by encoding single modal parts into dense vectors. For textual content, we design an attention-based network (i.e., attBiGRU), to incorporate various textual information. For acoustic content, we introduce an effective DRCNN approach to embed temporal audio clips locally and globally. For visual content, we fine-tune a state-of-the-art general framework, DenseNet (Huang et al., 2017). We propose a novel fusion framework, which involves the cross-modal fusion and the attentive pooling strategies, to aggregate various modal information. Extensive experimental evaluations conducted on real-world datasets demonstrate that our proposed model outperforms state-of-the-art approaches by a large margin. The contributions of this paper are presented as follows:

- We introduce effective strategies to extract representative features of the three modalities, including the following. (1) For textual information, we design an attention based network, named as attBiGRU, to integrate various textual parts. The independent textual parts are considered as two separate roles, namely, the protagonist and the supporting players. The supporting players are encoded into an attention weight vector on the protagonist. (2) For acoustic information, we propose the DCRNN strategy based on the densely connected convolutional and recurrent networks. The densely connected convolutional networks are used to learn the acoustic features both locally and globally. The recurrent networks are designed to learn the temporal information. (3) For visual information, we introduce state-of-the-art strategies from (Simonyan and Zisserman, 2015; He et al., 2016; Huang et al., 2017).

- We propose a general multi-modal feature aggregation framework, JTAV, to learn information jointly. The framework considers the textual, acoustic, and visual contents to generate a unified representation of social media content with the help of the optimized feature fusion network, CMF-AP, which can learn inner and outer cross-modal information simultaneously.

- We conduct comprehensive experiments on two kinds of tasks, sentiment analysis and information

retrieval, to evaluate the effectiveness of the proposed JTAV framework. The experiments demonstrate that JTAV outperforms state-of-the-art approaches remarkably, that is, about 2% higher than the state-of-the-art approaches on all metrics in the sentiment analysis experiment and more than ten times better than the baseline on main metrics in music information retrieval experiment.

2 Related Work

Over the past decades, social media learning has gained considerable attention in related research literature. Social media content is utilized as raw material for recommendation (Wang et al., 2013), information retrieval (Agichtein et al., 2008), and so forth.

The dominance of the single-modal content in social media in the early stages, however, has caused most previous works to position themselves in single-modal exploration, e.g., natural language processing and image processing. (Han et al., 2013) focused on the short text messages in social media, and normalized lexical variants to their canonical forms. In (Hutto and Gilbert, 2014), combined lexical features of social media text were proposed for expressing and emphasizing sentiment intensity. An example of image processing was (Garimella et al., 2016), social media images, particularly geo-tagged images, were studied in predicting county-level health statistics.

In recent years, users have come to prefer presenting more attractive ingredients, such as image and audio in addition to natural words. Therefore, literature on social media analysis has been shifting its focus from single-modal to multi-modal learning. For example, (Wang et al., 2015) assume that visual and textual content have a shared sentiment label space, and the optimization problem can be converted to the minimization between the derivatives of both modalities. In (Li et al., 2017), the images and lyrics are mapped into a shared tag space. The lyrics, which have the smallest mean squared error with a given image, emerged as the matching object. (Chen et al., 2017) present a new end-to-end framework for visual and textual sentiment analysis; they began with the co-appearing image and text pairs that provide semantic information for each other, and use the concatenation of the vectors generated from the original image and text, in the shared sentiment space. However, the drawback of these works is that they utilized only partial information.

An intuitive idea to gain a comprehensive learning of the entire meaning of social media is to integrate more modalities effectively. The reason is that each representation of the individual modality encodes specific knowledge and is complementary, an aspect that can be explored to facilitate understanding on the entire meaning of the content. However, this task could be extremely challenging because we need to explore single-modal information deliberately and jointly learn the intrinsic correlation among various modalities. This work is the first study that focuses on the seamless integration of the three modalities (i.e., text, audio, and image), into a general framework to jointly learn the social media content.

3 Model Description

The architecture of our proposed framework is illustrated in Fig. 2. It has two main modules, the feature extraction and the feature aggregation. Let $\boldsymbol{t}$, $\boldsymbol{a}$, and $\boldsymbol{v}$ denote the textual, acoustic, and visual features, which are encoded from the feature extraction module, respectively. Let $\boldsymbol{u}$ denote the target unified representation of the multi-modal content. The feature aggregation module is designed to generate $\boldsymbol{u}$ from $\boldsymbol{t}$, $\boldsymbol{a}$, and $\boldsymbol{v}$ effectively and comprehensively. The example in Fig. 1 is utilized to ground our discussion and to illustrate the intuitive idea of this work.

3.1 Feature Extraction

Fine-grained features, which are related to the qualities of the input of the aggregation processing directly, are the foundation of multi-modal representation learning. The proposed strategies for generating appropriate features for text, audio, and image will be presented in the following subsections.

3.1.1 Text modeling

The purpose of text modeling is to encode raw textual parts into a latent representation $\boldsymbol{t}$. We design a bidirectional gated recurrent neural network (BiGRU) based attentive network (i.e., attBiGRU), to extract sufficient textual features carrying the long-range dependencies, as illustrated in Fig. 3.

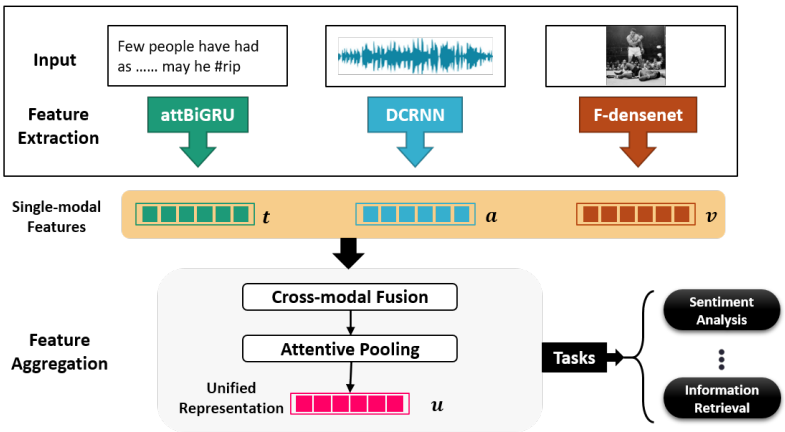

Figure 2: The architecture of the proposed JTAV framework

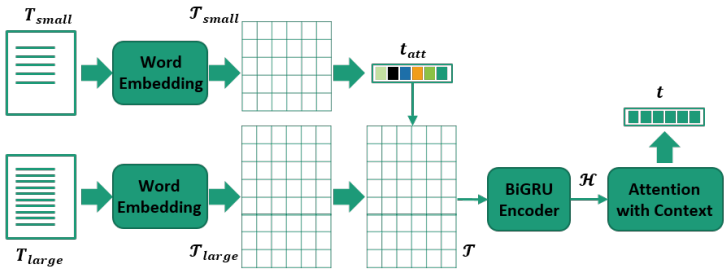

Figure 3: The attBiGRU strategy for modeling textual content

Generally, social media content contains more than one textual part, such as the lyrics and reviews of a song. It is reasonable to assume that a protagonist and supplying players exist among these textual parts. Intuitively and for sake of simplicity, we can regard the part with the maximum number of words as the protagonist and the other parts as the supplying players. Let $\boldsymbol{T_{large}}$ denote the protagonist and $\boldsymbol{T_{small}}$ denote the supplying roles. Inspired by (Li et al., 2017) to reduce the gap between image and text, we use a pre-trained word embedding model, e.g., FastText (Bojanowski et al., 2017), to encode $\boldsymbol{T_{small}}$ into a word matrix (i.e., $\boldsymbol{\mathcal{T}_{small}}$). $\boldsymbol{\mathcal{T}_{small}}$ is computed as $\boldsymbol{w_{small}} W_e$, where $\boldsymbol{w_{small}}$ is the words in $\boldsymbol{T_{small}}$ and W_e is a pre-trained embedding matrix. $\boldsymbol{t_{att}}$ is an attention vector generated from $\boldsymbol{\mathcal{T}_{small}}$ with an average pooling layer, and works on every word vector of $\boldsymbol{\mathcal{T}_{large}}$ through the element-wise product. We obtain an attented word matrix, denoted as $\boldsymbol{\mathcal{T}}$.

The BiGRU encoder is utilized to encode every word vector in the sequence into a latent representation and receive the aid of the other textual parts. Subsequently, we feed the attended word matrix $\boldsymbol{\mathcal{T}}$ into a BiGRU network. The output of the BiGRU encoder is a $2M \times N$ matrix, where M is the number of hidden units of a layer, and N is the number of words in $\boldsymbol{\mathcal{T}_{large}}$. We denote the output matrix as $\boldsymbol{\mathcal{H}}$.

The attention with context part is a simplified version of (Yang et al., 2016) without the sentence attention part. It is introduced to balance the importance among all words and is defined as follows:

$$
\begin{aligned}
\hat{\boldsymbol{h}}_{\boldsymbol{i}} &= tanh(\boldsymbol{W_u h_i} + \boldsymbol{b_u}), \\
\boldsymbol{\alpha_i} &= \frac{exp\left(\hat{\boldsymbol{h}}_{\boldsymbol{i}}{}^{\top} \hat{\boldsymbol{h}}_{\boldsymbol{c}}\right)}{\sum_{j=0}^{N-1} exp\left(\hat{\boldsymbol{h}}_{\boldsymbol{j}}{}^{\top} \hat{\boldsymbol{h}}_{\boldsymbol{c}}\right)}, \\
\boldsymbol{t} &= \sum_{j=0}^{N-1} \boldsymbol{\alpha_j h_j},
\end{aligned}
\tag{1}
$$

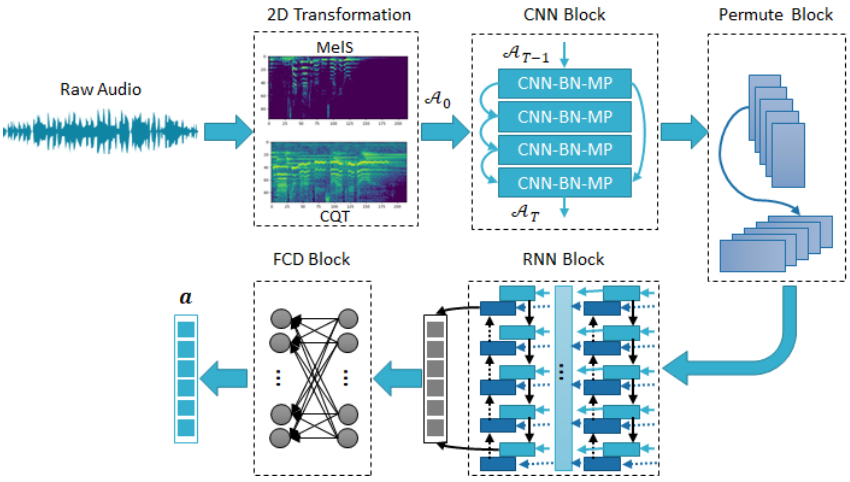

Figure 4: The DRCNN strategy for modeling acoustic content

where $\boldsymbol{h_i}(0 \leq i \leq N-1)$ is the i^{th} column of $\boldsymbol{\mathcal{H}}$, $\hat{\boldsymbol{h}}_{\boldsymbol{i}}$ is a latent vector computed from $\boldsymbol{h}_i$ using the tanh function, $\boldsymbol{\alpha_i}$ is the attention weight scalar computed from $\hat{\boldsymbol{h}}_{\boldsymbol{i}}$ and a random initialized context vector $\hat{\boldsymbol{h}}_{\boldsymbol{c}}$, $\boldsymbol{W_u}$ and $\boldsymbol{b_u}$ are parameters learned from training. The final textual representation $\boldsymbol{t}$ is a weighted sum of $\boldsymbol{h_j}(0 \leq j \leq N-1)$ on $\boldsymbol{\alpha_j}(0 \leq j \leq N-1)$.

3.1.2 Audio modeling

In this paper, we focus on polyphonic audio, such as music clips. To capture useful acoustic features, we design a densely connected convolutional recurrent neural network called DCRNN, which takes raw audio as input, and generates a distributed representation $\boldsymbol{a}$ to effectively represent the acoustic information. DCRNN consists of five phases, as illustrated in Fig. 4.

The first phase is named as 2D transformation, which transfers raw audio into two-dimensional vectors. Following the majorities of the deep learning approaches in music information retrieval (Choi et al., 2017b), we use two dimensional spectrograms instead of the discrete audio signals. We choose two kinds of spectrograms (i.e., mel-spectrogram (Boashash, 1996) and constant-Q transform (Brown and Puckette, 1992)). A mel-spectrogram (MelS) is a visual representation of the spectrum of frequencies of audio and is optimized for human auditory perception. A constant-Q transform (CQT) is computed with the logarithmic-scale of the central frequencies. The CQT is well suited with the frequency distribution of music pitch. MelS and CQT have been used frequently in various acoustic tasks (Zhu et al., 2017; Jansen et al., 2017), and are utilized as coarse-grained features in the current paper. We use $\boldsymbol{\mathcal{A}_0}$ to indicate the 2D spectrograms.

The second phase is a convolutional neural network (CNN) based block (called CNN block). $\boldsymbol{\mathcal{A}_0}$ is used as the input of the block. According to (Choi et al., 2017a), early layers of CNN have the ability to capture local information such as pitch and harmony, whereas deeper layers can capture global information such as melody. We introduce the densely connected CNN, which has been proved powerful at learning both local and global features of images (Huang et al., 2017). The CNN block is composed of several densely connected "CNN-BN-MP" sub-blocks, where "BN" represents batch normalization layers, and "MP" indicates max pooling layers. Suppose there are N densely connected "CNN-BN-MP" sub-blocks in the CNN block, each can be defined as:

$$
\begin{aligned}
\boldsymbol{\mathcal{A}_h^1} &= CNN - BN - MP(\boldsymbol{\mathcal{A}_{T-1}}), \\
\boldsymbol{\mathcal{A}_h^2} &= CNN - BN - MP(\boldsymbol{\mathcal{A}_h^1}), \\
\boldsymbol{\mathcal{A}_h^3} &= CNN - BN - MP(\boldsymbol{\mathcal{A}_h^2}), \\
\boldsymbol{\mathcal{A}_T} &= CNN - BN - MP(\boldsymbol{\mathcal{A}_h^1} \oplus \boldsymbol{\mathcal{A}_h^3}),
\end{aligned}
\tag{2}
$$

where $\boldsymbol{T} \in (1, N)$, $\boldsymbol{\mathcal{A}_{T-1}}$ represents the output of the $(\boldsymbol{T}-1)^{th}$ densely connected "CNN-BN-MP" sub-block, $\boldsymbol{\mathcal{A}_h^*}$ indicate the latent variables learned by the CNN block, $\oplus$ denotes the concatenation operation, and $\boldsymbol{\mathcal{A}_T}$ is the output of the $\boldsymbol{T}^{th}$ sub-block.

The permute block is adopted from the technique introduced in (Panwar et al., 2017). The output of the CNN block is permuted to time major form, and fed into the following recurrent neural network.

The recurrent neural network (RNN) block is built based on bidirectional RNN. The stacked RNN layers are used to learn the long-short term temporal context information. We take the concatenation of the last hidden state (in vector format) in the forward direction and the first hidden state in the backward direction as the output of this phase.

Several fully connected dense layers constitutes the fully connected dense (i.e., FCD) block. We use the output of the last dense layer as the acoustic representation $\boldsymbol{a}$. Note that all the parameters presented in this section, e.g., number of layers, are optimally tuned and will be clarified in the experiment section.

3.1.3 Image modeling

Extracting rewarding features from images is a well explored problem; hence, following the tradition of other image-related tasks (Li et al., 2017; Chen et al., 2017), we use pre-trained approaches on external visual tasks.

VGG (Simonyan and Zisserman, 2015) is a deep convolutional network with nineteen weight layers, ResNet (He et al., 2016) is a residual learning framework with 101 weight layers, and DenseNet is a deep densely connected convolutional network with 121 weight layer. All these models are pre-trained on the ImageNet dataset [1], and are fine-tuned on the experimental datasets by modifying the final densely-connected layers. The last dense layer is used as the visual representation $\boldsymbol{v}$.

3.2 Feature Aggregation

In this section, we propose a feature aggregation network, which consists of the cross-modal fusion (CMF) and the attentive pooling (AP) strategies to generate a unified representation of multi-modal information, as shown in the bottom part of Fig. 2. We call the feature aggregation approach as CMF-AP.

The first phase is cross-modal fusion. We introduce the concepts of the inner and outer information. The inner information refers to information remaining in single modality, like the visual information of an image or the acoustic information of a song clip. The outer mutual information cross modalities refers to the relevant information between two modalities. In addition to the inner information generated from the feature extraction module, we compute the matrix product ($\times$) pairwise on all modal vectors to calculate the cross-modal aware matrices. The cross-modal aware matrices contain outer mutual information cross modalities and the inner information.

However, handling the cross-modal aware matrices directly is not feasible, and thus, we reconstruct $\boldsymbol{t}$, $\boldsymbol{a}$, and $\boldsymbol{v}$ from the cross-modal aware matrices. The attentive pooling strategy is adapted from Eq. 1 to conduct row pooling and column pooling.

After the above procedure, two reconstructed $\boldsymbol{t}$, two reconstructed $\boldsymbol{a}$, and two reconstructed $\boldsymbol{v}$ are obtained. For instance, from the text-image matrix, we can obtain a text-enhanced visual vector and an image-enhanced textual vector. The reconstructed vectors carry both inner and outer information. Densely connected layers are deployed for dimensionality reduction purpose. The final unified representation $\boldsymbol{u}$ is the concatenation of the reconstructed vectors.

The feature aggregation module is formulated as follows:

[1] http://www.image-net.org.

$$
\begin{aligned}
&\boldsymbol{C_{mn}} = \boldsymbol{m} \times \boldsymbol{n}^{\top};\\
&\begin{cases}
\boldsymbol{C_m} = tanh(\boldsymbol{W_m C_{mn}} + \boldsymbol{b_m}),\\
\boldsymbol{\alpha_m} = softmax(\boldsymbol{C_m^{\top}} \boldsymbol{u_m}),\\
\hat{\boldsymbol{m}} = \sigma(\hat{\boldsymbol{W}}_{\boldsymbol{m}} \boldsymbol{C_{mn}} \boldsymbol{\alpha_m} + \hat{\boldsymbol{b}}_{\boldsymbol{m}});
\end{cases}\\
&\begin{cases}
\boldsymbol{C_n} = tanh(\boldsymbol{W_n C_{mn}^{\top}} + \boldsymbol{b_n}),\\
\boldsymbol{\alpha_n} = softmax(\boldsymbol{C_n^{\top}} \boldsymbol{u_n}),\\
\hat{\boldsymbol{n}} = \sigma(\hat{\boldsymbol{W}}_{\boldsymbol{n}} \boldsymbol{C_{mn}^{\top}} \boldsymbol{\alpha_n} + \hat{\boldsymbol{b}}_{\boldsymbol{n}});
\end{cases}\\
&\boldsymbol{u_{mn}} = \hat{\boldsymbol{m}} \oplus \hat{\boldsymbol{n}};
\end{aligned}
\tag{3}
$$

where $\boldsymbol{m}, \boldsymbol{n} \in \{\boldsymbol{t}, \boldsymbol{a}, \boldsymbol{v}\}$ and $\boldsymbol{m} \neq \boldsymbol{n}$, σ represents an activation function, $\hat{\boldsymbol{m}}$ and $\hat{\boldsymbol{n}}$ refer to the reconstructed vectors of $\boldsymbol{m}$ and $\boldsymbol{n}$, respectively, and the remaining variables stand for latent parameters learned from training. The final unified representation $\boldsymbol{u}$ is defined as $\boldsymbol{u} = \boldsymbol{u_{tv}} \oplus \boldsymbol{u_{ta}} \oplus \boldsymbol{u_{av}}$.

3.3 Training and Optimization

The Adam algorithm (Kingma and Ba, 2015) is used as optimizer to minimize the binary cross entropy function. The binary cross entropy is defined as follows:

$$
\mathcal{L} = -\frac{1}{N} \sum_{n=1}^{N} [y_n \log \hat{y}_n + (1 - y_n) \log(1 - \hat{y}_n)], \tag{4}
$$

where N denotes the number of target values, y_n denotes the $n^{th}(1 \leq n \leq N)$ true value, and $\hat{y}_n$ denotes the corresponding predicted value. For the information retrieval task, given a query, we randomly generate a fake candidate along with the correct candidate from the candidate corpus for effective training.

4 Experimental Evaluation

Evaluation is conducted on two kinds of tasks, sentiment analysis and music information retrieval, as presented in Sections 4.1 and 4.2, respectively[2].

4.1 Sentiment Analysis

Task Description. Sentiment analysis is a task that deals with the computational detection and extraction of opinions, beliefs, and emotions in given content (Paltoglou and Thelwall, 2017). In this paper, we analyze posts from a social media platform ShutterSong. Given a post, which includes the visual (image), textual (song lyrics and user defined caption), and acoustic (song clip) parts, the goal is to tag a "positive" or "negative" label for the multi-modal content. We use "1" to indicate the positive label, and "0" to indicate the negative label. The sentiment analysis task can be regarded as a binary classification task.

Dataset and Parameter Settings. We sort a sub dataset from the ShutterSong dataset[3] to conduct the sentiment analysis task. The user-defined mood tags are used as labels, and 3260 items have available moods. After removing duplications, we obtain 272 mood tags. We divide these mood tags into "positive" and "negative" on the basis of the related meaning manually. We obtain 2297 positive and 963 negative samples, with each including a user posted image, a song clip, and its corresponding lyrics, part of the samples have available captions. We call this dataset as MoodShutter, and separate it into train (80%), validation (10%), and test (10%) sets.

The song lyrics are truncated at 100 words, and captions are cleaned into five words according to a caption corpus. We use a 300 dimensional embedding matrix, which is pre-trained on the English

[2]The source code and more details on the experimental settings are available at `http://github.com/mengshor/JTAV`

[3]`https://drive.google.com/file/d/0B2N8XiDRrEgISXFJSXBEMWpUMDA/view`.

Wikipedia dataset[4] through FastText, as W_e. The number of the hidden units of the BiGRU encoder is set as 50. Raw song clips are transformed into spectrograms with the *librosa* tool (McFee et al., 2017). We cut all the audio files into 10-second-segments. Audio sample rates are set as 22050Hz, hop lengths are 1024, and the numbers of frequency bins are 96. The parameter N of DCRNN is set as $N = 2$. The images are sized to $224 \times 224 \times 3$.

Baseline approaches. We compare our JTAV framework with:

- doc2vec (Le and Mikolov, 2014), a paragraph embedding approach;
- lyricsHAN (Alexandros, 2017), a hierarchical attention network which encodes songs into vectors;
- BiGRU, a bidirectional GRU network which utilizes the song lyrics as input;
- attBiGRU, our novel text modeling approach which adds the available captions as the supplying role based on BiGRU;
- MFCC (McFee et al., 2017), a type of cepstral representation of the audio clip generated by *librosa*;
- convnet (Choi et al., 2017a), an acoustic feature learning method based on transfer learning;
- DCRNN-MelS, our novel audio modeling approach which takes MelSs as input;
- DCRNN-CQT, our novel audio modeling approach which takes CQTs as input;
- F-VGG (Simonyan and Zisserman, 2015), a VGG network pre-trained on the ImageNet dataset and fine tuned on the MoodShutter dataset;
- F-ResNet (He et al., 2016), a ResNet pre-trained on the ImageNet dataset and fine tuned on the MoodShutter dataset;
- F-DenseNet (Huang et al., 2017), a DenseNet pre-trained on the ImageNet dataset and fine tuned on the MoodShutter dataset; and
- early fusion, a method which combines features learned by our methods before classification or regression tasks, and is very popularly used (Chen et al., 2017; Oramas et al., 2017).

Evaluation Metrics. The positive and negative samples are unbalanced and the ratio is about $7 : 3$. The weighted average area under the curve (AUC) score, F1 score, and precision score are chosen as evaluation metrics[5].

Results and Discussion. Table 1 presents the results between JTAV and the baseline approaches. For fair comparison, all feature vectors are obtained through optimized training; the classic logistic regression approach is utilized as the classier; and the reported results are the average values of 10 runs.The values in boldface represent the best results among all the approaches. The proposed JTAV performed the best on all metrics, with 0.623 AUC score, 0.691 F1 score, 68.8% precision score.

Observations on single modality. For textual content, attBiGRU obtained the best results, and was superior to doc2vec with about 7 percentage points promotion of AUC score, 11 percentage points promotion of F1 score, and 6 percentage points promotion of precision score. These results demonstrate the proposed BiGRU approach extracts more powerful features than doc2vec and lyricsHAN. And taking the omni textual component into consideration, the attBiGRU approach can generate better results. For acoustic content, DCRNN outperforms MFCC and convnet because it can learn acoustic information both locally and globally. Long-term temporal context dependency is also retained.We also observe that CQT works better than MelS. DenseNet is the best choice for encoding images into vectors as compared with VGG and ResNet.

[4] `https://en.wikipedia.org/wiki/Wikipedia:Database_download#English-language_Wikipedia`.

[5] We utilize the implementation in sklearn, `http://scikit-learn.org/`.

Table 1: Results of the sentiment analysis task

modal	materials	approaches	AUC score	F1 score	precision score
text	lyrics	doc2vec (Le and Mikolov, 2014)	0.513	0.545	0.593
		lyricsHAN (Alexandros, 2017)	0.518	0.575	0.596

		CMF-AP	0.611	0.688	0.683
audio+image	image+song clip	early fusion	0.589	0.624	0.653
		CMF-AP	0.603	0.654	0.665
text+audio+image	lyrics+caption+ image+song clip	early fusion	0.602	0.671	0.669
		CMF-AP	**0.623**	**0.691**	**0.688**
JTAV=attBiGRU+(F-DenseNet)+(DCRNN-CQT)+(CMF-AP)					

Observations on multiple modalities. When more modalities emerge, more information is included, and better results are obtained. For example, the performance of combining textual and acoustic information is much better than that of using texts or audio solely. Our CMF-AP approach works steadily better than the baseline approach, because it not only extracts the inner features inside single modality, but also the the outer information cross modalities. Moreover, the best results are presented when we utilize all modalities and all available materials (i.e., JTAV). The AUC score is 0.623, representing an improvement of 2.1 percentage points to the early fusion approach. The F1 score is 0.691, performing an improvement of 2 percentage points over the best baseline approach. The precision score is 0.688, representing about 1.9 percentage points improvement to the best baseline approach. It seems like that the promotions of the proposed JTAV over the best baseline approach is not that huge. As a matter of fact, the early fusion approach utilizes the effective features generated by our proposed work (i.e., attBiGRU, DCRNN-CQT, and F-DenseNet). We believe that, if compared to the original version of early fusion method which only uses the previous features, the margin would be larger. For the sake of space limitation, in Table 1 the early fusion approach on previous features are omitted.

4.2 Music Information Retrieval

We conduct an extended experiment, which is can be explained as given an image query and named as image2song (Li et al., 2017), to verify the general effectiveness of JTAV. Image2song is a music information retrieval task and aims to find the most relevant song.

We perform the image2song task on two benchmark datasets, they are the Shuttersong† dataset and the Shuttersong§ dataset (Li et al., 2017). Both datasets include no-repeat 620 songs with 3100 images, that is, each song is related to five images. Part of the images are attached with user-defined captions, and each song has an acoustic song clip and corresponding song lyrics. The difference lies in the partition strategy of the train and test dataset. In Shuttersong†, 100 songs and related images are selected randomly for testing, and the rest for training. While in Shuttersong§, the train and test set share the whole song

	Li et al., 2017	I+L	I+L+C	I+S	I+C+S	JTAV
R@1	2.6	49.0	79.2	48.2	62.0	95.2
R@5	9.4	53.8	80.0	49.4	63.8	95.2
R@10	16.8	58.0	81.8	51.6	66.4	95.6
Med r	41.5	24.5	12.1	28.2	16.8	3.5

	Li et al., 2017	I+L	I+L+C	I+S	I+C+S	JTAV
R@10	5.6	57.4	62.3	42.1	81.8	83.5
R@50	17.6	68.4	77.4	59.2	84.2	96.6
R@100	29.4	74.8	84.2	72.3	85.0	97.4
Med r	233.8	88.3	59.4	91.4	73.5	17.2

Figure 6: Results of image2song on Shuttersong§

set, while one of the five images of each song is chosen randomly for testing. The preprocessing settings of images, captions, song lyrics and song clips is the same as that of the sentiment analysis task.

We utilize the rank-based evaluation metrics to compare the results. For fair comparison, we adopt the evaluate metrics in (Li et al., 2017). Med r represents the medium rank of the ground truth retrieved song, and lower values indicate better performance. Recall@k (R@k for short), is the percentage of a ground truth song retrieved in the top-k ranked items, and higher values indicate better performance. In dataset†, $k = \{1, 5, 10\}$, and $1 \leq$ Med r ≤ 100; whereas in Shuttersong§, $k = \{10, 50, 100\}$, and $1 \leq$ Med r ≤ 620.

We compare the proposed JTAV with the state-of-the-art approach (Li et al., 2017). For a more comprehensive comparison, we design several baseline approaches based on our proposed strategies: I+L uses images as queries and song lyrics as candidates with a suit of BiGRU, F-DenseNet and CMF-AP; I+C+L uses images and available captions as queries while song lyrics as candidates with a suit of attBiGRU, F-DenseNet and CMF-AP; I+S uses images as queries and song clips as candidates with a suit of DCRNN-CQT, F-DenseNet and CMF-AP; and I+C+S uses images and available captions as queries while song clips as candidates with a suit of DCRNN-CQT, F-DenseNet and CMF-AP. In JTAV, the images and available captions form the queries, the song clips and lyrics form the candidates.

Fig. 5 and Fig. 6 display the results on Shuttersong† and Shuttersong§, respectively. Both prove JTAV is the most powerful one among all testing approaches. JTAV turns the image2song task from finding the most similar item to finding the most relevant item, which is nearer the real situation in cross-modal retrieval tasks. Notably, JTAV exceeds the state-of-the-art approaches soundly. In Shuttersong†, the Med r is no more than 5, and the R@1 score is more than 95%, which is more than 90% better than that obatined in (Li et al., 2017). In Shuttersong§, the Med r is no more than 20, which is less a tenth of that obtained in (Li et al., 2017), the R@10 score is more than 83%, and the R@100 score is more than 97%.

5 Conclusion

In this paper, we aim to address the issue of learning social media content from the multi-modal view. We have designed effective approaches (i.e., attBiGRU) for textual content, F-DenseNet for visual content, and DCRNN for acoustic content, to extract fine-grained features. We have introduced CMF-AP to generate cross-modal aware matrices and reconstructed modal vectors, which are used to produce an unified representation of the multi-modal content. The proposed framework has been intensively evaluated, and the experimental results have demonstrated the general validity of JTAV by comparing with the state-of-the-art approaches.

Abstract

Neural encoder-decoder models have been widely applied to conversational response generation, which is a research hot spot in recent years. However, conventional neural encoder-decoder models tend to generate commonplace responses like *"I don't know"* regardless of what the input is. In this paper, we analyze this problem from a new perspective: latent vectors. Based on it, we propose an easy-to-extend learning framework named MEMD (Multi-Encoder to Multi-Decoder), in which an auxiliary encoder and an auxiliary decoder are introduced to provide necessary training guidance without resorting to extra data or complicating network's inner structure. Experimental results demonstrate that our method effectively improve the quality of generated responses according to automatic metrics and human evaluations, yielding more diverse and smooth replies.

1 Introduction

Human-computer conversation is attracting particular attention recently. Research in this field falls into two categories: the retrieval-based method (Ji et al., 2014; Yan et al., 2017; Wu et al., 2017) and the generative method (Shang et al., 2015; Serban et al., 2016). While the retrieval-based method can guarantee completeness of output sentences, it fails to customized for particular posts from users. By contrast, the generative method may produce sentences with grammatical errors, however, it shows great promise in flexibility, which gives rise to a research hot spot.

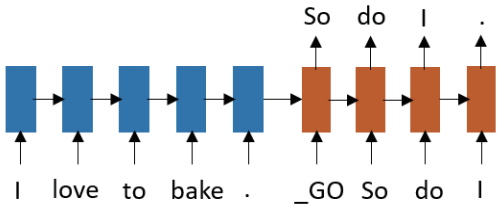

Figure 1: Conventional encoder-decoder model. Blue part represents the encoder, while red part represents the decoder.

Of the generative method, neural encoder-decoder based model (Sutskever et al., 2014) has become the mainstream (Figure 1). (Shang et al., 2015) firstly formalized the generation of response as a decoding process based on the latent representation of the input text, and both encoding and decoding are realized with recurrent neural networks (RNN). Such formalization is widely adopted by later work. However, the conventional encoder-decoder model's performance is far from satisfactory, for it tends to generate meaningless and generic responses like *"I don't know"*.

To tackle the issue of response diversity, lots of models have been proposed, and they can be broadly divided into three categories: (1) introducing external priori knowledge into the procedure of encoding/decoding (Mou et al., 2016; Xing et al., 2017), which usually requires pretreatment on extra large

Santa Fe, New Mexico, USA, August 20-26, 2018.

data. (2) complicating network's structure to enhance model's capacity for encoding/decoding (Zhou et al., 2017; Serban et al., 2017a; Serban et al., 2017b; Zhao et al., 2017; Clark and Cao, 2017; Shen et al., 2017). (3) directly modifying the objective function to penalize generation probability of trivial responses (Li et al., 2016). However, these models merely discuss the latent vector, which is the vital link connecting the encoder and the decoder together.

Different from previous work, we analyse the problem of general response generation from the perspective of latent vectors. We notice that in the basic encoder-decoder model, what the decoder needs to generate a response is only a hidden vector. In other words, for the same decoder, latent vectors directly decide what will be generated. If latent vectors are clustered, the decoder is likely to generate similar responses. If latent vectors are dispersed, the decoder is likely to generate diverse responses. Based on the conjecture that dispersion of latent vectors has positive correlation with diversity of generated responses, encoder-decoder model's poor performance can be discussed in the two following situations:

- Suppose that the decoder is capable to generate different sentences given different latent vectors, model's unsatisfying performance of generating meaningless sentences should be imputed to the encoder—it tends to map whatever inputs to similar vectors. In this situation, to promote diversity in generation, the encoder should be encouraged to generate different latent vectors given different inputs.

- Suppose that the encoder is capable to generate different latent vectors with specific and concrete semantics given different inputs, model's unsatisfying performance of generating meaningless sentences should be imputed to the decoder—it is insensitive to latent vectors and tends to generate similar sentences given whatever latent vectors. In this situation, to promote diversity in generation, decoder's capacity for generating sentences should be enhanced.

During training, however, since there is no constraint on the latent vector's specificity, neither encoder's capacity for latent vector generation nor decoder's capacity for sentence generation can be guaranteed, which leads to poor performance in conversation generation.

For the above motivation, we propose a learning framework named MEMD (Multi-Encoder to Multi-Decoder). In proposed framework, an auxiliary encoder, which aims at guiding the major encoder to generate diverse latent vectors, and an auxiliary decoder, which aims at providing latent vectors with specific and concrete semantics for the major decoder to "practice" decoding, are introduced. During training, parameters of these two encoders and two decoders are updated. While in test, only the major encoder and the major decoder are employed.

In summary, our contributions are as follows:

- We present a new angle to tackle the problem of response diversity—the latent vectors generated by the encoder.

- We propose an easy-to-extend learning framework: MEMD, which introduces necessary training guidance for both encoder and decoder without resorting to extra data or complicating inner structure of networks.

- Experimental results demonstrate that MEMD effectively improves the quality of generated responses according to automatic metrics and human evaluations, yielding more diverse and smooth replies.

2 Technical Background

2.1 Gated Recurrent Unit (GRU)

GRU (Cho et al., 2014) is a special kind of RNN, which is widely used for learning long-term dependencies. It is defined as follows: given a sequence of inputs $(w_1, w_2, \ldots, w_N)$, GRU iterates each timestep with an update gate z_n and a reset gate r_n. Let h_n denote the vector of hidden layer computed by GRU at time n, σ denote the sigmoid function and $\odot$ denote the element-wise product. The vector

representation of hidden layer for each timestep n is given by:

$$z_n = \sigma(W_{zw}w_n + W_{zh}h_{n-1}) \quad (1)$$
$$r_n = \sigma(W_{rw}w_n + W_{rh}h_{n-1}) \quad (2)$$
$$\widetilde{h}_n = tanh(W_{hw}w_n + W_{hh}(r_t \odot h_{t-1})) \quad (3)$$
$$h_n = (1 - z_n)h_{n-1} + z_n\widetilde{h}_n \quad (4)$$

where W_{*w} is the transformation matrix from the input to GRU states, W_{*h} is the recurrent transformation matrix between the recurrent states h_n.

2.2 Encoder-decoder Models

In an encoder-decoder model, given a source sequence message $X = (x_1, x_2, \ldots, x_M)$ and a target sequence response $Y = (y_1, y_2, \ldots, y_N)$, the model would maximizes the generation probability of Y conditioned on X. While the encoder reads X word by word and represents it as a latent vector h_X through a recurrent neural network (RNN), the decoder estimates the generation probability of Y with h_X as initial state. The objective function of the model is as follows:

$$p(y_1, \ldots, y_N|x_1, \ldots, x_M) = p(y_1|X)\prod_{t=2}^{N} p(y_t|y_1, \ldots, y_{t-1}, X), \quad (5)$$

The latent vector h_X is calculated by

$$h_t = f(x_t, h_{t-1}) \quad (6)$$
$$h_X = h_M \quad (7)$$

where h_t is the hidden state at time t and f is a non-linear transformation which can be a gated recurrent unit (GRU). The decoder is a standard RNN language model except the addition of the context vector c. The probability distribution p_t of candidate words at each timestep t is calculated as

$$s_0 = h_X \quad (8)$$
$$s_t = f(y_{t-1}, s_{t-1}) \quad (9)$$
$$p_t = softmax(s_t) \quad (10)$$

where s_t is the hidden state of the decoder RNN at timestep t.

2.3 Attention Mechanism

The traditional sequence-to-sequence model assumes that each word is generated from the same context vector. However, in practice, different words in Y might be related to different words or phrases in X. In order to solve this problem, attention mechanism (Bahdanau et al., 2015; Cho et al., 2014) is introduced into this model. With attention, the context vector c_i corresponded to each y_i in Y is a weighted average of all hidden states of the encoder. Formally, c_i is defined as

$$c_i = \sum_{j=1}^{M} \alpha_{ij}h_j \quad (11)$$
$$\alpha_{ij} = \frac{exp(e_{ij})}{\sum_{k=1}^{M} exp(e_{ik})} \quad (12)$$
$$e_{ij} = \eta(s_{i-1}, h_j) \quad (13)$$

where η is a multi-layer perceptron (MLP).

3 Proposed Framework

The basic idea of MEMD is simple: we want the encoder to be able to generate different latent vectors given different inputs and the decoder to be able to generate sentence given a latent vector. We prevent the encoder from generating similar vectors by requiring that posts themselves should be reconstructed from the latent vectors, since if vectors are similar, they cannot be interpreted into diverse sentences by the same decoder. And for decoder, we strengthen its decoding ability by requiring it to reconstruct responses given vectors that really encode responses, since latent vectors' effectiveness cannot be guarantee when the encoder takes as input not responses but posts.

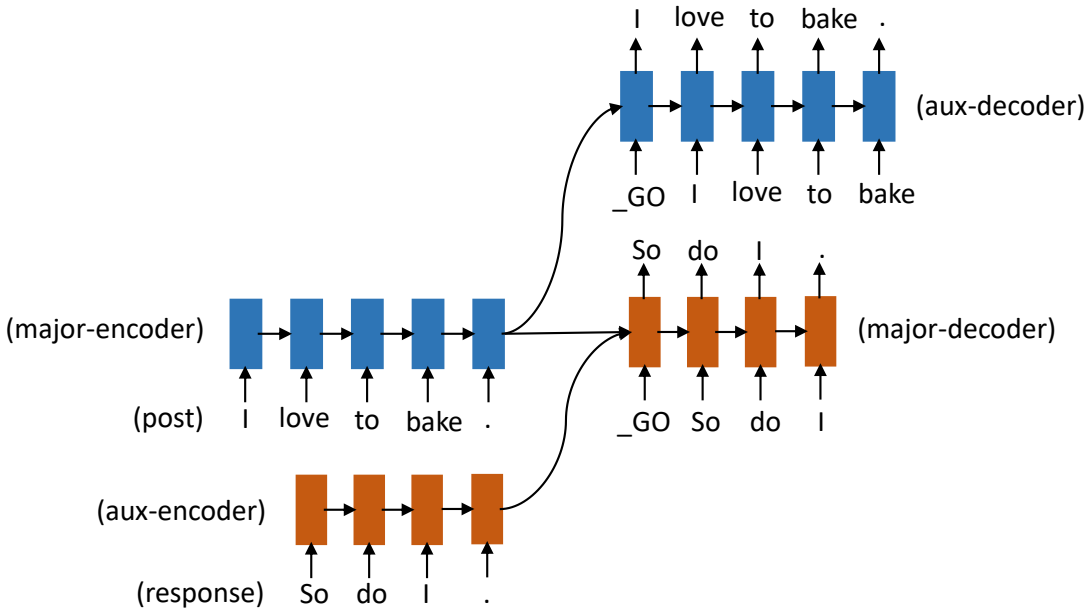

Figure 2: Architecture of MEMD. This framework contains four main components: 1) a major encoder, 2) a major decoder, 3) an auxiliary encoder, and 4) an auxiliary decoder. Three training paths are constructed: 1) from major-encoder to aux-decoder, 2) from major-encoder to major-decoder, and 3) from aux-encoder to major-decoder. Blue parts' inputs/targets are posts, while red parts' inputs/targets are responses.

3.1 Model Architecture

Suppose that short-text conversation consists of a post and a response, we denote a post of length M as $X = [x_1, \ldots, x_M]$ and a response of length N as $Y = [\_GO, y_1, \ldots, y_N]$ where $\_GO$ is a special symbol indicating the begin of a response. Each training example is a (post, response) pair, namely, (X, Y).

Figure 2 illustrates the architecture of MEMD, in which there are two encoders—major encoder (major-encoder) and auxiliary encoder (aux-encoder), and two decoders—major decoder (major-decoder) and auxiliary decoder (aux-decoder). These four components constitute three training paths: path 1 is from major-encoder to aux-decoder, path 2 is from major-encoder to major-decoder, and path 3 is from aux-encoder to major-decoder. Note that the major-encoder produces only one latent vector when fed one post, and the major-decoder receives only one latent vector per decoding procedure. In other words, the major-encoder is shared between path 1 and path 2, and the major-decoder is shared between the path 2 and path 3.

The major-encoder takes as input a post X, and returns its hidden state vector at the last step, i.e., h_M, as output. The aux-encoder has the same structure as the major-encoder, but takes as input the response Y. The output of the aux-encoder is also it's hidden state vector at the last step, i.e., $\hat{h}_N$. The major-decoder takes as input h_M or $\hat{h}_N$, and it's generation target is Y. When it takes h_M as input, it constitutes

a conventional encoder-decoder model with the major-encoder. When it takes $\hat{h}_N$ as input, it constitutes an auto-encoder with the aux-encoder. The aux-decoder has same structure as the major-decoder. It takes as input h_M, and its generation target is X.

3.2 Training Procedure

We first present the training objective along each path, and then give the whole training algorithm.

We denote the parameters of the major-encoder as θ_{ME}, and the parameters of aux-decoder as θ_{AD}. The training objective of path 1 (from the major-encoder to the aux-decoder) is:

$$\min_{\theta_{ME},\theta_{AD}} L_{ME-AD} = -\log p_1(X|X) \tag{14}$$

The parameters of the major-decoder are denoted as θ_{MD}. The training objective of path 2 (from the major-encoder to the major-decoder) is:

$$\min_{\theta_{ME},\theta_{MD}} L_{ME-MD} = -\log p_2(Y|X) \tag{15}$$

The parameters of the aux-encoder are denoted as θ_{AE}. The training objective of path 3 (from the aux-encoder to the major-decoder) is:

$$\min_{\theta_{AE},\theta_{MD}} L_{AE-MD} = -\log p_3(Y|Y) \tag{16}$$

The overall training objective is:

$$\min_{\theta_{ME},\theta_{AE},\theta_{MD},\theta_{AD}} L = L_{ME-AD} + L_{ME-MD} + L_{AE-MD} \tag{17}$$

In actual implementation, for the sake of flexibility and extendibility, we don't directly optimize Eq.(17) but interleave the optimization of Eq.(14), Eq.(15) and Eq.(16) at each iteration, which is inspired by the alternating training approach (Dong et al., 2015). Algorithm 1 summarizes the training procedure.

Algorithm 1 MEMD for short-text conversation

Input: Training data $\{(X, Y)_n\}$
Output: major-encoder, aux-encoder, major-decoder, aux-decoder

1: Initialize $\theta_{ME}, \theta_{AE}, \theta_{MD}, \theta_{AD}$
2: **repeat**
3: Train through path 1 by Eq.(14)
4: Train through path 2 by Eq.(15)
5: Train through path 3 by Eq.(16)
6: **until** convergence

3.3 Discussion

Our proposed framework MEMD is seemingly similar to the many-to-many setting in multi-task sequence-sequence learning (Luong et al., 2015). However, there are obvious distinctions between MEMD and multi-task sequence-sequence learning. MEMD aims at introducing constrains for encoder and decoder from the perspective of latent vectors, and does not require extra data for training. These introduced constrains are designed based on the characteristics of conversational response generation task. The many-to-many setting in multi-task sequence-sequence learning, however, aims at improving the generalization performance of the central task by resorting to training data of other related tasks.

4 Experiments

4.1 Dataset

We carry out experiment on an open-domain dialogue dataset: STC-weibo corpus developed by (Shang et al., 2015). STC-weibo corpus consists of millions of post-response pairs crawled from Weibo[1], which is popular Twitter-like microblogging service in China and has length limit of 140 Chinese characters on both posts and responses. We filter post-response pairs that include "alink" which represents a hyperlink, since we find that sentences are low-quality when "alink" appears. Besides, each post corresponds to 28 different responses at average. To minimize noise, we selected the response that contains the maximum number of frequent bigram in the whole corpus. After data cleaning, we finally get 199384 post-response pairs, and conduct the train/dev/test split of 197424/1000/960.

4.2 Baselines

We use the following models that needn't resort to extra data as our baselines for fair comparison:

Enc-Dec: the standard encoder-decoder model.

Enc-Dec-A: the standard encoder-decoder model with attention.

MMI: the best performing model in (Li et al., 2016).

For each baseline, there is a corresponding version of MEMD, whose major-encoder and major-decoder are the same to the baseline's encoder and decoder respectively. In other words, the baseline and its corresponding MEMD are structurally identical in test. Under this controlled setting we can validate the effectiveness of the proposed learning framework.

4.3 Implementation Details

We implement models in TensorFlow[2] and train them using Adam. The encoder is implemented as bidirectional GRU, and the decoder is implemented as multi-layer GRU (3 layers in Enc-Dec and Enc-Dec-A, 2 layers in MMI). The dimensions of hidden state are set to be 512 in Enc-Dec and Enc-Dec-A, and 256 in MMI. We use 100-dimension word embedding, and keep the size of vocabulary to be 60000. The word embedding is pretrained on the training set and updated during training. We set the learning rate to be 2×10^{-3} for path 2 and 3×10^{-4} for path 1 and path 3. And the batch size is set to be 48. We test the model on development data every 1000 mini-batches. When the model's performance on object function doesn't improve within 4 successive tests on development data, we view it convergent and stop training.

4.4 Evaluation metrics

Distinct-1 & distinct-2: Follow (Xing et al., 2017), we counted numbers of distinct unigrams and bigrams in the generated responses, and divide them by the total number of unigram and bigram respectively. The higher these two metrics are, the more informative and diverse the generated responses are.

Distinct-B & distinct-S: To measure the diversity of sentence pattern, we counted the number of distinct four words at the beginning of sentences, and divide them by the total number of generated sentences. We denote this metric as distinct-B. Moreover, we count the number of distinct sentence, and also calculate the ratio of distinct sentence to the total number of generated sentences. We denote this metric as distinct-S. The higher these two metrics are , the more diverse the generated responses are.

Sentence-level BLEU: Inspired by metrics used for evaluating machine translation, we use BLEU (Chen and Cherry, 2014) to evaluate the responses generated by different models.

Human annotation: Since automatic metrics may not consistently agree with human perception (Stent et al., 2005), we conduct human evaluation on 50 randomly sampled generated sentences. Three labelers with rich Weibo experience were invited to do evaluation. Responses generated by different models were pooled and randomly shuffled for each labeler. we adopt the criteria used in (Xing et al., 2017):

+2:The response is not only relevant and natural, but also informative and interesting.

[1]http://www.weibo.com/.

[2]https://www.tensorflow.org/

+1: The response can be used as a reply to the message, but it is too universal like “Yes, I see”, “Me too” and “I don’t know”.

0: The response cannot be used as a reply to the message. It is either semantically irrelevant or disfluent (e.g., with grammatical errors).

4.5 Results and Analysis

We investigate three strategies to initialize parameters of the major-encoder and the major-decoder. From Table 1 we can find that the way of initialization have a great influence on model's performance. When major-encoder and the major-decoder are pretained through path 1 and path 3 (advance-1&3), which in fact constitute two independent auto-encoders, the model tends to use the same words, and lacks variety on sentence pattern according to distinct-1, distinct-2, distinct-B and distinct-S. What's more, results of human annotation suggest that generated sentences are low-quality. When no pretraining is adopted, the model's diversity and generation quality are improved. When pretraining is conducted on path 2 (advance-2), which means the major-encoder and the major-decoder are initialized with a convergent Enc-Dec, the model gets significant improvement on diversity and generation quality. We notice that BLEU scores are somewhat incompatible to human annotation, here we put more priority on human annotation, and use BLEU scores as reference.

pretrain strategy	distinct-1	distinct-2	distinct-B	distinct-S	BLEU	+2	+1	0
advance-1&3	102/.010	308/.038	69/.072	388/.404	**0.569**	16%	54%	30%
no pretrain	172/.017	478/.059	154/.160	456/.475	0.536	26%	52%	22%
advance-2	**882/.086**	**2294/.276**	**547/.570**	**910/.948**	0.559	**40%**	36%	24%

Table 1: Results of MEMD on evaluation metrics. The first four columns are in the format of "the total number/proportion". Before employing algorithm 1, three strategies are adopted to initialize major-encoder's and major-decoder's parameters: 1) train them on path 1 and path 3 in advance. 2)no pretrain. 3)train them on path 2 in advance.

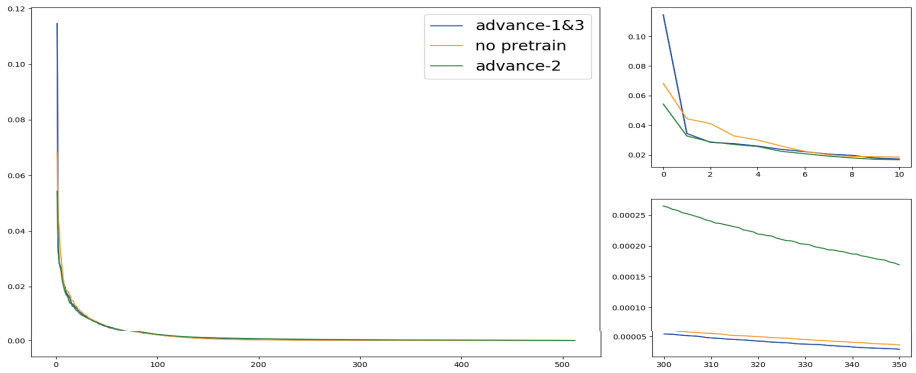

Figure 3: The left subfigure shows models' all 512 sorted PV under different pretraining strategies. The upper-right subfigure shows PV in the interval of 1 to 10, and the lower-right subfigure shows PV in the interval of 300 to 350.

Besides of evaluation metrics, we carry out analysis on latent vectors' distribution under different pretraining strategies. Since latent vectors under different pretraining strategies aren't in the same semantic space, direct comparison is infeasible. To tackle this problem, we utilize PCA (Principal Component Analysis) to get variances along each axes, which are represented by eigenvalues of covariance matrix subtracted the mean of each latent vectors. By dividing the eigenvalue by the sum of all eigenvalues, we get the percentage of variance (PV) explained by corresponding axis. If the variance of PV is large, which indicates variances are mainly distributed along a few axes, latent vectors are clustered. If the variance of

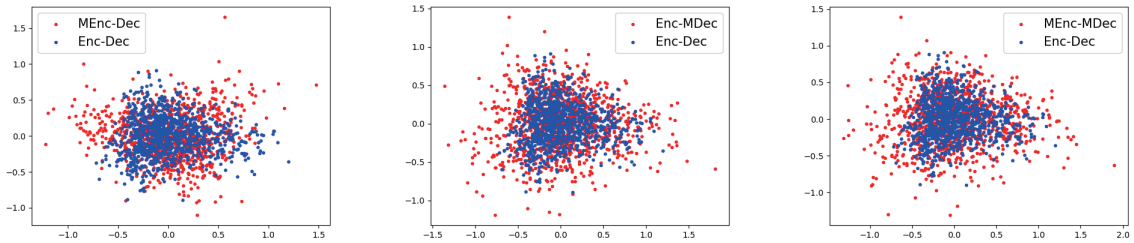
PV is small, which indicates they may have high variances along many axes, latent vectors are scattered. We use the variance of PV to indicate the dispersion of latent vectors. Models' sorted PV along all 512 axes are showed in Figure 3.

From Figure 3 we can clearly observe that the blue line has the largest value among three lines at the very beginning, then it drops down most sharply, and keeps small value later. This indicates that its most part of variances are occur on only a few axes, which means the latent vectors are clustered in the semantic space. The green line has the smallest value among three lines at the beginning and drops down most smoothly. This indicates its variances are distributed more evenly on all axes, so the latent vectors are more scattered in the whole semantic space. The PV variances of advance-1&3, no pretrain, and advance-2 are 4.251×10^{-5}, 3.142×10^{-5}, and 2.138×10^{-5} respectively, indicating that latent vectors of them are more scattered accordingly. The sorted PV distribution and variances of PV echo the results from Table 1.

To validate the effectiveness of the aux-encoder and the aux-encoder in the proposed MEMD, we designed two variations: 1) MEnc-Dec, which only has aux-encoder. 2)Enc-MDec, which only has aux-decoder. Together with MEMD, we get three models and train them with pretraining method of advance-2. The evaluation results are shown in Table 2. Both MEnc-Dec and Enc-MDec get higher scores on distinct-1, distinct-2, distinct-B, distinct-S, and human annotation comparing with Enc-Dec, which can prove that both aux-encoder and the aux-encoder do help promote diversity in response generation. The effectiveness of aux-decoder and aux-encoder support the two situations discussed in introduction. When compare Enc-MDec with MEnc-Dec, we find the latter brings greater promotion to the baseline on human annotation, which indicates that the aux-encoder plays important role in digesting the major decoder's ability to generate smooth sentences. When both aux-encoder and aux-decoder are adopted, MEMD's performance is further improved and gets best results on distinct-1, distinct-2, distinct-B， distinct-S, and human annotation.

	distinct-1	distinct-2	distinct-B	distinct-S	BLEU	+2	+1	0
Enc-Dec	148/.016	412/.055	145/.151	383/.399	0.555	18%	46%	36%
MEnc-Dec	796/.079	2125/.259	512/.533	870/.906	**0.568**	32%	42%	26%
Enc-MDec	730/.068	2133/.241	536/.558	877/.914	0.554	22%	50%	28%
MEMD	**882/.086**	**2294/.276**	**547/.570**	**910/.948**	0.559	**40%**	36%	24%

Table 2: Results of MEMD's variations on evaluation metrics. The first four columns are in the format of "the total number/proportion". Enc-Dec is the baseline, MEnc-Dec represents Enc-Dec with aux-encoder, and Enc-MDec represents Enc-Dec with aux-decoder.



(a) (b) (c)

Figure 4: Visualization of all latent vectors generated by Enc-Dec, Menc-Dec, Enc-MDec and MEnc-MDec in test.

We visualize two sets of all 960 latent vectors which are generated by Enc-Dec, MEnc-Dec, Dec-MDec and MEMD respectively in Figure 4. Note that the major-encoders and the major-decoders of MEnc-Dec, Dec-MDec and MEMD are initialized using Enc-Dec's parameters. We can clearly observe that after training under the MEMD framework, latent vectors become much scattered. Taking Figure 4

and Table 2 together, we find that dispersion of latent vectors has positive correlation with diversity of generated responses, which supports our conjecture.

	distinct-1	distinct-2	distinct-B	distinct-S	BLEU	+2	+1	0
Enc-Dec	148/.016	412/.055	145/.151	383/.399	0.555	18%	46%	36%
MEMD	**882/.086**	**2294/.276**	547/.570	**910/.948**	0.559	40%	36%	24%
Enc-Dec-A	310/.032	683/.088	162/.168	447/.466	**0.571**	20%	42%	38%
MEMD-A	822/.074	2157/.236	**550/.573**	873/.909	0.562	42%	36%	22%
MMI	345/.056	661/.157	317/.330	500/.521	0.440	32%	48%	20 %
MEMD-M	478/.073	820/.178	344/.358	572/.596	0.463	**46%**	32%	22%

Table 3: Results of baselines and their corresponding MEMD on evaluation metrics. The first four columns are in the format of "the total number/proportion".

To reveal the expansibility of the proposed learning framework, we apply MEMD to the other two baselines—Enc-Dec-A and MMI. From Table 3 we can see that MEMD-A has superior performance than Enc-Dec-A on distinct-1, distinct-2, distinct-B, distinct-S and human annotation, which indicates better diversity and quality of generated responses. MMI can produce smoother and more specific sentences than Enc-Dec and Enc-Dec-A, and MEMD-M gets better performance on distinct-1, distinct-2, distinct-B, distinct-S and human annotation than MMI. We also find that better performance on distinct-1, distinct-2, distinct-B, and distinct-S cannot guarantee better performance on human annotation, which can be explained as sentences contain varied words but have poor quality or are irrelevant to posts. Table 4 exhibits some examples. From Table 4 we can see that responses generated by Enc-Dec are general and lack pertinency to posts, while MEMD can catch some keywords in posts like "Hangzhou", "snow", and "talk". For Enc-Dec-A and MMI, they can sometimes generate natural responses, and based on them, MEMD-A and MEMD-M generate more informative and relevant responses.

5 Conclusion

In this paper, we view the generation diversity from a new angle: the latent vectors. Base on it, we propose an easy but effective learning framework named MEMD. In experiment, we found that the initialization method for the major-encoder and the major-decoder have great impact on the model's performance. Besides, we verify the effectiveness of the aux-encoder and the aux-decoder, and transfer the basic MEMD to MEMD-A and MEMD-M. We analyze the distribution of latent vectors, and find it consistent with evaluation metrics, which supports our conjecture that dispersion of latent vectors has positive correlation with diversity of generated responses.

Abstract

Although neural machine translation with the encoder-decoder framework has achieved great success recently, it still suffers drawbacks of forgetting distant information, which is an inherent disadvantage of recurrent neural network structure, and disregarding relationship between source words during encoding step. Whereas in practice, the former information and relationship are often useful in current step. We target on solving these problems and thus introduce relation networks to learn better representations of the source. The relation networks are able to facilitate memorization capability of recurrent neural network via associating source words with each other, this would also help retain their relationships. Then the source representations and all the relations are fed into the attention component together while decoding, with the main encoder-decoder framework unchanged. Experiments on several datasets show that our method can improve the translation performance significantly over the conventional encoder-decoder model and even outperform the approach involving supervised syntactic knowledge.

1 Introduction

In recent years, Neural Machine Translation (NMT) (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Bahdanau et al., 2015) has achieved great success in some language pairs, rivalling the state-of-the-art Statistical Machine Translation (SMT). The Recurrent Neural Network (RNN) encoder-decoder architecture is widely used framework for NMT, the principle behind which is that: encoding the meaning of the input bidirectionally into a concept space via RNNs and decoding into target words with RNNs based on this encoding (Sutskever et al., 2014; Bahdanau et al., 2015). This means that encoding principle leads to a deeper understanding and learning of the translation rules, and hence better translation than conventional SMT that considers only surface forms, e.g., words and phrases.

The RNNs with gating, such as Gated Recurrent Unit (GRU) (Cho et al., 2014) or Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997), are designed to memorize useful history information and meanwhile forget irrelative information. Together with attention technique which makes the decoding process only focus on the most related source words, the RNN encoder-decoder framework is expected to be able to handle long sequences and consider the globally related information. However, the practical situation is that RNNs tend to forget old history information, especially the far older one. Sometimes the older information is indispensable for generating proper translation, e.g., for the source sentence "take the heavy box away", when translating "away", "take" should be considered together. In addition, it has been proven that using phrases rather than words in SMT (Koehn et al., 2003) brings performance improvement, while in NMT the attention is only modeled in the unit of words. In the same sense, improvement is expected if attention is operated on more words rather than one.

Moreover, NMT produces the representation for the source by running through the source words sequentially with a bidirectional RNN (Schuster and Paliwal, 1997), so it only employs word order information and ignores the relation between words. Although some researchers have demonstrated that

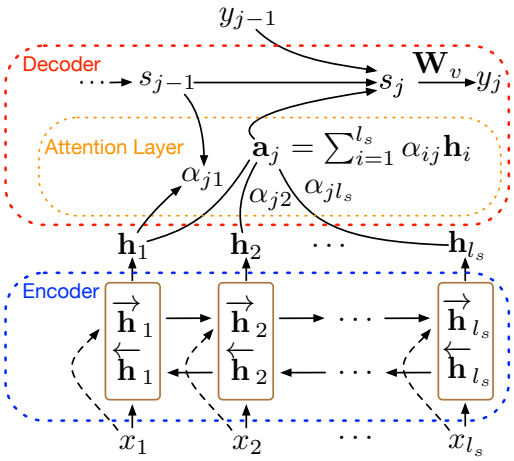

Figure 1: The architecture of attention-based NMT

NMT is able to capture certain syntactic phenomena (e.g. subject-verb agreement) without external syntactic information (Linzen et al., 2016; Shi et al., 2016), there are some other works which has shown their superior performance by modeling word relationship explicitly. However, these works usually need to introduce external syntactic knowledge or connect words according to their relations in the syntactic structure (Sennrich et al., 2016; Bastings et al., 2017; Aharoni and Goldberg, 2017; Li et al., 2017).

In this paper, we present a method to refine the NMT based on the above two points. The main idea is to learn relationship between the source word pairs. Corresponding to the first point, our method employs Convolutional Neural Networks (CNNs) to collect local information around one word and relates each word with its neighbors, which ensures the subsequent operations are performed in the unit of multiple words. As for the second point, Relation Network (RN) (Santoro et al., 2017) is introduced to establish pairwise relationship between words, meanwhile, there's no need to attain external input of syntactic knowledge. In this way, our model can memorize all words ahead and behind via additional connection between words no matter how distant they are. In the RNs, the representations of the source words produced by RNNs are taken as objects and the relationships between them are reasoned.

Specifically, our method introduces a RN component between the encoder and the attention layer in the RNN encoder-decoder framework (Sutskever et al., 2014; Bahdanau et al., 2015). The RN component is composed of three layers: first, the CNN layer slides window along the output of the encoder to capture information among multiple words around one word, then the graph propagation layer constructs a fully connected graph with the information of one window as one node and transfers messages along the edges, so that each node can collect the information from all other nodes, and last the multi-layer perceptron layer transforms the information of each node to the form which is suitable for the attention component to use. We performed experiments on several datasets and got significant improvements over vanilla NMT and SMT systems. Besides, our model significantly outperforms two other models, which introduced latent variables to capture the implicit semantics and employed explicitly external syntactic knowledge respectively.

2 Background

As the main idea of our method is to introduce relation networks into the attention-based NMT (Bahdanau et al., 2015) to learn word relationship and keep all source words in memory, in this section we will briefly describe the baseline model – the attention-based NMT first and the technique used in this paper – relation networks.

2.1 Attention-based NMT

The attention-based NMT follows the encoder-decoder framework, with an additional attention module. It works on the assumption that the source sentence and the target translation share a common continuous

space. It first encodes the source sentence into a continuous space and then performs decoding based on this space, meanwhile, employing attention to indicate the relevance of each source word to the current translation. Figure 1 shows the architecture of the attention-based NMT (Bahdanau et al., 2015), which is composed of three components: the encoder, the attention layer and the decoder.

The Encoder The encoder uses a pair of GRUs to run through source words bidirectionally to get two sequences of hidden states, which are concatenated to produce corresponding hidden state for the i-th source word

$$\overrightarrow{\mathbf{h}}_i = \overrightarrow{\mathbf{GRU}}\left(x_i, \overrightarrow{\mathbf{h}}_{i-1}\right); \qquad \overleftarrow{\mathbf{h}}_i = \overleftarrow{\mathbf{GRU}}\left(x_i, \overleftarrow{\mathbf{h}}_{i+1}\right); \qquad \mathbf{h}_i = \left[\overrightarrow{\mathbf{h}}_i; \overleftarrow{\mathbf{h}}_i\right] \tag{1}$$

The Attention Layer The attention layer aims to extract the source information (called attention) which is highly related to the generation of the current target word. To get the attention of the j-th decoding step, the correlation degree between current target word y_j and $\mathbf{h}_i$ is first evaluated as

$$e_{ij} = \mathbf{v}_a^T \tanh(\mathbf{W}_a \boldsymbol{s}_{j-1} + \mathbf{U}_a \mathbf{h}_i) \tag{2}$$

Then, for the j-th decoding step, the correlation degree is normalized over the whole source sequence, all source hidden states are added weightedly according to the normalized correlation degree to obtain the attention $\mathbf{a}_j$

$$\alpha_{ij} = \frac{\exp\left(e_{ij}\right)}{\sum_{i'=1}^{l_s} \exp\left(e_{i'j}\right)}; \qquad \mathbf{a}_j = \sum\nolimits_{i=1}^{l_s} \alpha_{ij} \mathbf{h}_i \tag{3}$$

The Decoder The decoder first employs a variant of GRU to roll the target information according to previous target word y_{j-1}, previous hidden state $\boldsymbol{s}_{j-1}$ and the attention $\mathbf{a}_j$. The details are described in Bahdanau et al. (2015). The current target hidden state $\boldsymbol{s}_j$ is calculated by

$$\boldsymbol{s}_j = g(y_{j-1}, \boldsymbol{s}_{j-1}, \mathbf{a}_j) \tag{4}$$

After that, the decoder gives a probability distribution over all the words in the target vocabulary and selects the target word with the highest probability as the output of the current step

$$p(y_j | \mathbf{y}_{<j}, \mathbf{x}) \propto \exp(f(\boldsymbol{s}_j, y_{j-1}, \mathbf{a}_j) \cdot \mathbf{W}_{\boldsymbol{v}}) \tag{5}$$

where f stands for a linear transformation and $\mathbf{W}_{\boldsymbol{v}}$ is a weight matrix.

2.2 Relation Networks

A relation network (RN) is a neural network with a structure integrated for relational reasoning. The RN is designed to constrain the functional form of a neural network so that it can capture the core common properties of relational reasoning. Hence its capability of computing relations is inherent without needing to be learned specially.

Formally, given a set of input "objects" denoted as $\mathrm{O} = \{o_1, o_2, \cdots, o_n\}$, RN can be formed as a composition function of objects (Santoro et al., 2017), represented as

$$\mathrm{RN}(\mathrm{O}) = f_\phi\left(\sum\nolimits_{i,j} g_\theta\left(o_i, o_j\right)\right) \tag{6}$$

where o_i is the i-th object, and f_ϕ and g_θ are functions used to calculate relations. Multi-layer perceptrons are often used for f_ϕ and g_θ, as their parameters are learnable synaptic weights, making RNs end-to-end differentiable. Here the role of g_θ is to infer how two objects are related, or whether they are related, and hence the output of g_θ can be treated as "relations".

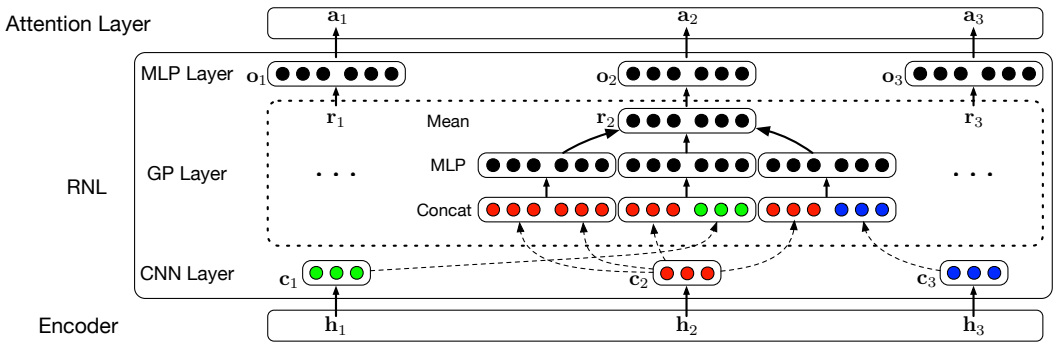

Figure 2: NMT with one RNL. Residual connection is not embodied here. The kernel width of the CNN layer is 3. We take the second word colored in red as an example to show the operations in the RNL, where three colors of green, red and blue indicate the information from the CNN layer of the first, second and third word, respectively.

3 NMT with Relation Networks

In this paper, we introduce a Relation Network Layer (denoted as RNL) on the basis of the attention-based NMT (Bahdanau et al., 2015) and frame it between the encoder and the attention layer. The RNL first employs CNNs to collect information in the unit of multi-words rather than one single word, then takes the outputs of CNNs as objects and makes them fully connected to build a graph propagation layer and associate with each other, finally transforms the acquired representations with word relations via MLP into the form suitable for the attention layer to use. Next, the outputs of the RNL are directly fed into the attention layer, so the RNL can still fit the encoder-decoder framework well. The architecture of our RNL is shown in Figure 2. Briefly, the RNL is composed of three components: the CNN layer, the Graph Propagation (GP) layer and the Multi-layer Perceptron (MLP) layer.

The CNN Layer CNNs are used to collect local information around one word. In this way, not only the information of a single word but their neighbors are considered. The number of neighbors to be considered depends on the kernel width k but can also vary by stacking several convolution layers, e.g., stacking 2 convolution layers with the kernel width $k = 3$ can collect information from 5 words at the same time.

In the CNN layer, the input is the hidden states produced by the bidirectional GRUs (Bi-GRUs), denoted as $\mathbf{h} = \{\mathbf{h}_1, ..., \mathbf{h}_i, ..., \mathbf{h}_{l_s}\}$, so each source word is represented by its hidden state. A filter is applied to convolute over a window of k words to get the convolutional representation. Given the i-th source word and its hidden state $\mathbf{h}_i \in \mathbb{R}^d$, the hidden states covered by the window with the width of k are concatenated and then are fed to the filter where we denote the concatenated vector as $\mathbf{h}_i^k = \left[\mathbf{h}_{i-\lfloor(k-1)/2\rfloor}; \cdots; \mathbf{h}_i; \cdots; \mathbf{h}_{i+\lfloor(k-1)/2\rfloor}\right]$. For the first and last $\lfloor(k-1)/2\rfloor$ words of a sentence, the hidden state $\mathbf{h}_i$ with $i < 1$ or $i > l_s$ are set to zeros (padding). Then the filtering process mentioned above can be formed as

$$\mathbf{c}_i = f\left(\mathbf{W}_{cnn}\mathbf{h}_i^k + \mathbf{b}_{cnn}\right) \tag{7}$$

$\mathbf{W}_{cnn} \in \mathbb{R}^{k\times d}$ is the convolution weights and $\mathbf{b}_{cnn}$ is the bias, where the two together define a linear operation. f is the leaky RELU with the coefficient 0.1 to control the angle of the negative slope. In the RNL, leaky RELU is used as all the nonlinear activation functions. The output of the CNN layer is $\mathbf{c} = \{\mathbf{c}_1, ..., \mathbf{c}_i, ..., \mathbf{c}_{l_s}\}$.

The GP Layer The GP layer is used to learn the relationships between source words. It adopts the outputs of the CNN layer $\mathbf{c} = \{\mathbf{c}_1, \mathbf{c}_2, ..., \mathbf{c}_{l_s}\}$ as input and formulates the relationships between them into a graph. Here $\mathbf{c}_i$ can be thought as the object mentioned in Section 2.2. In this graph, each input $\mathbf{c}_i$ is taken as a node and has edges connected to all other nodes. Then information flows along the edges and each node receives messages from all its direct neighbors. We call this process graph propagation.

After graph propagation process, another sequence of vectors $\{\mathbf{r}_1, \mathbf{r}_2, ..., \mathbf{r}_{l_s}\}$ is produced. The generation of $\mathbf{r}_i$ can be decomposed into three steps:

- Each input vector $\mathbf{c}_i$ in $\mathbf{c}$ is concatenated with all vectors in $\mathbf{c}$ (including itself) to get a set of vectors $\mathbf{C}_i = \{\mathbf{c}_{i1}, \cdots \mathbf{c}_{ij}, \cdots, \mathbf{c}_{il_s}\}$ where $\mathbf{c}_{ij} = [\mathbf{c}_i; \mathbf{c}_j]$.
- Each $\mathbf{c}_{ij}$ is converted into vector $\mathbf{r}_{ij}$ by a 4-hidden-layers MLP. The conversion with 1-hidden-layer MLP can be represented as
$$\mathbf{r}_{ij} = f\left(\mathbf{W}_{gp}\mathbf{c}_{ij} + \mathbf{b}_{gp}\right) \tag{8}$$
- Average over all the outputs above to get the final representation for the i-th source word
$$\mathbf{r}_i = \frac{1}{l_s}\sum\nolimits_{j=1}^{l_s} \mathbf{r}_{ij} \tag{9}$$

The MLP Layer There are several nonlinear transformations which map the inputs into different vector spaces in the GP layer. In order to reduce computation complexity, the output features size of the nonlinear transformations is set to small. Hence we use another MLP layer to map the feature back into the original space, usually the same as that of $\mathbf{h}_i$ to have more powerful representation. The final state $\mathbf{o}_i$ for the i-th source word after the entire RN layer can be got by another 2-hidden-layers MLP, 1-hidden-layer MLP can be written as

$$\mathbf{o}_i = f(\mathbf{W}_{mlp}\mathbf{r}_i + \mathbf{b}_{mlp}) \tag{10}$$

Residual Stacking technique is used in our method. Concretely, we stack multiple layers inside the encoder and meanwhile apply residual connection for two adjacent layers. Assume h^l_{in} and h^l_{out} are the input and the output of the l-th layer, respectively, then residual connection is conducted to get the final output of the l-th layer in the following two steps. First, the input and the output of the l-th layer are added together:

$$\mathrm{h}^l = \mathrm{h}^l_{in} + \mathrm{h}^l_{out} \tag{11}$$

Next, dense concatenation (Huang et al., 2017) is employed to receives features from all previous layers and the final output of the l-th layer is produced by

$$\mathrm{h}^l_{dc} = \mathbf{W}_{dc}\left[\mathrm{h}^1; \mathrm{h}^2; \cdots; \mathrm{h}^l\right] + \mathbf{b}_{dc} \tag{12}$$

where weight matrix $\mathbf{W}_{dc}$ and bias $\mathbf{b}_{dc}$ are adjusted to map the dense-concatenated vectors into the same feature space as the input. Then h^l_{dc} is fed to the next layer which means $\mathrm{h}^{l+1}_{in} = \mathrm{h}^l_{dc}$.

4 Related Work

Many researchers have worked on learning the relationships of the source words to improve translation performance. One line is to refine source presentations by adding relationships between source words or between source and target words, with the main architecture remaining the RNN encoder-decoder framework. Sennrich et al. (2016) enriched source representations with POS tags, dependency labels and other linguistic features. Bastings et al. (2017) employed graph convolutional networks to model relations of words in dependency trees for the source embeddings to include these relations. These two models both require extra supervised syntax input while our method does not need external knowledge and learn the relationship by its own.

Another line is to change the structure of the neural network. Gehring et al. (2017a) and Gehring et al. (2017b) proposed to substitute the conventional RNN encoder with the CNN encoder in order to train faster. They employed stacked CNNs to capture relationships between source words which can be calculated simultaneously, not like RNNs, the computation of which is constrained by temporal dependencies. The attention scores are also computed based on the output of the CNNs and the decoder is still the RNN-based decoder. Vaswani et al. (2017) is another work to eschew the recurrence. It instead

relied entirely on the attention mechanism to draw the global dependencies between input and output. Su et al. (2018) introduced latent random variables into the decoder of NMT and generated these variables recurrently to capture the global semantic contexts and model strong and complex dependencies among target words at different timesteps.

Our method still follows the RNN encoder-decoder framework, giving full play to the advantages of RNNs, which transfers information through words bidirectionally. In addition, we also employs RNs in our method to connect the source words explicitly, further captures relationships between source words without any external knowledge injection, which enables the model to learn the relationships itself and facilitates easy application.

5 Experiments

In the experiment section, we first compare our system with two baseline systems on a Chinese-English (Zh-En) dataset and the WMT17 English-German (En-De) dataset, then compare our method with a related approach on the WMT16 En-De dataset. Finally, we give some analyses about our method in different aspects.

5.1 Data Preparation

We performed experiments on three datasets:

NIST The training data consisted of 1.25M Zh-En parallel sentence pairs with 25M Chinese tokens and 27M English tokens[1]. We used NIST 2002 test dataset (878 sentences) as the validation set, and another four NIST test datasets as the test datasets: NIST 2003 (MT03), NIST 2004 (MT04), NIST 2005 (MT05) and NIST 2006 (MT06), which contain 919, 1788, 1082 and 1357 sentences respectively.

WMT17 The training data was composed of 5.6M En-De preprocessed parallel sentence pairs [2] with 141M English tokens and 194M German tokens. The test dataset of newstest2014 (3003 sentences) was used as the validation set and the following test datasets were used as the test datasets: newstest2015 (2169 sentences), newstest2016 (2999 sentences) and newstest2017 (3004 sentences). Besides, $8k$ merging operations were performed to learn byte-pair encodings (BPE) (Sennrich et al., 2016) on the target side of the parallel training data.

WMT16 We conducted experiments on WMT16 dataset, the same dataset as the work of Bastings et al. (2017) for comparison. We kept the same settings as those in Bastings et al. (2017): The original dataset consists of 4500966 sentence pairs, with 4173550 left after filtering pairs which contains more than 50 tokens on either side after tokenization. newstest2015 and newstest2016 were used as the validation set and test dataset, respectively. $16k$ BPE merging operations were conducted on the target side of the bilingual training data.

For WMT16 dataset, case-sensitive 4-gram BLEU score (Papineni et al., 2002) was reported by using the *multi-bleu.pl* script. The results on the other two datasets were evaluated with case-insensitive 4-gram BLEU score.

5.2 Systems

Results of five systems on different datasets were reported:

RNNsearch We implemented the attention-based NMT of Bahdanau et al. (2015) by PyTorch framework[3] with the following settings: the length of the sentences on both sides was limited up to 50 tokens with 30K vocabulary, and the source and target word embedding sizes were both set to 512, the size of all hidden units in both encoder and decoder RNNs was also set to 512, and all parameters were initialized by using uniform distribution over $[-0.1, 0.1]$. The mini-batch stochastic gradient descent (SGD) algorithm was employed to train the model with batch size of 80. In addition, the learning rate was adjusted by Adadelta optimizer (Zeiler, 2012) with $\rho = 0.95$ and $\epsilon = 1e$-6. Dropout was applied on the output layer with dropout rate of 0.5. The beam size was set to 10.

[1]We chose LDC2002E18, LDC2003E07, LDC2003E14, Hansard's portion of LDC2004T07, LDC2004T08 and LDC2005T06 from the LDC corpora. There were 1.11M sentence pairs left after filtering.

Systems	test16
BiRNN+GCN	23.9
RNMT	**25.4**

Table 3: Performance comparison with the related work on the WMT16 En-De dataset.

RNNsearch* This system is an improved version of RNNsearch where the decoder employs a conditional GRU layer with attention module, consisting of two GRUs and an attention module for each step[4]. Specifically, Equation 4 is substituted with the following two equations:

$$\tilde{\boldsymbol{s}}_j = \mathbf{GRU}_1(y_{j-1}, \boldsymbol{s}_{j-1}); \qquad \boldsymbol{s}_j = \mathbf{GRU}_2(\mathbf{a}_j, \tilde{\boldsymbol{s}}_j) \tag{13}$$

Besides, for the calculation of attention in Equation 2, $\boldsymbol{s}_{j-1}$ is replaced with $\tilde{\boldsymbol{s}}_{j-1}$. The other components of the system keep the same as RNNsearch. We used the same settings for RNNsearch and RNNsearch*.

VRNMT A novel Variational Recurrent NMT (VRNMT) model, proposed by Su et al. (2018), captures more semantic context and complex dependencies among target words by generating latent random variables recurrently in the NMT decoder.

BiRNN+GCN This is the model presented by Bastings et al. (2017). They incorporated dependency syntactic structure into the bidirectional RNN (BiRNN) encoder of NMT and modeled the relation among the source words by using graph convolutional networks (GCNs).

RNMT Our system was implemented by embedding the RNLs into the Bi-GRUs of RNNsearch*. The overall structure used alternatively stacked GRUs and RNLs, in which the two GRU layers are in opposite direction. Inside the RNL, the GP layer employed a 4-hidden-layers MLP (shown in Equation 8) and the MLP layer contained 2 hidden layers (as in Equation 10). For the Zh-En translation task, two convolution layers with kernel width of 1 and 3 were stacked, the output channel sizes of CNN were 128 and 256 respectively, followed by batch normalization (BN) (Ioffe and Szegedy, 2015) with learnable parameters, and MLP contained 256 units. For the En-De translation task, only one convolution layer was used with kernel width of 3, the output channel size was 96, 128 was adopted as the hidden size of MLP. All of the other settings were the same with those of RNNsearch*.

5.3 Performance Comparison

We compared our system RNMT with the two baseline systems RNNsearch and RNNsearch* both on the NIST Zh-En and the WMT17 En-De translation tasks. As RNMT was implemented on the basis of RNNsearch*, in the strict sense, RNNsearch* is the baseline. From the results shown in Table 1, we can see that RNMT significantly improves translation quality on all test datasets and outperforms RNNsearch* by 1.48 BLEU points averagely on the Zh-En dataset. Besides, comparison between our model to VRNMT shows that proposed simple model stably produces better performance on all test datasets and outperforms VRNMT 1.04 BLEU score on average.

[4] https://github.com/nyu-dl/dl4mt-tutorial/blob/master/docs/cgru.pdf

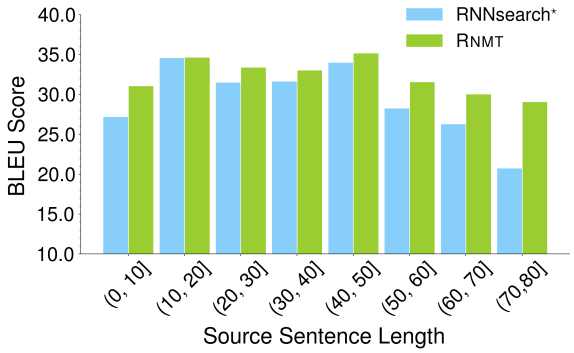

Figure 3: Results on different bins contain sentences of length within corresponding spans.

On the WMT17 En-De dataset, as shown in Table 2, RNMT shows superiority on three test datasets stably, and averagely achieves the gains of 1.7 BLEU points over RNNsearch*, with only 4.1M parameters more. Given the above results, we can conclude that RN can indeed learn the relationships between the source words and these relationships are useful and bring improvement on the translation performance.

We also compared our method with the work of Bastings et al. (2017) which requires the injection of external syntactic knowledge, to see whether the relationships produced by RNs can lead to better translation than the syntax from supervised learning. The results in Table 3 show that our system can achieve an improvement of 1.5 BLEU scores. We believe that the relationships of the source words derived from RNs do not necessarily conform to human cognition, but it can be simultaneously tailored with the other parts of the translation system. In this way, RNs can generate the relationships more suitable for the NMT.

5.4 Impact of Input Length

One motivation of adding RNs is that RNNs tend to forget the distant history which RNs memorize it by explicitly introducing relations between pairs of words. Therefore, we assume that our method suppose to bring greater improvement on relative long sentences, which contains more distant history information than shorter ones that usually forgotten by RNNs. Based on this sense, we split the source sentences in the MT03 test dataset into different bins according to their length and evaluated BLEU scores of the translations from RNNsearch* and RNMT on the different bins, respectively.

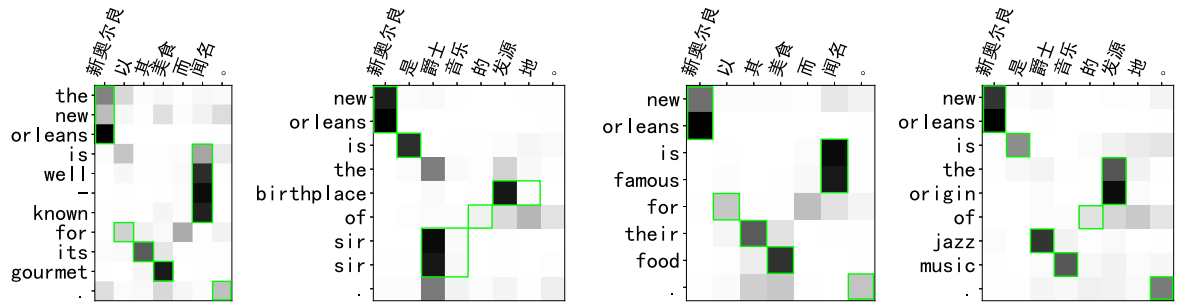
The results are shown in Figure 3. In the bins holding sentences no longer than 50, the BLEU scores of the two systems are close to each other. When the sentence length surpasses 50, RNMT shows its superiority over RNNsearch*. As the sentence length grows, the difference becomes increasingly large. This verifies the deduce that our method can not only memorize history information but capture the relationship between words, both of which are beneficial to translate long sentences.

5.5 Word Alignment

Systems	BLEU	AER
RNNsearch*	22.40	46.76
RNMT	**24.12**	**45.66**

Table 4: Comparison of alignment quality on NIST Zh-En translation task.

In this section, we will verify the translation performance of our model from another perspective. Intuitively, the better translation should have better alignment to the source sentence, so we evaluated the quality of the alignments derived from the attention module of the NMT using Alignment Error Rate (AER) (Och, 2003). We did this experiment on the artificially aligned dataset from Liu and Sun (2015) which contains 900 Zh-En sentence pairs. The alignments were got in this way for both RNNsearch*



(a) RNNsearch* (b) RNMT

Figure 4: Word alignment comparison. The green boxes show the manual golden alignments.

system and our system. When one target word was generated, we retained the alignment link with the highest probability α_{ij} in Equation 3.

The comparison results are shown in Table 4. It illustrates that our system RNMT can produce better translations than the baseline RNNsearch*, a difference of 1.72 BLEU points. Besides, the AER score is 1.1 points lower than the baseline model. Note that the smaller the AER score, the better the alignment quality.

Along with the translation results, we also produce the word alignment matrix based on each target word's attention probability distribution over the whole source sentence. Two source sentences are randomly sampled from websites, both comparisons between baseline alignment and improved alignment generated by RNNsearch* and RNMT are shown in Figure 4.

For the first example, from the view of source side, it is obviously unreasonable that the Chinese word *yi* is contributed to generate three discontinuous English words *the*, *is* and *for*, grammatical knowledge show that the word *yi* should be only aligned to the English word *for*, just like the result of our model. Besides, on the target's ground, if one Chinese word is translated into an English phrase, all words in the phrase should be aligned to the Chinese word, RNNsearch* model improperly aligns *new* and *is* to some other irrelevant words besides the correct one. When generating word *is*, almost the whole source sentence should be considered, our model gets more centralized alignment for it.

In the second case, unlike the baseline model, our model produces correct translation *jazz music* for *jueshi yinyue* and alignment. *the* together with *origin* is aligned to the source word *fayuan*, while RNNsearch* mistakenly aligns *the* to two source words almost with equal probability.

5.6 Translation Examples

As shown in Table 5, we give two example translations generated from baseline model and proposed model. Comparing the translation results between two systems, we can observe that RNNsearch* often miss some information of the source sentence, especially for the long sentence. Both of the sentences are complex sentences with long dependent adversative relation, for the first example, the baseline model forgets the information of the long distance clause about *women jinnian yizhi* $\cdots$ *toumingdu* and ignores to translate the second clause. It similarly happens that, when producing the target text for the second sample, RNNsearch* loses the information after *chengnuo dongaohui* and fails to capture the latter clause with adversative relation. In addition, another phenomenon observed is that the longer the source sentence is, it is easier to ignore important information for RNNsearch*. However, as can be seen from the boldfaced sections marked in results generated with RNMT, proposed model with CNN could captures more source information successfully.

Specifically, RNNs are skilled in modeling the order information of a sequence, while CNNs mainly focus on local features around some specific word. Both of them are weak to capture the long-distance dependency information, However, facts prove that proposed relation layer succeeds in alleviating the deficiencies of the two by integrating CNNs with bidirectional RNNs subtly.

6 Conclusion

As RNNs are not good at remembering the old history and cannot consider word relationship either, sometimes conventional NMT cannot get enough source information and hence emphasizes too much on the fluency of the target. As a result, it suffers from meaning-drift and generates “inaccurate” translation. Even so, NMT can still benefit from the recurrence of RNNs. In this paper, we propose to incorporate RNLs into the attentional NMT. The RNs employs CNNs to collect information around one word and explicitly connect each word with all the other words. In this way, it provides the opportunities for NMT to capture relationship between source words and hence leads to a better source representation. Our method can get better translation on the NIST Zh-En dataset and the WMT En-De dataset and can even outperform the system with supervised syntactic knowledge.

Abstract

Neural machine translation (NMT) is a deep learning based approach for machine translation, which yields the state-of-the-art translation performance in scenarios where large-scale parallel corpora are available. Although the high-quality and domain-specific translation is crucial in the real world, domain-specific corpora are usually scarce or nonexistent, and thus vanilla NMT performs poorly in such scenarios. Domain adaptation that leverages both out-of-domain parallel corpora as well as monolingual corpora for in-domain translation, is very important for domain-specific translation. In this paper, we give a comprehensive survey of the state-of-the-art domain adaptation techniques for NMT.

1 Introduction

Neural machine translation (NMT) (Cho et al., 2014; Sutskever et al., 2014; Bahdanau et al., 2015) allows for end-to-end training of a translation system without the need to deal with word alignments, translation rules and complicated decoding algorithms, which are characteristics of statistical machine translation (SMT) systems (Koehn et al., 2007). NMT yields the state-of-the-art translation performance in resource rich scenarios (Bojar et al., 2017; Nakazawa et al., 2017). However, currently, high quality parallel corpora of sufficient size are only available for a few language pairs such as languages paired with English and several European language pairs. Furthermore, for each language pair the sizes of the domain specific corpora and the number of domains available are limited. As such, for the majority of language pairs and domains, only few or no parallel corpora are available. It has been known that both vanilla SMT and NMT perform poorly for domain specific translation in low resource scenarios (Duh et al., 2013; Sennrich et al., 2013; Zoph et al., 2016; Koehn and Knowles, 2017).

High quality domain specific machine translation (MT) systems are in high demand whereas general purpose MT has limited applications. In addition, general purpose translation systems usually perform poorly and hence it is important to develop translation systems for specific domains (Koehn and Knowles, 2017). Leveraging out-of-domain parallel corpora and in-domain monolingual corpora to improve in-domain translation is known as domain adaptation for MT (Wang et al., 2016; Chu et al., 2018). For example, the Chinese-English patent domain parallel corpus has 1M sentence pairs (Goto et al., 2013), but for the spoken language domain parallel corpus there are only 200k sentences available (Cettolo et al., 2015). MT typically performs poorly in a resource poor or domain mismatching scenario and thus it is important to leverage the spoken language domain data with the patent domain data (Chu et al., 2017). Furthermore, there are monolingual corpora containing millions of sentences for the spoken language domain, which can also be leveraged (Sennrich et al., 2016b).

There are many studies of domain adaptation for SMT, which can be mainly divided into two categories: data centric and model centric. Data centric methods focus on either selecting training data from out-of-domain parallel corpora based a language model (LM) (Moore and Lewis, 2010; Axelrod et al., 2011; Duh et al., 2013; Hoang and Sima'an, 2014; Durrani et al., 2015; Chen et al., 2016) or generating pseudo parallel data (Utiyama and Isahara, 2003; Wang et al., 2014; Chu, 2015; Wang et al.,

Proceedings of the 27th International Conference on Computational Linguistics, pages 1304–1319
Santa Fe, New Mexico, USA, August 20-26, 2018.

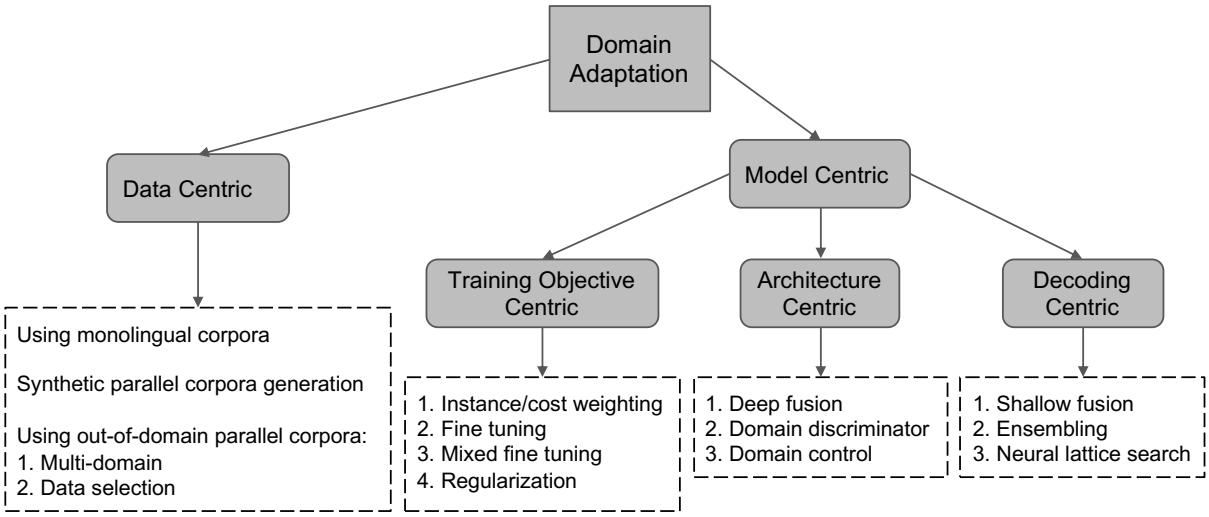

Figure 1: Overview of domain adaptation for NMT.

2016; Marie and Fujita, 2017). Model centric methods interpolate in-domain and out-of-domain models in either a model level (Sennrich et al., 2013; Durrani et al., 2015; Imamura and Sumita, 2016) or an instance level (Matsoukas et al., 2009; Foster et al., 2010; Shah et al., 2010; Rousseau et al., 2011; Zhou et al., 2015). However, due to the different characteristics of SMT and NMT, many methods developed for SMT cannot be applied to NMT directly.

Domain adaptation for NMT is rather new and has attracted plenty of attention in the research community. In the past two years, NMT has become the most popular MT approach and many domain adaptation techniques have been proposed and evaluated for NMT. These studies either borrow ideas from previous SMT studies and apply these ideas for NMT, or develop unique methods for NMT. Despite the rapid development in domain adaptation for NMT, there is no single compilation that summarizes and categorizes all approaches. As such a study will greatly benefit the community, we present in this paper a survey of all prominent domain adaptation techniques for NMT. There are survey papers for NMT (Neubig, 2017; Koehn, 2017); however, they focus on general NMT and more diverse topics. Domain adaptation surveys have been done in the perspective of computer vision (Csurka, 2017) and machine learning (Pan and Yang, 2010; Weiss et al., 2016). However, such survey has not been done for NMT. To the best of our knowledge, this is the first comprehensive survey of domain adaptation for NMT.

In this paper, similar to SMT, we categorize domain adaptation for NMT into two main categories: data centric and model centric. The data centric category focuses on the data being used rather than specialized models for domain adaptation. The data used can be either in-domain monolingual corpora (Zhang and Zong, 2016b; Cheng et al., 2016; Currey et al., 2017; Domhan and Hieber, 2017), synthetic corpora (Sennrich et al., 2016b; Zhang and Zong, 2016b; Park et al., 2017), or parallel copora (Chu et al., 2017; Sajjad et al., 2017; Britz et al., 2017; Wang et al., 2017a; van der Wees et al., 2017). On the other hand, the model centric category focuses on NMT models that are specialized for domain adaptation, which can be either the training objective (Luong and Manning, 2015; Sennrich et al., 2016b; Servan et al., 2016; Freitag and Al-Onaizan, 2016; Wang et al., 2017b; Chen et al., 2017a; Varga, 2017; Dakwale and Monz, 2017; Chu et al., 2017; Miceli Barone et al., 2017), the NMT architecture (Kobus et al., 2016; Gülçehre et al., 2015; Britz et al., 2017) or the decoding algorithm (Gülçehre et al., 2015; Dakwale and Monz, 2017; Khayrallah et al., 2017). An overview of these two categories is shown in Figure 1. Note that as model centric methods also use either monolingual or parallel corpora, there are overlaps between these two categories.

The remainder of this paper is structured as follows: We first give a brief introduction of NMT, and describe the reason for the difficulty of low resource domains and languages in NMT (Section 2); Next, we briefly review the historical domain adaptation techniques being developed for SMT (Section 3); Under these background knowledge, we then present and compare the domain adaptation methods for

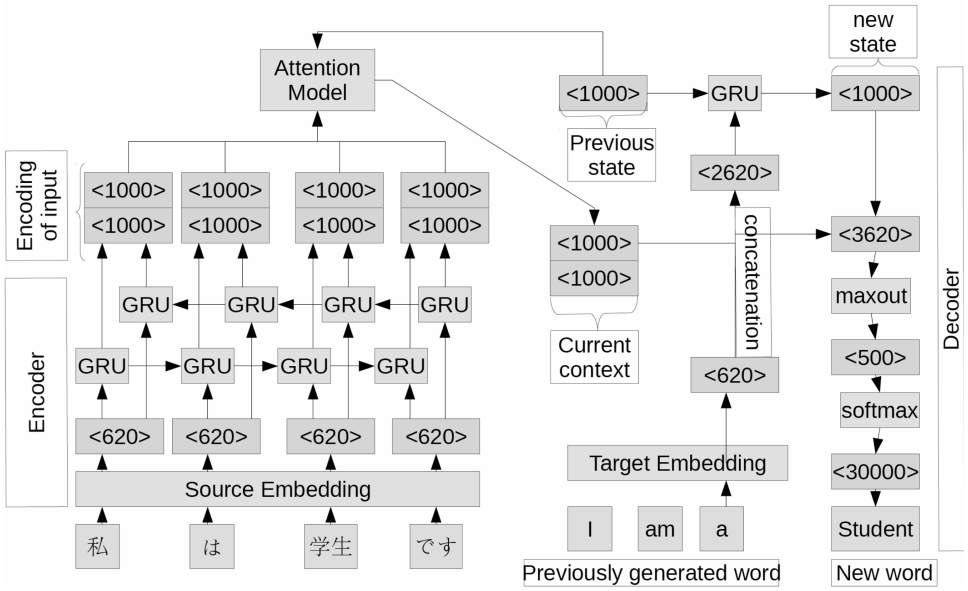

Figure 2: The architecture of the NMT system with attention, as described in (Bahdanau et al., 2015). The notation "<1000>" means a vector of size 1000. The vector sizes shown here are the ones suggested in the original paper.

NMT in detail (Section 4); After that, we introduce domain adaptation for NMT in real word scenarios, which is crucial for the practical use of MT (Section 5); Finally, we give our opinions of future research directions in this field (Section 6) and conclude this paper (Section 7).

2 Neural Machine Translation

NMT is an end-to-end approach for translating from one language to another, which relies on deep learning to train a translation model (Cho et al., 2014; Sutskever et al., 2014; Bahdanau et al., 2015). The encoder-decoder model with attention (Bahdanau et al., 2015) is the most commonly used NMT architecture. This model is also known as RNNsearch. Figure 2 describes the RNNsearch model (Bahdanau et al., 2015), which takes in an input sentence $\mathbf{x} = \{x_1, ..., x_n\}$ and its translation $\mathbf{y} = \{y_1, ..., y_m\}$. The translation is generated as:

$$p(\mathbf{y}|\mathbf{x};\theta) = \prod_{j=1}^{m} p(y_j|y_{<j}, \mathbf{x};\theta), \tag{1}$$

where θ is a set of parameters, m is the entire number of words in $\mathbf{y}$, y_j is the current predicted word, and $y_{<j}$ are the previously predicted words. Suppose we have a parallel corpus C consisting of a set of parallel sentence pairs $(\mathbf{x}, \mathbf{y})$. The training object is to minimize the cross-entropy loss L w.r.t θ:

$$L_\theta = \sum_{(\mathbf{x},\mathbf{y})\in\mathbf{C}} -\log p(\mathbf{y}|\mathbf{x};\theta). \tag{2}$$

The model consists of three main parts, namely, the encoder, decoder and attention model. The encoder uses an embedding mechanism to convert words into their continuous space representations. These embeddings by themselves do not contain information about relationships between words and their positions in the sentence. Using a recurrent neural network (RNN) layer, gated recurrent unit (GRU) in this case, this can be accomplished. An RNN maintains a hidden state (also called a memory or history), which allows it to generate a continuous space representation for a word given all past words that have been seen. There are two GRU layers which encode forward and backward information. Each word x_i is represented by concatenating the forward hidden state $\overrightarrow{h_i}$ and the backward one $\overleftarrow{h_i}$ as $h_i = [\overrightarrow{h_i}; \overleftarrow{h_i}]$. In this way, the source sentence $\mathbf{x} = \{x_1, ..., x_n\}$ can be represented as $\mathbf{h} = \{h_1, ..., h_n\}$. By using both

forward and backward recurrent information, one obtains a continuous space representation for a word given all words before as well as after it.

The decoder is conceptually an RNN language model (RNNLM) with its own embedding mechanism, a GRU layer to remember previously generated words and a softmax layer to predict a target word. The encoder and decoder are coupled by using an attention mechanism, which computes a weighted average of the recurrent representations generated by the encoder thereby acting as a soft alignment mechanism. This weighted averaged vector, also known as the context or attention vector, is fed to the decoder GRU along with the previously predicted word to produce a representation that is passed to the softmax layer to predict the next word. In equation, an RNN hidden state s_j for time j of the decoder is computed by:

$$s_j = f(s_{j-1}, y_{j-1}, c_j), \tag{3}$$

where f is an activation function of GRU, s_{j-1} is the prvious RNN hidden state, y_{j-1} is the previous word, c_j is the context vector. c_j is computed as a weighted sum of the encoder hidden states $\mathbf{h} = \{h_1, ..., h_n\}$, by using alignment weight a_{ji}:

$$c_j = \sum_{j=1}^{n} a_{ji} h_i, \quad a_{ji} = \frac{\exp(e_{ji})}{\sum_{k=1}^{m} \exp(e_{ki})}, \quad e_{ji} = a(s_{j-1}, h_i), \tag{4}$$

where a is an alignment model that scores the match level of the inputs around position i and the output at position j. The softmax layer contains a maxout layer which is a feedforward layer with max pooling. The maxout layer takes the recurrent hidden state generated by the decoder GRU, the previous word and the context vector to compute a final representation, which is fed to a simple softmax layer:

$$P(y_j | y_{<j}, \mathbf{x}) = \text{softmax}(\text{maxout}(s_j, y_{j-1}, c_j)). \tag{5}$$

An abundance of parallel corpora are required to train an NMT system to avoid overfitting, due to the large amounts of parameters in the encoder, decoder, and attention model. This is the main bottleneck of NMT for low resource domains and languages.

3 Domain Adaptation for SMT

In SMT, many domain adaptation methods have been proposed to overcome the problem of the lack of substantial data in specific domains and languages. Most SMT domain adaptation methods can be broken down broadly into two main categories:

3.1 Data Centric

This category focuses on selecting or generating the domain-related data using existing in-domain data.

i) When there are sufficient parallel corpora from other domains, the main idea is to score the out-domain data using models trained from the in-domain and out-of-domain data and select training data from the out-of-domain data using a cut-off threshold on the resulting scores. LMs (Moore and Lewis, 2010; Axelrod et al., 2011; Duh et al., 2013), as well as joint models (Hoang and Sima'an, 2014; Durrani et al., 2015), and more recently convolutional neural network (CNN) models (Chen et al., 2016) can be used to score sentences.

ii) When there are not enough parallel corpora, there are also studies that generate pseudo-parallel sentences using information retrieval (Utiyama and Isahara, 2003), self-enhancing (Lambert et al., 2011) or parallel word embeddings (Marie and Fujita, 2017). Besides sentence generation, there are also studies that generate monolingual n-grams (Wang et al., 2014) and parallel phrase pairs (Chu, 2015; Wang et al., 2016).

Most of the data centric-based methods in SMT can be directly applied to NMT. However, most of these methods adopt the criteria of data selection or generation that are not related to NMT. Therefore, these methods can only achieve modest improvements in NMT (Wang et al., 2017a).

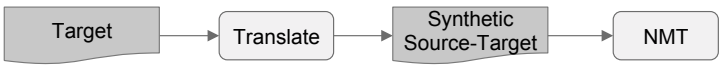

Figure 3: Synthetic data generation for NMT (Sennrich et al., 2016b).

3.2 Model Centric

This category focuses on interpolating the models from different domains.

i) Model level interpolation. Several SMT models, such as LMs, translation models, and reordering models, individually corresponding to each corpus, are trained. These models are then combined to achieve the best performance (Foster and Kuhn, 2007; Bisazza et al., 2011; Niehues and Waibel, 2012; Sennrich et al., 2013; Durrani et al., 2015; Imamura and Sumita, 2016).

ii) Instance level interpolation. Instance weighting has been applied to several natural language processing (NLP) domain adaptation tasks (Jiang and Zhai, 2007), especially SMT (Matsoukas et al., 2009; Foster et al., 2010; Shah et al., 2012; Mansour and Ney, 2012; Zhou et al., 2015). They firstly score each instance/domain by using rules or statistical methods as a weight, and then train SMT models by giving each instance/domain the weight. An alternative way is to weight the corpora by data re-sampling (Shah et al., 2010; Rousseau et al., 2011).

For NMT, several methods have been proposed to interpolate model/data like SMT does. For model-level interpolation, the most related NMT technique is model ensemble (Jean et al., 2015). For instance-level interpolation, the most related method is to assign a weight in NMT objective function (Chen et al., 2017a; Wang et al., 2017b). However, the model structures of SMT and NMT are quite different. SMT is a combination of several independent models; in comparison, NMT is an integral model itself. Therefore, most of these methods cannot be directly applied to NMT.

4 Domain Adaptation for NMT

4.1 Data Centric

4.1.1 Using Monolingual Corpora

Unlike SMT, in-domain monolingual data cannot be used as an LM for conventional NMT directly, and many studies have been conducted for this. Gülçehre et al. (2015) train an RNNLM on monolingual data, and fuse the RNNLM and NMT models. Currey et al. (2017) copy the target monolingual data to the source side and use the copied data for training NMT. Domhan and Hieber (2017) propose using target monolingual data for the decoder with LM and NMT multitask learning. Zhang and Zong (2016b) use source side monolingual data to strengthen the NMT encoder via multitask learning for predicting both translation and reordered source sentences. Cheng et al. (2016) use both source and target monolingual data for NMT through reconstructing the monolingual data by using NMT as an autoencoder.

4.1.2 Synthetic Parallel Corpora Generation

As NMT itself has the ability of learning LMs, target monolingual data also can be used for the NMT system to strengthen the decoder after back translating target sentences to generate a synthetic parallel corpus (Sennrich et al., 2016b). Figure 3 shows the flowchart of this method. It has also been shown that synthetic data generation is very effective for domain adaptation using either the target side monolingual data (Sennrich et al., 2016c), the source side monolingual data (Zhang and Zong, 2016b), or both (Park et al., 2017).

4.1.3 Using Out-of-Domain Parallel Corpora

With both in-domain and out-of-domain parallel corpora, it is ideal to train a mixed domain MT system that can improve in-domain translation while do not decrease the quality of out-of-domain translation. We categorize these efforts as *multi-domain* methods, which have been successfully developed for NMT. In addition, the idea of data selection from SMT also have been developed for NMT.

Multi-Domain The *multi-domain* method in Chu et al. (2017) is originally motivated by Sennrich et al. (2016a), which uses tags to control the politeness of NMT. The overview of this method is shown in

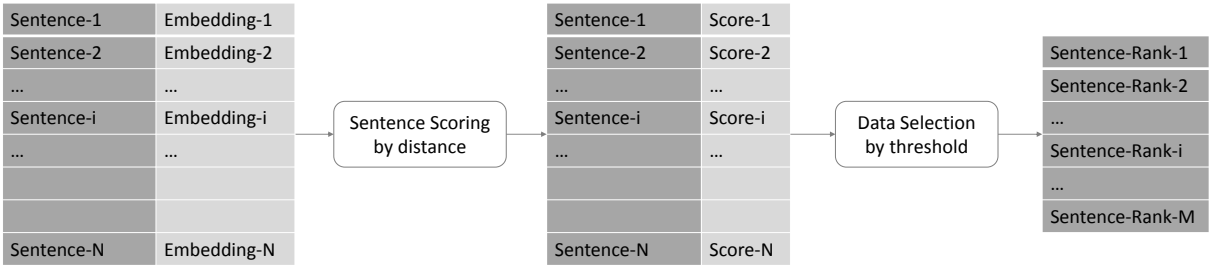

Figure 4: Data selection for NMT (Wang et al., 2017a).

the dotted section in Figure 6. In this method, the corpora of multiple domains are concatenated with two small modifications:

- Appending the domain tag "<2domain>" to the source sentences of the respective corpora. This primes the NMT decoder to generate sentences for the specific domain.
- Oversampling the smaller corpus so that the training procedure pays equal attention to each domain.

Sajjad et al. (2017) further compare different methods for training a multi-domain system. In particular, they compare *concatenation* that simply concatenates the multi-domain corpora, *staking* that iteratively trains the NMT system on each domain corpus, *selection* that selects a set of out-of-domain data which is close to the in-domain data, and *ensemble* that ensembles the multiple NMT models trained independently. They find that fine tuning the concatenation system on in-domain data shows the best performance. Britz et al. (2017) compare the *multi-domain* method with a discriminative method (see Section 4.2.2 for details). They show that the discriminative method performs better than the *multi-domain* method.

Data Selection As mentioned in the SMT section (Section 3.1), the data selection methods in SMT can improve NMT performance modestly, because their criteria of data selection are not very related to NMT (Wang et al., 2017a). To address this problem, Wang et al. (2017a) exploit the internal embedding of the source sentence in NMT, and use the sentence embedding similarity to select the sentences that are close to in-domain data from out-of-domain data (Figure 4). Van der Wees et al. (2017) propose a dynamic data selection method, in which they change the selected subset of training data among different training epochs for NMT. They show that gradually decreasing the training data based on the in-domain similarity gives the best performance.

Although all the data centric methods for NMT are complementary to each other in principle, there are no studies that try to combine these methods, which is considered to be one future direction.

4.2 Model Centric

4.2.1 Training Objective Centric

The methods in this section change the training functions or procedures for obtaining an optimal in-domain training objective.

Instance/Cost Weighting The main challenge for instance weighting in NMT is that NMT is not a linear model or a combination of linear models, which means the instance weight cannot be integrated into NMT directly. There is only one work concerning instance weighting in NMT (Wang et al., 2017b). They set a weight for the objective function, and this weight is learned from the cross-entropy by an in-domain LM and an out-of-domain LM (Axelrod et al., 2011) (Figure 5). Instead of instance weighting, Chen et al. (2017a) modify the NMT cost function with a domain classifier. The output probability of the domain classifier is transferred into the domain weight. This classifier is trained using development data. Recently, Wang et al. (2018) proposed a joint framework of sentence selection and weighting for NMT.

Fine Tuning *Fine tuning* is the conventional way for domain adaptation (Luong and Manning, 2015; Sennrich et al., 2016b; Servan et al., 2016; Freitag and Al-Onaizan, 2016). In this method, an NMT

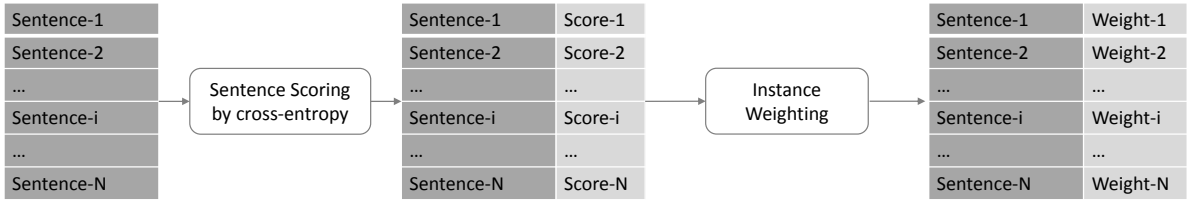

Figure 5: Instance weighting for NMT (Wang et al., 2017b).

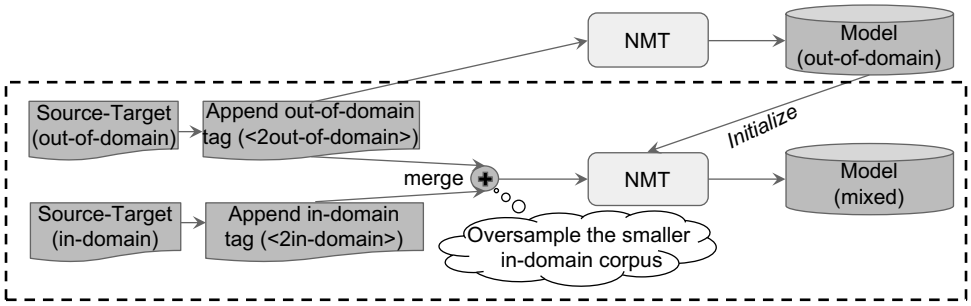

Figure 6: Mixed fine tuning with domain tags for domain adaptation (Chu et al., 2017). The section in the dotted rectangle denotes the *multi-domain* method .

system on a resource rich out-of-domain corpus is trained until convergence, and then its parameters are fine tuned on a resource poor in-domain corpus. Conventionally, fine tuning is applied on in-domain parallel corpora. Varga et al. (2017) apply it on parallel sentences extracted from comparable corpora. Comparable corpora have been widely used for SMT by extracting parallel data from them (Chu, 2015). To prevent degradation of out-of-domain translation after fine tuning on in-domain data, Dakwale and Monz (2017) propose an extension of fine tuning that keeps the distribution of the out-of-domain model based on knowledge distillation (Hinton et al., 2015).

Mixed Fine Tuning This method is a combination of the *multi-domain* and *fine tuning* methods (Figure 6). The training procedure is as follows:

1. Train an NMT model on out-of-domain data until convergence.
2. Resume training the NMT model from step 1 on a mix of in-domain and out-of-domain data (by oversampling the in-domain data) until convergence.

Mixed fine tuning addresses the overfitting problem of fine tuning due to the small size of the in-domain data. It is easier to train a good model with out-of-domain data, compared to training a multi-domain model. Once we obtained good model parameters, we can use these parameters for fine tuning on the mixed domain data to obtain better performance for the in-domain model. In addition, mixed fine tuning is faster than multi-domain because training an out-of-domain model convergences faster than training a multi-domain model, which also convergences very fast in fine tuning on the mixed domain data. Chu et al. (2017) show that mixed fine tuning works better than both *multi-domain* and *fine tuning*. In addition, mixed fine tuning has the similar effect as the ensembling method in Dakw and Monz (2017), which does not decrease the out-of-domain translation performance.

Regularization Barone et al. (2017) also realize the overfitting problem during fine tuning. Their strategy to address this problem is to explore regularization techniques such as dropout and L2-regularization. In addition, they also propose *tuneout* that is a variant of dropout for regularization. We think that mixed fine tuning and regularization techniques are complementary to each other.

4.2.2 Architecture Centric

The methods in this section change the NMT architecture for domain adaptation.

Deep Fusion One technique of adaptation with in-domain monolingual data is to train an in-domain RNNLM for the NMT decoder and combine it (also known as fusion) with an NMT model (Gülçehre et

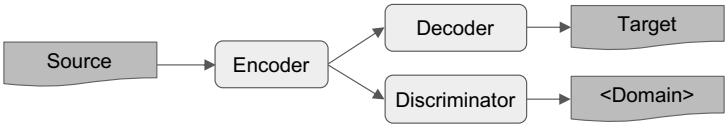

Figure 7: Domain discriminator (Britz et al., 2017).

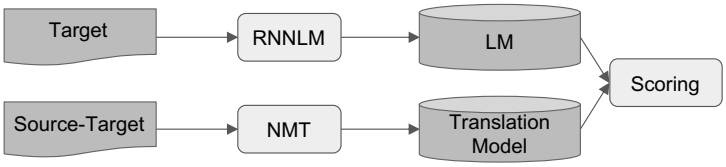

Figure 8: LM shallow fusion (Gülçehre et al., 2015).

al., 2015). Fusion can either be shallow or deep. Formally, deep fusion indicates that the LM and NMT are integrated as a single decoder (i.e., integrating the RNNLM into the NMT architecture). Shallow fusion indicates that the scores of the LM and NMT are considered together (i.e., rescoring the NMT model with the RNNLM model).

In deep fusion, the RNNLM and the decoder of the NMT are integrated by concatenating their hidden states. When computing the output probability of the next word, the model is fine tuned to use the hidden states of both the RNNLM and NMT models. Domhan and Hieber (2017) propose a method similar to the deep fusion method (Gülçehre et al., 2015). However, unlike training the RNNLM and NMT model separately (Gülçehre et al., 2015), Domhan and Hieber (2017) train RNNLM and NMT models jointly.

Domain Discriminator To leverage the diversity of information in multi-domain corpora, Britz et al. (2017) propose a discriminative method. In their discriminative method, they add a feed-forward network (FFNN) as a discriminator on top of the encoder that uses the attention to predict the domain of the source sentence. The discriminator is optimized jointly with the NMT network. Figure 7 shows an overview of this method.

Domain Control Besides using domain tokens to control the domains, Kobus et al. (2016) propose to append word-level features to the embedding layer of NMT to control the domains. In particular, they append a domain tag to each word. They also propose a term frequency - inverse document frequency (tf-idf) based method to predict the domain tag for input sentences.

4.2.3 Decoding Centric

Decoding centric methods focus on the decoding algorithm for domain adaptation, which are essentially complementary to the other model centric methods.

Shallow Fusion Shallow fusion is an approach where LMs are trained on large monolingual corpora, following which they are combined with a previously trained NMT model (Gülçehre et al., 2015). In the shallow fusion (Gülçehre et al., 2015), the next word hypotheses generated by an NMT model is rescored by the weighted sum of the NMT and RNNLM probabilities (Figure 8).

Ensembling Freitag and Al-Onaizan (2016) propose to ensemble the out-of-domain domain and the fine tuned in-domain models. Their motivation is exactly the same as the work of Dakwale and Monz (2017), which is preventing degradation of out-of-domain translation after fine tuning on in-domain data.

Neural Lattice Search Khayrallah et al. (2017) propose a stack-based decoding algorithm over word lattices, while the lattices are generated by SMT (Dyer et al., 2008). In their domain adaptation experiments, they show that stack-based decoding is better than conventional decoding.

5 Domain Adaptation in Real-World Scenarios

A domain adaptation method should be adopted according to the certain scenarios. For example, when there are some pseudo parallel in-domain data in the out-of-domain data, sentence selection is preferred; when only additional monolingual data is available, LM and NMT fusion can be adopted. In many cases, both out-of-domain parallel data and monolingual in-domain data are available, making the combination

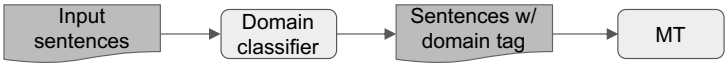

Figure 9: Domain adaptation in an input domain unknown scenario.

of different methods possible. Chu et al. (2018) conduct a study that applys mixed fine tuning (Chu et al., 2017) on synthetic parallel data (Sennrich et al., 2016b), which shows better performance than either method. Therefore, we do not recommend any particular techniques in this paper but recommend readers to choose the best method for their own scenarios.

Most of the above domain adaptation studies assume that the domain of the data is given. However, in a practical view such as an online translation engine, the domain of the sentences input by the users are not given. For such scenario, predicting the domains of the input sentences is crucial for good translation. To address this problem, a common method in SMT is to firstly classify the domains and then translate input sentences in classified domains using corresponding models (Huck et al., 2015). Xu et al. (2007) perform domain classification for a Chinese-English translation task. The classifiers operate on whole documents rather than on individual sentences, using LM interpolation and vocabulary similarities. Huck et al. (2015) extend the work of Xu et al. (2007) on the sentence level. They use LMs and maximum entropy classifiers to predict the target domain. Banerjee et al. (2010) build a support vector machine classifier using tf-idf features over bigrams of stemmed content words. Classification is carried out on the level of individual sentences. Wang et al. (2012) rely on averaged perceptron classifiers with various phrase-based features.

For NMT, Kobus et al. (2016) propose an NMT domain control method, by appending either domain tags or features to the word embedding layer of NMT. They adopt an in-house classifier to distinguish the domain information. Li et al. (2016) propose to search similar sentences in the training data using the test sentence as a query, and then fine tune the NMT model using the retrieved training sentences for translating the test sentence. Farajian et al. (2017) follow the strategy of Li et al. (2016), but propose to dynamically set the hyperparameters (i.e., learning rate and number of epochs) of the learning algorithm based on the similarity of the input sentence and the retrieved sentences for updating the NMT model. Figure 9 shows an overview of domain adaptation for MT in the input domain unknown scenario.

6 Future Directions

6.1 Domain Adaptation for State-of-the-art NMT Architectures

Since the success of RNN based NMT (Cho et al., 2014; Sutskever et al., 2014; Bahdanau et al., 2015), other architectures of NMT have been developed. One representative architecture is CNN based NMT (Gehring et al., 2017). Compared to RNN based models, CNN based models can be computed fully parallel during training and are much easier to optimize. Another representative architecture is the *Transformer*, which is based on attention only (Vaswani et al., 2017). It has been shown that CNN based NMT and the *Transformer* significantly outperform the state-of-the-art RNN based NMT model of Wu et al. (2016) in both the translation quality and speed perspectives. However, currently, most of the domain adaptation studies for NMT are based on the RNN based model (Bahdanau et al., 2015). The research of domain adaptation techniques for these latest state-of-the-art NMT models is obviously an important future direction.

6.2 Domain Specific Dictionary Incorporation

How to use external knowledge such as dictionaries and knowledge bases for NMT remains a big research question. In domain adaptation, the use of domain specific dictionaries is a very crucial problem. In the practical perspective, many translation companies have created domain specific dictionaries but not domain specific corpora. If we can study a good way to use domain specific dictionaries, it will significantly promote the practical use of MT. There are some studies that try to use dictionaries for NMT, but the usage is limited to help low frequent or rare word translation (Arthur et al., 2016; Zhang and Zong, 2016a). Arcan and Buitelaar (2017) use a domain specific dictionary for terminology translation,

but they simply apply the unknown word replacement method proposed by Luong et al. (2015), which suffers from noisy attention.

6.3 Multilingual and Multi-Domain Adaptation

It may not always be possible to use an out-of-domain parallel corpus in the same language pair and thus it is important to use data from other languages (Johnson et al., 2016). This approach is known as cross-lingual transfer learning, which transfers NMT model parameters among multiple languages. It is known that a multilingual model, which relies on parameter sharing, helps in improving the translation quality for low resource languages especially when the target language is the same (Zoph et al., 2016). There are studies where either multilingual (Firat et al., 2016; Johnson et al., 2017) or multi-domain models (Sajjad et al., 2017) are trained, but none that attempt to package multiple language pairs and multiple domains into a single translation system. Even if out-of-domain data in the same language pair exists, it is possible that using both multilingual and multi-domain data can boost the translation performance. Therefore, we think that multilingual and multi-domain adaptation for NMT can be another future direction. Chu and Dabre (2018) conduct a preliminary study for this topic.

6.4 Adversarial Domain Adaptation and Domain Generation

Generative adversarial networks are a class of artificial intelligence algorithms used in unsupervised machine learning, which are introduced by (Goodfellow et al., 2014). Adversarial methods have become popular in domain adaptation (Ganin et al., 2016), which minimize an approximate domain discrepancy distance through an adversarial objective with respect to a domain discriminator (Tzeng et al., 2017). They have been applied to domain adaptation tasks in computer vision and machine learning (Tzeng et al., 2017; Motiian et al., 2017; Volpi et al., 2017; Zhao et al., 2017; Pei et al., 2018). Recently, some of the adversarial methods began to be introduced into some NLP tasks (Liu et al., 2017; Chen et al., 2017b) and NMT (Britz et al., 2017).

Most of the existing methods focus on adapting from a general domain into a specific domain. In the real scenario, training data and test data have different distributions and the target domains are sometimes unseen. Irvine et al. (2013) analyze the translation errors in such scenarios. Domain generalization aims to apply knowledge gained from labeled source domains to unseen target domains (Li et al., 2018). It provides a way to match the distribution of training data and test data in real-world MT, which may be a future trend of domain adaptation for NMT.

7 Conclusion

Domain adaptation for NMT is a rather new but very important research topic to promote MT for practical use. In this paper, we gave the first comprehensive review of the techniques mainly being developed in the last two years. We compared domain adaptation techniques for NMT with the techniques being studied in SMT, which has been the main research area in the last two decades. In addition, we outlooked the future research directions. Connecting domain adaptation techniques in NMT to the techniques in general NLP, computer vision and machine learning is our future work. We hope that this survey paper could significantly promote the research in domain adaptation for NMT.

An Evaluation of Neural Machine Translation Models on Historical Spelling Normalization

Gongbo Tang, Fabienne Cap, Eva Pettersson, and Joakim Nivre
Uppsala University
Uppsala, Sweden
firstname.lastname@lingfil.uu.se

Abstract

In this paper, we apply different NMT models to the problem of historical spelling normalization for five languages: English, German, Hungarian, Icelandic, and Swedish. The NMT models are at different levels, have different attention mechanisms, and different neural network architectures. Our results show that NMT models are much better than SMT models in terms of character error rate. The vanilla RNNs are competitive to GRUs/LSTMs in historical spelling normalization. Transformer models perform better only when provided with more training data. We also find that subword-level models with a small subword vocabulary are better than character-level models. In addition, we propose a hybrid method which further improves the performance of historical spelling normalization.

1 Introduction

With increasing access to digital historical text, the processing of these historical texts is attracting more and more interest. However, in contrast to modern text, historical text processing faces more challenges. First, for historical text, there is little annotated data for training a model, which leads to data sparsity issues when using statistical methods, similar to the situation for low-resource languages. Second, there are a lot of variations in historical texts from different time periods, not only in spelling but also in lexical semantics and syntax. Therefore, the NLP tools developed for modern text cannot be used for these historical texts directly. Spelling normalization is the task of mapping a historical spelling to its modern spelling. It is usually used as a preprocessing step before feeding the historical text into modern NLP tools (Pettersson et al., 2013b; Bollmann, 2013; Sánchez-Martínez et al., 2013), which leads to much better results compared to analyzing unnormalized historical texts.

There are some papers in which neural machine translation (NMT) models are employed for the spelling normalization task. Korchagina (2017) utilizes a character-level NMT model for medieval German texts. Bollmann et al. (2017) apply an attention-based NMT model to historical German texts. The evidence so far is too incomplete to draw any general conclusions about the utility of different NMT models for historical spelling normalization. We are interested in exploring how different properties of NMT models interact with different aspects of the spelling normalization problem and find some generalizations about the use of NMT models for this task.

In this paper, we apply different NMT models to the spelling normalization task for historical stages of five languages, English, German, Hungarian, Icelandic, and Swedish. We compare our result to those of Pettersson et al. (2014), which are obtained with statistical machine translation (SMT) models. We investigate whether NMT models outperform SMT models in general, and explore which properties of NMT models are suitable for spelling normalization. Compared to the conventional machine translation (MT) tasks, we train models on token pairs instead of sentence pairs. Token length is usually shorter than sentence length. After reviewing related work in Section 2, we give our hypotheses about utilizing NMT models for the spelling normalization task and select different NMT models based on our hypotheses in Section 3. The selected NMT models are at different levels (character-level, subword-level), have

Proceedings of the 27th International Conference on Computational Linguistics, pages 1320–1331
Santa Fe, New Mexico, USA, August 20-26, 2018.

different attention mechanisms (no attention, soft-attention, multi-head-attention), and different neural network architectures (vanilla recurrent neural networks (RNNs), gated recurrent units (GRUs), long short-term memory units (LSTMs), and self-attention). In Section 4, we describe the datasets and our detailed experimental settings. In Section 5, we give our results and analyze the performance of different NMT models. Our conclusions and future work are in Section 6.

To conclude, our main contributions can be summarized as follows:

- We evaluate different NMT models on historical spelling normalization in a multilingual setting.
- We find that NMT models are better than SMT models considering character error rate (CER).
- We show that vanilla RNNs are competitive to GRUs/LSTMs.
- We demonstrate that transformer models perform better when provided with more training data.
- We reveal that models with a small subword vocabulary are better than character-level models.

2.1 Historical Spelling Normalization

Various methods have been employed for historical spelling normalization. Rayson et al. (2005) use a dictionary to map tokens to their modernized spellings, and many different edit-distance-based methods have been proposed to deal with spelling normalization (Bollmann et al., 2011; Pettersson et al., 2013a). In addition, character-level SMT models have been applied to spelling normalization, where models are trained on token pairs instead of sentence pairs (Pettersson et al., 2013b; Scherrer and Erjavec, 2013; Sánchez-Martínez et al., 2013). Each character of a token is viewed as a word of a sentence. The language models are trained on character N-grams instead of word N-grams. Pettersson et al. (2014) evaluate dictionary-based methods, edit distance-based methods, and SMT methods on five different historical languages. The results show that the character-level SMT model performs best on four out of five historical languages.

With the development of deep learning, various neural networks have been applied to many tasks. In recent years, NMT models (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Cho et al., 2014; Bahdanau et al., 2015) have outperformed SMT models (Koehn et al., 2003) distinctly in various translation tasks. We hypothesize that NMT models also perform better than SMT models for the historical spelling normalization task. Bollmann and Søgaard (2016) view the spelling normalization as a character-level sequence labeling task, and utilize a bi-directional LSTM for this task, which is better than a conditional random field (CRF) model. They also use additional data with similar but not the same historical spelling for a multi-task learning model, and gain further improvement. Korchagina (2017) applies a character-level NMT model to medieval German text, and finds that the NMT models can only outperform the SMT models with a larger training set. Bollmann et al. (2017) test attention-based NMT models, and multi-task learning models which learn to normalize and pronounce with a grapheme-to-phoneme dictionary, on spelling normalization. Both of them achieve good performance. They hypothesize that the reason why the combination of these two models does not gain more improvement is that the multi-task learning has already learned the attention patterns.

2.2 Neural Machine Translation

In vanilla NMT models, the source sentence is encoded into a fixed-size vector by the encoder. Then, this vector is fed into a decoder. The decoder generates the target sentence word by word conditioned on the fixed-size vector and the generated target words (Kalchbrenner and Blunsom, 2013). Various RNN architectures are usually used as encoders and decoders. Cho et al. (2014) find that the vanilla RNN-based NMT models perform poorly in translating long sentences, which means that vanilla RNNs have problems with long-distance dependencies. To deal with these problems, Cho et al. (2014) propose GRUs, while Sutskever et al. (2014) use LSTMs (Hochreiter and Schmidhuber, 1997) to replace the vanilla RNNs. However, any two tokens in RNNs still have a linear distance. Thus, Vaswani et al. (2017) replace RNNs with self-attention networks which connect any two tokens in a sentence directly.

Due to the expensive computation of NMT models, the vocabulary size is usually very limited, which causes a lot of out-of-vocabulary (OOV) words. Character-level models (Ling et al., 2015; Costa-jussà

and Fonollosa, 2016; Chung et al., 2016) and subword-level models (Sennrich et al., 2016; Wu et al., 2016) are widely used to deal with OOV problems. These two kinds of models need additional segmentation compared to word-level models. For character-level models, we just need to separate each character by space. But we need more complicated segmentation methods for subword-level models. Sennrich et al. (2016) utilize character n-grams and a byte pair encoding (BPE) algorithm (Gage, 1994) for segmentation. Wu et al. (2016) apply the wordpiece model (Schuster and Nakajima, 2012) to segmentation. Based on their experiments, subword-level models outperform word-level and character-level models.

Attention-based NMT models have outperformed all the other architectures in NMT in recent years. Many improved attention-based models have been proposed. Bahdanau et al. (2015) propose an attention-based model which can automatically search for source words that their hidden states are relevant to predicting a target word during decoding. Source words which have a higher correlation with the predicting target word will be assigned a higher weight. Most of the attention-based models use this kind of attention, which is called soft-attention in Xu et al. (2015). Vaswani et al. (2017) propose a model named *Transformer*, with multi-layer and multi-head attention mechanism which is more fine-grained.

3 NMT Models

When we apply NMT models to the historical spelling normalization task, the first research question is which NMT model is most suitable for this task. In this section, we first give four hypotheses about NMT models for spelling normalization, based on the data features of historical spellings and the features of NMT models. Then, we list 8 different NMT models to consider for the spelling normalization task.

3.1 Hypotheses

Hypothesis 1 The performance gap between vanilla RNNs and GRUs/LSTMs is small. In contrast to conventional NMT models, the historical and modern token pairs are our training data instead of parallel sentence pairs. In our experiments, the average token length varies from 4 to 6, which means that we build the model on much shorter sequences. The long-distance problem will be alleviated. It should be noted that we compare the gap to the gap in NMT (Bahdanau et al., 2015)[1].

Hypothesis 2 The gap between NMT models with attention and without attention is also small. Since the average token length is only around five, additionally paying attention to all the tokens in the source sentence may be unnecessary. Thus, we hypothesize that the decoder in the vanilla Encoder-Decoder model can predict most of the targets correctly with only one fixed-size vector from the encoder, even without any attention mechanisms. It should be mentioned that we compare the gap to the gap in NMT (Britz et al., 2017)[2].

Hypothesis 3 Transformer models perform better than soft-attention-based models. Transformer models have more advanced self-attention networks and more fine-grained multi-head attention mechanisms compared to RNN-based models with soft-attention. Thus, transformer models have better performance in conventional translation tasks. We hypothesize that it is the same in the spelling normalization task.

Hypothesis 4 Subword-level NMT models perform better than character-level NMT models. Character-level and subword-level models are proposed to deal with the problem of out-of-vocabulary words mainly, and subword-level NMT models usually outperform character-level models. As we only have small sets of token pairs, it is better to use character-level or subword-level NMT models rather than word-level models.

3.2 Models

To test our hypotheses proposed in the previous section, we will explore 8 different NMT models for the spelling normalization task. The NMT models vary in attention mechanism, neural network architecture, and token granularity. Table 1 gives a more detailed overview.

[1]The BLEU (Papineni et al., 2002) scores are 15.73, and 21.83.

[2]The BLEU scores are 17.82, and 26.75.

Name	Level	Attention	Architecture
NoAtt-RNN	character	no	RNN
NoAtt-GRU			GRU
NoAtt-LSTM			LSTM
Att-RNN		soft	RNN
Att-GRU			GRU
Att-LSTM			LSTM
Transformer		multi-head	Self-attention
BPE-Soft	subword	soft	LSTM

Table 1: NMT models for the spelling normalization task. *RNN* means vanilla RNNs.

Since we have hypothesized that different RNN architectures have slight differences, all the subword-level models with soft-attention are trained on LSTMs.

4 Experimental Setup

4.1 Data

All the datasets[3] are exactly the same as the parallel datasets for the SMT models in Pettersson et al. (2014), which are described in Table 2. Data details are shown in Table 3. The datasets consist of a list of token pairs, which have one historical spelling and the corresponding modernized spelling. Note that the same modern spelling may occur with different historical spellings. Moreover, some historical words may be extinct, and people have to use a spelling with a similar meaning but different lexemes as its normalization. Some illustrative English examples are given in Table 4. If a historical spelling is identical to its modern spellings, we call it an *unchanged spelling*. Otherwise, it is called a *changed spelling*. In different languages, the number of unchanged spellings is different.

Language	Time period	Origin
English	1386–1698	*Innsbruck Corpus of English Letters*, a subset of the *Innsbruck Computer Archive if Machine-Readable English Texts* (Markus, 1999)
German	1659–1780	*GerManC* corpus (Scheible et al., 2011)
Hungarian	1440–1541	*Hungarian Generative Diachronic Syntax* project (Simon, 2014)
Icelandic	1150–2008	*Icelandic Parsed Historical Corpus* (Rögnvaldsson et al., 2012)
Swedish	1527–1812	*Gender and Work corpus* (GaW) (Fiebranz et al., 2011)

Table 2: Origin and time periods of the datasets.

Language	Training	Development	Test	Unchanged	Token	Char	Max	Avg
English	148,852	16,461	17,791	75.8	22,302	102	22	4.16
German	39,887	5,418	5,005	84.4	11,521	100	27	4.74
Hungarian	137,669	17,181	17,214	17.1	69,624	128	27	5.91
Icelandic	52,440	6,443	6,384	50.5	14,845	89	16	4.14
Swedish	28,327	2,590	33,544	64.6	11,129	92	36	4.55

Table 3: Statistics of the datasets. The figures in *Training*, *Development*, and *Test* are the numbers of token pairs. The *Unchanged* (%) means the rate of unchanged spellings in the test set. *Token* and *Char* show the token and the character vocabulary sizes in the training set. *Max* and *Avg* show the max length and average length of token in the training set. All counts are based on case-sensitive data.

[3] http://stp.lingfil.uu.se/histcorp/tools.html

Historical	citee	gyve	gyf	late
Modern	city	give	give	late

Table 4: Token pair examples in English.

From Table 3, we can see that English and Hungarian have more training data, around 140,000 token pairs, while Swedish only has about 28,000 token pairs. Swedish has the largest test set with more than 33,000 token pairs. The unchanged rate also differs a lot. There are 84.4% and 75.8% historical spellings that are identical to their modern spellings in German and English, respectively. However, the unchanged rate is only 17.1% in Hungarian. In addition, Hungarian has the largest token vocabulary and character vocabulary[4]. The longest token in Icelandic is only 16, but the longest token in Swedish is 36. The average token length of Hungarian is 5.91, which is the longest in all five languages. This is because Hungarian is an agglutinative language.

4.2 Experimental Settings

Different architectures are hard to compare fairly because many factors affect performance. We aim to create a level playing field for the comparison by training with the same toolkit, Marian (Junczys-Dowmunt et al., 2018). Since there is no implementation of models without attention in Marian, we modify the decoder part to enable Marian to train models without attention.[5] We assume that the case of letters is useful for predicting the modern spellings. Thus, the letters in the training set and the tuning set are case-sensitive. The historical spellings in the test set which are the inputs of the model are also case-sensitive. However, to keep consistency with the baseline, we lowercase all the predicted modern spellings during evaluation.

For character-level models, all the characters are added into the vocabulary, even if they only appear once. For subword-level models, we utilize the BPE method in Sennrich et al. (2016) to generate subword units. We try different BPE vocabulary sizes, varying between 100, 200, 300, 500, 1,000 and 5,000.

The vanilla RNN chooses the "tanh" RNN cell. We enable "mini-bach-fit" which automatically choose the mini-batch size for the given "workspace" size, and the "workspace" is set to 7500. We use *Adam* (Kingma and Ba, 2015) as the optimizer. The learning rate is set to 0.0003, but we set the warmup steps to 16,000, which means that the learning rate increases linearly before 16,000 steps. A model checkpoint is saved every 500 updates. The evaluation metrics on the development set are cross-entropy and perplexity. We set the early stopping patience to 8 checkpoints. All the neural networks have 6 layers. The size of embeddings is 512. We tie the target embeddings and the output embeddings in the output layer. We use the checkpoint that achieves the best perplexity to generate the normalizations. We set the beam size to 5 during decoding.

5 Results

The baseline from Pettersson et al. (2014) has very high word accuracy and low CER scores in all five languages. The results in the baseline are obtained using character-level SMT models except for Icelandic, where the combination of a Levenshtein-based method and a dictionary-based method achieved the best results. We use word accuracy and CER to evaluate the predictions. For the historical spelling normalization task, word accuracy is a very important evaluation metric. Moreover, word accuracy is the only evaluation metric in Bollmann and Søgaard (2016) and Bollmann et al. (2017). However, CER is a good supplement to word accuracy. It is more fine-grained and evaluates the character-level normalizations. In our experiments, we use Levenshtein distance to compute CER. Table 5 gives the detailed results of different models in five languages.

[4]The character vocabulary includes both alphabetic and non-alphabetic characters.

[5]The modification, the NMT model settings, and the code are available in `https://github.com/tanggongbo/normalization-NMT`

	English		German		Hungarian		Icelandic		Swedish	
	Acc	CER	Acc	CER	Acc	CER	Acc	CER	Acc	CER

Table 5: Evaluation results in word accuracy (Acc, %) and CER. The best results in each language have background color. Many identical values in CER are different, but the difference is irrelevant in Chi-square test.

5.1 Word Accuracy

Table 5 shows that NMT models outperform SMT models in four out of five languages, except for Swedish, when we use word accuracy as the evaluation metric. Compared to the other four languages, we get a huge absolute improvement of 12.04% in Hungarian, improving the word accuracy from 80.1% to 92.14%. We get 0.04%, 0.86%, and 2.99% absolute improvement in German, English, and Icelandic, respectively. Our best NMT result in Swedish is still a little lower than the baseline in word accuracy. We attribute the reason to the dataset size, because Swedish has the smallest training set.

We divide the incorrectly normalized spellings into three groups by checking the normalizations of the test set automatically:

1. *Change*: modern spelling is identical to historical spelling, but the model normalized the historical spelling to another spelling.
2. *Copy*: modern spelling is different from historical spelling, but the model copied the historical spelling as the normalization.
3. *Other*: other types of error.

	English	German	Hungarian	Icelandic	Swedish
Change	22.3	28.5	6.1	33.8	25.0
Copy	22.7	41.7	6.1	20.8	23.6
Other	55	29.8	87.8	45.4	51.4

Table 6: Error distributions (%).

Table 6 gives us the error distributions of the best model in each language. The *Change* and *Copy* errors only account for 12.2% in Hungarian which is reasonable, because the changed rate in Hungarian is only 17.1%. The other four languages still have a lot of *Change* and *Copy* errors. This finding reveals that it is a little bit difficult for the NMT model trained on the data that mixed with changed and unchanged spellings to normalize unchanged spellings. However, there are only very few unchanged translations in the MT task.

Therefore, we explore a hybrid method, combining the NMT-based method and the dictionary-based method. More specifically, we first extract a list of unchanged spellings from the training set. During the evaluation, if a word is in this list, we simply copy it as its normalization. If it is not in the list, we feed it to the NMT models. The results in Table 7 show that this hybrid method improves the accuracy further. In particular, the improvements on Icelandic are around 5%.

	English		German		Hungarian		Icelandic		Swedish	
	Acc	△	Acc	△	Acc	△	Acc	△	Acc	△
NoAtt-RNN	95.92	1.19	95.78	0.90	91.81	0.82	91.92	5.18	91.83	0.39
NoAtt-GRU	95.93	1.14	95.44	0.60	91.87	0.84	91.70	4.71	91.73	0.39
NoAtt-LSTM	95.81	1.20	96.42	0.64	91.75	0.83	91.78	5.17	91.69	0.41
Att-RNN	95.90	1.21	94.93	0.70	92.47	0.77	92.54	4.95	91.94	0.38
Att-GRU	95.99	1.19	95.48	0.66	92.49	0.82	92.25	5.08	92.04	0.36
Att-LSTM	96.02	1.17	96.44	0.44	92.36	0.78	91.76	4.93	92.08	0.36
Transformer	96.33	1.17	95.70	0.48	92.94	0.80	91.60	5.15	89.48	0.49
BPE-Soft	96.19	1.18	96.96	0.32	92.74	0.78	92.14	4.95	91.56	0.35

Table 7: The results of combining the NMT-based method and the dictionary-based method. "△" denotes the absolute improvement on accuracy (%) compared to the NMT-based method.

5.2 CER

With the CER measure, we calculate the number of correctly normalized characters, without considering the word level. CER is similar to the BLEU score in MT, and we evaluate at sub-sequence-level rather than the overall accuracy. When we use CER as the evaluation metric, NMT models get the best results for all five languages, even though some models achieve lower accuracy than the baseline. This result is different from the result of Korchagina (2017). In her paper, if the SMT models are better than the NMT models in word accuracy, these SMT models are better than the NMT models in CER as well. We assume that this may be due to different neural network architectures: they use CNNs while we use RNNs and self-attention networks.

	English	German	Hungarian	Icelandic	Swedish
Changed	1.45	1.07	2.58	1.41	1.32
Incorrect	1.81	1.64	1.78	1.64	1.54

Table 8: The average edit distance of the changed spellings in test set and the average edit distance of the incorrectly normalized changed spellings.

Table 8 shows the edit distance of spellings. For the incorrectly normalized changed spellings, the average edit distance is smaller than 2. In other words, we just need less than two edits to translate an incorrectly normalized spelling into the correct one. In the incorrect normalizations, Swedish has the shortest average edit distance 1.54, and English has the longest average edit distance 1.81.

Intuitively, if a spelling has smaller edit distance, it is easier for the model to normalize this spelling correctly. That is to say, the average edit distance of incorrectly normalized spellings will be larger compared to the average edit distance before normalization. However, Hungarian is the exception in Table 8, which indicates that spellings with longer edit distance are more likely to be normalized close to modern spellings in Hungarian. For example, the edit distance between “mōdanac” and “mondák” is 6, yet the model can normalize it correctly. Although the model normalized “mėgbètėgeitnc̣” into “megbetegíteniúk”, which is not identical to the modern spelling “megbetegítenék”, the edit distance nevertheless decreased from 9 to 2. We hypothesize that this could be due to the fact that Hungarian belongs to a different language family than the other four languages.

Table 9 gives some incorrectly normalized examples from the development set. Most of the edit distances of spellings are longer than 1. In addition to *Change* and *Copy* errors, some historical spellings are quite different from their modern spelling, such as “wett” in English. For the historical word “wett”, it is extinct, people just mapped a semantic related modern word to it. “know” has no relations with “wett” in spelling and pronunciation. Characters with different accents also cause mistakes easily. For example, “vetém” in Hungarian and “sér” in Icelandic.

	English	German	Hungarian	Icelandic	Swedish
Historical	alys	julius	vètē	uopn	sielffuer
Normalized	alis	jiues	vetem	opnu	själver
Modern	alice	julius	vetém	vopn	själv
Historical	wett	cohærentz	haila	sier	herrskaper
Normalized	wit	cohaerenz	hajola	sjer	herrskaper
Modern	know	kohärenz	hajla	sér	herrskapen

Table 9: Some incorrectly normalized examples from the development set.

5.3 NMT versus SMT

In the conventional MT tasks, NMT models usually outperform SMT models. The first reason is that the dense embeddings in NMT are powerful representations. The second reason is that NMT models usually consider a larger context compared to SMT models. This is the same in historical spelling normalization. In our experiments, the most obvious example is Hungarian. The absolute improvement is 12.04% in word accuracy. Compared to other languages, Hungarian has the largest token and character vocabularies and the highest changed rate. It also has the longest average token length. Thus, NMT models can represent these larger vocabularies better than SMT models. NMT models are also better at capturing the context information when generating the normalization. For example, the NMT models can normalize a 14-character spelling "aldozatt'oknak" into "áldoza**tuk**nak" correctly, while the SMT models normalize it into "áldoza**tok**nak". In the training set, 'tok' is much more frequent than 'tuk'. Since SMT models are more focused on a local context, the SMT models choose 'tok' rather than 'tuk'.

However, in terms of accuracy, it is still hard for NMT models to exceed SMT models in Swedish. We also find that the performance of NMT models is quite close to the baseline in German which has the second smallest training dataset. We hypothesize that the size of training data is crucial for NMT models to exceed SMT models.

As there is much more test data in Swedish compared to other languages, we test our hypothesis by moving some token pairs from test sets to training sets and development sets. More specifically, we create two new datasets, in which 27,000 and 30,000 token pairs are moved from the beginning of the test set to the training set and the development set, respectively. Both the datasets and results are described in Table 10.

Training	Development	Test	Att-RNN	Att-GRU	Att-LSTM	Transformer
28,327	2,590	33,544	91.56	91.68	91.72	88.99
51,237	6,590	6,544	95.45	94.79	94.97	95.18
57,637	3,190	3,544	96.02	95.77	95.65	95.77

Table 10: The accuracy of different models in Swedish with different dataset settings.

Table 10 shows that the NMT models achieve much higher accuracy with more training data. This result indicates that the performance of NMT models is highly related to the size of training set.

5.4 Different NMT Models

Hypothesis 1 is that the performance gap between vanilla RNNs and GRUs/LSTMs will not be huge. The results in Table 5 reveal that the vanilla RNNs are competitive to the GRUs/LSTMs in this task. *Att-RNN* even performs better than *Att-GRU/LSTM* in Icelandic. However, *Att-RNN* is clearly worse than *Att-LSTM* in German. These results support our Hypothesis 1 well.

Hypothesis 2 states that NMT models with and without attention will not differ a lot. The models with attention are slightly better than models without attention in our experiments, which is in line with the results in Bollmann et al. (2017). However, the gap is quite small. Thus, it fits our Hypothesis 2.

Hypothesis 3 is that transformer models are better than soft-attention-based models. From Table 5,

we can see that *Transformer*, with self-attention and multi-head attention, achieves higher word accuracy in English and Hungarian compared to soft-attention-based models. It is interesting that English and Hungarian have much more training data compared to the other three languages. This result reveals that transformer models need more data to exceed RNN-based models.

Hypothesis 4, finally, states that subword-level models are better than character-level models. Our experimental results for four languages (except Swedish) show that subword-level models are superior to character-level models when the BPE vocabulary is small. In subword-level models, the vocabulary includes all the characters and learned subword units. We try different BPE vocabulary sizes. All the subword-level models are trained on LSTMs. Table 11 gives the results with different BPE sizes. Many historical spellings only have several instances in the training set. The NMT model cannot translate the token well at the token level. Moreover, there is also a data sparsity problem for the subwords when we set a larger BPE vocabulary. We assume that BPE maybe cannot learn rare subword units very well, because of the data sparsity. That is why subword-level models perform better in the conventional MT tasks, which have a much larger training set. We find that the subword-level models perform worse than character-level models when the BPE vocabulary is larger than 300 in all five languages.

BPE-size	English	German	Hungarian	Icelandic	Swedish
0	94.85	96	91.57	86.83	**91.72**
100	**95.02**	**96.64**	91.87	**87.19**	91.21
200	94.91	96.28	91.81	86.89	91.13
300	94.69	96.5	**91.96**	86.76	90.84
500	94.54	96.42	91.52	86.51	90.57
1,000	94.52	96.18	91.44	86.29	89.67
5,000	93.71	95.06	89.43	84.87	85.47

Table 11: Accuracy (%) with different BPE vocabulary sizes. "0" represents the character-level models.

Historical languages are considered as low-resource languages. Hence the result of Hypothesis 4 can be interpreted to mean that subword-level models with a small subword vocabulary can further improve the performance compared to character-level models in low-resource languages.

6 Conclusions and Future Work

In this paper, we explore different NMT models for the historical spelling normalization task in five languages, English, German, Hungarian, Icelandic, and Swedish. We propose four hypotheses on NMT models, which are the general questions to ask when applying NMT models to the historical spelling normalization task.

We find that the performance gap between vanilla RNNs and GRUs/LSTMs is very small, vanilla RNNs are even competitive to GRUs/LSTMs in Hungarian and Icelandic. We demonstrate that the gap between NMT models with or without attention is also slight. We show that the subword-level models with a small subword vocabulary are better than character-level models. However, subword-level models with a larger vocabulary suffer from data sparsity.

When we use word accuracy as the evaluation metric, NMT models can get better results for four languages compared to SMT models. However, all NMT models perform better than SMT models for all five languages when we use CER as the evaluation metric. In addition, the size of the training set is crucial to NMT models. Particularly, transformer models are superior to RNN-based models only when provided with more training data. These findings could contribute to the development of general NMT systems, especially for low-resource languages. Since NMT models are more likely to generate incorrect normalizations of unchanged spellings, we propose a hybrid method using both NMT-based methods and dictionary-based method which improves the performance further.

In the future, we could 1) explore some hard-attention-based models, 2) introduce phoneme knowledge into NMT models, and 3) use sentence pairs for spelling normalization. Compared to soft attention,

hard attention (Xu et al., 2015) only pays attention to one or several specified source word annotations. Aharoni and Goldberg (2017) employ hard monotonic attention for a morphological inflection generation task. The variation between historical spelling and modern spelling is usually monotonic, which is similar to morphological inflection. Thus, hard attention should work well in historical spelling normalization as well.

Many words have changed their spellings, but they keep the same pronunciation. Thus, Bollmann et al. (2017) use an additional grapheme-to-phoneme dictionary in a multi-task learning setting. We can add the phonetic dictionaries as additional training data to improve the performance.

In addition to token-pair-based normalization, Ljubešić et al. (2016) use segment pairs with context information to do spelling normalization. NMT models are powerful in using context information. Thus, training the NMT models on sentence pairs is likely to improve the spelling normalization task further, which introduces more context information.

Acknowledgments

Abstract

Previous work on the problem of Arabic Dialect Identification typically targeted coarse-grained five dialect classes plus Standard Arabic (6-way classification). This paper presents the first results on a fine-grained dialect classification task covering 25 specific cities from across the Arab World, in addition to Standard Arabic – a very challenging task. We build several classification systems and explore a large space of features. Our results show that we can identify the exact city of a speaker at an accuracy of 67.9% for sentences with an average length of 7 words (a 9% relative error reduction over the state-of-the-art technique for Arabic dialect identification) and reach more than 90% when we consider 16 words. We also report on additional insights from a data analysis of similarity and difference across Arabic dialects.

Title and Abstract in Arabic

التصنيف الدقيق في تحديد اللّهجات العربية

اعتمدت الأبحاث السابقة في مسألة تحديد اللهجات العربية على تصنيف عام يتضمن المناطق العربية (خليجي، عراقي، شامي، مصري، مغاربي) بالإضافة للغة العربية الفصحى. خلافا للتصنيف السابق، يعرض هذا البحث العلمي النتائج الأولى في تحديد اللهجات باستخدام تصنيفات دقيقة تشمل ٢٥ مدينة من جميع أنحاء العالم العربي بالإضافة للعربية الفصحى، مما يزيد المسألة صعوبة. في هذا السياق، نبني عدة أنظمة للتصنيف بين اللهجات من خلال الإستطلاع على الخصائص اللغوية المستخرجة من الجمل. تظهر النتائج التي توصلنا إليها انّه بامكاننا تحديد لهجة المدينة للمتحدث بدقة ٦٧،٩ % من خلال نص كتابي يحتوي على معدل ٧ كلمات، وبدقة ٩٠ % من خلال تحليل ١٦ كلمة. بالإضافة، يتضمن البحث تقريرا مبنيا على تحليل الجمل يبرز مدى التشابه والاختلاف بين اللهجات العربية.

1 Introduction

Dialect identification (DID) is the task of automatically identifying the dialect of a particular segment of speech or text of any size (i.e., word, sentence, or document). This task has attracted increasing attention in recent years. For instance, several evaluation campaigns were dedicated to discriminating between language varieties (Malmasi et al., 2016; Zampieri et al., 2017). This is not surprising considering the importance of automatic DID for several NLP tasks, where prior knowledge about the dialect of an input text can be helpful, such as machine translation (Salloum et al., 2014), sentiment analysis (Al-Twairesh et al., 2016), or author profiling (Sadat et al., 2014).

For Arabic DID, previous work typically targeted coarse-grained five dialect classes plus Standard Arabic at most (6-way classification) (Zaidan and Callison-Burch, 2014; Elfardy and Diab, 2013; Darwish et al., 2014). In this paper, we tackle a finer-grained dialect classification task, covering 25 cities from across the Arab World (from Rabat to Muscat), in addition to Standard Arabic. Table 1 shows the break up we follow in choosing these cities. The table relates the typical five-way regional break up of Arabic dialects (Habash, 2010) to a more refined ten-way sub-region division, and even further into 25 cities.

Table 1: Different region, sub-region, and city dialects. The bolded cities are our regional representatives.

We build several classification systems and explore a large space of features. Our results show that we can identify the exact city of a speaker at an accuracy of 67.9% for sentences with an average length of 7 words (a 9% relative error reduction over the state-of-the-art technique for Arabic dialect identification (Zaidan and Callison-Burch, 2014)) and reach more than 90% when we consider 16 words.

We also report the results of training and evaluating our model using datasets obtained from different sources: (i) A large-scale parallel corpus of five regional representative dialects and MSA (CORPUS-6); (ii) A smaller-scale parallel corpus of 25 dialects and MSA (CORPUS-26); and (iii) A corpus of dialectal sentences extracted from Twitter. Furthermore, we report the additional insights we obtain from analyzing the data with respect to similarity and difference across Arabic dialects.

Our research contributions are the following:

- We extend the problem of Arabic DID to predict 25 fine-grained city-level dialects.
- We demonstrate a solution for leveraging relatively rich resources for a small number of city dialects to help with the fine-grained DID task for 25 city dialects.
- We present a detailed analysis of dialect similarity and confusability and add insights on top of the traditional map presented in the literature.
- We show that, on average, it takes 52 words to reach an optimal classification of the dialect and 16 words to reach 90% accuracy.
- We evaluate our system on dialectal sentences extracted from social media.

The remainder of this paper is organized as follows. In section 2, we review the main previous efforts for DID. In Section 3, we present the main challenges in processing Arabic and its dialects. In Section 4, we describe our experimental setup and discuss the datasets, models, features, evaluation metrics used as well as our results. In Section 5, we present a detailed analysis and discussion on dialect confusability, optimal classification and tweet dialect classification. Finally, we conclude and give our future directions in Section 6.

2 Related Work

Working on DID is more challenging than just recognizing a specific language (Etman and Beex, 2015). Since Arabic dialects use the same script and share part of the vocabulary, it is quite arduous to distinguish between them. Hence, developing an automatic identification system working at different levels of representation and exploring different datasets has attracted increasing attention in recent years. Shoufan and Alameri (2015) and Al-Ayyoub et al. (2017) present a survey on NLP and deep learning methods for processing Arabic dialectal data with an overview on Arabic DID of text and speech.

Biadsy and Hirschberg (2009) presented a system that identifies dialectal words in speech and their dialect of origin (on four regional Arabic dialects) from acoustic signals. In the same context, Bougrine et al. (2017) propose a hierarchical classification approach for spoken Arabic Algerian DID, using prosody.

Diab and Elfardy (2012) presented a set of guidelines for token-level identification of dialectness. They later proposed a supervised approach for identifying whether a given sentence is prevalently MSA or Egyptian (Elfardy and Diab, 2013) using the Arabic online commentary dataset (AOC) (Zaidan and Callison-Burch, 2011). Their system (Elfardy and Diab, 2012) combines a token-level DID approach with other features to train a Naive-Bayes classifier. Similarly, Tillmann et al. (2014) use a linear SVM

classifier to label the AOC dataset. Also, El-Haj et al. (2018) used grammatical, stylistic and Subtractive Bivalency Profiling features for dialect identification on the AOC dataset.

Sadat et al. (2014) presented a bi-gram character-level model to identify the dialect of sentences in the social media context among dialects of 18 Arab countries. More recently, discriminating between Arabic Dialects has been the goal of a dedicated shared task (Zampieri et al., 2017; Malmasi et al., 2016), encouraging researchers to submit systems to recognize the dialect of speech transcripts along with acoustic features for dialects of four main regions: Egyptian, Gulf, Levantine and North African, in addition to MSA. The dataset used in these tasks is different from the dataset we use in this work in its genre, size and the dialects covered.

Several systems implementing a range of traditional supervised learning and more advanced deep learning methods were submitted. High-order character n-grams extracted from speech or phonetic transcripts and i-vectors (a low-dimensional representation of audio recordings) were shown to be the most successful and efficient features (Butnaru and Ionescu, 2018), while deep learning approaches (Belinkov and Glass, 2016) did not perform well.

Recently, there are more efforts to collect and annotate datasets for dialect identification. Abdul-Mageed et al. (2018) present a large dataset from Twitter domain covering dialects from 29 major Arab cities in 10 Arab countries. Al-Badrashiny and Diab (2016) present a system that detects points of code-switching in sentences between MSA and dialectal Arabic.

Most, if not all of the approaches, proposed in the literature have been exploring DID at the regional or country level. To the best of our knowledge, this is the first fine-grained DID system covering the dialects of 25 cities from several countries, including cities in the same country in the Arab World. Moreover, this is the first study pinpointing Arabic DID, discussing the difference between regional and city-level identification and redrawing the geographical map for Arabic DID. Furthermore, this is the first work leveraging a parallel corpus covering 25 dialects in addition to MSA (Bouamor et al., 2018).

3 Arabic and its Dialects

Dialectal Arabic (DA) refers to the collection of language varieties used by Arabic speakers in their daily interactions. DA lives side by side with Modern Standard Arabic (MSA), the official language in most Arab countries. Although MSA is not acquired natively (through spoken input at home and in the community), it has an extensive presence in various settings: media, education, business, arts and literature, and official and legal written documents. The dialects are not standardized, they are not taught, and they do not have official status. However, they are the primary vehicles of communication (face-to-face and recently, online) and have a significant presence in the arts as well.

Arabic dialects are often classified in terms of geography. Typical regional groupings cluster the dialects into Levantine Arabic (Lebanon, Syria, Jordan, and Palestine), Gulf Arabic (Qatar, Kuwait, Saudi Arabia, United Arab Emirates and Bahrain, with Iraqi and Omani Arabic included sometimes), Egyptian Arabic (which may include Sudan), North African Arabic (vaguely covering Morocco, Algeria, Tunisia, Libya and Mauritania), and Yemeni Arabic (Habash, 2010). However, within each of these regional groups, there is significant variation down to the village, town, and city levels.

Arabic dialects differ from one another and from MSA on all levels of linguistic representation, from phonology and morphology to lexicon and syntax (Watson, 2007).[1] The number of lexical differences is significant i.e., Egyptian أوضة *ÂwDĎħ* 'room' corresponds to MSA غرفة *γrfħ*, Lybian دار *dAr* and Tunisian بيت *byt* (Habash et al., 2012a).[2] Morphological differences are also quite common. One example is the future marker particle which appears as +س *sa+* or سوف *sawfa* in MSA, +ح*Ha+* or رح *raH* in Levantine dialects and باش *bAš* in Tunisian. This together with the variation in the templatic morphology make the forms of some verbs rather different: e.g., *'I will write'* is سأكتب *sa Âaktubu* in MSA, حاكتب *HaÂaktub*

[1] Comparative studies of several Arabic dialects suggest that the syntactic differences between the dialects are minor (Benmamoun, 2012).

[2] Arabic transliteration is presented in the Habash-Soudi-Buckwalter scheme (Habash et al., 2007): (in alphabetical order) *AbtθjHxdðrzsšSDTĎς γfqklmnhwy* and the additional symbols: ' ء, Â أ, Ă إ, Ā آ, ŵ ؤ , ŷ ئ , ħ ة, ý ى.

in Palestinian, هكتب *haktib* in Egyptian and باش نكتب *bAš niktib* in Tunisian.

An example of phonological differences is in the pronunciation of dialectal words whose MSA cognate has the letter Qaf (ق *q*). It is often observed that in Tunisian Arabic, this consonant appears as /q/ (similar to MSA), while in Egyptian and Levantine Arabic it is /ʔ/ (glottal stop) and in Gulf Arabic it is /G/ (Haeri, 1991; Habash, 2010).

It should be also noted that while MSA has an established standard orthography, the dialects do not. Often people write words reflecting the phonology or the history (etymology) of these words. DA is sometimes written in Roman script (Bies et al., 2014). In the context of NLP, a set of conventional orthography guidelines (CODA) has been proposed, but only for specific dialects (Habash et al., 2018).

Despite these differences, distinguishing between dialects is a very challenging task because: (i) dialects use the same writing script (not in a conventionalized way) and share part of the vocabulary; and (ii) Arabic speakers usually resort to repeated code-switching between their dialect and MSA (Abu-Melhim, 1991; Bassiouney, 2009), creating sentences with different levels/percentages of dialectness. More discussion on the similarity between dialects of 25 cities in the Arab World and MSA is given in Section 4.1.

4 Experimental Setup

4.1 Data

In this work, we use a large-scale collection of parallel sentences built to cover the dialects of 25 cities from the Arab World (illustrated in Table 1), in addition to English, French and MSA (Bouamor et al., 2018). This resource was created as a commissioned translation of the Basic Traveling Expression Corpus (BTEC) (Takezawa et al., 2007) sentences from English and French to the different dialects. It contains two corpora. The first consists of 2,000 sentences translated into dialects of 25 cities. Each of these sentences has a corresponding 25 parallel translations. We refer to it as CORPUS-26 (25 cities plus MSA). The second corpus has 10,000 additional sentences (non-overlapping with the 2,000 sentences) from the BTEC corpus translated to the dialects of only five selected cities: Beirut, Cairo, Doha, Tunis and Rabat. We refer to it as CORPUS-6 (5 cities plus MSA). Effectively, the five selected cities will each have 12,000 sentences that are five-way parallel translations. An example of a 28-way parallel sentence (25 cities plus MSA, English and French) extracted from CORPUS-26 is given in Figure 1.

Data pre-processing and splitting In our experiments, we only tokenize the sentences in both CORPUS-6 and CORPUS-26 using punctuation marks. Morphological analysis has been shown to improve the performance of DID systems for a small number of dialects (Darwish et al., 2014). However, the number and sophistication of morphological analysis and segmentation tools for DA are very limited (Pasha et al., 2014), cover only a small number of dialects (Habash and Rambow, 2006; Habash et al., 2012b; Khalifa et al., 2017) and unavailable for most of the others. We split each corpus into Train, Development (Dev) and Test sets. The splits are balanced for each dialect and the distribution of each split is given in Table 2. We use TRAIN, DEVELOPMENT and TEST terms with CORPUS-6 and CORPUS-26 to refer to the training, development and test sets of the specified corpus. We use the term MODEL to refer to the trained system.

Pairwise similarity between dialects In order to get a sense of the complexity of our task, we explore the degrees of similarity and variation between the dialects in CORPUS-26. We accomplish this by building a similarity matrix representing the lexical similarity between the dialects of every two cities D_1 and D_2 (i.e., BEI and CAI, TUN and MUS, etc.). We measure the similarity by computing the percentage of common tokens between the corpus of D_1 and the corpus of D_2. This is solely a bag of word comparison.

	Train	Dev	Test	Classes
CORPUS-6	9000	1000	2000	6
CORPUS-26	1600	200	200	26

Table 2: Distribution of the Train, Dev and Test sets used in our experiments.

Then, we apply a hierarchical agglomerative clustering algorithm to the similarity matrix. We group the clusters using single linkage clustering, thus combining two clusters that contain the closest pair of

dialects (have the largest number of common tokens). The dendrogram in Figure 2 illustrates the result of this clustering algorithm, with the y-axis showing the token dissimilarity ratio between the clusters.

The dendrogram shows the not surprising closeness of dialects of cities within the same countries, and in the same geographic region. For example, Damascus and Aleppo dialects are different from each other only by 32% and from Beirut dialect by 38%. While the dissimilarity between the cluster enclosing Tunis and Sfax and the cluster containing the rest of the dialects is more than 50%. Thus, the high degree of similarity among some dialects shows that discriminating between dialects on the word-level is rather challenging. This can affect the accuracy of our models due to the increase of confusability among similar dialects.

4.2 Multi-level Dialect Identification Models

We formulate our DID problem as a multi-class classification task. We consider a Multinomial Naive Bayes (MNB) classifier for the learning task.[3] MNB is a variation of Naive Bayes that estimates the conditional probability of a token given its class as the relative frequency of the token t in all documents belonging to class c. MNB has proven to be suitable for classification tasks with discrete features (e.g.,

[3]Our experiments with MNB outperform other classification models such as Linear SVM, Convolutional Neural Networks models with multiple words and characters filter sizes (Belinkov and Glass, 2016), and Bi-directional LSTM models. The latter two had lower accuracy than the simple Language Model baseline, which could be explained by the small size of our training data.

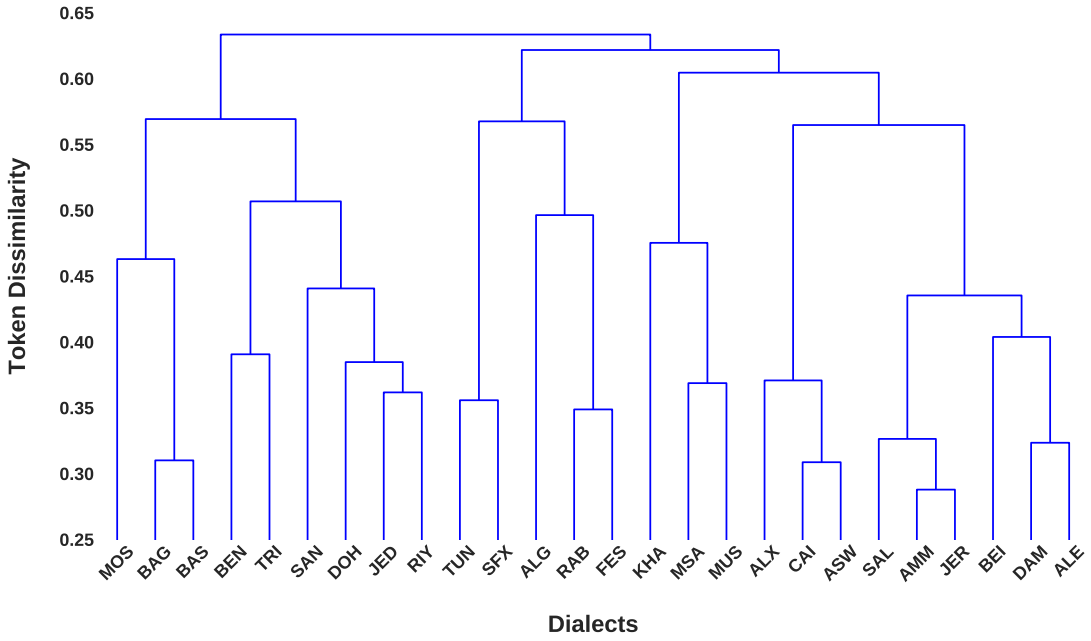

Figure 2: Pairwise similarity between dialects in Corpus-26

word or character counts or representation for text classification) (Manning et al., 2008).

Baseline We follow the approach described in Zaidan and Callison-Burch (2014) for dialect identification and adapt it to build our baseline model. For each dialect, we train a 5-gram character level language model (LM) using KenLM (Heafield, 2011) with default parameters and Kneser–Ney smoothing. Then, we use the LM to assign to each sentence S, the dialect D_i that maximizes its conditional probability score $\text{argmax}_i\, P(D_i|S)$. Character-based LMs leverage subword information and are generally good for capturing particular peculiarities that are specific to certain dialects such as the use of certain clitics, affixes or internal base word structure. For example, the word prefixes أدي *Âdy*, بت *bt* and هالـ *hAl* depicted by the character n-gram LM in أديش بتخدم هالفيزا ؟ *Âdyš btxdm hAlfyzA ? 'How long is this visa good for?'* are good indicators that the dialect of the sentence might be from the Levantine region. Furthermore, character-level models mitigate the ineffectiveness of word-based LMs caused by the presence of out-of-vocabulary words (OOVs) that are prominent in dialects, due to the lack of standard orthography (Habash et al., 2012a).

4.3 Learning Features

We use a suite of features that have been used in works related to DID and text classification. These features are extracted from CORPUS-6 and CORPUS-26 without any preprocessing beyond punctuation tokenization.

Word n-grams Word unigrams are extensively used in text classification tasks. For our task, we extract surface word n-grams ranging from unigrams to 5-grams and use them as features. Word unigrams are useful for our DID task as they depict words unique to some dialects. As shown in Figure 2, lexical variations are prominent and could be predictive for certain regions, countries, and cities.

Character n-grams Character n-grams have shown to be the most effective in language and dialect identification tasks (Zampieri et al., 2017). For DAs, Character n-grams are good at capturing several morphological features that are distinctive between Arabic dialects, especially the clitical and affixal use (as described in section 3). In our experiments, we extract character n-grams ranging from 1-grams to 5-grams. We use Term Frequency-Inverse Document Frequency (Tf-Idf) scores as it has been shown to empirically outperform count weights.

		N-gram Features		Other Features	Corpus-6		Corpus-26	
		Word	**Character**		**Dev**	**Test**	**Dev**	**Test**

Table 3: Accuracy on the dev and test sets for both CORPUS-6 and CORPUS-26. The n-grams features show the n-gram orders for word and characters in the MNB models.

Language model probability scores We train n LMs each pertaining to the n dialects, on CORPUS-6 and CORPUS-26. We score the sentences in the TRAIN, DEVELOPMENT and TEST sets, using these LMs. Then, we use the probability scores of the sentence as features. Thus, each sentence will have n probability scores, one for each dialect. The probability scores measure how close each sentence is to the dialect. We experiment using probability scores from word 5-grams LM, character 5-gram LM, and adding both as features.

4.4 Evaluation Metrics

We report the results on CORPUS-6 and CORPUS-26 using the *accuracy* metric, which calculates the percentage of the sentences whose dialect is correctly predicted. We also report the precision, recall and F_1 scores metrics for our best systems on both corpora. The scores are calculated per class for our best system, which can provide a better understanding on the confusability of the classes and sensitivity of our model.

4.5 Results

In this section, we present the results of the different MNB models and compare them to the baseline. In Table 3, we report the results on the DEVELOPMENT and TEST sets for both CORPUS-6 and CORPUS-26 using the accuracy metric. First, we analyze the use of n-grams as features for our MNB model and the effect of increasing the n-gram order on the accuracy of the model. Training the MNB classifier on character n-grams (rows b. to f.) shows an increase in the accuracy on the DEVELOPMENT and TEST set of both corpora, when increasing the n-gram order. A steep increase is observed from unigrams to trigrams, while it diminishes from 4-grams to 5-grams. We hypothesize that the morphological features in the words' structure are well captured within character LMs.

However, increasing the word n-gram order has a negative effect on the system's accuracy (rows g. to k.). It results in a decrease of one and two accuracy points on CORPUS-6 and CORPUS-26 respectively, as we add higher order n-gram features on the top of unigrams. Still, the of use word unigrams features alone (row g.) is able to beat 1-to-5-grams character features (row f.)

We experiment with different combinations of word and character n-grams features. Our best combination is the one using word unigrams with character unigrams, bigrams and trigrams (row l.). Yet, this combination could not outperform the 5-gram LM baseline (row a.) for both CORPUS-6 and CORPUS-26, which emphasizes the power of LMs and align with previous results on language and dialect identification. This important result suggests adding LM probability scores as features to our model. Adding

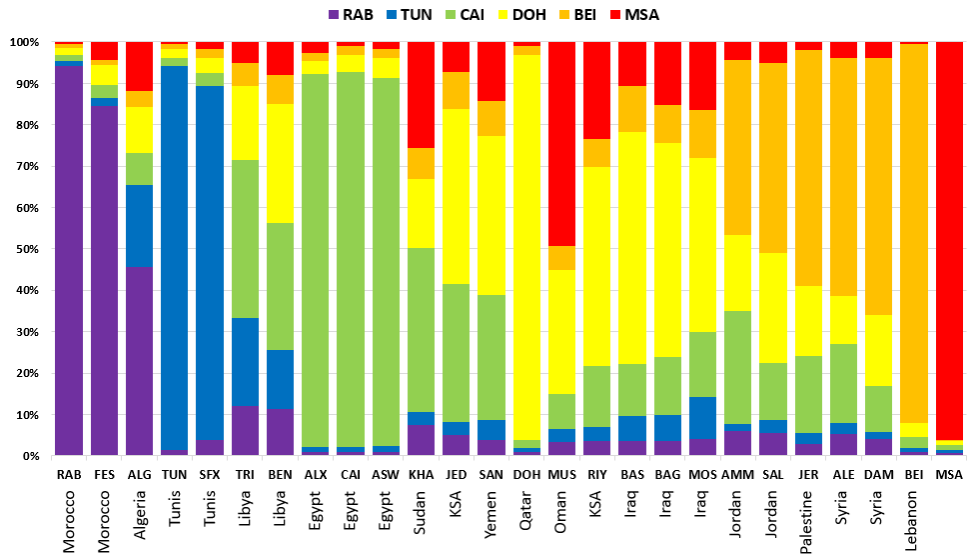

Figure 3: Confusability patterns of our 26 dialects in terms of the best MODEL-6 system.

LM scores (row m.) improves the accuracy on CORPUS-6 while it hurts the system on CORPUS-26. This can be attributed to the small size of CORPUS-26 TRAIN data used to train the 5-gram LM and the large number of classes. However, adding 5-gram character LM scores as features (row n.) beats the baseline scores (row a.). The accuracy is further improved when we include 5-gram word LM scores.

CORPUS-26 TRAIN is considered small with a large number of labels. We can make use of CORPUS-6 MODEL for providing evidence about the region that sentences of CORPUS-26 belong to. Our intuition is that sentences from CORPUS-26 can be weighed by how close to the five main cities and MSA in CORPUS-6. Thus, we train a model on CORPUS-6 TRAIN and run it on CORPUS-26 TRAIN, DEVELOPMENT, and TEST. We use the six probability scores generated by CORPUS-6 MODEL, each corresponding to a probability of the dialect given a sentence from CORPUS-6, as extra features to train CORPUS-26 model. The combination of these features with features from row (o.) resulted in the best performance of our model among all the experiments. Overall, our best CORPUS-6 and CORPUS-26 models achieve a 12% and 9% relative error reduction rate over the character Language Model baseline respectively.

5 Analysis and Discussion

5.1 Dialect Confusability and Identifiability

In this section, we present an analysis of the MODEL-6 *Classifier Probability* features that gave us our best MODEL-26 system results. In Figure 3, we show the average probability distribution of MODEL-6 for the sentences in CORPUS-26 TRAIN. The colors in the columns refer to the probability of assigning a specific MODEL-6 label from the six dialects we consider as *anchors*. The 25 cities are organized in a general West-to-East order, with some exceptions: we start from Rabat in the west and head to Alexandria; then we go up the Nile to southern Egypt and Sudan and jump over the Red Sea to the south of the Arabian Peninsula; then we head north through Iraq and visit the Levant ending in Beirut. MSA is presented at the end by itself. The first thing we observe is that there is general anchor-dialect diffusion pattern: e.g., the Rabat-ness is strong in Rabat, but it fades away in Algiers as more Tunis-ness sets in. Another example is how cities in the South Levant (Amman, Salt, Jerusalem) seem to have less of the Beirut-ness which strongly marks North Levantine cities, and more of Cairo-ness and Doha-ness. These confusability patterns correlate with geography independently of any pre-design of the data sets is a very interesting result. But furthermore, these patterns are valuable as unique *identifying* markers that help distinguish among the fine-grained 26-labels in CORPUS-26. It suggests that in the future as we go into more fine-grained distinctions, we can rely on a small number of anchors to help with identifiability through patterns of confusability.

5.2 Region Level Identification

Dialect	Precision	Recall	F_1

Average	94%	94%	94%

Table 4: Results in terms of Precision, Recall and F_1 of our best model on the CORPUS-26 and CORPUS-6 test sets.

The upper part of Table 4 presents the precision, recall and F1 score for the 25 dialects, in addition to MSA from the best MODEL-26 system, ordered by F1 score. It is interesting to note that the top four cities classified with F1 scores ranging between 77% and 86% (MOS, ALG, TRI, ALX) are not members of CORPUS-6. Also, the dialects of CORPUS-6 keep the same relative order when classified using MODEL-26, that they have in MODEL-6 (See the bottom part of Table 4), but with Cairo lagging behind.

Upon examining the full confusion matrix (which we do not show in this paper), we observed two phenomena: (i) most confusion patterns tend to be bigger within limited geographical regions, e.g., Baghdad is more confused with other Iraqi cities, than with Maghreb (i.e., RAB, FES, etc.) or Egyptian cities (ALX, ASW, CAI); (ii) some cities are predicted a lot more than others, with Damascus being the most predicted (281 times) compared to Cairo (162 times). The most predicted cities tended to come from bigger regions (Levant and Gulf) which are more represented in our data.

In Table 5, we present a reduced confusion matrix in which we collapse our 25 dialects into eight *regions*. The regions are geographically organized and ordered followed by MSA. Naturally, the eight-region scores are higher than the 25-dialect and MSA scores (more coarse, less labels). However, interestingly, the scores are generally higher for smaller regions compared to larger regions. In the future, we will consider different methods for training varying regional granularities.

5.3 Sample Size and Optimal Classification

With more *test input* examples from the same source and the same dialect, the dialect could be determined with higher accuracy. This allows any system to get more evidence that could support the selection of one dialect over others. In this section, we present two experiments to measure the effect of increasing the length of the inputs of our test set by: (i) adding additional sentences, and (ii) adding additional words.

The main goal of these experiments is to answer the following question: how many sentences or words are needed on average to guarantee an optimal classification into a certain dialect? To answer this, we run CORPUS-26 MODEL on CORPUS-26 TEST.

For each sentence having an incorrectly predicted dialect label, we sample a sentence from the subset of sentences belonging to its correct dialect class and append it to it. We keep randomly sampling sentences until the system correctly predicts the right label. Interestingly, on average, it takes 1.52 sentences to predict the right class of a given sentence. With more examples of text by a writer, our system can confidently determine the correct dialect of the writer with a high accuracy reaching 100%.

Our CORPUS-26 has short sentences with an average length of seven words per sentence. The corpus includes sentences that are common among several dialects such as صباح الخير *SbAH Alxyr* 'good morn-

	MAG	TUN	LIB	EGY	GLF	IRQ	LEV	MSA	Match	Predict	Gold	Prec	Rec	F1
MAG 3 (RAB, FES, ALG)	**539**	7	8	10	19	3	10	4	539	591	600	91	90	91
TUN 2 (TUN, SFX)	15	**356**	4	0	10	6	9	0	356	386	400	92	89	91
LIB 2 (TRI, BEN)	8	8	**308**	20	34	2	20	0	308	370	400	83	77	80

MSA 1 (MSA)	3	0	3	5	28	3	3	**155**	155	215	200	72	78	75

Table 5: Confusion matrix of MODEL-26 over eight geographical regions. Column 1 indicates the label of the region, the number of cities and the labels of the cities. The regions are (in order): Maghreb, Tunisia, Libya, Egypt and Sudan, Gulf, Iraq, Levant, and MSA.

ing'. We want to answer the question of how many words per sentence do we need in order to have an optimal classification. Given that short sentences and common phrases among dialects are less indicative of the dialect, we append the sentences in CORPUS-26 TEST with sentences randomly selected from the set with similar dialect. We continuously append each sentence until the total number of words reaches at least 65 words. We run CORPUS-26 MODEL on the modified test set over several iterations, by considering a fixed number of words at each iteration, starting from a sentence length of 1 until 60. Figure 4 illustrates the accuracy of CORPUS-26 MODEL with respect to the number of words in the sentences. It is important to note that the accuracy increases proportionally to the number of words considered in a sentences. Our system reaches an accuracy of 69.4% (compared to an accuracy of %67.9 on the original test set) using examples with fixed length of six words. We reach a score above 90% when we consider 16 words, while the optimal classification is reached using 51 words. This could be explained by the importance of longer context and its impact on improving the accuracy of the classifier.

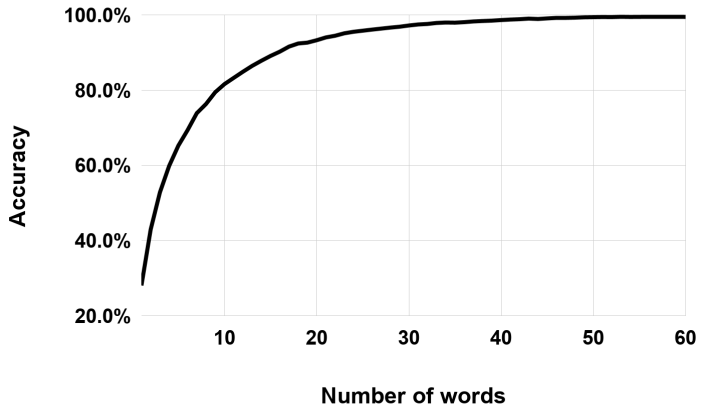

Figure 4: Accuracy on Corpus-26 with respect to the number of words in the input.

5.4 Initial Results on Classifying Tweets

The datasets we use in our experiments (CORPUS-6 and CORPUS-26) are built using a controlled approach, as dialectal translations of English and French sentences in the travel domain (Bouamor et al., 2018). We would like to evaluate the performance of our best CORPUS-6 MODEL on naturally occurring data from social media. For this, we revert to Twitter for collecting Arabic tweets using dialectal function words as seeds to guarantee that the content of the tweet is dialectal. We run CORPUS-6 MODEL on one million tweets. For each of the five cities, we retrieve the top 500 tweets predicted with a probability greater than 0.9. Each of the 500-tweets set is annotated and evaluated by an annotator who is familiar with the dialect. We evaluate the performance of CORPUS-6 MODEL on Beirut, Cairo, Doha, Tunis and Rabat dialects. We obtained an accuracy of 87.0%, 99.6%, 91.4%, 20.2%, 82.6%, respectively for each

city. The high accuracy on Cairo and Doha dialects could be explained by the large number of users who are actively using Twitter in this Arab cities.

As we noticed that the accuracy for Tunis dialect is lower than the other cities, we asked a native speaker to inspect a set of 100 tweets labeled by our system as 'Tunis'. The result obtained showed that 70% of the tweets happen to be tweets from Libya, which is the closest country to Tunisia geographically. Also, this could be explained by the fact that some of the words we consider in the "Tunis" seed list could also be used in Libya, especially that some of the Southern Tunisian dialects are structurally similar to those in close cities in the borders between Tunisia and Libya (Čéplö et al., 2016).

Overall, these initial results are encouraging and suggest a further exploration of Twitter, as it could be mined to extend CORPUS-26 in terms of size, dialects and text genres.

6 Conclusion and Future Work

In this paper, we explored the problem of Arabic DID from the typically studied variety of coarse-grained classification into a finer-grained classification problem covering 25 specific cities from the Arab World, in addition to Modern Standard Arabic (MSA). We presented a detailed analysis of dialect similarity and confusability and added interesting insights on top of the traditional map presented in the literature. We showed that using our best model, we can identify the exact city of a speaker at an accuracy of 67.9% for sentences with an average length of 7 words (a 9% relative error reduction over the state-of-the-art technique for Arabic dialect identification) and reach more than 90% when we consider 16 words. We also showed that a model trained on a commissioned dataset can be used to classify sentences in a corpus of naturally occurring dialectal sentences appearing in social media platforms such as Twitter.

In the future, we plan to explore DID for social media text and improve our model to deal with its complexities. We also plan to experiment on multi-level hierarchical classification, by classifying into regional, subregional and then city level.

Who Feels What and Why?
Annotation of a Literature Corpus with Semantic Roles of Emotions

Abstract

Most approaches to emotion analysis in fictional texts focus on detecting the emotion expressed in text. We argue that this is a simplification which leads to an overgeneralized interpretation of the results, as it does not take into account who experiences an emotion and why. Emotions play a crucial role in the interaction between characters and the events they are involved in. Until today, no specific corpora that capture such an interaction were available for literature. We aim at filling this gap and present a publicly available corpus based on Project Gutenberg, REMAN (Relational EMotion ANnotation), manually annotated for spans which correspond to emotion trigger phrases and entities/events in the roles of experiencers, targets, and causes of the emotion. We provide baseline results for the automatic prediction of these relational structures and show that emotion lexicons are not able to encompass the high variability of emotion expressions and demonstrate that statistical models benefit from joint modeling of emotions with its roles in all subtasks. The corpus that we provide enables future research on the recognition of emotions and associated entities in text. It supports qualitative literary studies and digital humanities. The corpus is available at http://www.ims.uni-stuttgart.de/data/reman.

Title and Abstract in German

Wer fühlt was und warum?
Annotation eines Literaturkorpus mit Semantischen Rollen von Emotionen

Die meisten Ansätze in der Emotionsanalyse in Literatur beschränken sich auf die Erkennung der Emotion. Wir nehmen in dieser Arbeit an, dass dies eine starke Vereinfachung darstellt. Es wird ignoriert, welche Figur die Emotion empfindet und wodurch sie ausgelöst wurde. Dies ist ungünstig, da Emotionen eine entscheidende Rolle bei der Interaktion zwischen Figuren und mit Ereignissen spielen. Allerdings war bisher kein annotiertes Korpus verfügbar, welches all diese Komponenten erfasst. In diesem Aufsatz präsentieren wir das Korpus REMAN (Relational EMotion ANotation), welches diese Lücke füllt. Es basiert auf Ausschnitten von Texten aus dem Projekt Gutenberg, welche auf Phrasenebene mit Emotionen sowie dem Empfindenden, dem Ziel sowie der Ursache der Emotion annotiert sind. Wir präsentieren eine Analyse des Korpus und stellen erste Ergebnisse eines automatischen Vorhersagemodells vor, welches die Grenzen von Wörterbuch-Verfahren aufzeigt. Des Weiteren zeigen wir, dass statistische Modelle von einer gemeinsamen Modellierung der verschiedenen Teilaufgaben profitieren. Unser Korpus unterstützt die Literaturwissenschaften sowie digitalen Geisteswissenschaften und ermöglicht die Erstellung von Modellen zur feingranularen automatischen Vorhersage von Emotionen. Das Korpus ist verfügbar unter http://www.ims.uni-stuttgart.de/data/reman.

Proceedings of the 27th International Conference on Computational Linguistics, pages 1345–1359
Santa Fe, New Mexico, USA, August 20-26, 2018.

1 Introduction

Emotions are one of the crucial aspects of compelling narratives (Oatley, 2002; Ingermanson and Economy, 2009; Hogan, 2015). Not only do emotions help readers in literature comprehension (Barton, 1996; Robinson, 2005) but they also improve readers' abilities of empathy and understanding of others' lives (Mar et al., 2009; Kidd and Castano, 2013). This makes literature an interesting resource for the study of emotions, hence there is a growing interest in emotion-oriented text analysis among digital humanities scholars.

Emotion analysis and classification is a challenging task which has mostly been tackled with comparably straight-forward approaches, at least in literary studies. For instance, Kim et al. (2017) and Reagan et al. (2016) show that emotions, recognized with dictionaries or bag-of-words models, serve as features for genre classification in fiction, however, only with limited performance. One reason is, presumably, that such approaches assume linearity of the story and ignore the semantic role structure of emotions: who feels the emotion and why, what caused the emotion, what is the target of it (Scarantino, 2016; Russell and Barrett, 1999). Consider the sentence "*Jack is afraid of John because John has a knife*". Following structural approaches to defining emotional episodes, the sentence can be rephrased as "emotion of fear is experienced by Jack (experiencer) because John (target) has a knife (cause)". Here, dictionary-based or bag-of-words approaches would probably capture that this sentence describes fear, however, would fail in attributing correct semantic roles to John and Jack and we would be forced to assume that their emotional experiences are equal, which is not the case.

To overcome these limitations of dictionary-based and bag-of-words approaches to emotion recognition from literary text, we contribute the corpus REMAN (Relational Emotion Annotation). To the best of our knowledge, this is the first dataset of literary excerpts which has annotations for emotions on a phrase level, for experiencers of each emotion, and for their targets and causes. Our work loosely follows the concept of directed emotions, as defined in FrameNet (Fillmore et al., 2003), and extends the work of Ghazi et al. (2015), who focus on detecting emotion stimulus in the FrameNet exemplary sentences annotated for emotions and causes. Our study is different in terms of the type of texts used for the annotation and the conceptualization of certain emotion components.

Our main contributions are therefore: (1) We present the first resource of fictional texts annotated for emotions, experiencers, causes, and targets. (2) We show that emotion annotation that takes into account not only strong emotion indicators ("afraid"), but also implicit emotions ("shaking fingers") is valuable for the study of the language of emotions. (3) We provide results of baseline models to predict emotion words and roles separately and (4) show that the prediction performance of all subtasks benefits from joint prediction of experiencer, emotion words, and targets.

2 Related Work

Emotions have strong linguistic markers that define the tone of the text (Johnson-Laird and Oatley, 1989). This allows for different granularities of emotion annotation. The corpus which originates from the ISEAR project (Scherer and Wallbott, 1994) is an example of document-level annotation that includes descriptions of situations in which respondents had experienced various emotions. Examples of sentence-level annotations include the work by Alm et al. (2005), who annotate a corpus of children stories, and Strapparava and Mihalcea (2007), who label news headlines, but without specifying the textual markers of emotion. An early work which includes textual markers of emotions is Aman and Szpakowicz (2007), who annotate blogposts. Wiebe et al. (2005) annotate a corpus of news articles with emotions at a word and phrase level.

Recent works have mainly diverged from plain emotion annotation, following the idea of emotion theorists (Russell, 2003, *i.a.*) that causes of emotions are inseparable from emotions: Russo et al. (2011) build a corpus of Italian newspaper articles annotated with emotion key words and emotion cause phrases. Both Mei et al. (2012) and Gui et al. (2016) construct emotion-cause-annotated corpora for Chinese. Chen et al. (2010) adopt a rule-based approach based on linguistic patterns to detect emotion causes in the annotated Chinese corpus. Gui et al. (2017) present a question-answering approach to emotion cause extraction, also for Chinese.

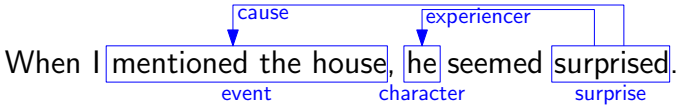

Figure 1: Example annotation from Hugo (1885), with one character, an emotion word, and event and cause and experiencer annotations.

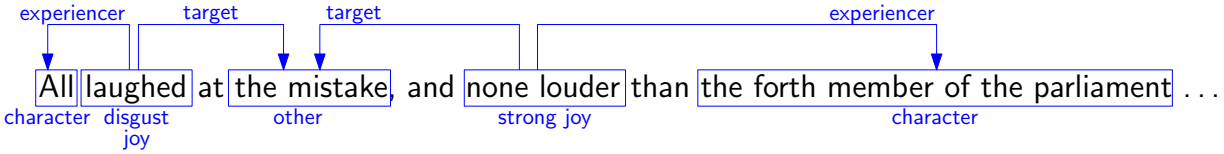

Figure 2: Example annotation from Stimson (1943), with two characters who are experiencers of different emotions. Disgust and joy are annotated as a mixture of emotions. Both emotions have the same target.

Fewer works exist for English. Neviarouskaya and Aono (2013) annotate 500 sentences from an online forum with experiencer, emotion, and emotion cause and present a method for extracting linguistic relations between an emotion and its cause. Ghazi et al. (2015) collect exemplary sentences from FrameNet that have cause annotation and implement a model that extracts the causes of emotions. Following a similar approach, Mohammad et al. (2014) annotate Tweets for semantic roles.

Conceptually, our work partially overlaps with the FactBank corpus (Saurí and Pustejovsky, 2009), where "who thinks what" is taken into account as well. However, in contrast to FactBank, we do not predefine event-selecting predicates for emotion causes and targets, as those are defined by the annotators. In this sense, our work is also different from aspect-based sentiment analysis, where aspects of reviewed products are often predefined.

3 Annotation Task

The goal of the REMAN annotation project is to create a dataset of excerpts from fictional texts that are annotated for the phrases that lead to the association of the text with an emotion, the experiencer of the emotion (a character in the text, if mentioned), the target and the cause of the emotion, if mentioned (*e. g.*, an entity, or event). An example of such an annotation is shown in Figures 1 and 2. As it can be seen from these depictions, each annotation includes textual span annotations such as emotions, characters, events, as well as relation annotations that establish relations between different text spans (cause, experiencer, target). In the following, we describe the conceptual background for each annotation layer in detail. The complete annotation guidelines are available online together with the corpus.

3.1 Phrase Annotation

3.1.1 Emotion

We conceptualize emotions as one's experience that falls in the categories in Plutchik's classification of emotions, namely *anger*, *fear*, *trust*, *disgust*, *joy*, *sadness*, *surprise*, and *anticipation*. In addition, we allow annotation with the class *other emotion* that covers cases when the emotion expressed in the text cannot be reliably categorized into one of the predefined eight classes. A list of the emotions along with example realizations can be found in Appendix A, Table 5.

Annotators are instructed to prefer span annotations of key words (*e. g.*, "afraid"), except cases when emotions are only expressed with a phrase (*e. g.*, "tense and frightened") or indirectly (*e. g.*, "the corners of her mouth went down"). Additionally, emotion spans are marked to be intensified (*i. e.*, amplified), diminished (*i. e.*, downtoned) and negated without marking the modifier or including the modifier. Each span is associated with one or more emotions (exemplified in Figure 2).

3.1.2 Entity

We conceptualize entities as mentions of something that has a clear identity of a person, object, concept, state, or event (see Table 6 in Appendix A). Entities are only annotated if they are experiencer, cause, or target of an emotion.

Character An entity that acts as a character in the text. Character annotation should not omit important information (*e. g.*, the annotation of "the man with two rings of the Royal Naval Reserve on his sleeve" is preferred over only annotating "the man").

Event An event is an occasion or happening that plays a role in the text. Events can be expressed in many ways (see Table 6 in Appendix A for examples from the annotated dataset) and annotators are instructed to label the entire phrases including complementizers or determiners.

Other This is an umbrella concept for everything else that is neither a character nor an event, but fills as relation, described in the following.

3.1.3 Relation Annotation

Relations are semantic links between an emotion and other text spans and can be of type *experiencer*, *cause*, and *target*. In addition, we partially annotate *coreferences* to link personal pronouns to proper nouns. All relations, except Coreference, can only originate from the emotion annotations.

Experiencer The experiencer relation links an emotion span and entity of type *character* who experiences the emotion. If the text contains multiple emotions with multiple experiencers, they all are subject to relation annotation.

Target The target relation links an emotion span and entity of any type towards which the emotion experienced by the experiencer is directed. If there are multiple targets of the emotion, then all of them should also be included in the relation annotation. See Figure 2 for the example of a target annotation.

Cause The cause relation links an emotion span and entity of any type, which serves as a stimulus, something that evokes the emotional response in the experiencer. If there are multiple causes for the emotion, then all of them are included in separate relation annotations.

Coreference The annotators are instructed to annotate as an experiencer the character that is the closest to the emotion phrase in terms of token distance. If the closest mention of the character is a pronoun and the text provides a referent that has a higher level of specificity than the pronoun (*i. e.*, a proper noun or a noun denoting a group or class of objects), then the annotators are asked to resolve the coreference.

4 Corpus Construction and Annotation

4.1 Selection

The corpus of 200 books is sampled from Project Gutenberg[1]. All books belong to the genre of fiction and were written by authors born after the year 1800. More detailed information on the distribution of authors and genres can be found in Appendix B.

We sample consecutive triples of sentences from this subsample of books. A triple is accepted for inclusion for annotation if the middle sentence includes a word from the NRC dictionary (Mohammad and Turney, 2013). We consider this middle sentence the target sentence and the annotators are instructed to label emotions in this second sentence only. Experiencers, causes and targets are annotated in the whole sentence triple if they refer to an emotion in the target sentence.

The sampling procedure is motivated by our observation that triples of sentences sampled with emotion dictionary show the best coverage in terms of the roles that are associated with the emotion. Ghazi et al. (2015) annotate only one sentence and speculate whether adding one sentence before and after will lead to better results. To check their hypothesis, we conduct a small pre-study experiment by extracting 100 random sentences from the Project Gutenberg with the NRC dictionary and analyze how often the roles of experiencer, cause, and target are found in the target sentence and in the window of up to five sentences before and after. The analysis shows that 98% of the texts include the experiencer in the target

[1] http://www.gutenberg.org/

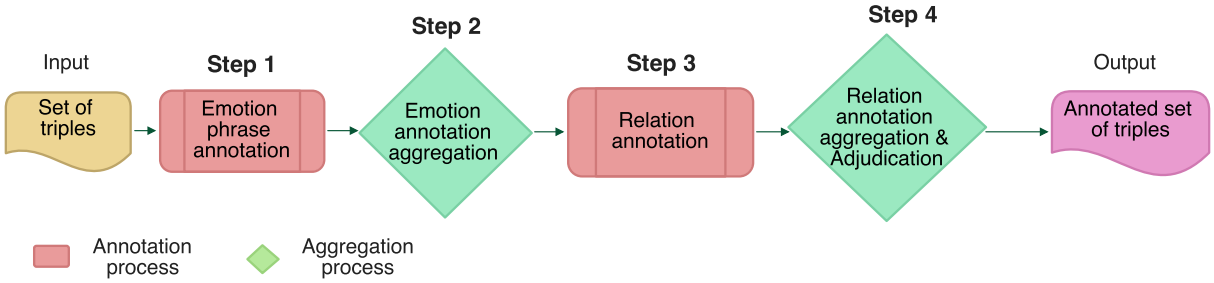

Figure 3: A visualization of the multi-step annotation process.

sentence, while cause and target is found in the target sentence in 67% of the texts. Another 29% of the texts include cause and target in the window of one sentence before and after the target sentence. The remaining texts include cause and target in the window of two (2%), three (1%), and four (1%) sentences around the target sentence. We therefore opt for three-sentence spans as they provide enough information regarding "who feels what and why" without creating unnecessary annotation overhead (cumulatively, 96 % of cause and target are found in such sentence triples).

4.2 Annotation Procedure

The annotations were generated in a multistep process, visualized in Figure 3. The people involved in the annotation were either *annotators* or *experts*, whose roles did not overlap. The annotations (of spans and relations) were performed by three graduate students of computational linguistics (two native English speakers, one non-native speaker) within a three-month period. Arising questions were discussed in weekly meetings with the experts (the authors of the paper) and the results documented in the annotation guidelines. We used WebAnno[2] (Yimam et al., 2013) as annotation framework. In the following, we discuss the four steps of generating the corpus.

Step 1: Emotion phrase annotation The *annotators* were asked to first decide whether the text expresses an emotion and which emotion that is. If any exists, they label the phrase, which led to their decision. The annotators were instructed to search for emotions that are expressed either as single words or phrases.

Step 2: Emotion phrase aggregation In the previous step, each annotator generates set of annotations. In this step, the *expert* heuristically aggregates all spans that overlap between annotators in a semi-automatic process: Concrete emotions are preferred over the "other-emotion", annotations with modifier are preferred over annotations without, and shorter spans are preferred over longer spans. Overlapping annotations with different emotion labels are all accepted.

Step 3: Relation annotation *Annotators* are given the same texts they annotated for emotions in Step 1 with the aggregation from Step 2 from all annotators. Therefore, all annotators see the same texts and annotations as input in this step. For each emotion, the task is to annotate entities that are experiencers, targets, or causes of the emotion and establish relations between them. The annotators were instructed to tag only those entities that have a role of an experiencer, cause, and target. The decision on the entity and relation annotation is made simultaneously: For each emotion the annotators find who experiences the emotion (which *character*) and why (because of event, object, or other character).

Step 4: Relation annotation aggregation and adjudication This final step is a manual *expert* step: Aggregate the relation annotations provided by the annotators. Heuristically, we prefer shorter spans for entities, but guide ourselves with common sense. For instance, consider the phrase "[. . .] *wishing rather to amuse and flatter himself by merely inspiring her with passion*". "*Wishing*" is labelled as emotion. One annotator tagged "*to amuse and flatter himself by merely inspiring her with passion*" as event, another tagged only "*by merely inspiring her with passion*", which is incomplete, as the target of the emotion is the act of amusing and flattering oneself.

Note that we do not discard the rejected annotations but publish all annotations of all annotators.

Table 1: Pairwise inter-annotator agreement for the phrase annotation and relation annotation. F_1 is in %. Regarding the relation scores, in strict F_1, a TP holds if the relation annotation is the same and the entity it points to has the same label and span. In fuzzy F_1, a TP holds if the relation annotation is the same and the entity it points to is the same, but the span boundary of the entity is not necessarily the same.

5 Results

In the following, we first discuss annotation statistics and then provide results of baseline models trained on our resource.

5.1 Inter-annotator Agreement and Consistency of the Annotations

We use pairwise Cohen's Kappa coefficient (κ) on the token level and F_1 on a phrase level with exact and fuzzy match to calculate the agreement of the phrase annotation and F_1 to estimate the agreement of the relation annotation. For F_1 calculation, we use two approaches: strict that requires labels and spans to be identical, and fuzzy that accepts an annotation to be a true positive if the annotations of two annotators overlap by at least one token. Table 1 reports the agreement scores for emotion, entity, and relation annotations between each pair of annotators.

Joy has the highest number of instances (336) and the highest agreement scores (average $\kappa = 35$), followed by *fear* ($\kappa = 0.30$) and *sadness* ($\kappa = 0.24$). *Other emotion* has the lowest agreement with average $\kappa = 0.07$. For entity annotation, especially for *character* annotation, the agreement is higher, with the highest agreement between two annotators being $\kappa = 0.63$. The agreement on the *event* and *other* entities is low ($\kappa = 0.23$ and 0.14 and $F_1 = 25$ and 14, respectively). This is presumably the case because event annotations are often comparably long. This also holds, to a lower extend, for *character* annotations. If we allow partial overlaps to count as a match, the average F_1 increases to 57 for *character* (an increase of 4 percentage points (pp)), 44 for *event* (increase by 19 pp), and 23 for *other* category (increase by 9 pp).

For relation annotations, higher agreement scores are also observed with fuzzy evaluation (F_1 increase for *experiencer*, *cause* and *target* by 10 pp, 7 pp, and 12 pp respectively). These results are in line with previous studies on emotion cause annotation (Russo et al., 2011), and show that disagreements mainly come from the different spans of the entities, though they overlap.

5.2 Difficulties with Measuring IAA

As we showed in Section 5.1, the agreement across all annotation layers is comparably low. There are several reasons for that. Indeed, emotion annotation is highly subjective, but it is not the only subjective category. The cause and target of the emotion are not always clearly recognizable in the text and are also

	Type	Total	Adjudic.	Modifier strong	weak	neg.	Annotation Length 1 token		≥ 2 token		in NRC1		in NRC2

Table 3: Corpus statistics for relation annotation. Columns indicate the number of times each role was assigned to an entity and how often the respective emotions are in relation to the entity.

subjective categories (two annotators may find two different causes for the same emotion), hence the low agreement scores across all categories. The only exception are *experiencer* annotations, which are the most reliable among all annotations and match the substantial agreement scores of character annotation (the only type of entities that can be involved in an experiencer relation).

We illustrate the difficulties the annotators face when annotating emotions with roles with the following example: "they had never seen ... what was really hateful in his face; ... they could only express it by saying that the arched brows and the long emphatic chin gave it always a look of being lit from below ..." All annotators agree on the character ("they") and the emotion ("hateful" expressing disgust). Similarly, both annotators agree that the disgust is related to properties of the face which is described, however, one annotator marks "his face" as target, the other marks the more specific but longer "the arched brows and the long emphatic chin gave it always a look of being lit from below" as cause.

If we abstract away from the text spans, both annotators agree that the emotion of disgust has something to do with "his face", however they disagree on the target annotation and the cause annotation. So, though conceptually, the annotations by two people are similar, this is not captured by our calculation of inter-annotator agreement.

5.3 Corpus Details

Tables 2 and 3 show the total number of annotations for each category. The REMAN corpus consists of 1720 sentence triples, 1115 of which include an emotion. For the emotion category, *joy* has the highest number of annotations, while *anger* has the lowest number of annotations. In most cases, emotion phrases are single tokens (*e. g.*, "monster","irksome"), out of which 47% on average are found in the NRC dictionary. *Other emotion* has the largest proportion of annotations that span more than one token (36% out of all annotations in this category), which is in line with our expectation that lower levels of specificity for emotion annotation make it more difficult to find a single token that indicates an emotion.

For entities, *character* has the highest number of annotations. As one can see, the *experiencer* relation dominates the dataset (48%), followed by *target* (28%) and *cause* (24%) relations. Note that each character can experience more than one emotion, hence the difference between the number of characters and the experiencers. Table 3 also shows how many times each emotion triggered certain relation. In this sense, *joy* has triggered the most *experiencer* and *cause* relations, which is still related to the prevalence of the annotations for this emotion in the dataset.

6 Baseline Model

We provide a baseline for automatically predicting the structures we annotated. For this first model, we map the relations to span prediction tasks. This is feasible because characters, entities, and other were only annotated if they fill one of the roles, *experiencer*, *target*, or *cause*. Therefore, the prediction task boils down to a sequence prediction task of emotion phrases (for the different emotions) and the potential mentions of experiencers, targets, and causes. Note that we lose the actual relation information in this simplification.

Consider the example depicted in Figure 1: The phrase "I mentioned the house" is labelled as an event and is assigned a role of a *cause* for the emotion of *surprise*, and the word "he" is labelled as a character and is assigned a role of an *experiencer* of the same emotion. We represent these relationships by tagging "I mentioned the house" as *cause* and "he" as *experiencer* using inside-outside-beginning (IOB) encoding capturing the text spans that are linked by relations with an emotion.

We use two sequence labelling models, conditional random fields (CRF) (Lafferty et al., 2001) and bidirectional long short-term memory networks with a CRF layer (biLSTM-CRF), which both provide a good performance in sequence prediction tasks (Benikova et al., 2014; Huang et al., 2015). In addition, we analyze the difficulty of predicting the emotion for a full sentence triple, independent of segments. In the following, we further specify the experimental setting in detail.

6.1 Experimental setting

Experiment 1: Coarse-grained emotion classification In this experiment, the task is to classify the emotions which occur in the sentence triple which forms the instance under consideration. This is therefore a coarse abstraction of the structured prediction tasks presented in this paper. However, this constitutes the most straight-forward task in emotion analysis. We use a dictionary-based approach and a bag-of-words-based classifier.

For the dictionary-based classification, we take the intersection between the words in the triple and NRC dictionary and assign the triple with the corresponding emotion labels. The F_1 score is calculated by comparing the set of labels predicted by dictionaries against the set of gold labels for each triple. The gold labels come from the annotation of words and phrases within each triple. For the BOW approach, we convert each triple into a sparse matrix using all words in the corpus as features. We then classify the triples with a multi-layer perceptron with three hidden layers, 128 neurons each, with an initial learning rate of 0.01 that is divided by 5 if the validation score does not increase after two consecutive epochs by at least 0.001.

Experiment 2: Fine-grained emotion and role detection In this experiment, we evaluate the performance of fine-grained emotion and role (experiencer, target, and cause) prediction in a sequence labelling fashion, as described above. We instantiate separate CRF and biLSTM-CRF models for each relation, as

Category	Annotations	Exp	Model	Features	Strict			Fuzzy		
					P	R	F_1	P	R	F_1

Table 4: Results in % for the baseline experiments. F_1 for *cause* with CRF and biLSTM-CRF and for *target* with biLSTM-CRF is zero and therefore not shown here. The column Exp refers to the experimental settings described in Section 6.1.

some annotations overlap (*e. g.*, experiencers can also be targets/causes). The CRF uses part-of-speech tags (detected with spaCy[3] (Honnibal, 2013)), the head of the dependency, if it is capitalized, and offset conjunction with the features of previous and succeeding words as features. For the *emotion* category, we use the presence in the NRC dictionary in addition and, for *experiencer*, the presence in a list of English pronouns. We train for 500 iterations with L-BFGS (Liu and Nocedal, 1989) and L1 regularization.

The biLSTM-CRF model uses a concatenated output of two biLSTM models (one trained on word embeddings with dimension 300, and one trained on character embeddings from the corpus with dimension 100) as an input to a CRF layer. The word embeddings that we use as input are pre-trained on Wikipedia[4] using *fastText*. We use Adam as activation function, a dropout value of 0.5, and train the model for 100 epochs with early stopping if no improvement is observed after ten consecutive epochs.

Experiment 3: Potential for joint modelling of emotion and role prediction The goal of this experiment is to understand if joint modelling of relations has the chance to contribute over learning each relation separately. To that end, we analyze the potential interactions between predictions with gold labels of all other predictions. Specifically, when training our models, we provide the classifier with the information which sequence of tokens is an experiencer (in the case of emotion phrase prediction) and which sequence of tokens is an emotion (in case of experiencer, cause, and target detection).

6.2 Results and Discussion

The results of all the experiments are summarized in Table 4. We evaluate our models in the same way we use F_1 for inter-annotator agreement: Firstly, by accepting a TP if it is exactly found (exact) and secondly, if at least one token is overlapping with the annotation (fuzzy).

Experiment 1 Emotion classification with dictionaries and bag of words show mediocre performance. The recall with the dictionary classification is comparably high ($F_1 = 83$), which is due to the fact that texts were sampled using these dictionaries. However, as we said earlier, annotators are free to label any words and phrases as emotion-bearing, hence low precision and F_1 score. The MLP with BOW features does not perform better but shows increased precision at the cost of lower recall. A possible reason is that each triple may contain only one word that expresses the emotion with the rest of the words being neutral.

Experiment 2 As results of this experiment show, the recall is low for all categories. A presumable reason is, as discussed in Section 5, that substantial number of emotion annotations are words or phrases that are not found in the NRC dictionary. On average, only 46% of emotion annotations are single tokens

[3] `https://spacy.io/`

[4] As available at `https://github.com/facebookresearch/fastText` (Bojanowski et al., 2017)

that can be found in the NRC dictionary, but for some emotions this number is much lower (only 14% of *anticipation* annotation). The same applies to cause and target categories, as in most cases these are long spans of text (*e. g.*, 94% of events are multiword expressions). This explains zero F_1 score for cause prediction with CRF and biLSTM-CRF and a better performance for target prediction with CRF, taking into account that most target relations is triggered by characters, 75% of which are single tokens (see Table 3).

The highest precision and F_1 across all categories is observed for the *emotion* category with biLSTM-CRF (strict $F_1 = 43$ and fuzzy $F_1 = 48$). The strict F_1 is by 12 pp higher than predicted with dictionaries and with BOW in text classification experiment.

The *experiencer* category is second best, however, the recall for this category is still very low. This can be explained by the fact that experiencers are expressed in the text mostly as personal pronouns. As far as the number of personal pronouns in our texts is relatively low (13% of all tokens in a sentence on average), and only a small fraction of them act as experiencers ($< 1\%$ of all tokens in a sentence on average), the classifier cannot learn when an entity is an experiencer or not.

Experiment 3 The goal of this experiment was to estimate if joint modelling of emotion and roles is feasible. We observe that, for the *emotion* category, F_1 increases by 5 pp in strict and by 9 pp in fuzzy evaluation if we provide the classifier with the information, which sequence of tokens is an *experiencer*. For *experiencer* prediction, F_1 increases by 20 pp in strict and by 22 pp in fuzzy evaluation if we tell the classifier which word or sequence is labelled as emotion. These results indicate the complementarity of both categories. A qualitative study on a subsample of linguistic properties of emotions and experiencers shows that when the emotion expression and experiencer are parts of the same phrase (verb or adjectival phrase), the emotion word serves as a head to the word that represents an experiencer. Hence, the classifier is able to partially learn that any phrase that is a part of the emotion phrase, whose head is a personal pronoun or a proper name, is a potential *experiencer*.

The same applies to *experiencer*: if the head of the governing phrase is an emotion, then the head of the current phrase is a potential *experiencer*. However, due to variability of emotion expressions, this cannot always be the case.

7 Discussion, Conclusion, and Future Work

As evaluation of inter-annotator agreement and sequence labelling results of the baseline model show, the task of annotating emotions and corresponding roles, as well as their subsequent prediction is a difficult one. A high variability of emotion expressions (see Table 5) and a variability of cause and target expressions make it hard. At the same time, the resource we present provides interesting and valuable insights in the language of emotion expression and, therefore, is useful to the community of linguists who are interested in the study of linguistic properties of emotions.

However, we also note that developing such a resource has its limitations: Due to the subjective nature of emotions, it is challenging, if not impossible, to come up with an annotation methodology that would lead to less disparate annotations, especially if in addition to emotion, other categories should be annotated together with roles. That is in line with previous research. For instance Schuff et al. (2017) and Russo et al. (2011) found that aggregating labels by multiple annotators without a majority vote procedure but by merging is easier to model computationally.

We tackle this problem by employing a multi-step procedure that helps to improve the agreement of the relation annotation. This does not help in the emotion annotation itself, but helps in the role assignment. The introduction of our multi-step annotation procedure lead to an increased inter-annotator agreement for *experiencer* and *cause* annotations by 13 pp and 5 pp in strict evaluation. This indicates that the task seems easier to annotators if they perform role assignment with predefined emotion annotations.

Another difficulty arises from the nature of the texts we work with. Fictional texts are highly metaphoric and full of allusions and metonymies, which requires thoughtful reading (often reading between the lines) and a broader context. However, this is something that our annotators do not have: all the context they have at their disposal is a triple of sentences, each of which can rely on information that is available in other parts of the book, but not in the annotation unit. Therefore, it is not always possible to annotate the

cause, target, or even the experiencer. This is a trade-off: On the one side, we did not want to annotate full books to have a representative corpus. On the other side, we might not have provided sufficient context. Future work will therefore aim at better understanding how to preselect the relevant context that is needed for reliable annotation and secondly use such knowledge for a follow-up annotation project.

Nonetheless, we are confident that the dataset we present is useful to linguists and digital humanities scholars, as it contains valuable information about complex interactions of emotions, characters, and events in fictional texts, and gives interesting insights into the language of emotion expression in general.

Last but not least, the dataset constitutes a difficult task for structured prediction, as our baseline analysis has shown. Our experiments suggest that the prediction of emotions with their roles is a task that should be tackled with joint models. Therefore, this corpus adds an interesting relation extraction task to the set of existing challenges.

A Concepts used for Phrase Annotation

Table 5 provides a list of concepts defined for the annotation of emotions, modifiers, and entities. The Examples column contains examples of annotations from the final corpus. Table 6 provides examples of linguistic realization of entities along with examples from the annotated dataset.

	Concept Value	Examples
Emotion	Anger	*angry, defend themselves by force, break your little finger, loss of my temper*
	Anticipation	*want, wish, wholly absorbed, looked listlessly round, wholly absorbed*
	Disgust	*repellent, cheap excitement, turn away from, beg never to hear again*
	Fear	*horrified, tense and frightened, shaking fingers*
	Joy	*cheerful, grateful, boisterous and hilarious, violins moved and touched him*
	Sadness	*failed, despair, the cloudy thoughts, staring at the floor*
	Surprise	*perplexing, suddenly, petrified with astonishment, loss for words, with his mouth open*
	Trust	*honor, true blue, immeasurable patience*
	Other	*careful, brave, had but a tongue, break in her voice, bit deeply into his thumb*
Modifier	strong	*I loved her the more*
	weak	*with a little pity*
	negated	*could not be content*
Entity	character	*the chairman of the board*
	event	*marry a man I did not love, because of his gold*
	other	*Lily's beauty*

Table 5: Concepts used for the phrase annotation layer.

Entity type	**Linguistic realiz.**	**Examples**
Character	noun phrase	*his son*
	adjectival phrase	*old man*
Event	verb phrase	*Mrs. Walton had got another baby.*
	adverbial phrase	*Jesus spoke unkindly to his mother when he said that to her.*
	prepositional phrase	[. . .] *giving her up.*
	clause	[. . .] *what she said to him* [. . .]
	noun phrase	*the journey*
Other	adjectival phrase	[. . .] *old age* [. . .]
	noun phrase	[. . .] *the heavens and the earth.*
	tense phrase	*She was the only treasure on the face of the Earth that my heart coveted.*

Table 6: Typical linguistic realization of entities.

Abstract

We show that the general problem of string transduction can be reduced to the problem of sequence labeling. While character deletions and insertions are allowed in string transduction, they do not exist in sequence labeling. We show how to overcome this difference. Our approach can be used with any sequence labeling algorithm and it works best for problems in which string transduction imposes a strong notion of locality (no long range dependencies). We experiment with spelling correction for social media, OCR correction, and morphological inflection, and we see that it behaves better than seq2seq models and yields state-of-the-art results in several cases.

1 Introduction

String transduction (mapping one string to another) is an essential ingredient in the natural language processing (NLP) toolkit that helps solve problems ranging from morphological inflection (Dreyer et al., 2008) and lemmatization to spelling correction (Cotterell et al., 2014), text normalization (Porta and Sancho, 2013) and machine translation (Kumar et al., 2006).

Finite-state technology is often used with string transduction (Allauzen et al., 2007), especially when there is a strong notion of locality in the transduction problem, i.e., when there are no long range dependencies between the predicted characters. More recently, neural network methods have become more common for such problems using the seq2seq models that were introduced for machine translation (Bahdanau et al., 2015).

Similarly, sequence labeling algorithms have been the mainstay for an array of problems in NLP, including part-of-speech tagging, named entity recognition and semantic role labeling. Various models have been proposed to do sequence labeling, including conditional random fields, hidden Markov models and neural networks.

String transduction and sequence labeling are often treated as two separate entities, and indeed, usually give treatment to different problems in NLP. We claim and show that there is a great similarity between them, and that one can be reduced to the other.

Sequence labeling is often associated with a set of problems in which the set of labels is small compared to the vocabulary. Still, this labeling essentially associates each symbol (usually a word) in a sequence (usually a sentence) with a label. As such, it can be seen as a specific case of string transduction that imposes a one-to-one correspondence between input and output symbols. This is the easier side of the reduction between sequence labeling and string transduction, and it has been exploited in the deep learning literature with seq2seq models.

In this paper, we come to address the reduction in the reverse direction – i.e. *we show how to frame string transduction as sequence labeling*. We do this by decomposing the transduction process into two parts: first, we induce an alignment between the characters of the input and output strings and then we use a sequence labeling model to predict the final output of the string.

The main difficulty here is not in the size of the vocabulary compared to the label set, but the fact that string transduction can yield to arbitrary output string length compared to the input string. In machine

Proceedings of the 27th International Conference on Computational Linguistics, pages 1360–1371
Santa Fe, New Mexico, USA, August 20-26, 2018.

translation, for example, a classic example of string transduction, the sentence in the target language can be shorter, longer, and contain a significant amount of re-ordering. Indeed, re-ordering is a challenge with string transduction. A sequence labeling model usually maintains higher order of monotonicity (such as with Markovian models), while for general string transduction problems, one needs models such as encoder-decoders or grammatical models. Such expressive models, on the other hand, are *not* a good fit for string transduction problems with a strong notion of locality, as they are too complex and lead to weaker generalization power for such problems (Rastogi et al., 2016). We show this weakness in our experiments with seq2seq models supporting similar conclusions in previous work such as by Schnober et al. (2016). Our experiments show that even when seq2seq models are incorporated with hard monotonic attention (Aharoni and Goldberg, 2017), our reduction to sequence labeling outperforms such models on certain problems with a strong notion of locality.

Our approach to reduce string transduction to sequence labeling relies on a simple observation: in most cases in transduction, it is easier to *delete* a symbol than to *insert* a symbol. This is true because insertion requires identifying both the point of insertion and the character that needs to be inserted, while deletion is a "binary" decision – either the decoding algorithm chooses to delete a specific symbol or not to. A similar observation was made by Schnober et al. (2016), Rosca and Breuel (2016) and Chandlee (2014) and is also present in much earlier work by Koskenniemi (1983) and later in Chandlee (2014). String transduction is treated by Koskenniemi (1983) as a two-layer problem: two strings (a surface representation and a lexical representation) were aligned according to a set of "two-layer" handwritten rules. In this paper, we propose a similar setup to Koskenniemi's but instead, we use various sequence labeling methods to automatically create these alignments (instead of hand-engineer them). This is possible by considering the three character operations used in string transduction – *deletions*, *insertions* and *substitutions* – as tagging operations. While Koskenniemi's work was done only in the context of morphology, we extend the idea further and apply it to a wider set of problems. However, our approach, like Koskenniemi's, is for now limited to character level tasks.

Our observation leads to an approach which is simple, yet powerful. We explain it in §3 and then perform an extensive experimentation with it in various scenarios, comparing it to models such as seq2seq. We test our approach thoroughly on three string transduction problems with a strong notion of locality: social media spelling correction, optical character recognition and morphological inflection. Each problem is tested with several sequence labeling algorithms. In all cases, we find that our approach is competitive with strong baselines and in some cases outperforms them. Our approach is independent of the sequence labeling algorithm that is used, and indeed we experiment with it in conjunction with four different sequence labeling learning algorithms.

2 Problem Formulation

We give a treatment to the problem of string transduction. Given an input alphabet, Σ, an output alphabet Λ, and training data, we aim to learn a function $f\colon \Sigma^* \to \Lambda^*$ that maps input strings to output strings. The training data comes in the form of pairs of strings $(x^{(i)}, y^{(i)})$ for $i \in \{1, \ldots, M\}$. Note that the input string and output string can be of different length.

We reduce the problem of learning f to sequence labeling. With sequence labeling, we aim to learn a function $g\colon \Sigma^* \to \Lambda^*$ such that the length of $y = g(x)$ is the same as of x. This means that the training data we receive to learn g has input and output strings of the same length. With sequence labeling, $g(x)$ is referred to as the "labels" of x, as each element in x is mapped to a single element in $g(x)$ (elements from the input string are not deleted and new ones are not inserted).

Clearly, the problem of string transduction subsumes the problem of sequence labeling, as one can always try to learn a mapping f from a given training data of strings of identical length. However, there is a significant distinction that is usually made between the two, as string transduction can re-write a string into a completely different string, while sequence labeling has a stronger notion of locality.

As such, sequence labeling is considered an easier problem than general string transduction. Yet, we show in this paper how to exploit sequence labeling algorithms, with their flexibility and efficiency, to do general string transduction.

3 Transduction as Insertion and Labeling

Most approaches to string transduction involve inducing an alignment between symbols in the input and output strings (Knight and Graehl, 1998; Clark, 2001; Eisner, 2002; Azawi et al., 2013; Bailly et al., 2013). In an alignment, unaligned input symbols are called deletions, while unaligned output symbols are called insertions.

It is challenging to jointly induce alignments and learn a transduction model.

A second challenge is that, at prediction time, it is difficult to predict the insertions, as there can be an arbitrary number of them between any two input symbols. The prediction problem would be much simpler if the insertion positions were in place, because the model would only need to decide which symbol goes in each position.

Our approach is based on this idea. We decompose the transduction process into first predicting insertion positions in the input string, and then labeling the modified input string to produce the final output string. The insertion function might predict insertion positions that should not be there —we call these *spurious* insertions. In this case we rely on the labeling function to eliminate these spurious insertions. It is an easier task to *delete* a symbol than to *insert* one for string transduction. Therefore, marking the potential insertions in the string and then deleting them if necessary during decoding reduces the problem of string transduction to sequence labeling and as such allows using the Viterbi algorithm for decoding.[1] In addition, to avoid the challenge of inducing alignments, our approach relies on existing ones — for our experiments, we use the edit distance algorithm. From these initial alignments, our approach learns an insertion function and a sequence labeler, which perform string transduction when composed. This simple approach is also very flexible, because potential insertions can later be deleted. We found this approach to yield quite good alignments, as the accuracy of our algorithm when the alignment is *known* is quite high and supersedes state-of-the-art results in several cases. We now explain this technique more in detail.

3.1 Insertion Algorithm

We learn an "insertion context function" $\sigma\colon \mathbb{N} \times \Sigma^* \to \mathbb{N}$. Given a string $x = x_1 \cdots x_k$ over Σ and an index in that string (between 0 and k),[2] this function tells how many *potential* insertions could happen in that position.

For example, say we would like to transduce the string `say` from its base form to its past form `said`. The insertion context function might learn that there needs to be an insertion following the `y` that corresponds to the `d`. Therefore, the insertion function values for `say` would be:

$$\sigma(i, \texttt{say}) = 0 \qquad \forall i \in \{0, 1, 2\}$$
$$\sigma(3, \texttt{say}) = 1.$$

and therefore the string we would try to transduce to `said` would be the string `say`ε, where ε is a special symbol marking potential insertion.

Learning σ To learn σ, we use the following procedure. We first align each pair of strings in the training set using an algorithm such as edit distance (see §4.1). We then check for all contexts in which an insertion, or a sequence of insertions happen. A context is defined to be the preceding character before the sequence of insertions and the character that follows the sequence of insertions – for instance, in the previous example `say`, the context for the letter `a` would be the letters `s` and `y`. All of these contexts are added to a dictionary of insertion contexts, always keeping the maximal number of insertions for each specific context. Then the function σ adds a sequence of insertions any time a specific context fires. For the example above, the context we learn is `y`ε\$ where \$ denotes the end of a string. Therefore, for a

[1] Finite state transducers that allow insertions or deletions, in practice, need to bound the number of insertions at any specific point, similarly to our insertion context function. This is done by operating on a lattice, where a path in that lattice corresponds to a string transduction with a specific alignment. Decoding using a lattice is equivalent to using the Viterbi algorithm. See, for example, Rastogi et al. (2016).

[2] The index really marks a *space* between two characters in the string, with 0 denoting the beginning of the string.

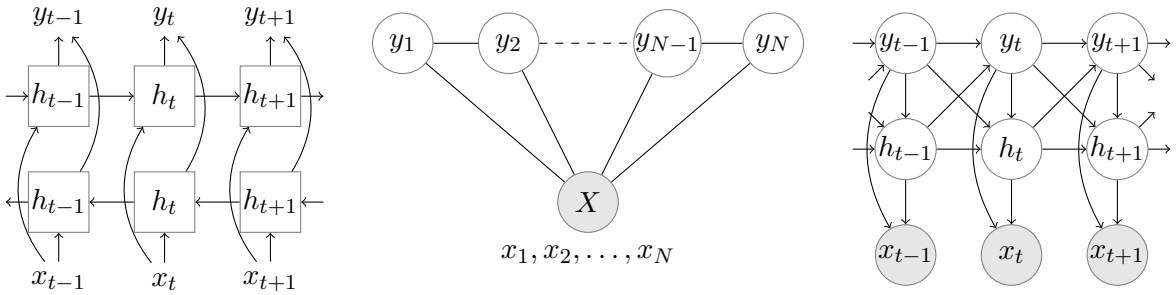

Figure 1: Graphical depictions of BiLSTMs (left), conditional random fields (middle) and refinement hidden Markov models (right). In practice, for the R-HMMs and CRFs we use a trigram model and not a bigram model as depicted.

decoded string that has the same context as the one found before, for instance, the string `slay` we would have $\sigma(4, \texttt{slay}) = 1$.

For all contexts, we calculate (based on the training data) a frequency table, that gives the probability of an insertion given the specific context. In some cases, we then tune a threshold (based on a development set) so that we add insertions only in cases where the frequency is larger than that threshold. We found out that while it perhaps prevents insertions in legitimate positions, if the frequency threshold is low enough, it does not have an adverse effect. On the contrary, it prevents adding spurious insertions that cannot be correctly recovered as deletions. For more details, see §4.

In the morphology tasks we experiment with, insertions tend to happen as suffixes or prefixes. To capture this, we also learn a pair of thresholds τ_0 and τ_1 (by grid search on the training set) such that $\sigma(i, x)$ is set to 0 if $\tau_0 \leq \frac{i}{|x|} \leq \tau_1$.

Learning the Labeling Model with σ Once we have the σ function applied to all aligned training data, we mark in the *output* sequences in the training data the spurious insertions that should not be in the input sequence with a special symbol `D` (for deletion). Therefore, the learning algorithm is now also required to learn where to delete these extra insertions that σ elicits. For example, if we consider the previously mentioned example of `say` and `said`, the input sequence in this case would be `say`ε and the output sequence would be `said`. However, it is not always the case that the past tense of a verb with a *ay* ending is the same word root with the suffix *-d* (and the transformation of the final *y* to *i* to accommodate the new suffix). For example, the past tense of `may` is also `may`, and in this case, if the string `may` was also in the training set, `may` should retain its form and be transduced to `may`. With the context function mentioned above we would have the pair `may`ε (input sequence), `mayD` (output sequence) to learn from. During decoding, we apply the σ function on the input string and then remove the `D` symbols from the string.

3.2 Sequence Labeling Models

We experiment with three models for sequence labeling: refinement hidden Markov models (R-HMMs; Stratos et al., 2013), conditional random fields (CRFs; Lafferty et al., 2001) and bidirectional Long Short Term Memory neural networks (biLSTMs; Graves and Schmidhuber, 2005). A graphical depiction of the models that we experiment with is given in Figure 1. For R-HMMs, we experiment with two learning algorithms, the expectation-maximization algorithm (EM; Dempster et al., 1977) and an L-PCFG spectral learning algorithm (Cohen et al., 2012; Cohen et al., 2013).[3]

4 Experiments

We describe in this section a set of experiments on datasets from three problems: social media spelling correction, optical character recognition (OCR) correction and morphological inflection. We believe that this array of datasets represents a broad set of problems in which string transduction as sequence

[3]We use the code from `https://github.com/shashiongithub/Rainbow-Parser`.

labeling can be tested. We apply the insertion technique to a set of sequence labelers: conditional random fields, refinement HMMs with expectation-maximization, spectral algorithms, and neural networks with biLSTM. All the results reported are at word level.

Our experiments require hyperparameter tuning of all algorithms, which we do over a fixed set of hyperparameters in the development set. For the latent-variable models, we vary the number of latent states between 1 and 48. For the biLSTM, we try a number of layers between 1 and 4 and a number of neurons ranging between 100 and 500.

The CRF is used with trigram modeling, and as such, the features it uses are very similar to the features used by the spectral algorithm. The main difference is that the spectral algorithm uses these features only during training, while the CRF uses them both during training and decoding.

In addition, we compare all our models to a seq2seq model implementation (Bahdanau et al., 2015). The model includes an attention mechanism, and we optimize the number of latent units over the development sets, ranging it from 10 to 100. We also include a comparison to seq2seq models with a "hard" attention mechanism (Aharoni and Goldberg, 2017), designed for string transduction with monotonic alignments.

4.1 Twitter Spelling Correction

In our first set of experiments, we use a corpus of spelling corrections for Twitter (Aramaki, 2010). The corpus includes 39,172 words in their original form and their correct form. We split this dataset into three parts (consecutively): 31,172 entries for a training set, 4,000 entries for a development set and another 4,000 entries for a test set.

Further Tuning In our experiments with EM and the spectral algorithm, we also tried to tune the σ context function on the development set. We discovered that the best context function is the one that adds ε slots for every context $a - b$ that appears in the data, if the relative frequency of $a - b$ to $a \star b$ is larger than $p = 0.0001$ (where $\star$ stands for a wildcard; the interpretation of this relative frequency division is that we check whether the conditional probability of having an ε given the context $a \star b$ is larger than p). This is not particularly surprising given the fact that the Twitter dataset is composed of single words, each having a single typo. Therefore, each pair of misspelled and correctly spelled words often needs at most one insertion to be aligned. Even though this threshold may seem small, it was enough to remove all the isolated, non-representative context cases.

We try both a bigram and a trigram model. The trigram model greatly outperforms the bigram model, so we focus on it. We also did some preliminary experiments with a 4-gram model, but this model did not seem to do better than the trigram model. For the biLSTM architecture, we find on the development set that the smallest error is with 2 layers and 350 neurons.

In our experiments, we compare two latent-variable learning methods: the EM algorithm and the spectral algorithm described by Stratos et al. (2013). EM was run for 8 iterations – in some preliminary experiments where we ran EM for much longer, we noticed it converges after very few iterations. We then choose the iteration that gave the best result on the development set. We range the number of latent states, m, between 2 and 48.

The Dictionary Layer We also experiment with an additional layer that we add to our transduction algorithm. In this layer, we use a dictionary (a fixed set of words) for which we find the closest entry (in edit distance) to the output of our algorithm. In that case, our transduction algorithm can be thought of as producing an *intermediate* string, i.e., a string that may or may not already be a correct word but that is closer to the correct word in terms of edit distance. The intermediate string representation is intended to correct mistakes while actually relying on the type of substitutions, deletions and insertions done by users of social media. However, it is still prone to character-based mistakes, since it is a learned component. This is the reason why we also include the second edit distance layer.

We use two types of dictionaries. The first dictionary is the set of all correctly spelled words in the training data. The second dictionary is the English dictionary extracted from the GNU aspell software.[4] In our results, we report four types of accuracy levels: the accuracy for the whole test set (where accuracy

[4] `ftp://ftp.gnu.org/gnu/aspell/dict/0index.html`.

method	acc	acc4+	acc6+	acc10+
aspell	30.1	41.1	56.6	82.6
train	40.1	59.6	**71.6**	71.9

EM+aspell	41.7	48.7	55.7	82.6

Table 1: Final results on the test set for the Twitter dataset. "aspell" stands for edit distance minimization using the aspell dictionary. "train" stands for the same with the dictionary extracted from the training set. "GNU aspell" stands for the results of running the GNU aspell software. "acc" denotes the accuracy over the whole dev/test set, "acc$n$+" for words of length $\geq n$. For each method the best model was chosen as follows: for CRF, over the dictionary; for EM, over iterations, number of latent states, and dictionary; and for spectral, over the hyperparameters, number of latent states and dictionary. The best model was chosen for each accuracy length criterion separately. The best result in each column is in bold. Top part are baselines. Bottom part uses our reduction to sequence labeling.

is measured as the number of words we fixed to the correct form), and also accuracy only for (correct) words which are longer than 4 characters, 6 characters and 10 characters.

We experimented with two types of edit distance algorithms. The first one allows only deletions, insertions and substitutions, and the other also allows transpositions. We discovered that edit distance with transposition behaves better, so we focus on it.

Results Table 1 gives the final result on the test set for the Twitter data (for different word lengths). The first thing to note is that there are some models that perform well on words longer than 10 characters. In general, it is easier to correct the spelling of longer words with the aspell dictionary because: (a) longer words are more likely to originate in words that appear in the dictionary; (b) there is more evidence in a long string for the misspelled string than in a short string.

Still, high accuracy on long words does not necessarily indicate the total accuracy is higher. We see that the spectral algorithm and the biLSTM model tend to give higher results on all words lengths overall than both the conditional random field and the EM algorithm. The GNU aspell software itself does not perform well on this dataset. This perhaps should not come as a surprise, as the GNU aspell software is designed for less informal text.

In addition, we see that sequence labeling performs consistently better than seq2seq models with attention. This should not come as a surprise, as seq2seq models encode the whole string before decoding it, even when the attention mechanism is used. This finding is also supported by (Schnober et al., 2016). The seq2seq method of Aharoni and Goldberg (2017) behaves even worse without using a dictionary,

context	dictionary	average	std
left	none	42.2	0.67
right	none	42.1	0.63
both	none	42.3	0.61
left	aspell	48.6	0.52
right	aspell	48.6	0.54
both	aspell	48.8	0.56
left	train	58.3	0.49
right	train	58.3	0.27
both	train	58.6	0.46

Table 2: Sensitivity analysis of the different context functions as a function of the probability threshold for insertion in a context. The contexts vary over left character ("left"), right character, or characters both on the left and the right ("both"). In addition, we use dictionaries (the aspell dictionary or the training data as dictionary). "average" gives the average result over the different thresholds, and "std" gives the standard deviation of that average.

especially for long words.

The Role of the Context Function We note that the choice of the context function is important, and extra ε symbols have to be added based on data-oriented choices. For example, when we experimented with a constant context function that adds an additional ε symbol after every character during training and decoding, the accuracy on the test set was much lower, whether we used a dictionary or not. To be more precise, the accuracy without using a dictionary was 33%, with the "train" dictionary mitigating the low performance to an accuracy of 61.1% (which is significantly lower than the biLSTM result and the spectral result) and 54.0% for the "aspell" dictionary.

To test the role of the context function, we further evaluated it more thoroughly. We created three types of context functions: one that looks at context only to the left of the current character, one that looks at context only on the right, and finally one that looks on context both on the left and on the right (as originally defined). In addition, we varied the threshold that activates an insertion in a specific context (see §3). The threshold was varied over the values in the set $\{0.0001, 0.0005, 0.001, 0.002, 0.005, 0.01, 0.05, 0.1, 0.15, 0.2\}$. The higher the threshold is, the less spurious insertions happen (or insertions in general).

We experimented with a single learning algorithm: the biLSTM neural network. Table 2 summarizes this sensitivity analysis. The "average" results give the performance on the development set, averaging over the different thresholds. The "std" result gives the corresponding standard deviation. As can be seen, on average, right context functions have smaller standard deviation than other contexts, while the accuracy levels are similar for all contexts. In addition, there is relatively not a very large sensitivity to the actual threshold use.

The same dataset was also used by Cotterell et al. (2014) and by Silfverberg et al. (2016) though in both cases the results are not comparable as the experimental setup and the errors reported are different than the one used in this paper. For example, Cotterell et al. do not report accuracy at all, but instead plot mean edit distance as a function of the number of training examples.

4.2 Optical Character Recognition Correction

In our second set of experiments we used the Finnish OCR dataset used by Silfverberg et al. (2016). This corpus consists of 36,470 word pairs and it was generated from processing Early Modern Finnish texts through an OCR engine. According to Silfverberg et al. (2016) this corpus is a subset of a larger corpus comprising historical newspapers and magazines digitized by the National Library of Finland. This dataset has been both manually edited by the Institute of Languages of Finland as well as through crowdsourcing. In order to run our experiments we used the same setup and the same 10 non-overlapping parts described in Silfverberg et al. (2016).

Method	acc	acc4+	acc6+	acc10+
Unstructured	20.0	-	-	-
+ Lexicon	21.6	-	-	-
Perceptron	32.1	-	-	-
+ Lexicon	35.1	-	-	-
seq2seq	79.9	80.0	78.8	78.6
seq2seq (hard)	58.4	55.4	55.3	53.7
Spectral	77.3	77.9	76.3	73.8
CRF	**81.8**	**81.9**	**80.7**	**78.8**
EM	79.9	80.5	79.3	77.4
biLSTM	81.7	81.7	80.3	78.3

Table 3: Finnish OCR results. The first set of baselines (upper part) are reported by Silfverberg et al. (2016), and as such, the numbers are not available for all columns. Bottom part is our method.

Further Tuning In our experiments, we use 10-fold cross validation. The results are averaged over these ten folds. The hyperparameters for the spectral algorithm were tuned on the development set of the first fold, and then we used the hyperparameters identified at that phase for the rest of the folds.

We tuned the neural network architecture parameters on the development set of the first fold. We found out that the biLSTM model works best with 1 layer with 200 neurons.

We tuned the context function on development data again (for fold 1). We discovered that the best context function includes a pair of ε in any context of the form $a - \ - b$ that it appeared in the training data, and a single ε in any context with conditional probability larger than 0.0001. See more in §4.1. The OCR dataset is quite different in its structure from the Twitter dataset. It has both words that do not need any correction, and words in which more than one character was not labeled with the correct character. Another important difference is the fact the "typos" were often grammatical in the Twitter dataset (as they were human misspellings), while that is not the case in the OCR dataset. It is also worth noting that Finnish relies heavily on double letters in its spelling, which could explain why this choice of σ function works best in this case but not in the Twitter one.

Silfverberg et al. (2016) present two approaches for this problem, both relying on finite-state technology. In one approach, "unstructured," they extract finite-state rules from pairs of strings and then apply them during decoding. In the "structured" case there is an additional Perceptron layer which is trained based on features extracted from the unstructured classifier. In addition, they have an additional layer which relies on a lexicon to find the best correction for a given input string.

Results Table 3 gives the results. We see that all uses of sequence labeling significantly outperform the results of Silfverberg et al. (2016). Even with an external lexicon, the results of the unstructured and structured classifiers of Silfverberg et al. significantly lag behind our results. Our results are also relatively stable with regards to word length. While the results are slightly lower for words of length 10 or more, the accuracy level is rather stable for other lengths. This is actually a different finding than the one we found with the Twitter spelling correction experiment. We see yet again that seq2seq modeling performs worse than our approach with biLSTM. seq2seq do not perform well with the hard monotonic attention model. This is on par with the results for the Twitter spelling dataset, on which we see bad behavior on long words. The OCR dataset indeed includes relatively long words.

4.3 Morphological Inflection

We also run experiments on the morphological inflection dataset used by Rastogi et al. (2016).[5] This dataset was first processed by Dreyer (2011) and we use the same setup in our experiments, i.e., in each experiment we use the same 2,500 example dataset sampled from the CELEX database (Baayen et al., 1993) divided into three sets, 500 examples for training, and 1,000 for both development and testing. This

Spectral (ensemble)	84.0	93.8	83.7	83.5
Spectral (oracle)	*85.8*	*99.6*	*92.4*	*87.5*

Table 4: Results on the morphological inflection datasets. Baselines (upper part of the table) are reported by Rastogi et al. (2016) and Dreyer (2011). The best result in each column is in bold. Results for seq2seq are reported by Aharoni and Goldberg (2017). Kann results are reported by Kann and Schütze (2016).

corpus is divided in four subsets, each defining an inflection task between different verb tenses in German. These are labeled as follows:

- 13SIA→13SKE - 1st/3rd persons singular of the indicative past to 1st/3rd persons singular of the subjunctive present.
- 2PIE→13PKE - 2nd person plural of the indicative present to 1st/3rd person plural of the subjunctive present.
- 2PKE→z - 2nd person plural of the subjunctive present to the infinitive.
- rP→pA - imperative plural to the past participle.

Further Tuning For the 13SIA dataset, we discovered on development data (fold 1) that the best context function is one that adds a single ε any time it appeared in the training data with a context $a\varepsilon b$. For 2PIE, we discovered similarly that adding a single ε is best in all cases it appears in the end of the word in the training set. Finally, for 2PKE and rP, we discovered the best context function is such that it adds a single ε or a pair of ε in any context it appears in the training data (with a character to the left and a character to the right).

The morphological inflection dataset is the most different of the three datasets mostly because it allows for the insertion or deletion of full suffixes. We speculate it is the main factor as to why the best context functions for the morphological datasets are different than for the previous two datasets (Twitter and OCR).

With the biLSTM model we discovered on the development set of the first fold of each dataset that: 13SIA works best with 2 layers of size 300; 2PIE works best with 1 layer of size 150; 2PKE works best with 1 layer of size 250; and rP-pA works best with 2 layers of size 250.

Results The results are in Table 4. The biLSTM results reported in the upper part of the table do not use our sequence labeling technique, and are re-iterated as reported by Rastogi et al. (2016).

In general, the spectral algorithm does not perform as well as the LSTM baseline with finite state transducers, but does better than it on the rP-pA dataset. The spectral algorithm performs significantly better than some of the other baselines, such as Moses or the baselines from Dreyer (2011). This is especially true for the 2PKE and the rP-pA datasets.

An additional observation is that the way we handle insertions has a significant impact on the performance. In oracle mode (meaning, when the two strings are aligned using edit distance even at decoding time, and the spurious insertions are not used), the spectral algorithm performs significantly better. This should not come as a surprise, but does point to a direction on how to improve the use of our sequence labeling technique – better handling of insertions and the addition of less spurious insertion placeholders that are deleted during decoding.

In contrast to the other datasets, where perhaps the assumption of monotonicity is too strong, seq2seq models with an attention mechanism designed to handle monotonic alignments (Aharoni and Goldberg, 2017) perform quite well on this task, even better than the vanilla seq2seq models.

Finally, we also consider the case in which we use an ensemble method, combining several spectral models together (the top 50 performing models on the development set from the hyperparameter sweep). We combine the models using a MaxEnt reranker such as described by Charniak and Johnson (2005) and Narayan and Cohen (2015). We find that the ensemble approach does improve the results significantly for the 13SIA dataset, and also for the 2PKE-z dataset.

5 Conclusion

We presented a technique to frame general string transduction problems as sequence labeling. Our technique works by adding to the string to be transduced additional insertion markers, which are later potentially deleted during the sequence labeling process. Our approach is general and works with any sequence labeling algorithm. We developed our technique with conditional random fields, refinement hidden Markov models and neural networks. We tested our approach on problems from three challenging domains: spelling correction for social media, optical character recognition correction and morphological inflection. We demonstrated that our approach performs comparably to strong baselines and state of the art.

While the idea of using redundant epsilons in string transduction problems has been used in the past (Azawi et al., 2013; Schnober et al., 2016), it has traditionally been treated in an ad-hoc narrow manner, for example by adding a fixed number of epsilons after every character. To the best of our knowledge, we are the first to rigorously define this idea as a learning problem while performing a comprehensive empirical evaluation for it, both with respect to the type of datasets used and the sequence labeling algorithms covered.

Acknowledgements

We would like to thank Ariadna Quattoni, Adam Lopez and other members of the Edinburgh NLP group for their feedback and comments on this paper. We would also like to thank Tao Meng for his help with running the BiLSTM experiments. We gratefully acknowledge the support of the the European Union under the Horizon 2020 SUMMA project (grant agreement 688139), and the support of EPSRC (award number 1644752).

Abstract

Wikipedia provides an invaluable source of parallel multilingual data, which are in high demand for various sorts of linguistic inquiry, including both theoretical and practical studies. We introduce a novel end-to-end neural model for large-scale parallel data harvesting from Wikipedia. Our model is language-independent, robust, and highly scalable. We use our system for collecting parallel German-English, French-English and Persian-English sentences. Human evaluations at the end show the strong performance of this model in collecting high-quality parallel data. We also propose a statistical framework which extends the results of our human evaluation to other language pairs. Our model also obtained a state-of-the-art result on the German-English dataset of BUCC 2017 shared task on parallel sentence extraction from comparable corpora.

Title and Abstract in German

Tiefe Neuronale Netze im Dienste der Extraktion mehrsprachiger paralleler Satzpaare

Wikipedia ist eine überaus wertvolle Quelle von mehrsprachigen Paralleldaten, die für eine Vielzahl von theoretischen und praktischen sprachbezogenen Fragestellungen benötigt werden. Wir stellen ein neuartiges neuronales End-to-End-System für das massenhafte Sammeln von Paralleldaten aus der Wikipedia vor. Das System ist sprachenpaarunabhängig, robust und weist eine hohe Skalierbarkeit auf. Wir nutzen es zur Extraktion von parallelen Satzpaaren in den Sprachenpaaren Deutsch-Englisch, Französisch-Englisch und Persisch-Englisch. Die hohe Genauigkeit unseres Systems wird durch manuelle Evaluation bestätigt. Darüber hinaus stellen wir einen statistischen Ansatz vor, mit dessen Hilfe menschliche Qualitätsurteile auf weitere Sprachenpaare übertragen werden können. Unser System erzielt State-of-the-Art-Ergebnisse gemessen am deutsch-englischen Datensatz der BUCC 2017 Shared Task zur Extraktion von parallelen Satzpaaren aus Vergleichskorpora.

1 Introduction

Parallel texts are an important resource in Natural Language Processing (NLP) applications and tasks. From Statistical and Neural Machine Translation (SMT, NMT) (Brown et al., 1990; Och and Ney, 2002; Kalchbrenner and Blunsom, 2013; Cho et al., 2014), to automatic lexical acquisition (Gale and Church, 1993; Melamed, 1997), cross-lingual Information Retrieval (Davis and Dunning, 1995; Oard, 1997) and annotation projection (Yarowsky et al., 2001; Diab and Resnik, 2002) all are dependent on parallel data.

Generating parallel corpora from scratch is a highly time consuming and expensive task. Therefore, many studies focus on extracting parallel texts from comparable corpora (Munteanu and Marcu, 2005) such as Wikipedia.

Wikipedia is a useful source of parallel sentences since humans already annotated its comparable documents. In Wikipedia, one can find both parallel, and comparable articles[1]. The reason is that some

[1]In a parallel bilingual corpus like Europarl (Koehn, 2005), all sentences in source and target languages are parallel (i.e., translations of each other) while in two comparable corpora the same topic may be described with entirely different sentences.

Proceedings of the 27th International Conference on Computational Linguistics, pages 1372–1383
Santa Fe, New Mexico, USA, August 20-26, 2018.

authors prefer to explain an issue in their own words, while others use existing articles to translate them into their languages. Still, there are others who may combine the two approaches discussed above by borrowing some sentences from a source article and add some other contents by themselves. Generally, even in comparable articles with partial translations, there is a high chance of finding parallel sentences, since both articles are talking about the same topic.

A simple way of retrieving parallel sentences from comparable articles is to align the sentences in source and target pages together using a sentence alignment algorithm (Gale and Church, 1993; Fung and Church, 1994; Wu, 1994; Moore, 2002). However, these aligners are designed to align parallel corpora in which the source and target sentences are in the same order (i.e., no cross-alignment) or in proximity to each other and in which each sentence has only one matching sentence (i.e., no many-to-many alignment). These assumptions are largely violated in comparable corpora.

To address these issues, we designed a novel neural model which estimates a global probability distribution given each pair of sentences in comparable documents. We train an alignment model using German-English parallel data from the Europarl corpus (Koehn, 2005) and use the trained model to extract parallel sentences for the German-English, French-English, and Persian-English language pairs from Wikipedia.

Our model achieved statistically significant improvement over two baselines on Europarl test data (please see Section 5). Since we assumed we had no access to any gold parallel data in Wikipedia, we used human evaluation to determine the performance of our model using a two-tier evaluation design. Still, to make our results more comparable, we applied our model on the German-English dataset of BUCC 2017 second shared task on parallel sentence extraction from comparable corpora (Zweigenbaum et al., 2017) and we obtained a state-of-the-art result on it too.

In this work, we intend to model parallel sentences as accurate as possible. Hence we consider two sentences as parallel only if they have the same semantic content (i.e., convey the same message) and do not have any more or less content that is mentioned in one and missing in another (e.g., an extra or missing prepositional phrase). The sentences that do not satisfy this requirement are considered partial parallel sentences. The accuracy with which each of these partial parallel sentences represents the meaning of their source sentence is expressed in terms of a Normal distribution which is discussed in Section 6.

Moreover, we treat parallel sentences asymmetrically since professional translators often translate from their second language to their native language. Even when the translator's competency level in the source and target languages are the same, the target language could be influenced by the source language. Therefore, we trained all our models on language pairs whose target language is always English and recruited native English speakers for our evaluation tasks.

2 Related Work

Parallel data are considered an asset both in theoretical (e.g., contrastive corpus linguistics, translation studies, language use, and change) and applied (Machine Translation (MT), word sense disambiguation, bilingual lexicography) computational linguistics. There is a wealth of studies on the extraction of parallel data from the Internet in general and Wikipedia in particular. (Adafre and de Rijke, 2006) were among the first researchers who used Wikipedia for parallel data extraction. They generated a pack of source and target documents as the Cartesian product between 30 Wikipedia pages and utilized an MT system to translate target pages into English. Then, they used a similarity measure based on word overlap between the source and target sentences. In another approach, they used matching hyperlinks in Wikipedia pages to identify similar sentences.

To decrease the search space in (Adafre and de Rijke, 2006) work which is evidently too big for large-scale data extraction projects, (Mohammadi and GhasemAghaee, 2010) integrated the idea of length-based sentence alignment in (Gale and Church, 1993)[2] as a heuristic to decrease the complexity of the algorithm.

For larger-scale studies, (Barbosa et al., 2012) used bilingual dictionaries and online translation services (e.g., Google Translate or Microsoft Bing) and (Zhang et al., 2006) proposed the use of aligners

[2]Long source sentences are usually translated into long target ones and short source sentence to short target ones.

Language Pairs	Comparable articles
French-English	1,491,578
German-English	1,247,102
Persian-English	866,408

Table 1: The number of interlanguage links in Wikipedia for selected language pairs. English has interlanguage links with more than 300 other languages.

for content similarity estimation in candidate parallel web pages. (Štromajerová et al., 2016) enhanced Zhang et al.'s system by using Wikipedia's translation templates to locate comparable Czech-English parallel pages and subsequently by using the Hunalign tool (Varga et al., 2005) to extract parallel sentences.

In large-scale data extraction projects, checking all possible sentences for all pages in two languages is neither feasible nor necessary when document-level alignments are already available. (Smith et al., 2010) and (Ştefănescu and Ion, 2013) did their studies on document-aligned articles of Wikipedia. Smith et al. used a feature-based model on aligned documents. Similarly, Ştefănescu and Ion used cross-lingual Wikipedia links embedded within the documents and a trainable model to generate similarity scores for parallel sentence identification.

Classifiers are used for parallel sentence detection as well. (Chu et al., 2014) studied the use of classifiers for parallel sentence identification. They proposed a filtering scheme for Chinese-Japanese language pairs and used a binary classifier on the pruned sentences for parallel sentence classification.

In our work, we let a deep neural architecture learn the most relevant features on its own. We use Interwiki links available in Wikipedia to locate comparable pages. Using an end-to-end deep neural model we extract the most likely parallel sentences given two comparable pages by projecting the sentences into n-dimensional space. In this way, the model learns the most relevant features on its own without knowing much about the source and target languages.

3 Dataset

Wikipedia is an online encyclopedia of human knowledge. As of December 2017, it hosted over 14 million articles in more than 300 languages. While English as the biggest Wikipedia contains more than 3 million articles and 14K active users, there are 28 languages with more than 100K and 60 languages with more than 10K articles. Wikipedia is a crowd-sourced resource of information authored and translated collaboratively on a non-profit basis. Wikipedia provides a collection of similar pages in different languages by linking them together with interlanguage links. These links appear either in a sidebar on the left side or in the text of a page as in-line links. Table 1 represents the number of available English links for German, French, and Persian languages.

Our model is trained on parallel sentences from Europarl and is used to extract parallel sentences from German-English, French-English, and Persian-English comparable pages in Wikipedia. To train our model, we compiled a dataset of first 200K parallel German-English sentences from Europarl. The German sentences were translated using Google translate service and were used as pointers to original target sentences. Online translation in this phase is not a crucial step since a simple word replacement utilizing a dictionary can do the job.

We preprocessed all textual data including source and target sentences by eliminating all non-alphanumeric characters. Numeric characters were changed to 9 to retain the numeric semantic value of numeric tokens. We used 90%, 5%, and 5% of the sentences in our dataset to compile training, validation and test sets respectively in the following way.

Similar to (dos Santos et al., 2014), our model is trained by contrasting positive and negative parallel sentences. Therefore, to compile our training set, given each source sentence, we generated a positive parallel pair by taking its correct target sentence and a negative parallel pair by taking a randomly chosen sentence from target sentences. We make sure that the randomly selected sentence is not the same as the correct target sentence. To compile the validation and test sets, given each source sentence, we take a context of ten surrounding sentences including the correct target sentence. We used these sets to train,

validate and test the alignment system.

When the alignment system is trained and optimized, it is ready to extract parallel sentences from Wikipedia. For parallel sentence extraction, in the first step, we need to find comparable data in Wikipedia. Wikipedia connects comparable pages using interlanguage links. These links are available as an SQL database containing pointers to comparable pages. In Table 1 a few language pairs with their available comparable pages are reported. Using this database, we extract the page contents and use some simple preprocessing tasks to extract sentences from the pages by removing images, tables, graphs, formula, etc. In the end, we package source and target sentences of a comparable pair in one packet.

For each packet, our trained model estimates a probability distribution over all target sentences given each source sentence. In Wikipedia, we do not have access to standard gold data (i.e., we do not know which source-target sentence combination is parallel) hence, we use human evaluation (see Section 6) to estimate the system performance. We report the results of these experiments in Sections 5 and 6

4 Model Architecture

To compare source and target sentences in the mathematical sense, in the first step, we need to project them into n-dimensional space. To do this, we made use of Recurrent Neural Network (RNN) (Elman, 1990) architectures to encode textual strings into vector representations. Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) and Gated Recurrent Unit (GRU) (Cho et al., 2014) are two widely studied variants of RNNs. In our study, we used LSTM cells since they showed better and more stable performance in our experiments.

To provide LSTM layers with their inputs, in the first layer, we used a lookup table to cast words into word embeddings (Equation 1). $\mathbf{W}$ in Equations 1 is the one-hot representation of the words in sentences whose production with pre-trained embedding matrix $\mathbf{E}$ generates word vector $\mathbf{W}_{i,t}$ for the words in the i$^{\text{th}}$ sample sentence each in time step t.

In the next layer, a forward RNN layer accepts word vectors and generates a sequence of vectors for each time step. A similar RNN does the same job but in opposite order to generate backward RNN vectors. We did max pooling ($\mathbf{MP}$) (Equations 3 and 5) over RNN vectors to get the most relevant features and then concatenated them in Equation 6. The final result of this process, $\mathbf{S}$ is a forward and backward vector representation of textual strings. We used this architecture to encode our source sentences.

$$\mathbf{W}_{i,t} = \mathbf{E}^{\intercal}\mathbf{W}_k \tag{1}$$

$$\overrightarrow{\mathbf{S}}_{i,t} = RNN(\overrightarrow{\mathbf{S}}_{i,t-1}, \mathbf{W}_{i,t}) \tag{2}$$

$$\overrightarrow{\mathbf{S}}_{i} = \mathbf{MP}(\overrightarrow{\mathbf{S}}_{i,t}) \tag{3}$$

$$\overleftarrow{\mathbf{S}}_{i,t} = RNN(\overleftarrow{\mathbf{S}}_{i,t+1}, \mathbf{W}_{i,t}) \tag{4}$$

$$\overleftarrow{\mathbf{S}}_{i} = \mathbf{MP}(\overleftarrow{\mathbf{S}}_{i,t}) \tag{5}$$

$$\mathbf{S}_i = [\overrightarrow{\mathbf{S}}_{i}; \overleftarrow{\mathbf{S}}_{i}] \tag{6}$$

Target sentences are encoded like source sentences with an additional attention layer, which helps the encoder to recognize the most relevant features by emphasizing on critical points of the target sentence given each source sentence. Likewise, the target language encoder receives the initial embeddings from a lookup table over a pre-trained embedding matrix. The forward RNN in the next layer transforms the embeddings into a sequence of vectors which finally are fed into an attention layer with attention on source sentence vectors (Equation 7). The resulted vector then is max pooled to be eliminated from non-relevant and useless features. The same process is done for the backward RNN, and the resulting vectors are concatenated.

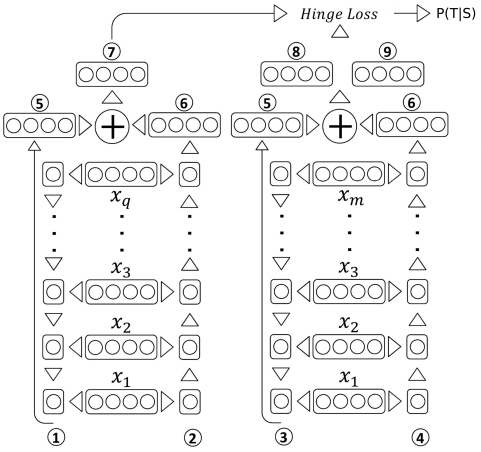

Figure 1: Abstract model architecture. Numbered components in the figure are 1-Forward LSTM, 2-Backward LSTM, 3-Forward Attentive LSTM, 4-Backward Attentive LSTM, 5-Backward max-pooling, 6-Forward max-pooling, 7-Question vector, 8-Positive sample vector, 9-Negative sample vector.

$$
\begin{aligned}
\mathbf{W}_{i,t} &= \mathbf{E}^{\intercal}\mathbf{W}_k \\
\overrightarrow{\mathbf{T}}_{i,t} &= RNN(\overrightarrow{\mathbf{T}}_{i,t-1}, \mathbf{W}_{i,t}) \\
\overrightarrow{\mathbf{T}}_{i,t} &= ATT(\overrightarrow{\mathbf{T}}_{i,t}, \mathbf{S}_i) \qquad (7) \\
\overrightarrow{\mathbf{T}}_{i} &= \mathbf{MP}(\overrightarrow{\mathbf{T}}_{i,t}) \\
\overleftarrow{\mathbf{T}}_{i,t} &= RNN(\overleftarrow{\mathbf{T}}_{i,t+1}, \mathbf{W}_{i,t}) \\
\overrightarrow{\mathbf{T}}_{i,t} &= ATT(\overleftarrow{\mathbf{T}}_{i,t}, \mathbf{S}_i) \qquad (8) \\
\overleftarrow{\mathbf{T}}_{i} &= \mathbf{MP}(\overleftarrow{\mathbf{T}}_{i,t}) \\
\mathbf{T}_i &= [\overrightarrow{\mathbf{T}}_i; \overleftarrow{\mathbf{T}}_i]
\end{aligned}
$$

All target sentences including positive and negative sentences are encoded using this procedure. In the end, source sentence vectors, positive target vectors, and negative target vectors are ready to be used as the inputs of a Hinge objective function. Using this function, we try to maximize the similarity in parallel sentences while minimizing the similarity in non-parallel ones. Therefore, the next step is to measure the similarity between sentences in a parallel set.

The similarity between two vectors can be estimated via different approaches such as Jaccard, Cosine, Polynomial or Manhattan, etc. However, we got better results using the Geometric mean of Euclidean and Sigmoid Dot product (GESD) proposed by (Feng et al., 2015). GESD (Equation 9) combines the angular and forward-line semantic distance between two vectors.

$$SIM(V1, V2) = \frac{1}{1+exp(-(V1 \cdot V2))} * \frac{1}{1+||V1-V2||} \qquad (9)$$

To distinguish parallel sentences from non-parallel ones, we need to train their vectors in a way that increases the similarity for parallel and decreases it for non-parallel sentences. Hinge objective function does the trick for us (Equation 10).

$$\ell = \sum_i \max(0, m + SIM(\mathbf{S}_i, \mathbf{T}_i^-) - SIM(\mathbf{S}_i, \mathbf{T}_i^+)) \qquad (10)$$

After training, the model estimates a probability for each pair of source and target sentences (i.e., $p(target|source)$). In the next section, we describe how we use these probabilities to distinguish parallel sentences from non-parallel ones.

5 Results

We trained our model on the dataset compiled from Europarl parallel data. We used 128-dimensional LSTMs for all RNNs in our model, and for the embedding layer, we used GloVe word vectors (Pennington et al., 2014). To prevent the model from over-fitting, we set the drop-out rate to 0.5 for the last layer

in each module. We used an attention model similar to the one proposed by (dos Santos et al., 2014). The model was trained on two GPUs and converged after around 3 hours of training. We used random assignment and the Bleualign tool (Sennrich and Volk, 2011) as two baselines. The results of the model on the test and validation sets are reported in Table 2. These results are the accuracy of the system for sentence alignment on the German-English dataset. Since our model is trained with source sentences translated into English, the same encoder can be used for any other source languages as long as we use the same mechanism for translation.

Up to this point, we trained our aligner. In the next step, we use this alignment system to extract parallel sentences. To estimate the performance of the model on parallel sentence extraction from Wikipedia, we designed a two-tier human evaluation, which is described in the next section.

Europarl German-English	**Baseline**	**Bleualign**	**This work**
Validation set	11.94 %	92.45 %	**96.83 %**
Test set	11.34 %	93.05 %	**97.24 %**

Table 2: Comparative evaluation of German-English alignment system. The baseline is random target sentence assignment.

6 Human Evaluation

As described in Section 3, our comparable data extraction yields more than one million comparable packets for the German and French and around 800K packets for the Persian languages (Table 1). Each comparable packet consists of two files, one of which contains source text lines and the other includes target text lines.

For each comparable packet, the model as described in Section 4 estimates a probability distribution over all target sentences given each source sentence. Each source sentence and the target sentence with the highest probability forms a probable parallel pair.

Not having access to standard gold data in Wikipedia, we do not know which of these pairs are, in fact, parallel, irrespective of the probability estimated by the model.

To estimate a threshold for the probabilities and to validate it, we designed a two-step human evaluation procedure. In the first step, we establish a threshold for the model-generated probabilities above which a sentence pair could be considered a parallel pair. Irrespective of the size of each comparable packet, this probability is a global metric of how much two sentences are semantically correlated. So we only need to establish a threshold and validate it using statistical inference. After that, we can accept source and target sentences with probabilities above the threshold as correct parallel sentences.

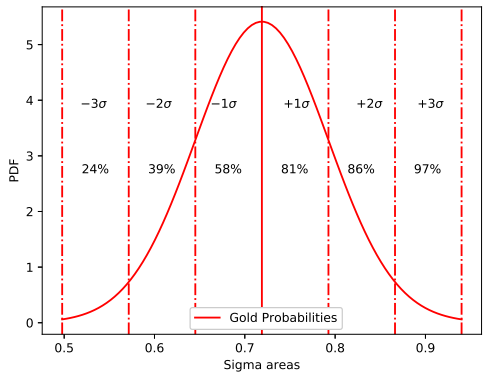
In the second step, we validate our thresholds by asking our evaluators to decide which of the extracted pairs are parallel. For this purpose, we randomly extract some sentence pairs under the curve of a Normal distribution parametrized by μ and σ obtained from the last step and ask some evaluators to decide which pairs are parallel and which ones are not.

Based on the information obtained from the evaluators, we try to reject the null hypothesis of our study (i.e., sentence pairs with a probability above the thresholds are not parallel) and to analyze the errors qualitatively.

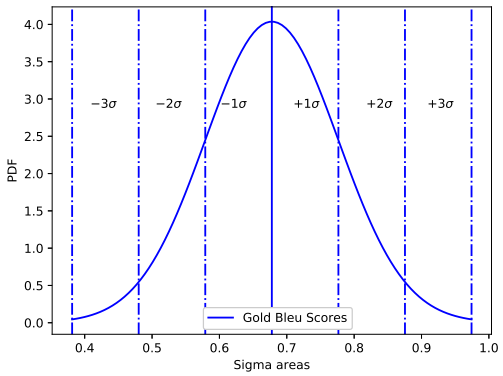
6.1 Establishing a Threshold

To establish a threshold for the model, we randomly extracted two hundred German sentences and asked two native English and fluent German translators to translate them into English. We returned these translations and their German source sentences into their original containing packets to provide them with their original contexts. Knowing that these are correct parallel sentences, we used our model to estimate their probabilities. Then, using these probabilities, we computed the μ and σ of the samples based on which we estimated a Normal distribution on the probability range of parallel sentences (Figure 2a).

Moreover, using Google translate service, we converted these sentences into English and computed their BLEU scores (Papineni et al., 1993) by using our gold translations produced by our translators as



(a) Normal Distribution on System Probabilities



(b) Normal Distribution on BLEU Scores

Figure 2: (a): Normal distribution parametrized by $\mu = 0.71$ and $\sigma = 0.07$ obtained from gold parallel sentences translated by human translators and scored by the model. The percentage in each σ region is the ratio of the sentence pairs evaluated as parallel in the second task.
(b): Normal distribution ($\mu = 0.67, \sigma = 0.09$) over the BLEU scores of English translations of 200 true parallel target sentences done by Google translate service. BLEU scores are transformed to percent.

the reference. We calculated the average of these two scores and used them for estimating a Normal distribution by computing their μ and σ (Figure 2b).

In any further parallel sentence extraction, to estimate the performance of the model without human evaluation, we only need to translate target sentences into English, to compute their BLEU score using source sentences as a reference and to compare them with the BLEU score curve obtained above. In the next section, we use this method to estimate the quality of extracted parallel sentences for French-English and Persian-English language pairs.

	-3σ	-2σ	-1σ	1σ	2σ	3σ
Observed Agreement	95 %	76 %	71 %	76 %	85 %	98 %
Cohen's kappa	85 %	69 %	45 %	50 %	81 %	89 %
Prediction Reliability	Strong	Average	Weak	Average	Strong	very Strong
Model probability Range	50%-57%	57%-64%	64%-71%	71%-78%	78%-85%	85%-92%
Bleu Score Range	40%-49%	49%-58%	58%-67%	67%-76% %	76%-85%	85%-94%
Collected parallel Sentences	24 %	39 %	58 %	81 %	86 %	97 %

Table 3: Human evaluation results. The Observed Agreement is the ratio of sentence pairs which were evaluated the same, either as true or false parallel pairs by both evaluators. Cohen's Kappa integrates chance agreement into the Observed Agreement. As mentioned in Prediction Reliability row, σ regions with Cohen's Kappa less than 0.8 are not reliably evaluated. Model Probability Ranges are the probabilities estimated by the model for 200 correct parallel sentences compile by our evaluators, and the BLEU Score Range is the BLEU scores of these sentences when translated using Google Translate. The ranges for last two rows are computed using a Normal distribution on their data. Collected Parallel Sentences are the ratio of sentence pairs which are evaluated as parallel in each σ region.

6.2 Validating the Thresholds

In Figure 2a the Normal distribution and the percentage of parallel data in each σ regions are illustrated. To validate these thresholds, we randomly and evenly sampled 1000 sentences from all σ regions and asked our evaluators to determine whether they are parallel or not. We statistically analyzed these data to assess the validity of the outcomes.

Given that our data in this task are nominal and have no order and that it is necessary to take into account the probability of chance in evaluation, we used Cohen's kappa to estimate the inter-rater reliability. We calculated the observed agreement probability for each σ region as well. The data analysis is done by considering $p > 0.95$ and 1000 data samples. The results are reported in Table 3. As is shown in this table, in $2\sigma^+$ and $3\sigma^+$ regions we have 81% and 89% inter-rater reliability accordingly, which indicates strong predictability in these regions.

The observed agreement and collected parallel sentences in these regions are quite high. In $3\sigma^+$ and $2\sigma^+$ regions, we managed to reject the null hypothesis (i.e., that all sentences in these regions are non-parallel), hence confirming that with 95% confidence, the established thresholds in these regions are statistically sufficient enough to decide whether a pair is parallel or not.

Since the thresholds are computed using the same scheme for both languages, the obtained results are valid for all language pairs. To prove this idea (i.e., the validity of the determined thresholds for other languages without human validation), we used this system for French-English and Persian-English language pairs as well. We randomly extracted 1000 pairs from the Normal distribution over Fr-En and Fa-En pairs and used Google translate service to generate the translations of these sentences in English. Then, we computed the BLEU scores of the English sentences in parallel sentences and compared them to the Normal curve of BLEU scores in Section 6.1. Since the translation service is the same, the computed BLEU scores are comparable. We observed that 98% of French-English and 96% of Persian-English sentence pairs, which fall in $3\sigma^+$ and $2\sigma^+$ regions of the model probability curve, are in the range of $2\sigma^+$ and $3\sigma^+$ area of the BLEU score Normal curve, too. This gives us an estimate of the quality of parallel data as well. As we discussed earlier, we are interested in perfect parallel sentences which are clustered in the highest σ regions. However partial parallel sentences in lower regions can be used for certain purposes too.

As we see in Table 3 there is a high correlation between the scores generated by the model and the BLEU scores of the parallel sentences. Therefore, we argue that irrespective of the language, the model is capable of extracting parallel sentences from any available language pair in Wikipedia with at least 95% accuracy in the last two σ regions. For other σ regions, although the confidence levels and respective accuracies are lower than the higher regions, partial parallel sentences still can be identified. In Figure 3 some parallel sentences with their probabilities estimated by the model are presented.

At the end to compare our results with other similar works, we applied our model on the German-English dataset of BUCC 2017 second shared task on parallel sentence extraction from comparable corpora (Zweigenbaum et al., 2017) and we obtained a state-of-the-art result on it. The results are presented in Table 4

Model	**Precision**	**Recall**	**F1**
VIC (Azpeitia et al., 2017)	88%	80%	84%
This work	**89%**	**83%**	**86%**

Table 4: System results on the German-English dataset of the second shared task of BUCC 2017

7 Error Analysis

As a qualitative study and a complement to the second task, we asked our evaluators to mention a reason why they think a pair of sentences might not be parallel. Based on a short data inquiry, we provided the evaluators with five major error types. We asked them to expand the list of errors if none of the provided error types explains why a given sentence pair is not parallel. They added other three errors to our list. These reasons are listed in Box 1. We can categorize these errors in noncritical, neutral and critical categories.

Sentences with noncritical errors such as error 4, 6 and 8 have slight problems and can be considered parallel in some cases. However, to enhance the quality of parallel sentences, these sentences are excluded from the system output. Neutral errors like errors 5 and 7 do not lead to a significant decrease in system performance, while critical mistakes like errors 1, 2, and 3, cause severe system malfunctioning.

Figure 3: Parallel Sentences and their model generated probabilities. The two boxes in the first row are gold parallel sentences translated by our translators. We returned the sentences to their original documents and used our model to estimate their probabilities. The two boxes in the second and third rows are test English-French and English-Persian sentences, respectively.

In the following, we analyze each of these categories in detail.

1. Errors 4 and 6 are opposite of each other: either source or target sentence contains more information than its counterpart. It is mainly caused by translators adding information to the translated version. In case 8, there are minor discrepancies between source and target sentences. Some of these cases can be considered parallel pairs though. The majority of errors in $3\sigma^+$ and $2\sigma^+$ belong to this category.

2. In case 5, a semi-parallel sentence is detected as a parallel sentence. However, the two sentences do not have enough semantic overlap and are therefore not parallel. In case 7, despite dealing with the same topic, sentence pairs have diverging contexts and settings and are consequently not parallel. We found a few errors of this type only in the $1\sigma^+$ region.

3. In case 1, the source and target sentences are different with no semantic overlap. In case 2, the source or target sentence is incomplete, which is caused by a malfunctioning sentence segmenter. In case 3, extracted source and target sentences are in the same language, which occasionally happens when

- for whatever reason - some sentences are not translated in the target text. The majority of errors in $3\sigma^-$, $2\sigma^-$, and $1\sigma^-$ belong to this category.

The errors in the first category require more elaborate linguistic analysis to be eradicated than the errors in the third category. The errors in the second category are barely detrimental to the system performance.

Default Reasons:
1- Totally different sentences
2- Incomplete sentences
3- Source and target sentences are in the same language.
4- More than half of the meaning is conveyed but not parallel.
5- Less than half of the meaning is conveyed.

Added Reasons:
6- Target sentence is correct but contains more information than the source sentence.
7- Information incorrect/different
8- Small detail(s) missing

Box 1: Human-judged reasons for lacking parallelity of extracted sentence pairs. Although items 4, 6, and 8 are strong candidates for parallel sentences, they are excluded from parallel sentence extraction to increase overall quality. Items 5 and 7 are trivial to the system performance. Items 1, 2, and 3 are serious system errors.

8 Conclusion

We introduced a language-independent parallel sentence extractor using an end-to-end deep neural network architecture. Our system extracts parallel sentences form comparable pages in Wikipedia. Using the gold parallel data compiled by our human evaluators for the German-English language pair, we showed that the system is highly accurate in extracting parallel sentences in other languages as well. Using the system thresholds estimated by human evaluation, we extracted high-quality parallel sentences for German-English, French-English, and Persian-English language pairs. Our model also obtained a state-of-the-art result on the German-English dataset of BUCC 2017 second shared task. In future work, we aim to improve the system by eradicating its errors and performing the translation step seamlessly without the need for any external translation services[3].

Abstract

Recent years have witnessed a surge of publications aimed at tracing temporal changes in lexical semantics using distributional methods, particularly prediction-based word embedding models. However, this vein of research lacks the cohesion, common terminology and shared practices of more established areas of natural language processing. In this paper, we survey the current state of academic research related to diachronic word embeddings and semantic shifts detection. We start with discussing the notion of semantic shifts, and then continue with an overview of the existing methods for tracing such time-related shifts with word embedding models. We propose several axes along which these methods can be compared, and outline the main challenges before this emerging subfield of NLP, as well as prospects and possible applications.

1 Introduction

The meanings of words continuously change over time, reflecting complicated processes in language and society. Examples include both changes to the core meaning of words (like the word *gay* shifting from meaning 'carefree' to 'homosexual' during the 20th century) and subtle shifts of cultural associations (like *Iraq* or *Syria* being associated with the concept of 'war' after armed conflicts had started in these countries). Studying these types of changes in meaning enables researchers to learn more about human language and to extract temporal-dependent data from texts.

The availability of large corpora and the development of computational semantics have given rise to a number of research initiatives trying to capture *diachronic semantic shifts* in a data-driven way. Recently, *word embeddings* (Mikolov et al., 2013b) have become a widely used input representation for this task. There are dozens of papers on the topic, mostly published after 2011 (we survey them in Section 3 and further below). However, this emerging field is highly heterogenous. There are at least three different research communities interested in it: natural language processing (and computational linguistics), information retrieval (and computer science in general), and political science. This is reflected in the terminology, which is far from being standardized. One can find mentions of 'temporal embeddings,' 'diachronic embeddings,' 'dynamic embeddings,' etc., depending on the background of a particular research group. The present survey paper attempts to describe this diversity, introduce some axes of comparison and outline main challenges which the practitioners face. Figure 1 shows the timeline of events that influenced the research in this area: in the following sections we cover them in detail.

This survey is restricted in scope to research which traces semantic shifts using distributional word embedding models (that is, representing lexical meaning with dense vectors produced from co-occurrence data). We only briefly mention other data-driven approaches also employed to analyze temporal-labeled corpora (for example, topic modeling). Also, we do not cover syntactic shifts and other changes in the functions rather than meaning of words.

The paper is structured as follows. In Section 2 we introduce the notion of 'semantic shift' and provide some linguistic background for it. Section 3 aims to compare different approaches to the task of

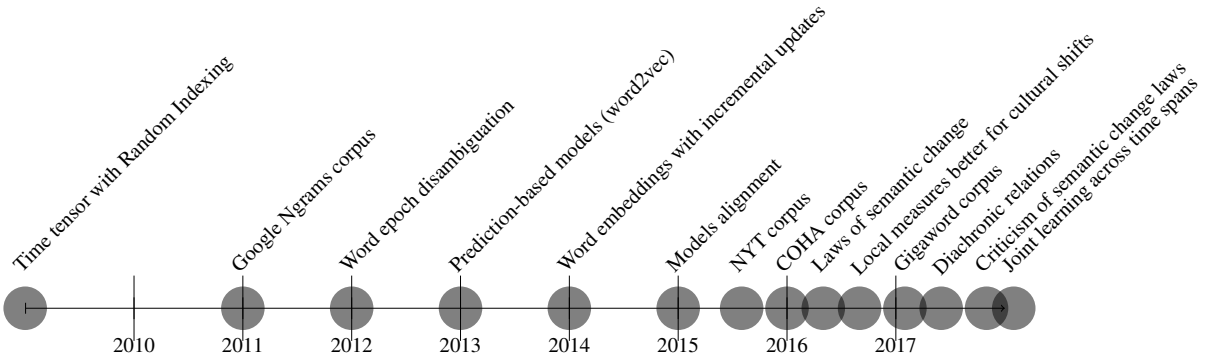

Figure 1: Distributional models in the task of tracing diachronic semantic shifts: research timeline

automatic detection of semantic shifts: in the choice of diachronic data, evaluation strategies, methodology of extracting semantic shifts from data, and the methods to compare word vectors across time spans. Sections 4 and 5 describe two particularly interesting results of diachronic embeddings research: namely, the statistical laws of semantic change and temporal semantic relations. In Section 6 we outline possible applications of systems that trace semantic shifts. Section 7 presents open challenges which we believe to be most important for the field, and in Section 8 we summarize and conclude.

2 The concept of semantic shifts

Human languages change over time, due to a variety of linguistic and non-linguistic factors and at all levels of linguistic analysis. In the field of theoretical (diachronic) linguistics, much attention has been devoted to expressing regularities of linguistic change. For instance, laws of phonological change have been formulated (e.g., Grimm's law or the great vowel shift) to account for changes in the linguistic sound system. When it comes to lexical semantics, linguists have studied the evolution of word meaning over time, describing so-called lexical *semantic shifts* or *semantic change*, which Bloomfield (1933) defines as "innovations which change the lexical meaning rather than the grammatical function of a form."

Historically, much of the theoretical work on semantic shifts has been devoted to documenting and categorizing various types of semantic shifts (Bréal, 1899; Stern, 1931; Bloomfield, 1933). The categorization found in Bloomfield (1933) is arguably the most used and has inspired a number of more recent studies (Blank and Koch, 1999; Geeraerts, 1997; Traugott and Dasher, 2001). Bloomfield (1933) originally proposed nine classes of semantic shifts, six of which are complimentary pairs along a dimension. For instance, the pair 'narrowing' – 'broadening' describes the observation that word meaning often changes to become either more specific or more general, e.g. Old English *mete* 'food' becomes English *meat* 'edible flesh,' or that the more general English word *dog* is derived from Middle English *dogge* which described a dog of a particular breed. Bloomfield (1933) also describes change along the spectrum from positive to negative, describing the speaker's attitude as one of either degeneration or elevation, e.g. from Old English *cniht* 'boy, servant' to the more elevated *knight*.

The driving forces of semantic shifts are varied, but include linguistic, psychological, sociocultural or cultural/encyclopedic causes (Blank and Koch, 1999; Grzega and Schoener, 2007). Linguistic processes that cause semantic shifts generally involve the interaction between words of the vocabulary and their meanings. This may be illustrated by the process of ellipsis, whereby the meaning of one word is transferred to a word with which it frequently co-occurs, or by the need for discrimination of synonyms caused by lexical borrowings from other languages. Semantic shifts may be also be caused by changes in the attitudes of speakers or in the general environment of the speakers. Thus, semantic shifts are naturally separated into two important classes: linguistic drifts (slow and regular changes in core meaning of words) and cultural shifts (culturally determined changes in associations of a given word). Researchers studying semantic shifts from a computational point of view have shown the existence of this division empirically (Hamilton et al., 2016c). In the traditional classification of Stern (1931), the semantic shift category of *substitution* describes a change that has a non-linguistic cause, namely that of technologi-

cal progress. This may be exemplified by the word *car* which shifted its meaning from non-motorized vehicles after the introduction of the automobile.

The availability of large corpora have enabled the development of new methodologies for the study of lexical semantic shifts within general linguistics (Traugott, 2017). A key assumption in much of this work is that changes in a word's collocational patterns reflect changes in word meaning (Hilpert, 2008), thus providing a usage-based account of semantics (Gries, 1999). For instance, Kerremans et al. (2010) study the very recent neologism *detweet*, showing the development of two separate usages/meanings for this word ('to delete from twitter,' vs 'to avoid tweeting') based on large amounts of web-crawled data. The usage-based view of lexical semantics aligns well with the assumptions underlying the distributional semantic approach (Firth, 1957) often employed in NLP . Here, the time spans studied are often considerably shorter (decades, rather than centuries) and we find that these distributional methods seem well suited for monitoring the gradual process of meaning change. Gulordava and Baroni (2011), for instance, showed that distributional models capture cultural shifts, like the word *sleep* acquiring more negative connotations related to sleep disorders, when comparing its 1960s contexts to its 1990s contexts.

To sum up, semantic shifts are often reflected in large corpora through change in the context of the word which is undergoing a shift, as measured by co-occurring words. It is thus natural to try to detect semantic shifts automatically, in a 'data-driven' way. This vein of research is what we cover in the present survey. In the following sections, we overview the methods currently used for the automatic detection of semantic shifts and the recent academic achievements related to this problem.

3 Tracing semantic shifts distributionally

Conceptually, the task of discovery of semantic shifts from data can be formulated as follows. Given corpora $[C_1, C_2, ...C_n]$ containing texts created in time periods $[1, 2, ...n]$, the task is to locate words with different meaning in different time periods, or to locate the words which changed most. Other related tasks are possible: discovering general trends in semantic shifts (see Section 4) or tracing the dynamics of the relationships between words (see Section 5). In the next subsections, we address several axes along which one can categorize the research on detecting semantic shifts with distributional models.

3.1 Sources of diachronic data for training and testing

When automatically detecting semantic shifts, the types of generalizations we will be able to infer are influenced by properties of the textual data being used, such as the source of the datasets and the temporal granularity of the data. In this subsection we discuss the data choices made by researchers (of course, not pretending to cover the whole range of the diachronic corpora used).

3.1.1 Training data

The time unit (the granularity of the temporal dimension) can be chosen before slicing the text collection into subcorpora. Earlier works dealt mainly with long-term semantic shifts (spanning decades or even centuries), as they are easier to trace. One of the early examples is Sagi et al. (2011) who studied differences between Early Middle, Late Middle and Early Modern English, using the Helsinki Corpus (Rissanen and others, 1993).

The release of the Google Books Ngrams corpus[1] played an important role in the development of the field and spurred work on the new discipline of 'culturomics,' studying human culture through digital media (Michel et al., 2011). Mihalcea and Nastase (2012) used this dataset to detect differences in word usage and meaning across 50-years time spans, while Gulordava and Baroni (2011) compared word meanings in the 1960s and in the 1990s, achieving good correlation with human judgments. Unfortunately, Google Ngrams is inherently limited in that it does not contain full texts. However, for many cases, this corpus was enough, and its usage as the source of diachronic data continued in Mitra et al. (2014) (employing syntactic ngrams), who detected word sense changes over several different time periods spanning from 3 to 200 years.

[1] https://books.google.com/ngrams

In more recent work, time spans tend to decrease in size and become more granular. In general, corpora with smaller time spans are useful for analyzing socio-cultural semantic shifts, while corpora with longer spans are necessary for the study of linguistically motivated semantic shifts. As researchers are attempting to trace increasingly subtle cultural semantic shifts (more relevant for practical tasks), the granularity of time spans is decreasing: for example, Kim et al. (2014) and Liao and Cheng (2016) analyzed the *yearly* changes of words. Note that, instead of using granular 'bins', time can also be represented as a continuous differentiable value (Rosenfeld and Erk, 2018).

In addition to the Google Ngrams dataset (with granularity of 5 years), Kulkarni et al. (2015) used Amazon Movie Reviews (with granularity of 1 year) and Twitter data (with granularity of 1 month). Their results indicated that computational methods for the detection of semantic shifts can be robustly applied to time spans less than a decade. Zhang et al. (2015) used another yearly text collection, the New-York Times Annotated Corpus (Sandhaus, 2008), again managing to trace subtle semantic shifts. The same corpus was employed by Szymanski (2017), with 21 separate models, one for each year from 1987 to 2007, and to some extent by Yao et al. (2018), who crawled the NYT web site to get 27 yearly subcorpora (from 1990 to 2016). The inventory of diachronic corpora used in tracing semantic shifts was expanded by Eger and Mehler (2016), who used the Corpus of Historical American (COHA[2]), with time slices equal to one decade. Hamilton et al. (2016a) continued the usage of COHA (along with the Google Ngrams corpus). Kutuzov et al. (2017b) started to employ the yearly slices of the English Gigaword corpus (Parker et al., 2011) in the analysis of cultural semantic drift related to armed conflicts.

3.1.2 Test sets

Diachronic corpora are needed not only as a source of *training* data for developing semantic shift detection systems, but also as a source of *test* sets to evaluate such systems. In this case, however, the situation is more complicated. Ideally, diachronic approaches should be evaluated on human-annotated lists of semantically shifted words (ranked by the degree of the shift). However, such gold standard data is difficult to obtain, even for English, let alone for other languages. General linguistics research on language change like that of Traugott and Dasher (2001) and others usually contain only a small number of hand-picked examples, which is not sufficient to properly evaluate an automatic unsupervised system.

Various ways of overcoming this problem have been proposed. For example, Mihalcea and Nastase (2012) evaluated the ability of a system to detect the time span that specific contexts of a word undergoing a shift belong to (*word epoch disambiguation*). A similar problem was offered as SemEval-2015 Task 7: 'Diachronic Text Evaluation' (Popescu and Strapparava, 2015). Another possible evaluation method is so-called cross-time alignment, where a system has to find equivalents for certain words in different time periods (for example, 'Obama' in 2015 corresponds to 'Trump' in 2017). There exist several datasets containing such temporal equivalents for English (Yao et al., 2018). Yet another evaluation strategy is to use the detected diachronic semantic shifts to trace or predict real-world events like armed conflicts (Kutuzov et al., 2017b). Unfortunately, all these evaluation methods still require the existence of large manually annotated semantic shift datasets. The work to properly create and curate such datasets is in its infancy.

One reported approach to avoid this requirement is borrowed from research on word sense disambiguation and consists of making a synthetic task by merging two real words together and then modifying the training and test data according to a predefined sense-shifting function. Rosenfeld and Erk (2018) successfully employed this approach to evaluate their system; however, it still operates on synthetic words, limiting the ability of this evaluation scheme to measure the models' performance with regards to real semantic shift data. Thus, the problem of evaluating semantic shift detection approaches is far from being solved, and practitioners often rely on self-created test sets, or even simply manually inspecting the results.

3.2 Methodology of extracting semantic shifts from data

After settling on a diachronic data set to be used in the system, one has to choose the methods to analyze it. Before the broad adoption of word embedding models, it was quite common to use change in raw

[2] http://corpus.byu.edu/coha/

word frequencies in order to trace semantic shifts or other kinds of linguistic change; see, among others, Juola (2003), Hilpert and Gries (2009), Michel et al. (2011), Lijffijt et al. (2012), or Choi and Varian (2012) for frequency analysis of words in web search queries. Researchers also studied the increase or decrease in the frequency of a word A collocating with another word B over time, and based on this inferred changes in the meaning of A (Heyer et al., 2009).

However, it is clear that semantic shifts are not always accompanied with changes in word frequency (or this connection may be very subtle and non-direct). Thus, if one were able to more directly model word meaning, such an approach should be superior to frequency-proxied methods. A number of recent publications have showed that *distributional word representations* (Turney et al., 2010; Baroni et al., 2014) provide an efficient way to solve these tasks. They represent meaning with sparse or dense (embedding) vectors, produced from word co-occurrence counts. Although conceptually the source of the data for these models is still word frequencies, they 'compress' this information into continuous lexical representations which are both efficient and convenient to work with. Indeed, Kulkarni et al. (2015) explicitly demonstrated that distributional models outperform the frequency-based methods in detecting semantic shifts. They managed to trace semantic shifts more precisely and with greater explanatory power. One of the examples from their work is the semantic evolution of the word *gay*: through time, its nearest semantic neighbors changed, manifesting the gradual move away from the sense of 'cheerful' to the sense of 'homosexual.'

In fact, distributional models were being used in diachronic research long before the paper of Kulkarni et al. (2015), although there was no rigorous comparison to the frequentist methods. Already in 2009, it was proposed that one can use distributional methods to detect semantic shifts in a quantitative way. The pioneering work by Jurgens and Stevens (2009) described an insightful conceptualization of a sequence of distributional model updates through time: it is effectively a Word:Semantic Vector:Time tensor, in the sense that each word in a distributional model possesses a set of semantic vectors for each time span we are interested in. It paved the way for quantitatively comparing not only words with regard to their meaning, but also different stages in the development of word meaning over time.

Jurgens and Stevens (2009) employed the *Random Indexing* (RI) algorithm (Kanerva et al., 2000) to create word vectors. Two years later, Gulordava and Baroni (2011) used explicit count-based models, consisting of sparse co-occurrence matrices weighted by Local Mutual Information, while Sagi et al. (2011) turned to Latent Semantic Analysis (Deerwester et al., 1990). In Basile et al. (2014), an extension to RI dubbed *Temporal Random Indexing* (TRI) was proposed. However, no quantitative evaluation of this approach was offered (only a few hand-picked examples based on the Italian texts from the *Gutenberg Project*), and thus it is unclear whether TRI is any better than other distributional models for the task of semantic shift detection.

Further on, the diversity of the employed methods started to increase. For example, Mitra et al. (2014) analyzed clusters of the word similarity graph in the subcorpora corresponding to different time periods. Their distributional model consisted of lexical nodes in the graphs connected with weighted edges. The weights corresponded to the number of shared most salient syntactic dependency contexts, where saliency was determined by co-occurrence counts scaled by Mutual Information (MI). Importantly, they were able to detect not only the mere fact of a semantic shift, but also its type: the birth of a new sense, splitting of an old sense into several new ones, or merging of several senses into one. Thus, this work goes into a much less represented class of 'fine-grained' approaches to semantic shift detection. It is also important that Mitra et al. (2014) handle natively the issue of polysemous words, putting the much-neglected problem of word senses in the spotlight.

The work of Kim et al. (2014) was seminal in the sense that it is arguably the first one employing *prediction-based word embedding models* to trace diachronic semantic shifts. Particularly, they used incremental updates (see below) and Continuous Skipgram with negative sampling (SGNS) (Mikolov et al., 2013a).[3] Hamilton et al. (2016a) showed the superiority of SGNS over explicit PPMI-based distributional models in semantic shifts analysis, although they noted that low-rank SVD approximations (Bullinaria and Levy, 2007) can perform on par with SGNS, especially on smaller datasets. Since then,

[3]Continuous Bag-of-Words (CBOW) from the same paper is another popular choice for learning semantic vectors.

the majority of publications in the field started using dense word representations: either in the form of SVD-factorized PPMI matrices, or in the form of prediction-based shallow neural models like SGNS.[4]

There are some works employing other distributional approaches to semantic shifts detection. For instance, there is a strong vein of research based on dynamic topic modeling (Blei and Lafferty, 2006; Wang and McCallum, 2006), which learns the evolution of topics over time. In Wijaya and Yeniterzi (2011), it helped solve a typical digital humanities task of finding traces of real-world events in the texts. Heyer et al. (2016) employed topic analysis to trace the so-called 'context volatility' of words. In the political science, topic models are also sometimes used as proxies to social trends developing over time: for example, Mueller and Rauh (2017) employed LDA to predict timing of civil wars and armed conflicts. Frermann and Lapata (2016) drew on these ideas to trace diachronic word senses development. But most scholars nowadays seem to prefer parametric distributional models, particularly prediction-based embedding algorithms like SGNS, CBOW or GloVe (Pennington et al., 2014). Following their widespread adoption in NLP in general, they have become the dominant representations for the analysis of diachronic semantic shifts as well.

3.3 Comparing vectors across time

It is rather straightforward to train separate word embedding models using time-specific corpora containing texts from several different time periods. As a consequence, these models are also time-specific. However, it is not that straightforward to compare word vectors across different models.

It usually does not make sense to, for example, directly calculate cosine similarities between embeddings of one and the same word in two different models. The reason is that most modern word embedding algorithms are inherently stochastic and the resulting embedding sets are invariant under rotation. Thus, even when trained on the same data, separate learning runs will produce entirely different numerical vectors (though with roughly the same pairwise similarities between vectors for particular words). This is expressed even stronger for models trained on different corpora. It means that even if word meaning is completely stable, the direct cosine similarity between its vectors from different time periods can still be quite low, simply because the random initializations of the two models were different. To alleviate this, Kulkarni et al. (2015) suggested that before calculating similarities, one should first *align* the models to fit them in one vector space, using linear transformations preserving general vector space structure. After that, cosine similarities across models become meaningful and can be used as indicators of semantic shifts. They also proposed constructing the time series of a word embedding over time, which allows for the detection of 'bursts' in its meaning with the *Mean Shift* model (Taylor, 2000). Notably, almost simultaneously the idea of aligning diachronic word embedding models using a distance-preserving projection technique was proposed by Zhang et al. (2015). Later, Zhang et al. (2016) expanded on this by adding the so called 'local anchors': that is, they used both linear projections for the whole models and small sets of nearest neighbors for mapping the query words to their correct temporal counterparts.

Instead of aligning their diachronic models using linear transformations, Eger and Mehler (2016) compared word meaning using so-called 'second-order embeddings,' that is, the vectors of words' similarities to all other words in the shared vocabulary of all models. This approach does not require any transformations: basically, one simply analyzes the word's position compared to other words. At the same time, Hamilton et al. (2016a) and Hamilton et al. (2016c) showed that these two approaches can be used simultaneously: they employed both 'second order embeddings' and orthogonal Procrustes transformations to align diachronic models.

Recently, it was shown in Bamler and Mandt (2017) ('*dynamic skip-gram*' model) and Yao et al. (2018) ('*dynamic Word2Vec*' model) that it is possible to learn the word embeddings across several time periods jointly, enforcing alignment across all of them simultaneously, and positioning all the models in the same vector space in one step. This develops the idea of model alignment even further and eliminates the need to first learn separate embeddings for each time period, and then align subsequent model pairs. Bamler and Mandt (2017) additionally describe two variations of their approach: a) for the cases when data slices arrive sequentially, as in streaming applications, where one can not use future observations, and b) for

[4]Levy and Goldberg (2014) showed that these two approaches are equivalent from the mathematical point of view.

the cases when data slices are available all at once, allowing for training on the whole sequence from the very beginning. A similar approach is taken by Rosenfeld and Erk (2018) who train a deep neural network on word and time representations. Word vectors in this setup turn into linear transformations applied to a continuous time variable, and thus producing an embedding of word w at time t.

Yet another way to make the models comparable is made possible by the fact that prediction-based word embedding approaches (as well as RI) allow for incremental updates of the models with new data without any modifications. This is not the case for the traditional explicit count-based algorithms, which usually require a computationally expensive dimensionality reduction step. Kim et al. (2014) proposed the idea of *incrementally updated diachronic embedding models*: that is, they train a model on the year y_i, and then the model for the year y_{i+1} is initialized with the word vectors from y_i. This can be considered as an alternative to model alignment: instead of aligning models trained from scratch on different time periods, one starts with training a model on the diachronically first period, and then updates this same model with the data from the successive time periods, saving its state each time. Thus, all the models are inherently related to each other, which, again, makes it possible to directly calculate cosine similarities between the same word in different time period models, or at least makes the models more comparable.

Several works have appeared recently which aim to address the technical issues accompanying this approach of incremental updating. Among others, Peng et al. (2017) described a novel method of incrementally learning the *hierarchical softmax* function for the CBOW and Continuous Skipgram algorithms. In this way, one can update word embedding models with new data and new vocabulary much more efficiently, achieving faster training than when doing it from scratch, while at the same time preserving comparable performance. Continuing this line of research, Kaji and Kobayashi (2017) proposed a conceptually similar incremental extension for *negative sampling*, which is a method of training examples selection, widely used with prediction-based models as a faster replacement for *hierarchical softmax*.

Even after the models for different time periods are made comparable in this or that way, one still has to choose the exact method of comparing word vectors across these models. Hamilton et al. (2016a) and Hamilton et al. (2016c) made an important observation that the distinction between linguistic and cultural semantic shifts is correlated with the distinction between *global* and *local* embedding comparison methods. The former take into account the whole model (for example, 'second-order embeddings,' when we compare the word's similarities to all other words in the lexicon), while the latter focus on the word's immediate neighborhood (for example, when comparing the lists of k nearest neighbors). They concluded that global measures are sensitive to regular processes of linguistic shifts, while local measures are better suited to detect slight cultural shifts in word meaning. Thus, the choice of particular embedding comparison approach should depend on what type of semantic shifts one seeks to detect.

4 Laws of semantic change

The use of diachronic word embeddings for studying the dynamics of word meaning has resulted in several hypothesized 'laws' of semantic change. We review some of these law-like generalizations below, before finally describing a study that questions their validity.

Dubossarsky et al. (2015) experimented with K-means clustering applied to SGNS embeddings trained for evenly sized yearly samples for the period 1850–2009. They found that the degree of semantic change for a given word – quantified as the change in self-similarity over time – negatively correlates with its distance to the centroid of its cluster. They proposed that the likelihood for semantic shift correlates with the degree of prototypicality (the *'law of prototypicality'* in Dubossarsky et al. (2017)).

Another relevant study is reported by Eger and Mehler (2016), based on two different graph models; one being a time-series model relating embeddings across time periods to model semantic shifts and the other modeling the self-similarity of words across time. Experiments were performed with time-indexed historical corpora of English, German and Latin, using time-periods corresponding to decades, years and centuries, respectively. To enable comparison of embeddings across time, second-order embeddings encoding similarities to other words were used, as described in 3.3, limited to the 'core vocabulary' (words occurring at least 100 times in all time periods). Based on linear relationships observed in the graphs, Eger and Mehler (2016) postulate two 'laws' of semantic change:

1. word vectors can be expressed as linear combinations of their neighbors in previous time periods;

2. the meaning of words tend to decay linearly in time, in terms of the similarity of a word to itself; this is in line with the '*law of differentiation*' proposed by Xu and Kemp (2015).

In another study, Hamilton et al. (2016a) considered historical corpora for English, German, French and Chinese, spanning 200 years and using time spans of decades. The goal was to investigate the role of frequency and polysemy with respect to semantic shifts. As in Eger and Mehler (2016), the rate of semantic change was quantified by self-similarity across time-points (with words represented by Procrustes-aligned SVD embeddings). Through a regression analysis, Hamilton et al. (2016a) investigated how the change rates correlate with frequency and polysemy, and proposed another two 'laws':

1. frequent words change more slowly ('*the law of conformity*');

2. polysemous words (controlled for frequency) change more quickly ('*the law of innovation*').

Azarbonyad et al. (2017) showed that these laws (at least the law of conformity) hold not only for diachronic corpora, but also for other 'viewpoints': for example, semantic shifts across models trained on texts produced by different political actors or written in different genres (Kutuzov et al., 2016). However, the temporal dimension allows for a view of the corpora under analysis as a sequence, making the notion of 'semantic shift' more meaningful.

Later, Dubossarsky et al. (2017) questioned the validity of some of these proposed 'laws' of semantic change. In a series of replication and control experiments, they demonstrated that some of the regularities observed in previous studies are largely artifacts of the models used and frequency effects. In particular, they considered 10-year bins comprising equally sized yearly samples from Google Books 5-grams of English fiction for the period 1990–1999. For control experiments, they constructed two additional data sets; one with chronologically shuffled data where each bin contains data from all decades evenly distributed, and one synchronous variant containing repeated random samples from the year 1999 alone. Any measured semantic shifts within these two alternative data sets would have to be due to random sampling noise.

Dubossarsky et al. (2017) performed experiments using raw co-occurrence counts, PPMI weighted counts, and SVD transformations (Procrustes aligned), and conclude that the 'laws' proposed in previous studies – that semantic change is correlated with frequency, polysemy (Hamilton et al., 2016a) and prototypicality (Dubossarsky et al., 2015) – are not valid as they are also observed in the control conditions. Dubossarsky et al. (2017) suggested that these spurious effects are instead due to the type of word representation used – count vectors – and that semantic shifts must be explained by a more diverse set of factors than distributional ones alone. Thus, the discussion on the existence of the 'laws of semantic change' manifested by distributional trends is still open.

5 Diachronic semantic relations

Word embedding models are known to successfully capture complex *relationships* between concepts, as manifested in the well-known word analogies task (Mikolov et al., 2013a), where a model must 'solve' equations of the form 'A is to B is as C is to what?' A famous example is the distributional model capturing the fact that the relation between '*man*' and '*woman*' is the same as between '*king*' and '*queen*' (by adding and subtracting the corresponding word vectors). Thus, it is a natural development to investigate whether changes in semantic relationships across time can also be traced by looking at the diachronic development of distributional models.

Zhang et al. (2015) considered the *temporal correspondences problem*, wherein the objective is to identify the word in a target time period which corresponds to a query term in the source time period (for example, given the query term *iPod* in the 2000s, the counterpart term in the 1980s time period is *Walkman*). This is proposed as a means to improve the results of information retrieval from document collections with significant time spans. Szymanski (2017) frames this as the *temporal word analogy* problem, extending the word analogies concept into the temporal dimension. This work shows that

diachronic word embeddings can successfully model relations like 'word w_1 at time period t_α is like word w_2 at time period t_β'. To this end, embedding models trained on different time periods are aligned using linear transformations. Then, the temporal analogies are solved by simply finding out which word vector in the time period t_β is the closest to the vector of w_1 in the time period t_α.

A variation of this task was studied in Rosin et al. (2017), where the authors learn the relatedness of words over time, answering queries like 'in which time period were the words *Obama* and *president* maximally related'. This technique can be used for a more efficient user query expansion in general-purpose search engines. Kutuzov et al. (2017a) modeled a different semantic relation: 'words w_1 and w_2 at time period t_α are in the same semantic relation as words w_3 and w_4 at time period t_β'. To trace the temporal dynamics of these relations, they re-applied linear projections learned on sets of w_1 and w_2 pairs from the model for the period t_n to the model trained on the subsequent time period t_{n+1}. This was used to solve the task of detecting lasting or emerging armed conflicts and the violent groups involved in these conflicts.

6 Applications

Applications of diachronic word embeddings approaches can generally be grouped into two broad categories: *linguistic studies* which investigate the how and why of semantic shifts, and *event detection* approaches which mine text data for actionable purposes.

The first category generally involves corpora with longer time spans, since linguistic changes happen at a relatively slow pace. Some examples falling into this category include tracking semantic drift of particular words (Kulkarni et al., 2015) or of word sentiment (Hamilton et al., 2016b), identifying the breakpoints between epochs (Sagi et al., 2011; Mihalcea and Nastase, 2012), studying the laws of semantic change at scale (Hamilton et al., 2016c) and finding different words with similar meanings at different points in time (Szymanski, 2017). This has been held up as a good use case of deep learning for research in computational linguistics (Manning, 2015), and there are opportunities for future work applying diachronic word embeddings not only in the field of historical linguistics, but also in related areas like sociolinguistics and digital humanities.

The second category involves mining texts for cultural semantic shifts (usually on shorter time spans) indicating real-world events. Examples of this category are temporal information retrieval (Rosin et al., 2017), predicting civil turmoils (Kutuzov et al., 2017b; Mueller and Rauh, 2017), or tracing the popularity of entities using norms of word vectors (Yao et al., 2018). They can potentially be employed to improve user experience in production systems or for policy-making in governmental structures.

We believe that the near future will see a more diverse landscape of applications for diachronic word embeddings, especially related to the real-time analysis of large-scale news streams. 'Between the lines,' these data sources contain a tremendous amount of information about processes in our world, manifested in semantic shifts of various sorts. The task of researchers is to reveal this information and make it reliable and practically useful.

7 Open challenges

The study of temporal aspects of semantic shifts using distributional models (including word embeddings) is far from being a solved problem. The field still has a considerable number of open challenges. Below we briefly describe the most demanding ones.

- The existing methods should be expanded to a *wider scope of languages*. Hamilton et al. (2016a), Kutuzov and Kuzmenko (2018) and others have started to analyze other languages, but the overwhelming majority of publications still apply only to English corpora. It might be the case that the best methodologies are the same for different languages, but this should be shown empirically.

- There is a clear need to devise algorithms that work on *small datasets*, as they are very common in historical linguistics, digital humanities, and similar disciplines.

- Carefully designed and robust *gold standard test sets* of semantic shifts (of different kinds) should be created. This is a difficult task in itself, but the experience from synchronic word embeddings evaluation (Hill et al., 2015) and other NLP areas proves that it is possible.

- There is a need for rigorous *formal mathematical models of diachronic embeddings*. Arguably, this will follow the vein of research in joint learning across several time spans, started by Bamler and Mandt (2017) and Yao et al. (2018), but other directions are also open.

- Most current studies stop after stating the simple fact that a semantic shift has occurred. However, more detailed analysis of the nature of the shift is needed. This includes:

    1. *Sub-classification of types of semantic shifts* (broadening, narrowing, etc). This problem was to some degree addressed by Mitra et al. (2014), but much more work is certainly required to empirically test classification schemes proposed in much of the theoretical work described in Section 2.
    2. *Identifying the source of a shift* (for example, linguistic or extra-linguistic causes). This causation detection is closely linked to the division between linguistic drifts and cultural shifts, as proposed in Hamilton et al. (2016c).
    3. *Quantifying the weight of senses* acquired over time. Many words are polysemous, and the relative importance of senses is flexible (Frermann and Lapata, 2016). The issue of handling senses is central for detecting semantic shifts, but most of the algorithms described in this survey are not sense-aware. To address this, methods from sense embeddings research (Bartunov et al., 2016) might be employed.
    4. *Identifying groups of words that shift together* in correlated ways. Some work in this direction was started in Dubossarsky et al. (2016), who showed that verbs change more than nouns, and nouns change more than adjectives. This is also naturally related to proving the (non-)existence of the 'laws of semantic change' (see Section 4).

- Last but not least, we believe that the community around diachronic word embeddings research severely lacks relevant forums, like *topical workshops* or *shared tasks*. Diachronic text evaluation tasks like the one at *SemEval-2015* (Popescu and Strapparava, 2015) are important but not enough, since they focus on identifying the time period when a text was authored, not the process of shifting meanings of a word. Organizing such events can promote the field and help address many of the challenges described above.

8 Summary

We have presented an outline of the current research related to computational detection of semantic shifts using diachronic (temporal) word embeddings. We covered the linguistic nature of semantic shifts, the typical sources of diachronic data and the distributional approaches used to model it, from frequentist methods to contemporary prediction-based models. To sum up, Figure 1 shows the timeline of events that have been influential in the development of research in this area: introducing concepts, usage of corpora and important findings.

This emerging field is still relatively new, and although recent years has seen a string of significant discoveries and academic interchange, much of the research still appears slightly fragmented, not least due to the lack of dedicated venues like workshops, special issues, or shared tasks. We hope that this survey will be useful to those who want to understand how this field has developed, and gain an overview of what defines the current state-of-the-art and what challenges lie ahead.

Abstract

Traditional topic models are insufficient for topic extraction in social media. The existing methods only consider text information or simultaneously model the posts and the static characteristics of social media. They ignore that one discusses diverse topics when dynamically interacting with different people. Moreover, people who talk about the same topic have different effects on the topic. In this paper, we propose an Interaction-Aware Topic Model (IATM) for microblog conversations by integrating network embedding and user attention. A conversation network linking users based on reposting and replying relationship is constructed to mine the dynamic user behaviours. We model dynamic interactions and user attention so as to learn interaction-aware edge embeddings with social context. Then they are incorporated into neural variational inference for generating the more consistent topics. The experiments on three real-world datasets show that our proposed model is effective.

1 Introduction

The prosperity of microblog platforms, such as Twitter[1] and Sina Weibo[2] brings the large scale, noisy and user-generated short posts. Automatically extracting topics in social media aims to reveal thematic information of the underlying collection, which can be used in summarization (Zhuang et al., 2016), hashtag recommendation (Li et al., 2016b), response generation (Xing et al., 2017) and so on.

The conventional topic models, like Latent Dirichlet Allocation (LDA) (Blei et al., 2003), infer the hidden topics based on word co-occurrences in documents. They could not be directly transferred in social media due to the data sparsity and the noise of short texts.

The existing relevant researches can be roughly categorized into: (1) Methods exploit the content of short texts by aggregation strategy (Mehrotra et al., 2013) or modeling word-pair co-occurrence (Yan et al., 2013). (2) Models incorporating with word embedding try to deeply understand the posts by representation learning (Sridhar, 2015; Hu and Tsujii, 2016), yet they ignore the social context of microblog messages. Essentially, social media content and network structures influence each other (Bi et al., 2014), the only content analysis is insufficient. (3) (Li et al., 2016a; Chen and Ren, 2017) take into account the content and static characteristics of network structures to deduce topics. However, they ignore dynamic user behaviours.

Actually, a user may talk about various topics when interacting with diverse neighbours in a social network. For instance, Fig. 1(a) shows two conversation trees, where [U0] communicates with [U1] and [U2] about the topic of United Kingdom European Union membership referendum, while [U0] talks a game with [U3]. Hence, we need to infer topics according to the interactions between users. Moreover, although [U0] and [U1] argue about the same topic, [U0] contains salient content in topic description, e.g., *UK, EU, referendum* while the reply of [U1] is nothing but simply response to [U0], e.g., *Yes, agree*.

* Indicates equal contribution.

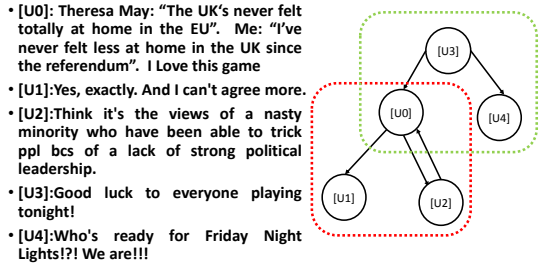
(a) Two conversation trees. [Ui]: the i-th user; Arrow lines: reposting/replying relations.



(b) An example of a conversation network. The green box shows the topic about a game; The red one exhibits the topic of Brexit referendum.

Figure 1: A conversation network is transformed from two conversation trees.

Thus, it is intuitive that during the topic extraction of United Kingdom European Union membership referendum, [U0] is more important than [U1]. The **dynamic interactions** and **diverse user attention** on the topic provide us heuristic insights for topic extraction.

Note that conversation trees can be transformed into conversation networks through user relations, as illustrated in the Fig. 1. Inspired by network embedding and social user behaviour researches, we propose an **I**nteraction **A**ware **T**opic **M**odel (IATM) integrating dynamic interactions and various effects of users on the topic. The contributions are as follows.

- We propose a novel Interaction-Aware Topic Model (IATM) for microblog conversations, which simultaneously considers social media content and network topology.
- Our method models dynamic interactions and various effects of users, and encodes them as interaction-aware edge embeddings through network embedding and user attention.
- The deeper edge representations are employed in neural variational inference for generating the more consistent topics.
- The experiments verify that the proposed IATM is effective. Dynamic user behaviours are useful for topic extraction of short texts in social media.

2 Related Work

Previous researches for topic extraction in social media can be mainly classified into two aspects.

2.1 Focusing on Content Information

They depend on pure content to generate document-topic distribution and topic-word distribution. (1) **Aggregation Strategy Based.** To solve the data sparsity short texts, some use different strategies to heuristically aggregate microblog messages based on authorship (Hong and Davison, 2010; Zhao et al., 2011) or hashtags (Mehrotra et al., 2013; Tang et al., 2013) before applying traditional topic model. Self-Aggregation based Topic Model (SATM) (Quan et al., 2015) combines short texts aggregation and topic induction into a unified model. Others use Biterm Topic Model (BTM) (Yan et al., 2013) and RNN-IDF based Biterm Short-text Topic Model (RIBSTM) (Lu et al., 2017) modeling biterm co-occurrence in the whole corpus to enhance topic discovery. (2) **Word Embedding Based.** Since word embeddings have been shown their ability to form clusters of conceptually similar words in the embedding space (Mikolov et al., 2013c), Gaussian Mixture Topic Model (GMTM) (Sridhar, 2015) and Latent Concept Topic Model (LCTM) (Hu and Tsujii, 2016) utilize word embeddings to improve topic generation. However, since social media content and network structures influence with each other, only focusing on content is insufficient.

2.2 Integrating Content and Network Structure information

This kind of researches considers social content and network structures together, including followship and repostship. (1) **Followship Based**. Lim et al.(2013) jointly model the text and user-follower network during topic inference. Yet the appearance of *Zombie Fans* purchased by those who would like to increase their influence, disturbs the followship network. (2) **Repostship Based**. LeadLDA (Li et al., 2016a) generates words according to topic dependencies derived from conversation trees by differentiating messages from leader and follower. Leader is the post that contains salient and new information in topic description while follower is the post that simply responds to its reposted or replied messages. Chen and Ren (2017) propose ForumLDA to infer topics by distinguishing response messages from relevant and irrelevant to the original post.

However, due to the zombie fans in followship network, or exploring the static characteristics in repostship network, these methods ignore the dynamic user behaviours latent in reciprocal interactions between users. Therefore we emphasize on exploring whether user interactions and user attention can help topic generation in social media.

2.3 Network Embedding and Neural Variational Inference

The further researches (Perozzi et al., 2014; Tu et al., 2017) about network embedding make it possible to suitably model the dynamic user behaviours. Meanwhile, comparing with topic models based on word embedding, Miao et al. (2017) and Srivastava and Sutton (2017) apply topic model with neural variational inference (Kingma and Welling, 2014) on traditional long documents, which consistently produces the better topics. A small change in the document will produce a small change in topics. Yet they have not taken into account sparse and noisy texts and network structures in social media.

Therefore, we model dynamic user behaviours and content information as interaction-aware edge embeddings, which combine network embedding and user attention. Further, they are incorporated into variational auto-encoder for topic extraction in social media, which can produce the more consistent and precise topics.

3 Interaction-Aware Topic Model

The large scale short and noisy texts in social media bring the more serious data sparseness and inconsistency in topics. Yet the dynamic user behaviours also provide us opportunities. Here, we propose two hypotheses and explore whether they are useful for topic extraction.

H1: Dynamic Interactions. One discusses various topics with different people.

H2: User Attention. Users who debate the same topic have diverse effects on the topic.

We need to construct a conversation network, shown in Fig. 1(b), transformed from conversation trees.

3.1 Conversation Network

Conversation networks are transformed from conversation trees through user relations, which are exhibited in Fig. 1(b). We first give the basic notations and definitions of a conversation network. Given $G = (V, E, T)$, where V is the set of vertices, $E \subseteq V \times V$ is the edges between vertices and T denotes text information of vertices. Each vertex $v \in V$ represents a user and every edge $e_{(u,v)} \in E$ stands for the reposting or replying relationship between two vertices (u, v). To solve the sparsity of short texts, we aggregate all the messages posted by the same user, including the original and the reposting messages[3]. Text information of the unique vertex $v \in V$ is the messages $M_v = (w_1, w_2, ..., w_n)$, where n is the count of words in M_v.

In order to illustrate the proposed IATM model, we firstly give two definitions:

D1: Edge Embedding. The edge embedding $\mathbf{e}$ for every edge $e_{(u,v)}$ is acquired by concatenating the vertex embeddings $\mathbf{u}$ and $\mathbf{v}$. It encodes user representations with respect to various neighbours.

D2: Interaction-aware Edge Embedding. It models the various effects of u and v on a topic via user attention mechanism, and makes edge embedding as an interaction-aware style.

[3]Both of replying and reposting messages are called reposting messages.

3.2 Model

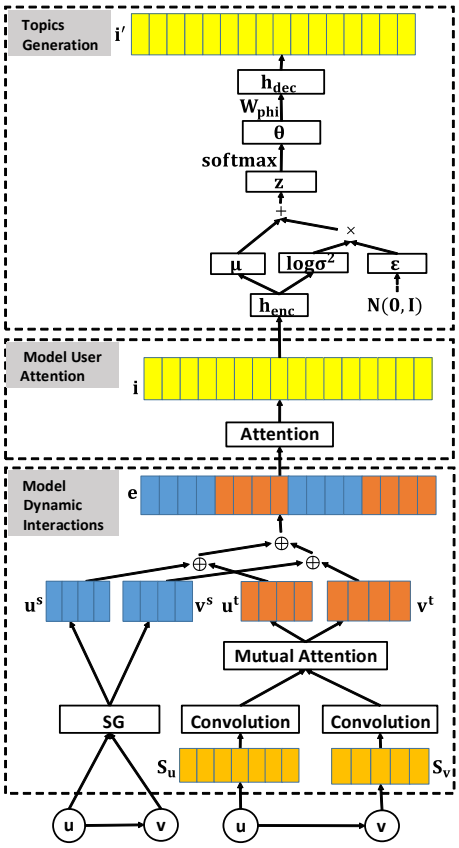


Figure 2: The IATM framework.

The proposed IATM framework is shown in Fig. 2. The generative process of IATM mainly includes three parts: (1) model dynamic interactions, (2) model user attention and (3) topics generation. A basis of three parts is that each word is represented as a low dimensional, continuous and real-valued vector, also known as word embedding (Mikolov et al., 2013c). Given text information of a vertex v, we take the embedding $\mathbf{w}_i \in \mathbb{R}^{d'}$ for each word to obtain embedding sequence as $\mathbf{S}_v = (\mathbf{w}_1, \mathbf{w}_2, ..., \mathbf{w}_n)$. Here, d' indicates the dimension of word embeddings.

3.2.1 Model Dynamic Interactions

Corresponding to the assumption H1, a specific vertex should have its own diverse points with distinct neighbours, which leads to different edge embeddings.

To make full use of network structures and associated text information, we encode each vertex v as a concatenation of a structure-based embedding $\mathbf{v}^{(s)}$ and a text-based embedding $\mathbf{v}^{(t)}$, and get the vertex embedding $\mathbf{v} = \mathbf{v}^{(s)} \oplus \mathbf{v}^{(t)} (\mathbf{v} \in \mathbb{R}^d)$.

Structure-based Embedding. We adopt a neural language model (SkipGram, or SG for short) (Mikolov et al., 2013a) for $\mathbf{v}^{(s)}$. To maximize the probability of a node's neighbourhood co-occurrence, we define the objective function of structure-based embeddings as follows

$$L_s = -\log \sum_{-k \le j \le k} p(\mathbf{v}_{i+j}^{(s)} | \mathbf{v}_i^{(s)}) \tag{1}$$

where $\mathbf{v}_i^{(s)}$ is corresponding to the i-th vertex, the window size is k, and $p(\mathbf{v}_{i+j}^{(s)} | \mathbf{v}_i^{(s)})$ is defined using

the *softmax* fuction

$$p(\mathbf{v}_{i+j}^{(s)}|\mathbf{v}_i^{(s)}) = \frac{\exp((\mathbf{v}_{i+j}^{(s)})^T \mathbf{v}_i^{(s)})}{\sum_{t=1}^{|V|} \exp((\mathbf{v}_t^{(s)})^T \mathbf{v}_i^{(s)})}. \tag{2}$$

In this way, nodes with similar neighbours share the similar structure-based embeddings.

Text-based Embedding. To discover the thematic information of the vertex pair in an edge, we utilize mutual attention (Santos et al., 2016; Tu et al., 2017) to obtain text-based embeddings, which allows the pooling operation to be aware of the topic of an edge $e_{(u,v)}$. To some extent, content information from a vertex can directly affect the text-based embedding of the other vertex, and vice versa.

Convolutional neural network (CNN) has gained great performance on the textual information encoding (Chen et al., 2015; Wang et al., 2017). Given the embedding sequence $\mathbf{S}_v$, we conduct convolution operation over $\mathbf{S}_v$ within the i-th window as follows

$$\mathbf{x}_i = \mathbf{C} \cdot (\mathbf{S}_v)_{i:i+l-1} + \mathbf{b} \tag{3}$$

where $\mathbf{C} \in \mathbb{R}^{d \times (l \times d')}$ is a convolution matrix, $\mathbf{b}$ is the bias vector and window size is l. The same operation is also on $\mathbf{S}_u$. The outputs of convolution, $\mathbf{P} \in \mathbb{R}^{d \times m}$ and $\mathbf{Q} \in \mathbb{R}^{d \times n}$ where m and n mean the length of $\mathbf{S}_u$ and $\mathbf{S}_v$ respectively, are as the input of mutual attention layer to compute the correlation matrix $\mathbf{F}$.

$$\mathbf{F} = relu(\mathbf{P^T A Q})(\mathbf{F} \in \mathbb{R}^{m \times n}) \tag{4}$$

$\mathbf{A} \in \mathbb{R}^{d \times d}$ is a matrix to be learned by the neural network and we emlpoy $relu$ as activation function. Note that, the element $\mathbf{F}_{i,j} \in \mathbf{F}$ is the pair-wise correlation score of the hidden vectors $\mathbf{P}_i$ and $\mathbf{Q}_j$.

Then, we employ the mean-pooling along rows and columns of $\mathbf{F}$ to generate pooling vectors by

$$g_i^{(p)} = \mathbf{mean}(\mathbf{F}_{i,1}, ..., \mathbf{F}_{i,n}) \quad g_j^{(q)} = \mathbf{mean}(\mathbf{F}_{1,j}, ..., \mathbf{F}_{m,j}). \tag{5}$$

The pooling vectors of $\mathbf{P}$ and $\mathbf{Q}$ are obtained as

$$\mathbf{g}^{(p)} = (g_1^{(p)}, ..., g_m^{(p)})^T \quad \mathbf{g}^{(q)} = (g_1^{(q)}, ..., g_n^{(q)})^T. \tag{6}$$

Next, the $softmax$ function is operated on $\mathbf{g}^{(p)}$ and $\mathbf{g}^{(q)}$ to get the mutual attentive vectors $\mathbf{a}^{(p)}$ and $\mathbf{a}^{(q)}$. For instance, the i-th element of mutual attentive vector $\mathbf{a}^{(p)}$ is computed as

$$a_i^{(p)} = \frac{\exp(g_i^{(p)})}{\sum_{t=1}^{m} \exp(g_t^{(p)})}. \tag{7}$$

Finally, we get the text-based embeddings $\mathbf{u}^{(t)}$ and $\mathbf{v}^{(t)}$ by $\mathbf{u}^{(t)} = \mathbf{P}\mathbf{a}^{(p)}$ and $\mathbf{v}^{(t)} = \mathbf{Q}\mathbf{a}^{(q)}$. The objective function of text-based embeddings is as

$$L_t(e) = \alpha \log p(\mathbf{v}^{(t)}|\mathbf{u}^{(t)}) + \beta \log p(\mathbf{v}^{(t)}|\mathbf{u}^{(s)}) + \gamma \log p(\mathbf{v}^{(s)}|\mathbf{u}^{(t)}) \tag{8}$$

where α, β and γ control the weights of corresponding parts. Similarly, we employ $softmax$ function for calculating the conditional probabilities in Eq. (8) as in Eq. (2).

Edge Embedding. Here, we obtain the vertex embeddings $\mathbf{u}$ and $\mathbf{v}$ by $\mathbf{u} = \mathbf{u}^{(s)} \oplus \mathbf{u}^{(t)}$ and $\mathbf{v} = \mathbf{v}^{(s)} \oplus \mathbf{v}^{(t)}$. In this way, we operate $\mathbf{e} = \mathbf{u} \oplus \mathbf{v}$ to get the edge embedding $\mathbf{e} \in \mathbb{R}^{2d}$ for $e_{(u,v)}$, which is dynamic context-aware.

3.2.2 Model User Attention

As referred before, we assume that users who discuss the identical topic may take different effects on the topic. Attention mechanism is designed for mining the different significance of users on the topic. Since edge embedding is incorporated by the vertex-pair embeddings in an edge and each vertex denotes a user, the attention of users on the topic are transformed into the user attention vector $\mathbf{a}^{(e)} \in \mathbb{R}^{2d}$. $\mathbf{a}^{(e)}$

is computed by conducting $softmax$ function on the edge embedding $\mathbf{e}$. To formulate, the i-th element of $\mathbf{a}^{(e)}$ is computed as

$$a_i^{(e)} = \frac{\exp(\mathbf{e}_i)}{\sum_{t=1}^{2d} \exp(\mathbf{e}_t)}. \tag{9}$$

After that, through combining topic information of the vertex-pair in an edge with user attention on the topic, we obtain interaction-aware edge embedding $\mathbf{i} \in \mathbb{R}^{2d}$ by using element-wise product as $\mathbf{i} = (\mathbf{e}_1\mathbf{a}_1^{(e)}, ..., \mathbf{e}_{2d}\mathbf{a}_{2d}^{(e)})$.

3.2.3 Topics Generation

Neural variational inference (Miao et al., 2017) approximates the posterior of a generative model with a variational distribution parameterized by a neural network, which consistently generates the better topics. With respect to social media, we input the interaction-aware edge embedding, which is encoded with dynamic user behaviours and content information, into variational auto-encoder. To formulate, suppose $\hat{d}$ is a document, w is a word in $\hat{d}$ and the number of topics is K. Here, we adopt neural variational inference to infer the multinomial document-topic distribution $\theta_{\hat{d}} = (p(t_1|\hat{d}), ..., p(t_K|\hat{d}))$ and topic-word distribution $\phi_w = (p(w|t_1), ..., p(w|t_K))$, where t_i is the i-th topic.

Document-topic distribution. Precisely, given the interaction-aware edge embedding $\mathbf{i}$, we first encode it to a hidden space as

$$\mathbf{h}_{enc} = relu(\mathbf{W}^{(ih)}\mathbf{i} + \mathbf{b}^{(ih)}) \tag{10}$$

where $\mathbf{W}^{(ih)}$ and $\mathbf{b}^{(ih)}$ are the parameters of the neural network. Then the Gaussian parameters $\mu_{\hat{d}}$ and $\sigma_{\hat{d}}^2$ can be obtained as

$$\mu_{\hat{d}} = \mathbf{W}^{(h\mu)}\mathbf{h}_{enc} + \mathbf{b}^{(h\mu)} \quad \log(\sigma_{\hat{d}}^2) = \mathbf{W}^{(h\sigma)}\mathbf{h}_{enc} + \mathbf{b}^{(h\sigma)}. \tag{11}$$

The latent semantic vector $\mathbf{z} \in \mathbb{R}^K$ can be calculated using the reparameterization trick as $\mathbf{z} = \mu_{\hat{d}} + \epsilon \times \sigma_{\hat{d}}$ where $\epsilon \sim \mathcal{N}(\mu_0, \sigma_0^2)$ is the prior Gaussian distribution. The hyper-parameters μ_0 and σ_0^2 is set to a zero mean and unit variance Gaussian. Here we pass the Gaussian random vector $\mathbf{z}$ through the $softmax$ function to parameterize the multinomial document-topic distribution $\theta_{\hat{d}}$.

Topic-word distribution. The conventional topic models compute the conditional probability $p(w|\hat{d})$ as

$$p(w|\hat{d}) = \phi_w \times (\theta_{\hat{d}})^T. \tag{12}$$

Therefore, we compute the topic-word distribution ϕ_w as the parameter of neural network by

$$\mathbf{h}_{dec} = softmax(\phi_w \times (\theta_{\hat{d}})^T). \tag{13}$$

Thereafter, a new interaction-aware edge embedding $\mathbf{i}'$ is generated as

$$\mathbf{i}' = relu(\mathbf{W}^{(hi)}\mathbf{h}_{dec} + \mathbf{b}^{(hi)}) \tag{14}$$

where $\mathbf{W}^{(hi)}$ and $\mathbf{b}^{(hi)}$ are the parameters of neural network.

The objective for this part is as

$$L_{\theta,\phi}(e) = \mathbb{E}_{q(\theta,\mathbf{z}|\mathbf{i})}[\log p(\mathbf{i}|\mathbf{z},\theta,\phi)] - D_{KL}[q(\theta,\mathbf{z}|\mathbf{i})||p(\theta|\mu_{\hat{d}},\sigma_{\hat{d}}^2)] \tag{15}$$

where the variational distribution $q(\theta, \mathbf{z}|\mathbf{i})$ approximates the true posterior $p(\theta|\mu_{\hat{d}}, \sigma_{\hat{d}}^2)$ through Kullback-Leibler divergence.

3.3 Model Training

We need to minimize the overall objective function as

$$L = L_s + \sum_{e \in E}(L_t(e) + L_{\theta,\phi}(e)). \tag{16}$$

The conditional probability exploiting $softmax$ function is computationally expensive according to Eq. (1) and Eq. (8). Therefore, we employ negative sampling (Mikolov et al., 2013b) and Adam (Kingma and Ba, 2015) to optimize the overall objective function. In order to prevent overfitting, we also employ dropout (Srivastava et al., 2014) during the generation of document-topic and topic-word distribution.

4 Experiments

4.1 Datasets

We obtain the datasets shown in Tab. 1 based on the original microblog corpus used by Li et al., (2016a). They collected the posts of 50 frequent hashtags during May 1 -July 31, 2014 through Sina Weibo hashtag-search API[4]. Then they split the whole corpus into 3 datasets and each month represented a datasets. We further deal with the original datasets as follows: 1) Remove the posts whose length is less than 3 words or that have no poster username; 2) Filter users who have no reposting or replying relationship; 3) Aggregate all the original and the reposting posts from the same user to form text information of a user vertex.

Month	#Users	#Reposting
May	8907	10435
June	19293	25962
July	16990	20971

Table 1: Statistics of Datasets.

4.2 Evaluation Metrics

In previous work, a popular metric for topic model, perplexity, is evaluated based on the likelihood of held-out documents. Nonetheless, Chang et al. (2009) have proved that higher likelihood of held-out documents doesn't necessarily correspond to human perception of semantically coherent topics. Instead-ly, we follow (Mimno et al., 2011) to calculate the coherence score of a topic given the top *N* words as

$$\mathcal{C} = \frac{1}{K} \cdot \sum_{k=1}^{K} \sum_{i=2}^{N} \sum_{j=1}^{i-1} \log \frac{D(w_i^k, w_j^k) + 1}{D(w_j^k)} \tag{17}$$

where w_i^k refers to the i-th word in topic k ranked by topic distribution over words, $D(w_i^k, w_j^k)$ stands for the count of documents where w_i^k and w_j^k co-occur,and $D(w_j^k)$ indicates the number of documents that contain word w_j^k. In this paper, a document is the aggregated text of a user.

4.3 Baselines

To validate whether two assumptions mentioned in Section 3 are useful for topic extraction, we compare the proposed IATM with the following state-of-the-art baselines and its two variants:

Text Analysis Only:

(1) **SATM** (Quan et al., 2015) combines the aggregation of short texts and topic inference into an unified model.

(2) **BTM** (Yan et al., 2013) directly models the word co-occurrence patterns in the whole corpus.

(3) **LCTM** (Hu and Tsujii, 2016) uses word embeddings pretrained by a log-linear word2vec model[5] to deduce topics for tackling the data sparsity.

Text and Stucture Analysis:

(4) **LeadLDA** (Li et al., 2016a) generates words according to topic dependencies derived from conversation trees.

(5) **ForumLDA** (Chen and Ren, 2017) models the generation of topics by discriminating response messages relevant or irrelevant to the original post.

Two Variants:

(6) **IATM (-interaction)** is the IATM without dynamic interactions between users, which just takes text information into account and also uses neural variational inference to deduce topics.

[4]http://open.weibo.com/wiki/2/search/topics

[5]https://code.google.com/archive/p/word2vec/

(7) **IATM (-user attention)** considers the interactions between users, but not the various effects of users on the topic.

4.4 Experiment Settings

The hyperparameters of SATM, BTM, LCTM, LeadLDA and ForumLDA are set according to the best hyperparameters reported in their original papers. We run Gibbs samplings (in SATM, BTM, LCTM, LeadLDA and ForumLDA) with 1000 iterations to ensure convergence. For IATM (-interaction) and IATM (-user attention), the parameter settings are kept the same as IATM. Here, we set the vertex embedding dimension d as 200. We take the hyperparameters which achieve the best performance on datasets via an small grid search over combinations of the initial learning rate $[0.001, 0.0001]$, $\alpha \in [0.1, 1]$, $\beta \in [0.1, 1]$ and $\gamma \in [0.1, 1]$. Finally, learning rate is set as 0.001, α as 1.0, β as 0.3 and γ as 0.3. The other parameters are initialized by randomly sampling from normal distribution $\mathcal{N}(1.0, 0.3^2)$.

4.5 Performance Evaluation

Model	$K = 50$			$K = 100$		
	$N = 10$	$N = 15$	$N = 20$	$N = 10$	$N = 15$	$N = 20$
SATM	-76.10	-190.38	-341.22	-76.07	-190.48	-341.46
BTM	-79.27	-181.95	-326.77	-79.58	-183.00	-319.28
LCTM	-70.91	-165.37	-296.36	-58.65	-140.10	-261.40
LeadLDA	-53.91	-138.53	-258.38	-58.15	-141.34	-261.65
ForumLDA	-55.76	-129.57	-231.90	-55.84	-132.23	-236.89
IATM (-interaction)	-60.33	-145.98	-274.08	-64.26	-152.74	-280.40
IATM (-user attention)	-57.77	-126.06	-240.66	-59.57	-131.79	-233.54
IATM	**-43.34**	**-112.64**	**-228.27**	**-47.32**	**-121.46**	**-219.96**

Table 2: Coherence scores on May. Higher is better.

Model	$K = 50$			$K = 100$		
	$N = 10$	$N = 15$	$N = 20$	$N = 10$	$N = 15$	$N = 20$

Table 4: Coherence scores on July. Higher is better.

Following (Li et al., 2016a; Yan et al., 2013), we set the number of topics to 50 ($K = 50$) and 100 ($K = 100$). $K = 50$ is to match the count of hashtags and $K = 100$ is much larger than the real number of topics. As shown in Tab. 2, 3 and 4, we evaluate the top $N = 10$, 15, 20 words of $K = 50$ and $K = 100$. From these tables, we have the following overall observations:

(1) What call for special attention is that, SATM exhibits the unstable performance on various datasets. Specifically, SATM performs poorly on May, the worst on July and the best on June. It may be ascribed to its heavy reliance on the number of pseudo-documents. On the contrary, IATM has a stable performance and is only outperformed by SATM on June.

(2) Topic models that analyze text and structures perform better than the ones with only text except SATM on June. It indicates that considering texts and structures together is necessary due to their reciprocal influence in a social network.

(3) Our proposed IATM achieves crucial improvement in comparison with all the baselines on May and July, and it gives the greater coherence scores than the other baselines expect SATM on June. The reasons are two-fold: 1) It effectively identifies topics via simultaneously considering social media content and network topology. 2) It further produces interaction-aware edge embedding as a deeper edge representation combined dynamic user interactions and user attention.

Assumptions	$K = 50, N = 20$	$K = 100, N = 20$
Dynamic Interactions	27.32%	22.13%
User Attention	9.91%	11.87%

Table 5: The effects of two hypotheses by comparing IATM with its two variants.

To further evaluate the effectiveness of two assumptions, we compare IATM with its two variants, observations are as follows:

(4) IATM (-interaction) gives the worst coherence scores. The reason is that it has no consideration of social context. After introducing dynamic interactions, IATM (-user attention) obtains the considerable improvement. Moreover, IATM outperforms IATM (-user attention) on three datasets whatever different number of topics. It demonstrates the effectiveness of dynamic interactions (H1) and user attention (H2).

(5) For each component, we compute the average growth percentage under top $N = 20$ words of $K = 50$ and $K = 100$[6] in comparison of IATM and two variants. Seen from Tab. 5, two hypotheses are both useful for topic extraction in social media, and dynamic interactions modeling has greater influence than user attention.

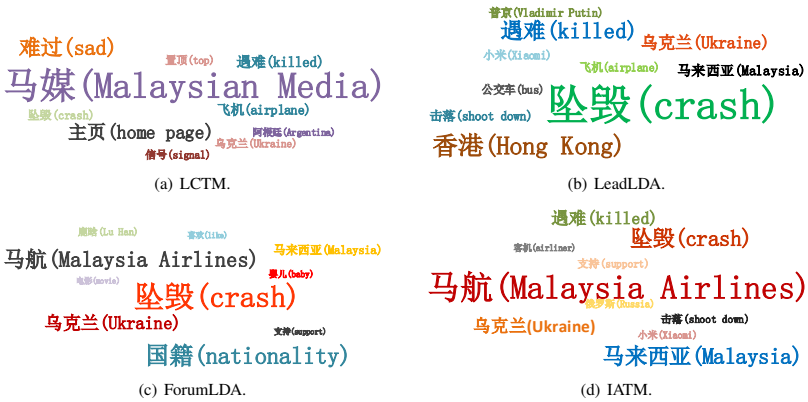
4.6 Case Study

To get an intuitive understanding of extracted topics, we design an experiment to visualize the top 10 words about "MH17 Crash" induced by the different models when $K = 50$, shown in Fig. 3. Due to "MH17 Crash" is included in the July dataset, LCTM gives the highest coherence score among the models of text analysis only. Then we choose LCTM, LeadLDA and ForumLDA as the competitors of our proposed method due to the limited space. Note that, individual words accompany with diverse font sizes. The larger the font size is, the more relevant the word is to the topic. We have the following observations from Fig. 3:

(1) As for LCTM based on word embeddings, "Malaysian Media" is the top one key word and "killed", "crash", "sad" and "Ukraine" is correlated to the topic. However, it mistakenly groups "Argentina lose the World Cup", which co-occurs with "sad" and "Argentina". Compared with LeadLDA, ForumLDA and IATM, LCTM performs the worst. It further testifies that the analysis of texts and structures in a social network is necessary due to their relevance in social media.

(2) With respect to LeadLDA, which distinguishes every message from leader and follower, "crash" is the top one key word and "killed", "Ukraine", "shoot down" and "Malaysia" is related to the topic. However, "bus" is falsely aggregated, which is relevant to the bus explosion in Guangzhou. Maybe it is

[6]The ones under other settings are not shown due to the limited space.



(a) LCTM. (b) LeadLDA. (c) ForumLDA. (d) IATM.

Figure 3: Word clouds describing "MH17 Crash" of different models. Each word cloud represents the similar topic generated by the corresponding model with top 10 words. English translations for the original Chinese words are inside the brackets.

because it wrongly recognizes the reposting message about the bus explosion in Guangzhou as a leader message.

(3) ForumLDA differentiates reposting messages from relevant and irrelevant response posts. It generates the top one key word "crash", and "Malaysia Airlines", "Ukraine", "Malaysia" and "nationality" are correlated to the topic. However, "Lu Han" and "movie" about a movie starring Lu Han, are mistakenly mixed. Perhaps it is because no prior knowledge is given to ensure the validity of relevance distinction.

(4) The top words generated by IATM, "Malaysia Airlines", "Malaysia", "crash" and "Ukrain", are related to the topic. Moreover, some detailed information "airliner" is also produced. Nevertheless, the generated "Xiaomi" is not relevant to the topic. We check the corpus and find that there are lots of posts tagged one hashtag, but expressing the other topic. For instance, someone makes product promotion of "Xiaomi" by utilizing the hot event "MH17 Crash". This belongs to a spam message.

5 Conclusion and Future Work

We propose an Interaction-Aware Topic Model (IATM) for microblog conversations through integrating dynamic interactions and various user attention. Our method not only makes full use of content and structure information in social media, but also keeps the better consistency of generated topics by variational auto-encoder. We model user behaviours through transforming conversation trees into network. Further interaction-aware embeddings produced by adding diverse effects of different users on a topic, encode the content and structure information of two neighbour users. This helps to incorporate the conversation context, and is easy to absorb user attention. Then it is plugged in neural variational inference to generate topics. Experiments on three real-world microblog datasets demonstrate that the proposed IATM is effective.

Yet lots of people would like to utilize hot events to have a product promotion and post some irrelevant messages. These spams damagingly affect the performance of IATM. In the future, we will unify spam posts separation during topics deduction.

Abstract

In realistic scenarios, a user profiling model (e.g., gender classification or age regression) learned from one social media might perform rather poorly when tested on another social media due to the different data distributions in the two media. In this paper, we address cross-media user profiling by bridging the knowledge between the *source* and *target* media with a uniform user embedding learning approach. In our approach, we first construct a cross-media user-word network to capture the relationship among users through the textual information and a modified cross-media user-user network to capture the relationship among users through the social information. Then, we learn user embedding by jointly learning the heterogeneous network composed of above two networks. Finally, we train a classification (or regression) model with the obtained user embeddings as input to perform user profiling. Empirical studies demonstrate the effectiveness of the proposed approach to two cross-media user profiling tasks, i.e., cross-media gender classification and cross-media age regression.

1 Introduction

User profiling is a task which leverages user generated content (UGC) to automatically identify the data about a user, such as gender (Wang et al., 2017; Li et al., 2016; Li et al., 2015) and age (Marquardt et al., 2014) identification. Recently, along with the boom of social media, user profiling has been drawing more and more attention in various social applications, such as personality analysis (Li et al., 2016; Sarawgi et al., 2011; O'Connor et al., 2010), intelligent marking (Preotiuc-Pietro et al., 2015) and online advertising (Zhang et al., 2016; Volkova et al., 2013).

In the literature, conventional approaches normally recast user profiling as a supervised learning problem (Marquardt et al., 2014; Zhang et al., 2016; Ciot et al., 2013; Corney et al., 2002) by exploring various user generated textual features and user social connection features. However, the performance largely depends on a large amount of labeled data and the performance normally degrades dramatically when the model is tested on a different social media. Even worse, many real scenarios may involve several social media with some of them lacking sufficient labeled data to train a well-performed model in each social media. For example, Facebook.com is a social media site where many users publicize their age attribute in their homepages, making the collection of labeled data easy, while Linkedin.com is a social media site where age attribute information is not available in users homepages, making the collection of labeled data rather difficult. These scenarios raise a challenging user classification task, which leverages labeled data from a social media to train a model and evaluate it on the test data from a different social media. Briefly, we refer to this task as cross-media user profiling where the social media with labeled data is called the *source* media and the social media with only unlabeled data the *target* media.

In this paper, we address cross-media user profiling by bridging the knowledge between the *source* and *target* media with a uniform user embedding learning approach. As a user representation way, user

(2) *Big surprise! So amazing Louis Vuitton's necklace for Christmas gift. Love you forever, dear boyfriend.*

User **B** from *TIEBA*

Gender: *female* **Age:** *22*

Social Link Information (e.g., *followers*)
▷ **ID3:** *32d0aa2ce4*
▷ **ID4:** *7dfc636a6a*

Textual Information (e.g., *messages*)
(1) *UGH i don't wanna go to school tomorrow. Don't wanna see a teacher again. Oh wait, i have been 22! Wahooooo, forgive me, God..*
(2) *What a perfect necklace! Matching my earrings so perfect!! Don't cut my hands, please, haha.*

Figure 1: The user examples from two different social media, i.e., *SINA* and *TIEBA* social media

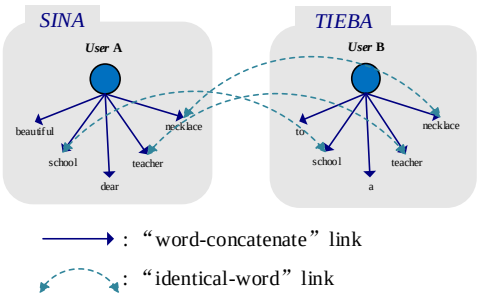

Figure 2: Cross-media user-word network

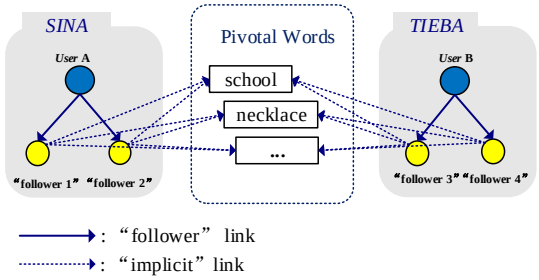

Figure 3: Cross-media user-user network with pivotal word vertices

embedding maps a user to a vector of real numbers with the motivation that embedding learning is good at capturing the relationship among the instances in the unlabeled data from both the *source* and *target* media.

One straightforward way to learn user embedding is to construct two user-word networks. Due to the phenomenon of sharing some identical words by two users, these two user-word networks are naturally connected and thus can be merged to be a mixture network, namely cross-media user-word network. For instance, Figure 1 shows two users, i.e., *User* **A** and *User* **B**, from two social media, i.e., *SINA* and *TIEBA*. It is easy to construct a user-word network wherein the users from different social media are naturally connected due to their sharing some identical words, as shown in Figure 2. Given this network, a network embedding approach, e.g., the LINE approach by Tang et al. (2015b), could be applied to learn vertex embedding and thus as user embedding.

Obviously, one main drawback of the above approach is that it much depends on the textual information and ignores the social link information which is important for user classification. Thus, a better approach to learn user embedding is to incorporate both the textual and social link information.

However, incorporating the social link information is challenging because user IDs in the different social media are totally different. As a result, the two user-user networks in the two social media are separated to each other, making it impossible to learn the relationship between two users from different social media. To tackle this challenge, we link the two user-user networks in the *source* and *target* media with some pivotal word vertices, as shown in Figure 3.

Besides, we learn better user embedding by learning a heterogeneous network composed of the two above networks, i.e., the cross-media user-word network and the cross-media user-user network. Once obtaining user embedding, we train a classifier (or regressor) on the labeled data from the *source* media

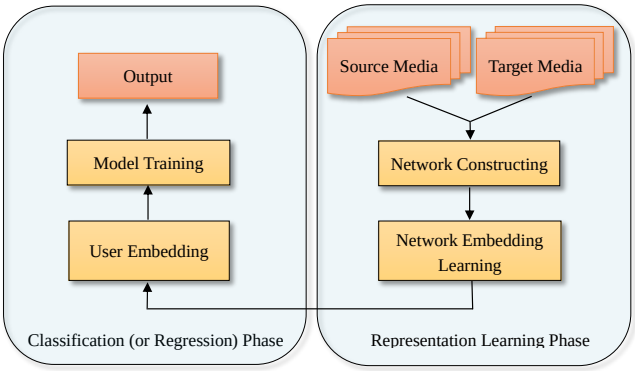

Figure 4: The overall architecture of our approach

and evaluate on the data from the *target* media. Empirical studies demonstrate that our approach outperforms both the straightforward baseline and conventional domain adaptation approaches on two different cross-media user profiling tasks, i.e., cross-media gender classification and age regression.

2 Related Work

In the last decade, many researchers have devoted their efforts on user profiling (e.g., gender identification and age identification) in several research communities, such as natural language processing and social network analysis.

For the gender identification task, Mohammad and Yang (2013) show that there are marked differences across genders in how they use emotion words in work-place email. Ciot et al. (2013) conduct the first assessment of latent attribute inference in various languages beyond English, focusing on gender inference of Twitter users. Li et al. (2015) aim to identify the genders of two interactive users on the basis of micro-blog text. Some other studies, such as Mukherjee and Liu (2010), Peersman et al. (2011) and Gianfortoni et al. (2011) focus on exploring more effective features to improve the performance. Wang et al. (2017) propose a joint learning approach in order to leverage the relationship features among relevant user attributes.

For the age identification task, most studies are devoted to explore efficient features in blog and social media. Schler et al. (2006) focus on textual features extracted from the blog text, such as word context features and POS stylistic features. Peersman et al. (2011) apply a text categorization approach to age classification with textual features extracted from the text in social media. More recently, Marquardt et al. (2014) propose a multi-label classification approach to predict both the gender and age of authors from texts adopting some sentiment and emotion features. Differently, in this paper, we cast age identification task as a regression problem instead of a classification problem.

Different from all above studies, we focus on the cross-media user profiling task. To the best of our knowledge, there are only two related papers by (Sap et al., 2014; Pardo et al., 2016) which mentions the cross-media user profiling issue. In their paper, only textual information is used in cross-media user profiling. Unlike their study, this paper firstly employs both textual and social information in cross-media user profiling.

3 Our Approach

3.1 Framework Overview

Our approach consists of two main phases, i.e., the representation learning phase and the classification (or regression) phase, which has been illustrated in Figure 4.

In the representation phase, we first construct two different types of cross-media networks, i.e., cross-media user-word network and cross-media user-user network. Second, we construct the heterogeneous user network, which is composed of the two cross-media networks. Third, we perform user embedding learning on a heterogeneous user network.

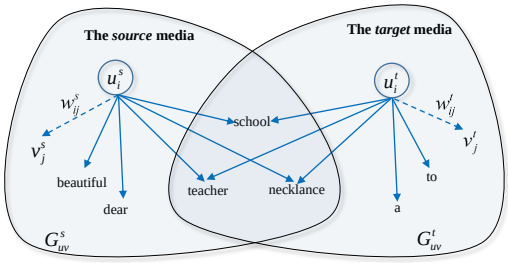

Figure 5: Cross-media user-word network G_{uv}^{cross}

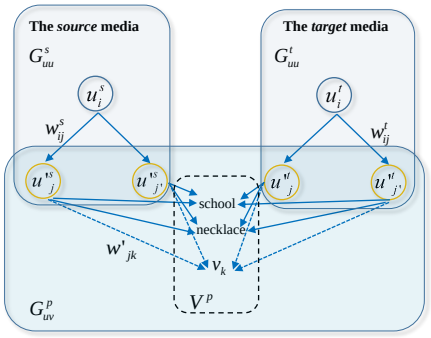

Figure 6: Cross-media user-user network G_{uu}^{cross}

In the classification (or regression) phase, we train a classifier (or regressor) with user embeddings in the *source* media for cross-media user profiling.

3.2 Basic Network Embedding Learning Approach

The goal of user embedding learning is to represent a user by a low dimensional real-value vector. In this study, we adopt the network embedding learning approach by Tang et al. (2015b) as our basic user embedding learning approach, of which we make use of the second-order proximity. Specifically, this approach is summarized as following.

Given a network $G = (V, E)$, where V is the set of vertices. E is the set of edges and the edge $e_{(i,j)}$ is directed from vertex v_i to the vertex v_j. To represent each vertex v_i with a low dimension vector $\vec{m}_i \in R^d$ where d is the dimension of this vector, we can minimize the following objective function (Tang et al., 2015b):

$$O = -\sum_{e_{(i,j)} \in E} w_{ij} \log p(v_j|v_i) \tag{1}$$

Where w_{ij} is the weight of the edge $e_{(i,j)}$. The conditional probability of vertex v_j generated by the vertex v_i, i.e., $p(v_j|v_i)$ is defined as follows:

$$p(v_j|u_i) = \frac{\exp(\vec{m}_j^\top \cdot \vec{m}_i)}{\sum_{k=1}^{|V|} \exp(\vec{m}_k^\top \cdot \vec{m}_i)} \tag{2}$$

where $\vec{m}_i$ is the embedding vector of the vertex v_i, and $\vec{m}_j$ is the embedding vector of the vertex v_j. $|V|$ is the number of all vertices in V.

3.3 Our Network Embedding Learning Approach

In our approach, we need to construct three different networks for learning network embedding, i.e., **(a)** Cross-Media User-Word Network; **(b)** Cross-Media User-User Network; **(c)** Heterogeneous User Network.

(a) Cross-Media User-Word Network Embedding

Figure 5 shows the cross-media user-word network G_{uv}^{cross}, which is composed of two user-word networks, i.e., G_{uv}^s and G_{uv}^t.

Formally, $G_{uv}^s = (U^s \bigcup V^s, E_{uv}^s)$ is a user-word network from the *source* media. It is a bipartite network where U^s and V^s are two disjoint sets of vertices, denoting the user vertices and word vertices respectively. E_{uv}^s is the set of edges between users and their published words in the *source* media.

$G_{uv}^t = (U^t \bigcup V^t, E_{uv}^t)$ is a user-word network from the *target* media. It is also a bipartite network where U^t and V^t are two disjoint sets of vertices, denoting the user vertices and word vertices respectively. E_{uv}^t is the set of edges between users and their published words in the *target* media.

For the network G_{uv}^{cross}, we can minimize the following objective function:

$$O_{uv} = -\sum_{e_{(i,j)} \in E_{uv}^{s}} w_{ij}^{s} \log p_{uv}(v_j^s | u_i^s) - \sum_{e_{(i,j)} \in E_{uv}^{t}} w_{ij}^{t} \log p_{uv}(v_j^t | u_i^t) \tag{3}$$

where the edge $e_{(i,j)} \in E_{uv}^{s}$ *or* E_{uv}^{t} is directed from user vertex u_i to word vertex v_j. The weight w_{ij} of the edge $e_{(i,j)}$ in both the *source* and *target* media is simply defined as the number of times v_j appears in the messages published by u_i. $p_{uv}(v_j^s|u_i^s)$ and $p_{uv}(v_j^t|u_i^t)$ are two conditional probabilities of a word vertex generated by a user vertex, which could be computed by the vertex embeddings, as shown in Equation (2).

(b) Cross-Media User-User Network Embedding

Figure 6 shows the cross-media user-user network G_{uu}^{cross}, which is a network composed of two user-user networks, i.e., G_{uu}^{s} and G_{uu}^{t}, and one user-pivotal_word network, i.e., G_{uv}^{p}.

Formally, $G_{uu}^{s} = (U^s, E_{uu}^{s})$ a user-user network from the *source* media. U^s is the entire set of users in the *source* media. E_{uu}^{s} is the set of edges between users and their "follower" users in the *source* media.

$G_{uu}^{t} = (U^t, E_{uu}^{t})$ is a user-user network from the *target* media. U^t is the entire set of users in *target* media. E_{uu}^{t} is the set of edges between users and their "follower" users in the *target* media.

As mentioned in Introduction, the user-user networks in both the *source* and *target* media share no identical users, i.e., $G_{uu}^{s} \bigcap G_{uu}^{t} = \Phi$, which makes it impossible to build connection among the users in both social media. Therefore, we attempt to construct another sub-network, a user-pivotal_word network G_{uv}^{p}, to bridge the users in both social media.

$G_{uv}^{p} = (U'^s \bigcup V^p \bigcup U'^t, E_{uu}^{p})$ is a user-pivotal_word network, which is constructed to link the above two networks G_{uu}^{s} and G_{uu}^{t}. It is a bipartite network where $U'^s \subseteq U^s$ is the set of "follower" users from the *source* media and $U'^t \subseteq U^t$ is the set of "follower" users from the *target* media. E_{uu}^{p} is the set of edges between each "follower" user and the words in V^p which are also published by his/her following user. The basic motivation of adding these edges is based on the assumption that one user's followers tend to have similar relationship to the words that are published by this user. The detailed process of constructing the network G_{uv}^{p} has been illustrated in **Algorithm 1**.

For the network G_{uu}^{cross}, we can minimize the following objective function:

$$O_{uu} = -\sum_{e_{(i,j)} \in E_{uu}^{s}} w_{ij}^{s} \log p_{uu}(u_j'^s | u_i^s) - \sum_{e_{(i,j)} \in E_{uu}^{t}} w_{ij}^{t} \log p_{uu}(u_j'^t | u_i^t) - \sum_{e_{(i,k)} \in E_{uu}^{p}} w_{ik}' \log p_{uu}(v_k | u_i') \tag{4}$$

where the edge $e_{(i,j)} \in E_{uu}^{s}$ *or* E_{uu}^{t} is directed from user vertex u_i to its "follower" vertex $u_j' \in U'^s or U'^t$. The edge $e_{(i,k)} \in E_{uu}^{p}$ is directed from a "follower" vertex u_i' to a pivotal word vertex $v_k \in V^p$. The weights of all above edges are defined as binary values (i.e., 0 or 1). $p_{uu}(u_j'^s|u_i^s)$ and $p_{uu}(u_j'^t|u_i^t)$ are two conditional probabilities of "follower" vertex $u_j'^s$ and $u_j'^t$ generated by user vertex u_i^s and u_i^t respectively. $p_{uu}(v_k|u_i')$ is the conditional probability of pivotal word vertex v_k generated by the "follower" vertex u_i'. These three kinds of probabilities could be computed by the vertex embeddings, as shown in Equation (2).

(c) Heterogeneous User Network Embedding

The heterogeneous user network G_{joint} is composed of two cross-media networks: the cross-media user-word network, i.e., G_{uv}^{cross} and the cross-media user-user network, i.e., G_{uu}^{cross}, where the user vertices are shared across the two networks.

To learn the embeddings of the heterogeneous user network, an intuitive approach is to collectively embed the two cross-media networks, which can be achieved by minimizing the following objective function:

$$O_{joint} = O_{uv} + O_{uu} \tag{5}$$

Algorithm 1: The Network G^p_{uv} Constructing

Input: U^s: users from the *source* media;
V^s: words from the *source* media;
U'^s: "follower" users from the *source* media;
U^t: users from the *target* media;
V^t: words from the *target* media;
U'^t: "follower" users from the *target* media
Output: V^p, E^p_{uu}
Initialization: $E^p_{uu} = \Phi$;
// V^p: words shared between *source* and *target* media;
$V^p = V^s \bigcap V^t$;
for $i = 1; i \leq |U^s|; i+ = 1$ **do**
  // $V_i \in V^s$: words published by u^s_i;
  for v_k *in* V_i **do**
    if $v_k \in V^p$ **then**
      // $U_i \in U'^s$: "follower" users of u^s_i;
      for u'_j *in* U_i **do**
        generate the edge $e_{(j,k)}$ from u'_j to v_k;
        $E^p_{uu} = E^p_{uu} \bigcup e_{(j,k)}$;
for $i = 1; i \leq |U^t|; i+ = 1$ **do**
  // $V_i \in V^t$: words published by u^t_i;
  for v_k *in* V_i **do**
    if $v_k \in V^p$ **then**
      // $U_i \in U'^t$: "follower" users of u^t_i;
      for u'_j *in* U_i **do**
        generate the edge $e_{(j,k)}$ from u'_j to v_k;
        $E^p_{uu} = E^p_{uu} \bigcup e_{(j,k)}$;
return V^p, E^p_{uu};

We adopt the asynchronous stochastic gradient descent (ASGD) (Recht et al., 2011) using the techniques of edge sampling (Tang et al., 2015b) and negative sampling (Mikolov et al., 2013) for optimizing Equation (3) and (4). In each step, we sample a binary edge $e_{(i,j)}$ with the sampling probabilities proportional to it's edge weight w_{ij}. Meanwhile, multiple negative edges $e_{(i,j)}$ are sampled from a noise distribution $p_n(i) \propto d_i^{3/4}$ as proposed in (Mikolov et al., 2013), where d_i is the out-degree of user vertex u_i. The Equation (5) can be optimized with the textual data (the user-word network) and the social link data (the user-user network) simultaneously. We call this approach joint learning. In joint learning, both the two types of cross-media networks are used together. When the network G_{joint} is heterogeneous, the weights of the edges in the two different networks, i.e., G^{cross}_{uv} and G^{cross}_{uu} are not comparable to each other. Therefore, in our approach, we alternatively sample from the two sets of edges instead of merging all the edges together to sample as the way by Tang et al. (2015a).

4 Experimentation

4.1 Experimental Settings

Data Setting: The users are collected from *SINA*[1] and *TIEBA*[2], two famous social media in China. From these two social media, we crawl each user's homepage containing user information (e.g. *name*, *gender*,*age*), messages and "follower" users. The data collection process starts from some randomly selected users, and then iteratively gets the data of their followers. In total, we collect 10000 users from *SINA* and *TIEBA* respectively. For cross-media gender classification task, in each social media, we randomly select a balanced data set containing 3000 male users and 3000 female users. For cross-media age regression task, we focus on the age from 19-28, totally 10 age categories and extract 6000 users from each social media. This data contains a balanced data set in each age, i.e., 600 samples in each age. For

[1] https://weibo.com/
[2] https://tieba.baidu.com/index.html

both above two cross-media user profiling tasks, We randomly select 80% users in each category from the *source* media as the labeled data, 80% users in each category from the *target* media as the unlabeled data and the remaining 20% users from the *target* media as test data. Then, we consider two cases: one is to consider *TIEBA* as the *source* media and *SINA* as the *target* media, i.e., TIEBA → SINA, and the other is to consider *SINA* as the *source* media and *TIEBA* as the *target* media, i.e., SINA → TIEBA.

Representations: In our experiment, we use three different representation models to represent each user. (1) **BOW**: Each user is represented by a bag of features consisting of four types of textual features, including word unigram and two kinds of complex features, i.e., F-measure, POS-pattern, are employed. These kinds of textual features yield the state-of-the-art performance for gender classification (Li et al., 2015); To get the word, POS and parse tree features, we use the public toolkit ICTCLAS[3] to perform word segmentation, POS tagging and stanford parser[4] to perform parsing on the Chinese text. (2) **Word Embeddings**: We learn word embedding matrices of each user from training a mixed training data set consisting of labeled data in the *source* media and unlabeled data in the *target* media with skip-gram algorithm[5]. The dimensionality of word vector is set to be 200. (3) **User Embeddings**: We learn the embedding vector of each user from training three different cross-media networks, i.e., G_{uv}^{cross}, G_{uu}^{cross} and G_{joint}, which are constructed from a mixed training data set consisting of the labeled data in *source* media and unlabeled data in *target* media. For the new user vertex which not present in the training data, we get its user embedding by averaging the embedding vectors of all words published by this user. The dimensionality of user embedding vector and word embedding vector are both set to be 200.

Model Training and Parameter Settings: In the classification (or regression) phase, we employ L2-regularized SVM (or support vector regression, SVR) model in the LibLinear package[6]. For Word Embeddings and User Embeddings, the mini-batch size of the stochastic gradient descent is set to be 1; the learning rate is set to be $\rho_t = \rho_0(1 - t/T)$, in which T is the total number of edge samples and $\rho_0 = 0.025$; the number of negative samples is set to be 5; the window size is set as 5 in Skip-gram.

Evaluation Metrics and Significance test: For gender classification task, the performance is evaluated using Macro-F1 (F). For age regression task, we employ the coefficient of determination R^2 to measure the regression performance (Cameron, 1996). Furthermore, t-test is used to evaluate the significance of the performance difference between two approaches (Yang and Liu, 1999).

4.2 Impact of Using User-pivotal_word Network G_{uv}^{p}

In order to test the effectiveness of using user-pivotal_word network G_{uv}^{p} to form the cross-media user-user network, the following two approaches are implemented for cross-media user profiling.

- **Cross-uu without Pivotal Words:** our model with **User Embeddings** as input. The user embeddings are learned from the cross-media user-user network which is composed of two user-user networks, i.e., $G_{uu}^{cross} = G_{uu}^{s} + G_{uu}^{t}$.

- **Cross-uu with Pivotal Words:** our model with **User Embeddings** as input. The user embeddings are learned from the cross-media user-user network which is composed of two user-user networks and one user-pivotal_word network, i.e., $G_{uu}^{cross} = G_{uu}^{s} + G_{uu}^{t} + G_{uv}^{p}$.

Figure 7(a) and 7(b) shows the results of the two approaches to cross-media gender classification and cross-media age regression respectively. From this figure, we can see that **Cross-uu without Pivotal Words** performs similar to a random classification, achieving about 50% in terms of Macro-F1 in gender classification task. This result is not strange because the involved two user-user networks share nothing and thus could not capture the relationship among the users in the two social media. In contrast, **Cross-uu with Pivotal Words** performs much better than a random performance. Especially, in gender classification task, in the case of TIEBA → SINA, our approach achieves 0.69 in terms of Macro-F1,

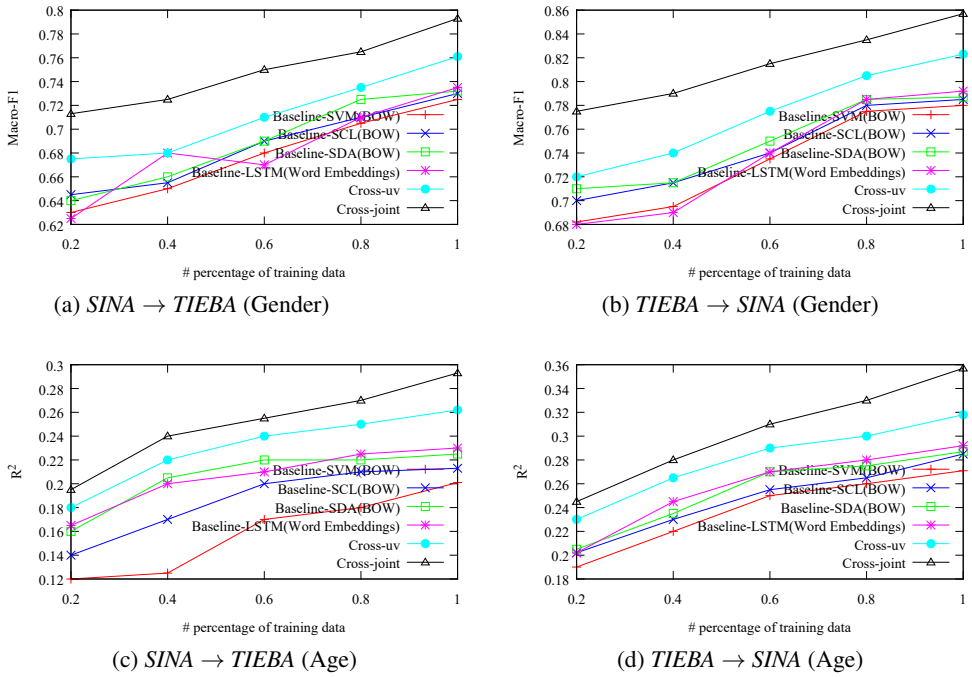
which is 16.8% better than **Cross-uu without Pivotal Words**. Moreover, in age aggression task, **Cross-uu with Pivotal Words** still outperforms **Cross-uu without Pivotal Words** about 4.5% in terms of R^2. These results confirm that constructing the user-pivotal_word network is beneficial for learning a better user embedding for cross-media user profiling.

4.3 Performance Comparison

For thorough comparison, several approaches are implemented for cross-media user profiling:

- **Baseline-SVM(BOW):** a SVM classifier (or SVR regressor) trained with only labeled data in the *source* media and the representation model is **BOW**. This approach is proposed by Li et al. (2015).
- **Baseline-SCL(BOW):** a famous textual domain adaptation approach named SCL which bridges the knowledge between the *source* and *target* domains using some pivotal features (Blitzer et al., 2007) and the representation model is **BOW**. We consider the *source* media as the *source* domain and the *target* media as the *target* domain. The number of the pivotal features is set to be 200.
- **Baseline-SDA(BOW):** another famous textual domain adaptation approach with stacked denoising auto-encoder to extract meaningful representation (Glorot et al., 2011) and the representation model is **BOW**. Similar to SCL, we consider the *source* media as the *source* domain and the *target* media as the *target* domain.
- **Baseline-LSTM(Word Embeddings):** a LSTM classification (or regression) model using **Word Embeddings** as input. This is a state-of-the-art approach to user profiling proposed by Wang et al. (2017).
- **Cross-uv:** our model with **User Embeddings** as input. The user embeddings are learned from the cross-media user-word network, i.e., G_{uv}^{cross}.



(a) *SINA* → *TIEBA* (Gender)

(b) *TIEBA* → *SINA* (Gender)

(c) *SINA* → *TIEBA* (Age)

(d) *TIEBA* → *SINA* (Age)

Figure 9: Performance of different approaches on various sizes of training data

- **Cross-joint:** our model with **User Embeddings** as input. The user embeddings are learned from the heterogeneous user network, i.e., G_{joint}.

Figure 8(a) and 8(b) shows the comparison results of different approaches to cross-media gender classification and cross-media age regression respectively. From these two figures, we can see that: The textual domain adaptation approaches including **Baseline-SCL(BOW)** and **Baseline-SDA(BOW)** are effective for cross-media user profiling and they both performs slightly better than **Baseline-SVM(BOW)**. Our approach **Cross-uv** performs consistently better than the textual domain adaptation approaches. The improvements are about 2% in terms of both Macro-F1 and R^2. The significance test shows that the improvements are significant (p-value<0.05). Besides, our approach performs better than **Baseline-LSTM(Word Embeddings)**, which indicates that our approach yields better user embeddings than the traditional word embedding approach.

Our approach **Cross-joint** performs best among all approaches. Compared to **Baseline-SVM(BOW)**, the average improvement is impressive, reaching 7.25% (Macro-F1) and 8.9% (R^2) in gender classification and age regression respectively. Furthermore, **Cross-joint** significantly performs better than **Cross-uv** (p-value<0.05), which encourages to incorporate the social link information for cross-media user profiling.

Figure 9 shows the performance of the approaches to cross-media user profiling by changing the sizes of the training data in the *source* media. From this figure, we can see that when the size of training data is small, the performance of **Baseline-LSTM(Word Embeddings)** is rather unstable, performing worse than **Baseline-SDA(BOW)** and **Baseline-SCL(BOW)** in some times and could even performs worse than **Baseline-SVM(BOW)**. However, our approach **Cross-joint** and **Cross-uv** consistently perform better than the other approaches, whatever sizes of training data are used.

5 Conclusion

In this paper, we propose a user embedding learning method to address cross-media user profiling. Specifically, we first propose a heterogeneous user network composed of two cross-media networks for learning user embedding and then employ the user embedding to train the model for classification (or regression). Empirical studies demonstrate that our approach significantly outperforms other strong baseline approaches in both cross-media gender classification and cross-media age regression tasks.

In our future work, we would like to incorporate some other types of information, e.g., label information, to better learn user embedding. Moreover, we would like to apply our approach to some other user profiling tasks, e.g., user profession identification.

Incorporating Syntactic Uncertainty in Neural Machine Translation with a Forest-to-Sequence Model

Poorya Zaremoodi **Gholamreza Haffari**
Faculty of Information Technology, Monash University
firstname.lastname@monash.edu

Abstract

Incorporating syntactic information in Neural Machine Translation (NMT) can lead to better reorderings, particularly useful when the language pairs are syntactically highly divergent or when the training bitext is not large. Previous work on using syntactic information, provided by top-1 parse trees generated by (inevitably error-prone) parsers, has been promising. In this paper, we propose a *forest*-to-sequence NMT model to make use of exponentially many parse trees of the source sentence to compensate for the parser errors. Our method represents the collection of parse trees as a packed forest, and learns a neural transducer to translate from the input forest to the target sentence. Experiments on English to German, Chinese and Farsi translation tasks show the superiority of our approach over the sequence-to-sequence and tree-to-sequence neural translation models.

1 Introduction

The neural approach is revolutionising machine translation (MT). The main neural approach to MT is based on the encoder-decoder architecture (Cho et al., 2014; Sutskever et al., 2014), where an encoder (e.g a recurrent neural network) reads the source sentences *sequentially* to produce a fixed-length vector representation. Then, a decoder generates the translation from the encoded vector, which can dynamically change using the *attention* mechanism.

One of the main premises about natural language is that words of a sentence are inter-related according to a (latent) hierarchical structure, i.e. a syntactic tree. Therefore, it is expected that modeling the syntactic structure should improve the performance of NMT, especially in low-resource or linguistically divergent scenarios, such as English-Farsi. In this direction, (Li et al., 2017) uses a sequence-to-sequence model, making use of *linearised* parse trees. (Chen et al., 2017b) has proposed a model which uses syntax to constrain the dynamic encoding of the source sentence via structurally constrained attention. (Bastings et al., 2017; Shuangzhi Wu, 2017) have incorporated syntactic information provided by the dependency tree of the source sentence. (Marcheggiani et al., 2018) has proposed a model to inject semantic bias into the encoder of NMT model.

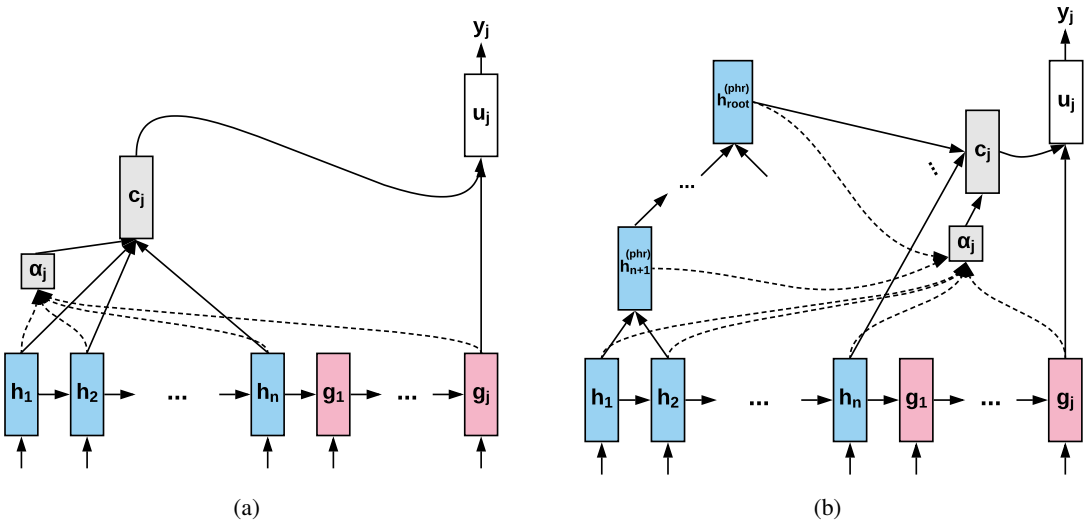
Recently, (Eriguchi et al., 2016; Chen et al., 2017a) have proposed methods to incorporate the hierarchical syntactic constituency information of the source sentence. In addition to the embedding of words, computed using the vanilla sequential encoder, they compute the embeddings of phrases recursively, directed by the top-1 parse tree of the source sentence generated by a parser. Though the results are promising, the top-1 trees are prone to parser error, and furthermore cannot capture semantic ambiguities of the source sentence.

In this paper, we address the aforementioned issues by using exponentially many trees encoded in a forest instead of a single top-1 parse tree. We capture the parser uncertainty by considering many parse trees and their probabilities. The encoding of each source sentence is guided by the forest, and includes the forest nodes whose representations are computed in a bottom-up fashion using our ForestLSTM architecture (§3). Thus, in the encoding stage of this approach, different ways of constructing a phrase

Proceedings of the 27th International Conference on Computational Linguistics, pages 1421–1429
Santa Fe, New Mexico, USA, August 20-26, 2018.

are taken into consideration along with the probability of rules in the corresponding trees. We evaluate our approach on English to Chinese, Farsi and German translation tasks, showing that forests lead to better performance compared to top-1 tree and sequential encoders (§4).

2 Neural Machine Translation



(a) (b)

Figure 1: (a) Attentional SEQ2SEQ model (b) Attentional TREE2SEQ model.

2.1 Attentional Sequence-to-Sequence model

This model is based on the attentional encoder-decoder architecture for SEQ2SEQ transduction. It contains a sequential encoder to read the input sentence and a sequential decoder to generate the output. An example is depicted in Figure 1(a).

Sequential Encoder The source sentence is encoded by a sequential LSTM:

$$\boldsymbol{h}_i = \text{SeqLSTM}(\boldsymbol{h}_{i-1}, \boldsymbol{E}_x[x_i])$$

where $\boldsymbol{E}_x[x_i]$ is the embedding of the word x_i in the embedding table $\boldsymbol{E}_x$ of the source language, and $\boldsymbol{h}_i$ is the context-dependent embedding of x_i.

Sequential Decoder For the generation of each target word j, a dynamic context $\boldsymbol{c}_j$ is produced to summarise the relevant parts of the source sentence. Then, the decoder generates the j-th word as follows:

$$\begin{aligned} \boldsymbol{g}_j &= \tanh(\boldsymbol{W}^{gh}\boldsymbol{g}_{j-1} + \boldsymbol{W}^{gi}\boldsymbol{E}_y[\boldsymbol{y}_{j-1}] + \boldsymbol{W}^{ga}\boldsymbol{c}_j + \boldsymbol{W}^{gu}\boldsymbol{u}_{j-1}) \\ \boldsymbol{u}_j &= \tanh(\boldsymbol{W}^{uc}\boldsymbol{c}_j + \boldsymbol{W}^{ui}\boldsymbol{E}_y[\boldsymbol{y}_{j-1}] + \boldsymbol{g_j}) \\ y_j|\boldsymbol{y}_{<j}, \boldsymbol{x} &\sim \text{softmax}(\boldsymbol{W}^{ou}\boldsymbol{u_j} + \boldsymbol{b}^o) \end{aligned}$$

where $\boldsymbol{E}_y[y_j]$ is the embedding of word y_j looked-up from target language embedding table $\boldsymbol{E}_y$, and $\boldsymbol{W}$ matrices and $\boldsymbol{b}^o$ are the parameters.

The attention mechanism provides relevant information from the source sentence with respect to the current state of the decoder. In each decoding step, the dynamic context is computed as follows:

$$\begin{aligned} a_{ij} &= \boldsymbol{v}^\top \tanh(\boldsymbol{W}^{ae}\boldsymbol{h}_i + \boldsymbol{W}^{ag}\boldsymbol{g}_{j-1}) \\ a_{i'j} &= \boldsymbol{v}^\top \tanh(\boldsymbol{W}^{ae}\boldsymbol{h}^{phr}_{i'} + \boldsymbol{W}^{ag}\boldsymbol{g}_{j-1}) \\ \boldsymbol{\alpha}_j &= \text{softmax}(\boldsymbol{a}_j) \end{aligned}$$

$$\boldsymbol{c}_j = \sum_{i=1}^{n} \alpha_{ji} \boldsymbol{h}_i$$

where a_{ij} and $a_{i'j}$ are the attention scores, and $\boldsymbol{h}_i$ refers to embedding of words. n is the length of the input sentence, and n_p is the number of forest nodes.

2.2 Attentional Tree-to-Sequence model

The majority of NMT models are based on sequential encoding of the source sentence. An exception is the TREE2SEQ model in (Eriguchi et al., 2016), where the encoding of the source sentence is directed by the top-1 parse tree. This model computes the embeddings of phrases in addition to the words, then attend on both words and phrases in the decoder. An example is depicted in Figure 1(b).

Tree Encoder It consists of sequential and recursive parts. The sequential part is the vanilla sequence encoder discussed in Section 2.1, which computes the embeddings of words. Then, the embeddings of phrases are computed using the embeddings of their constituent words in a recursive bottom-up fashion:

$$\boldsymbol{h}_k^{(phr)} = \text{TreeLSTM}(\boldsymbol{h}_k^l, \boldsymbol{h}_k^r).$$

where $\boldsymbol{h}_k^l$ and $\boldsymbol{h}_k^r$ are hidden states of left and right children respectively. This method uses TreeLSTM units (Tai et al., 2015) to calculate the embedding of a parent node using its two two children units as follow:

$$\begin{aligned}
\boldsymbol{i} &= \sigma(\boldsymbol{U}_l^{(i)} \boldsymbol{h}^l + \boldsymbol{U}_r^{(i)} \boldsymbol{h}^r + \boldsymbol{b}^{(i)}) \\
\boldsymbol{f}^l &= \sigma(\boldsymbol{U}_l^{(f_l)} \boldsymbol{h}^l + \boldsymbol{U}_r^{(f_l)} \boldsymbol{h}^r + \boldsymbol{b}^{(f_l)}) \\
\boldsymbol{f}^r &= \sigma(\boldsymbol{U}_l^{(f_r)} \boldsymbol{h}^r + \boldsymbol{U}_r^{(f_r)} \boldsymbol{h}^r + \boldsymbol{b}^{(f_r)}) \\
\boldsymbol{o} &= \sigma(\boldsymbol{U}_l^{(o)} \boldsymbol{h}^l + \boldsymbol{U}_r^{(o)} \boldsymbol{h}^r + \boldsymbol{b}^{(o)}) \\
\tilde{\boldsymbol{c}} &= \tanh(\boldsymbol{U}_l^{(\tilde{c})} \boldsymbol{h}^l + \boldsymbol{U}_r^{(\tilde{c})} \boldsymbol{h}^r + \boldsymbol{b}^{(\tilde{c})}) \\
\boldsymbol{c}^{(phr)} &= \boldsymbol{i} \odot \tilde{\boldsymbol{c}} + \boldsymbol{f}^l \odot \boldsymbol{c}^l + \boldsymbol{f}^r \odot \boldsymbol{c}^r \\
\boldsymbol{h}^{(phr)} &= \boldsymbol{o} \odot \tanh(\boldsymbol{c}^{(phr)})
\end{aligned}$$

where $\boldsymbol{i}$, $\boldsymbol{f}^l$, $\boldsymbol{f}^r$, $\boldsymbol{o}_j$,$\tilde{\boldsymbol{c}}_j$ are the input gate, left and right forget gates, output gate, and a state for updating memory cell; $\boldsymbol{c}^r$ and $\boldsymbol{c}^l$ are memory cells of the right and left units.

Sequential Decoder Eriguchi et al. set the initial state of the decoder by combining the final state of the sequential and tree encoders as follow:

$$\boldsymbol{g}_0 = \text{TreeLSTM}(\boldsymbol{h}_n, \boldsymbol{h}_{root}^{(phr)}),$$

The rest of the decoder is similar to the vanilla attentional decoder discussed in Section 2.1. The difference is that, in this model, the attention mechanism makes use of phrases as well as words. Thus, the dynamic context is computed as follows:

$$\boldsymbol{c}_j = \sum_{i=1}^{n} \alpha_{ji} \boldsymbol{h}_i + \sum_{i'=n+1}^{2n-1} \alpha_{ji'} \boldsymbol{h}_{i'}^{phr}$$

3 Neural Forest-to-Sequence Translation

The TREE2SEQ model uses the top-1 parse tree generated by a parser. Mistakes and uncertainty in parsing eventually affect the performance of the translation. To address these issues, we propose a method to consider exponentially many parse trees along with their corresponding probabilities. It consists of a *forest* encoder to encode a collection of packed parse trees, in order to reduce error propagation due to using only the top-1 parse tree. Our forest encoder computes representations for words and phrases of the source sentence with respect to its parse forest. A sequential decoder, then, generates output words one-by-one from left-to-right by attending to both words and phrases (i.e. forest nodes).

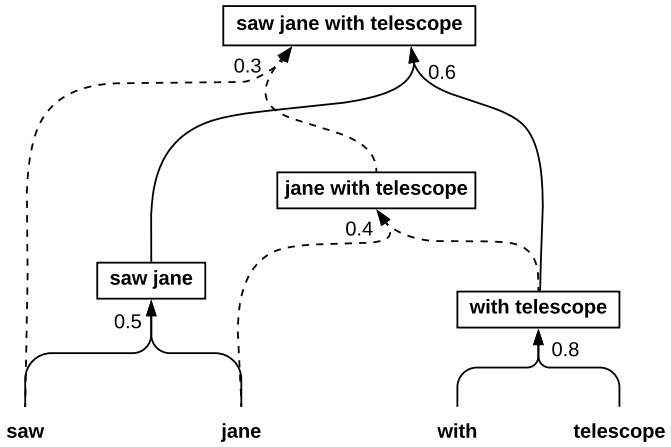


Figure 2: An example of generating a phrase from two different parse trees

3.1 Forest Encoder

The representation of words are computed using sequential encoder (Section 2.1). Then, the embeddings of phrases are computed with respect to the source sentence parse forest in a recursive bottom-up fashion.

Embedding of Phrases. We compute the embedding of the forest nodes (phrases) in a bottom-up fashion. For each hyperedge, we compute the embedding of the head with respect to its tails using a TreeLSTM unit (Tai et al., 2015). In a forest, however, a phrase can be constructed in multiple ways using the incoming hyperedges to a forest node, with different probabilities (see Figure 2). Our ForestLSTM combines the phrase embeddings resulted from these hyperedges, and takes into account their probabilities in order to obtain a unified embedding for the forest node and its corresponding phrase:

$$
\begin{aligned}
\boldsymbol{\gamma}^l &= \tanh\left(\boldsymbol{U}^{\gamma}\sum_{l'=1}^{N}\mathbf{1}_{l\neq l'}\boldsymbol{h}^{l'} + \boldsymbol{W}^{\gamma}\boldsymbol{h}^{l} + \boldsymbol{v}^{\gamma}p^{l} + \boldsymbol{b}^{\gamma}\right)\\
\boldsymbol{f}^l &= \sigma\left(\boldsymbol{U}^{f}\sum_{l'=1}^{N}\mathbf{1}_{l\neq l'}[\boldsymbol{h}^{l'};\boldsymbol{\gamma}^{l'}] + \boldsymbol{W}^{f}[\boldsymbol{h}^{l};\boldsymbol{\gamma}^{l}] + \boldsymbol{b}^{l}\right)\\
\boldsymbol{i} &= \sigma\left(\boldsymbol{U}^{i}\sum_{l=1}^{N}[\boldsymbol{h}^{l};\boldsymbol{\gamma}^{l}] + \boldsymbol{b}^{i}\right)\\
\boldsymbol{o} &= \sigma\left(\boldsymbol{U}^{o}\sum_{l=1}^{N}[\boldsymbol{h}^{l};\boldsymbol{\gamma}^{l}] + \boldsymbol{b}^{o}\right)
\end{aligned}
$$

where N is the number of incoming hyperedges, $\boldsymbol{h}^l$ is the embedding for the head of the l-th incoming hyperedge and p^l is its probability and $\boldsymbol{v}^{\gamma}$ is the learned weight for the probablity. $\boldsymbol{\gamma}^l$ is a probability-sensitive intermediate representation for the l-th incoming hyperedge, which is then used in the computations of the forget gate $\boldsymbol{f}^l$, the input gate $\boldsymbol{i}$, and the output gate $\boldsymbol{o}$. The representation of the phrase $\boldsymbol{h}^{phr}$ is then computed as

$$
\begin{aligned}
\tilde{\boldsymbol{c}} &= \tanh\left(\boldsymbol{U}^{\tilde{c}}\sum_{l=1}^{N}[\boldsymbol{h}^{l};\boldsymbol{\gamma}^{l}] + \boldsymbol{b}^{\tilde{c}}\right)\\
\boldsymbol{c}^{phr} &= \boldsymbol{i}\odot\tilde{\boldsymbol{c}} + \sum_{l=1}^{N}\boldsymbol{f}^{l}\odot\boldsymbol{c}^{l}\\
\boldsymbol{h}^{phr} &= \boldsymbol{o}\odot\tanh(\boldsymbol{c}^{phr})
\end{aligned}
$$

where $\boldsymbol{c}^l$ is the memory cell of the TreeLSTM unit used to compute the representation of the head for the l-th hyperedge from its tail nodes.

3.2 Sequential Decoder

We use a sequential attentional decoder similar to that of the TREE2SEQ model, where the attention mechanism attends to both words and phrases in the forest:

$$\boldsymbol{c}_j = \sum_{i=1}^{n} \alpha_{ji} \boldsymbol{h}_i + \sum_{i'=1+n}^{n_p+n} \alpha_{ji'} \boldsymbol{h}_{i'}^{phr}$$

where n is the length of the input sentence, and n_p is the number of forest nodes.

We initialize the decoder's first state by combining the embeddings of the last word in the source sentence and the root of the forest:

$$\boldsymbol{g}_0 = \text{TreeLSTM}(\boldsymbol{h}_n, \boldsymbol{h}_{root}^{phr}).$$

This provides a summary of phrases and words in the source sentence to the decoder.

3.3 Training

Training is done end-to-end by minimising the cross entropy objective:

$$J(\theta) = \sum_{(\boldsymbol{x},\boldsymbol{y},\boldsymbol{F}_{\boldsymbol{x}}) \in D} -\log p(\boldsymbol{y}|\boldsymbol{x}, \boldsymbol{F}_{\boldsymbol{x}})$$

where D is the set of triples consists of the bilingual training sentences $(\boldsymbol{x}, \boldsymbol{y})$ paired with the parse forests of the source sentences $\boldsymbol{F}_{\boldsymbol{x}}$.

4 Computational Complexity Analysis

We now analyse the computational complexity of inference for SEQ2SEQ, TREE2SEQ and FOREST2SEQ models. We show that, interestingly, our method process exponentially many trees with only a small linear overhead.

Let $|x|$ denotes the length of the source sentence and $O(W_s)$ and $O(W_r)$ are computational complexity of forward-pass for the sequential and Tree/Forest LSTM units, respectively. Having N nodes in the tree/forest, the computational complexity of the encoding phase would be:

$$O(2W_s|x| + W_r N)$$

where the first term shows the computational complexity of a bidirectional sequential encoder to compute the embeddings of words, and the latter one is the time for computing the embeddings of phrases with respect to the corresponding tree/forest.

For generating each word in the target sentence, the attention mechanism performs soft attention on words and phrases of the source sentence. If $O(W_t)$ be the time for updating the decoder state and generating the next target word, for a target sentence with length $|y|$ the decoding phase computational complexity would be:

$$O(W_t|y| + |y|(N + |x|))$$

Hence, the total inference time for a sentence pair is:

$$O(2W_s|x| + W_r N + W_t|y| + |y|(N + x))$$

The difference among the three methods is N. For the SEQ2SEQ model N is 0. For the TREE2SEQ model the number of nodes in the tree is a constant function of the input size: $N = |x| - 1$. Since

Sentence Length	Avg. tree nodes	Avg. forest nodes	Avg. # of trees in forests
<10	7.94	9.77	6.13E+4
10-19	12.3	18.99	2.62E+16
20-29	21.18	41.79	2.76E+22
>30	31	78.72	2.21E+15
all	10.33	14.84	1.41E+20

Table 1: The average number of nodes in trees and forests along with average number of trees in forests for En→Fa bucketed dataset.

we used *pruned* forests obtained from the parser in (Huang, 2008), the number of nodes in the forest is variable. Table 1 shows the average value of N for trees/forests for different source lengths for one of the datasets we used in experiments. As seen, while forests contain exponentially many trees, on average, the number of nodes in parse forests is less than twice the number of nodes in the corresponding top-1 parse trees. It shows that our method considers exponentially many trees instead of top-1 tree using only a small linear overhead.

5 Experiments

5.1 The Setup

Datasets. We make use of three different language pairs: English (En) to Farsi (Fa), Chinese (Ch), and German (De). Our research focus is to tackle NMT issues for bilingually low-resource scenarios and En→Fa is intrinsically a low-resource language. Moreover, we used small datasets for En→Ch and En→De language pairs to simulate low-resource scenarios, where the source and target languages are linguistically divergent and close, respectively. For En→Fa, we use the TEP corpus (Tiedemann, 2009) which is extracted from movie subtitles. It has about 341K sentence pairs, where we split into 337K for training, 2K for development, and 2K for test. For En→Ch, we use BTEC where 'devset1_2' and 'devset_3' are used as the development and test sets, and training consists of 44,016 sentence pairs. For En→De, we use the first 100K sentences of Europarl[1] for training, 'newstest2013' for development, and 'newstest2014' for test.

We lowercase and tokenise the corpora using Moses scripts (Koehn et al., 2007). Sentences longer than 50 words are removed, and words with frequency less than 5 are replaced with <UNK>. Compact forests and trees for source English sentences are obtained from the parser in (Huang, 2008), where the forests are binarised, i.e. hyperedges with more than two tail nodes are converted to multiple hyperedges with two tail nodes. This is to ensure a fair comparison between our model and the TREE2SEQ model (Eriguchi et al., 2016) where they use binary HPSG parse trees. Furthermore, we prune the forests by removing low probability hyperedges, which significantly reduces the size of the forests. In all experiments, we use the development sets for setting the hyper-parameters, and the test sets for evaluation.

Implementation Details. We use Mantis implementation of attentional NMT (Cohn et al., 2016) to develop our code for FOREST2SEQ and TREE2SEQ with DyNet (Neubig et al., 2017). All neural models are trained end-to-end using Stochastic Gradient Descent, where the mini-batch size is set to 128. The maximum training epochs is set to 20, and we use early stopping on the development set as a stopping condition. We generate the translations using greedy decoding. The BLEU score is computed using 'multi-bleu.perl' script in Moses.

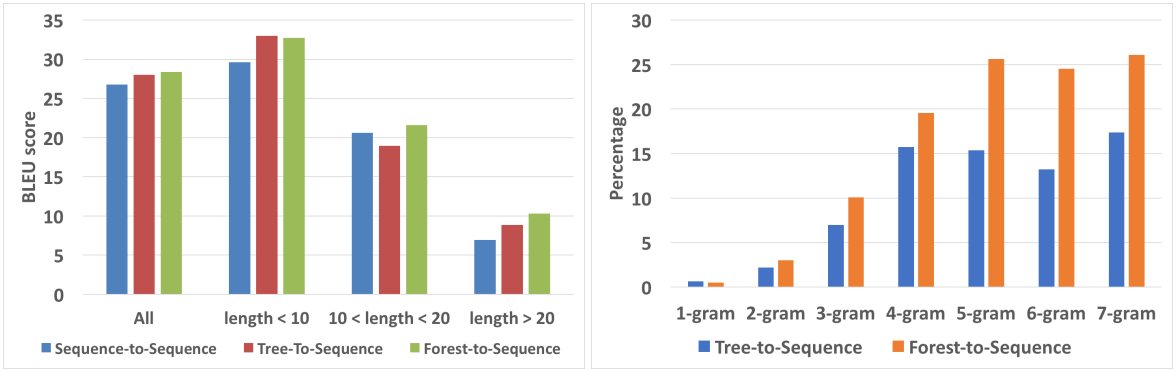
5.2 Results

The perplexity and BLEU scores of different models for all translation tasks are presented in Table 2. In all translation tasks, FOREST2SEQ outperforms TREE2SEQ as it reduces syntactic errors by using forests instead of top-1 parse trees. Our results confirm those in (Eriguchi et al., 2016), and show that using syntactic trees in TREE2SEQ improve the translation quality compared to the vanilla SEQ2SEQ.

[1] http://www.statmt.org/wmt14/translation-task.html

Method	H	En → De		En → Ch		En → Fa	
		Perplexity	BLEU	Perplexity	BLEU	Perplexity	BLEU
SEQ2SEQ	256	33.07	11.98	6.48	25.43	19.21	10.17
(Luong et al., 2015)	512	32.61	12.21	6.12	26.77	18.4	10.93
TREE2SEQ	256	30.13	13	6.17	26.85	17.94	11.32
(Eriguchi et al., 2016)	512	31.86	13.05	5.71	28	16.28	11.71
our	256	30.83	**13.54**	6.16	27.08	17.62	11.91
FOREST2SEQ	512	**29.25**	13.43	**5.49**	**28.39**	**16.66**	**12.38**

Table 2: Comparison of the methods together with different hidden dimension size (H) for all datasets.



(a) (b)

Figure 3: (a) BLEU scores for bucketed En→Ch dataset. (b) Percentage of more correct n-grams generated by the TREE2SEQ and FOREST2SEQ models compared to SEQ2SEQ model for En→Ch dataset.

Comparing BLEU scores of the forest-based and tree-based models, the largest increase is observed for En→Fa. This can be attributed to the syntactic divergence between English and Farsi (SVO vs SOV) as well as the reduction of significant errors in the top-1 parser trees for this translation task, resulted from the domain mismatch between the parser's training data (i.e. Penn Tree Bank) and the English source (i.e. informal movie subtitles).

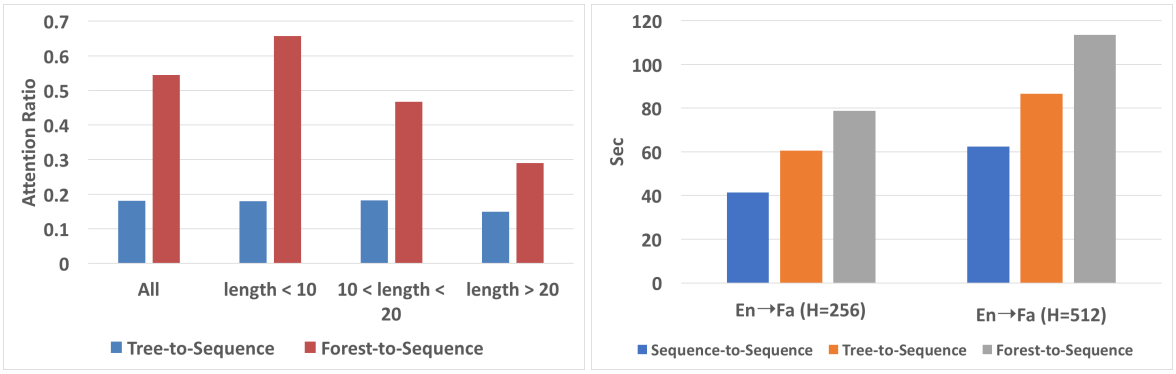
5.3 Analysis

The effect of sequential part in the forest encoder The forest encoder consists of sequential and recursive parts, where the former is the vanilla sequence encoder. We investigate the effect of the sequential part in the proposed forest encoder. Table 3 shows the results on the test set of En → Fa dataset. The results show that the sequential part in the forest encoder lead to improvement in results. Speculatively, the sequential part helps the forest encoder by providing the context-aware embeddings for words which then be used to construct phrase embeddings.

For which sentence lengths the forest-based model is more helpful? To investigate the effect of source sentence length, we divide En→Ch dataset into three buckets with respect to the length of source sentences. Figure 3(a) depicts the BLEU scores resulted from the models for different buckets. The FOREST2SEQ model performs better than vanilla SEQ2SEQ model on all buckets. Interestingly, while TREE2SEQ model has a lower BLEU compared to SEQ2SEQ model for the sentences whose lengths are between 10 and 20, the FOREST2SEQ model has a better BLEU possibly due to reducing parsing errors.

	Perplexity	BLEU
Forest encoder W/ sequential part	16.66	12.38
Forest encoder W/O sequential part	17.48	11.97

Table 3: The Effect of the sequential part in our proposed forest encoder on the En → Fa test set.



(a) (b)

Figure 4: (a) Attention ratios for En→Fa bucketed dataset.(b) Inference time (seconds) required for the test set of En→Fa dataset using trained models.

The forest-based model results in correct larger n-grams in translations We further analyse the effect of the incorporated syntactic knowledge on improving the number of generated gold n-grams in translations. For each sentence, we compute the number of n-grams in the generated translations which are common with those in the gold translation. Then, after aggregating the results over the entire test set, we compute the percentage of additional gold n-grams generated by syntax aware models, i.e. TREE2SEQ and FOREST2SEQ, compared to the SEQ2SEQ model. The results are depicted in Figure 3(b). Generating correct high order n-grams is hard, and results show that incorporating syntax is beneficial. As n increases, the FOREST2SEQ model performs significantly better than the TREE2SEQ model in generating gold n-grams, possibly due to better reorderings between the source and target.

How much attention the forest-based and tree-based models pay to the syntactic information? We next analyse the extent by which the syntactic information is used by the TREE2SEQ and FOREST2SEQ models. We compute the ratio of attention on phrases to words for both of the syntax-aware models in En→Fa translation task, where the source and target languages are highly syntactically divergent. For each triple in the test set, we calculate the sum of attention on words and phrases during decoding. Then, the ratio of attention on phrases to words are computed and is averaged for all triples. Figure 4(a) shows these attention ratios for bucketed En→Fa dataset. It shows that for all sentence lengths, the FOREST2SEQ model provides richer phrase embeddings compared to the TREE2SEQ model, leading to a more usage of the syntactic information.

Investigating the effect of using trees/forests on inference time We measured the inference time required for the test set of EN→FA dataset using the trained models. The results are depicted in Figure 4(b). As seen, while using one parse tree increases the inference time linearly, interestingly, our FOREST2SEQ model considers exponentially many trees also with a small linear overhead.

6 Conclusion

We have proposed a forest-to-sequence attentional NMT model, which uses a packed forest instead of the top-1 parse tree in the encoder.

Using a forest of parse trees, our method efficiently considers exponentially many constituency trees in order to take into account parser uncertainties and errors. Experimental results show our method is superior to the attentional tree-to-sequence model, which is more prone to the parsing errors.

Abstract

In this paper, we investigate the sentence summarization task that produces a summary from a source sentence. Neural sequence-to-sequence models have gained considerable success for this task, while most existing approaches only focus on improving word overlap between the generated summary and the reference, which ignore the correctness, i.e., the summary should not contain error messages with respect to the source sentence. We argue that correctness is an essential requirement for summarization systems. Considering a correct summary is semantically entailed by the source sentence, we incorporate entailment knowledge into abstractive summarization models. We propose an entailment-aware encoder under multi-task framework (i.e., summarization generation and entailment recognition) and an entailment-aware decoder by entailment Reward Augmented Maximum Likelihood (RAML) training. Experimental results demonstrate that our models significantly outperform baselines from the aspects of informativeness and correctness.

1 Introduction

Sentence summarization is a well-studied task that creates a condensed version of a long source sentence. Sequence-to-sequence (seq2seq) model that encodes a source sequence into a latent representation and outputs another sequence is the dominating framework for sentence summarization (Rush et al., 2015; Chopra et al., 2016; Takase et al., 2016; Zhou et al., 2017; Li et al., 2017b; Li et al., 2018). Despite substantial improvements on this task, most of the existing researches typically aim to improve word overlap between the generated summary and the references, which is measured by n-gram matching metrics (e.g., ROUGE (Lin, 2004)). Hence, it cannot guarantee the semantic correctness of the summary as a whole. Therefore, in some cases, the summary giving high matching scores may contain critical error messages, which makes the summary fail to capture the correct information with respect to the source sentence. Previous study shows that about 30% of the summaries generated by state-of-the-art seq2seq system are subject to this problem (Cao et al., 2017). Here is an example (the digits are replaced by "#"):

Source sentence: franch won the gold medal at women 's epee team event of the fie #### world championships by beating china ##-## .
Reference: france beats china for women 's epee team gold
State-of-the-art seq2seq model: canada wins women 's epee team event

For the example shown above, the seq2seq system produces a fluent summary which contains an obvious mistake. The true winner of the "women 's epee team event" is "france", while the summarization model wrongly generates "canada", which is probably due to similar word representations for country names. Though the word overlap between the generated summary and the reference is considerable, leading to high ROUGE scores, the summary is invalid.

Proceedings of the 27th International Conference on Computational Linguistics, pages 1430–1441
Santa Fe, New Mexico, USA, August 20-26, 2018.

We argue that correctness is an essential requirement for summarization systems, while most existing systems ignore it. Generally, a correct summary is semantically entailed by the source sentence, thus we believe entailment[1] (Bos and Markert, 2005) knowledge is beneficial to avoid producing contradictory or unrelated information in the summary.

To incorporate entailment knowledge into abstractive summarization models, we propose in this work an entailment-aware encoder and an entailment-aware decoder. We share the encoder of the summarization generation system with the entailment recognition system, so that the encoder can grasp both the gist of the source sentence and be aware of entailment relationships. Furthermore, we propose an entailment Reward Augmented Maximum Likelihood (RAML) (Norouzi et al., 2016) training that encourages the decoder of the summarization system to produce summary entailed by the source. Experimental results demonstrate that our models significantly outperform some solid baselines on objective evaluation for informativeness and manual evaluation for correctness. Further analysis suggests that our summarization model is aware of entailment knowledge.

Our main contributions are as follows:

- We incorporate entailment knowledge into summarization models to avoid producing unrelated information with respect to the source sentence.
- We propose an entailment-aware encoder by jointly modeling summarization generation and entailment recognition.
- We introduce an entailment-aware decoder via entailment RAML training.

2 Background: Seq2seq Learning

In this section, we describe the basic seq2seq learning framework. Given a dataset of input-output pairs, $\mathcal{D} \triangleq (\mathbf{x}_i, \mathbf{y}_i^*)_{i=1}^N$, the seq2seq model maximizes the conditional probability of a target sequence $\mathbf{y}^*$: $p(\mathbf{y}^*|\mathbf{x})$. Recurrent Neural Networks (RNN) encoder (Cho et al., 2014) reads and converts a variable-length input sequence $\mathbf{x}$ into a context representation c as follows:

$$h_t = f_{\text{enc}}(\mathrm{x_t}, h_{t-1}) \tag{1}$$

$$c_t = f_c(h_1, \cdots, h_t) \tag{2}$$

where $h_t \in \mathbb{R}^n$ is a hidden state at time t, and c_t is a context vector generated from the sequence of the hidden states. f_{enc} and f_{c} are nonlinear activation functions.

The decoder generates word $\mathrm{y_t}$ given the context vector c_t and the previously generated words:

$$p(\mathrm{y}_t|\{\mathrm{y}_1, \cdots, \mathrm{y}_{t-1}\}, c_t) = f_{\text{dec}}(\mathrm{y}_{t-1}, s_t, c_t) \tag{3}$$

where s_t is the hidden state of the decoder and f_{dec} is a nonlinear activation function. The maximum likelihood (ML) framework tries to minimize negative log-likelihood of the parameters as follows:

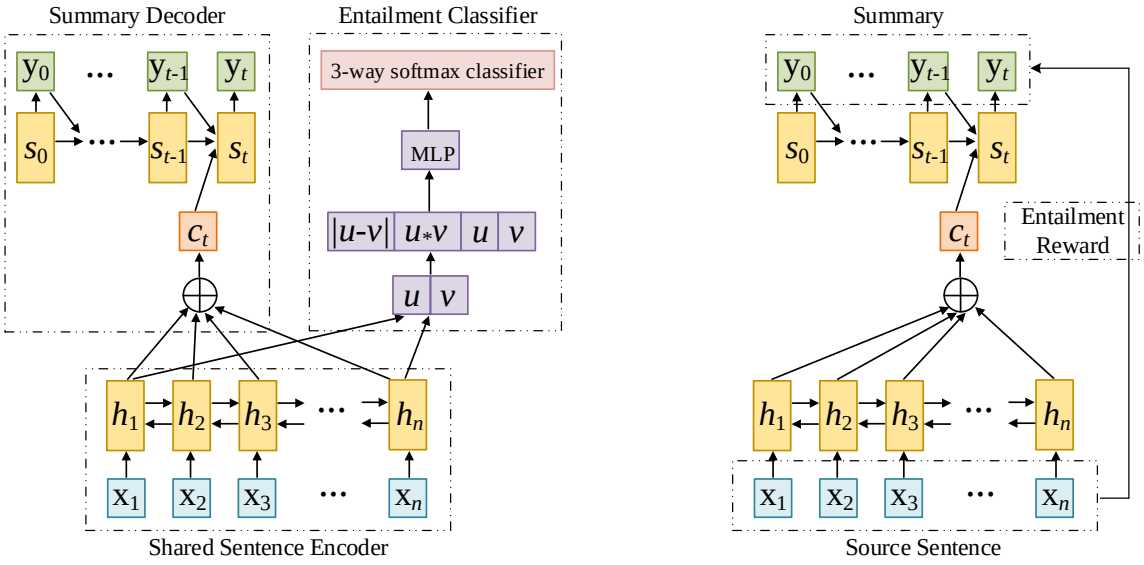
$$\mathcal{L}_{\text{ML}}(\mathcal{D}) = \sum_{(\mathbf{x},\mathbf{y}^*)\in\mathcal{D}} -\log p(\mathbf{y}^*|\mathbf{x}) \tag{4}$$

3 Our Proposed Model

3.1 Overview

In order to avoid generating unrelated summary with respect to the source sentence, we propose two strategies to incorporate entailment knowledge into seq2seq summarization model. We first introduce an entailment-aware encoder using multi-task learning for summarization generation and entailment recognition. Then, we introduce an entailment-aware decoder by entailment RAML training.

[1]Entailment is a kind of relationships between two sentences for natural language inference. Sentence A entailing sentence B means A can infer B. Other relationships include contradiction and neutral. A correct summary should be inferred by the source sentence. Thus, we argue that entailment is a useful criterion for the correctness of the summary.



(a) Entailment-aware Encoder

(b) Entailment-aware Decoder

Figure 1: The framework of our model. Entailment-aware encoder is learned by jointly training summarization generation (left part of (a), which is a seq2seq model) and entailment recognition (right part of (a), in which sentence pair in the entailment recognition corpus are encoded as u and v). Entailment-aware decoder is learned by entailment RAML training, in which the summary will be rewarded if it is entailed by the source sentence.

3.2 Entailment-aware Encoder

In this section, we propose a multi-task learning for abstractive summarization by sharing the encoder with the task of entailment recognition. By doing so, we can learn an entailment-aware encoder for sentence summarization task. In this way, we can improve the correctness aspect of the summarization model, while maintaining the salient information extraction aspects. Note that the training data for summarization and entailment task is from summarization and entailment corpus, respectively.

3.2.1 Shared Sentence Encoder

Given a source sentence $\mathbf{x} = (\mathrm{x}_1, \cdots, \mathrm{x}_n)$, we employ a bidirectional LSTM (BiLSTM) to build its hidden representation $(h_1, \cdots, h_n)$.

The BiLSTM encodes source sentence forwardly and backwardly to generate two sequences of the hidden states: $(\overrightarrow{h}_1, \cdots, \overrightarrow{h}_n)$ and $(\overleftarrow{h}_1, \cdots, \overleftarrow{h}_n)$, respectively, where:

$$\overrightarrow{h}_i = \mathrm{LSTM}(\mathrm{x}_i, \overrightarrow{h}_{i-1}) \tag{5}$$

$$\overleftarrow{h}_i = \mathrm{LSTM}(\mathrm{x}_i, \overleftarrow{h}_{i+1}) \tag{6}$$

The final sentence representation h_i is the concatenation of the forward and backward vectors: $h_i = [\overrightarrow{h}_i; \overleftarrow{h}_i]$.

3.2.2 Attention-based Summarization Decoder

At each time step t, the state of the decoder s_t is calculated as follows:

$$s_t = \mathrm{LSTM}(s_{t-1}, \mathrm{y}_{t-1}, c_t) \tag{7}$$

$$s_0 = \tanh(\mathbf{W}_h[\overrightarrow{h}_n; \overleftarrow{h}_1]) \tag{8}$$

We compute the context vector c_t as a weighted sum of the source annotations as follows:

$$c_t = \sum_{i=1}^{N} \alpha_{t,i} h_i \tag{9}$$

where each vector is weighted by the attention weight $\alpha_{t,i}$, as calculated in Equations 10 and 11:

$$e_{t,i} = v_c^T \tanh(\mathbf{W}_s s_t + \mathbf{W}_e h_i) \tag{10}$$

$$\alpha_{t,i} = \frac{\exp(e_{t,i})}{\sum_{j=1}^{N} \exp(e_{t,j})} \tag{11}$$

The probability for the next target word y_t is computed using hidden state s_t and the previously emitted word y_{t-1} as follows:

$$p(\mathrm{y}_t|\{\mathrm{y}_1, \cdots, \mathrm{y}_{t-1}\}) \propto \exp(\mathbf{L}_e \tanh(\mathbf{L}_s s_t + \mathbf{L}_y \mathrm{y}_{t-1})) \tag{12}$$

where $\mathbf{W}_h$, $\mathbf{W}_s$, $\mathbf{W}_e$, $\mathbf{L}_e$, $\mathbf{L}_s$ and $\mathbf{L}_y$ are model parameters. The summarization model is trained by minimizing negative log-likelihood loss as in Equation 4.

3.2.3 Matching-based Entailment Inference Model

To infer entailment relation, input sentence pairs from the entailment recognition corpus are fed into sentence encoder to obtain hidden representation $(h_1^u, \cdots, h_n^u)$ and $(h_1^v, \cdots, h_n^v)$, respectively. Then, the sentence pairs are encoded as vectors $u = [\overrightarrow{h}_n^u; \overleftarrow{h}_1^u]$ and $v = [\overrightarrow{h}_n^v; \overleftarrow{h}_1^v]$, respectively. Next, the absolute difference and the element-wise product for the tuple $[u, v]$ are concatenated with the original vectors u and v (Mou et al., 2016) as follows:

$$q = [|u - v|; u * v; u; v] \tag{13}$$

We then feed q into a 3-layer multilayer perceptron (MLP) classifier. The 3-class softmax output layer is on top of MLP. The entailment recognition model is trained by minimizing cross-entropy loss.

3.2.4 Multi-Task Learning (MTL)

In our multi-task setup, we share the encoder parameters of both the tasks, as shown in Figure 1(a). Traditional MTL considers equal contribution for all tasks. In our model, two tasks are significantly different. The summary generation task is much more complicated than entailment recognition, leading to different learning difficulties and convergence rates. Therefore, summarization generation is regarded as the main task and entailment recognition as the auxiliary task, and our goal is to optimize the main task with assistance of auxiliary task. To this end, we optimize the two loss functions alternatively during training. Let α be the number of mini-batches of training for entailment recognition after 100 mini-batches of training for summarization generation (Pasunuru et al., 2017). We adopt $\alpha = 10$ and performance with different α is discussed in Section 6.6.3.

3.3 Entailment-aware Decoder

In order to encourage the decoder of the summarization system to produce summary entailed by the source sentence, we apply an entailment-aware decoder by entailment RAML training (Norouzi et al., 2016).

3.3.1 Reward Augmented Maximum Likelihood (RAML) Training

RAML provides a computationally efficient approach to optimize task-specific reward (loss) directly. In our work, we apply RAML to incorporate entailment-based reward into our summarization model, as shown in Figure 1(b).

The RAML objective function is defined as follows:

$$\mathcal{L}_{\mathrm{RAML}} = \sum_{(\mathbf{x},\mathbf{y}^*)\in\mathcal{D}} \left\{ -\sum_{\mathbf{y}\in\mathcal{Y}} q\left(\mathbf{y}|\mathbf{x}, \mathbf{y}^*; \tau\right) \log p(\mathbf{y}|\mathbf{x}) \right\} \tag{14}$$

$$q\left(\mathbf{y}|\mathbf{x}, \mathbf{y}^*; \tau\right) = \frac{1}{Z(\mathbf{x}, \mathbf{y}^*, \tau)} \exp\{r(\mathbf{x}, \mathbf{y}, \mathbf{y}^*)/\tau\} \tag{15}$$

$$Z(\mathbf{x}, \mathbf{y}^*, \tau) = \sum_{\mathbf{y}\in\mathcal{Y}} \exp\{r(\mathbf{x}, \mathbf{y}, \mathbf{y}^*)/\tau\} \tag{16}$$

where $\mathcal{Y}$ is the set of possible model outputs. $r(\mathbf{x}, \mathbf{y}, \mathbf{y}^*)$ denotes the reward function and τ is the regularization parameter.

3.3.2 Optimizing by Entailment-based Sampling

We can express the gradient of $\mathcal{L}_{\mathrm{RAML}}$ in terms of an expectation over samples from $q(\mathbf{y}|\mathbf{x}, \mathbf{y}^*; \tau)$:

$$\mathcal{L}_{\mathrm{RAML}} = E_{q(\mathbf{y}|\mathbf{x},\mathbf{y}^*;\tau)}\left[-\nabla \log p(\mathbf{y}|\mathbf{x})\right] \tag{17}$$

RAML training adds a sampling step over typical ML objective. Instead of optimizing ML on training samples, given training input $(\mathbf{x}, \mathbf{y}^*)$, RAML training first samples an output $\mathbf{y}$ proportionally to the reward. Then, RAML optimizes log-likelihood on such sample given the corresponding input. Thus, we need to sample auxiliary outputs from the exponentiated payoff distribution, $q(\mathbf{y}|\mathbf{x}, \mathbf{y}^*; \tau)$. In this work, we first use reward values defined by negative Hamming distance and then re-weight the reward based on entailment reward $s(\mathbf{x}, \mathbf{y}, \mathbf{y}^*)$. Particularly, given a sentence $\mathbf{y}^*$ of length ℓ, we count the number of sentences within an edit distance d, where $d \in \{0, \ldots, 2\ell\}$. Then, we weight the counts by $\exp\{-d/\tau\}$ and perform normalization. Finally, we apply importance sampling by the weight $\exp\{(s(\mathbf{x}, \mathbf{y}, \mathbf{y}^*) + d)/\tau\}$ and perform normalization, where the proposal distribution is Hamming distance sampling[2].

We define entailment reward $s(\mathbf{x}, \mathbf{y}, \mathbf{y}^*)$ as follows:

$$s(\mathbf{x}, \mathbf{y}, \mathbf{y}^*) = \min\{e(\mathbf{x}, \mathbf{y}), e(\mathbf{x}, \mathbf{y}^*)\} \tag{18}$$

where $e(\mathbf{x}, \mathbf{y})$ denotes entailment score for sentence pairs $(\mathbf{x}, \mathbf{y})$. Our goal is to maximize the entailment reward of the summary towards the reference, given the source sentence. Here we adopt the model of Parikh et al. (2016) trained on the MultiNLI corpus[3] (Williams et al., 2017) to obtain $e(\mathbf{x}, \mathbf{y})$.

4 Related work

Text summarization methods can be categorized into extraction-based methods (Erkan and Radev, 2004; Wan et al., 2007; Cheng and Lapata, 2016; Zhang et al., 2016; Nallapati et al., 2017; Li et al., 2017a) and abstraction-based methods. Rush et al. (2015) first apply the seq2seq model to abstractive sentence summarization. They propose an attentive CNN encoder and a neural network language model (Bengio et al., 2003) decoder. Chopra et al. (2016) use RNN as the decoder and achieve better performance. Nallapati et al. (2016) further replace the encoder with an RNN, forming a full RNN seq2seq model. Gu et al. (2016) and Zeng et al. (2016) incorporate a copying mechanism into seq2seq learning and Gulcehre et al. (2016) propose a switch gate to control whether to copy from the source or generate a word by the decoder. Copying mechanism intends to replicate segments in the source to the target, which cannot guarantee the correctness of the summary as a whole. Ma et al. (2017) focus on improving the semantic relevance between source and summary by encouraging high similarity of their representation. Zhou et al. (2017) employ a selective encoding model to control the information flow from encoder to decoder. Li et al. (2017b) apply a deep recurrent generative decoder to seq2seq framework. Cao et al. (2017) solve the problem of fake facts in a summary. They use Open Information Extraction to extract fact descriptions in the source sentence and propose the dual-attention seq2seq framework to force the generation conditioned on both source sentence and the fact descriptions. To the best of our knowledge, our work is the first to directly explore the correctness of summary without any preprocessing.

Some previous work (Mehdad et al., 2013; Gupta et al., 2014) has used textual entailment recognition to reduce redundancy for extractive summarization task. Our work is partially inspired by the models of Pasunuru et al. (2017) with following differences: Pasunuru et al. (2017) model the entailment task as the seq2seq generation problem and enforce sharing of the same decoder between summarization and entailment. However, the entailment task is more reasonable to be considered as a multi-label classification problem rather than a generation problem. We thus design a multi-task learning framework in which the summarization generation task shares the same encoder with the entailment recognition task.

[2]We adopt the implement at https://github.com/pcyin/pytorch_nmt

[3]Multi-Genre Natural Language Inference (MultiNLI) is one of the largest corpora available for the task of natural language inference. It consists of sentences from ten different sources of text, which can be used for cross-genre domain adaptation.

5 Dataset

We conduct experiments on English Gigaword and DUC 2004 datasets.

Gigaword Corpus. We use the annotated Gigaword corpus provided by Rush et al. (2015). The dataset has about 3.8 million training pairs. Following Zhou et al. (2017), we use 8, 000 pairs as validation set and the test samples provided by Rush et al. (2015) and Zhou et al. (2017) as our test sets.

DUC 2004 Corpus. DUC-2004 corpus for tasks 1 & 2 (Over et al., 2007) consists of 500 documents. Each document in these datasets has four human annotated summaries. For experiments on this corpus, we directly use the model trained on the Gigaword to test on the DUC 2004 corpus.

6 Experiment

6.1 Experimental Settings

Word embedding size is set to 300 and LSTM hidden state size is set to 512. We use the full source and target vocabularies collected from the training data, which have 119, 505 and 68, 885 words, respectively. Adam (Kingma and Ba, 2014) optimizer is applied with the learning rate of 0.001, momentum parameters $\beta_1 = 0.9$ and $\beta_1 = 0.999$, and $\epsilon = 10^{-8}$. For RAML, $\tau = 0.85$. The mini-batch size is set to 64. We test the model performance (ROUGE-2 F1 score) on validation set for every 2,000 batches. We halve the learning rate if the ROUGE-2 F1 score drops for twelve consecutive tests on validation set. We also apply gradient clipping (Pascanu et al., 2012) with range $[-5, 5]$ during training. Our model with entailment-aware encode requires less than 300,000 training iterations to train with early stopping (Prechelt, 1998). To speed up the training for our RAML model, we continue the RAML training based on the pre-trained model with ML training with the current decayed learning rate. At test time, we use beam search with beam size 10 to generate the summary. We report ROUGE F1 score including ROUGE-1, ROUGE-2 and ROUGE-L for Gigaword corpus and ROUGE recall score for DUC 2004 corpus.

6.2 Comparative Methods

We compare a set of sentence summarization baselines.

ABS. Rush et al. (2015) first apply the seq2seq model to abstractive sentence summarization. They use an attentive CNN encoder and neural network language model decoder to summarize sentence.

ABS+. Rush et al. (2015) further tune ABS model on DUC 2003 dataset, then test on DUC 2004 test set.

CAs2s. Chopra et al. (2016) extend the ABS model with a convolutional encoder and RNN decoder, which performs better than the ABS model.

Feats2s. Nallapati et al. (2016) use a full RNN seq2seq model and add some lexical features to enhance the encoder, including POS, NER tags and TF-IDF values.

Luong-NMT. Luong et al. (2015) propose a neural machine translation model with two-layer LSTMs for the encoder-decoder.

Seq2seq. This is a standard seq2seq model with attention mechanism.

Seq2seq + MTL. This is our proposed model with entailment-aware encoder, which applies a multi-task learning (MTL) framework to seq2seq model.

Seq2seq + MTL (Share decoder). Pasunuru et al. (2017) propose a multi-task learning (MTL) framework in which the decoder is shared for summarization generation and entailment generation task.

Seq2seq + ERAML. This is our proposed model with entailment-aware decoder, which conducts an Entailment Reward Augmented Maximum Likelihood (ERAML) training framework.

Seq2seq + ROUGE-2 RAML. We apply ROUGE-2 RAML training for seq2seq model.

Seq2seq + RL. We implement Reinforcement Learning (RL) models (policy gradient) with reward metrics of **Entailment** and **ROUGE-2**.

Seq2seq + selective. Zhou et al. (2017) employ a selective encoding model to control the information flow from encoder to decoder. To verify the generalization of our entailment-based strategies, we adopt selective encoding mechanism to our seq2seq model and apply MTL and RAML to **Seq2seq + selective** model, which is denoted as the **Seq2seq + selective + MTL + RAML** model.

Model	ROUGE-1	ROUGE-2	ROUGE-L
ABS (Rush et al., 2015)	37.41	15.87	34.70
Seq2seq (Zhou et al., 2017)	43.76	22.28	41.14
Seq2seq + MTL	45.11	23.87	42.50
Seq2seq + MTL (Share decoder) (Pasunuru et al., 2017)	44.69	22.91	42.04
Seq2seq + ERAML	44.71	23.74	42.11
Seq2seq + ROUGE-2 RAML	43.75	23.63	41.31
Seq2seq + RL (Entailment)	44.39	23.31	41.86
Seq2seq + RL (ROUGE-2)	43.55	22.97	41.01
Seq2seq + MTL + ERAML	45.36	24.12	42.74
Seq2seq + selective	45.58	24.02	42.88
Seq2seq + selective + MTL + ERAML	**46.28**	**24.60**	**43.47**

Table 1: Experimental results (%) on the English Gigaword test set of Zhou et al. (2017). Our models perform significantly better than baselines by the 95% confidence interval measured by the official ROUGE script.

6.3 Experimental Results: Gigaword Corpus

In Table 1, we report the ROUGE F1 score of our model and the baseline methods on the English Gigaword test set provided by Zhou et al. (2017). Our entailment-aware models outperform all baseline models by a large margin. Our final model, **Seq2seq + selective + MTL + ERAML**, achieves the best results, which improves 2.52 (%) ROUGE-1, 2.32 ROUGE-2 and 2.33 ROUGE-L over seq2seq model. Our seq2seq model with entailment-aware encoder (**Seq2seq + MTL**) surpasses the state-of-the-art seq2seq model of 1.35 ROUGE-1, 1.59 ROUGE-2, 1.36 ROUGE-L, and entailment-aware decoder (**Seq2seq + ERAML**) gains improvement of 0.95 ROUGE-1, 1.46 ROUGE-2, 0.97 ROUGE-L. Compared to the another MTL model via sharing decoder for entailment generation task (**Seq2seq + MTL (Share decoder)**), our MTL model (**Seq2seq + MTL**) has obvious ROUGE score gains. The **Seq2seq + ROUGE-2 RAML** model also shows promising performance, especially for ROUGE-2 score. RAML has a clear advantage over RL. In principle, RL samples from the model distribution, which slows down training and several tricks are needed to get better estimates of the gradient (Ranzato et al., 2015). The comparison to the model of **Seq2seq + selective** shows that our entailment-aware strategies are also useful for seq2seq model with selective encoding framework, which demonstrates the good generalization of our method. The results on English Gigaword test set provided by Rush et al. (2015) are shown in Table 2. Our model performs better than the previous works.

6.4 Experimental Results: DUC 2004 Test Corpus

We evaluate our model with the ROUGE recall score. The reference summaries of the DUC 2004 test set are fixed to 75 bytes and we set the maximum length of the summary to 18 following Zhou et al. (2017). In Table 2, experimental results also show our **Seq2seq + selective + MTL + ERAML** model achieves significant improvements over baseline models, surpassing Feats2s (Nallapati et al., 2016) by 0.98% ROUGE-1, 0.78% ROUGE-2 and 0.65% ROUGE-L without fine-tuning on DUC data.

6.5 Manual Evaluation

Next, we conduct a manual evaluation to inspect the correctness of the generated summaries. We randomly select 500 samples in the test set and employ five postgraduates to classify the generated summaries as correct (i.e., not contain wrong information) or not. As shown in Table 3, 60.6% of the summaries generated by seq2seq model are correct, and it rises to 69.4% and 74.2% for our model with selective encoding and entailment-aware strategies, respectively, which indicates the effectiveness of our model to generate a correct summary.

	Test set of Rush et al. (2015)			DUC 2004 test set		
Model	RG-1	RG-2	RG-L	RG-1	RG-2	RG-L
ABS (Rush et al., 2015)	29.55	11.32	26.42	26.55	7.06	22.05
ABS+ (Rush et al., 2015)	29.76	11.88	26.96	28.18	8.49	23.81
Feats2s (Nallapati et al., 2016)	32.67	15.59	30.64	28.35	9.46	24.59
CAs2s (Chopra et al., 2016)	33.78	15.97	31.15	28.97	8.26	24.06
Luong-NMT (Luong et al., 2015)	33.10	14.45	30.71	28.55	8.79	24.43
Seq2seq (Zhou et al., 2017)	34.04	15.95	31.68	28.13	9.25	24.76
Seq2seq + MTL	34.69	16.68	32.32	28.61	9.67	24.86
Seq2seq + ERAML	34.34	16.59	32.26	28.37	9.61	24.81
Seq2seq + MTL + ERAML	34.88	16.86	32.51	28.89	9.87	24.94
Seq2seq + selective	35.01	16.71	32.88	29.01	9.89	25.01
Seq2seq + selective + MTL + ERAML	**35.33**	**17.27**	**33.19**	**29.33**	**10.24**	**25.24**

Table 2: Experimental results (%) on the English Gigaword test set of Rush et al. (2015) and DUC 2004 test set. Our models perform significantly better than baseline models by the 95% confidence interval measured by the official ROUGE (RG) script.

Model	Correctness(%)
Seq2seq	60.6
Seq2seq + selective	69.4
Seq2seq + selective + MTL + ERAML	74.2

Table 3: Manual evaluation for correctness.

6.6 Further Analysis

To further investigate the effectiveness of our model, we perform analysis on the entailment score improvement, the abstraction degree of our model and the impact for entailment recognition task.

6.6.1 Does our summarization model learn entailment knowledge?

The motivation of our work is to encourage summarization model to generate summaries that are entailed by the source sentences. To verify this goal, we investigate the entailment score for source-summary pairs for different models. For the test set of Zhou et al. (2017), the average entailment score for the reference is 0.72, while for the basic seq2seq model, the entailment score is only 0.46. When we adopt entailment-based strategies, the entailment score rises to 0.63 for seq2seq model. Note that the entailment score is 0.57 for seq2seq model with selective encoding, and we believe that the selective mechanism can filter out secondary information in the input, which will reduce the possibility to generate irrelevant information. Entailment-aware selective model achieves a high entailment reward of 0.71. In part at least, we can conclude that our model has successfully learned entailment knowledge.

6.6.2 Is it less abstractive for our model?

We have shown that our entailment-aware model can generate correct summaries more frequently (Section 6.5). Intuitively, it is more likely to be correct if summary segments are directly extracted from the source. Thus, readers may wonder whether our model is less abstractive. Figure 2 shows that the seq2seq model produces more novel words (i.e., words that do not appear in the article) than our model, indicating a lower degree of abstraction for our model. However, when we exclude all the words not in the reference (these words may lead to wrong information), our model generates more novel words, suggesting that our model provides a compromise solution for informativeness and correctness. Thus, our model can generate summary with fewer mistakes.

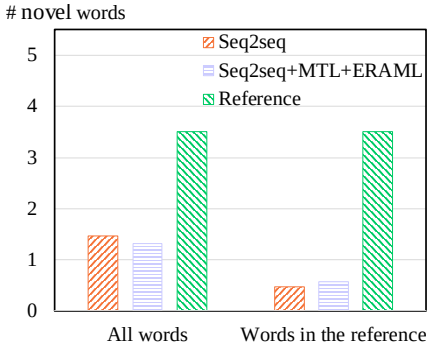


Figure 2: Average count of novel words (words that do not appear in the article). Seq2seq model generates more novel words, but less words are in the reference compared to our model.

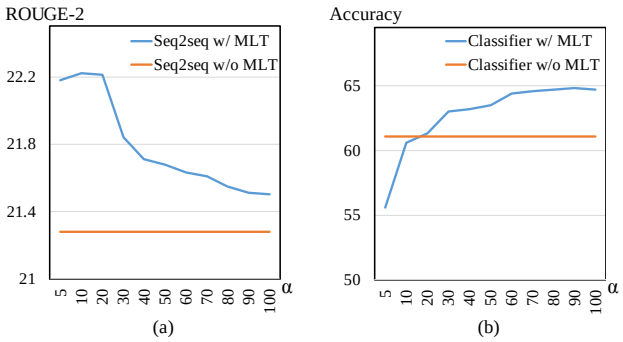

Figure 3: The performance of (a) summarization generation on Gigaword validation set and (b) entailment recognition on SNLI (Bowman et al., 2015) validation set with different task batch switches (α).

Table 4: Cases Study.

6.6.3 Could the entailment recognition also be improved?

Multi-task learning (MTL) involves sharing parameters between related tasks, whereby each task can benefit from extra information of other tasks in the training process. In this section, we explore whether the entailment recognition can benefit from summarization generation task. Figure 3 shows that our summarization model with MTL outperforms basic seq2seq model. As α increases, the accuracy of entailment recognition improves and finally exceeds that of the model without MTL, which reveals the advantage of MTL framework.

7 Case Study

We illustrate the examples of outputs in Table 4. As shown in the table, seq2seq model generates summaries that are not relevant to the source sentence, while the output of our model obtains higher entailment scores than those of seq2seq model. For the first example, seq2seq model regards the reason for "brazil stocks rise" as "consumer credit concerns", while in fact, "consumer" is not worried because "government said it would n't impose restraints on consumer credit". By contrast, since our model incorporates entailment knowledge, the true reason is captured and the output of our model is related to the source sentence. A similar problem happens in example 2, and seq2seq model generates a summary that is contradictory to the source. The "demonstration" is "denied" by the "authorities", while seq2seq model confirms the "demonstration". In Example 3, neither seq2seq nor our model performs satisfactorily. Seq2seq model again misunderstands the meaning of the source and outputs summary containing wrong information. Though the summary generated by our model is entailed by the source, the summary fails to produce an integrated sentence and misses the key points of the source, such as the object of the event, "queens taxi driver". A mixed reward, i.e., combining entailment and ROUGE-2, may address this

issue. We leave it for our future work.

8 Conclusion

This paper investigates the correctness problem in abstractive summarization. We propose an entailment-aware encoder by jointly learning summarization generation and entailment recognition. We present an entailment-aware decoder by entailment reward augmented maximum likelihood training. By enriching the encoder and decoder with entailment information, our model makes the summary more likely be entailed by the source input. Experimental results on Gigaword and DUC 2004 datasets demonstrate that our model achieves significant improvements over strong baselines on both informativeness and correctness. Our code is available online[4].

Extracting Parallel Sentences with Bidirectional Recurrent Neural Networks to Improve Machine Translation

Abstract

Parallel sentence extraction is a task addressing the data sparsity problem found in multilingual natural language processing applications. We propose a bidirectional recurrent neural network based approach to extract parallel sentences from collections of multilingual texts. Our experiments with noisy parallel corpora show that we can achieve promising results against a competitive baseline by removing the need of specific feature engineering or additional external resources. To justify the utility of our approach, we extract sentence pairs from Wikipedia articles to train machine translation systems and show significant improvements in translation performance.

1 Introduction

Parallel corpora are a prerequisite for many multilingual natural language processing (NLP) applications. Unfortunately, parallel data is available for a relatively small number of language pairs and for few specific domains. With the increasing amount of comparable corpora on the World Wide Web, a potential solution to alleviate the parallel data sparsity issue is to extract parallel sentences from this more abundant source of information. Therefore, the objective of parallel sentence extraction is to extract parallel sentences from such comparable corpora to increase the quantity of parallel data and the range of the covered domains. Comparable corpora can be defined as collections of topic-aligned but non-sentence-aligned multilingual texts.

Recent advances in deep learning architectures with recurrent neural networks (RNNs) have shown that they can successfully learn complex mappings from variable-length sequences to continuous vector representations. While numerous natural language processing tasks have successfully applied those models, ranging from handwriting generation (Graves, 2013) to machine comprehension (Hermann et al., 2015), most of the multilingual efforts have been devoted to machine translation (Sutskever et al., 2014; Cho et al., 2014), although more research interests have been recently devoted to multilingual semantic textual similarity.[1]

In this paper, we propose a parallel sentence extraction system to measure the translational equivalence between sentences in two languages. Our system is based on bidirectional recurrent neural networks that can learn sentence representations in a shared vector space by explicitly maximizing the similarity between parallel sentences. In contrast to previous approaches, by leveraging these continuous vector representation of sentences we remove the need to rely on multiple models and specific feature engineering. Experiments on noisy parallel corpora show that our approach outperforms a competitive baseline. To justify the utility of our approach, we add the sentence pairs extracted from Wikipedia articles to a parallel corpus to train machine translation systems and show improvements in translation performance. Our experimental results lead us to believe that our system is a promising tool to create new aligned multilingual resources.

2 Related work

Traditional systems developed to extract parallel sentences from comparable corpora typically rely on multiples models or metadata from articles structure. Munteanu and Marcu (2005) present a complete system based on statistical word alignment models and a maximum entropy classifier to automatically extract sentence pairs from newspaper collections. The authors evaluate the quality of the extracted sentences by showing that they improve the performance of statistical machine translation (SMT) systems. The overall structure of this approach is still considered state-of-the-art. Adafre and Rijke (2006) is the first work to observe that articles from Wikipedia are likely to generate parallel corpora useful for machine translation. These two approaches are extended by Smith et al. (2010) where the authors introduce several new features by exploiting the structure and metadata of Wikipedia article pairs. They use their augmented set of features in a conditional random field and obtain state-of-the-art results on a small set of 20 manually annotated Wikipedia article pairs. The work of Abdul-Rauf and Schwenk (2009) proposes a different approach, in which they use an SMT system built from a small parallel corpus. Instead of using a classifier, they translate the source language side of a comparable corpus to find candidate sentences on the target language side. They determine if a translated source sentence and a candidate target sentence are parallel by measuring the word error rate and the translation error rate. A simplification of these systems is proposed in (Azpeitia et al., 2017), where the similarity between two sentences is defined as the average of the Jaccard similarity coefficients obtained between sentence token sets and lexical translations determined by IBM models (Brown et al., 1993). Their approach also combine various features, such as longest common prefix matching, numbers and capitalized truecased tokens.

Chu et al. (2016) train a neural machine translation (NMT) system to generate sentence representations with the encoder, which are then used as additional features to the system of Munteanu and Marcu (2005). Similarly, Cristina et al. (2017) study sentence representations obtained from the encoder of an NMT system to detect new parallel sentence pairs. By comparing cosine similarities, they show that they can distinguish parallel and non-parallel sentences. A different approach exploiting continuous vector representations is proposed in Grover and Mitra (2017). After learning word representations using the bilingual word embeddings model of (Luong et al., 2015), they use a convolutional neural network on a similarity matrix to classify if a pair of sentences is aligned or not. These approaches are different from ours, where we use a single end-to-end model to estimate the conditional probability distribution that two sentences are parallel.

3 Approach

3.1 Negative sampling

As positive examples, we use a parallel corpus C consisting of n parallel sentence pairs $\left\{(\mathbf{s}_k^S, \mathbf{s}_k^T)\right\}_{k=1}^n$, where S and T denote the source sentences and target sentences. Since we want a model that learns differentiable vector representations to distinguish parallel from non-parallel sentences, we use negative sampling to generate negative examples. Therefore, we randomly sample m non-parallel target sentences for every positive source sentence, such that $(\mathbf{s}_k^S, \mathbf{s}_j^T)$ for $j \neq k$. This process is repeated at the beginning of each training epoch to allow the model to learn on a larger number of non-parallel sentence pairs. Hence, our training set contains $n(1+m)$ triples $(\mathbf{s}_i^S, \mathbf{s}_i^T, y_i)$, where $\mathbf{s}_i^S = (w_{i,1}^S, \ldots, w_{i,N}^S)$ is a source sentence of N tokens, $\mathbf{s}_i^T = (w_{i,1}^T, \ldots, w_{i,M}^T)$ is a target sentence of M tokens, and y_i is the label representing the translation relationship between $\mathbf{s}_i^S$ and $\mathbf{s}_i^T$, so that $y_i = 1$ if $(\mathbf{s}_i^S, \mathbf{s}_i^T) \in C$ and $y_i = 0$ otherwise.

The advantage of negative sampling is its simplicity. However, relying only on randomness to select negative sentence pairs makes most of the examples very non-parallel and easy to classify. An interesting way to generate negative examples would be to replace only a segment of a sentence. Similarly, we could replace a sentence from a parallel pair with another sentence that is close to it in the vector space. This would make the problem harder, but potentially could make the classifier stronger. We leave such investigations as future work.

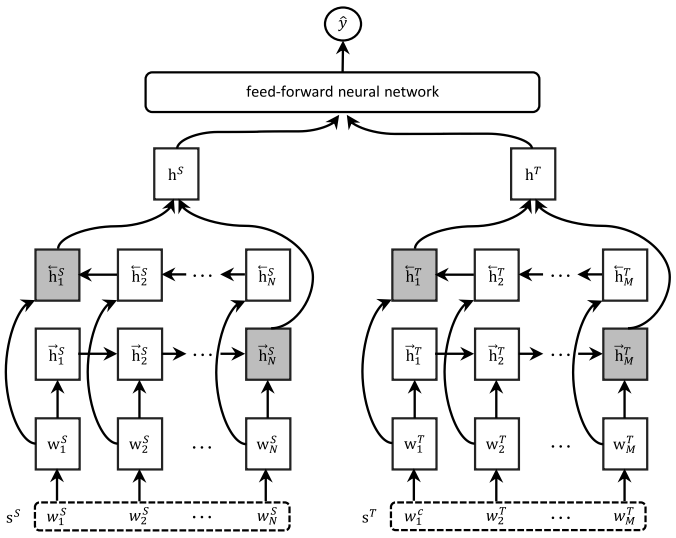

Figure 1: Graphical illustration of the siamese bidirectional recurrent neural networks. The final recurrent state of the forward and backward RNNs are concatenated and then fed into a feed-forward neural network culminating in a sigmoid output layer.

3.2 Model

Our idea is to use RNNs to learn cross-language semantics between sentence pairs to estimate the probability that they are translations of each other. The proposed model architecture consists of a bidirectional RNNs (BiRNN) (Schuster and Paliwal, 1997) sentence encoder with recurrent activation functions such as long short-term memory units (LSTM) (Hochreiter and Schmidhuber, 1997) or gated recurrent units (GRU) (Cho et al., 2014). Since we want vector representations in a shared vector space we use a siamese network (Bromley et al., 1993) with tied weights, which is equivalent to using a single BiRNN to encode a pair of sentences into two continuous vector representations. The source and target sentence representations are then fed into a feed-forward neural network with a sigmoid output layer which calculates the probability that they are parallel. The architecture of our approach is illustrated in Figure 1.

To avoid repetition and for clarity, we only define equations of the BiRNN encoding the source sentence. For the target sentence, simply substitute S for T. At each time step t, the token in the i-th sentence, $w^S_{i,t}$, defined by its integer index k in the vocabulary V^S, is represented as a one-hot vector, $\mathbf{x}^S_k \in \{0,1\}^{|V|}$. This one-hot vector is multiplied with an embedding matrix, $\mathbf{E}^S \in \mathbb{R}^{|V^S| \times d_e}$, to get a continuous vector representation of this token, $\mathbf{w}^S_{i,t} \in \mathbb{R}^{d_e}$, which serves as an input for the forward and backward recurrent states of the BiRNN encoder, $\overrightarrow{\mathbf{h}}^S_{i,t}$ and $\overleftarrow{\mathbf{h}}^S_{i,t}$. The forward RNN reads the variable-length sentence and updates its recurrent state from the first token until the last one to create a fixed-size continuous vector representation of the sentence, $\mathbf{h}^S_{i,N} \in \mathbb{R}^{d_h}$. The backward RNN processes the sentence in reverse. We use the concatenation of the last recurrent state in both directions as a final representation $\mathbf{h}^S_i = [\overrightarrow{\mathbf{h}}^S_{i,N} ; \overleftarrow{\mathbf{h}}^S_{i,1}]$.[2] The steps we described to encode a sentence are defined as:

$$\mathbf{w}^S_{i,t} = \mathbf{E}^{S^\top} \mathbf{w}^S_k, \tag{1}$$

$$\overrightarrow{\mathbf{h}}^S_{i,t} = \phi(\overrightarrow{\mathbf{h}}^S_{i,t-1}, \mathbf{w}^S_{i,t}), \tag{2}$$

$$\overleftarrow{\mathbf{h}}^S_{i,t} = \phi(\overleftarrow{\mathbf{h}}^S_{i,t+1}, \mathbf{w}^S_{i,t}), \tag{3}$$

where $\phi(\cdot)$ is an LSTM or GRU.

After both source and target sentences have been encoded, we capture their matching information by using their element-wise product and absolute element-wise difference. We estimate the conditional

[2] We considered combining the recurrent states with mean pooling and max pooling to obtain a fixed-size vector representation, but obtained inferior performance.

probability that the sentences are parallel by feeding the matching vectors into a feed-forward neural network with a sigmoid output layer:

$$\mathbf{h}_i^{(1)} = \mathbf{h}_i^S \odot \mathbf{h}_i^T, \tag{4}$$

$$\mathbf{h}_i^{(2)} = |\mathbf{h}_i^S - \mathbf{h}_i^T|, \tag{5}$$

$$\mathbf{h}_i = \tanh(\mathbf{W}^{(1)}\mathbf{h}_i^{(1)} + \mathbf{W}^{(2)}\mathbf{h}_i^{(2)} + \mathbf{b}), \tag{6}$$

$$p(y_i = 1|\mathbf{h}_i) = \sigma(\mathbf{v}\mathbf{h}_i + b), \tag{7}$$

where $\sigma(\cdot)$ is the sigmoid function, $\mathbf{W}^{(1)} \in \mathbb{R}^{d_f \times d_h}$, $\mathbf{W}^{(2)} \in \mathbb{R}^{d_f \times d_h}$, $\mathbf{v} \in \mathbb{R}^{d_f}$, $\mathbf{b} \in \mathbb{R}^{d_f}$ and b are model parameters. The value d_f is the size of the hidden layer in the feed-forward neural network.

The model is trained by minimizing the cross entropy of our labeled sentence pairs:

$$\mathcal{L} = -\sum_{i=1}^{n(1+m)} \Big(y_i \log \sigma(\mathbf{v}\mathbf{h}_i + b) + (1 - y_i) \log(1 - \sigma(\mathbf{v}\mathbf{h}_i + b)) \Big). \tag{8}$$

For prediction, a sentence pair is classified as parallel if its probability is greater than or equal to a decision threshold ρ that we need to fix:

$$\hat{y}_i = \begin{cases} 1 & \text{if } p(y_i = 1|\mathbf{h}_i) \geq \rho, \\ 0 & \text{otherwise.} \end{cases} \tag{9}$$

The two embedding matrices $\mathbf{E}^S$ and $\mathbf{E}^T$ are parameters of the model that we must learn. As the size of the vocabulary and the dimension d_e increase, the number of parameters can become considerably expensive to estimate. For that reason, it is common to initialize the embedding matrices using word embeddings pre-trained on a large collection of texts.[3]

4 Experiments and Results

To assess the effectiveness of our approach, we compare it in multiple settings. In Section 4.1, we measure its capacity to extract parallel sentences found in parallel corpora in which we inserted non-parallel sentences. We extract sentence pairs from real comparable corpora in Section 4.2 and validate their utility by measuring their impact on SMT and NMT systems.

4.1 System comparison

4.1.1 Data

To create our training and test sets we use the WMT'15 English–French datasets.[4] The positive examples of our training set consist of 500,000 parallel sentence pairs randomly selected from the Europarl corpus (Koehn, 2005). To generate negative examples, at the beginning of each training epoch we sample m non-parallel sentences per positive example, as described in Section 3.1. The vocabulary size is 69,381 for English and 84,182 for French.

The most reliable way to create test sets to compare different approaches would be to have professional translators manually annotate parallel sentences from comparable corpora. However, this option is expensive and impractical. Therefore, it is common practice to compare parallel sentence extraction systems on artificially-created noisy parallel data by inserting non-parallel sentences into a parallel corpus. Thus, to create our test sets we use parallel sentences from the newstest2012 and Europarl corpora and insert artificial noise by substituting target sentences with non-parallel target sentences from their respective held-out dataset. We sample 1,000 parallel sentences from the newstest2012 corpus and create ten test sets with a noise ratio $r \in \{0\%, 10\%, \ldots, 80\%, 90\%\}$, where r is the ratio of artificial

[3] We pre-trained bilingual word embeddings as proposed by (Gouws et al., 2015) and (Smith et al., 2017). While we observed faster learning and a small improvement in the performance of our model, we prefer to learn the embedding matrices from scratch instead of relying on additional external resources.

[4] http://www.statmt.org/wmt15/translation-task.html

non-parallel sentences. The same process is repeated with the Europarl corpus to create three test sets with $r \in \{0\%, 50\%, 90\%\}$. Each final test set consists of 1,000,000 sentence pairs generated from the Cartesian product between the sentences in both languages. For example, 400 out of the 1,000 sentence pairs are parallel if $r = 60\%$, in which only 0.04% of the 1,000,000 sentence pairs generated from the Cartesian product are truly parallel.

We tokenize all datasets with the scripts from Moses (Koehn et al., 2007).[5] The maximum sentence length is set to 80 tokens. Each out-of-vocabulary word is mapped to a special UNK token.

4.1.2 Evaluation metrics

For evaluating the performance of our models, a sentence pair predicted as parallel is correct if it is present in the set of parallel sentences of the test set. Precision is the proportion of truly parallel sentence pairs among all extracted sentence pairs. Recall is the proportion of truly parallel extracted sentence pairs among all parallel sentence pairs in the test set. The F_1 score is the harmonic mean of precision and recall.

4.1.3 Baseline

For comparison, we use a parallel sentence extraction system developed in-house based on the works of (Munteanu and Marcu, 2005) and (Smith et al., 2010). The system consists of a candidate sentence pair filtering process and three models; two word alignment models and a maximum entropy classifier. The word alignment models are trained on both language directions using our training set of 500,000 parallel sentence pairs. To train the classifier, we select another 100,000 parallel sentence pairs from the held-out Europarl dataset. To generate negative examples, we use 100,000 non-parallel sentence pairs that have successfully passed the candidate sentence pair selection process.[6]

Candidate sentence pair selection A sentence pair filtering process is used to select a fixed number of negative sentence pairs to train the maximum entropy classifier. The objective is to select similar non-parallel sentence pairs to make the classifier more robust to noise. It is also used during prediction to filter out the unlikely sentence pairs of the Cartesian product. Since most of these sentence pairs are not parallel, the filtering process significantly reduces the number of sentence pairs to evaluate. The filtering process consists of a two-step procedure. First, it verifies that the ratio of the lengths between two sentences is not greater than 2.[7] It then uses a word-overlap filter to check for both sentences that at least 50% of their words have a translation in the other sentence. Every pair that does not fulfill these two conditions is discarded. The filtering process is only applied to the baseline model.

Word alignment models The translation and alignment tables are estimated using the HMM alignment model of (Vogel et al., 1996). These probability tables are required to calculate the value of many alignment features used in the classifier.

Maximum entropy classifier The classifier relies on word-level alignment features between two sentences, such as the number of connected words, top three largest fertilities, length of the longest connected substring, log probability of the alignments, and also general features, such as the lengths of the sentences, length difference and the percentage of words on each side that have a translation on the other side. For each sentence pair, a total of 31 features must be calculated and it is classified as parallel if the classifier outputs a probability score greater than or equal to a decision threshold ρ which needs to be fixed.

4.1.4 Training settings

The models of our approach are implemented in TensorFlow (Abadi et al., 2016). We use a BiRNN with a single layer in each direction with 512-dimensional word embeddings and 512-dimensional recurrent states. We use LSTM as recurrent activation functions. The hidden layer of the feed-forward neural network has 256 hidden units. To train our models, we use Adam (Kingma and Ba, 2014) with a learning rate of 0.0002 and a minibatch of 128 examples. Models are trained for a total of 15 epochs. To avoid

[5] https://github.com/moses-smt/mosesdecoder

[6] During our experiments, we did not observe any significant gain by using more than 100,000 parallel sentence pairs.

[7] Most parallel sentence extraction systems use a length ratio value equals to 2.

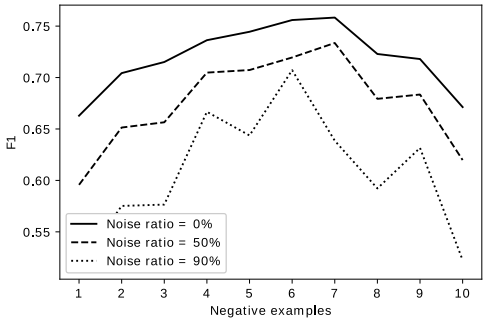

Figure 2: F_1 scores of BiRNN as we increase the number of negative examples m per parallel sentence in the training set. The models are evaluated on newstest2012 with noise ratios of 0%, 50% and 90%.

exploding gradients, we apply gradient clipping such that the norm of all gradients is no larger than 5 (Pascanu et al., 2013). We apply dropout to prevent overfitting with a probability of 0.2 and 0.3 for the non-recurrent input and output connections respectively (Zaremba et al., 2014).

4.1.5 Number of negative examples

We evaluate the performance of our approach as we increase the number of negative examples m per parallel sentence pair in our training set. We trained a total of 10 models with $m \in \{1, \ldots, 10\}$, such that with $m = 1$ and $m = 10$ a model is respectively trained on 1,000,000 and 5,500,000 sentence pairs per epoch, with a positive to negative sentence pairs ratio of 50% and 9%. The more the value of m increases, the more the training set becomes unbalanced. We know that extracting parallel sentences from comparable corpora in practice is an unbalanced classification task in which non-parallel sentences represent the majority class. Although an unbalanced training set is not desired since a classifier trained on such data will typically tend to predict the majority class and have a poor precision, the overall impact on the performance of BiRNN is not clear. Figure 2 shows the F_1 scores of BiRNN with respect to the value of m evaluated on newstest2012 with noise ratios of 0%, 50% and 90%. Each reported F_1 score is the one calculated at the decision threshold value maximizing the area under the precision-recall curve. For $m \geq 7$, we observe a deterioration in the performance of our systems evaluated on test sets with noise ratios of 0% and 50%, whereas $m = 6$ is the best performing model on the test set with a noise ratio of 90%. We see that having a balanced training set with $m = 1$ is not the optimal solution for our approach. On the contrary, having an unbalanced training set improves its performance. From these observations, in the following experiments we train our models with a value of m fixed at 6.[8]

4.1.6 Evaluation on noisy parallel corpora

In this experiment, we compare our approach to the baseline system described in Section 4.1.3. Table 1 shows the precision, recall and F_1 scores for the two systems evaluated on the newstest2012 and Europarl test sets with noise ratios of 0%, 50% and 90%. We see that BiRNN is able to constantly outperform the results obtained with the baseline by a significant margin. By using newstest2012 as out-of-domain test sets, our approach gets an absolute improvement in the F_1 score of 10.99%, 13.03% and 23.53%. The precision-recall curves of the two systems evaluated on test sets with noise ratios of 0% and 90% are shown in Figure 3. These curves illustrate the consistency of our approach, whereas the performance of the baseline is greatly impacted when the number of non-parallel sentences in the test set is high.

When BIRNN is evaluated on Europarl, it obtains F_1 scores over 95% on the three test sets. On the other hand, given that the underlying models of the baseline system are trained on Europarl data, it is surprising to observe again a significant deterioration in its performance when the number of non-parallel sentences increases. In Figure 4, we compare the precision, recall and F_1 scores as the noise ratio r applied to our newstest2012 test set increases. We observe that it becomes harder to identify

[8]It takes about 1.5 hours to train an epoch with the model settings described in 4.1.4 using a single GTX 1080 Ti GPU.

Noise	Model	newstest2012				Europarl			
		P (%)	**R (%)**	**F_1 (%)**	ρ	**P (%)**	**R (%)**	**F_1 (%)**	ρ
0%	BiRNN	**83.72**	**68.90**	**75.79**	0.99	**99.26**	**93.50**	**96.29**	0.99

50%	BiRNN	**79.95**	**65.40**	**71.95**	0.99	**98.32**	**93.60**	**95.90**	0.99
	Baseline	73.43	49.20	58.92	0.98	80.19	82.60	81.38	0.99
90%	BiRNN	**79.01**	**64.00**	**70.72**	0.99	**97.94**	**95.00**	**96.45**	0.99
	Baseline	53.85	42.00	47.19	0.99	63.89	69.00	66.35	0.99

Table 1: Precision (P), recall (R) and F_1 scores where the decision threshold ρ maximizes the area under the precision-recall curve of the test sets with noise ratios of 0%, 50% and 90%.

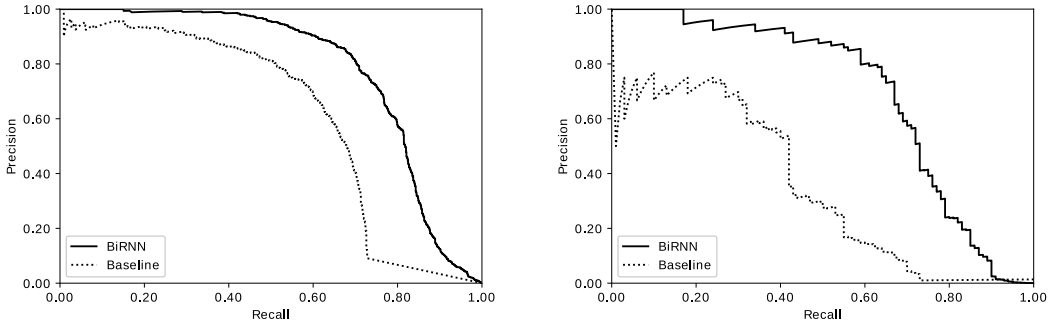

Figure 3: Precision-recall curves of the systems evaluated on newstest2012 with noise ratios of 0% (left) and 90% (right).

parallel sentences as the number of non-parallel sentences increases in the test set. However, we see that our neural network based approach obtains better performances by a significant margin. In contrast to the baseline, the performance of our method stays relatively stable and starts to degrade at very high noise ratios. At that level of noise, we believe our test set is more representative to texts found in real comparable corpora.

In this experiment, all our evaluation metrics (BiRNN and Baseline) are reported at the value ρ which maximizes the area under a precision-recall curve. These performances are therefore upper bound results. The decision threshold has a direct impact on the quality and the quantity of the extracted sentence pairs. Through our experiments, we observed that the optimal value ρ of BiRNN was constantly around a value of 0.99, while the one of the baseline system varied considerably from one test set to another. Thus, the stability of our approach is preferable in practice. We believe that the high optimal decision threshold value $\rho = 0.99$ is caused by the fact that we use a sigmoid output layer with highly unbalanced training and test sets.

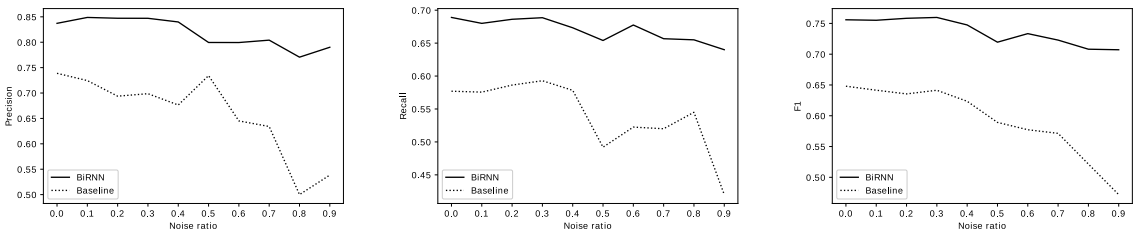

Figure 4: Precision (left), recall (middle) and F_1 (right) scores of the systems evaluated on newstest2012 as the noise ratio r increases.

4.2 Machine Translation Comparison

4.2.1 Data

As training sets, we use the English–French Europarl corpus and sentence pairs extracted by the two parallel sentence extraction systems. The comparable corpora used to extract parallel sentences are 919,000 pairs of English–French articles obtained from Wikipedia dumps.[9] The newstest2012 corpus is our validation set and we evaluate the machine translation systems on the newstest2013 corpus. All datasets are tokenized using the scripts from Moses. The maximum length of each sentence is set to 80 tokens. For the NMT systems, the vocabulary size for both languages is limited to the 150,000 most frequent words of their corresponding training set. All unknown words are replaced by the UNK token.

4.2.2 Evaluation metric

To evaluate the translation performance of our systems we use the BLEU score (Papineni et al., 2002) using the multi-bleu script from Moses.

4.2.3 Training settings

The SMT systems are phrase-based systems (Koehn et al., 2003) that are trained with Moses. We use the GIZA++ implementation (Och and Ney, 2003)[10] to train word alignment models in both directions. The phrases and lexical reordering are extracted using the default values of Moses. The language models are 5-gram models learned using the KenLM toolkit (Heafield, 2011)[11] on the monolingual parts of the same parallel corpus used for training the translation models. The parameters are optimized on the newstest2012 corpus.

To train the NMT systems, we use the PyTorch implementation of OpenNMT (Klein et al., 2017).[12] The NMT systems are one layer BiLSTMs with an attention mechanism (Bahdanau et al., 2014). The dimensions of the word embeddings and recurrent states for the encoder and decoder are all set to 256. The systems are trained for 10 epochs with minibatch of 64 sentence pairs using SGD with an initial learning rate of 1.0 and linear decay.[13] The norm of the gradient is clipped such that it is not greater than 5.

4.2.4 Evaluation on machine translation systems

For each of the SMT and NMT approaches, we trained 14 machine translation systems. The first two systems,[14] which serve as reference systems, are trained with 500,000 and 2,000,000 parallel sentences from the Europarl corpus, respectively. The system trained with 2,000,000 parallel sentences is used to compare the benefits of the sentence pairs extracted from Wikipedia against a large training corpus that we easily have at hand. For the 12 remaining systems, we sort the sentence pairs extracted by an extraction system in descending order according to the probability scores and append the top $\{250000, 500000, \ldots, 1250000, 1500000\}$ sentence pairs to the training set containing 500,000 parallel sentences from the Europarl corpus.

Table 2 shows the BLEU scores obtained by the machine translation systems we trained for the SMT and NMT approaches. The figures in parentheses show the absolute gains in BLEU score compared to the reference systems trained with 500,000 parallel sentences from the Europarl corpus.[15] We see that adding the subsets of sentence pairs extracted by both extraction systems leads to significant gains compared to the reference systems. Adding 1,500,000 sentence pairs extracted by BiRNN improves the BLEU score of the SMT and NMT systems by 3.71 and 9.47, respectively. We observe that translation systems trained on 1,000,000 sentence pairs have better BLEU scores than the reference systems trained on 2,000,000 parallel sentences from Europarl, showing that parallel sentence extraction allows translation systems to

+Top1.5M	BiRNN	**25.18 (+3.71)**	**27.10 (+9.47)**	2M
	Baseline	25.01 (+3.54)	26.85 (+9.22)	2M

Table 2: BLEU scores obtained by the SMT and NMT systems on newstest2013. Pairs is the number of sentence pairs in a training set. The numbers in parentheses are the translation gains with respect to the reference system trained with 500,000 sentence pairs from the Europarl corpus.

generalize better with less data. We are surprised that the BLEU scores obtained with the BiRNN data are so close to those obtained with the data from the baseline system. This may indicate that article pairs from Wikipedia share a relatively high degree of similarity. Still, the gain obtained with BiRNN compared to the baseline extraction system is consistent for all machine translation systems. These results confirm the quality of the 1,500,000 extracted sentence pairs. Hence, we could reduce the value of the decision threshold in order to extract corpora of larger sizes. Given the out-of-domain nature of the Wikipedia article pairs, we see that our approach could be applied to comparable corpora with a lower degree of comparability.

5 Discussion

Most parallel sentence extraction systems developed so far were based on a series of models that required the computation of several features that did not necessarily adapt well to different text structures. To alleviate this problem, we have shown that we can create new parallel corpora from a collection of texts in different languages with a single end-to-end model based on bidirectional recurrent neural networks. Our approach deals directly with raw sentence pairs to determine if two sentences are a translation of each other. In addition to being more flexible than traditional systems, we demonstrate that our approach obtains better results than a competitive baseline system. We found that new sentence pairs extracted from comparable corpora is a considerable resource to exploit for SMT and NMT systems.

Our parallel sentence extraction system is completely based on neural network models and we believe that our work enables exploration for researchers who want to apply future research ideas. In this study we did not consider out-of-vocabulary words. Therefore, it would be beneficial to use word segments (Sennrich et al., 2015) as lexical units instead of words to limit the size of the vocabulary and to be more robust when handling out-of-domain texts found in comparable corpora. The main challenge with our approach (and the majority of parallel sentence extraction systems) is that it needs to be trained on a parallel corpus. Thus, we need parallel sentences to extract parallel sentences, which can be problematic. Despite that it is possible to start from a small parallel corpus and to bootstrap the learning process with extracted sentence pairs, this method is limited for the many language pairs having few resources available. In order to lessen the need of a parallel corpus, an interesting and promising avenue could be

to apply methods from some of the recent works (Xia et al., 2016; Conneau et al., 2017; Artetxe et al., 2017) which allow machine translation systems to learn directly from non-parallel texts. Although our simple neural network architecture was able to extract parallel sentence pairs from comparable corpora, we believe that more sophisticated approaches, such as using two different sentence encoders trained by mutual information neural estimation (MINE) (Belghazi et al., 2018) could improve the flexibility and the performance of our approach. Even though we believe that our approach is easily scalable across multiple language pairs, in this paper we only evaluated it on English–French texts. Therefore, it would be interesting to study a larger set of language pairs. In addition, we emphasize that it would be pertinent to evaluate our approach with distant language pairs which are poor in parallel resources. Our code is available on GitHub and the extracted parallel corpora will be released to the public.[16]

Fast and Accurate Reordering with ITG Transition RNN

Abstract

Attention-based sequence-to-sequence neural network models learn to jointly align and translate. The quadratic-time attention mechanism is powerful as it is capable of handling arbitrary long-distance reordering, but computationally expensive. In this paper, with the goal of making neural translation both accurate and efficient, we follow the traditional pre-reordering approach to decouple reordering from translation. We add a reordering RNN that shares the input encoder with the decoder. The RNNs are trained jointly with a multi-task loss function and applied sequentially at inference time. The task of the reordering model is to predict the permutation of the input words following the target language word order. After reordering, the attention in the decoder becomes more peaked and monotonic. For reordering, we adopt Inversion Transduction Grammars (ITG) and propose a transition system to parse input to trees for reordering. We harness the ITG transition system with RNN. With the modeling power of RNNs, we achieve superior reordering accuracy without any feature engineering. In experiments, we apply the model to the task of text normalization. Compared to a strong baseline of attention-based RNN, our ITG RNN reordering model can reach the same reordering accuracy with only 1/10 of the training data and is 2.5x faster in decoding.

1 Introduction

The encoder-decoder neural network architecture for sequence-to-sequence problems has achieved enormous success especially after the introduction of the attention mechanism (Bahdanau et al., 2014). Its applications in NLP range from machine translation (Bahdanau et al., 2014) and sentence summarization (Rush et al., 2015) to text normalization (Sproat and Jaitly, 2017). The attention mechanism is effectively a random memory access mechanism, enabling access to any source sequence position at any decoding step. In principle, it can handle arbitrary reordering of any input length. But its power comes with a high computational cost. The time complexity of the attention mechanism is $O(N^2)$ if the number of decoding steps is proportional to the input length N. In addition to the computational concern, for dominantly-monotonic translation tasks, such as text normalization (Sproat and Jaitly, 2017), soft attention can be too relaxed and sub-optimal in terms of modeling efficiency. Hence, to reduce computational complexity as well as to improve model accuracy, recently there has been a surge of research interest in enforcing monotonic attention (Raffel et al., 2017) and hard attention (Aharoni and Goldberg, 2017) based on the observation that many sequence-to-sequence tasks are monotonic, including speech recognition and morphological inflection.

In reality, the monotonicity assumption has to be made carefully. Even in the highly monotonic translation task of text normalization, which is mapping written text to spoken text, there are systematic reordering patterns like from "*2018-10-03*" to "*October third, two thousand eighteen*", and from "*$100*" to "*one hundred dollars*". These reordering patterns can involve arbitrarily long chunks of input. Without handling the infrequent but systematic reordering, monotonic attention models are doomed. We claim there is hope for efficient and accurate systematic reordering by combining grammars with RNNs. The

Santa Fe, New Mexico, USA, August 20-26, 2018.

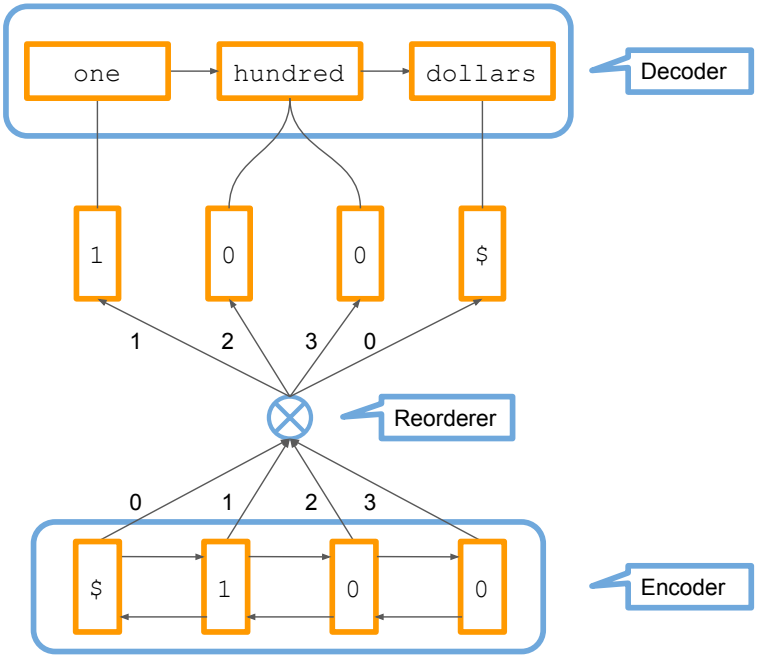

Figure 1: The encoder-reorderer-decoder architecture. The input encoder is shared by the reorderer and the decoder. The reorderer permutes the RNN states of the encoder.

key to our solution is the Inversion Transduction Grammars (Wu, 1997), a type of synchronous context free grammar limiting reordering to adjacent source spans. For machine translation across very different languages, ITGs have been reported to cover most of the alignments observed in parallel data (Zhang et al., 2006). For text normalization, we have not found a single example of reordering that cannot be covered by an ITG. This observation motivates us to factorize translation into two steps: an ITG reordering step followed by a monotonic translation step. The task of the reordering step is to handle systematic reordering through swapping of adjacent source spans. This step "normalizes" the input in terms of word order which opens up the capacity for improvement in translation accuracy. It also opens up the opportunity for more "lightweight" neural translation models such as monotonic attention models of Raffel et al. (2017) and Aharoni and Goldberg (2017). Of course, the burden of reordering has shifted from the attention mechanism to the dedicated reordering model. This idea has produced fruitful results in the era of phrase-based machine translation (Collins et al., 2005; Xu et al., 2009; Neubig et al., 2012; Lerner and Petrov, 2013; Nakagawa, 2015). In this paper, we revive the old idea with a neural treatment.

First of all, we modify the encoder-decoder architecture by adding a reorderer which shares the encoder with the decoder. Figure 1 shows the architecture. This change enables multi-task training of the encoder states and turns the inference into three steps: encoding, reordering, decoding, each of which is a linear chain RNN. Our main algorithmic contribution is an ITG-transition-based RNN reorderer. What we feed to the RNN for training are input strings paired with their permutations, for example *$100* with $(1, 2, 3, 0)$ to indicate it should be reordered to *100$* in order to be translated monotonically. Within the ITG framework, we will show the goal is equivalent to parsing the input into a parse tree annotated with reordering information, in this case $\langle$ *$* [[*1* *0*] *0*] $\rangle$, where $\langle$ $\rangle$ indicates a swapping of two subtrees and [ ] indicates no swapping. For efficiency and compatibility with linear chain RNN, we use a transition system for parsing. The transition system has three actions: SHIFT, REDUCE S, and REDUCE I. In this example, the transition sequence to learn is SHIFT, SHIFT, SHIFT, REDUCE S, SHIFT, REDUCE S, REDUCE I. To learn the conditional distributions of the three actions, we rely on the strength of RNN to condition on the entire transition history without any feature engineering. We report results for both the intrinsic task of reordering and the end-to-end task of translation.

The paper is organized in the following way. In Section 2, we formally introduce ITG and its transition-based parsing system. In Section 3, we introduce the ITG-based RNN model. In Section 4, we formally introduce the end-to-end neural architecture. In Section 5, we discuss related works. In Section 6.1, we carry out two sets of reordering experiments: one on synthetic sequence permutation data, the other on money expression reordering data coming from the task of English text normalization (Sproat and Jaitly, 2017). In Section 6.2, we conduct an end-to-end experiment for text normalization and compare the two-step approach with the baseline approach.

2 ITG Transition System

An Inversion Transduction Grammar is a grammar for generating a pair of languages recursively and synchronously. In our problem of source language reordering, we essentially pair the source language with a virtual target language that shares the vocabulary with the source but follows the word order of the real target language. To be concrete, we use the simplest ITG with just one nonterminal and the following context free production rules.

$$X \rightarrow [X\ X]$$
$$X \rightarrow \langle X\ X \rangle$$
$$X \rightarrow w_0/w_0$$
$$...$$
$$X \rightarrow w_{n-1}/w_{n-1}$$

The first rule is called the *straight rule* because it keeps the order of two constituents unchanged on the target side. The second rule is called the *inverted rule* because it inverts the order of two constituents on the target side. For example, a sentence pair $(w_0, w_1, w_2 \mid w_0, w_2, w_1)$ can be derived with three pre-terminal rules to link the words with the same subscripts on both sides, plus one inverted rule for grouping w_1 and w_2 and one straight rule on the top for grouping w_0 and the phrase of w_1, w_2.

We can also devise a transition system following (Nivre, 2003). The following is the deductive description of the transition system. Each configuration in the transition system consists of a stack and a pointer to the next word in the input buffer. At the beginning, we have an empty stack and a pointer to the first input word. At each time step, we can choose SHIFT if the buffer is not empty and choose to apply REDUCE S or REDUCE I if the stack has a height of at least two. We use four indices to uniquely represent each synchronous constituent that is constructed in the parsing process. The first two index into the source side and the last two index into the target side. The transition system stops when the buffer is empty and the stack has been reduced to size one.

$$\text{INITIAL} : [\phi,\ 0]$$
$$\text{SHIFT} : \frac{[S, i]}{[S|(i, i, i, i),\ i+1]}$$
$$\text{REDUCE S} : \frac{[S|(i, j, l_1, r_1)(j+1, k, l_0, r_0),\ k+1]}{[S|(i, k, l_1, r_0),\ k+1]}$$
$$\text{REDUCE I} : \frac{[S|(i, j, l_1, r_1)(j+1, k, l_0, r_0),\ k+1]}{[S|(i, k, l_0, r_1),\ k+1]}$$
$$\text{FINAL} : [(0, n-1, *, *),\ n]$$

When training a model, we are given a sequence of words $w_0, ..., w_{n-1}$, along with the permutation P indicating its corresponding target word order. It has the equivalent information as a pair of bijectively aligned sequences:

$$w_0, ..., w_{n-1} \quad w_{P(0)}, ...w_{P(n-1)}$$

Zhang et al. (2006) have shown for any P there exists a greedy shift-reduce algorithm to produce a *canonical parse* along with a *canonical transition sequence*. If we take the *$100* example, the canonical

transition sequence is SHIFT, SHIFT, SHIFT, REDUCE S, SHIFT, REDUCE S, REDUCE I, and the corresponding cannonical parse is $\langle$ *$* [[*1 0*] *0*] $\rangle$. Therefore, given $w_0, ..., w_{n-1}$ and P, the learning problem is mapping from $w_0, ...w_{n-1}$ to the canonical transition TRANSITION(P). There are two good properties of the output space. First, the output sequence is always of length $2n - 1$. Second, the output vocabulary is fixed to {SHIFT, REDUCE S, REDUCE I}.

Once a model is learned, at testing time, only the input sequence is given, the task is to predict a transition sequence which in turn corresponds to a permutation.

3 ITG RNN

A recurrent neural network computes the representation of a new state based on the representation of its previous state and input at the current step. Formally, this is

$$h_t = RNN(f(t), h_{t-1})$$

where h is the hidden state representation and f is the input function, and RNN can be a LSTM or GRU cell for instance.

A transition system also has a timeline recurrence. The recurrence of the ITG transition system is the following.

$$s_t = ITG(a(t), s_{t-1})$$

where s is the configuration and a is the action.

To make an ITG controlled by an RNN, we need to unroll an ITG transition system along with an RNN. Figure 2 shows an example of completely unrolled computation graph of ITG-RNN. For input f, we want this to be a function of s. The information in s is a stack along with an input buffer pointer. In Section 2, we specified each stack element as a tuple of (i, j, l, r) that indexes into the source sequence and the reordered target sequence. It is clear that the deduction rules involve at most top two stack elements. Therefore, we extract the indices stored at the top of the stack which are potentially directly involved in any next action: l_1, r_1, l_0, r_0, and the buffer pointer i. With these input indices, we can create a concatenated embedding vector of the input sequence. This will be what the ITG feeds into the RNN as input.

The task of the RNN is to predict the possible next actions. As the ITG transition system constrains the valid next actions at s_t, h_t should only emit action labels allowed by s_t. This will be what ITG places as constraints in the RNN output and will indirectly influence the training of the underlying RNN cells by moving probability mass away from invalid actions. The output constraints are implemented as masks over invalid output actions before applying softmax.

What RNN feeds back to ITG is the predicted actions after softmax. That is how the RNN controls the ITG at inference time. At training time, the action sequence is known.

4 Encoder-Reorderer-Decoder Architecture

As we discussed in Section 1 and demonstrated with Figure 1, a reorderer is designed to solve translation into two steps: reordering and monotonic decoding. In this section, we define the training and decoding objectives mathematically.

Given an input sequence $(x_1, \ldots, x_{T_x})$, a BiRNN, i.e., a pair of forward RNN $\overrightarrow{f}$ and backward RNN $\overleftarrow{f}$ is used to encode it into a pair of *forward hidden states* and *backward hidden states* $(\overrightarrow{h}_1, \ldots, \overrightarrow{h}_{T_x})$ and $(\overleftarrow{h}_1, \ldots, \overleftarrow{h}_{T_x})$, where $\overrightarrow{h}_t = \overrightarrow{f}(x_t, \overrightarrow{h}_{t-1})$ and $\overleftarrow{h}_t = \overleftarrow{f}(x_t, \overleftarrow{h}_{t+1})$. The forward and backward states are concatenated to summarize contexts in both directions: $h_t = [\overrightarrow{h}_t^\mathsf{T}; \overrightarrow{h}_t^\mathsf{T}]^\mathsf{T}$. This is how the encoder works.

Here we depart from the attention-based encoder-decoder architecture. The reorderer defines a probability of the ITG transition sequence $z_1, \ldots, z_{2T_x-1}$ as a product of conditionals.

$$p(z_1, \ldots, z_{2T_x-1} | x_1, \ldots, x_{T_x}) = \prod_{t=1}^{2T_x-1} p(z_t | z_1, \ldots, z_{t-1}, h_1, \ldots, h_{T_x}) \quad (1)$$

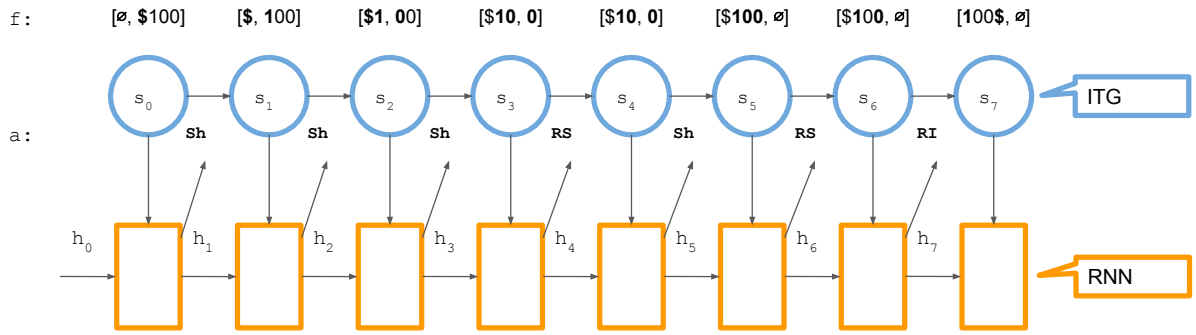

Figure 2: An unrolled computation graph of ITG-RNN. s is for the states of the ITG. h is for the states of the RNN. f is for the input function to the RNN. a is for actions of the ITG and softmax over output of the RNN. For conciseness, we use SH for SHIFT, RS for REDUCE S, and RI for REDUCE I. We use boldface to indicate function f as input focus over the stack and the buffer.

For the ITG RNN, the conditional probability is based on softmax over the output at each step t. As we mentioned in Section 2, for each transition sequence, there exists a functional mapping to a permutation P. Therefore, the probability of reordering is derived in the following way.

$$p(x_{P(1)}, \ldots, x_{P(T_x)} | x_1, \ldots, x_{T_x}) = p(z_1, \ldots, z_{2T_x-1} | x_1, \ldots, x_{T_x})$$

The key change following reordering is that the probability of the output sequence $(y_1, \ldots, y_{T_y})$ is based on the permuted sequence $(x_{P(1)}, \ldots, x_{P(T_x)})$ and we make an independence assumption with respect to the original input sequence.

$$p(y_1, \ldots, y_{T_y} | x_1, \ldots, x_{T_x}) = p(y_1, \ldots, y_{T_y} | x_{P(1)}, \ldots, x_{P(T_x)}) \cdot p(x_{P(1)}, \ldots, x_{P(T_x)} | x_1, \ldots, x_{T_x})$$

where

$$p(y_1, \ldots, y_{T_y} | x_{P(1)}, \ldots, x_{P(T_x)}) = \prod_{t=1}^{T_y} p(y_t | y_1, \ldots, y_{t-1}, h_{P(1)}, \ldots, h_{P(T_x)})$$

Usually, a soft attention is applied to attend enough context from h. But since the sequence of hidden states is reordered, the attention can be made monotonic.

Let's use $S = (x_1, \ldots, x_{T_x})$, $P(S) = (x_{P(1)}, \ldots, x_{P(T_x)})$, and $T = (y_1, \ldots, y_{T_y})$.

The training objective is

$$1/\mathcal{S} \sum_{(T,S) \in \mathcal{S}} \log p(P|S) + \log p(T|P(S)) \tag{2}$$

and the decoding objective is

$$\hat{T} = \arg \max_{T,P} p(P|S) \cdot p(T|P(S)) \tag{3}$$

The term $-\log p(P|S)$ is the reordering loss and the term $-\log p(T|P(S))$ is the translation loss. Both share the input S. In a computation graph, they share the BiRNN component. The hidden states $(h_1, \ldots, h_{T_x})$ are trained for both tasks. At decoding time, we approximate the decoding objective with a beam search over P, followed by another beam search over T.

5 Related Work

There are three papers that are most relevant to ours that relate to ITG pre-ordering. DeNero and Uszkoreit (2011) induce binary source trees first and learn pre-reordering rules for these binary trees from parallel data. Neubig et al. (2012) discriminatively train an ITG parser with CYK parsing for pre-reordering, essentially combining the two steps in DeNero and Uszkoreit (2011) into one. Nakagawa (2015) improve upon Neubig et al. (2012) with a linear time top-down ITG parsing algorithm. They all rely on feature engineering as they use linear models for training. None of them does transition-based parsing for ITG.

There are two papers most relevant to ours that relate to combining transition systems with RNNs. Dyer et al. (2015) propose a stack-LSTM for transition-based parsing. The difference with our approach to modeling is that we do not encode the entire stack explicitly. At each time step, we only feed the context indexed by the current stack and buffer configuration. We do not have an stack RNN, which can be expensive. Our transition RNN can be viewed as a special case of DRAGNN (Kong et al., 2017) which combines fixed features as input with recurrence links at each time step. Our recurrence link is only to the previous time step.

For the approach of incorporating syntactic constraints into neural translation, the following papers are most relevant. Eriguchi et al. (2016) and Chen et al. (2017) assume the existence of source parse trees and enhance the encoder and the attention mechanism to attend to both words and syntactic phrases. We do not rely on external parsers. Stahlberg et al. (2016) let a hierarchical phrase-based decoder guide neural machine translation decoding. Reordering decisions can only be indirectly influenced by the hierarchical decoder. In contrast, we have an explicit hierarchical reordering model applied pre-translation. Eriguchi et al. (2017) train a joint parsing and translation model to maximize the log likelihood of output sequence and input parsing action sequence. This is similar to our multi-task training setup. The key difference is our subtask is ITG parsing for reordering instead of linguistically-motivated parsing.

The idea of adding a reordering layer into neural MT models has also been studied by Huang et al. (2018). They use a simple feed-forward soft and local reordering layer similar to the soft attention mechanism. A fixed window size is used for local reordering. Our RNN reordering layer can handle long distance reordering. Another important difference is that we use discrete variables (permutations) for reordering while the soft reordering mechanism has no latent variables. We leave it as future work to train the end-to-end system by treating ITG transitions and permutations as latent variables.

6 Experiments

6.1 Reordering Experiments

In this part, we analyze the effectiveness of the ITG RNN reordering model. We first create a baseline system using a standard attention-based RNN. This basically implements the right-hand-side conditional in Equation 1 with an attention-based RNN instead of an ITG-RNN. The encoder is a bidirectional GRU cell RNN with one layer in each direction. The input embedding size is 32. The number of GRU cells is 32. The decoder is again a one-layer GRU RNN with 32 cells. The output embedding size is also 32. To make side-by-side comparison fair, we duplicate the network specification in ITG RNN. The only difference is that Equation 1 is implemented with ITG RNN.

6.1.1 Synthetic Reordering Data

The first set of experiments uses synthetic reordering data. We generated all permutations that have valid ITG transition action sequences up to permutation length 10. There are 258,563 such permutations. Then we scrambled letters "A" through "J" using these permutations and paired them up. So, the task is to sort letter sequences. But the models have no prior knowledge of the alphabet. We shuffled the examples and trained on 80% of the data, validated on 10% of the data, and tested on the rest 10%. Figure 3 shows the contrast between ITG RNN and attention-based RNN as we varied the training data size. ITG RNN is much more efficient in utilizing training examples. It only needs roughly 10% of the training data to get the same accuracy as the attention-based system. The attention-based model never reached zero error rate even after training 2 million steps with batch size 32 using the entire training set.

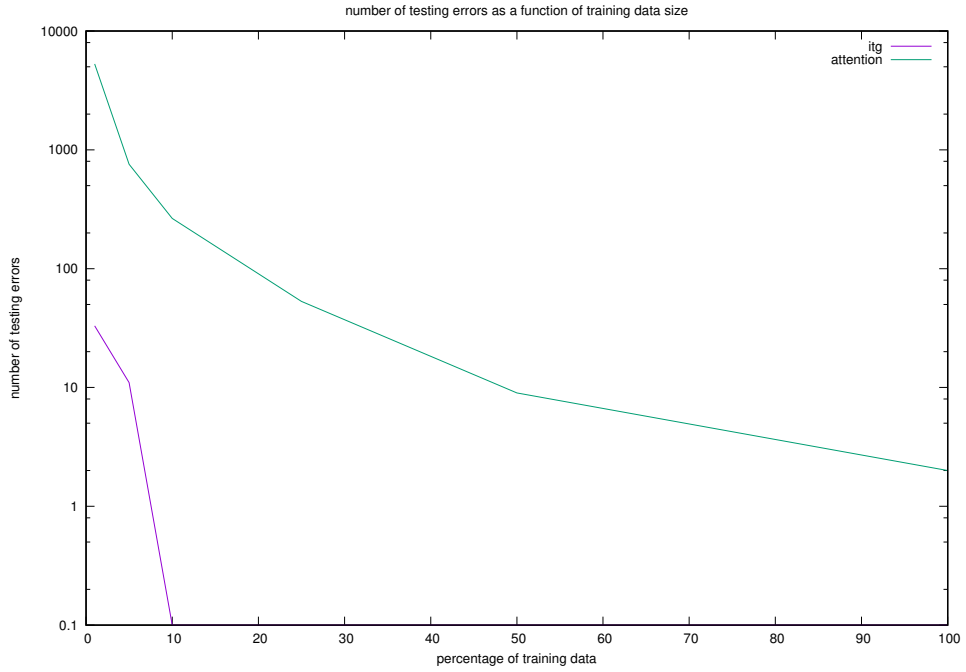

Figure 3: The ITG RNN model reaches zero error rate much faster than the attention-based RNN on the synthetic data set.

	attention-based RNN	*ITG RNN*
all	8×10^{-5}	6×10^{-6}
non-identity	8×10^{-3}	2×10^{-3}

Table 1: Text normalization reordering error rates.

6.1.2 Text Normalization Reordering

For text normalization, interesting reordering patterns include ISO dates such as *1990-09-01*, which should be verbalized as *September first, nineteen ninety*, which indicates a reordering of the last two date components. In measure expressions, interesting cases include *5* km^2, which should be read as *five square kilometers*. There are many more money expressions in real data such as *$100*, *USD100*, *RMB 2 million*, but also cases where no reordering is necessary, like *2 million dollars*. These cases make for a good mixture of reordering patterns.

Focusing on money expressions have a total of 615,642 such reordering examples. We did the same 80-10-10 split for train/validate/test. We use the same network configurations as in section 6.1.1. Figure 4 shows the accuracy comparison. We have a similar trend as with the synthetic data, namely that the ITG RNN is much more effective. We also measured the CPU decoding speed of the two models. Using a single core, the ITG RNN is 2.5x the speed of attention-based RNN. It is worth noting that the two models have encoder and decoder RNNs with the same network dimensions. The reduction of attention accounts for most of the saving.

6.2 End-to-end Text Normalization

For end-to-end translation, we annotated reordering information on 10,561,377 tokens of training data used by Sproat and Jaitly (2017). There are 349,537 DATE/MONEY expressions, and 14,795 non-identity reordering examples. This is a realistic data set because it reflects that only a tiny portion of all tokens require reordering. Table 1 shows the sequence error rate of the reordering model alone. It can reach 99.8% accuracy on the non-identity reordering subset, while an attention-based reordering component can only give 99.2%.

Table 2 summarizes the end-to-end text normalization results, comparing ITG RNN pre-reordering followed by hard monotonic attention (Raffel et al., 2017) against soft (unordered) attention (Bahdanau

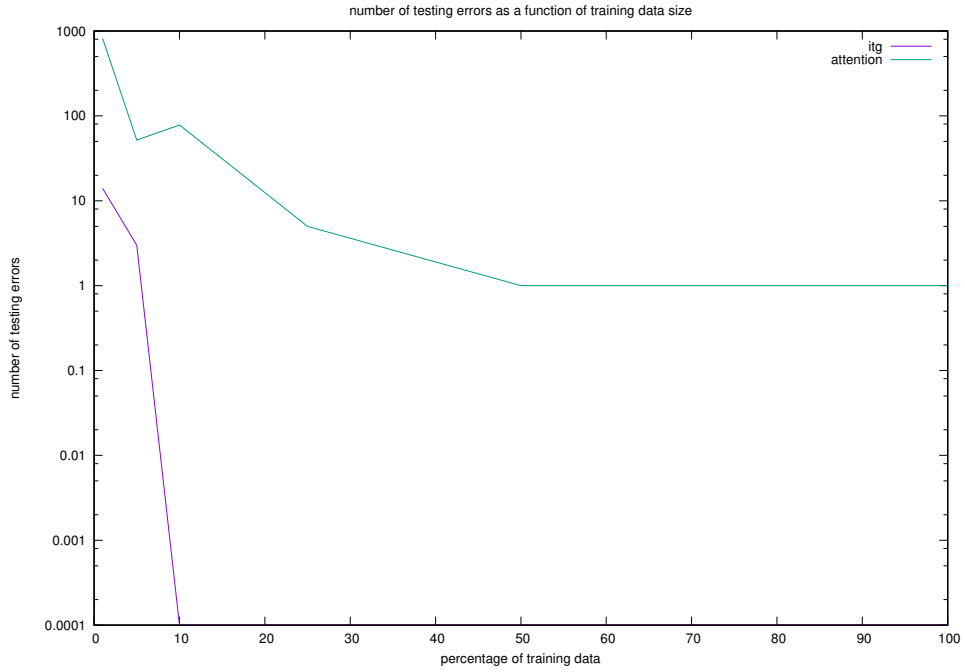

Figure 4: The ITG RNN model reaches zero error rate much faster than the attention-based RNN on the money expression text normalization data set.

	attention-based		*reorderer-based*	
Semiotic Class	Correct	Accuracy	Correct	Accuracy
ALL	143797	99.73%	143778	99.72%
DATE	10438	99.94%	10437	99.93%
MONEY	5838	97.07%	5815	96.69%

Table 2: Text normalization results.

et al., 2014). The details of the baseline normalization model can be found in Sproat and Jaitly (2017). The new system differs only in the attention mechanism. Essentially, the two systems have the same overall accuracy and DATE accuracy. But unfortunately the reorderer-based one is worse in MONEY accuracy.

The overall result indicates that for neural text normalization pre-reordering is feasible with comparable accuracy and has the potential for higher computational efficiency as shown by Raffel et al. (2017). But why do we not observe improvements in accuracy on this data set even though the intrinsic reordering accuracy has reached 99.8%? We suspect that interesting reordering is too rare on this data set and over time, the soft-attention model is fully capable of learning the reordering. We also suspect that the beam search for the reorderer-based system is more prune to search errors because it has two passes: one for the permutation and the other for the actual output based on the permutation produced by the first pass.

7 Conclusion

We propose a neural pre-reordering approach. It reorders the encoder output of the input sequence before feeding it to the decoder RNN. As a result, the burden of modeling reordering is shifted from the attention network to a dedicated reordering model. In particular, we find that combining an Inversion Transduction Grammar based transition system with a RNN results a reordering model that is both fast and accurate. It requires only 1/10 of samples to get to the same reordering sequence accuracy compared to an attention-based RNN reorderer. This demonstrates that reordering can be done more efficiently and accurately

with proper structural constraints.

Our future work has two directions. First, we will apply the model to machine translation data, using automatically aligned data like pre-reordering models for phrase-based machine translation models. Second, we will treat the reordering decisions as latent variables and train the model without alignment annotation and decode without an additional beam search.

Abstract

Neural Machine Translation (NMT) with source side attention have achieved remarkable performance. however, there has been little work exploring to attend to the target side which can potentially enhance the memory capbility of NMT. We reformulate a *Decoding-History Enhanced Attention mechanism* (DHEA) to render NMT model better at selecting both source side and target side information. DHEA enables a dynamic control on the ratios at which source and target contexts contribute to the generation of target words, offering a way to weakly induce structure relations among both source and target tokens. It also allows training errors to be directly back-propagated through short-cut connections and effectively alleviates the gradient vanishing problem. The empirical study on Chinese-English translation shows that our model with proper configuration can improve by 0.9 BLEU upon Transformer and achieve the best reported results in the same dataset. On WMT14 English-German task and a larger WMT14 English-French task, our model achieves comparable results with the state-of-the-art NMT systems.

1 Introduction

Neural Machine Translation(Sutskever et al., 2014) generally adopts an encoder-decoder framework, where the encoder reads and encodes the input text into a distributed representation and the decoder generates translated text conditioned on the input representation. A potential issue with this encoder-decoder approach is that a neural network needs to be able to compress all the necessary information of a source sentence into a fixed-length vector. This may make it difficult for the neural network to cope with translating long sentences. A recent successful extension of NMT models is the attention mechanism which conducts a soft search over source tokens and yields an *attentive vector* to represent the most relevant segments of the source sentence for the current decoding state (Bahdanau et al., 2014; Jean et al., 2015; Luong et al., 2014; Vaswani et al., 2017).

The typical attention mechanism frees the neural translation model from having to squash all the information of the source sentence into a fixed vector, however, it ignores some important information hidden in the target sequence (Cheng et al., 2016). At least three challenges still remains in the translation process. The first issue relates to the memory compression problems in the decoding process. During each translation step, a hidden state vector implicitly maintains at least two types of information, including both the most relevant source contexts and the language model over the partially translated sentence. The memory capacity of a single dense vector is not powerful enough to store these information. The second challenge comes with the training and optimization problem associated with vanishing or exploding gradients, which has been studied in the context of vanilla RNNs. Although some RNN variants such as LSTMs provide a temporal shortcut path to avoid the problem in the temporal domain, it is not guaranteed to be sufficient. At last, it should be acknowledged that the target side context is solely based on the sequence model which, in practice, is prone to a fixed vector and lacks the ability to capture effectively nonsequential dependencies among words.

Proceedings of the 27th International Conference on Computational Linguistics, pages 1464–1473
Santa Fe, New Mexico, USA, August 20-26, 2018.

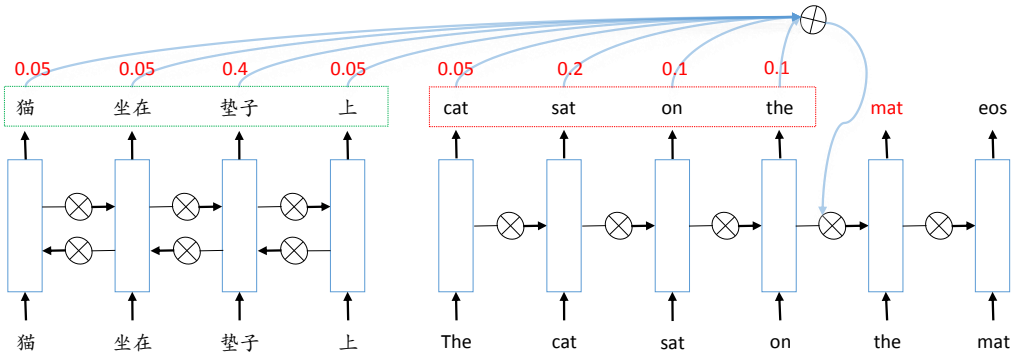

Figure 1: DHEA: *Decoding-History Enhanced Attention mechanism.* The interaction with hidden states that cross both the source and target side can be enhanced by these short-cut connections. The attention weights controls the individual contribution of each hidden states. In this example, the semantic dependency between the word "sat" and "mat" can be be explicitly captured.

In order to address these limitations, we introduce a *Decoding History Enhanced Attention* (DHEA) as a powerful extension to the typical attention based NMT architecture, where the attention over decoding history contributes directly to the prediction of the next word. As illustrated in Figure 1, DHEA explicitly looks back at multiple preceding steps and automatically decides how much previous information should be "seen" by weighting them. Basically, this sort of attention paid on the decoding history facilitates the flow of information from the distant past and is able to emphasize any of the previously translated words, hence it enables the learning of syntactic structures which are useful for the translation task. It also introduces some shortcut connections which connect far-away states to ensure training error signal to be back-propagated directly and alleviate gradient vanishing problem. Further more, we apply attention on the source and target side contexts synchronously, which can better characterize the dependencies within the two sides. Acting in this way, the system learns to determine the ratos of information from the two sides and properly select the amount of context information with regard to the generation of next word in the decoding process. For example, content words in the target sentence should depend more on the source context but less on its prefix (*e.g.* "*mat*" depends more one "*dianzi*" and takes "*cat*" as complementarity). In contrast, function words in the target sentence are often more related to the target context (*e.g.* "*on*" after "*sat*").

Our evaluation on three language pairs shows that the proposed model improves over several baselines, with only a small increase in computational overhead. On the NIST Chinese-English task, DHEA with proper settings yields the best reported result and a 0.9 BLEU improvement over a strong NMT system (Transformer). On WMT English-German and English-French tasks, it again leads to consistent improvements and achieves performance superior or comparable to the state-of-the-art. Finally, we analyze the learned attention function, providing additional insights to its actual contributions.

2 Neural Machine Translation

The NMT model aims to compute the conditional distribution of generating a sentence in a target language given a sentence in a source language, denoted by $p_\theta(y|x)$, where $x = \{x_1 \cdots, x_T\}$ and $y = \{y_1, \cdots, y_{T'}\}$ represent the source and target sentences as sequences of words respectively. θ is a set of parameters usually trained to maximize the conditional log-probability of the correct translation y given the source sentence x:

$$\theta^* = \arg\max_\theta \sum_{i=1}^{N} \log p(y^{(i)}|x^{(i)}) \quad (1)$$

where N is the size of the training corpus. In this section, we will first briefly introduce the NMT model used in our work. Our model modifies the attention based architecture proposed by Bahdanau et

al. (2014), and implements as a deep stack LSTM framework. The whole architecture has three main components: encoder, decoder and attention mechanism.

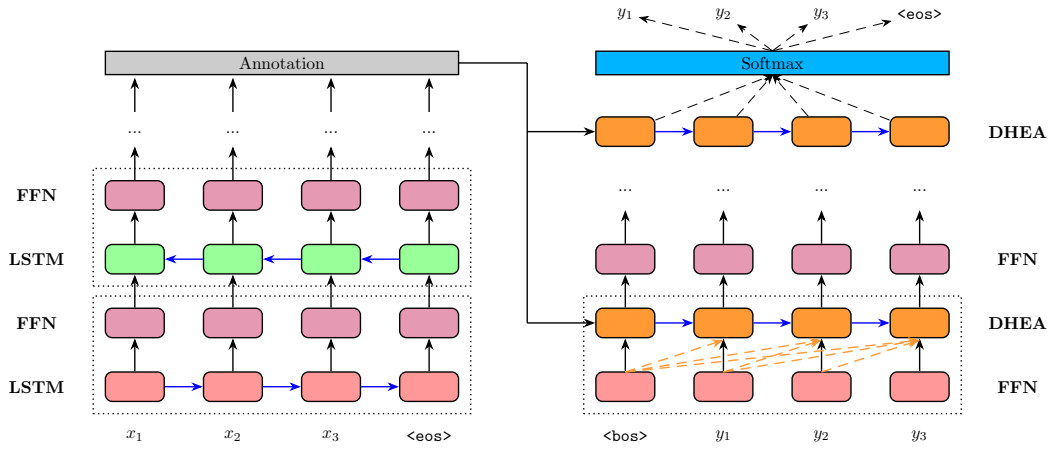

Figure 2: The structure of deep neural machine translation model with DHEA. The dashed arrow directly connects the decoding history and the current state. If we remove this connection, the model degrades to the source side attention based NMT.

Encoder The goal of the encoder is to build meaningful representations of source sentences. The typical encoder consists of a bidirectional RNN which processes the raw input in backward and forward direction with two separate layers, and then concatenates them together. In this work, we choose another bidirectional approach to process the sequence in order to learn more temporal dependencies. Specifically, an RNN layer processes the input sequence in a forward direction. The output of this layer is taken by an upper RNN layer as input, processed in a reverse direction (Zhou et al., 2016).

More formally,The encoder network reads the source input $x = \{x_1, ..., x_T\}$ and processes it into a source side memory $M^{\mathrm{s}} = \{h_1, h_2 \cdots, h_T\}$. where $x_i \in \mathbb{R}^{d_x}$. The output on layer ℓ is

$$h_t^\ell = \begin{cases} x_t, & \ell = 1 \\ \mathrm{LSTM}(h_{t+d}^\ell, h_t^{\ell-1}), & \ell > 1 \end{cases} \tag{2}$$

where

- $h_t^\ell \in \mathbb{R}^{d_h}$ gives the output of layer ℓ at location t.
- The directions are marked by a direction term $d = (-1)^\ell$. If we fixed d to -1, the input will be processed in forward direction, otherwise backward direction.
- We only apply the top-most hidden states as the source side memory which is then fed to the decoder.

Decoder The decoder uses another RNN to generate the translation $y = \{y_1, \cdots, y_{T'}\}$ based on the source side memory M^{s} produced by the encoder. In this work, we use a unidirectional deep stacked LSTM for the decoder RNN. More formally, the hidden state $s_t^\ell \in \mathbb{R}^{d_s}$ on decoder layer ℓ is

$$s_t^\ell = \begin{cases} y_t, & \ell = 1 \\ \mathrm{LSTM}(s_{t-1}^\ell, s_t^{\ell-1}, c_t^\ell), & \ell > 1 \end{cases} \tag{3}$$

Where y_t is the target word embedding at time step t and the context vector $c_t^\ell \in \mathbb{R}^{d_h}$ is dynamically obtained from M^{s} by the attention mechanism. At inference stage, we only utilize the top-most hidden states s to make the final prediction with a softmax layer:

$$p(y_i | y_{<i}, x) = \mathrm{softmax}(s_i W_o) \tag{4}$$

Attention The attention mechanism allows the decoder to select which parts of the source sentence are more useful to predict the next output word. It can be viewed as mapping a query and a set of key-value pairs to an output. The output is computed as a weighted sum of the values, where the weight assigned to each value is computed by a compatibility function of the query with the corresponding key. More specifically, the attention model get context vector c_t after reading from the source representation M^{src}:

$$\begin{aligned} c_i^\ell &= \text{Read}(s_i, M^{\text{s}}) \\ &= \sum_{j=1}^{T} \alpha_{ij}^\ell (h_j W_V^\ell) \end{aligned} \tag{5}$$

Each weight coefficient, α_{ij}^ℓ , is computed using a softmax function:

$$\alpha_{ij} = \frac{\exp(e_{ij})}{\sum_{k=1}^{n} \exp(e_{ik})} \tag{6}$$

And e_{ij}^ℓ is computed using a compatibility function that compares two input elements. The two most commonly used attention functions are additive attention, and dot-product attention. Additive attention computes the weights of the values using a feed-forward network with a single hidden layer. In this work, we consider dot-product with a scaling factor as the compatibility function for its simplicity and efficiency:

$$e_{ij}^\ell = \frac{1}{\sqrt{d_s}} (s_i^{\ell-1} W_Q^\ell)(h_j W_K^\ell)^T \tag{7}$$

Linear transformations of the inputs add sufficient expressive power. $W_K, W_V \in \mathbb{R}^{d_h \times d_s}$ and $W_Q \in \mathbb{R}^{d_s \times d_s}$ are parameter matrices. In general d_s and d_h are set to the same. These parameter matrices are unique per layer. It should be noticed that in Eqn.(7), we apply $s_i^{\ell-1}$ to compute the weights of layer ℓ on the values. In this way the query vector can be prepared in anvance which benifits the implementation of using highly optimized matrix multiplication code.

3 Decoding-History Enhanced Attention for NMT

From Eqn.(5), it is not difficult to observe that the attention weights are associated with the only source side memory. As we have argued before, it is easy for the conventional attention-based NMT models to suffer from generating incoherent texts due to the conflict between the source side attention mechanism and the decoding history. We therefore propose decoding-history enhanced attention to better control over target side contexts. In addition to the source memory M^{s}, DHEA is equipped with a buffer memory M^B as an extension to the conventional approach. M^B is identical to the source side memory M^{S}, except that M^B changes per time step. M_i^B is defined as $\{s_1, s_2, \cdots, s_i\}$. The new context vector is then defined as a combination of the two sides contexts:

$$\hat{c} = \text{Read}(s, M^{\text{S}}, M^{\text{B}}) \tag{8}$$

In this work investigate three strategies for integrating these contexts.

Sum Combination At time step i, DHEA reads from M^B:

$$\begin{aligned} z_i^\ell &= \text{Read}(s_i, M^{\text{B}}) \\ &= \sum_{j=1}^{i} \alpha_{ij}^\ell (s_j^{\ell-1} W_V^\ell) \end{aligned} \tag{9}$$

Similarly, α_{ij} is computed by Eqn.(6) where $j \leq i$ and e_{ij}^ℓ is computed as :

$$e_{ij}^\ell = \frac{1}{\sqrt{d_s}} (s_i^{\ell-1} W_Q^\ell)(s_j^{\ell-1} W_K^\ell)^T \tag{10}$$

One simple way to aggregate information from z_i and c_i is by summing them, then the new context vector is computed as:

$$\hat{c} = z + c \tag{11}$$

It is also worth mentioning that we use $s^{\ell-1}$ as the context information to update the hidden state on layer ℓ, since the lower layer states can be perpared in advance to facilitate parallel training.

Gate Combination As argued by Tu et al. (2016a), the source side context and the target side context plays a different role during the decoding process, we therefore design a context gate which assigns an element-wise weight to the two-side input:

$$\hat{c} = g(c, z) \cdot c + (1 - g(c, z)) \cdot z \tag{12}$$

where $g(c, z) \in (0, 1)$ is a sigmoid neural network which dynamically controls the amount of information flowing from the source and target contexts. $\hat{c}$ is the new context vector fed to the decoder in Eqn.(3) which refines $s_t^\ell = \text{LSTM}(s_{t-1}^\ell, s_t^{\ell-1}, \hat{c}_t^\ell)$.

With the gated control, the new context vector $\hat{c}$ can be rectified based on the decoding history and the source side information. The memory storing useful information of the partial translation can encourage the model to translate contents that are less repeated compared with the already translated contents.

Hybird Combination Considering that we apply the similar attention function to read from the sourc-side memory and the target side memory, it is natural to merge these two memorys into a hybird memory block $M^{\text{S+B}}$. After that, the decoder directly reads from this memory block.

$$\hat{c} = \text{Read}(s, M^{\text{S+B}}) \tag{13}$$

Where the memory block $M^{\text{S+B}}$ is the concatenation of M^{S} and M^{B}. The method can be viewd as a simple implementation of gate combination where the the gating weights are equal to the attention weights.

4 Experiments

4.1 Datasets

We mainly evaluated our approaches on the widely used NIST Chinese-English translation task. In order to show the usefulness of our approaches, we also provide results on other two translation tasks: English-French, English-German. The evaluation metric is BLEU. For Chinese-English task, we apply case-insensitive NIST BLEU. For other tasks, we tokenized the reference and evaluated the performance with multi-bleu.pl. The metrics are exactly the same as in previous work (Papineni et al., 2002).

For Chinese-English, our training data consists of 1.25M sentence pairs extracted from LDC corpora[1], with 27.9M Chinese words and 34.5M English words respectively. We choose NIST 2002 (MT02) dataset as our development set, and the NIST 2003 (MT03), 2004 (MT04), 2005 (MT05), and 2006 (MT06) datasets as our test sets.

For English-German, to compare with the results reported by previous work, we used the same subset of the WMT 2014 training corpus that contains 4.5M sentence pairs with 91M English words and 87M German words. The concatenation of news-test 2012 and news-test 2013 is used as the validation set and news-test 2014 as the test set.

To evaluate at scale, we also report the results of English-French. To compare with the results reported by previous work on end-to-end NMT, we used the same subset of the WMT 2014 training corpus that contains 36M sentence pairs. The concatenation of news-test 2012 and news-test 2013 serves as the validation set and news-test 2014 as the test set.

[1]The corpora include LDC2002E18, LDC2003E07, LDC2003E14, Hansards portion of LDC2004T07, LDC2004T08 and LDC2005T06.

4.2 Training details

Our training procedure and hyper parameter choices are similar to those used by (Vaswani et al., 2017). In more details, we limited the source and target vocabularies to the most frequent $30K$ words in Chinese-English translation. For English-German translation and English-French translation, we use $50K$ sub-word tokens as vocabulary based on Byte Pair Encoding(Sennrich et al., 2015).

We initialized parameters by sampling each element from the Gaussian distribution with mean 0 and variance 0.01^2. Parameter optimization was performed using stochastic gradient descent. Adam (Kingma and Ba, 2015) was used to automatically adapt the learning rate of each parameter ($\beta_1 = 0.9, \beta_2 = 0.98$ and $\epsilon = 10^{-8}$). To avoid gradient explosion, the gradients of the cost function which had ℓ_2 norm larger than a predefined threshold 25 were normalized to the threshold (Pascanu et al., 2013). We batched sentence pairs by approximate length, and limited input and output tokens per batch to 8192 per GPU. Each resulting training batch contained approximately 60,000 source and 60,000 target tokens. We trained our NMT model with the sentences of length up to 150 words in the training data. During training, we employed label smoothing of value $\epsilon = 0.1$(**?**).

Translations were generated by a beam search and log-likelihood scores were normalized by the sentence length. We used a beam width of 8 and length penalty $\alpha = 0.6$ in all the experiments. Dropout was applied on each layer to avoid over-fitting (Hinton et al., 2012). The dropout rate was set to 0.1. Except when otherwise mentioned, NMT systems had 6 layers encoders and 4 layers decoders. We trained for 300,000 steps on 8 M40 GPUs, and averaged the last 20 checkpoints, saved at 30 minute intervals. For our small model, the dimensions of all the hidden states were set to 512 and for the big model, the dimensions were set to 1024.

4.3 Results on Chinese-English Translation

SYSTEM	MT03	MT04	MT05	MT06	AVE.
Existing systems					
Moses	31.61	33.48	30.75	30.85	31.67
DEEPLAU(Wang et al., 2017)	39.35	41.15	38.07	37.29	38.97
FRNN+PRNN (Zheng et al., 2017)	37.90	40.37	36.75	34.55	37.39
COVERAGE+Context Gate(Tu et al., 2016a)	-	-	34.13	34.83	-
Transformer (Vaswani et al., 2017)	45.16	46.81	44.62	43.53	45.03
Our deep NMT systems

DHEA + Gate Comb.	46.60	47.73	45.35	43.97	**45.90**

Table 1: Case-insensitive BLEU scores on Chinese-English translation.

Table 1 shows BLEU scores on Chinese-English datasets. Clearly DHEA leads to remarkable improvements over their competitors. Compared to the source side attention based model, DHEA is $+1.05$ BLEU score higher on average four test sets, showing the modeling power gained from the decoding history. Among the combination method of the contexts, the context gate function drives consistent improvements over sum and hybrid function by $+0.4$ and $+0.2$ in terms of BLEU. We conjecture it is because the adaptive gate function conditioned on the decoding history make it able to automatically decide how much information should be transferred during decoding to the next step.

To show the power of DHEA, we also make a comparison with previous work. Our best single model outperforms both a phrased-based MT system (Moses) as well as a strong source attention-based NMT system (DeepLau) by $+14.2$ and $+6.8$ BLEU points respectively on average. The result is also better than some other state-of-the-art variants of attention-based NMT model with big margins. Compared to Transformer, DHEA yields a gain of $+0.9$ BLEU and achieves the best performance ever reported this dataset.

4.4 Results on English-German and English-French Translation

SYSTEM	Architecture	EN-Fr BLEU	EN-DE BLEU
Existing systems			
Buck et al. (2014)	Winning WMT14 system	35.7	20.7
Wu et al. (2016)	GNMT + Ensemble	40.4	26.3
Gehring et al. (2017)	ConvS2S	40.51	25.16
Vaswani et al. (2017)	Transformer (small)	38.1	27.3
Vaswani et al. (2017)	Transformer (large)	41.0	28.4
Our deep NMT systems			
this work	Source Attn (small)	39.3	27.5
this work	DHEA + Gate Comb. (small)	40.4	27.9
this work	DHEA + Gate Comb. (large)	**41.6**	**28.7**

Table 2: Case-sensitive BLEU scores on English-German and English-French translation. Our proposed model outperforms the state-of-the-art models including the Transformer (Vaswani et al., 2017).

The results on English-German and English-French translation are presented in Table 2. We compare our NMT systems with various other systems including the winning system in WMT14 (Buck et al., 2014), a phrase-based system whose language models were trained on a huge monolingual text, the Common Crawl corpus. For end-to-end NMT systems, to the best of our knowledge, GNMT is the best RNN based NMT system. Transformer (Vaswani et al., 2017) is currently the SOTA system which is about 2 BLEU points better than GNMT on the English-German task and 0.6 BLEU points better than GNMT on the English-French task.

DHEA achieves a 0.6 BLEU score improvement over the state-of-the-art on the English-to-German task for the smaller network and 0.3 BLEU improvement for the larger network. In the case of the larger English-to-French task, we obtain a 2.3 BLEU improvement for the smaller model and a 0.6 improvement for the larger one. Also, note that the performance of the smaller model for DHEA is close to that of the larger baseline model, especially for the English-to-French task. This suggests that DHEA better utilizes available model capacity.

4.5 Analysis

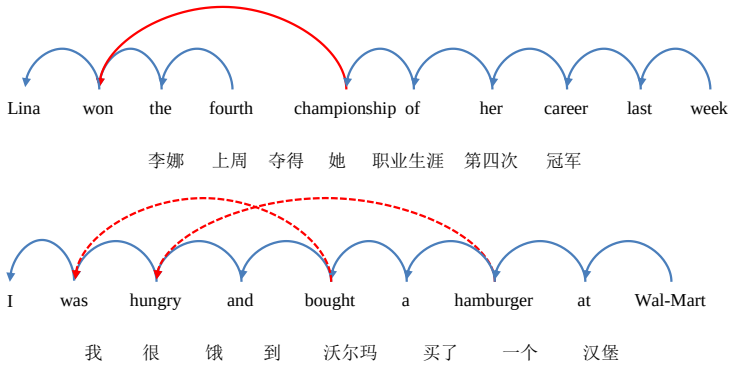

Figure 3: Examples of the target side attention during decoding process. Solid arrows denote which word is being focused when attention is computed, but not the direction of the relation. Red lines indicate long-term dependencies. Dashed lines denote which word is bing second focused.

In order to better understand whether the network benefits from the decoding history, we biefly visualized the skeleton of the target side attention. In Figure 3, although we explicitly allow DHEA to attend to any memory cell, much attention selects the immediately previous word. This agrees with the linguistic intuition that long-term dependencies are relatively rare and hard to learn. This model still finds some

long-term dependencies among words (e.g., the dependency between *won* and *championship*, *bought* and *was*, *hungry* and *hamburger*). These detected dependencies reflect some head-modifier relations in dependency graphs.

5 Related Work

Memory Networks There are variety of studies proposed to increase the LSTM memory capacity by using memory networks. The two most salient examples are Neural Turing Machine (NTM) (Graves et al., 2014) and Memory Network (Weston et al., 2014). Cheng et al. (2016) propose a machine reading simulator which processes text incrementally from left to right. In the NMT task, Wang et al. (2016) present a decoder enhanced decoder with an external shared memory which extends the capacity of the network and has the potential to read, write, and forget information. In fact DHEA can be viewed as a special case of memory networks, with only reading mechanism for the translation task. Quite remarkably DHEA incorporates two different types of memory (source memory and decoding history memory) and significantly improves upon state-of-the-arts.

Attention Mechanism Attention in neural networks (Bahdanau et al., 2014; Luong et al., 2015) is designed to assign weights to different inputs instead of threating all input sequences equally as original neural networks do. A number of efforts have been made to improve the attention mechanism(Tu et al., 2016b; Mi et al., 2016; Zhang et al., 2017). Some of them incorporated the previous attention history into the current attention for better alignment, but none of them are based on the decoding history.

The application of self-attention mechanisms in RNNs have been previously studied, and in general, it appears to capture syntactic dependencies among distant words (Liu and Lapata, 2017; Lee et al., 2017; Kim et al., 2017; Lin et al., 2017). Vaswani et al. (2017) resort to self-attention mechanism and showed outstanding performance. Our approach is diffrent from their work in two aspect. First, our method can be viewed as a variant of RNN decoder which allows a form of memory, thus has the the potential to better handle sentences of arbitrary length. Second, we forcus on controlling the information flow between the source side memory and the target side memory and design a gate to balance the contribution of the two-sides.

Recurrent Residual Networks Our work is also related to residual connections, which have been shown to improve the learning process of deep neural networks by addressing the vanishing gradient problem (He et al., 2015; Szegedy et al., 2016). Recently, several architectures using residual connections with LSTMs have been proposed (Kim et al., 2017; Wang, 2017; Wang and Tian, 2016) for sequence prediction. These connections create a direct path from previous layers, helping the transmission of information. Related to our work, Miculicich et al. (2018) propose a target sideattentive residual recurrent network for decoding, where attention over previous words contributes directly to the prediction of the next word. Comparatively, DHEA attends to the previous hidden state and make a combination with the source context.

Exploiting Contextual Information A thread of work in sequence to sequence learning attempts to exploit auxiliary context information(Wang and Cho, 2016; Li et al., 2017; Zhang and Zong, 2016). Recently Tu et al. (2016a) propose using context gates in NMT to dynamically control the contributions from the source contexts and the RNN hidden state. Our approach focuses on integrating the decoding history and the source side context to NMT architecture. In addition, we have a multi-layer approach to better utilize the contextual information. Experiments in Section 4.3 show the superiority of DHEA.

In the same period of our work, Lin et al. (2018) and Xia et al. (2017) first turn eyes to the target side attention of NMT architecture. Our approach share the similar idea with these work. The diffrence lies in that we concernd more about the integrating of the souce side context and the target side context and designed three types of combination functions. In addition, we approached in a multi-layer way which is more effective.

6 Conclusion

We presented a decoder history enhanced attention mechanism to enrich the target side contextual information for neural machine translation. Our empirical study in three translation tasks shows that it can significantly improve the performance of NMT.

Transfer Learning for a Letter-Ngrams to Word Decoder in the Context of Historical Handwriting Recognition with Scarce Resources

Adeline GRANET, Emmanuel MORIN, Harold MOUCHÈRE, Solen QUINIOU, Christian VIARD-GAUDIN

LS2N, UMR CNRS 6004, Université de Nantes, France
firstname.lastname@ls2n.fr

Abstract

Lack of data can be an issue when beginning a new study on historical handwritten documents. In order to deal with this, we present the character-based decoder part of a multilingual approach based on transductive transfer learning for a historical handwriting recognition task on Italian Comedy Registers. The decoder must build a sequence of characters that corresponds to a word from a vector of letter-ngrams. As learning data, we created a new dataset from untapped resources that covers the same domain and period of our Italian Comedy data, as well as resources from common domains, periods, or languages. We obtain a 97.42% Character Recognition Rate and a 86.57% Word Recognition Rate on our Italian Comedy data, despite a lexical coverage of 67% between the Italian Comedy data and the training data. These results show that an efficient system can be obtained by a carefully selecting the datasets used for the transfer learning.

1 Introduction

An increasing amount of handwritten historical documents is becoming digitally available, as a mean for preserving this heritage and making it accessible to all. However, digitization is not sufficient to make the documents usable: it is necessary to extract informations in order to index them. Researchers and historians in the humanities and in the social sciences need to be able to query them and find answers rapidly. Therefore, new projects involve the domains of language processing, document recognition, and information retrieval for historical studies.

In the field of Natural Language Processing (NLP) for historical documents, the main challenge is currently to analyse and normalize the spelling of texts (Garrette and Alpert-Abrams, 2016; Bollmann et al., 2017) whereas challenges of Computer Vision for historical documents are more diverse: they involve segmentation into words, lines, or paragraphs, as well as keyword spotting, or handwriting recognition (HWR). In recent years, the number of competitions regarding historical documents has increased (Cloppet et al., 2016; Pratikakis et al., 2016; Sanchez et al., 2017). Such systems have to deal with the complexity of the task as well as the document medium, its level of deterioration, or even its written language. All of these can have a strong impact on the system efficiency.

Lately, the trend in HWR is the use of deep neural networks and, more recently, the integration of attention models in the networks (Bluche et al., 2017). The handwriting systems are built with a Multidimensional Long Short-Term Memory (MDLSTM) network or even with a Convolutional Recurrent Neural Network (CRNN) stacked with a Bidirectional Long Short-Term Memory (BLSTM) (Granell et al., 2018). The neural network training includes a Connectionist Temporal Classification (CTC) cost function proposed by (Graves et al., 2006). Those approaches enable the use of all the available contexts. To decode sequences, there are several strategies: a dictionary, a language model, or a Weighted Finite State Transducer (WFST) including several dictionaries. Nevertheless, results are constrained by the size of the vocabulary used. When too many words are out-of-vocabulary, the results are degraded. To improve the results, methods can be employed to increase the size of the vocabulary by using Wikipedia

Proceedings of the 27th International Conference on Computational Linguistics, pages 1474–1484
Santa Fe, New Mexico, USA, August 20-26, 2018.

or other available resources. Whether improving the results or training the networks, the HWR systems require a lot of data.

We are now working on a new resource (the financial records of the Italian Comedy) with no ground-truth. The changing layout of these documents, the multilingualism (French and Italian), and their special writing make them more complex to study. Moreover, an annotation step would be time-consuming for experts to create a ground-truth. Therefore, transductive transfer learning is an interesting approach when no ground-truth is provided. Indeed, it uses different sources of data to train a system for a specific task by applying various target data (Pan and Yang, 2010). It enables us to use available existing resources to annotate unknown data. It is eagerly used to supply the lack of data for greedy systems such as word spotting in historical documents (Lladós et al., 2012) or translation models with multimodal systems such as (Nakayama and Nishida, 2017).

The standard of machine translation is an encoder-decoder system based on a recurrent neural network (Cho et al., 2014). The first component encodes the source language into a fixed vector and the last one decodes the sequence into the target language. Similarly, (Vinyals et al., 2015) proposed a neural image caption generator that consists of two sub-networks: a pre-trained Convolutional Neural Network (CNN) encoding an image into a fixed size vector, using the last hidden layer from GoogleNet, and a LSTM model generating the corresponding description. We were inspired by this idea to split up our handwriting recognition system into an encoder and a decoder. First, an image encoder takes a word image as input and, thanks to a fully convolutional network (FCN), converts it into a vector of letter-ngrams as in (Huang et al., 2013; Bengio and Heigold, 2014). Here, the transfer learning is performed during the training step that uses available labelled image data. Then, the decoder is built with a recurrent layer in order to generate a sequence of characters from the vector of letter-ngrams. Here, a second transfer learning is independently made on the vocabulary. Contrary to the machine translation and description generator works, the sub-networks are trained independently from each other.

In this paper, we investigate the robustness of the decoder part to infer rules on the order of characters from the letter-ngrams vector only. Within this context, we present three contributions:

1. we propose a character-based decoder and evaluate it on the historical vocabulary of the Italian Comedy;
2. we show that historical resources are more appropriate than Wikipedia to complement the vocabulary of historical documents;
3. we also show that the transfer learning across languages and periods of time works based on a bag of letter-ngrams.

This paper is organized as follows. We describe our transfer model within the encoder and decoder components in Section 2. Section 3 presents the datasets used and their preprocessing. The experimental setups are presented in Section 4 which is followed by the report of our experiments and results in Section 5.

2 Transfer Models

In this section, we present the architecture of our system. We aim to build a handwriting recognition system for multilingual historical documents using multiple resources with different languages and different creation periods.

2.1 Prior Work

Our first approach was based on a BLSTM-CTC network intergrating the transfer learning (Granet et al., 2018b). Firstly, an image is provided to a fully convolutional neural network to automatically extract features. Then, the extracted features were given to a BLSTM network. The cost was computed by the CTC activation function. The CTC enables the use of an unsegmented input image at a word or a character level and provides a sequence of characters as output. We implemented and evaluated this system with a training and test data from the same resource and, then, used the system on unknown data. The model did not use a dictionary nor a language model during the decoding. The resources were in French, Spanish, and English for the training set and in French, and Italian for the target datatest. The

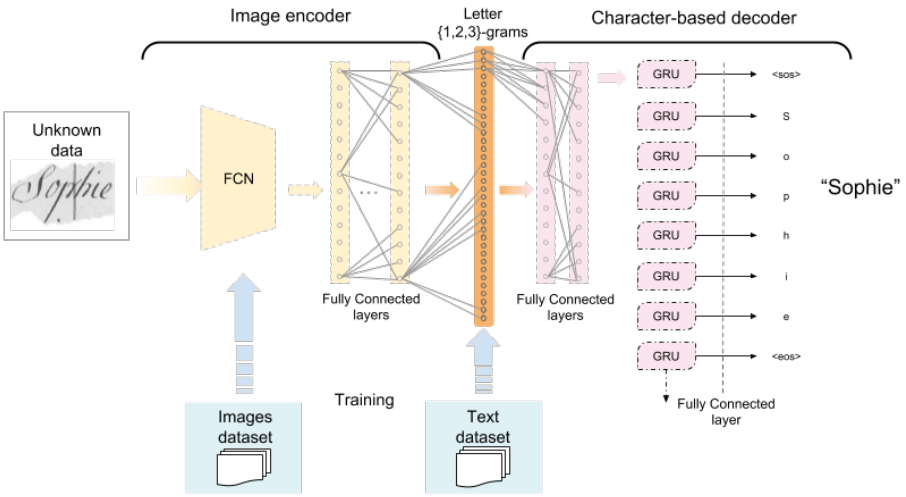

Figure 1: Overview of our encoder-decoder using transfer learning on new historical documents. On the left, the yellow component corresponds to the image encoder from which the features are extracted thanks to a FCN and two connected layers with 1,024 units each and a vector of letter-ngrams is built. On the right, the pink component corresponds to the sequence generation decoder that provides the word, character by character, corresponding to the input vector.

results of this system showed that a language model was learned implicitly to generate the sequence of characters and that the correctly recognized words were words close from one language to the other. Therefore, without a specialized training on a small part of the data to be transcribed, the transfer learning did not work well. The model allowed to reach only 10% of characters which are correctly recognized. From these results, we concluded that a BLSTM-CTC network was unsuitable for the transfer learning case.

Word classification could have been a solution. Nevertheless, in the field of transfer learning, this strategy quickly reaches its limits when working on target data with a closed vocabulary with many named entities, and a significant number of out-of-vocabulary words. Therefore, classification could not be applied to our data.

2.2 Encoder-Decoder for Transfer Learning

Based on the work on image description generation, we define a new system that is divided into two complementary components: an image encoder and a character decoder, as shown in Figure 1. The first one encodes a word image into a vector and the second one decodes the vector into a character sequence or word. The interface vector that links these two parts is a bag of characters or letter n-grams. We estimated the set of letter-ngrams on all resources used for both the training data and the transfer target data. The originality in using a letter-ngrams vector as a pivot is that we encode the input into a non-latent space which is transferable as long as the training data and transfer target data share the same alphabet. In this paper, we focus on the character-based decoder to generate corresponding words. Nonetheless, it is interesting to give informations on the whole system to understand the overall approach.

Image Encoder We define our encoder as shown on the left part of Figure 1:

- a fully convolutional network;
- 2 fully connected layers with a ReLU activation function (Nair and Hinton, 2010) and 1,024 hidden units each;
- one last fully connected layer with a sigmoid and L+1 units where L is the number of estimated letter-ngrams and the additional unitias a joker if the letter-ngram is unknown.

The last layer with the sigmoid activation function allows us to have a probability for each letter-ngram independently of the others.

Character-Based Decoder We turned to neural encoder-decoder architectures in NLP as it enables us to map one sequence to another one without having them to have the same length or word order such as in machine translation (Bahdanau et al., 2014) and description generation (Vinyals et al., 2015). We define the architecture for the character-based decoder as shown on the right part of Figure 1:

- one fully connected layer with a ReLU activation function;
- one Gated Recurrent Unit layer (GRU) (Cho et al., 2014);
- one fully connected layer with a softmax activation function.

These components were designed to be the most minimalist. Moreover, they do not use an embedding layer since it might interfer with the transfer learning that has to deal with different languages.

For the sequence generation task, we used a recurrent layer to add a temporality followed by a softmax layer that gives one character at the time until the word end symbol *J* is given. We chose not to include a bidirectional recurrent layer contrary to encoder-decoder models that are used in machine translation. Since our character-based decoder uses a vector without any order indication on characters from words, all the information and context are included in the vector. Therefore, a bidirectional recurrent layer is useless. Overall the system must infer sequences of characters from the vector content. If we analyse the simple short word "are", it consists of 3 unigrams, 4 bigrams, and 3 trigrams. This decomposition includes the n-grams with the beginning and end symbols of the word. So the decoder needs to deduce the order of characters from the letter-ngrams.

3 Dataset Collection and Statistics

In this section, we present the resources used in our experiments as well as their representation.

3.1 Target Data: Financial Records of the Italian Comedy

The studied documents consist of more than 28,000 pages of financial records of the Italian Comedy from 1716 to 1791. These pages give the list of daily, monthly and annual receipts, with details on the composition of the troupe of actors for each season. We noticed several evolutions over the years:

- the language switches from Italian (with several dialects) to French;
- the structure changes but keeps the same amount of information;
- the writing style is irregular at the beginning of the century but, after that, a cashier was nominated so the style became stable.

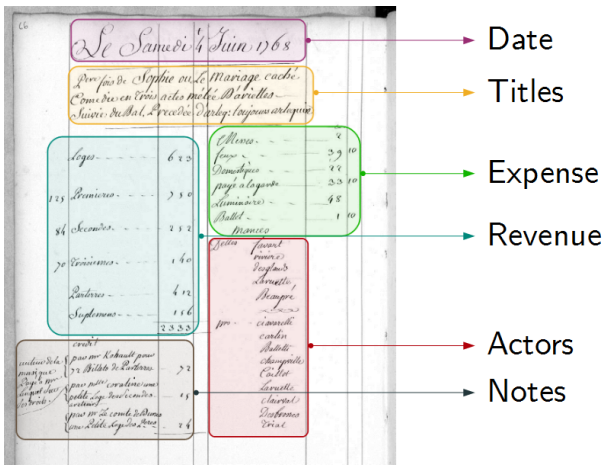

Figure 2: Example of a financial daily record of the Italian Comedy with fields identified.

Figure 2 shows all the information that can be found in a daily record such as the date, the titles of the plays, the revenues and expenses, the actor names, and also some notes. Our study focuses on the title field which contains the list of plays that were performed that day. This list can be extended by some indications as if it was the first performance of the play, if the performance took place at the king's court, or if a new actor started to play. An example of this additional information is shown in Figure 2: the

title field explains that it was a performance of *"Sophie ou le mariage caché"* (lit. *"Sophie or the secret marriage"*) which was a comedy in three acts preceded by *"Arlequin toujours Arlequin"* (lit. *"Arlequin always Arlequin"*). Moreover, a title can be written in many ways with the complete title or a shorter title. Titles were mostly constituted by named entities such as "Raton and Rosette" or "Zemire and Azor".

The language and writing style are essential for the decoder part. We explained above that the language can be either Italian or French. Compared to the modern writing of these languages, we note some differences such as special characters like the long form of 's', the evolution of the 'y' spelling to 'i' or using 'i' and 'j' indiscriminately, or some weak and strong abbreviations. We define as weak abbreviation, a symbol that replaces few characters of a word, while a strong abbreviation reduces a long title to only two or three words.

Thanks to recent works and a participative annotation website (Granet et al., 2018a), we collected and validated 971 annotated title lines. We used all of these annotations to test our decoder system: this dataset is thereafter called Italian Comedy Registers (ICR).

3.2 Training Datasets

In order to build an efficient decoder, we must carefully select the training datasets. Table 1 presents the vocabulary size for each dataset that are used to train the decoder. We choose to create a new dataset from available digitized historical books, as well as to use three existing image resources (RIMES, George Washington, and Los Esposalles) and the French version of Wikipedia since it is a widely used resource in NLP tasks.

	Google IC	RIMES	Los Esposalles	Georges Washington	Wikipedia Fr	IC Registers
Train	26,573	4,477	2,565	660	24,456	0
Validation	2,953	1,578	629	521	3,843	0
Test	0	1,627	629	431	1.928	1,431

Table 1: Vocabulary size of the training, validation, and test sets of each dataset.

New Dataset (Frinken et al., 2013) built a very large vocabulary gathered from a Google N-grams project and an edition of a manually transcribed book from the 16^{th} century. We had a similar approach to this work as we built a new dataset from digitized books of the same century of our data, with a similar closed vocabulary. To preserve the cultural heritage for future generations, copies of books have been digitized, automatically OCRized, and distributed via *Google Book*, for example. We selected 23 books dealing with the Italian Comedy from (and published in) the 18^{th} century. These books include bilingual scripts of plays (French and Italian), collections of plays, and anecdotal stories of the Italian theater. The extracted texts were cleaned to remove the noise such as the structure of the texts and special characters. This new resource, called Google Italian Comedy (GIC), has the advantage of having the same closed vocabulary with specific writings as in the records of the Italian Comedy.

Existing Datasets For our transfer learning approach, we carried out experiments with four available datasets of images, sharing at least one common feature with our target data, as well as Wikipedia to compare the effect of a modern and general resource on the Italian Comedy data:

- RIMES (RM) stands for Recognition and Indexing of Handwritten Documents and Faxes) and is a French database developed to evaluate automatic systems that recognizes and indexes handwritten letters (Grosicki and El-Abed, 2011);
- George Washington (GW) is an English database created from the George Washington Papers at the Library of Congress (Fischer et al., 2012);
- Los Esposalles (ESP) is a Spanish database compiled from a marriage licence book collection from the 15^th and 17^th centuries (Fischer et al., 2012);
- Wikipedia Fr data (Wiki), as used and distributed by (Bojanowski et al., 2017), provides all words whose frequency is greater than 5 in Wikipedia. From this dataset, we randomly selected 30 000

words.

To our knowledge, no other experiments dedicated to the construction of a decoder use the resources RM and ESP which are initially image resources. However, we found it interesting to observe the impact of trained models because ESP is mainly composed of named entities, and RM is a contemporary base with an administrative vocabulary. Therefore, they are far from our Italian Comedy data.

3.3 Representation

Preprocessing of the Training Datasets In all the datasets, we replaced the diacritical marks by their simple form, such as {é, è} are *e* characters, and the typical long form of *s* from the 18^{th} as a short form for the decoder input and also the target data. All words are case sensitive. For GIC only, text lines were split on whitespaces and punctuation marks. In contrast, ICR title lines were only split on whitespaces and we kept with the punctuations in the data.

Letter-Ngrams As suggested by (Bengio and Heigold, 2014; Vania and Lopez, 2017), we use letter-ngrams as a pivot in our multimodal encoder-decoder. Initially, the authors selected the 50 000 most popular letter-ngrams to represent words. Adding *[* and *]* to symbolize the beginning and end of a word, respectively, we computed all the possible letter-ngrams with a maximum length of 3 on all the datasets. Therefore, we selected around 12,500 letter-ngrams. The large difference in the number of ngrams comes from the choice of keeping only letter-ngrams appearing in at least 2 different datasets: a *joker* was created to replace the non-selected letter-ngrams. With our example in Figure 1, the name *Sophie* is thus decomposed as {S,o,p,[S,So,op,[So ,. . . ,ie],e]}.

Regarding the choice of having at most 3-grams, this allows to give the system an idea on the order in which the characters are arranged in the word. In the case where there are only unigrams, the learning process is longer and tends towards over-learning to be able to have sequences of characters forming words. Including 4-grams into the vector would dramatically increase its length and would make it more difficult to select the ngrams recognized in a word by the optical model.

Decoder Input and Output The input of the decoder input consists of the normalized frequencies of the n-grams in the input word. The frequencies are normalized by the length of the word to provide a vector with values between 0 and 1, corresponding to probabilities for each n-gram. Using frequencies enables us to hold information about the word length and to compensate the lost temporality. For the sequence generation, we have 79 output units for all the upper and lower characters, the digits, the punctuation symbols including the space, the start and the end of word. The last added symbol is a *blank* label that allows the system to provide an out-of-character answer after the end of a word.

4 Experimental Setup

This section presents the experimental setup of our decoder as well as the evaluation metrics we used.

4.1 Decoder Training

The size of the datasets varies from 660k to 25k words. For this reason, we trained the system with either one dataset or several datasets, except for GW. Its size is too small so we always combined it with other datasets.

To avoid overfitting, we used the classical technique of early stopping. The training process was stopped after five epochs if the validation loss did not decrease anymore. For the sequence generation, we used the loss defined by Equation (1) that computes the multi-classification with a normalization through all the output units.

$$L_i = -\sum_j t_{i,j} \log(p_{i,j}) \tag{1}$$

4.2 Decoder Parameters

We defined the structure of the decoder part with 1,024 units in the fully connected layer to extract features, 500 hidden units in the GRU layer, and 79 units with the Softmax activation function on the last

layer. To be sure to stay in the same configuration, we used the Adam function that controls the learning rate which is initialized at 0.0001 for the stochastic optimization. As we have less data than the others experiments of the state-of-the-art, our rate is lower. In the scope of sequence generation, we padded the length of the sequence with blank labels up to 50 characters. Therefore, the network is free to define any sequence without any constraints.

4.3 Evaluation Metrics

To evaluate the performance of our system, we used the recognition rate at the character level (*CRR*) and at the word level (*WRR*). The Character Recognition Rate is defined as:

$$\text{CRR} = \frac{N - (Ins + Subs + Dels)}{N}$$

with N the number of characters of the reference words, $Subs$ the number of character substitutions, $Dels$ the number of character deletions, and Ins the number of character insertions. The Word Recognition Rate corresponds to the Word Accuracy and is defined as the number of correctly recognized words divided by the total number of words to recognize. The WRR is computed with and without using the Levenshtein edit distance to correct the output sequence with a multilingual dictionary. The dictionary was built from the training and the validation parts of the vocabulary of all the datasets, except Wikipedia. The dictionary contains 39,051 words.

We also computed the lexical coverage of a training set with respect to the test set. It is defined as the number of words shared between the training set and the test set, normalized by the size of the test vocabulary. This metric defines a high boundary for the word recognition using a dictionary. Since the dictionary is built on the training and the validation sets, out-of-vocabulary words of the test set could not be correctly recognized.

4.4 Baseline Approach

As a baseline approach we used a vector of unigrams to represent each word in the decoder input. We added the symbols for the beginning and the end of words so each word is represented by 2 bigrams and several unigrams.

5 Results and Analysis

In this section, we present the results of our experiments for the sequence generation decoder, in Table 2 which is divided into 3 parts following the test resources. We performed three types of experiments corresponding to the sub-parts of the table, for each validation and test data:

1. the same resource for the training and the test parts (training domain = target domain);
2. adding other resources during the training part (training domain $>$ target domain);
3. different resources for the training and the test parts, *i.e.* transductive transfer learning (training domain $\neq$ target domain).

The experiments are done with the artificial true n-gram vectors so the input is not noisy. Overall, the results in Table 2 prove that using letter-ngrams is a better choice than only using unigrams and the use of a dictionary degrades the results. In all the experiments, the models provide a CRR greater than 75% on the validation sets and greater that 85% on the test sets, even if the lexical coverage is less than 25%. Furthermore, WRR also exceed the lexical coverage. To decode the ICR vocabulary, the model must be trained with at least GIC as a resource. All following analyses are presented on the validation sets to evaluate the best ressources to train the model. The last analysis relates to the test sets.

Baseline Whether experimenting with RM on RM (validation and test set) or with GIC on GIC (validation set) and ICR (test set), we found that the results obtained with letter-ngrams are better than with unigrams. On GIC, letter-ngrams dramatically outperformed unigrams with a 70% relative increase of WRR without the dictionary. It should also be noted that only 5% of the characters were incorrectly recognized with letter-ngrams. These results corroborate other studies using trigrams such as (Vania and Lopez, 2017).

Test	Train	Expe. Id	Letter ngrams	Lexical Coverage (%)	Validation			Test		
					CRR	WRR	WRR dict.	CRR	WRR	WRR dict.
ICR	GIC	1	1	65.57	69.11	13.05	14.65	69.27	14.54	10.83
	GIC	2	1,2,3		95.85	77.83	66.47	97.10	86.22	39.30

Table 2: Sequence generation results. CRR and WRR with/without the dictionary on the Italian Comedy Records (ICR), Rimes (RM), and Los Esposalles (ESP) validation and test datasets. Several experiments are presented: evaluation of the baseline, combination of the resources, and transductive transfer learning with all the resources. The lexical coverage is computed between the training and the test datasets.

Use of a Dictionary Using the dictionary drops performances except for Expe. Id 6, 7, 8, and 20. We notice that when the lexicon coverage is greater than 20%, WRR always remains lower. We notice that a dictionary misleads the decoder when it generates a correct sequence but there is only another form (e.g., plural) of this word, in the dictionary. However, the dictionary sometimes helps to get closer to the original word even if this word does not exist in the dictionary and if the training and the test data are from different periods or different languages. Nevertheless, these cases are too rare to improve CRR with the dictionary.

Results on ICR (our Target Data) We focus on the central part of the ICR experiments, where GIC is combined with other resources. The CRR and WRR results are very similar to those of the training step with only GIC (Expe. Id 2 vs. Expe. Id 3, 4, and 5). Therefore, the increase in the number of resources does not always have a great impact on the performance. Nonetheless, training on GIC and ESP achieved better than GIC and RM despite the fact that languages are mixed.

For the transfer learning process with an out-of-domain vocabulary (Expe. Id 6, 7, and 8), the lexical coverage is extremely low (around 15%). Nevertheless, the system reaches a maximum of 19.49 % WRR using only RM and 41.18 % WRR using Wikipedia, which are the two modern French resources.

Results on Rimes (RM) These results are impressive because Rimes is the only modern image base we used. For transductive transfer learning, without RM during the training step, CRR and WRR reach the same results obtained with only RM as a training data. Moreover, they exceed the lexical coverage of 15%. When we work with historical training data applied to modern data but with the same language, the lexical coverage is greater than using a modern training data and testing on ICR. It seems that the historical spelling is easier to extend to the modern spelling for the decoder. The results obtained with Wikipedia show a CRR 6.89% lower and a WRR 9.49% lower than with GIC, despite the fact that the

vocabulary used in RM and Wikipedia is modern French.

Results on Los Esposalles (ESP) The vocabulary of Los Esposalles is built primarily with named entities as it is extracted from 18^{th} century Spanish wedding registers. This explains the low lexical coverage for the transductive transfer learning. Nevertheless, CRR is greater than 90% except with RM (Expe. Id 19) and WRR outperforms the lexical coverage. We did not experiment the decoding with unigrams on this resource because there are too few words. Expe. Id 21 using GIC, GW, and RM shows that this decoder enables to learn a representation from one language (mainly in French) to another.

Analysis on Test Sets Finally, creating and using a new dataset in the field of the Italian Comedy is an interesting approach to decode ICR. This enables a better word reconstruction since the lexical coverage is increased by more than 20%. Among the unknown but well-recognized words can be found light abbreviations such as *"arleq."* instead of *"Arlequin"*. Contrary to the validation results, the best results are obtained thanks to the combination with RM dataset (Expe. Id 3 versus 4). This can be explain by the difference of the vocabulary, the validation set is composed of GIC while the test set is composed of ICR. For the transductive transfer learning process, the results with Wikipedia are similar ($+1.20\%$) to using mixed resources with less data (Expe. Id 7 versus Expe. Id 8) contrary to the results on the validation set, where there is a significant difference around 15% on WRR with and without dictionary.

Error Analysis Table 3 shows some mistakes made by the decoder. For words with a repeated character such as *"cavalcade"* and *"clemence"*, it is common for the system to fail to generate the characters inserted between each repetition. Common mistakes are a permutation between two consecutive characters such as *"suitte"* and one doubled character to replace another one. In the last example, *"Soldat"*, the decoder predicts two start symbols: the second one replaces the first letter of the word. This happens when small resources are used to train the system.

Table 4 shows the distribution of the different types of errors presented in Table 3 for 3 selected experimentations (Expe. Id 2, 5, and 8). The most common mistake is a simple switch between two characters: this represents 65.14% to 88.32% of the errors, depending on the considered experiments. For the experiments including GIC in the training step, the redundant character errors and wrong starting character are similar. They represent only 10% and 20% of all the identified errors. Expe. Id 8 has a high rate of wrong starting characters that can be explained by the lack of lexical coverage between Wiki and ICR. Despite the equivalent quantity of words used for the training step with Wiki than with GIC, the system has difficulties finding out the start of words. Indeed, Wiki has been preprocessed and normalized by removing capitalization so the information seems to be important for the system.

To conclude, we can see that, in Expe. Id 2, there is on average 1.14 character error by word while, in Expe. Id 8, there is on average 1.73 character error by word: that can be explained by the 45.8% drop of WRR between these two experiments.

Type Error	Expe. Id	Correct Word	Retrieved Word
Multiple Char.	4	cavalcade	cacaadade
	3	clemence	ccceeene
Swich Char.	6	suitte	usitte
	5	belle	blll
Starting Char.	5	[diverstissemens]	ddevvestissemens]
	6	Soldat	[ollat

Table 3: Examples of mistakes made by our decoder.

Expe. Id	% Error Redundant Character	% Error Switch	% Error Starting Char.
2	9.13	81.22	9.65
5	4.81	88.32	6.87
8	8.44	65.14	26.42

Table 4: Quantitative analysis of the different error types on 3 ICR results.

6 Conclusion and Future Work

In this paper, we presented a transfer learning approach dealing with the lack of ground truth of our Italian Comedy data, for sequence generation. We selected some available resources with the same domain and from the same time period to achieve the transfer learning. We chose an approach that did not use

an indication of the order of characters in words rather than usual sequence-to-sequence approaches to facilitate the transfer learning.

Our results show that a character-based decoder can infer a word from a letter-ngrams vector. Moreover, the lexical coverage between the training and test data is reached by the word recognition rate and mostly exceeded without the dictionary. The dictionary misleads the decoder rather than helping it because only some forms of a word are included in the dictionary. We demonstrated that transfer learning is more efficient from historical spelling to modern vocabulary than the opposite. The difference in languages implies a low coverage of the words but it still enables a correct decoding of the words as long as the resources come from the same time period. Therefore, the letter-ngrams models are efficient across languages sharing the same alphabet. Nevertheless, the decoder encounters some difficulties with specific words. We might be wondering whether the letter-ngram size limit of 3 is large enough, or whether a higher amount of training data could solve this issue. Despite this, our simple decoder built with only 4 layers obtained good results. This strengthens our idea of looking for new untapped resources instead of relying on resources traditionally used such as Wikipedia.

Currently, we are carrying out experiments with this approach at the word-level only and without punctuation marks. The next step for the decoder would be to extend it to the sentence-level, more specifically to deal with the space character. Initially, we aim at implementing a new handwriting recognition system with an encoder-decoder model. We consider that the decoder presented in this article is operational. Our future work is going to look at the encoder components independently. The main difficulty could be to handle the errors by encoding them in the vector of letter-ngrams. Indeed, unlike the experiments carried out in this paper, the input data of the decoder will be noisy.

Abstract

Mental health is a significant and growing public health concern. As language usage can be leveraged to obtain crucial insights into mental health conditions, there is a need for large-scale, labeled, mental health-related datasets of users who have been diagnosed with one or more of such conditions. In this paper, we investigate the creation of high-precision patterns to identify self-reported diagnoses of nine different mental health conditions, and obtain high-quality labeled data without the need for manual labelling. We introduce the SMHD (Self-reported Mental Health Diagnoses) dataset and make it available. SMHD is a novel large dataset of social media posts from users with one or multiple mental health conditions along with matched control users. We examine distinctions in users' language, as measured by linguistic and psychological variables. We further explore text classification methods to identify individuals with mental conditions through their language.

1 Introduction

Mental health is a significant challenge in healthcare. Mental disorders have the potential to tremendously affect the quality of life and wellness of individuals in society (Strine et al., 2008; Mowery et al., 2017a). Social media have become an increasingly important source of data related to mental health conditions (Cohan et al., 2017; Mowery et al., 2017b; Coppersmith et al., 2017; Yates et al., 2017), as it is now a prominent platform for individuals to engage in daily discussions, share information, seek advice and simply communicate with peers that have shared interests. In addition to its ubiquity and ease of access, the possibility to disclose mental health matters anonymously or pseudo-anonymously further drives users to online self-disclosure.

At the same time, the close connection between language and mental health makes social media an invaluable resource of mental health-related data. Lack of data has been one of the key limitations to understanding and addressing the challenges the domain is facing (Coppersmith et al., 2014a). Data from social media can not only be used to potentially provide clinical help to users in need, but also to broaden our understanding of the various mental health conditions. Social media analysis has already been proven valuable for identifying depression (Coppersmith et al., 2014a; Yates et al., 2017), suicide ideation (Cohan et al., 2017; De Choudhury and Kıcıman, 2017; Kshirsagar et al., 2017; Desmet and Hoste, 2018), and other conditions such as schizophrenia (Mitchell et al., 2015). While social media data is abundantly available, the amount of labeled data for studying mental health conditions is limited. This is due to the high cost of annotation and the difficulty of access to experts.

Prior research has investigated self-disclosure as a means of obtaining labeled data from social media. De Choudhury et al. (2013a) used it to identify new mothers and track post-partum changes in emotions.

* Equal contribution.

Seasonal Affective	100	n/a

Table 1: Comparison between the number of self-reported diagnosed users per condition in the dataset of Coppersmith et al. (2015a) and ours (SMHD).

I was officially diagnosed with ADHD last year.
I have a diagnosed history of PTSD.
my dr just diagnosed me as schizo.

Figure 1: Examples of self-reported diagnoses statements.

Coppersmith et al. (2014a) specifically focused on self-reports of mental health diagnoses. In particular, Coppersmith et al. (2015a) constructed a dataset of various mental health conditions using Twitter statements. Finally, Yates et al. (2017) introduced a large dataset of depressed users obtained from Reddit.

We extend the previous efforts on addressing the lack of large-scale mental health-related language data. Particularly, we propose improved data collection methods through which we can obtain high-quality large-scale datasets of labeled diagnosed conditions paired with appropriate control users. Consequently, we introduce SMHD (Self-reported Mental Health Diagnoses), a large dataset of diverse mental health conditions that can provide further insight into the mental health-related language. We leverage self-reported diagnosis statements where a user declares to have been diagnosed with a mental health condition such as depression. Examples of self-reported diagnoses are shown in Figure 1. Our dataset can be used not only to develop methods for better identifying mental health conditions through natural language, but also allows us to investigate the characteristics of language usage within each condition. We hope the availability of this new resource will foster further research into these problems and enhance reproducibility of suggested approaches.

Our work has the following significant distinctions compared to existing social media datasets related to mental health. Previous work has studied self-reported diagnosis posts in Twitter (Coppersmith et al., 2015a), where the post length is limited to 140 characters.[1] This makes the Twitter language use rather different from real life discussions. Instead, we use data from Reddit, an interactive discussion-centric forum without any length constraints. Our dataset contains up to two orders of magnitude more diagnosed individuals for each condition than the Twitter dataset by Coppersmith et al. (2015a), making it suitable for exploring more recent data-driven learning methods (see Table 1). We choose our control users in a systematic way that makes classification experiments on the dataset realistic.

We normalize language usage between the users: by removing specific mental health signals and discussions, we focus on patterns of language in normal (general) discussions. While our dataset creation method is close to Yates et al. (2017), we extend theirs by investigating multiple high-precision matching patterns to identify self-reported diagnoses for a range of conditions. Part of our patterns are obtained through synonym discovery. Considering relevant synonyms from reliable sources increases the variety of the diagnosed users and linguistic nuances. We also explore nine common mental health

[1]This limitation was doubled to 280 characters in late 2017.

conditions while Yates et al. (2017) focus only on depression. We explore classification methods for identifying mental health conditions through social media language and provide detailed analysis that helps us understand the differences in language usage between conditions, and between diagnosed users and controls.

Our contributions are as follows: *(i)* We investigate the creation of high-precision matching patterns to identify self-reported diagnoses of nine different mental health conditions. *(ii)* We introduce a large-scale dataset of nine mental health conditions that has significant extensions to existing datasets and we make our data publicly available. Our dataset includes users who might suffer from more than one condition, thus allowing language study of interacting mental conditions. *(iii)* We investigate language characteristics of each mental health group. *(iv)* We explore classification methods for detecting users with various mental health conditions.

2 Related work

Social media offers a considerable amount of accessible common language, attracting the attention of those who study the language of individuals with mental health conditions. Twitter is a natural source, being a popular platform that enables users to share short messages publicly. Early work used crowd-sourcing to identify Twitter users who report a depression diagnosis in a survey, and proposed features that are able to identify depressed users prior to the onset of depression (De Choudhury et al., 2013b). Others found that these characteristics hold in both English and Japanese tweets (Tsugawa et al., 2015), indicating similar cross-cultural tendencies.

Due to the cost and bias introduced by relying on surveys, work shifted to identifying mental health conditions by examining the content shared by social media users. Coppersmith et al. (2014a) identified approximately 1,200 Twitter users with 4 mental health conditions (bipolar, depression, PTSD, SAD) using diagnosis statements found in tweets (e.g., "I was diagnosed with depression"). Following this work, detailed studies were conducted on users experiencing PTSD (Coppersmith et al., 2014b), and schizophrenia (Mitchell et al., 2015; Ernala et al., 2017). The shared task at the 2nd Computational Linguistics and Clinical Psychology Workshop (CLPsych 2015) focused on identifying depression and PTSD users on Twitter (Coppersmith et al., 2015b). This included a set of approximately 1,800 Twitter users with self-identified diagnoses. Leading submissions to CLPsych 2015 relied on the LIWC lexicon (Pennebaker et al., 2015), topic modeling, manual lexicons, and other domain-dependent features (Resnik et al., 2015; Preotiuc-Pietro et al., 2015). Coppersmith et al. (2015a) expands the research on Twitter to eleven self-identified mental health conditions. (Benton et al., 2017) uses this dataset (and others) with a neural multi-task learning approach to identify language characteristics. Mowery et al. (2016) investigates specific symptoms of depression in tweets, including depressed mood, disturbed sleep, and loss of energy.

While the abundant short texts of Twitter can provide some insight into language characteristics of those with mental health conditions, long-form content can provide additional linguistic insights. Some have investigated the language of users of an online crisis forum to identify posts of users who are at highest risk to allow for faster intervention (Milne et al., 2016; Cohan et al., 2017). Losada and Crestani (2016) applied the self-reported diagnosis strategy to identify approximately 150 Reddit users who suffer from depression, and paired them with 750 control users. Yates et al. (2017) also used self-reported diagnoses to identify clinically depressed users, but applied it to a larger set of Reddit, yielding the Reddit Self-reported Depression Diagnosis (RSDD) dataset of over 9,000 users with depression and over 100,000 control users (using an improved user control identification technique). The corpus was also used to study the temporal aspects of self-reported diagnoses (MacAvaney et al., 2018).

Others have used data sources beyond social media to examine the language of people with mental health conditions. Resnik et al. (2013) uses topic models to predict depression and neuroticism based on student-written essays, finding clear clusters of words when students are asked to write about their feelings in a stream-of-consciousness setting. Althoff et al. (2016) uses text message conversations from a mental health crisis center to improve counseling techniques.

This work addresses important limitations of previous efforts. Similar to RSDD (Yates et al., 2017), we

build our corpus from Reddit using self-reported diagnoses. This results in a large amount of long-form post content that is not constrained by a character limit. Furthermore, because there are no character limits (as exist for Twitter), the mode of language is more typical of general writing. Unlike Yates et al. (2017), we investigate extended self-diagnoses matching patterns derived from mental health-related synonyms. We also focus on nine mental health conditions (rather than just a single condition). This results in a collection that can be used to compare and contrast the language characteristics of each condition.

3 Data

In this section we describe the construction and characteristics of the Self-reported Mental Health Diagnoses (SMHD) dataset. The studied conditions correspond to branches in the DSM-5 (American Psychiatric Association, 2013), an authoritative taxonomy for psychiatric diagnoses. Six conditions are top-level DSM-5 disorders: schizophrenia spectrum disorders (*schizophrenia*), bipolar disorders (*bipolar*), depressive disorders (*depression*), anxiety disorders (*anxiety*), obsessive-compulsive disorders (*ocd*) and feeding and eating disorders (*eating*). The three other conditions are one rank lower: post-traumatic stress disorder (*ptsd*) is classified under trauma- and stress-related disorders, and autism spectrum disorders (*autism*) and attention-deficit/hyperactivity disorder (*adhd*) under neurodevelopmental disorders. We use these lower-rank conditions to provide more definition when they are clearly distinguishable from sibling disorders.

3.1 Dataset construction

The SMHD dataset was created by using high precision patterns to identify Reddit users who claimed to have been diagnosed with a mental health condition (*diagnosed users*) and using exclusion criteria to match these diagnosed users with control users who are unlikely to have one of the mental health conditions studied (*control users*). SMHD consists of user labels indicating the mental health condition(s) associated with each user and all Reddit posts made by each user between January 2006 and December 2017 (inclusive). Users and posts were extracted from a publicly available Reddit corpus[2]. This approach is based on the method used to create the Reddit Self-reported Depression Diagnosis (RSDD) dataset (Yates et al., 2017). SMHD expands on RSDD by incorporating synonyms in matching patterns and including diagnoses for eight new conditions in addition to depression.[3]

Diagnosed users were identified using high precision diagnosis patterns in a manner similar to that used in prior work that studied depression on Reddit (Yates et al., 2017); we describe these patterns in more detail in section 3.2. After identifying candidate diagnosed users who matched a diagnosis pattern (see Figure 1), we removed any candidates who *(1)* matched a negative diagnosis pattern[4] or *(2)* had fewer than 50 posts talking about topics other than mental health (*mental health posts*). This is done to ensure enough data remains for a diagnosed user after removing their mental health-related content. After removing these candidate diagnosed users, 36948 diagnosed users remain.

Mental health posts were defined as posts that were either made to a subreddit (i.e., a subforum devoted to a specific topic) related to mental health or that included language related to mental health, such as the name of a condition (e.g., *OCD*) and general terms like *diagnosis*, *mental illness*, or *suffering from*. We constructed a list of subreddits related to mental health by beginning with lists from prior work studying depression on Reddit (Pavalanathan and De Choudhury, 2015; Yates et al., 2017) and expanding them to include discussion and support subreddits for each of the other mental health conditions. All mental health posts are removed for diagnosed users and control users alike. Classification therefore happens on the set of posts that do not contain any of the mental health terms, and that have not been posted in any of the mental health-related subreddits. Our methodology does not guarantee, however, that all potentially relevant terms or subreddits have been excluded.

Control users were chosen from a pool of candidate control users based on their similarity with

[2] `https://files.pushshift.io/reddit/`

[3] Patterns are available from `http://ir.cs.georgetown.edu/data/smhd/`.

[4] e.g., *I was never clinically diagnosed.*

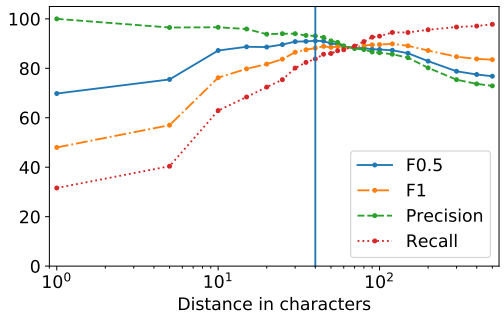

Figure 2: Precision, recall, F1 and F0.5 of the condition diagnosis patterns as a function of the maximum allowable distance (in characters) between a diagnosis and a condition keyword. Chosen threshold indicated at 40 characters.

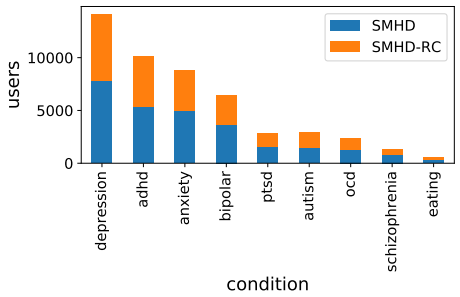

Figure 3: Number of users per condition for SMHD (in blue) and SMHD-RC (in orange).

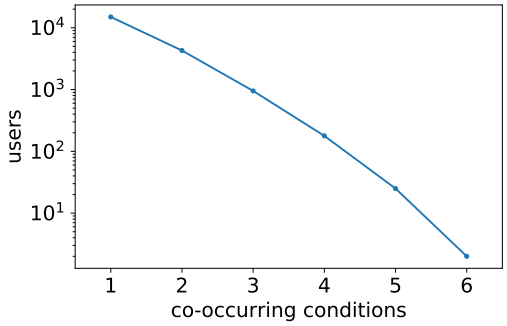

Figure 4: Number of users with a single or multiple co-occurring conditions.

Figure 5: Concomitance of condition diagnoses. Rows contain relative co-occurences of the row condition with other conditions.

the diagnosed users as measured by their number of posts and the subreddits they posted in. This is done to prevent biases between the control and diagnosed groups in the dataset and prevent making the task of identifying such users artificially easy. In more detail, every Reddit user who *(1)* had no mental health post[5] and *(2)* had at least 50 posts became a candidate control user. Given this pool of candidate control users, we matched each diagnosed user with 9 candidate control users (on average) after excluding controls who had never posted in the same subreddit as the diagnosed user or who had more than twice as many posts or less than half as many posts as the target diagnosed user.

The selection criteria for potential control users are stringent: users are removed if they do not have the required subreddit overlap or minimum post count, or if they use any of the mental health-related terms in any of their posts. The latter is necessary because we found that the prior probability of using an exclusion term in any given subreddit (e.g. *depressed*) is almost always higher for diagnosed users than for controls, even in popular subreddits on general topics (e.g. *r/politics*). As a result, the pool of candidate controls for matching to diagnosed users is significantly diminished. Because control users are picked from the pool without replacement, we were unable to meet the target of 9 appropriate controls for some of the diagnosed users. We release the users who have at least 9 control users as SMHD, and use this

[5]When defining language related to mental health, we consider *add* to be a mental health term. However, this term is often used as a verb that does not refer to Attention Deficit Disorder. We therefore do not exclude candidate control users who have used this term. We instead remove any post containing the term *add*, which matches our treatment of the diagnosed users where all mental health posts are removed.

dataset for all analyses in this paper. It contains 20,406 diagnosed users and 335,952 matched controls. A secondary dataset containing the remaining 16,542 diagnosed users with fewer than 9 controls will be made available as SMHD-RC (*Relaxed Controls*) for studies that require additional data for analysing differences between mental health conditions, rather than between diagnosed users and controls.

3.2 Diagnosis patterns

To identify Reddit users who report a diagnosis for one or more mental health conditions, we developed detection patterns with a focus on high precision. The patterns consist of two components: one that matches a self-reported diagnosis, and another that maps relevant diagnosis keywords to the 9 mental health conditions. A user is included for a condition if one of the condition keywords occurs within a certain distance of the diagnosis pattern (as discussed below).

For each condition, a seed list of diagnosis keywords was collected from the corresponding DSM-5 headings. To increase the likelihood of matching diagnostic posts, we expanded each set of medical expressions to include synonyms, common misspellings, vernacular terms and abbreviations. Our steps mirror the ones of Soldaini and Yom-Tov (2017), who were also interested in identifying self-diagnosed users, albeit on query logs. In particular, we leveraged two synonym mappings to generate alternative formulations of the disorders of interest:

- *MedSyn* (Yates and Goharian, 2013) is a laypeople-oriented synonym mapping ontology. It was generated from a subset of *UMLS*[6] filtered to remove irrelevant semantic types.
- *Behavioral* (Yom-Tov and Gabrilovich, 2013) maps expressions commonly used by laypeople to describe their medical condition to concepts in UMLS. The synonyms were generated by first identifying the most frequent search terms Yahoo! search used to retrieve Wikipedia medical pages. Then, frequent lexical affinities (Carmel et al., 2002) to the aforementioned were added to synonyms lists.

The resulting expansions were vetted manually to remove terms that did not describe the condition precisely (e.g., hypernyms) or that were ambiguous (e.g., "add"), and missing items were added.

Using the diagnosis patterns without condition keywords, all self-reported diagnosis posts were collected from the Reddit dataset, and 500 posts were randomly sampled for manual annotation. False positive matches were found in 18 of those, i.e. the precision for self-diagnosis detection was 96.4%. False positives included negations, hypotheticals (e.g., "I'm not sure if I was diagnosed"), and diagnoses that are uncertain or wrong ("I was diagnosed with autism, then undiagnosed."). Out of 500 diagnosis posts, 241 reported a mental health condition. The ones that were annotated as belonging to one of the 9 conditions were used to tune the condition term lists and the optimal distance between a diagnosis pattern and a condition term. Figure 2 plots the effect of this distance on precision, recall, F1 and F0.5 (which emphasizes precision). A maximum distance of 40 characters was chosen, where F0.5 score is highest. We thus achieve high precision (93%) with good recall (84%). Since the optimal distance threshold was tuned on this development set, it may overfit the data and the reported scores should be considered a ceiling performance.

To validate the final diagnosis matching approach on a held-out set, 900 posts (corresponding to 9 samples of 100 diagnosis posts, one for each condition) was manually checked for false positives. We obtain high precision, with a minimum precision of 90% for *anxiety* and macro-averaged precision of 95.8%. Most false positives are caused by terms for a condition occurring close to a diagnosis for another condition (e.g. "My doctor diagnosed me with depression, and I also have an anxiety problem."). While a user might also suffer from these conditions, they are not explicitly reporting a diagnosis.

3.3 Dataset statistics

Figure 3 shows the distribution of diagnosed users per condition in both datasets. Users who self-reported a diagnosis of depression, ADHD, anxiety or bipolar are most common. Interestingly, 26.7% of diagnosed users in the dataset reported more than one diagnosis (Figure 4). Such concomitant conditions are not uncommon, and were also reported in the work of Coppersmith et al. (2015a). As can be seen in

[6]Unified Medical Language System

condition	posts		tokens		characters
	per user	total	per post	total	per post
control	310.0 (157.8)	115,669k	26.2 (48.3)	3,031.6M	133.9 (252.9)
depression	162.2 (84.2)	1,272k	45.1 (80.0)	57.4M	227.5 (406.9)
adhd	164.7 (83.6)	872k	46.5 (82.7)	40.5M	237.5 (433.5)
anxiety	159.7 (83.0)	795k	46.4 (83.0)	36.9M	233.9 (422.8)
bipolar	157.6 (82.4)	575k	45.5 (86.5)	26.2M	230.6 (447.0)
ptsd	160.7 (84.7)	258k	53.1 (114.0)	13.7M	267.8 (581.7)
autism	168.3 (84.5)	248k	46.5 (82.3)	11.6M	237.9 (434.0)
ocd	158.8 (81.4)	203k	46.4 (90.1)	9.4M	234.2 (459.5)
schizophrenia	157.3 (80.5)	123k	49.2 (105.6)	6.1M	253.8 (566.6)
eating	161.4 (81.0)	53k	46.3 (73.7)	2.5M	232.6 (372.8)

Table 2: Average (Stdev.) and count of posts, tokens and characters for diagnosed and control users.

Figure 5, depression co-occurs with high frequency with most of the other conditions, almost 30% of users with depression, OCD or PTSD also suffer from anxiety, and schizophrenia is most likely to be diagnosed alongside bipolar disorder.

An important characteristic of the SMHD dataset is its scale. Reddit allows its users to write long-form posts, so unlike datasets collected on Twitter, a large amount of text is available for each diagnosed user. Table 2 gives an overview of the average and total number of posts, tokens and characters per condition, and for controls. Control users post on average twice as many posts as diagnosed users, but these posts tend to be considerably shorter. Although this may be a valid signal for certain mental health conditions, it can be removed for classification experiments by truncating the length and number of posts. This is common practice for technical reasons, and truncating post length has been shown in previous work to improve classification performance (Yates et al., 2017).

3.4 Ethics and privacy

Even though we rely on publicly available Reddit posts in our work, mental health is a sensitive matter and measures to prevent risk to individuals in social media research should always be considered (Hovy and Spruit, 2016; Šuster et al., 2017). The risks associated with the data collection methods and our resulting SMHD dataset is minimal. We refrain from publicly posting any excerpts of the data, we made no attempt to contact users, and we made no attempt to identify or link users to other social media accounts. We further replace usernames with random identifiers to prevent users' identities from being known without the use of external information. The SMHD dataset is available through a Data Usage Agreement (DUA)[7] protecting the users' privacy. In particular, the DUA specifies that no attempt should be made to publish portions of the dataset (which could result in users being identified), contact users, identify them, or link them with other user information.

4 Analysis

To investigate the differences between the language of mental health condition groups and the control group, we categorize language of users based on measures of psycholinguistic attributes through the LIWC lexicon (Pennebaker et al., 2015). These categories include variables that characterize linguistic style as well as psychological aspects of language (e.g., cognitive attributes and affective attributes). For each user, we obtain LIWC categories based on their posts and then compare these categories across users in each mental health condition group versus the control group using Welch's t-test (Welch, 1947). We adjust p-values with Bonferroni correction. To better see the differences between the categories, we also report the Cohen's d statistic (Cohen, 1988). Table 3 shows the results.

In general, we observe a variety of differences in language use between the diagnosed and the control groups. The effect sizes range from a very small effect to medium ($0.05<d<0.5$), which is typical of large datasets (Sakai, 2016). These differences span across both the linguistic style and psychological

Table 3: Differences between the linguistic and psycholinguistic variables obtained from LIWC between users treatment groups and control users. Statistical significance is based on t-test with Bonferroni adjustment. Numbers in the cells are effect sizes (Cohen's d). $\star$, $\dagger$, and $\ddagger$ respectively show adjusted p-values of <0.01, <0.001 and <0.0001. This is also indicated by shading colors, red shading shows that the corresponding category is observed with more intensity in the treatment group, where as blue shading shows more significance in the control group. For brevity, only significant attributes are shown.

attributes. Particularly, we observe that clout, an attribute regarding language that indicates high social status, is more prominent among control users compared to the depression and anxiety groups. Related work in psychology shows that depression and anxiety are more prevalent in lower socioeconomic status demographics (Murphy et al., 1991), which is in line with the observation in our dataset. Next, authentic language is stronger among most of the mental health groups compared with control groups. This correlates with the use of personal and first person pronouns. This is backed by prior research showing that fewer self-references are associated with unauthentic language (Newman et al., 2003). We also observe that among most of the conditions the usage of first-person singular pronouns is higher than in control groups. Related studies arrive at the same conclusion that people with mental health conditions tend to use more first-person pronouns and references, possibly because mental health conditions result in greater self-focused attention and rumination (Bucci and Freedman, 1981; Pennebaker et al., 2015; Watkins and Brown, 2002; Van der Zanden et al., 2014).

Social processes, the language related to human interaction and sharing, appears to be higher in depressed, anxiety and PTSD users. A potential explanation for this is that sharing and support-seeking behaviors have been shown to improve an individual's state of mind (Turner et al., 1983; De Choudhury and Kıcıman, 2017). People with conditions such as bipolar, depression and anxiety show significantly

Table 4: Classification performance on target users in SMHD. All methods rely on the official SMHD split introduced in Section 3 for training, tuning, and testing. We report the performance of each classifier as binary predictor (i.e., given a condition, predict if a user belongs to the diagnosed or control group) as well as in a multi-label, multi-class setting (i.e., given a user, predict if and which conditions they were diagnosed with).

more female references. This might point to a gender bias in the corpus towards males, which would shift an increased preoccupation with romantic relationships towards references of female partners. Cognitive processes (markers of cognitive activity associated with rational thought and argumentation) are also observed more in people with mental health conditions. This could be due to the observation that these groups tend to express their feelings more. Other attributes such as health, focus on past time, and biological processes are observed more in conditions such as depression. Unsurprisingly, attributes like leisure and money are more prevalent among controls.

5 Experiments

In order to provide a more thorough understanding of SMHD, we explored several classification methods for each of the conditions included in the dataset. We train our classifiers both in a binary and multi-label multi-class setting. For the binary tasks, all classifiers are trained only on the subset of diagnosed users in SMHD who are associated with any condition and their respective control users. Recall that, as discussed in 3.3, users can be diagnosed with one or more conditions; as such, we also evaluate the baseline classifiers in a multi-class, multi-label setting. In other words, given a user, classifiers are trained to predict if and which conditions the user was diagnosed with. In detail, we consider the following methods:

Logistic regression: we trained a simple discriminative model using bag-of-words features extracted over all posts by all users in the training set. Posts were concatenated and split on non-alphanumeric characters; we normalized tokens by folding them to lowercase. Words occurring less than 20 times in the training set were removed. Features were weighted using *tf-idf* and ℓ_2-normalized.

XGBoost (Chen and Guestrin, 2016): we evaluated the performance of an ensemble of decision trees. For this model, the same features described above were used. We set the number of estimators to 100.

Support vector machine (SVM): we included a SVM classifier with linear kernel among our baselines. Like the methods above, this model was trained on *tf-idf* bag-of-words features.

Supervised FastText (Joulin et al., 2016): we trained a shallow neural net model using FastText. After tuning on the development set, we set the dimension of the hidden layer to 100. The model leverages sub-word information by using character ngrams of size 3 to 6; it was trained for 100 epochs.

Convolutional neural network (CNN): Finally, we tested a CNN approach to learn ngram sequences indicative of each condition. We used a model architecture based on the work of Kim (2014), with

a filter size of 3 and a pooling size of 4. A model was trained for each condition, and each model was trained for 100 epochs. Each user's posts are concatenated and truncated to 15,000 tokens. This representation combines tractability with density. We do not pad posts individually hence no space is wasted by including short posts. Each token is represented by the FastText embeddings from above.

Results of the classification methods are reported in Table 4. All classifiers are trained, tuned, and tested on binary labels, except for the results reported in the rightmost column ("multi-label"). Overall, FastText obtained the best performance in terms of F1 score across all conditions except bipolar, in which it is outperformed by the SVM model, and eating disorder, where it is outperformed by a CNN. FastText also outperforms all other classifiers in the multi-label, multi-class test setting. We observe that models trained on bag-of-words features favor precision over recall, while the two neural models we tested offer more balanced performance. This can be explained by the fact that bag-of-words models are more likely to give more weight to strongly indicative text features, potentially causing some overfitting on the training data.

Comparing across conditions, we note that the performance on models is strongly affected by the number of diagnosed users in the training set. All classifiers struggle on the three conditions with fewest users (OCD, schizophrenia, and eating). This observation is consistent with the analysis on LIWC categories reported in Section 4.

Finally, we note that the simpler neural model (FastText) outperformed the richer CNN method. We explain this result by observing that FastText considers all posts by a user, while CNN samples a portion of them. This strategy, which is motivated by efficiency reasons, was based on the work of Yates et al. (2017), in which sampling was found to be an effective strategy to make the classification problem tractable. However, this result suggests that novel methods ought to be studied to achieve a robust sampling strategy across all conditions included in SMHD.

6 Conclusion

We presented SMHD, a large dataset of Reddit users with diverse mental health conditions and matched control users. Our dataset was constructed using high-precision diagnosis patterns and carefully selected control users. To our knowledge, SMHD is the largest dataset that supports a variety of mental health conditions and is up to two orders of magnitude larger than the largest published similar resource. We further examined differences in language use between mental health condition (diagnosed users) and control groups as measured by various linguistic and psychological signals. Several text classification methods were explored to identify the diagnosed users, with FastText being the most effective approach overall. We make our dataset available to the community, and hope that it will foster further research into these problems and enhance reproducibility of suggested approaches.

Abstract

Clickbait has become a nuisance on social media. To address the urging task of clickbait detection, we constructed a new corpus of 38,517 annotated Twitter tweets, the Webis Clickbait Corpus 2017. To avoid biases in terms of publisher and topic, tweets were sampled from the top 27 most retweeted news publishers, covering a period of 150 days. Each tweet has been annotated on 4-point scale by five annotators recruited at Amazon's Mechanical Turk. The corpus has been employed to evaluate 12 clickbait detectors submitted to the Clickbait Challenge 2017.

1 Introduction

For publishers of online content, the most popular revenue model is advertising. On freely accessible web pages ads are displayed along the content, and publishers earn fees for each ad seen by the visitors of these pages. Online content is often expected "to pay for itself:" it has to attract enough visitors such that the earned fees exceed the investment made in creating it. Assuming that each piece of content has its target audience, generating profit boils down to letting the respective target audience know where to find it. Ironically, this requires the content itself to be advertised.

Notwithstanding other means of advertisement, today, most publishers advertise their content on social media. By spreading "teaser messages" (be it with or without paying promotion fees), publishers engage in viral marketing. Teaser messages consist of two or three parts: (1) a short text, (2) an optional media attachment such as an image or a video, and (3) a link to the publisher's page where the advertised content is found. From a publisher's perspective, the ideal teaser message discloses its advertised content to the least possible extent, so that its target audience (better: everyone) is tempted to visit the publisher's pages. Conversely, from a reader's perspective, the ideal teaser message is a self-contained summary, so that visiting the publisher's page is subject only to cases where not everything important could be fitted into the summary, or where the reader wants to learn more about the backgrounds. The two ideals are naturally at odds, and the social network operators may need to reconcile between them.

Figure 1 shows examples of teaser messages in the above sense, advertising news content on Twitter. The left-to-right ordering of the messages in the figure is indicative of the degree to which an average reader might feel sufficiently informed without clicking the link (left), less informed but rather curious and urged to click (right), or something in-between (middle). The messages more to the right side of the figure are examples of what is called "clickbait" today. Clickbait is an umbrella term that encompasses all kinds of teaser messages in social media capable of instigating an (on average) increased click-through.

This paper introduces the Webis Clickbait Corpus 2017, a large-scale corpus of teaser messages, which has been built to address automatic clickbait detection. All messages in the corpus have been carefully sampled and annotated via crowdsourcing regarding their degree of clickbaitiness. After reviewing related work in Section 2, Section 3 defines clickbait and its operationalization, and Sections 4 and 5 detail the corpus construction process, including a first corpus analysis.

Figure 1: Examples of teaser messages from news publishers on Twitter. The tweets have been redacted, removing information identifying the publishers in order not to pillory them.

2 Related Work

To the best of our knowledge, Table 1 lists all clickbait-related resources available to date. The Webis Clickbait Corpus 2017 (Webis-Clickbait-17, for short) was preceded by the Webis Clickbait Corpus 2016 built by Potthast et al. (2016) to study clickbait detection for the first time. Given that clickbait itself is a fairly recent subject of inquiry, all of these resources have been published within the past two years. The resources can be distinguished in terms of genre, teaser type, approaches to acquisition and annotation, whether the linked articles are archived, and their size. A discussion of each aspect follows.

Genre. All resources to date, including ours, cover news. News are of particular importance, since the use of clickbait in this domain raises concerns: rather than maximizing the informative value of the teaser messages employed for news dissemination, news publishers also misuse them to maximize their ad revenue. Because of their important societal role, though, news publishers must be held to high standards, and the self-imposed codes of conduct of major news publishers clearly reject manipulative means to increase readership. Clickbait has been dismissed as "digital yellow journalism," i.e., as nothing new or noteworthy,[1] but this view is short-sighted: our previous work shows that nearly 25% of a sample of 2,992 tweets shared by the top-20 most retweeted news publishers are clickbait (Potthast et al., 2016)—a finding which is now confirmed by our 10 times larger corpus. Besides news, clickbait does occur in other genres, too. For example, on entertainment platforms such as YouTube (Qu et al., 2018). In fact, all kinds of social media where users are referred to another web page are susceptible to clickbait.

Teaser type. Two teaser types have been covered for corpus construction so far, namely the headline of a news article, and tweets about news articles. Headlines must be considered an approximation of an actual teaser message on social media; they are often used as textual component of a teaser, but not necessarily verbatim, and typically in combination with media attachments. The corpora using headlines lack associated media attachments, however. Only our previous corpus (Potthast et al., 2016) and the one presented in this paper incorporate realistic teaser messages. The teasers found on platforms like Facebook, LinkedIn, YouTube, and the like, are all similar to tweets, but differ in terms of allowed text length, media arrangement, and available meta data. Other teaser types are found on portal pages of websites where users are referred to more specific content found elsewhere (e.g., consider the teaser messages found on a news publisher's front page). Yet others may be found in discussion forums, comment boards, and emails, where more free-form text is allowed. However, when used as clickbait, these kinds of messages more often resemble spam, which is distinctly different from clickbait, but shares the goal of luring readers to their sender's web pages. One may expect that the clickbait message style will eventually become part of the repertoire of spammers.

Acquisition approach. Key to the representativeness of a language resource is the corpus acquisition strategy applied. Here, the news domain presents difficulties for sampling, since an average researcher hardly has access to all news published in a given period of time, so that directly sampling from the population of news is infeasible. To circumvent this issue, three strategies have been devised for clickbait corpus acquisition, namely reputation-based, gatekeeper-based, and importance-based acquisition.

With reputation-based acquisition, teaser messages (or news articles) are selected from publishers with a good reputation to obtain a relatively clean sample of non-clickbait, and from publishers with correspondingly bad reputation to obtain as much clickbait as possible. For instance, according to the

[1] http://theconcourse.deadspin.com/shut-up-about-clickbait-1551902024

Publication	Genre	Teaser	Acquisition	Annotation (Scale, People, κ)			Articles	Size
Agrawal (2016)	News	Headline	Gatekeeper-based	Binary	3	0.84	No	2,388
Potthast et al. (2016)	News	Tweet	Importance-based	Binary	3	0.35	Yes	2,992

Chakraborty et al. (2016)	News	Headline	Reputation-based	Binary	3	0.79	No	15,000
Rony et al. (2017)	News	Headline	Reputation-based	Binary	3	0.79?	No	32,000
Webis-Clickbait-17	News	Tweet	Importance-based	Graded	5	0.36	Yes	38,517

Table 1: Overview of clickbait corpora. All are in English; question marks (?) indicate lack of clarity.

literature, the latter publishers include BuzzFeed, Huffington Post, Upworthy, ViralNova, Scoopwhoop, and ViralStories. This approach has been applied by Chakraborty et al. (2016) whose corpus formed the basis for the one of Rony et al. (2017). The description of Biyani et al. (2016) is very superficial, but they do mention certain publishers, and the fact that almost half of their teasers are clickbait suggests that they have actively searched for such messages. Gatekeeper-based acquisition makes use of, e.g., web forums where news are curated. Agrawal (2016) obtain their selection of news from Reddit forums, where one forum pre-selects news of interest for the benefit of users, and where another collects clickbait to "spoil" it, e.g., by giving away the information withheld from a teaser. Both, reputation-based and gatekeeper-based acquisition, directly induce a ground truth. However, especially the reputation-based approach must be taken with a grain of salt, since many publishers with a comparably low reputation, such as BuzzFeed and Huffington Post, still publish a significant amount of news without resorting to clickbait teaser messages. Rony et al. (2017), Chakraborty et al. (2016), and Agrawal (2016) report to have double-checked the induced labels; each instance has been reviewed by at least three student volunteers. But the substantial inter-annotator agreements must be taken with a grain of salt, too, since as Agrawal (2016) reports, "the reason for such a high value of inter-assessor agreement is due to the fact that these headlines are already in their well defined categories owing to the nature of data collection." This conscientious observation hints at a bias that has been introduced by reputation-based acquisition and *not* disguising the sources or at least randomizing the messages before review.

By comparison, under importance-based acquisition as applied in (Potthast et al., 2016) as well as for our new corpus, publishers are ranked with respect to a specific criterion, such as sales or shares, and teasers are sampled from the top-ranked publishers. This way, it is ensured that a corpus covers the news seen by the largest portion of the target audience. Moreover, no assumptions are made about the nature of a publisher, so that the proportion of clickbait observed is not artificially amplified as is the case with the aforementioned acquisition approaches. Importance-based acquisition does not induce a ground truth, so that all teasers collected must be reviewed and annotated.

Annotation approach. Previous clickbait corpora consider only a binary scale for annotation, where a teaser is either clickbait or not. In our own annotation experiments, we found the binary scale to be lacking, since, as illustrated by the examples depicted in Figure 1, the degree to which a certain teaser message tries to manipulate its reader varies depending on the person reading it. For example, it may be that one person is hardly affected by any of these examples, whereas another more strongly experiences an urge to click. This is also why a single opinion does not suffice to arrive at an objective judgment about a teaser message, but a number of opinions should be collected and averaged.

Article archival. Teaser messages do not occur in isolation but link to some content on another web page. While the task of clickbait detection has typically been cast as an assessment of teaser messages in isolation, the linked content may still play an important role for subsequent analyses. Only our two corpora Webis-Clickbait-16 and 17 incorporate the linked web pages.

Size. Finally, in terms of size, our corpus is on par with that of Rony et al. (2017), albeit, as discussed above, our sampling and annotation approaches are significantly more sophisticated.

3 Defining, Understanding, and Operationalizing Clickbait

Clickbait turns out to be an elusive concept. Characterizing clickbait as an enumeration of properties exhibited by a teaser message proves difficult. Having reviewed thousands of examples, we would say that clickbait withholds crucial information, and that it is emotional, sensational, condescending, inflammatory, know-it-all, or any combination thereof. However, this list of properties is likely not exhaustive, leaves lots of room for interpretation, and none appear to be a strict necessity. Furthermore, these properties are difficult to be operationalized. But despite the apparent difficulty of capturing in a clear-cut definition the essence of what makes clickbait clickbait, the term has been in use since 1999, according to Merriam Webster's. Apparently, the underlying phenomenon, namely that messages are spread designed to entice readers into clicking a link, has been around ever since the ad revenue business model took off on the web. And the phenomenon has been nagging enough so that web users took note of it and coined the term. This is evidence that people are able to tell apart clickbait from other forms of messages found online and gives us hope that machine learning technology, too, can be taught to detect clickbait.

A better way of understanding and explaining clickbait is by describing it in terms of what happens at publisher site and at reader site. The following four definitions contrast the emergence of clickbait and publisher intentions with the effects of clickbait and reader perception:

- *Emergence.* Clickbait is the result of optimizing teaser messages to maximize click-through.
- *Intention.* Clickbait are teaser messages whose authors intend to lure as many people as possible to a web page, disregarding the content's target audience.
- *Effects.* Clickbait are teaser messages that manipulate its readers into clicking a link.
- *Perception.* Clickbait are teaser messages perceived by (some) readers as bait to click a link.

These definitions capture important aspects of clickbait that a mere listing of properties cannot convey, and they reflect how clickbait is described, e.g., at Merriam Webster and on Wikipedia. The question remains, though, which of these definitions is best suited to *operationalize* clickbait.

For publishers, the availability of facilities to analyze user interactions with postings in real time on social networks naturally has given rise to their optimization to maximize click-through. Today's shape and form of clickbait can be attributed to Upworthy (Koechley, 2012), who "pioneered" and popularized clickbait by flooding Facebook at a scale that prompted Facebook to change its algorithms to reduce it (El-Arini and Tang, 2014). Other publishers quickly learned from Upworthy's example. To learn more, we asked professional journalists who use social network analytics on a daily basis: On the upside, seeing a recently finished article spread is gratifying, and they are thankful for the opportunity to adjust teasers, e.g., to fix mistakes or misconceptions. On the downside, this feedback about personal success or failure is also available to their department heads. When encountering clickbait, some form of malicious intent, be it voluntary or forced, can hence be presumed. From a reader's perspective, clickbait is mainly a form of manipulation. The manipulative power of clickbait has been attributed to the curiosity gap (Loewenstein, 1994), a gap of knowledge created in a reader's mind by withholding crucial information from a teaser message. Once experienced, the gap causes an urge to be filled, which may be explained as a kind of curiosity. This is at least what is proclaimed by Koechley (2012) as to why clickbait worked for Upworthy, and what has henceforth been cited. The connection between Loewenstein's theory and clickbait has not been shown scientifically, though, so that it remains an open question how the relatively short teaser messages can have such a strong effect. More generally, we say that clickbait appeals to human urges and exploits cognitive dissonances to fulfill its goal.

Our best bet at operationalizing clickbait is the fact that clickbait is perceptible to (some) readers, whereas proving malicious intent of individual journalists or publishers as a whole (i.e., reputation-based annotation) is virtually impossible. An obvious limitation of the former operationalization is that we cannot capture clickbait that eludes conscious reflection while still successfully manipulating (some) readers. This is why each teaser is judged by more than one annotator, and why our assessors have the freedom to judge the baitiness of a teaser message on a Likert scale rather enforcing a binary decision.

4 Corpus Acquisition

In order to make a valuable contribution to the research community, we set out to render the Webis Clickbait Corpus 2017 authentic, representative, rich in terms of potential features, unbiased, and large-scale. An overview of the main characteristics of our acquisition approach is provided in Table 2. We follow and extend the approach taken to construct our previous, small Webis-Clickbait-16 corpus (Potthast et al., 2016), rendering both corpora comparable. In what follows, we outline the design choices we were required to make regarding the selection of publishers, the crawling of their news, and the sampling of news items for annotation.

4.1 Platform and Publisher Selection

As teaser type for our corpus, we chose Twitter tweets. Twitter was chosen because (1) the platform has a large user base, and (2) virtually all major US news publishers disseminate their articles through Twitter. Facebook would have been equally suited, but we opted for Twitter for its more rigorous limitations of shape and form of teaser messages. This way, we hoped to ensure less variability in terms of how clickbait can be constructed, lest the more free-form teaser messages on Facebook may have caused more ambiguity. At any rate, all publishers under consideration disseminate their news on both platforms simultaneously. A cursory comparison of teasers shared on both platforms for the same news item shows that their contents are typically roughly equivalent, so that our platform choice may not significantly limit the generalizability of results obtained based on our corpus.

Our sample of news publishers is governed by publisher importance in terms of retweets. Restricting ourselves to English-language publishers, we obtain a ranking of the top-most retweeted news publishers from the NewsWhip social media analytics service.[2] Taking the top 27 publishers,[3] we ensured that the news covered reflect what a large population of English-speaking internet users is confronted with on a daily basis. Although many of the top-most publishers (say, the top 10) remain the same over long time spans, others make an appearance on lower ranks and are displaced again as time goes by and publishers compete for user attention. Our sample of publishers reflects the ranking of October 2016.

4.2 Crawling, Archiving, and Preprocessing News Teasers and Articles

Given the Twitter handles of the 27 news publishers selected, we used Twitter's API to record every tweet they published in the period from December 1, 2016, through April 30, 2017. To enable the research community to develop and experiment with a rich set of features, we included the tweet text, media attachements, and the meta data provided by Twitter. Due to technical limitations we had to omit tweets that contained video content. Further discarding tweets that did not contain exactly one hyperlink, we crawled the news article advertised. Besides technical difficulties arising from the HTTP forwarding associated with links on Twitter as well as publisher-specific forwarding, we found it insufficient to only download the HTML content of the linked news articles: many news publishers paginate articles, and some are at the forefront of dynamic web page design, so that we found cases where the article content was not part of the initial download, but resulted from JavaScript-based content loading. That, and the fact that the articles of some publishers tend to disappear or be reorganized rather quickly after publication, led us to adopt a more reproducible archiving approach. Using the tools underlying the Wayback Machine of the Internet Archive, we recorded the whole communication that takes place between a client (browser) requesting the web page of a news article and the publisher's web server hosting it, storing it within web archive (WARC) files (including, e.g., HTML, CSS, Javascript, and images). This way, every article page that forms part of our corpus can be reviewed as it was on the day we crawled it, allowing for corpus reviews even after years, hence maximizing its reproducibility.

Nevertheless, users of our corpus will not have to handle the raw WARC files. For convenience, we applied publisher-specific wrappers extracting a set of content-related fields (cf. fields prefixed with "target" in Table 2). In this regard, we discarded Boilerpipe and other generic content extraction tools, since their performance was surprisingly poor.

[2] https://www.newswhip.com

[3] We aimed for the top 30, but accidentally used the wrong Twitter handles of three, so that we excluded them altogether.

Corpus Acquisition	
Platform:	Twitter
Crawling period:	Dec 1 2016 – Apr 30 2017
Crawled tweets:	459,541
Publishers:	27. Names: abc, bbcworld, billboard, bleacherreport, breitbartnews, business, businessinsider, buzzfeed, cbsnews, cnn, complex, espn, forbes, foxnews, guardian, huffpost, independent, indiatimes, mailonline, mashable, nbcnews, nytimes, telegraph, usatoday, washingtonpost, wsj, yahoo
Filters:	- No videos in tweets. - Exactly one hyperlink in tweet. - Article archiving succeeded. - Main content extraction succeeded.
Recorded fields:	12. Names: postId, postTimestamp, postText, postMedia, postPublisher, targetUrl, targetTitle, targetDescription, targetKeywords, targetParagraphs, targetCaptions, targetWarcArchive
Sampling strategy:	Maximally 10 tweets per day and publisher
Sampled tweets:	38,517

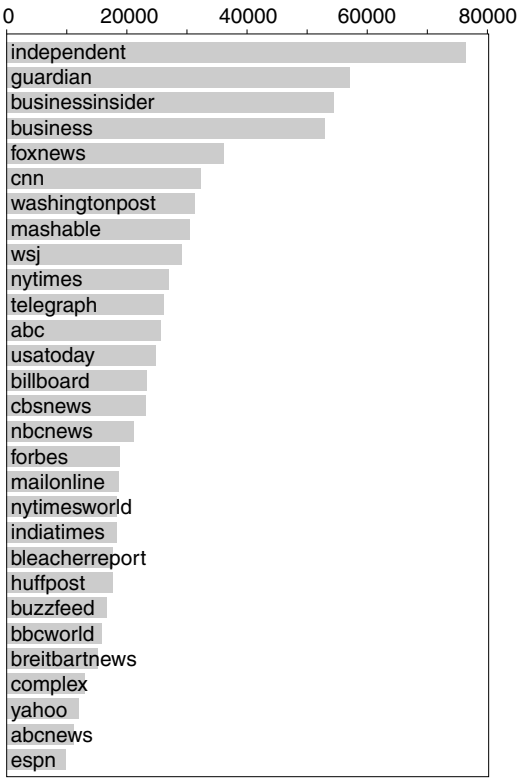

Table 2: Corpus acquisition overview (left), and number of tweets crawled from every publisher (right).

4.3 Sampling News

When sampling from a stream of news, special attention must be paid to avoid topic bias. This pertains particularly to the task of constructing a clickbait corpus, since clickbait is more a matter of teaser style rather than teaser topic. A clickbait detection model trained on too narrow a range of topics may not generalize well since it will likely pick up stylistic differences that result from differences between topics rather than differences between the style of clickbait and that of non-clickbait. Our previously published corpus Webis-Clickbait-16 suffers from this shortcoming, since it covers only one week worth of tweets. Although news coverage switches topics rather quickly, this is hardly enough to ensure topic diversity. To obtain a sample of tweets that has a high topic diversity, we crawled news as described above for five months in a row, yielding almost half a million tweets that fit our criteria and that were successfully archived.

From this population, we drew a random sample for annotation where, for budgetary reasons, the goal was to draw at least 30,000 tweets and at most 40,000. Since the distribution of tweets per publisher is highly skewed, we apply stratified sampling to avoid a corresponding publisher bias. Similarly, we ensure that tweets are sampled from each day of the five months worth of tweets to ensure coverage of the whole time period. Selecting a maximum of ten tweets per day and publisher yielded a set of 38,517 tweets and archived articles, which were then subjected to manual annotation.

5 Corpus Annotation

The annotation of the acquired tweets regarding their clickbaitiness was implemented with the crowdsourcing platform Amazon Mechanical Turk (AMT). To obtain high-quality annotations we invested substantial effort into preliminary evaluations of different task designs, alternative annotation scales, and, in particular, into the review of the annotations made. The following subsections detail our considerations, experiences, and insights.

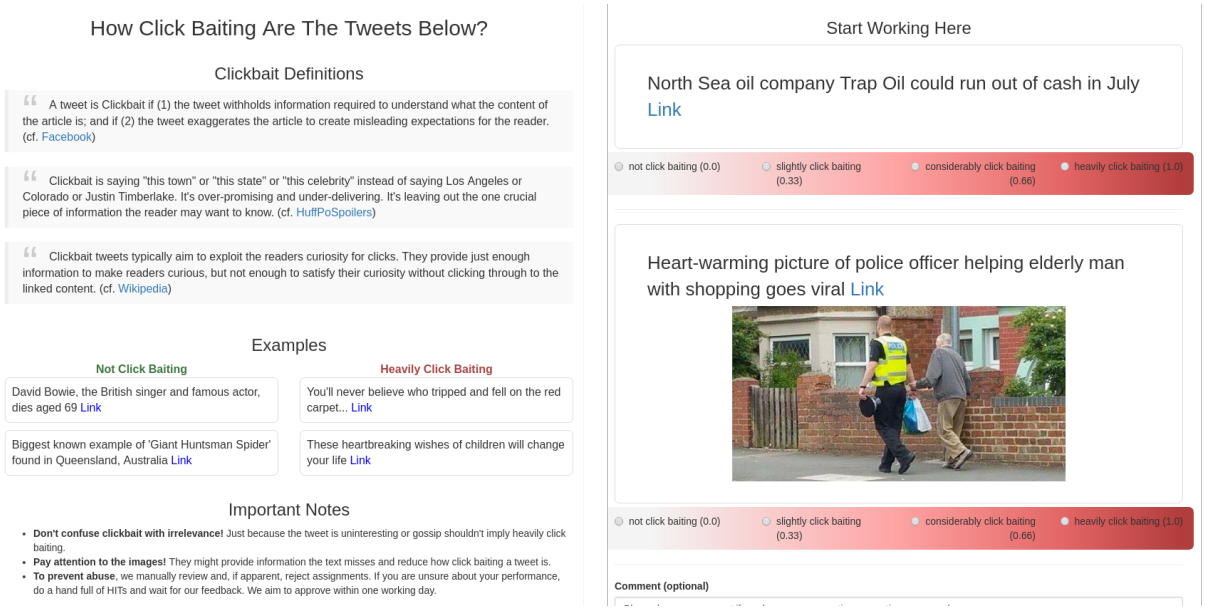

Figure 2: Screenshot of the final AMT task design.

5.1 Task Design

Designing a successful crowdsourcing task entails a number of design decisions, which can hardly be made without pilot studies. We conducted a series of AMT pilot studies to optimize the task design. In this regard, we employed the 2992 tweets of our previous clickbait corpus Webis-Clickbait-16. Figure 2 shows the final task design we used.

Clickbait is a concept with which crowd workers may not be familiar. To develop their "mental clickbait model," we quoted colloquial clickbait definitions from Facebook, HuffPoSpoilers, and Wikipedia as part of the task instructions (i.e., the aforementioned definitions are not suited for laymen). In addition, two typical clickbait and two non-clickbait examples were shown, drawn from our previous corpus. Since the annotations of the first pilot studies' tweets still showed an overly high variance, we extended the instructions again: first, since gossip was often misclassified as clickbait, we added a note that workers should not mix up irrelevance with clickbait. Second, since information in images attached to tweets was often overlooked, we added a note that special attention has to be paid to images. To avoid that workers get a high number of rejections because of misunderstanding the task, we suggested to complete at most two task instances and to await their approval before continuing.

The task instructions were followed by a list of tweets, each of which to be annotated regarding its clickbaitiness. We compared different annotation scales, the lengths of the tweet lists (five versus ten), and the number of *check instances* (one or two). As check instances we employed those tweets where all workers agreed; in order to bootstrap a pool of check instances, we started with tweets from our previous corpus. Check instances are of great value for the assessment of crowd workers. In our case it turned out that having two check instances per task instance—one that is clickbait and one that is not—allowed us to pinpoint underperforming workers of two kinds: (1) those with a tendency towards one of the extreme values, and (2) those who do not use the entire grading scale. Because of the (high) number of required check instances, we decided to have ten instead of five tweets per task in the final task design.

Within all studies, we payed one cent per tweet, an amount commensurate with the average time it took workers to complete a task so that a reasonable, albeit not generous, hourly wage would result. An exception was a particular pilot study where, in addition to the assessment of clickbait, workers had to mark words in the tweets which they considered indicative for their judgments. Having such a subtask was recently recommended for a search result relevance annotation task (McDonnell et al., 2016). In our case, this additional task increased the overall task completion time considerably while not improving worker agreement. We hence omitted this additional step in the final task design.

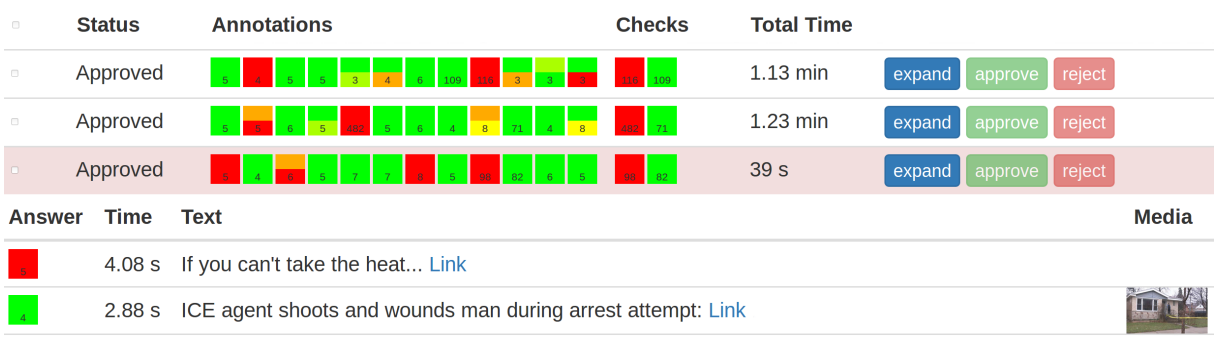

Figure 3: Screenshot of the system used for reviewing the crowdsourced clickbait assessments. Each row in the table refers to a HIT that has been worked on by a specific crowd worker.

5.2 Annotation Scale

Existing clickbait corpora use a binary scale for assessing clickbait. Although there are teaser messages that are obviously clickbait ("You won't believe what happened next!"), we noticed that making a binary decision about a teaser message is often not useful: even a teaser that can be rephrased in a more informative way may not be considered as clickbait if it conveys the idea of what the linked article is about. Hence, to account for different degrees of clickbait, we compared the use of a graded scale to the use of a binary scale. The graded scale has four values (Likert scale with forced choice) and ranges from "not" over "slightly" and "considerably" to "heavily" clickbaiting. For the ten annotations that we collected for each of the 2992 tweets in our previous corpus, the binary scale achieved an agreement of 85% (on average 8.5 annotators voted for the majority class). For the four point graded scale, the agreement dropped to 63%. However, when binarizing these annotations by combining the first two and the second two classes, an agreement of 84% is obtained. This shows that the graded scale is the more flexible choice: it can be abstracted into a binary scale without loss of agreement, and it allows for casting clickbait detection as a regression problem.

5.3 Reviewing Process

To guarantee a high quality dataset, all crowdsourced assessments were reviewed and, if necessary, discarded, resubmitting the respective assignment to AMT. Figure 3 shows a screenshot of the system that we have developed for efficient review of massive amounts of annotations: each row in the table shows a set of annotations (a single assignment) that has been submitted by a crowd worker. The Annotations column in turn shows a colored square for each tweet of the assignment. The upper half of a square color-codes the annotations made by the specific crowd worker, the lower half color-codes how (and how many) other workers annotated the tweet. By default, the color encodes the statistical mode of the annotations; other statistical location parameters such as mean and median are available from a menu. As mentioned above, each assignment included two check instances, which were displayed in the Checks column and which serve as an effective heads-up indicator: only if a worker frequently misclassified check instances, a more in-depth reviewing of the annotations was conducted. To this end, each of the rows in the table is expandable to display the tweets underlying the squares. As a further indicator, task completion time was measured and displayed as well (see the Total Time column). Obviously, a low agreement paired with a short completion time gives a strong bias that a worker did not work conscientiously. Altogether, more than 600 000 individual annotations were reviewed with the system for the clickbait corpus project; our rejection rate was 35.9%.

5.4 Corpus Analysis

The histogram in Figure 4 (left) shows the distribution of tweets across the four classes of our graded scale in the form of stacked bars. To classify a tweet into one of the four classes, the mode of its annotations is used, where, in case of multiple modes, the fifth annotation is used to determine the class. The different colors in the bars encode different levels of agreement. With a value of 0.21 in terms of Fleiss' κ, the annotator agreement is between slight and fair. However, when binarizing the classes

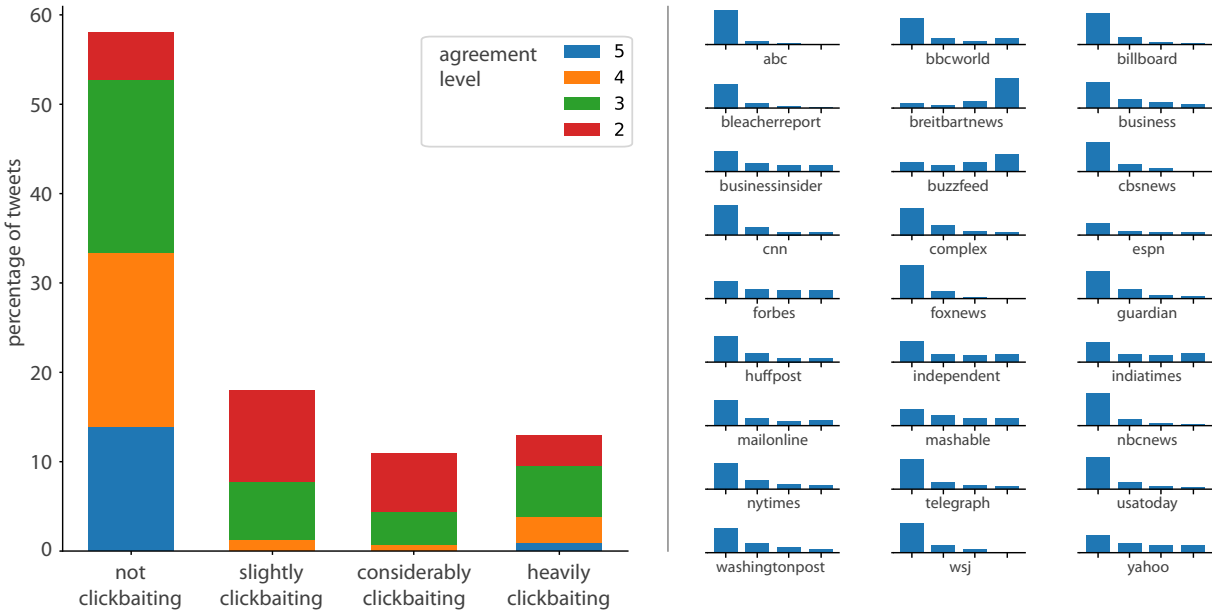

Figure 4: Left: Distribution of tweets over the four clickbait classes; the level of agreement about the class is color-coded. Right: Class distribution per publisher; no color coding is applied.

as described before, κ becomes 0.36, which corresponds to the respective value of 0.35 reported for our previous clickbait corpus (Potthast et al., 2016). Also note that the distribution of tweets across the binarized classes matches that of our previous corpus. Recalling that our previous corpus has been assessed by few trained experts, we conclude that our crowdsourcing strategy lives up to the state of the art and that it can be considered as successful: the two independently designed and operationalized annotation studies still achieve the same result, and hence our annotation experiment can be understood as a reproduction of our previous efforts, only at a larger scale. We summarize this results as follows: to scale the annotation of clickbait corpora, resorting to trained experts is not a necessary requirement.

Figure 4 (right) shows the distribution of tweets across the classes per publisher. Two of the 27 publishers, breitbartnews and buzzfeed, do obviously not follow the overall distribution; both send significantly more clickbait than the others. However, their contribution to the total amount of clickbaiting tweets (and hence to the corpus' publisher bias) is moderate only. Interestingly, TV networks in particular are among the publisher with least clickbait, avoiding even weakly clickbaiting messages.

6 Conclusion

Clickbait has quickly become one of the pests of social media, not unlike spam for email. While its working mechanisms are still barely understood, nearly every major publisher on social media employs it already to a greater or lesser extent to increase their readership. Although clickbait is apparently an effective marketing instrument, the ends do not justify the means: clickbait is also an effective instrument of manipulation. For example, the propagators of fake news make use of clickbait, too, to spread their disinformation. For news dissemination in general, clickbait must be rejected as well, since readers expect to be comprehensively informed, and journalistic codes of ethics typically prohibit unethical means of marketing.

To lay the groundwork for the emerging and ongoing investigation of clickbait by computer linguists and natural language processing alike, we have constructed the Webis Clickbait Corpus 2017, the first large-scale corpus of clickbait which has been carefully designed to be as representative as possible of teaser messages sent by the major publishers on Twitter. This way, our corpus will serve qualitative as well as quantitative research alike, allowing for deeper insights into the nature of clickbait, and the construction of technology to handle it, respectively. To foster the emerging research community on this subject, we share the resource itself and all the technologies that helped to compile it free of charge under permissible open source licenses.

To kickstart the use of our corpus, and to foster the development of new detection technology for clickbait messages, we have organized the Clickbait Challenge 2017, a shared task which used our corpus for evaluation. The corpus was divided into a training and test set, each comprising roughly half of the total number of tweets. Twelve teams of researchers participated in the challenge, submitting as many approaches for evaluation. A detailed review of the submitted approaches is out of the scope of this paper, however, it can be found in (Potthast et al., 2018).

Abstract

Considerable effort has been devoted to building commonsense knowledge bases. However, they are not available in many languages because the construction of KBs is expensive. To bridge the gap between languages, this paper addresses the problem of projecting the knowledge in English, a resource-rich language, into other languages, where the main challenge lies in projection ambiguity. This ambiguity is partially solved by machine translation and target-side knowledge base completion, but neither of them is adequately reliable by itself. We show their combination can project English commonsense knowledge into Japanese and Chinese with high precision. Our method also achieves a top-10 accuracy of 90% on the crowdsourced English–Japanese benchmark. Furthermore, we use our method to obtain 18,747 facts of accurate Japanese commonsense within a very short period.

1 Introduction

Commonsense has been considered to play a vital role in language understanding (LoBue and Yates, 2011), and considerable effort has been devoted to building knowledge bases (KBs) that organize commonsense (Zang et al., 2013). The largest multi-lingual commonsense KB is ConceptNet (Liu and Singh, 2004b). ConceptNet maintains knowledge as a triple of two concepts and relationship between them, which we call *fact*. The characteristic of ConceptNet is that concepts are represented in undisambiguated forms of words or phrases, which facilitates commonsense acquisition and inference in practice (Liu and Singh, 2004a) and recently has proven useful for building word representations (Speer et al., 2017; Camacho-Collados et al., 2017). We target ConceptNet in this paper.

A major problem lies in a large gap of quantity and quality between languages. The latest release (v5.5.0) of ConceptNet has 2,828,394 unique English facts[1], but the number of Japanese facts in ConceptNet is only 69,902 ($\approx 2.5\%$) even though Japanese knowledge takes up the eighth-largest portion of the database. This problem is not specific to ConceptNet. English KBs are typically larger and of higher quality than other languages. Although an adequate amount of knowledge of named entities is often available in many languages thanks to semi-structured text on the web such as Wikipedia infobox (Lehmann et al., 2014), commonsense is hard to obtain due to the lack of tractable and objective information (Gordon and Van Durme, 2013).

It is not realistic to develop large knowledge resources in every language from scratch because of cost constraints. Instead, this paper focuses on cross-lingual knowledge projection. We translate English commonsense facts into a target language, aiming to gain large commonsense resources in the target language efficiently.

The main challenge is projection ambiguity. For example, consider translating (bat, *CapableOf*, fly) shown in Figure 1. Bat has four Japanese translations such as koumori [bat (animal)] and batto [bat (stick)]. Fly has 27 translations such as tobu [fly (verb)] and hae [fly (insect)]. Thus, (bat, *CapableOf*, fly) results in $4 \times 27 = 108$ Japanese translation candidates in total, and even after filtering them

*This work was conducted while the first author was at Kyoto University.

[1] An English fact is a fact with two English concepts.

Proceedings of the 27th International Conference on Computational Linguistics, pages 1508–1520
Santa Fe, New Mexico, USA, August 20-26, 2018.

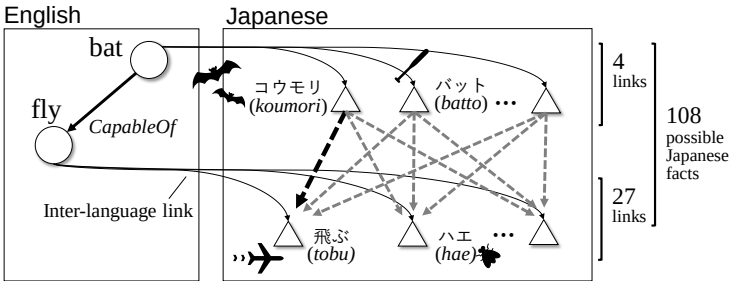

Figure 1: **Ambiguity of knowledge projection.** (bat, *CapableOf*, fly) in English and 108 possible translations in Japanese. The task is to identify the correct link between Japanese words (dash line) that corresponds to the English link (solid line.)

by considering part-of-speech constraints we still have 64 candidates. This problem happens very frequently because 42% of English concepts appearing in inter-language links have more than one Japanese translation.

This is in contrast to previous studies explored cross-lingual knowledge projection focused on knowledge of named entities (Feng et al., 2016; Klein et al., 2017; Chen et al., 2017). Their methods assume one-to-one mapping of concepts across languages. This assumption is reasonable if concepts are named entities because the majority of named entities has one or a few translations, *e.g.*, France (English) and Francia (Spanish).

In contrast, commonsense concepts are represented by common nouns, verbs, and phrases, and those words/phrases have many translations by nature as shown in Figure 1. Such translation ambiguity, that is, the knowledge projection ambiguity can be partially solved by machine translation (MT) and knowledge base completion (KBC) techniques. Cross-lingual knowledge projection can be seen as a structured version of an MT task. KBC models complete missing relations between concepts based on existing relations, which are also closely related to our task. Neither of them, however, can disambiguate knowledge projection with adequate precision. We do not have sufficient training data for building a translation model of facts because MT systems are generally developed not for structured knowledge but for unstructured text. KBC models need to be trained on a sufficiently large KB in a target language.

To alleviate these problems, we combine MT and target-side KBC. The MT and KBC models are trained on separate datasets, and our model weights the estimates from the two models to generate final results. To compute translation probabilities of facts with MT, we propose to convert a fact into plain text with hand-crafted templates.

Our contributions are three-fold.

1. We propose a cross-lingual projection method for undisambiguated forms of commonsense. Our method combines MT and target-side KBC to disambiguate knowledge projection across languages. To utilize an MT model trained on unstructured text, we develop rule-based conversion of structured knowledge.
2. We demonstrate that our method outperforms a projection method that assumes one-to-one mapping of concepts, and single KBC and MT models. Furthermore, an experiment on a crowdsourced dataset shows our method can find correct translations with a top-10 accuracy of 90%.
3. We obtained 18,747 accurate facts of Japanese commonsense using our method and crowdsourcing, which are an equivalent or larger amount of the existing facts in ConceptNet for 12 relation types. We release the resulting datasets as well as code to reproduce our experiments to the research community.[2]

2 Related Work

Developing human language technologies for low-resource languages has been an important challenge for years, and several studies attempted to bridge the resource gap across languages by cross-lingual

knowledge projection.

Klein et al. (2017) and Chen et al. (2017) represented concepts in multiple languages in a unified vector space, and built knowledge base completion models based on vector representations. Their methods ensure a concept in the source language has a similar vector representation to its target-side counterpart, assuming each concept in the source language corresponds to exactly one concept in the target language.

There is a rich body of work on sense embedding, which allows one surface form of a word to have sense-specific vectors (Neelakantan et al., 2014; Iacobacci et al., 2015). However, to the best of our knowledge, previous studies in this field do not target sense vectors of concepts for cross-lingual knowledge projection.

Several studies proposed methods for one-to-one projection of facts (Kuo and Hsu, 2010; Feng et al., 2016). The work by Feng et al. (2016) is the most related to our study. Their model learns mappings between English and Chinese facts by manually annotated alignments. Their experimental result showed the model successfully resolved the projection ambiguity. Their experiment was, however, limited to a narrow domain due to the cost of manual annotations, indicating the difficulty of obtaining sufficient resources for learning a model.

Various types of commonsense is vital to understanding languages in a wide range of tasks such as recognizing textual entailment (LoBue and Yates, 2011). Researchers have compiled resources to maintain such knowledge. Cyc (Lenat, 1995) is a seminal big project that aims to organize commonsense in logical forms. Logical forms are suitable for disambiguating the meaning of language, but we need high expertise to acquire or utilize them. In contrast, ConceptNet (Liu and Singh, 2004b; Speer et al., 2017) adopted natural language expressions such as words and phrases that may have ambiguities to represent knowledge, which made it possible to collect millions of commonsense facts in multiple languages via crowdsourcing.

3 Problem Setting

Suppose we project a fact f^s in a source language into a target language. We obtain n candidate translations by following inter-language links. In ConceptNet, the links are built from data sources such as Wiktionary and WordNet. We denote these candidates as $f_1^t, \cdots, f_n^t$.

Our goal is to estimate a projection score $h(f_i^t|f^s)$, and find the most appropriate target-side fact that maximizes the score.

$$\hat{f}^t = \underset{f_i^t}{\operatorname{argmax}}\, h(f_i^t|f^s) \tag{1}$$

4 Method

We propose two methods to combine MT and target-side KBC models for estimating projection scores.

4.1 Machine Translation (MT)

MT models consider contexts to find bilingual mapping of sentences. Given "I saw a bat in the zoo." as a source sentence, the model will assign a higher translation probability to "doubutsuen de koumori wo

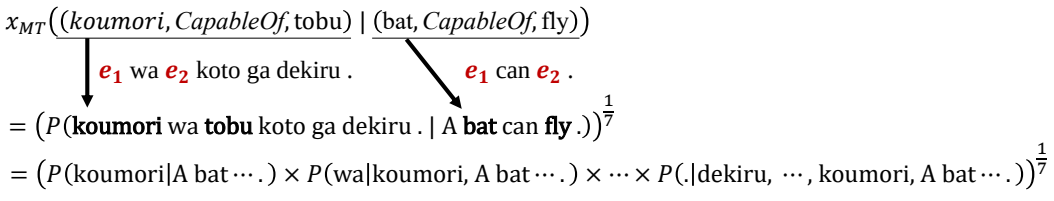

Figure 2: **Calculating a translation probability of a fact using an MT model.** For simplicity, this example does not use subword units. In addition, we omit special symbols that represent the beginning and end of a sentence in this figure.

mita." [I saw a bat (animal) in the zoo.] than to "doubutsuen de batto wo mita." [I saw a bat (stick) in the zoo.]

In contrast to our problem, typical MT focuses on plain texts, and only unstructured parallel texts are normally available for training MT models. Thus, we convert facts into natural language expressions beforehand. We use a rule-based approach to generate an expression for each fact, for example, "e_1 can e_2" corresponding to (e_1, *CapableOf*, e_2). Fortunately, some facts in ConceptNet already have such language expressions (Speer and Havasi, 2012). For the rest of the facts, we develop simple templates based on the existing expressions. Table 1 shows examples of templates in English, Japanese and Chinese.[3] We refer to part-of-speech tags of concepts to generate natural-sounding sentences.

Using sentences of facts, we define a score from the MT model as a translation probability of the language expression normalized by the target-side length m.

$$x_{\mathrm{MT}}(f^t|f^s) = \left(\mathrm{P}(W^t|W^s)\right)^{1/m}, \tag{2}$$

where W^t and W^s are sentences of f^t and f^s, respectively. To define $\mathrm{P}(W^t|W^s)$, we employ an off-the-shelf sequence-to-sequence model with an attention mechanism (Bahdanau et al., 2014), which is one of the recent successful MT models.

Figure 2 illustrates the translation probability of a Japanese fact (koumori, *CapableOf*, tobu) given an English fact (bat, *CapableOf*, fly). We first obtain language expressions of the facts using hand-crafted templates and compute a translation probability with the translation model.

4.2 Knowledge Base Completion (KBC)

KBC models evaluate the plausibility of a given fact based on existing information on the KB. For example, if we already know many animals with wings can fly and bats have wings, we can imagine that bats also can fly. We train a KBC model on the target-side KB.

We use a bilinear model used in several previous studies (*e.g.*, (Li et al., 2016)) as a component of our model, where concepts and relations are represented as vectors and matrices, respectively. This component can also be replaced with other KBC models.[4]

Given a fact $f^t = (e_1, r, e_2)$, the bilinear model outputs the value of plausibility as follows.

$$x_{\mathrm{KBC}}(f^t) = \sigma(\boldsymbol{u}_1^T \boldsymbol{M}_r \boldsymbol{u}_2), \tag{3}$$

where σ is a sigmoid function, $\boldsymbol{u}_i \in \mathbb{R}^d$ $(i = 1, 2)$ corresponds to vectors of concepts e_1 and e_2, $\boldsymbol{M}_r \in \mathbb{R}^{d \times d}$ corresponds to a matrix of relation r, and d is a hyper parameter. We construct concept vectors by averaging pre-trained d'-dimensional word embeddings as several previous studies did to boost the predictive performance (Socher et al., 2013; Li et al., 2016). The following nonlinear transformation reduces the dimensionality for computational efficiency.

$$\boldsymbol{u}_i = \tanh(\boldsymbol{W}\boldsymbol{v}_i + \boldsymbol{b}), \tag{4}$$

[3] We provide the templates in the released code.

[4] Potential alternatives can be found in the survey paper by Wang et al. (2017).

where $\boldsymbol{v}_i \in \mathbb{R}^{d'} (i = 1, 2)$ is a pre-trained concept vector, and $\boldsymbol{W} \in \mathbb{R}^{d \times d'}$ is a weight, $\boldsymbol{b} \in \mathbb{R}^d (d < d')$ is a bias term. The model parameters are learned to minimize a cross-entropy function on training facts.

4.3 Combination of Scores

We combine the two scores explained above to generate a score for each pair of f_i^t and f^s. Our model h takes $\boldsymbol{x}(f_i^t|f^s) = \left(x_{\text{KBC}}(f_i^t), x_{\text{MT}}(f_i^t|f^s)\right)$ as an input (for simplicity, we omit f_i^t and f^s, hereafter), and calculates a projection score, where x_{KBC} and x_{MT} are normalized before calculation.

We first describe two options for $h(\boldsymbol{x})$, (1) a linear transformation and (2) a multi-layer perceptron, and next explain the inference procedure of parameters below.

Linear Transformation: First, a *linear transformation* (LIN) model combines x_{KBC} and x_{MT} linearly. The model has a different weight vector and a bias term for each relation because the accuracy of KBC and MT varies for different relation types.

$$h(\boldsymbol{x}) = \boldsymbol{w}_r^T \boldsymbol{x} + b_r \quad \boldsymbol{w}_r \in \mathbb{R}^2, b_r \in \mathbb{R}. \tag{5}$$

Multi-layer Perceptron: LIN is a very simple model and may cause underfitting. Thus, we introduce a *multi-layer perceptron* (MLP) model with one hidden layer to increase the model capacity. The model has an input layer, one hidden layer, and an output layer. MLP calculates $h(\boldsymbol{x})$ by the equation below.

$$h(\boldsymbol{x}) = {\boldsymbol{w}_r^{(2)}}^T \boldsymbol{z}(\boldsymbol{x}) + b_r^{(2)} \tag{6}$$

$$\boldsymbol{z}(\boldsymbol{x}) = \tanh\left({\boldsymbol{W}^{(1)}}^T \boldsymbol{x} + \boldsymbol{b}^{(1)}\right) \tag{7}$$

$$\boldsymbol{W}^{(1)} \in \mathbb{R}^{2 \times c}, \boldsymbol{b}^{(1)} \in \mathbb{R}^c, \boldsymbol{w}_r^{(2)} \in \mathbb{R}^c, b_r^{(2)} \in \mathbb{R}.$$

Note that the common weight matrix and bias are used across relations in Equation (7) in order to capture the global intermediate representations of projections.

Inference: Given training instances of fact-to-fact projection, we estimate the model parameters that compute high scores to correct translations and low scores to incorrect translations. The training data consists of a correct translation set T_+ and an incorrect translation set T_-. $T_-(\boldsymbol{x}_+)$ denotes a set of incorrect translations that have the same English fact as $\boldsymbol{x}_+ \in T_+$.

For each $x_+ \in T_+$, we define the following margin-based loss function.

$$\text{loss}(\boldsymbol{x}_+) = \max\left(0, 1 + h(\boldsymbol{x}_+) - h(\boldsymbol{x}_-)\right), \tag{8}$$

where x_- is randomly extracted from $T_-(\boldsymbol{x}_+)$. We sum this loss function over T_+, and obtain the model parameters Θ by minimizing the summed loss function.

$$\hat{\Theta} = \underset{\Theta}{\text{argmin}} \sum_{\boldsymbol{x}_+ \in T_+} \text{loss}(\boldsymbol{x}_+) \tag{9}$$

5 Experiments

We conducted two experiments to compare our method with baseline methods.

5.1 Data

We use automatically and manually constructed datasets for evaluating knowledge projection methods. Throughout the experiments, facts are obtained from ConceptNet version 5.5.0.[5]

5.1.1 Automatically Built Datasets

The first experiment used semi-automatically built datasets of English–Japanese and English-Chinese projection. We call these AUTO datasets. The English–Japanese AUTO dataset was constructed in three steps:

[5] https://github.com/commonsense/conceptnet5/wiki/Downloads

Language	Fact (unique) f^t	Fact (unique) f^s	Translation T_+	Translation T_-
En→Ja	22,508	2,767,450	33,724	5,612,716
En→Zh	2,294	11,648	2,861	12,348

(a) AUTO

Fact (unique) f^t	Fact (unique) f^s	Translation T_+	Translation T_-
13194	200	832	12,365

(b) MANUAL (En → Ja)

Table 2: **Statistics of dataset.**

1. We translated each English fact f^s into Japanese facts $f^t_1, f^t_2, \cdots$ with inter-language links in ConceptNet. Those that violated part of speech constraints (Speer and Havasi, 2012) were discarded.
2. If a translated fact f^t_i already existed in Japanese ConceptNet, we considered the pair of the English and Japanese facts to be a positive projection, *i.e.*, $(f^s, f^t_i) \in T_+$. Otherwise, we include the pair in a set of negative projection T_-.
3. The previous step resulted in millions of obvious negative projection, which is often directed to rare Japanese words. To reduce such projection, we counted co-occurrences of all pairs of concepts in 200 million Japanese web sentences and discarded Japanese facts whose concepts do not occur together.

We applied the same procedure to Chinese facts, where we used the Chinese Gigaword Fifth Edition[6] in step 3. The size of the AUTO dataset is reported in Table 2(a). The English–Japanese dataset is larger than the English–Chinese dataset because the number of English–Japanese inter-language links in ConceptNet is four times larger than English–Chinese links. We can gain data by harvesting links from lexical resources such as dictionaries and multi-lingual WordNet, which is left as future work.

We conducted five-fold cross validation by splitting the datasets into training (60%), validation (20%) and test (20%) sets.

5.1.2 Manually Built Dataset

The AUTO datasets are large but may not be accurate enough to test methods because the target KBs were small by nature, and many true Japanese facts were not identified as correct projection in step 2. Thus, we next built an accurate but small testing dataset annotated by humans. We call this dataset MANUAL. Due to the cost constraint, this dataset was only built for English–Japanese projection.

We used crowdsourcing to annotate the data. Human workers were gathered in a Japanese crowdsourcing platform Yahoo! Crowdsourcing[7].

1. We extracted the 200 most confident English facts based on the scores in ConceptNet. We only used English concepts with fewer than 20 inter-language links.[8] In addition, we removed facts containing dirty words.[9]
2. We projected the English facts into Japanese with inter-language links as we did in step 1 of the AUTO datasets.
3. Crowd workers annotated the Japanese facts with five-level labels: (1) "false, or does not make sense", (2) "true only in a few contexts", (3) "true in several contexts", (4) "true in many contexts", and (5) "true". Each Japanese fact was judged by five workers.
4. We aggregated the collected judgments by taking median.

The size of the resulting dataset is reported in Table 2(b). An English fact had 66 translations on average. We used this dataset only for evaluation. To conduct this evaluation, we trained our models on the whole AUTO datasets.

[6]The LDC catalog number is LDC2011T13.

[7]`http://crowdsourcing.yahoo.co.jp`

[8]We found a few concepts had extremely many links (*e.g.*, `/c/en/person`), and most of the links are inappropriate.

[9]We use a dirty word list on google_twunter_lol (`https://gist.github.com/jamiew/1112488`).

5.2 Baselines and Proposed Methods

We compare the performance of our proposed methods with the following baselines.

- **PPMI:** Positive pointwise mutual information of two concepts consisting of a target-side fact f^t. We count the co-occurrence of the concepts in the 200 million web sentences for Japanese, and in the Chinese Gigaword Fifth Edition for Chinese concepts.
- **MT:** The neural MT model with an attention mechanism, which computes x_{MT} in the proposed methods. We used an implementation by Neubig (2015) and train a model on 3.25M (en-ja) and 2.97M (en-zh) sentence pairs from dictionaries and newswire corpora. BPE (Sennrich et al., 2016) was used to reduce the vocabulary size.
- **KBC:** The target-side bilinear KBC model which was used as the component to produce x_{KBC}. The Japanese and Chinese models were trained on 59,274 and 318,361 facts, respectively.
- **MTransE:** The multi-lingual translation-based KBC model (Chen et al., 2017) which learns TransE (Bordes et al., 2013) and concept-to-concept alignment jointly. Chen et al. (2017) proposed five different alignment models and reported the fourth variant performed best in their experiments. Thus we use the variant in our experiments.

The proposed methods **LIN** and **MLP** use estimates of MT and KBC models above. We also include **LIN (EQ)**, a variant of LIN, which equally combines scores from MT and KBC after normalizing each score to a $[0, 1]$-range. We use the Adam optimizer (Kingma and Ba, 2014) for training models. We provide implementation details and hyperparameter settings in the appendix.

5.3 Results

We report mean reciprocal rank (MRR), top-1 and -10 accuracy (Acc@1 and Acc@10) on the test set.[10] To calculate these metrics on the MANUAL dataset with five-way labels, we binarized the labels by considering (5) true label as positive and the others as negative because we aim to find the most appropriate projection for each English fact. We removed English facts which only had positive/negative Japanese translations when calculating MRR and accuracy. Besides, we also report nDCG (normalized discounted cumulated gain) using the five-way labels.

5.3.1 AUTO

Table 3 shows MRR, Acc@10 and Acc@1 on the test datasets for English–Japanese and English–Chinese projection. LIN (EQ), LIN and MLP outperformed MT and KBC in most cases, indicating combining them helped find correct translations. LIN (EQ) performed on par with LIN even though LIN (EQ) does not learn combination weights from the training data. This result could be attributed to the limited capacity of a linear model and motivates us to use MLP.

MTransE achieved high precision on the English–Chinese dataset, but failed to yield correct predictions on the English–Japanese dataset. The essential difference between the two language pairs is in

[10] Some previous studies reported meanrank, but MRR is more robust to outliers than meanrank.

Table 5: **Improved examples.** Top ranked projections by MLP are reported with labels and ranks given by MT and KBC.

the degree of the ambiguity, that is, the English–Chinese projection is not as ambiguous as the English–Japanese projection on our dataset because of the lack of English–Chinese links in ConceptNet v5.5.0. This characteristic boosted the performance of MTransE, which assumes one-to-one projection of concepts.

We observed the performance of the baselines varied across relations. MT was inaccurate at lexical relations such as *Antonym* and *Synonym* but outperformed KBC on *HasFirstSubevent*, *HasLastSubevent*, and *UsedFor*. MLP outpeformed single MT and KBC for the most of the relations by combining them.

5.3.2 MANUAL

Table 4 shows the result on the MANUAL dataset. The differences between the proposed methods and the baselines are statistically significant except for Acc@10 (paired t-test with $\alpha = 0.05$.) All the methods resulted in better scores on this dataset than on the AUTO dataset. Although PPMI appears to be accurate, in fact it failed to provide valid scores to 8,894 out of 13,197 examples as the co-occurrences of their concepts were not observed in the corpus. Likewise, the MANUAL dataset had many concepts that were not in the training data for MTransE, which seriously degraded its performance.

The examples in Table 5 show that MLP well combined the strength of MT and KBC models as we hypothesized. In Table 5(a), MLP put a weight on MT since it learned on the training set that MT tends to be more reliable at *RelatedTo* relation than KBC. The ratio *RelatedTo* facts was higher on the MANUAL dataset than the AUTO dataset, and we think this was the reason why MT outperformed KBC. Table 5(b) is an example in which KBC mitigated erroneous predictions by MT. MT preferred iwa [stone] to rokku [rock music], whereas KBC provided the high score to the latter. We found a pre-trained word vector of rokku was similar to those of music genres such as hevimetaru [heavy metal] and jazu [jazz], which could help KBC to identify the word sense of rock occurring with music.

Rank			Concepts		
MLP	KBC	MT	e_1	e_2	Label
1	11	5	*iso [rocky coast]	*sunago [sand/grit]	false
2	1	61	*iso [rocky coast]	suna [sand/grit]	true only in a few contexts
3	4	43	*umibe [seashore]	sand [sand/grit]	true in several contexts

(beach, *RelatedTo*, sand)

Table 6: **Failed example.** Top ranked projections by MLP are reported with labels and ranks given by MT and KBC. * denotes a rare Japanese word.

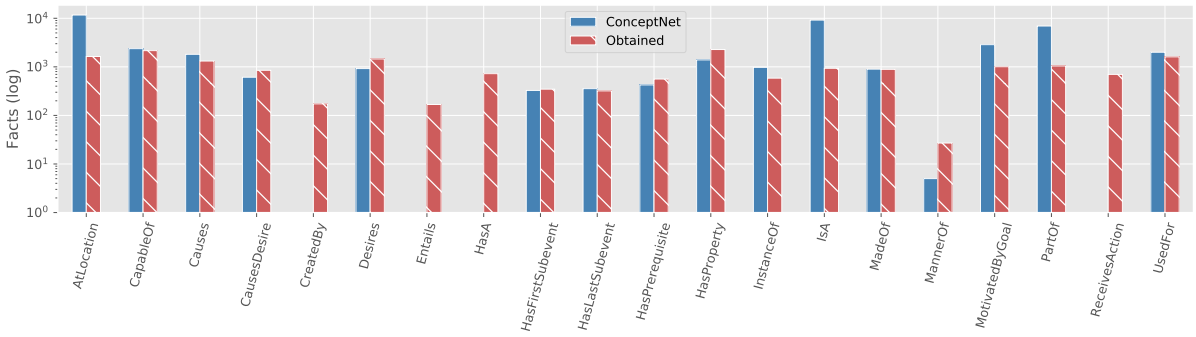

Figure 3: **Number of obtained and existing Japanese facts.**

Table 6 shows failed examples. KBC, MT, and the proposed methods produced low scores for the correct facts in these examples. This was because some negative examples contained rare words, and both MT and KBC gave them high scores. We found KBC was particularly inaccurate for facts containing OOV words. In practice, discarding rare words would be a reasonable choice in order to achieve high precision.

6 Japanese Commonsense Knowledge Construction

The previous experiments have shown our method can score projection candidates with high precision. We now use our method to collect Japanese commonsense resources of high quality.

We first sampled 10,000 English facts that cover 20 relation types.[11] In the same way as step 1 in Section 5.1.1, we obtained Japanese counterparts of them. We then used the MLP model, which achieved the best score on the MANUAL dataset, and computed scores of the projection candidates.

Although top-10 predictions are likely to contain correct projection as shown in Table 4, we further used crowdsourcing to refine the projected knowledge. We showed crowd workers top 10 confident Japanese facts that were generated from the same English fact, and the workers chose all correct Japanese facts if any. Each set of candidates was judged by five workers. Here, we converted facts into natural language by the hand-crafted templates described in Section 4.1 so that workers can easily understand the meaning. All the facts were checked by 838 workers only for 25 hours. Their annotations were aggregated by majority voting.

As a result, we obtained 18,747 facts. Note that one English fact can have multiple Japanese counterparts. Figure 3 shows the distribution of the obtained facts against the existing Japanese facts in ConceptNet. The current Japanese facts concentrated on a few relation types such as *IsA* and *RelatedTo*, and most of the relation types do not have many facts. Indeed, we have already collected an equivalent or larger amount of commonsense knowledge for 12 relation types.[12]

[11]The sampled English facts include *AtLocation*, *CapableOf*, *Causes*, *CausesDesire*, *CreatedBy*, *Desires*, *Entails*, *HasA*, *HasFirstSubevent*, *HasLastSubevent*, *HasPrerequisite*, *HasProperty*, *InstanceOf*, *IsA*, *MadeOf*, *MannerOf*, *MotivatedByGoal*, *PartOf*, *ReceivesAction*, and *UsedFor*.

[12]12 types include *CapableOf*, *CausesDesire*, *CreatedBy*, *Desires*, *Entails*, *HasA*, *HasFirstSubevent*, *HasPrerequisite*, *HasProperty*, *MadeOf*, *MannerOf*, and *ReceivesAction*.

7 Conclusion and Future Work

We proposed a method to project knowledge stored in English into other languages. We focused on commonsense knowledge that is required to understand human communications. The main challenge of cross-lingual knowledge projection is the ambiguity of projection. To resolve this ambiguity, our method combines MT and target-side KBC models. Experiments showed the proposed method outperformed baseline methods by large margins consistently. We projected 10,000 English into Japanese and obtained 18,747 accurate facts using our method and crowdsourcing. There are still more than 450,000 English facts with inter-language links to Japanese, and we are planning to project them into Japanese by our proposed method and crowdsourcing refinement. We will release the resulting resources to research communities in order to facilitate research in many languages.

A Experimental Setup

In experiments (Section 5), we built the baselines and our combination methods (Section 4) in the following procedures. Facts are from ConceptNet version 5.5.0. Japanese words in concepts are normalized using the morphological analyzer JUMAN++ (Morita et al., 2015). We used the Adam (Kingma and Ba, 2014) for training models. Initial learning rates α are described below.

A.1 MT Model

We built the neural MT model with lamtram (Neubig, 2015). The English–Japanese parallel corpora included 3,253,923 sentence pairs from dictionaries and newswire:

- JEC Basic Sentence Data[13]
- EDICT [14]
- Eijiro[15]
- Tatoeba Project[16]
- Open Multilingual WordNet (Bond and Foster, 2013)
- JENAAD (Utiyama and Isahara, 2003)

We extracted 2,965,845 English–Chinese sentence pairs from LDC[17]. We segmented words by byte-pair encoding (BPE) with vocabulary size 8,003 for each language. This vocabulary includes three special symbols indicating the beginning and the end of the sentence, and the out-of-vocabulary word. We trained the BPE model (Sennrich et al., 2016) on the training set with sentencepiece[18]. Hyper parameters were tuned based on perplexity on randomly selected 1,000 sentence pairs. The best setting was the encoder/decoder of LSTM with 512 hidden nodes, dropout of rate 0.25, and learning rate $\alpha = 0.001$ for the both language pairs.

A.2 KBC Model

A bilinear model (Section 4.2) was trained on 59,274 Japanese and 317,161 Chinese facts in ConceptNet. They are already sorted by a confidence score. We excluded facts in the training and evaluation datasets for knowledge projection (Section 5.1.)

Following Li et al. (2016), we define concept vectors by taking an average of predefined word embeddings. Japanese word embeddings of 256 dimensions were trained on 200 million sentences from the web. Chinese word embeddings of 300 dimensions were obtained from the CoNLL 2016 data.[19] We normalized concept vectors using the mean and variance calculated on the training set.

In hyper parameter tuning, the most confident 600 facts were used for evaluation, the second most confident 600 facts were used for early stopping in training, and the remaining facts were used for training. These facts were treated as positive examples, and we generated negative examples by randomly swapping one component of each fact. Once the best parameters were determined, the most confident 600 facts were used for early stopping, and the other facts were used to train a model.

We removed positive examples with out-of-vocabulary (OOV) words from the datasets. Instead, we added facts with a OOV vector as negative examples to the training data because rare words are often incorrect.

We selected dimensionality $d \in \{100, 150\}$, regularization coefficients for $\boldsymbol{M}_r$ and the other parameters $\lambda_1, \lambda_2 \in \{0.001, 0.0001, 0.00001\}$, learning rate $\alpha \in \{0.1, 0.01\}$, and batch size $\beta \in 200, 400, 800$.

[18] https://github.com/google/sentencepiece

[19] CoNLL 2016 Shared Task Multilingual Shallow Discourse Parsing, http://www.cs.brandeis.edu/~clp/conll16st/dataset.html

The resulting parameters for the Japanese facts were $d = 150$, $\lambda_1 = 0.00001$, $\lambda_2 = 0.001$, $\alpha = 0.1$, and $\beta = 200$. Those for the Chinese facts were $d = 100$, $\lambda_1 = 0.001$, $\lambda_2 = 0.0001$, $\alpha = 0.1$, and $\beta = 400$.

A.3 MTransE

MTransE (Chen et al., 2017) was trained with the implementation provided by Chen et al. (2017). We set batch size 100 to speed up training although the original code adopted online learning (*i.e.*, batch size is 1). We empirically found mini batch learning did not impair the performance. We enumerated all combinations reported by Chen et al. (2017) for tuning dimensionality d, weight of the alignment model γ, norm l, learning rate α. The resulting parameters for the English–Japanese dataset are $d = 100$, $\gamma = 2.5$, $l = L2$, and $\alpha = 0.5$. Those for the English–Chinese dataset are $d = 100$, $\gamma = 2.5$, $l = L2$, and $\alpha = 0.1$.

A.4 LIN and MLP

The proposed methods were trained using estimates of KBC and MT described above. The validation set was used for early stopping in training, and selecting the best hyper parameters. We conducted a grid search for learning rate $\alpha \in \{0.5, 0.25, 0.125, 0.0625, 0.03125\}$ and dimensionality $d \in \{8, 16, 32, 64, 128\}$ (only for MLP). The resulting configurations are reported below.

- **LIN:** $\alpha = 0.125$ for the English–Japanese dataset, and $\alpha = 0.5$ for the English–Chinese dataset
- **MLP:** $\alpha = 0.5$ and $d = 16$ for the English–Japanese dataset, and $\alpha = 0.5$ and $d = 32$ for the English–Chinese dataset

Assessing Quality Estimation Models for Sentence-Level Prediction

Hoang Cuong and Jia Xu
Cuny University of New York

Abstract

This paper provides an evaluation of a wide range of advanced sentence-level Quality Estimation models, including *Support Vector Regression*, *Ride Regression*, *Neural Networks*, *Gaussian Processes*, *Bayesian Neural Networks*, *Deep Kernel Learning* and *Deep Gaussian Processes*. Beside the accurateness, our main concerns are also the robustness of Quality Estimation models. Our work raises the difficulty in building strong models. Specifically, we show that Quality Estimation models often behave differently in Quality Estimation feature space, depending on whether the scale of feature space is small, medium or large. We also show that Quality Estimation models often behave differently in evaluation settings, depending on whether test data come from the same domain as the training data or not. Our work suggests several strong candidates to use in different circumstances.

1 Introduction

Quality Estimation (QE) (Blatz et al., 2004; Specia et al., 2009) is an important topic in Natural Language Processing (NLP). QE aims to predict the quality of Machine Translation (MT) outputs without human references. QE has a lot of potential. Such a case is automatically optimizing MT systems without having reference of translation outputs. Another example is MT for gisting by users of online translation systems. QE can also reduce post-editing human effort in disruptive ways. As most QE research has conducted at sentence level, we focus on the sentence level in this study.

Prior work developed strong QE predictors by creating powerful QE features. Hand-craft and syntactic feature templates have been proposed for a while (e.g. see Specia et al. (2009) and Martins et al. (2017)). The representation of words, phrases and sentences can also be learned automatically using Neural Networks, serving as powerful QE features (Kreutzer et al., 2015; Shah et al., 2015b; Kim and Lee, 2016; Kim et al., 2017; Chen et al., 2017; Biçici, 2017; Martins et al., 2017).

Meanwhile, using a relevant QE model is also very important in QE. Various QE models have been applied in different QE settings, such as *Support Vector Regression* (Cortes and Vapnik, 1995; Specia et al., 2009), *Ride Regression* (Hoerl and Kennard, 2000; Wisniewski et al., 2013), *Neural Networks* (NNs) (Avramidis, 2017; Paetzold and Specia, 2016; Paetzold and Specia, 2017) and *Gaussian Processes* (GPs) (Rasmussen and Williams, 2005; Cohn and Specia, 2013).

Given that there are many powerful regression models, it is tempting to have an understanding of which sentence-level QE models we should use. Prior work has been attempted to provide an answer (e.g. see Cohn and Specia (2013), Soricut et al. (2012), Wisniewski et al. (2013), and Beck et al. (2016)). However, the assessment of QE models is often limited in the number of QE features. For instance, Cohn and Specia (2013) conduct experiments with only 17 QE features. Also, the assessment is in only the *Standard* setting (i.e. test data come from the same domain as training data), which is often violated in practice.

Interesting and important questions are still open to date. For instance, given different scale of feature space, it is not clear which QE models we should use and how to build them properly (e.g. how *deep*

Proceedings of the 27th International Conference on Computational Linguistics, pages 1521–1533
Santa Fe, New Mexico, USA, August 20-26, 2018.

a NN we should use). Given different training/test settings, it is also not clear which models produce more robust QE performance than others.[1] Specifically, we are interested in both *Standard* and *Domain Adaptation* (DA) settings (i.e. test data come from a different domain to the training data). We also focus on *Knowledge Transfer* (KT) setting (i.e. QE model is trained on a dataset from a specific language pair but the model is tested on a test set with a different language pair).

This work provides an evaluation of a wide range of QE models and settings as the main contribution. Not only assessing popular QE models, we also propose to use several novel models for QE including *Bayesian Neural Networks* (Neal, 1996), *Deep Kernel Learning* (Wilson et al., 2016b), *Deep Gaussian Processes* (Damianou and Lawrence, 2013). Our results also raise concern about overfitting in applying QE models in different settings. We also show how complex the interactions are between QE features. Meanwhile, we also show that our proposed models work very well in certain circumstances.

In detail, we summarize the most interesting findings as follows. First, Support Vector Regression, despite being considered a strong QE model, is far from achieving top performance. It also provides a rather weak performance in DA and KT setting. Meanwhile, our experiments show that the QE feature space is highly complex. Specifically, we show that while the feature space could be large, most of the features in the space are usually useful so that applying sparse QE models is often less effective than non-sparse QE models.

Second, a shallow NN seems to gain a strong performance in the Standard setting. This is interesting, as previous attempt to use shallow NNs for QE (e.g. see Avramidis (2017)) failed to deliver a competitive result in the standard WMT setting (see Bojar et al. (2017) for a reference). Perhaps, their network parameter settings are not good enough to make the model work. We also attempt to use deep NNs for QE, and show that they do not contribute a better performance in the Standard setting. This is because training deep NNs for QE requires lots of labeled data to control the risk of overfitting.

Increasing the number of units in the hidden layer larger could degrade the performance. Specifically, we show that training a large NN could be overfitting, and available QE datasets are not large enough to reduce the risk. But can we still make a very large NN work for QE? This paper shows that we can do so by using Gaussian Processes (GPs).

We investigate GPs from the viewpoint of a non-parametric version of shallow NNs, and analyze their advantages over NNs: GP has an infinite number of hidden units in the hidden layer, GP has a built-in feature weighting mechanism and model is more robust to over-fitting. We also analyze their disadvantages, showing the cases where GPs completely fail to deliver good results. Finally, we also propose a solution to address their drawbacks.

Third, we observe a very weak performance of NNs in the DA and KT setting. While we are aware of concerns of applying NNs to different domains in other NLP tasks (e.g. Machine Translation (Koehn and Knowles, 2017) and Sentiment Analysis (Radford et al., 2017)), this is the first study to raise this issue in QE. We propose three methods that make NNs work well with the challenging setting.

First, we propose to use deep NNs for QE to DA and KT settings. We attribute this observation to the fact that deep NNs learn high-level (instead of low-level) features, which may work well across domains/datasets. Second, we propose to use GPs under these conditions because of their robustness.

These models, however, work well only when we train them with a small set of features. We then propose to use a combination of the two, a.k.a Deep Kernel Learning, to address the problem. For this deep model, the GP is put on top of a NN, aiming to combine the best of both worlds. We show that it provides an even stronger performance.

Third, we propose to use Bayesian NNs to the DA and KT setting. It is a type of neural networks with a prior distribution on its weights. The common perception is that it is hard to apply the model to NLP because of its difficulty in training. This paper shows that it is not the case, thanks to recent advances in Variation Inference (with stochastic variational inference (Hoffman et al., 2013), black-box variational inference (Ranganath et al., 2014) and the reparameterization trick (Kingma and Welling, 2014; Rezende et al., 2014)). We show that Bayesian NNs provide another powerful solution to the problem.

[1] We should note that we focus on the accurateness and robustness of QE models. However, calculation cost is not considered in comparing QE methods.

2 Related Work

Developing different regression QE model at sentence-level has been one of the main focuses in QE. *Support Vector Regression* is perhaps the most popular QE sentence-level model (Specia et al., 2009; Soricut et al., 2012; Kozlova et al., 2016). *Gaussian Processes* (GPs) (Cohn and Specia, 2013; Shah et al., 2013; Beck et al., 2015; Beck et al., 2016) and *Ride Regression* (Wisniewski et al., 2013) are also popular models in QE. NNs have been widely deployed as a non-linear classification model in QE (e.g. see Blatz et al. (2004), Esplà-Gomis et al. (2015) and Esplà-Gomis et al. (2016)). Recently, NNs have also been attempted to use as a regression QE model at sentence-level (Avramidis, 2017; Paetzold and Specia, 2016; Paetzold and Specia, 2017). Other less popular models are proposed, e.g. Regression Trees (Soricut et al., 2012; Wisniewski et al., 2013), Extremely Randomized Trees (Negri et al., 2014).

Given different QE models, it is tempting to have an understanding of which QE models we should use. There have been several attempts to answer this important question (e.g. (Cohn and Specia, 2013; Soricut et al., 2012; Wisniewski et al., 2013; Beck et al., 2016)). For instance, Cohn and Specia (2013) and Beck et al. (2015) show that choosing a model between GPs and SVR could make a difference. Meanwhile, Avramidis (2017) compares NNs with SVM. The comparison, however, limits in only a specific pair of models (e.g. GPs-SVR and SVR-NNs). Experiments are also with only medium-size feature space (17 features) and in the Standard setting. We extend the work extensively in regards to having a larger number of QE models, and having a systematic manner with different settings (testing with different feature space, different training/test settings). Moreover, our results not only provide a better understanding in regards to QE Models for sentence-level prediction, but also raise concern about overfitting in applying QE models in different settings.

Our work also puts attention to the setting where test data comes from different distributions or domains to the training/dev data (i.e. DA and KT). We share the same views with the work of Ríos and Sharoff (2016), Shah and Specia (2016), de Souza et al. (2014a), de Souza et al. (2014b) and de Souza et al. (2015) in regards to this setting. Specifically, we believe utilizing a dataset from one specific distribution/domain to use for other distribution/domain is very useful. The related studies focus on using multiple task learning (Shah and Specia, 2016; de Souza et al., 2014a), or utilizing unlabeled data (Ríos and Sharoff, 2016) to address the problem. Meanwhile, our work focuses on assessing the robustness of QE models to improve model performance in this setting.

Prior work revealed that the interactions between QE features are non-linear (e.g. see Shah et al. (2015a)). We extend the result in the sense that we show the interactions are not only non-linear but also highly complex. However, we show that we do not need a *non-stationary* function to model the relationship (i.e. whether there is a jump discontinuity or an isolated tall peak).

A distant research line is *feature selection*. Specifically, Soricut et al. (2012) use a computationally intensive method to find all 2^{24} possible combinations, from an initial set of 24 features to find the best combinations. Another distantly related work focuses on developing non-linear methods for feature selection in QE (Shah et al., 2015a). While the research line is distant to our study, we share the same views with the studies in that a complex combination of features, rather than a simple linear combination, may bring significant benefits to QE.

Our work also introduces Deep Kernel Learning, a hybrid NN with GPs, as a regression model to not only QE but also NLP for the first time. This combination model has been attempted recently in the Machine Learning community, pioneered by the work of Wilson et al. (2016a) and Al-Shedivat et al. (2017). Specifically, Wilson et al. (2016a) apply the framework to *airline* and *image* classification. Al-Shedivat et al. (2017) apply the framework to different regression problems in Machine Learning. Recently, Bradshaw et al. (2017) also apply the framework to image classification and *transfer* learning.

3 Models

This section contributes a survey of different models we used in the study.

3.1 Support Vector Regression

Support Vector Regression (SVR) is a standard model in QE. Our experiments are with a non-linear Radial Basis Function (RBF) kernel. Model parameters are optimised via grid search with 5-fold cross validation on the training set. SVR is a standard QE model. It is widely considered a very strong and robust model. However, this paper shows that some models can do far better.

3.2 Kernel Ridge Regression

The form of the model learned by Kernel Ridge Regression (KRR) is identical to SVR. However, KRR uses squared error loss while SVR uses epsilon-insensitive loss. The learned SVR is thus sparse while KRR is non-sparse. We are interested in KRR because a comparison between the model and SVR gives some hints about the feature space. If a sparse model (SVR) produces a better performance, the feature space may contain lots of irrelevant features. If this is not the case, then the feature space is highly complex as most of the features in the space are useful.

3.3 Neural Networks

Assessing the fitness of NNs to QE is the core of our study. We first study shallow NNs with three layers: 1 input layer, 1 hidden layer and 1 output layer. Prior work (e.g. see Avramidis (2017)) has tried shallow NNs, but failed to deliver a competitive result in the standard WMT setting (see Bojar et al. (2017) for a reference). This work, however, shows that shallow NNs bring competitive performance in the Standard setting. Extensive experiments are also conducted with deeper NNs with more hidden layers (e.g. 2, 3, 4, 5). Our goal is to investigate, for the first time, how deep models can help QE.

3.3.1 Gaussian Processes

Giving an infinite number of units plus a prior over weights and a Bayesian interpretation altogether turns Neural Networks to *Gaussian Processes* (GPs). Specifically, HTER scores Y are represented as a sample from a multivariate Gaussian distribution from input X as $Y \sim \mathcal{N}(0, K(X, X)$. Here, its mean is a zero-vector with length N as the number of data points, and K is an $N \times N$ matrix that we get by applying the kernel function to our data points.

The kernel function estimates the similarity of observed inputs. The intuition here is that the closer data points are, the closer their prediction is to the others. We use the standard Squared Exponential (SE) kernel function in our work:

$$k(x_i, x_{i'}) = \delta^2 \exp\Big[-\frac{1}{2}\sum\nolimits_{d=1}^{D}\Big(\frac{x_{i,d} - x_{i',d}}{\lambda_d}\Big)^2\Big]. \quad (1)$$

Here, $x_{i,d}$ denotes the d^{th} feature value of data point x_i, and D denotes the total number of features. The output variance δ and lengthscale λ_d are hyperparameters.

We now discuss how to do regression with GPs. First, note that for each new input x^*, its corresponding output y^* forms a distribution:

$$\begin{bmatrix} Y \\ y^* \end{bmatrix} \sim \mathcal{N}\left(0, \begin{bmatrix} K(X,X) & K(X,x^*) \\ K(x^*,X) & K(x^*,x^*) \end{bmatrix}\right). \quad (2)$$

We then can derive the conditional distribution $P(y^*|Y)$ as $P(y^*|Y) = \mathcal{N}(\bar{y^*}, \sigma^*)$, where: $\bar{y^*} = K(x^*, X)K(X, X)^{-1}Y$ and $\sigma^* = K(x^*, x^*) - K(x^*, X)K(X, X)^{-1}K(X, x^*)$. The model is robust because they marginalise over an infinitely large class of models.

For learning and prediction with GPs the inverse of the covariance matrix needs to be computed. This inversion of a matrix scales with the number of training data points, N, as O(N^3). Inference with a GP model is thus expensive, but this can be addressed by learning a small number M of pseudo data points and using them to train the model instead (Snelson and Ghahramani, 2006).[2] In other words, we can

[2]We can also use a very large but placed in a computationally efficient structure instead of a small number of pseudo data points (Wilson et al., 2015; Wilson and Nickisch, 2015).

approximate the inverse of the covariance matrix with the inverse of the $M \times M$ "pseudo matrix" instead. For this reason, we do not observe any problem with scaling GPs to QE datasets in our experiments. For our implementation, GPs are implemented in the standard GPflow, a Gaussian process library using TensorFlow (de G. Matthews et al., 2016).

3.3.2 Deep Gaussian Processes

This work will show that the relationship between the space of input features and corresponding output is non-linear and highly complex. A further question we asked is whether we need a *non-stationary* function to model the relationship (i.e. whether there is a jump discontinuity or an isolated tall peak). One additional contribution of this work is to provide an understanding of this issue.

Specifically, we introduce another kind of deeper NNs for QE, namely *Deep Gaussian Processes* (Damianou and Lawrence, 2013). Deep GPs combine GPs with deep architectures. Let us denote a GP model for Y as $Y \sim GP(0, K(X, X))$. Instead of having only a simple layer of GP, we can stack many more. This is mathematically equivalent to having the form:

$$Y \sim f^L(f^{L-1}(\dots f^1(X,\ X)\dots)), \tag{3}$$

where $f^l(\cdot) \sim GP(0, K^l(\cdot, \cdot))$. Stacking many more layers helps the model able to learn to approximate non-stationary functions (e.g. see Damianou and Lawrence (2013) and Vafa (2016)).

Training the model is more complicate, but doable with recent advanced approximate methods (e.g. Approximate Expectation Propagation (Bui et al., 2016), Doubly Stochastic Variational Inference (Salimbeni and Deisenroth, 2017)). In this work we choose the work of Salimbeni and Deisenroth (2017) to train the model because of its simplicity and efficiency.

3.3.3 Deep Kernel Learning

In theory, GP with the SE kernel function is an universal approximator (Micchelli et al., 2006). Unfortunately, the representational power offered by the kernel can be very limited as the kernel is perhaps too simple. This may make it less effective when applying the model to a high dimensional QE feature space. It is not easy to address the problem.

In this work, we propose to use Deep Kernel Learning (DKL) to address the challenge. This type of network is a deep network: it has input layer, hidden layers, and a GP model on the top. The formulation for the model is thus $Y \sim GP(0, NN(X))$ instead of $Y \sim GP(0, K(X, X))$, where $NN(X)$ represents a NN instead of a simple kernel function $K(\cdot, \cdot)$. In our experiments, DKL is a shallow NN plus a GP model stacked on the top.

Technically, all GPs parts are differentiable (Rasmussen and Williams, 2005), including the Cholesky decomposition that computes the inverse of the $M \times M$ "pseudo matrix". For this reason, the model can be trained in an end-to-end fashion with back-propagation. Specifically, the model can be trained end-to-end using stochastic variational approach (Wilson et al., 2016a) or semi-stochastic block-gradient approach (Al-Shedivat et al., 2017). We choose the work of Al-Shedivat et al. (2017) to train the model because of its efficiency.

We propose to use DKL for QE because of two potential benefits. First, such a combination may work well with high dimensional input space since the flow goes from a NN to the GP layer. Second, it may be more robust because the model enjoys the robustness of GPs in general. Indeed, while deep NNs are found to be overfitting, DKLs are found to be very robust in our experiments.

3.3.4 Bayesian Neural Networks

Bayesian NNs are a type of NNs with a prior distribution on the weights. We introduce the model to QE because of their robustness.

Specifically, we put network weights $\mathbf{w}$ with normal priors $p(\mathbf{w}) = \mathcal{N}(0, I)$ in our experiments. Pre-

dictive distribution of output y^* given a new input x^* can be computed as follows:

$$p(y^*|\ x^*, X, Y) = \int p(y^*|\ x^*, \mathbf{w}) p(\mathbf{w}|X, Y) d\mathbf{w}.$$

$$p(\mathbf{w}|X, Y) = \frac{p(\mathbf{w}) \prod_{i=1}^{N} p(y_i|x_i, \mathbf{w})}{p(Y|\ X)}.$$

Given a new input x^*, Monte Carlo estimation can be used to get an unbiased estimate of it by sampling from the variational posterior

$$p(y^*|x^*, X, Y) \simeq \frac{1}{M} \sum_{i=1}^{M} p(y^*|\ x^*, \mathbf{w}_i). \tag{4}$$

where each $\mathbf{w}_i$ is sampled from $p(\mathbf{w}|X,\ Y)$. We use Bayesian NNs with 50 hidden units in our experiments. We found that using a larger number of units hurts the performance.

The model comes with a cost: it is non-trivial to compute the posterior distribution of network parameters $p(\mathbf{w}|X, Y)$ because of the intractable marginal distribution $p(Y|\ X)$. Variational Inference can be used to address the problem. It uses a variational distribution $q_\theta(\mathbf{w}) = \prod_{i=1}^{L} q_{\theta_i}(\mathbf{w}_i)$ to directly approximate $p(\mathbf{w}|X, Y)$. Each $q_{\theta_i}(\mathbf{w}_i)$ is basically a normal distribution paramaterized by mean and standard deviation:

$$q_{\theta_i}(\mathbf{w}_i) = \mathcal{N}(\mathbf{w}_i|\mu_i, \delta_i^2) \tag{5}$$

Training the model is efficient, thanks to stochastic variational inference (Hoffman et al., 2013) and the reparameterization trick (Kingma and Welling, 2014; Rezende et al., 2014)).

As a side note, our Bayesian NNs implementation is based on ZhuSuan, a well-developed framework for Bayesian Deep Learning (Shi et al., 2017).

4 Experiments Settings

Our training data is a collection of a pair of source/target sentences together with a HTER score (Snover et al., 2006) - the minimum edit distance between the machine translation and its manually post-edited version. All the datasets we conducted experiments in our study are standard WMT shared task datasets. The datasets are all publicly available. We also release our implementation for the code,[3] making it available for reproducing results.

This work studies three different QE scenarios:

- Standard Setting: The test data comes from the same distribution as the training/validating data.
- Domain Adaptation Setting: The test data comes from a different distribution as the training/validating data.
- Knowledge Transfer Setting: The test data comes from a different language pair as the training/validating data.

Previous QE studies mainly focus on Standard setting. Our focus is also on DA setting, because we inevitably will come across data that is sampled from a different distribution to our training data when using QE models in the wild. Closely related to this is fine-tuning models on a new domain. However, we are interested in the aspect of NOT fine-tuning our models. This is because information of test data is not provided in advance when applying a QE model in the wild.

We are also interested in KT setting. Utilizing a dataset from one language pair to use for other language pairs is very useful, given that QE datasets are limited and language-specific.

Our experiments are with different feature sets. For medium-scale QE feature space, we use the standard 17 QE features (see Bojar et al. (2017)). For large-scale QE feature space, we enrich the feature

[3]The code is available at: *https://github.com/hoangcuong2011/QESentlevel*.

Table 1: Assessing QE Models for Sentence-Level Prediction (Medium-scale QE feature space).

set using unsupervised learning. Specifically, we trained a multiplicative LSTM (Krause et al., 2017) with $4,096$ units on a very large public *English* corpus (see McAuley et al. (2015)) to predict the next character for a string. These $4,096$ units are found to be meaningful in NLP tasks in general such as Sentiment Analysis (Radford et al., 2017). This work shows that they are very useful to QE as well. While we can add all units as extra features, this turns out to be expensive. We rather use only a *random* subset of them (53 and 123 units). In the end, our large-scale QE feature space experiments are with two feature sets with 70 and 140 features respectively.[4]

5 Standard Setting

We first present results with WMT QE 2017 shared task (EN-DE and DE-EN). There are various evaluation metrics that are often used in Quality Estimation, including Pearson's correlation, Mean Average Error and standard Root Mean Squared Error. Because of space constraints, we report only root-mean-square error (RMSE):

$$RMSE = \sqrt{\frac{\sum_1^N (HTER_{ref} - HTER_{pred})^2}{N}} * 100, \quad (6)$$

where N is the size of test data. Meanwhile, we emphasize that the important findings in our work are consistent with the other metrics.

5.1 Medium-scale setting

Table 1 presents the result with medium-scale QE feature space. We detail most important findings.

First, in this setting, we do not observe important advantages of using different models. There is not a clear winner, and the difference between the best model and other top models is quite *marginal*. As a site note, SVR is far from achieving top performance (e.g. 17.79 vs 17.01 for WMT QE DE-EN 2017 task).

Meanwhile, Table 1 reveals that the relationship between the space of input features and corresponding output is fully non-linear. Specifically, having a linear QE model provides a far suboptimal performance (e.g. 23.48 with EN-DE), compared to other complex models (e.g. Deep Kernel Learning: 17.35. We also do not observe any significant improvement by using SVR instead of KRR. The fact that a sparse model (SVR) does not help over a non-sparse model (KRR) indicates most features are useful. Combining with the fact that the feature space is non-linear, the QE feature space seems highly complex.

Shallow NNs with 512 units produce a competitive result. This is interesting, as previous attempt to use shallow NNs for QE (e.g. see Avramidis (2017)) failed to deliver a competitive result in the standard WMT setting (see Bojar et al. (2017) for a reference). Perhaps, their network parameter settings are not good enough to make the model work. For the sake of completeness, our network parameter setting is

[4]Surprisingly, we found that training a good QE model only with the set of 53 or 123 extra features improves the performance over the WMT 2017 shared task baseline (Bojar et al., 2017). These units are indeed very meaningful.

as follows. The models were regularized with dropout (Srivastava et al., 2014) with rate 0.5 and were trained with Adam (Kingma and Ba, 2014) with rate 0.0001.

Meanwhile, Bayesian NNs do not shine with this setting. Given that Bayesian NNs are suitable to the scenario of having little training data, we conclude that the quantity of being "little" should be much smaller than our QE training data. (Our training data are with around $10K$-$20K$ sentences.) Deep NNs and deep Bayesian NNs do not help much with Standard setting. Table 2 presents results with other settings of hidden layers for deep NNs.

DNNs	EN-DE	DE-EN	NNs	EN-DE	DE-EN	DGPs	DE-EN	GPs	DE-EN	EN-DE
1 Layer	17.46	17.15	512	17.46	17.15	1 Layer	17.01	w. FW	17.36	17.01
2 Layers	17.47	17.26	1024	17.44	17.14	2 Layers	17.28	w.o. FW	17.72	17.56
3 Layers	17.51	17.29	16384	17.51	17.34	3 Layers	17.36			
4 Layers	17.48	17.37	32768	17.40	17.32	4 Layers	17.22			
5 Layers	17.54	17.35	Infinite (GP)	17.36	17.05	5 Layers	17.34			

Table 2: Detailed analyses with different models in the Medium-scale setting. Specifically, using deep NNs (DNNs) does not help much. Using large NNs improves the performance, but only if the model is robust in training (i.e. as in GPs). It is also unlikely to need a QE model that is capable of approximating non-stationary functions, as we found deep GPs (DGPs) does not gain any significant improvements. Finally, feature weighting (F.W.) mechanism in GPs is also important. Turning it off rather gives worse results.

GPs are competitive with Standard setting and medium-scale QE feature space. We recall that GP is a non-parametric version of a shallow NN with an infinite number of units in the hidden layer (Neal, 1996). Detail analyses confirm that it is a good fit to medium-scale QE feature space because of the following reasons. First, having a substantially larger number of hidden units may help. However, we notice that having a larger NN may not improve performance, as in Table 2. That is, it helps only the case when the model is robust in training, as in GPs.

Second, most features in the feature space are useful. However, each of them should have a certain degree of relevance to the task. GPs can capture this. As in Eq 1, if λ_d is larger, then the d^{th} feature is less important. Meanwhile, a small λ_d indicates that the feature is crucial to the task. To this end, we noticed that their values are different in our experiments, and neither of them are too large or too small. We also noticed that once we use only a single hyper-parameter λ for all the features, we observe a significant drop in performance, as shown in Table 2. This confirms that the feature weighting mechanism is also important in GPs.

Meanwhile, deep GPs do not provide any improvement over GPs. We provide detailed statistics with other configurations of deep layers in Table 2. It is therefore unlikely to need a QE model that is capable of approximating non-stationary functions. In other words, the relationship between the space of input features and corresponding output is unlikely to have jump discontinuities or isolated tall peaks.

5.2 Large-scale setting

We now turn our attention to large-scale setting.[5] Table 3 presents the result in detail. Here, we do not report KRR and Deep GPs because they seem not to be a right model for QE. [6]

The three most important observations are as follows. First, it is surprising to see that there is also not a clear winner, and the difference between the best model and other top models is also quite *marginal*. Second, GPs do not provide competitive results with this setting. This is because simple SE kernel function is not representative enough to learn the similarity in high-dimensional QE feature space. We also tried other advanced kernel functions, such as Matern kernel (Rasmussen and Williams, 2005), Polynomial kernel (Rasmussen and Williams, 2005), mixture of SE kernels (Wilson and Adams, 2013) and Additive Kernels (Duvenaud et al., 2011) without success.

[5]We report the Standard setting for large-scale experiments only for DE-EN. Specifically, the pretrained LSTM model is made available at *https://github.com/openai/generating-reviews-discovering-sentiment* by Radford et al. (2017). Our large-scale feature experiments are thus reproducible.

[6]Our result with these models in the setting is also not promising.

Table 3: Assessing QE Models for Sentence-Level Prediction (large-scale QE feature space)

Perhaps, making GPs work well with this setting needs a fully different type of kernel function. As shown in Table 3, we found that DKL seems to be a right approach to address the difficulty. That is, replacing the simple SE kernel function with a NN improves the performance of GPs significantly. Overall DKL and shallow NNs provide the best result with large-scale QE feature space.

In summary, we recommend using shallow NNs and DKL for QE with Standard setting. We recommend using GPs only with medium-scale QE feature space. We recommend NOT using a deep NN in QE because of overfitting. Our results also show that using a suitable model is very important. For instance, good models (shallow NN and DKL) with a set of 70 features produce competitive results (16.39 and 16.37) to the best *single* model in WMT QE 2017 shared task (SHEF/QUEST-EMB-SCALE - 16.1) (see Bojar et al. (2017) for a reference). Other models including SVR are far from achieving top performance.[7]

6 Domain Adaptation and Knowledge Transfer

We study different DA and KT settings. Specifically, we use EN-DE training/validating data come from WMT 2016, and evaluate on WMT 2017 EN-DE test data. We also use WMT 2017 DE-EN training/validating data to train the model, but we evaluate on WMT 2013 DE-EN test data. Note that with the EN-DE training/validating data come from WMT 2016, the datasets contain HTER scores greater than 100. We therefore scale the HTER score in $[0, 1]$ by dividing the maximum HTER score.

In KT setting, we experiment with WMT 2015 EN-ES and WMT 2017 DE-EN training/validating data sets, and evaluate on WMT 2017 EN-DE test data. We also train models using WMT 2017 DE-EN training/validating data, but test on WMT 2013 ES-EN test data.

Tables 1 and 3 present results. There are several important findings as follows. First, there is a substantial difference in model performance in these settings. Second, we raise our concern of applying shallow NNs to these settings. Specifically, shallow NNs often predict an HTER score that is outside the range of [0:1] given an input that is not close to the input space of training data. This explains a substantially worse RMSE with 142.27 and 257.30 in Table 3.[8] While analysis of these cases requires future work, we should note that we did not observe similar problems for other models.

Using deep NNs for QE could reduce the effect of DA and KT setting. We attribute this observation

[7]We recall that we randomly selected 53 units from our $4,096$ units. We notice that by selecting top most relevant 53 units (by feature selection), we improve the performance of shallow NN and DKL to 16.1. However, our main concerns are assessing QE models rather than beating SOTA.

[8]Technically, we can "post-process" the output so that a prediction that is outside the range of [0:1] will be set to 0 or 1. We do not apply such post-processing procedures here.

to the fact that deep NNs learn high-level features, which may work well across domains/datasets. Unfortunately, this seems to be only the case with medium-scale QE feature space. With large-scale setting deep NNs produce a suboptimal performance. It is indeed non-trivial to train deep NNs with the settings given small training data we have. Deep NNs also often produce HTER scores that are outside the range of $[0{:}1]$ with these settings.

Third, using GPs for QE gains robust performance across various medium-scale QE feature space adaptation/knowledge transfer tasks. Unfortunately, this is not the case with large-scale setting.

Using Bayesian NNs and DKL provides a powerful solution to the DA and KT setting. Robustness is the key to their success under these settings. As a side note, deep Bayesian NNs provide good solution to DA and KT setting only with medium-scale setting.

Finally, our work shows if we choose a right QE model to apply in the wild, the QE prediction is robust. For instance, the performance of using deep NNs, DKL and deep Bayesian NNs is still very promising (19.45, 19.68 and 18.83 respectively) when they are trained with WMT EN-DE 2016 dataset but tested with WMT EN-DE 2017 test data.

Moreover, our results show that it is promising to utilize a QE dataset from one language pair to use for other language pairs. Let us present our good results with the WMT QE 2017 EN-DE test set as an example. Our result with DKL trained with WMT DE-ES 2015 is 19.93 while the best QE model trained on the in-domain training/validating data is 17.35.

Our work also raises the challenge of building a better QE model with a large feature set. As in Table 3, model performance is often far from being robust/accurate across different domains/datasets.

7 Conclusion

This paper contributes a significant amount of efforts of assessing advanced sentence-level QE models. We show that having powerful features is not enough, as we also need a right model to use. We recommend to use shallow NNs with Standard setting, but we do NOT recommend deep NNs with this setting. When it comes to medium-scale QE feature space, we recommend using GPs.

Meanwhile, we observe a very weak performance of NNs when applying the model in the wild (i.e. Adaptation and Knowledge Transfer setting). GPs model is a right option in these cases, but only with medium-scale setting. Bayesian NNs work well for both DA and KT settings, but not Standard setting.

Each model works well in certain circumstances. There is an exception, though, with Deep Kernel Learning. We found that the QE model is a strong candidate to use in real-world scenario.

Abstract

User demographic inference from social media text has the potential to improve a range of downstream applications, including real-time passive polling or quantifying demographic bias. This study focuses on developing models for user-level race and ethnicity prediction. We introduce a data set of users who self-report their race/ethnicity through a survey, in contrast to previous approaches that use distantly supervised data or perceived labels. We develop predictive models from text which accurately predict the membership of a user to the four largest racial and ethnic groups with up to .884 AUC and make these available to the research community.

1 Introduction

The popularity and ubiquity of social media allows access to a wide variety of spontaneous language enabling researchers to study language variation across space and time at large scale (Eisenstein et al., 2010; Eisenstein, 2016). Through language analysis, social media data showed the potential to compliment or in part replace traditional polling (O'Connor et al., 2010), with the caveat that its demographics is not a representative sample of the real population (Culotta, 2014). One of the most important demographic differences – especially across the US – is that of race and ethnicity. For example, in Twitter-based political polling applications it is important to adjust for the fact that ethnic minorities are overall less likely to support either party, but prefer the Democratic Party over the Republican Party (Hajnal and Lee, 2011).

In this paper, we present the first extensive study on identifying user-level race and ethnicity. So far, linguistic differences have mostly been studied in the context of dialects, usually African-American Vernacular English – AAVE (Jørgensen et al., 2015), using message-level data which offered insight into syntactic (Stewart, 2014) or lexical markers (Blodgett et al., 2016). However, not all users from a racial or ethnic group use these markers or, more generally, an associated dialect and usage is different across socio-demographic traits – use of the AAVE is correlated with lower income and education (Rickford, 1999). In addition, there are differences in language use across racial/ethnic groups not caused by dialects e.g., in the US, African Americans prefer basketball, Whites ice-hockey and Hispanic/Latinos football (OpenDorse, 2013) – and are consequently more likely to post about these sports.

In addition, previous studies used either perceived race labels (Mohammady and Culotta, 2015; Volkova and Bachrach, 2016; Culotta et al., 2016) which are subject to human stereotypes (Flekova et al., 2016a) or mapped geo-located tweets to census statistics (Mohammady and Culotta, 2014; Blodgett et al., 2016) which lead to other biases (Jørgensen et al., 2015) because: 1) census statistics are outdated; 2) the Twitter population is not a representative sample of the general population (Eisenstein et al., 2011) with African Americans over-represented on Twitter (Duggan, 2015); 3) users who geo-locate tweets are not a representative sample of the Twitter population (Eisenstein, 2016); 4) geo-located tweets might be posted from a different location than the user's home.

In this study, we introduce a new data set where user-level race and ethnicity labels are collected through an online survey of Twitter users. We build models for accurately classifying Twitter users into four of the largest racial and ethnic groups in the U.S. as defined by the Census Bureau: Non-Hispanic Whites,

Proceedings of the 27th International Conference on Computational Linguistics, pages 1534–1545
Santa Fe, New Mexico, USA, August 20-26, 2018.

Hispanic/Latinos, African-Americans and Asians.[1] We also measure the predictive power of various types of linguistic features and quantify usage of race/ethnicity revealing language across demographic groups. Finally, we perform a linguistic feature analysis to reveal the most important linguistic markers of race/ethnicity.

2 Data Set

We build a data set of Twitter users from participants in larger surveys taken through Qualtrics,[2] the largest platform for online experiments in social science, for which each user was compensated with 3$ per study.

As a first step, all participants were asked to take a standard demographic questionnaire which included selecting their race/ethnicity with the following options consistent with the US Census: African-American (AA, 374 users), Hispanic/Latino (Latino, 241 users), Asian (140 users), Non-Hispanic White (White, 3,182 users), Multiracial (153 users) or Other (free-text field prompt; 40 users, most frequently mentioned to be 'Native American'). In addition, we collected gender ('Male', 'Female' or open-ended field), age (13–90 interval), education (6 ordinal values ranging from 'No high-school' to 'Advanced Degree') and income level (8 ordinal values representing annual income from '<20k$/y' to '>200k$/y'). We restricted participation in our surveys to users based in the U.S. to limit the impact of potential cultural factors by using Qualtrics' filtering mechanisms.

The participants were asked to provide their public Twitter handle from which they had posted more than 100 tweets. We performed several checks on this Twitter handle to ensure that it was the user's own: *after* compensation we asked the users if they were truthful in reporting their handle and if not, we removed their data from analysis (22 users). We manually checked all handles which were verified by Twitter or had over 5000 followers and eliminated them if they were celebrities, as these were unlikely the users who participated in the survey (10 users in total). For each user, we downloaded their most recent 3,200 tweets, leading to a total data set size of 5,415,985 tweets.

We asked users to disclose their information, as this is the most efficient way to collect multiple demographic traits of users, despite the small possibility that some users are deceitful in reporting these traits. For ethical reasons, we only recruited participants who were willing to share their Twitter handles. This means our sample may not be fully representative of the general population, although we will account for any possible demographic skew in all our experiments.

After reporting demographics (including race/ethnicity) and their Twitter handles, users were directed to one of four collections of psychological questionnaires. The list of questions for each of these collections is very long (>30 questions) and bears no impact on the initial demographic information provided or to our experiments, hence we omit them from this paper. We have more 'White' users than the general U.S. population because participants were required to be part of this group in one of the sub-studies.

For the rest of the paper, we remove from our analysis the 'Multiracial' (153 users) and 'Other' (40 users) groups as these are small in sample size, heterogeneous in make-up and the sample may have been skewed towards a certain race/ethnicity mixture, but we could not know which.

3 About Race/Ethnicity

In our study, we used the definition of race/ethnicity as presented in the U.S. Census.[3,4]

We have chosen the U.S. Census definition of race/ethnicity for the following reasons:

- it is arguably most familiar to the participants, as users are all from the U.S., thus most have participated in the Census previously;
- multiple previous studies and applications such as polls rely on this classification to study the relationship between race/ethnicity and other variables;
- previous work on race-specific language used the same racial categorization (Blodgett et al., 2016);
- U.S. Census race/ethnicity surname statistics are available to benchmark our methods.

[1] Please refer to the 'About Race/Ethnicity' for a discussion about the definition of race/ethnicity used in this study.

[2] https://www.qualtrics.com/

[3] https://www.census.gov/topics/population/race/about.html

[4] https://www.census.gov/topics/population/hispanic-origin/about.html

We acknowledge that other racial/ethnic classifications exist or some groups are heterogeneous (e.g., Asian contains Chinese, Indian and Middle Eastern ethnicities) and that some argue the validity of the race construct entirely (Mukhopadhyay et al., 2013; Sen and Wasow, 2016).

4 Ethical Considerations

This experiment has received ethics approval from the Institutional Review Board (IRB) of our institution.

For reproducibility purposes, the data used in this paper is released in an anonymized and aggregated format.[5]. Any academic who wishes to gain access to the original user id's and labels will need to register with the authors, as per our IRB terms. Access will not be granted for any commercial applications and purposes.

Any individual-level predictions such as gender, age, religion, race or politics should be used with caution as they represent sensitive information. Race is, however, perhaps even more fraught with potential misunderstandings and abuses. We expect models for race prediction to be useful at an aggregate level, as the performance of the models do not warrant being be used at an individual level. For example, one could study how, in aggregate, tweets from youth of different races tweet about drug and alcohol use, where age and race make-up is estimated using predictive models.

We also highlight that Twitter's Terms of Service disallow targeting of individual users based on sensitive traits, including race: 'our Twitter Ads Policy also prohibits advertisers from targeting ads based on categories we consider sensitive, such as race, religion, politics, sex life, or health'.[6,7]

5 Features

In our analysis and predictive experiments, we use a broad range of linguistic features which are briefly described below.

Unigrams We use the bag-of-words representation to reduce each user's posting history to a normalised frequency distribution over the vocabulary consisting of all words used by at least 1% of the users (32,142 words).

LIWC Traditional psychological studies use a dictionary-based approach to representing text. The most popular method is based on Linguistic Inquiry and Word Count (LIWC) (Pennebaker et al., 2001) consisting of 73 manually constructed lists of words (Pennebaker et al., 2015) including some specific parts-of-speech, topical or stylistic categories. Each user is thereby represented as a frequency distribution over these categories.

Word2Vec Topics An alternative to LIWC is to use automatically generated word clusters. These clusters of words can be thought of as *topics*, i.e., groups of words that are semantically and/or syntactically similar. The clusters help reduce the feature space and provide good interpretability. To create these groups of words, we use an automatic method that leverages word co-occurrence patterns in large corpora by making use of the distributional hypothesis: similar words tend to co-occur in similar contexts (Harris, 1954).

We use the method from (Preoţiuc-Pietro et al., 2015a) to compute topics using word2vec similarity (Mikolov et al., 2013) and spectral clustering (Shi and Malik, 2000; von Luxburg, 2007) of different sizes (from 30 to 2000). We have tried other alternatives to building clusters: using other word similarities to generate clusters – such as NPMI (Lampos et al., 2014) or GloVe (Pennington et al., 2014) as proposed in (Preoţiuc-Pietro et al., 2015a) – or using standard topic modelling approached to create soft clusters of words e.g., Latent Dirichlet Allocation (Blei et al., 2003). For brevity and clarity, we present experiments with the best performing feature set containing 1000 Word2Vec topics after experimenting with other numbers of topics (from 30 through 2000). We aggregated all the words posted in a users tweets and represent each user as a distribution of the fraction of words belonging to each cluster.

Sentiment & Emotions We also investigate the extent to which racial groups differ in the type of emotions they express through their posts. The most popular model of discrete emotions is the Ekman model (Ekman, 1992; Strapparava and Mihalcea, 2008; Strapparava et al., 2004) which posits the existence of six basic

[5] http://www.preotiuc.ro

[6] https://twitter.com/privacy/

[7] https://support.twitter.com/articles/20170368\#/

emotions: anger, disgust, fear, joy, sadness and surprise. We automatically quantify these emotions from our Twitter data set using a publicly available model, which in addition to emotions also includes positive and negative sentiment (Volkova and Bachrach, 2016). We also used the word lexicon derived using crowd-sourcing from (Mohammad and Turney, 2010; Mohammad and Turney, 2013) and found it had slightly worse predictive results. Using these models, we assign sentiment and emotion probabilities to each message and then average across all users' posts to obtain user level emotion expression scores.

Part-of-Speech Tags We analyze part-of-speech tag usage across groups by POS tagging all tweets using the Twitter model of the Stanford Tagger (Derczynski et al., 2013), which showed best tagging results for AAVE (Jørgensen et al., 2015) and also uses the finer grained Penn Treebank tagset. Each user is thus represented as a distribution over POS tags.

Linear Ensemble Finally, we build a logistic regression model having as features the real-valued predictions of the models trained on all previous feature sets.

6 Baselines

We introduce the following competitive baselines:

Demographics User demographics collected from the users using our survey (age, gender, education and income level) are used as features. A classifier using only these demographics as features will establish the demographic tendencies of race/ethnicity in the data set.

Blodgett – User Model Blodgett et al. (2016) release a set of tweets with race/ethnicity probabilities obtained through distant supervision. In order to create user-level models for comparison, we take two separate approaches. From that data set, we identify the users that have more than 50 messages in the data set and label them with one of the four groups (AA, Latino, Other – mostly Asian – and White) if more than half of their messages are assigned a probability higher than 0.8 for that group. We build four one-vs-all unigram user-level classifiers and use these four models to predict the race/ethnicity of the users in our data set. These models were internally validated on the data set from (Blodgett et al., 2016) obtaining an average AUC $= .970$ prediction accuracy on 10-fold cross-validation within that data set. We also note that this method is trained on data from 26,009 users, an order of magnitude larger than our data set.

Blodgett – Message Model The second approach based on the (Blodgett et al., 2016) data set is to first train message-level logistic regression models for predicting how likely each message belongs to one of the four race/ethnicity groups. On internal validation, the average Pearson correlation between these models' prediction and the message-level scores released is R=.534 as measured using 10 fold cross-validation. We use these models to assign four prediction scores to all messages in our data set and compute an user-level average across these four predictions. We note that in this method we use 50 million tweets for training the message-level race/ethnicity classifiers, again an order of magnitude larger than our data set.

Perceived Race Labels We experiment with two data sets consisting of users for which race was determined by external annotators who analyzed the Twitter profile and tweets of users. The first data set was introduced in (Mohammady and Culotta, 2014) and consists of 362 users (all remaining public accounts from the original 770 users) labelled with three race categories (AA – 70, Latino – 104, White – 188). The second data set was introduced in (Volkova and Bachrach, 2016) and consists of 3380 users (all remaining public accounts from the original 5000 users) labelled with four race categories (AA – 1216, Latino – 150, Asian – 316, White – 1698) . All models trained on this data use bag-of-word unigram features and have been pre-processed in the same way as all other data sets.

Census Surnames Previous research used aggregate statistics about name distributions to estimate the demographic traits of Twitter users based on their name field, especially focusing on gender (Knowles et al., 2016). The U.S. 2010 Census aggregates statistics on race distribution for all surnames common to at least 100 US citizens, covering 95.9% of the population.[8] In total, 65.9% (2,592) of the users in our data set have a valid surname in their Twitter name field and could be matched to the Census statistics. For these, we selected the race with the highest frequency in the Census data as our prediction and for the rest, we use the most frequent race, namely White, as the prediction (**Census Surname – Most Likely**). We

also use the four Census race frequencies for the user's matched surname as features (**Census Surname – Distribution**). For users that are not matched, we use the average distribution. This has the effect to adjust for, at least partially, the race differences between the general U.S. population and the Twitter users in our data set.

NamePrism In addition to only looking at surnames as extracted from the Census, we also use a publicly available API [9] that enables race and nationality prediction from word formation patterns in surnames. This calls models that have obtained state-of-the-art accuracy for this task (Ye et al., 2017; Ambekar et al., 2009). Similarly to the Census name, we use both the actual prediction (**NamePrism – Most Likely**) and a model trained on the race probabilities predicted by the API **(NamePrism – Distribution**).

7 Predictive Experiments

In our predictive experiments we use logistic regression classification with Elastic Net regularization in a 10-fold cross-validation setup, where 8 folds are used for training, 1 for tuning the regularization parameters using grid search and 1 for testing. We have experimented with other methods for non-linear classification (e.g. SVMs), but results did not improve significantly.

7.1 One vs. All Classification

Results of one vs. all classifications are presented in Table 1. These are evaluated using ROC AUC (area under the receiver operating characteristic curve) because: a) the class distribution is imbalanced (up to

[9] http://www.name-prism.com/

1:19 for Asian vs. rest); b) AUC does not favor methods that use in training a similar class distribution as in the test set. Results using F1 score show the same patterns of improvement.

Overall performance of our best models are $>.7$ AUC (compared to AUC $= .5$ if random), with performance on the 'African American' group being highest (AUC $= .884$). Unigrams consistently obtain the best predictive results out of all feature sets, as they can capture idiosyncratic words and spellings which are very specific to certain racial/ethnic groups, while topic choice can only capture more generic topical relationships. Textual features – with a few exceptions for the 'Asian' group – make better predictions when compared to demographics, showing that language use carries information beyond purely demographics. Combining the predictions of all feature sets using a linear ensemble obtains the best results.

The two methods based on the data from (Blodgett et al., 2016) obtain overall good prediction results, with the message-level model surpassing the user-level model in all four cases. However, the performance is consistently lower than the best classifier trained on our data set, despite this being an order of magnitude smaller. Similar classifiers trained on perceived age labels result in models that are slightly, but consistently worse (.022 on average when comparing the 'Unigrams' only models) than when training on our data set. The results indicate that using perceived traits results in less accurate models when predicting real traits (Flekova et al., 2016a), as data set size is similar when using the data set from (Volkova and Bachrach, 2016). In addition, we have tried standard domain adaptation methods for combining both data sets (Daumé III, 2007) but found no additional gains.

The methods based on surnames obtain performance above chance, but below our best predictive models, except for the 'Latino' group where it exceeds our best model's performance due to the peculiarities posed by Hispanic/Latino surnames. Combining surname-based methods with the best text-based model results leads to significantly better results than using text alone, showing that these contain complementary information. However, further adding the demographics (age, gender, income, education) as features does not add to the predictive performance, showing that the results are not impacted by any imbalance in the demographic makeup of our data set.

7.2 Four-way Classification

Next, we experiment with four-way race/ethnicity classifiers using only unigram features for text-based methods, as these performed best in the previous experiment. In addition to experiments on the original data set, we also performed experiments with a balanced data set obtained by oversampling the smaller classes. In the 'Trained on this data set' setup, we oversampled in each fold and data split, such that no users from training are present in testing.

The results are presented in Table 2 with results showing both accuracy and F1 score (macro averaged). We notice a higher margin of improvement when using the data from our data set when compared perceived race labelled users. Surname distributions perform second best and are the only features that bring additional performance on top of the best performing method.

7.3 In-Sample Perceived Race Label Prediction

Finally, we compute the performance of models trained in-sample on perceived labels from previous work (Mohammady and Culotta, 2014; Volkova and Bachrach, 2016). All models are logistic regression classifiers with Elastic Net regularization. If these models achieve significantly higher accuracies compared to when tested on our data set, we can conclude that the race/ethnicity prediction task was over-simplified by the method of selecting users in the data set.

Results on in-sample 10-fold cross-validation on the two data sets with perceived race labels are presented for one-vs-all classification in Table 3. We notice that the results are very high compared to when applying the models on data with real race labels, with models suffering on average $>.10$ drop in AUC on data from (Volkova and Bachrach, 2016) and up to a .30 drop when trained on data from (Mohammady and Culotta, 2014).

Similarly, Table 4 shows 4-way classification results for in-sample perceived race prediction. We again note the larger margins of improvement over the baseline for both classifiers when compared to the same classifiers applied on real race labelled data in our data set in Table 2.

	AA	Latino	Asian	White
Baseline	.500	.500	.500	.500
Tested using Survey Labels				
(Mohammady and Culotta, 2014)	.798	.603	–	.700
(Volkova and Bachrach, 2016)	.859	.693	.736	.765
Tested using Perceived Labels				
(Mohammady and Culotta, 2014)	.954	.912	–	.928
(Volkova and Bachrach, 2016)	.946	.780	.767	.892

Table 3: Predictive results of unigram models using perceived race labels. Results are in ROC AUC.

	Original		Balanced	
	Acc	F1	Acc	F1
Random Guess	.519	.227	.333	.250
Trained on (Mohammady and Culotta, 2014)	.771	.770	.777	.768
Random Guess	.502	.167	.250	.100
Trained on (Volkova and Bachrach, 2016)	.764	.557	.639	.637

Table 4: User-level four way race unigram-based classification results on predicting perceived race labels. Results are on both the original data set split and on balanced classes obtained by over-sampling the less frequent classes.

8 Demographic Covariates

Next, we explore the hypothesis that the accuracy of race/ethnicity classification varies with the demographic traits of the users. For example, previous hypotheses state that AAVE usage is more prevalent in males, people of lower income and lower education levels (Rickford, 1999), thus making race prediction for this groups more accurate.

We focus our analysis on the African American user group. We build data splits that are matched in size, one demographic trait at a time (gender, age, education, income), by sub-sampling the larger demographic group when necessary. The, we sub-sample users such that the label proportions (AA vs. other) are the same in each task. For example, in studying the impact of gender in race classification we built a AA classifier for male users (122 AA vs. 122 Non-AA) and another one for female users (122 AA vs. 122 Non-AA). The split points between the two compared groups for age, education level and income level are 26 years old, completed High School degree and 40,000$/y respectively. All classifiers were trained using logistic regression with unigram features.

This experiment allows to uncover for which demographics automated methods are able to better classify users in belonging to the African American group, while keeping the training data size and label distribution constant. Classification results are shown in Table 5.

Classifiers reach different accuracies for age, gender and income, with younger, female and lower income users all being significantly easier to predict if they belong to the African American group. Further, in a separate experiment, the final classifier is more accurate for the same user categories (e.g., AUC $= .894$ for females compared to AUC $= .810$ for males). These results have implications in biases and classifier fairness.

Gender	Female: 0.858	Male: 0.772
Age	$<$26: 0.878	$>$26: 0.759
Education	$\leq$High School: 0.819	$>$High School: 0.802
Income	$<$40,000$/y: 0.853	$>$40,000$/y: 0.770

Table 5: Classification performance in ROC AUC when holding data set size constant across different demographic traits.

9 Feature Analysis

Finally, we perform a linguistic feature analysis with the goal of identifying the linguistic markers specific of each race/ethnicity group on Twitter.

First, Table 6 shows the features with the highest weights for each race/ethnicity category. The features represent the weights learnt a regularized bag-of-words unigram logistic regression models trained for predicting if a user is part of a race/ethnicity group, as described in Section 7.1. The results are intuitive, highlighting known dialectal variations (e.g., 'bout', 'naw') and references to in-group figures ('trayvon',

Latino	Asian
latinas, barely, maze, latina, remorse, dd, absorbed, ay	asian, neighbourhood, pho, ud, jg, consciousness
White	**African-American**
of, seriously, unhappy, sure, pumped, great, someday	trayvon, meek, bout, yaaasss, beyonce, smh, naw

Table 6: Unigrams most predictive of each race/ethnicity group when examining the feature weights learned by the classifiers.

r	Cluster	Words	r	Cluster	Words
Latino			**Asian**		
.144 → .063		22 Significant Clusters with mostly Spanish words	.145→ .060		13 Significant Clusters with words in Asian languages
.148	Spanish City names	los, san, diego, angeles, francisco, antonio, jose, fran	.107	Asian Place-names	china, japan, korea, tokyo, asia, philippines, seoul, hk

.091	Modals	say, could, wish, i'd, wouldn't, couldn't, meant, you'd, couldnt	.171	G-Dropping	tl, freaky, callin, actin, seein, tweetin, followin, ppls, sendin

Table 7: Word2Vec clusters most correlated with each race/ethnicity group (maximum 5 clusters per group, excluding topics made up of foreign words). The cluster name is manually assigned. All correlations are significant at $p < .05$, two-tailed t-test, **Simes corrected** for multiple comparisons and are controlled for gender, age, education and income. Words in a category are sorted by frequency in our data set. * highlights word variants where a character is repeated.

'beyonce') for AA users, names specific to a racial or ethnic group (e.g. 'latinas', 'latina', 'asian'), frequent foreign words (e.g. 'ay', 'ud') or more salient linguistic cues ('seriously', 'of', 'great', 'barely').

However, examining only the most predictive features assigned by a model with both L1 and L2 regularization is likely to overlook features are co-linear. For this reason, we perform analysis of Word2Vec clusters, POS Tags and Emotions using univariate correlation as introduced in (Schwartz et al., 2013). We compute univariate Pearson correlations independently for each feature between its distribution across users (features are first normalized to sum up to unit for each user) and the user-level outcome of interest (e.g., whether it belongs to a race/ethnicity group or not). In Section 8, we showed that user demographics (age, gender, education and income levels) impact the classification accuracies. In order to mitigate this effect, we introduce age, gender, education and income levels as controls and compute partial linear correlation for each feature. Since a large number of features are explored simultaneously, we consider coefficients significant if they meet a Simes-corrected two-tailed p-value of less than 0.05.

Table 7 shows the Word2Vec clusters with the highest correlations with users belonging to a group. For the 'Latino' and 'Asian' groups, we do not show clusters that contain more than 70% non-English words in their most frequent 20 words, as these only reflect the use of a particular language (e.g. Hindi or Tagalog for 'Asian' and Spanish for 'Latino') and are not interesting for analysis.

For Latinos we first note the use of Spanish-origin place names in the US and place names from Latin America. In addition, Latinos use words associated with polite constructs (e.g. 'offense' as in 'no offense', 'worries' as in 'no worries', 'excuses') and express frustration (variants of 'man', 'shit' and 'damn', as well as the Spanish version 'dayum') or love (heart shapes or variants of 'love'). The Asian group is, similarly to the 'Latino' group, first characterized by the use of words belonging to Asian languages and Asian name places. Asian users prefer a peculiar type of expressing 'yes' (e.g.,' 'yah', 'yaa', 'yee'), use a specific category of interjections (e.g., 'heh', 'pole') and prefer certain phonetic spellings (e.g., 'bcuz', 'h8') or contractions to typical English words (e.g. ikr – 'I know, right?', 'rly', 'rlly' – 'really'). Finally,

r	Tag	Words	r	Tag	Words
Latino			**Asian**

.054	CC	Coordinating conj. – and			
.044	NNS	Noun, plural – years			

Table 8: Part-of-Speech tags most correlated with each race/ethnicity group. All correlations are significant at $p < .05$, two-tailed t-test, **Simes corrected** for multiple comparisons and are controlled for gender, age, education and income.

Emotion	Latino	Asian	White	AA
Positive	-.060	–	–	.036
Negative	-.049	–	–	–
Anger	–	–	-.067	.118
Disgust	–	–	–	.083
Fear	–	–	–	.050
Joy	-.044	–	–	–
Sadness	-.040	–	–	.048
Surprise	-.041	–	–	–

Table 9: Pearson correlations between emotions and race/ethnicity groups. All reported correlations are significant at $p < .05$, two-tailed t-test, **Simes corrected** for multiple comparisons and are controlled for gender, age, education and income.

the cluster containing words about cricket highlights a more topical difference specific of Asian users, likely driven by users with ethnicity in the Indian subcontinent where this sport is popular. White users are best characterized by the use of temporal references (e.g., 'years', 'ago', 'weeks'). Many clusters uncover syntactic preferences of the White group including the use of superlatives (e.g., 'cutest'), adverbs of degree (e.g., 'quite') and modal verbs (e.g. 'could'). Finally, a topical cluster around the theme of rest (e.g., 'laying', 'cuddle') is also specific of the White group. Finally, the African American groups has the topics with the highest correlation coefficients. Clusters capture specific terms that reference other persons (e.g., 'lil', 'boo') or groups (e.g., 'dudes') and other typical AAVE words (e.g., 'naw', 'bout'). Similarly to the Asian group, we also observe a cluster dominated by phonetic spelling variants of words (e.g., 'urself', 'some1'). Finally, we observe a topic dominated by verbs missing the final 'g' (e.g., 'callin', 'sendin'). This represents one of the most well-known distinctive features of AAVE (Rickford, 1999).

Table 8 shows Part-of-Speech tags correlated with each race/ethnicity group. The Latino and Asian groups are characterized by the use of foreign words, interjections and singular proper nouns. This matches the findings of the cluster analysis, leading to the conclusion that these two groups use references of proper names and foreign words both related to their ethnic origin and, increased use of interjections. The POS usage results for the White and African-American groups highlight intriguing contrasts. While the White users prefer superlative adjectives, African American users prefer comparative adjectives. White users are predisposed to use more adverbs, however African Americans use more adverb particles (e.g., 'take off', 'put away'). African-American prefer non 3-rd person singular verbs and use more personal pronouns, while White users prefer 3-rd person verbs. This shows the tendency of African-Americans to post more on Twitter about their activities and whereabouts rather than other events or impersonal reporting. White users also use more conjunctions (subordinating and coordinating), perhaps an indicator of more complex syntactic constructions.

Lastly, emotion analysis results are presented in Table 9. The results show that emotions are mainly correlated with the Latino and AA groups, with only a single other significant correlation for the Asian and White groups. African American users on Twitter express overall more emotions than other groups, including both positive sentiment as well as a range of negative emotions, especially anger. On the other hand, Latino users express overall less sentiment, both positive and negative, and fewer emotions.

10 Conclusion

We presented a detailed study of user-level race/ethnicity prediction along the lines of previous work on predicting user traits from text (Burger et al., 2011; Rao et al., 2010; Pennacchiotti and Popescu, 2011; Schwartz et al., 2013; Sap et al., 2014; Volkova et al., 2014; Preoţiuc-Pietro et al., 2015b; Flekova et al., 2016b; Preoţiuc-Pietro et al., 2016; Preoţiuc-Pietro et al., 2017). In contrast with previous research on race/ethnicity, we used labels obtained by directly surveying Twitter users, rather than distantly supervised geo-located data or perceived race labels, which lead to multiple biases and lower accuracies on real data.

We built models that obtain state-of-the-art out-of-sample accuracy on predicting the four prominent racial/ethnic groups in the US. We presented an extensive linguistic feature analysis for each group and brought new evidence towards linguistic hypotheses on dialect use in Twitter across demographic groups. We believe this paper offers a solid basis for the study of race prediction online. Our models are readily usable for large-scale passive polling scenarios, where automatically quantifying existing racial sample differences can lead to improved predictive performance (Culotta, 2014).

Multi-Source Multi-Class Fake News Detection

Hamid Karimi, Proteek Chandan Roy, Sari Saba-Sadiya, and Jiliang Tang
Department of Computer Science and Engineering, Michigan State University
{karimiha,royprote,sadiyasa,tangjili}@msu.edu

Abstract

Fake news spreading through media outlets poses a real threat to the trustworthiness of information and detecting fake news has attracted increasing attention in recent years. Fake news is typically written intentionally to mislead readers, which determines that fake news detection merely based on news content is tremendously challenging. Meanwhile, fake news could contain true evidence to mock true news and presents different degrees of fakeness, which further exacerbates the detection difficulty. On the other hand, the spread of fake news produces various types of data from different perspectives. These multiple sources provide rich contextual information about fake news and offer unprecedented opportunities for advanced fake news detection. In this paper, we study fake news detection with different degrees of fakeness by integrating multiple sources. In particular, we introduce approaches to combine information from multiple sources and to discriminate between different degrees of fakeness, and propose a **M**ulti-source **M**ulti-class **F**ake news **D**etection framework MMFD, which combines automated feature extraction, multi-source fusion and automated degrees of fakeness detection into a coherent and interpretable model. Experimental results on the real-world data demonstrate the effectiveness of the proposed framework and extensive experiments are further conducted to understand the working of the proposed framework.

1 Introduction

Given its negative impacts, fake news has been identified as a global threat (Webb et al., 2016). Detecting fake news has become increasingly important and can benefit individuals and even our society in many aspects. First, people will be well-informed about events and news and their political and social activities will not be misguided. Second, despite a few recent initiatives by some social media providers like Facebook, there is no systematic fake news detection by social media platforms. Third, identifying fake news is one step toward targeting financial incentives encouraging the spreaders running their "business". For instance, Google attempts to stop providing its ad services to fake news websites (Wingfiled et al., 2016). Fourth, people would not lose their trust in web and social media.

However, fake news detection is naturally challenging especially in the era of social media. First, fake news is usually written intentionally to mislead its readers and the content of fake news is rather diverse in terms of length, topics, and styles (Shu et al., 2017a). For example, fake news in social media is short, informal and is often related to newly emerging and time-critical events. Thus, since we have not gained enough insights into the nature of fake news, hand-crafted features based on the news content are generally not sufficient (Ruchansky et al., 2017). Second, to mock true news, fake news could mix false statements with true ones. For example, fake news can cite true evidence to support a non-factual claim (Shu et al., 2017a). Hence, fake news has different degrees of *fakeness* such as half-true, false, etc. However, the majority of existing algorithms consider fake news detection as a binary classification in the form of the *true/false* dichotomy. Considering degrees of fakeness adds further difficulty on fake news detection.

Proceedings of the 27th International Conference on Computational Linguistics, pages 1546–1557
Santa Fe, New Mexico, USA, August 20-26, 2018.

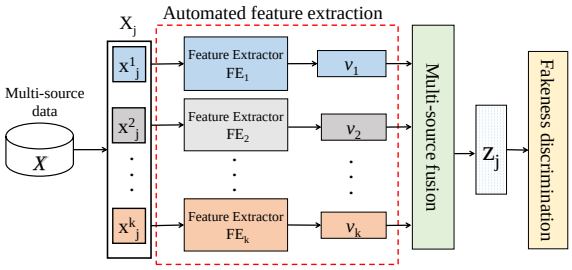

Figure 1: An overview of the proposed model for fake news detection (MMFD)

On the other hand, recent advances in mobile techniques and the popularity of emerging media (e.g., social media) enable the widespread of fake news and this process produces a large amount of data, which allows us to collect information about fake news from various perspectives such as the origin of fake news, the fake news writers and their historical data, etc. Such data provides rich contextual information beyond the news content. For example, a writer who created plenty of fake news is likely to create more fake news (Del Vicario et al., 2016); while news from authoritative organizations such as governments is less likely to be false. Thus, the availability of multiple sources related to fake news has the great potential to help fake news detection.

In this paper, we study the problem of multi-class fake news detection with multiple sources. In particular, we aim to answer two major research questions – (1) how to effectively combine information from multiple sources for fake news detection and (2) how to discriminate between degrees of fakeness mathematically. Our solutions to these two questions result in the proposed Multi-source Multi-class Fake news Detection (MMFD) framework. Our main contributions are summarized as a) we introduce an automated and interpretable way to integrate information from multiple sources; b) we provide a principled approach to discriminate between degrees of fakeness mathematically; c) the proposed framework MMFD coherently incorporates automated feature extraction, multi-source fusion and degrees of fakeness discrimination in an end-to-end way; and d) we conduct experiments on real-world data to demonstrate the effectiveness of the proposed framework.

The rest of the paper is organized in the following manner. In Section 2, we formally define the multi-source multi-class fake news detection problem. Section 3 describes the proposed approach for fake news detection. Section 4 evaluates the proposed method and presents the experimental results and discussions. In Section 5, we present the related work. Section 6 concludes the paper and sheds light onto the future directions.

2 Problem Definition

In this section, we introduce the mathematical notations and formally define the multi-source multi-class fake news detection problem. We follow the previous work (Allcott and Gentzkow, 2017; Shu et al., 2017b) and define fake news as follows.

Definition. A news item is called *fake* if its content is verified to be false and *true* otherwise.

Let $\mathcal{X} = \{X_1, X_2, \cdots, X_n\}$ denote a multi-source dataset containing n news items. Each new item $j \in [1, n]$ contains k sources of data and is denoted as $X_j = \{x_j^1, x_j^2, \cdots x_j^k\}$. Additionally, let $Y = \{y_1, y_2, \cdots, y_n\}$ denote a set of class labels associated with news items of dataset $\mathcal{X}$. Each class label $y_i \in Y$ takes a label from the label set $L = \{l_1, l_2, \cdots, l_m\}$ where m denotes the number of recognized degrees of fakeness in our framework and $l_j \in L$ is a particular degree of fakeness e.g., *half-true*. With the aforementioned notations and definitions, the problem of multi-source multi-class fake news detection is formally defined as follows:

Given the multi-source dataset $\mathcal{X}$ and its corresponding multi-class labels Y, we aim to learn the model $\mathcal{M}$ mapping $\mathcal{X}$ to Y, which can automatically predicts the degrees of fakeness for unlabeled news.

3 The Proposed Framework

Multi-source multi-class fake news detection faces three challenges. First, hand-crafted features based on news content are not very efficient for fake news, which calls for an automated feature extraction approach from multiple sources. Second, multiple sources of fake news data offer complementary information and combining the multiple sources while delivering an interpretable solution is another challenge. Third, degrees of fakeness offer a better understanding of fake news; however, fake news with different degrees may not be easily separable. In this work, we propose a framework which can tackle these challenges simultaneously. Figure 1 demonstrates an overview of the proposed **M**ulti-source **M**ulti-class **F**ake news **D**etection framework (MMFD). MMFD incorporates three coherent components into an end-to-end way – automated feature extraction (Section 3.1), interpretable multi-source fusion (Section 3.2), and fakeness discrimination (Section 3.3). In the following, we detail each component, followed by presenting the training procedure of the proposed model in Section 3.4.

3.1 Automated feature extraction

Since hand-crafted features (Gupta et al., 2014; Yang et al., 2012; Khurana and Intelligentie, 2017) are not very effective, automated feature extraction is more desired. Thus, we employ a deep neural network model to extract powerful features from each source inspired by the promising performance of deep learning in representation learning (Bengio et al., 2013). Different types of sources may need different deep network architectures. Since most of the sources in our dataset are textual sources (see Section 4), we propose a method to automatically extract features from a textual source.

The textual data can contain indicative information revealing the nature of fake news. Inspired by recent advancements in deep neural networks for modeling the text, we propose a deep model to extract features from textual sources based the CNN (convolutional Neural Network) (LeCun et al., 2015) and the LSTM (Long Short-Term Memory) network (Hochreiter and Schmidhuber, 1997). A CNN extracts local patters from a text similar to n-grams features (Kalchbrenner et al., 2014). Then, we apply an LSTM on top of the features extracted from the CNN aiming at capturing the temporal dependencies in the entire text.

Suppose a textual source contains x words. To apply the CNN model, we represent the text by an input matrix of word embeddings denoted as $W \in \mathbb{R}^{x \times e}$ where e is the dimension of the word embedding. More specifically, $w_j \in W$ is a e dimensional vector representing j-th word of the text and populates j-th row of matrix W. This matrix is produced from a word representation method such as word2vec (Mikolov et al., 2013). Then, convolution operations on W are performed M iterations (e.g., $\mathsf{M} = 2$ in Figure 2). At each iteration $m \in [1, \mathsf{M}]$, a filter (a weight matrix) $f^m \in \mathbb{R}^{l^m \times e}$ is convolved with W where l^m is the length of the filter. Convolution of f^m with the input matrix W produces feature maps $\mathbf{p}^m \in \mathbb{R}^{x-l^m+1}$. Each entry $p_j \in \mathbf{p}^m$ $(1 \leq j \leq x - l^m + 1)$ is generated as follows:

$$p_j = \mathcal{G}(r_j \odot f^m + b) \tag{1}$$

where $r_j = \{w_j, w_{j+1}, \cdots, w_{j+l^m-1}\}$ is a window of l^m consecutive words in W (a region of m words), $\mathcal{G}$ is a non-linear activation function such as sigmoid, $\odot$ denotes element-wise product operation, and $b \in \mathbb{R}$ is a bias term. Following the common way in CNNs, we repeat the process described above n_m times producing the sequence $U^m = [\mathbf{p}_1^m || \mathbf{p}_2^m || \cdots || \mathbf{p}_{n_m}^m]$ where $||$ denotes the vector concatenation operator (one can see U^1 and U^2 in Figure 2 shown as colorful column vectors). Rows of U^m represent the **local patterns** extracted from a text via the CNNs. In order to find the **global patterns** throughout the entire text, we feed rows of U^m to an LSTM network as depicted in Figure 2. The output of the LSTM network is considered as the hidden output of its last unit and is denoted as s^m having size q i.e., $|s^m| = q$. Then, the final feature vector of the proposed CNN-LSTM model is generated by passing the concatenation of all last hidden outputs through a Fully Connected Network (denoted as FCN in Figure 2) as follows:

$$v = \mathcal{G}([s^1 || s^2 || \cdots || s^{\mathsf{M}}]^T \times A + b) \tag{2}$$

where v denotes the extracted feature vector of a textual source, $A \in \mathbb{R}^{(\mathsf{M} \times q) \times d}$ is a weight matrix, and d is the desired final feature vector size. Note that $[s^1 || s^2 || \cdots || s^{\mathsf{M}}]$ is flattened into a vector of size $\mathsf{M} \times q$.

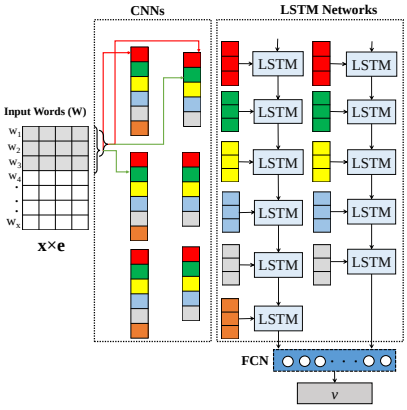

Figure 2: An illustration of the proposed deep model for fake news textual source feature extraction.

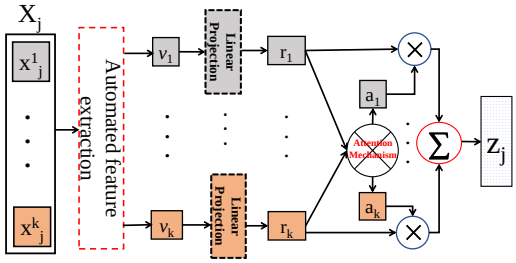

Figure 3: An illustration of the proposed interpretable multi-source fusion.

3.2 Interpretable multi-source fusion

The interpretable multi-source fusion component aims to combine features from different sources. A naive way of doing this is concatenating the feature vectors extracted by automated feature extraction component i.e., v_1 to v_k in Figure 1, into a single vector. This scheme considers all sources equally. However, different sources may have substantially different powers to detect fake news. Hence, when combining multiple sources, we propose to consider their contributions via an attention mechanism as shown in Figure 3. The attention mechanisms have achieved great success in many applications such as language translation (Bahdanau et al., 2014), image captioning (Xu et al., 2015), etc. Next, we present the details of the interpretable multi-source fusion component

The set of source-specific features of a news item is extracted by the automated feature extraction component as described in Section 3.1. Then suppose each source's extracted feature vector is denoted by $v_i \in \mathbb{R}^{d_i}$ $(1 \leq i \leq k)$ and has the dimension d_i. Now, to ensure feature vectors from different sources all have the same dimension h, we map each v_i to the vector r_i via a linear projection as follows:

$$r_i = v_i^T \times W_i + b_i, \quad \forall 1 \leq i \leq k \tag{3}$$

where $W_i \in \mathbb{R}^{d_i \times h}$ is a weight matrix, and $b_i \in \mathbb{R}^h$ is a bias vector. Then, the proposed attention method is carried out as follows:

$$z_j = \mathcal{G}(\sum_{i=1}^{k} a_i r_i), \quad \forall 1 \leq j \leq n \tag{4}$$

where z_j denotes the final feature vector of j-th news item and the scalar a_i is the attention score associated with i-th source i.e., the contribution of i-th source at z_j. Typically the attention scores are represented by a probability distribution. Therefore, each attention score a_i is normalized by the softmax function as follows.

$$a_i = \frac{e^{u_i}}{\sum_{l=1}^{k} e^{u_l}}, \quad \forall 1 \leq i \leq k \tag{5}$$

where u_i is a real value number denoting attention score of source i and is calculated according to Eq. 6:

$$u_i = w^T tanh(r_i), \quad \forall 1 \leq i \leq k \tag{6}$$

where $w \in \mathbb{R}^h$ is a weight matrix.

We should emphasize that attention scores a_i $(1 \leq i \leq k)$ are learned along with other parts of the model in an end-to-end manner where they are optimized to capture the informativeness of the different sources at the fake news detection task. As a result, capturing contributions of different sources reflected

at scalar values a_i ($1 \leq i \leq k$) makes the proposed framework somehow interpretable. This is due to the fact that now we can identify the roles of different sources in the determining the veracity of a news item as will be verified in Section 4.4.

3.3 Fakeness discrimination

Many of the existing fake news detection approaches look into the problem from a binary perspective. However, in practice, a piece of news might be a mixture of factual and false statements. Therefore, it is crucial to classify fake news into multiple classes reflecting degrees of fakeness. Nevertheless, multi-class fake news detection (i.e., fakeness discrimination) is challenging. The classifier needs to offer a better discriminative power because the boundary between two classes becomes more and more intertwined as the number of classes increases. To handle this challenge, we propose **M**ulti-class **D**iscriminative **F**unction (MDF) and is described in the following.

Classification accuracy on unknown test cases mostly depends on how we map our input data into a new feature space. In general, we want to group similar samples together and dissimilar ones far apart. To achieve this, we can learn the 'centers' of the classes in the feature space. If the centers are too close to one another, their samples might overlap resulting in less discriminative feature learning. Additionally, samples should be close to their class centers. This guarantees that samples belonging to the same class will be mapped into the same cluster (Wen et al., 2016). In general, the two aforementioned goals can be regarded as optimizing the precision and recall of the clusters in the learned feature space. Therefore, we include two terms in MDF: one which *pushes* the centers by a margin referred as *inter-class* term and one which *pulls* the samples toward their centers referred as *intra-class* term. The proposed inter-class term helps to learn discriminative features. Next, we introduce the MDF mathematically.

We present the MDF in a generalized non-convex form. The interpretable multi-source fusion component yields output feature vector of each news item (z_j in Eq. 4). For convenience, let $\mathcal{D}$ denote a dataset that contains features of all news items in $\mathcal{X}$ (i.e., $\mathcal{D} = \{z_1, z_2, \cdots, z_n\}$) and $\mathcal{D}_i$ denote all samples belonging to class i where $1 \leq i \leq m$. We calculate the centers of the different classes in the output feature space by the following equation.

$$c_i = \frac{1}{|\mathcal{D}_i|} \sum_{z_j \in \mathcal{D}_i} z_j, \forall i \in \mathcal{C} \tag{7}$$

During the optimization process, centers are not fixed anymore, as both weights and centers are getting updated. Also, the centers and feature outputs are normalized as $||c_j||_2 = 1$ and $||z_j||_2 = 1$, and therefore they reside on a unit hyper-sphere. Eq. 8 shows the formulation of MDF.

$$\begin{aligned} \varepsilon^{intra} &= \frac{1}{|\mathcal{D}|} \sum_{\forall \mathcal{D}_i \in D} \sum_{z_j \in \mathcal{D}_i} \|z_j - c_i\|_2^2 \\ \varepsilon^{inter} &= \frac{1}{\binom{m}{2}} \sum_{o=1}^{m} \sum_{r=1, r \neq o}^{m} max(0, \alpha - \|c_o - c_r\|_2^2) \\ MDF &= \beta_1 \varepsilon^{intra} + \beta_2 \varepsilon^{inter} \end{aligned} \tag{8}$$

where ε^{intra} term is the intra-class term that tries to minimize a sample's distance to its class center, and ε^{inter} is the inter-class term that is responsible for enforcing margin α between centers of every two classes. Two hyperparameters β_1 and β_2 control the intra-class and inter-class terms, respectively.

3.4 Training procedure

In this subsection, we describe the training procedure of MMFD as shown in Algorithm 1. At each iteration of the algorithm, a mini-batch of samples is selected for training (line 2). The features of each source are extracted by the automated feature extraction component described in Section 3.1 (line 5). The extracted features are re-weighted according to the proposed attention mechanism described in Section 3.2 (line 8). We combine MDF (Eq. 8) and cross entropy as the model loss function and their contributions

Algorithm 1: Training procedure of MMFD.

Data: Sample $\mathcal{X} = \{X_1, \cdots, X_n\}$ and labels $Y = \{y_1, \cdots, y_n\}$
Input: Learning rate: η; weight of MDF : λ; and hyperparameters of MDF: β_1, β_2 and α
Output: Model $\mathcal{M}$ and parameters $\theta = \{\theta_1, \cdots, \theta_p\}$

1 **while** *Not convergent* **do**
2 Select mini-batch $\mathcal{B} \subseteq \mathcal{X}$
3 **foreach** $X_j \in \mathcal{B}$ **do**
4 **foreach** $x_j^i \in X_j$ **do**
5 $v_i = FE_i(x_j^i)$ /* see Figure 1 */
6 $r_i = v_i^T \times W_i + b_i$ /* see Figure 3 */
7 **end**
8 $z_j = \mathcal{G}(\sum_{i=1}^{k} a_i r_i)$ /* see Figure 3 */
9 $p(z_j) = Softmax(z_j)$
10 **end**
11 $CrossEntropy = -\sum_{z_j} p(y_j) \times log(p(z_j))$
12 $J = \lambda \times CrossEntropy + (1 - \lambda)(\beta_1 \varepsilon^{intra} + \beta_2 \varepsilon^{inter})$ /* refer to Eq. 8 for ε terms */
13 Backpropagate the error to get $\nabla_\theta J(\theta)$
14 $\forall \theta_i \in \theta, \theta_i = \theta_i - \eta \nabla_{\theta_i} J(\theta)$
15 **end**
16 **if** *condition* = *TRUE* **then**
17 $CalculateCenters(\mathcal{X}; \mathcal{M})$
18 **end**
19 **return** $\mathcal{M}$, $\{\theta_1, \cdots, \theta_p\}$

are controlled by the hyperparameter λ (line 12). Algorithm 1 backpropagates the error to compute gradients of the loss function with respect to each parameter of the model. Following the common way, we use Stochastic Gradient Descent (SGD) to update the parameters (line 14). Finally, once the training converges, the optimized parameters are returned, which can be used for prediction.

4 Experiment

In this section, we empirically evaluate the proposed framework on a real-world fake news dataset. We demonstrate the effectiveness of the approach by conducting a set of experiments. Particularly, we seek to answer the following research questions.

- *Q1*. How does the proposed framework perform on fake news detection?
- *Q2*. Can the proposed framework handle multiple sources effectively?
- *Q3*. How does each component of the proposed framework affect the performance?

We first present the experimental settings. Then, the experiments and their results are conducted to answer the aforementioned questions. Finally, we present a case study to qualitatively demonstrate the effectiveness of the proposed approach.

4.1 Experimental settings

In this work, we use the dataset published in (Wang, 2017) known as LIAR. LIAR is one of the largest publicly available fake news datasets. It has been constructed from a collection of statements investigated by experts in *politifact.com*, which is a well-known fact-checking service. The author did split the dataset into three sets: train, test, and development. His sample selection for sets is random where the train, test, and development sets contain, respectively, 80%, 10%, and 10% of the entire dataset. We use the same split as Wang (Wang, 2017). LIAR contains three sources of data. We supplement it and add another source. In the following, we describe the sources used to evaluate the proposed framework.

- **Statements.** The statements are short sentence(s), mostly from American politicians covering different topics. The statements have been manually classified into six classes including *True*, *Mostly-True*, *Half-True*, *Barely-True*, *False*, and *Pants-on-Fire*. We use the architecture presented in Section 3.1 (Figure 2) to model the statements.

- **Metadata.** The metadata is a textual context about the statements or their speakers if known. This includes the name of a statement's speaker, his/her job title, his/her political party affiliation, the U.S state associated with a speaker, and the venue/location that a statement has been made. When a speaker is unknown, the related fields are blank. We combine all metadata fields and use the architecture presented in Section 3.1 (Figure 2) to model it.

- **History.** The history is a non-textual source. It is a 5-dimensional vector representing a speaker's count of statements on five classes, namely *Mostly-True*, *Half-True*, *Barely-True*, *False*, and *Pants-on-Fire*. The history is modeled by a single-layer fully connected network with 10 hidden units.

- **Report.** In addition to the sources described above, we supplement the dataset by adding the verdict reports generated by experts in *politifact.com*. The reports are longer than the statements and metadata. We remove the class labels from the reports. Similar to other textual sources, the architecture presented in Section 3.1 (Figure 2) is utilized to model the reports.

We use the train set to train the model. For the textual sources, we populate word embeddings (see Figure 2) from the Google word2vec embeddings trained on roughly 100 billion words from Google News (Mikolov et al., 2013). In all experiments, we utilize the development set to tune the hyperparameters, which have been done carefully with grid search over ranges of different values. We utilize the mini-batch 32, apply the dropout rate 60%, and use Adam optimizer (Kingma and Ba, 2014) to apply the gradient descent with the learning rate of 0.001. For center computation in MDF (Eq. 7), we gradually increase the center computation period starting from 20 optimization steps to 160 steps as the training proceeds. The hyperparameters β_1, β_2, and α are set to 0.6, 0.4, and 0.3, respectively. The number of hidden units in LSTM network is set to 200. The test set is used to evaluate the effectiveness of the model and the performance reported in this paper is based on the evaluation of the test set. For the performance metric, we use accuracy since the dataset is fairly balanced and also consistent with Wang (Wang, 2017), we found that f-measure performs similarly as accuracy.

4.2 Performance comparison

To answer questions *Q1* and *Q2*, we compare our approach, MMFD, with a set of representative baselines:

- Basic-SVM. For this baseline, we extract a set of features from sources. For the textual sources, we extract Bag-of-Words, bigrams, and 3-grams, and simply combine them with the history. Since the number of features is large, we apply PCA to reduce the dimension to 300. Finally, we train a SVM model (Support Vector Machine) on the extracted features. We use a grid search on the performance of the development set to tune the SVM classifier hyperparameters.

- Basic-RandomForests. This baseline is similar to Basic-SVM except that Random Forests is employed as the classifier.

- Basic-NN. In addition to the employed traditional classifiers, i.e., SVM and Random Forests, we also use a NN (Neural Network) as the baseline. The input to NN is the same with other two classifiers. We use a fully connected network with one layer. Again, the hyperparameters are set using the development set. Basic-NN further refines the initial features.

- Wang (Wang, 2017). Wang (Wang, 2017) developed a model based on CNN and BLSTM (Bi-directional LSTM) for fake news detection on LIAR dataset.

- Random. Random includes randomly selecting the class of a test sample.

- Majority. In this method, each test news item is labeled with a class having the largest number of samples i.e., the *Half-True* class.

Table 1: Performance comparison. S1: Statement, S2: Metadata, S3: History, S4: Report

Sources	Method	Accuracy (%)
–	Random	17.4
–	Majority	20.8
S1	Basic-SVM	20.12
	Basic-RandomForests	23.19
	Basic-NN	21.73
	Wang (Wang, 2017)	27.00
	MMFD	**29.06**
S1+S2+S3	Basic-SVM	25.07
	Basic-RandomForests	27.63
	Basic-NN	28.16
	Wang (Wang, 2017)	27.04
	MMFD	**34.77**
S1+S2+S3+S4	Basic-SVM	29.98
	Basic-RandomForests	27.01
	Basic-NN	29.12
	Wang (Wang, 2017)	N/A
	MMFD	**38.81**

The comparison results on different combinations of sources have been shown in Table 1. As mentioned before, the original dataset (Wang, 2017) contains only the sources "S1: Statement", "S2: Metadata" and "S3: History" and we enrich the dataset by adding the fourth source "S4: Report". Thus, we only report combinations with news content (i.e., S1), all sources in the original dataset (i.e., S1+S2+S3) and all sources in the enriched dataset (i.e., S1+S2+S3+S4). Note that the performance of Wang (Wang, 2017) is not available on the enriched dataset. We make the following observations from these results:

- MMDF outperforms Wang (Wang, 2017) when only using the news content (e.g., S1). Both methods are based on CNN + LSTM. However, the proposed framework also has the model component to discriminate between multiple classes. This observation supports the importance of the proposed discriminative function i.e., MDF.

- By incorporating more sources, the performance of all methods tends to increase. Compared to baselines, the proposed framework MMDF enjoys more performance improvement with more sources. These observations suggest that the proposed framework can effectively combine multiple sources.

- The proposed framework always obtains the best performance with all settings. In the following subsection, we further investigate how each model component contributes to the performance improvement.

To sum up, the proposed framework outperforms representative baselines and it is also effective in integrating information from multiple sources.

4.3 MMFD component analysis

In this subsection, we conduct several experiments to study the impact of model components on the performance of the proposed framework to answer *Q3*. The experiment are as follow:

- $MMFD_{PCA}$. In this experiment, we remove feature extractors in MMDF (FEs in Figure 1). Instead, we apply PCA (with dimension 100) on each input of the textual sources. We keep the history and the interpretable multi-source fusion and the fakeness discrimination components unchanged.

Table 2: Impact of model components on the proposed framework.

Investigated component	Setting	Accuracy (%)
Automated feature extraction	$MMDF_{PCA}$	26.06
	$MMDF_{NN}$	30.95
Multi-source fusion	$MMDF_{Concat}$	28.69
	$MMDF_{EQ}$	32.08
Fakeness discrimination	$MMDF_{CE}$	31.11
	$MMDF_{CL}$	35.17
–	MMFD	**38.81**

Table 3: A case study demonstrating the interpretability of the proposed framework.

Source	Content	Attention score
Statement	"Virtually every person across this country has seen premiums going up and up and up due to Obamacare"	0.17
Metadata	Ted Cruz, Senator Texas, Republican a conversation with reporters	0.09
History	[36 33 15 19 8]	0.43
Report	The full report is available from the URL[1]	0.31

- $MMFD_{NN}$. For this configuration, we perform the same feature extraction as $MMFD_{PCA}$ except that instead of PCA, we extract features from a NN.
- $MMFD_{Concat}$. In this setting, we keep the automated feature extraction and the fakeness discrimination components. However, we replace the interpretable multi-source fusion component by concatenating extracted features.
- $MMFD_{EQ}$. Similar to $MMFD_{Concat}$, in this setting, we keep the automated feature extraction and the fakeness discrimination components. However, we replace the interpretable multi-source fusion component by explicitly considering all the sources equally important. In other words, in Eq. 4 all a_is are set to the same value.
- $MMDF_{CE}$. In this setting, we evaluate the effectiveness of the fakeness discrimination component. We keep two other components and remove MDF from the loss function of the model and just keep Cross Entropy (CE).
- $MMDF_{CE}$. Center Loss (CL) was proposed in (Wen et al., 2016). This function penalizes cross entropy by an intra-class sparsity. In other words, it just tries to move samples toward their class centers. In this setting, we use Center Loss and cross entropy.

The results of component analysis with all sources in the enriched dataset are presented in Table 2. It can be observed that:

- Automated feature extraction effectively extracts features. Neither $MMFD_{FCN}$ nor $MMFD_{PCA}$ can extract informative features compared to the automated feature extraction component.
- Hand-crafted features are ineffective. Features in $MMFD_{FCN}$ and $MMFD_{PCA}$ are basic linguistic features which are not effective as much as the automated ones from deep networks.
- The interpretable multi-source fusion component integrates features effectively. Simple concatenation methods such as $MMFD_{Concat}$ and $MMFD_{EQ}$ fail to distinguish different sources. The reason for better performance of $MMFD_{EQ}$ is because the linear projection presented in Eq. 3.
- MMFD can discriminate different classes effectively. Neither $MMDF_{CE}$ nor $MMDF_{CL}$ can effectively discriminate different classes. The reason for better accuracy of $MMDF_{CL}$ is due to the extra penalty added to the cross entropy.

In conclusion, the three major model components including automated feature extraction, multi-source fusion, and fakeness discrimination can help boosting the performance of the proposed framework in detecting fake news.

4.4 A case study

As mentioned before, the interpretable multi-source fusion components equips the proposed framework with a sort of interpretability. To investigate the interpretability power of the framework , we present a case study demonstrated in Table 3. In this case study, we randomly select a sample news item from the test set. The ground truth label of this news item is *False* and the model correctly predicts it as *False*. Then, we show the attention score of each source. As shown in Table 3, the highest score is given to the history source. This seems reasonable as the history of the speaker, Ted Cruz, regarding the number of previous false statements is quite high. Moreover, the report attains the second highest attention score. This seems reasonable as well because the report includes contextual detail about a news item. In addition, it is quite hard to predict the fakeness of news from the short news statement and the writer's profile; hence low scores are given to these two sources.

5 Related Work

There have been substantial number of works studying fake news and misinformation detection in recent years. One well-known approach is taking advantage of linguistic features. In their seminal work (DePaulo et al., 2003), DePaulo et al. shed light on cues of fake stories from physiological point of view. They pointed out that fake stories contain an unusual language. Li et al. (Li et al.,) discovered that linguistic features such as sentiments and singular pronouns are informative in online spam reviews. In (Qazvinian et al., 2011), the authors used unigram, bigram and Part-of-Speech (POS) features of tweets for rumor detection. Martinez-Romo and Araujo (Martinez-Romo and Araujo, 2013) used discrepancy and lack of semantic relation between the language of spam tweets and that of the websites redirected by those tweets. Kumar et al. (Kumar et al., 2016) showed that Wikipedia hoaxes tend to contain more words than genuine articles. Also, Linguistic Inquiry and Word Count (LIWC) (Pennebaker et al., 2015) has been employed to investigate the role of individual words in a document for deception detection (Ott et al., 2011). For a review of other linguistic features, you can refer to survey papers (Conroy et al., 2015; Heydari et al., 2015).

Despite the success of aforementioned works, we still lack a comprehensive and optimized set of features for fake news. This is even more stressed for short statements as they offer little to fake news detection. Hence, deep neural networks as automatic feature extractors have gained attention for fake news detection (Ruchansky et al., 2017). Closely related to our work is (Wang, 2017). Wang (Wang, 2017) introduced the dataset used for our evaluation. Further, he developed a combination of CNN and LSTM for modeling fake news detection. Our model is substantially different from that of Wang (Wang, 2017) because, 1) we provide an interpretable model component to combine multiple sources, (2) we propose a new discriminative function, MDF, to discriminate degrees of fakeness, (3) we supplemented the dataset and modeled the verdict reports.

6 Conclusion

In this study, we investigated the challenging task of multi-source multi-class fake news detection. The task faces several challenges – how to incorporate multiple sources and how to discriminate degrees of fakeness. To address these challenges, we proposed a coherent and interpretable framework MMFD, which incorporates automated feature extraction, multi-source fusion and fakeness discrimination. Through extensive experiments, we demonstrated that our model can effectively distinguish different degrees of the fakeness of news. In fakeness discrimination, we treated all classes the same. Thus, we would like to incorporate class differences by enforcing larger margin between certain classes. By doing so, several classes can be merged easily if needed, allowing for a less fine grained but possibly more precise detection. Another possible research direction is to incorporate more sources such as temporal information, social networks and user interactions.

Killing Four Birds with Two Stones: Multi-Task Learning for Non-Literal Language Detection

Erik-Lân Do Dinh, Steffen Eger, and Iryna Gurevych

Abstract

Non-literal language phenomena such as idioms or metaphors are commonly studied in isolation from each other in NLP. However, often similar definitions and features are being used for different phenomena, challenging the distinction. Instead, we propose to view the detection problem as a generalized non-literal language classification problem. In this paper, we investigate multi-task learning for related non-literal language phenomena. We show that in contrast to simply joining the data of multiple tasks, multi-task learning consistently improves upon four metaphor and idiom detection tasks in two languages, English and German. Comparing two state-of-the-art multi-task learning architectures, we also investigate when soft parameter sharing and learned information flow can be beneficial for our related tasks. We make our adapted code publicly available[1].

1 Introduction

As Lakoff and Johnson (1980) argued, metaphorical concept mappings, often from concrete to more abstract concepts, are ubiquitous in everyday life, thus they are ubiquitous in written texts. But the same is true for other kinds of so-called *non-literal language*, e.g., for idioms. Boundaries between these instances of non-literality are not always clear: for instance, "[...] a swathe of sunlight lay across the red-tiled floor."[2] can be classified as a metaphor because of its non-lexicalized figurative meaning. Few would dispute the idiomaticity of "kicking the bucket", as the non-literal meaning in this multi-word expression is largely conventionalized. However, in the sentence "One approach would be to draw the line by reference [...]" the expression "draw the line" could be classified as either metaphorical (because it still evokes the literal senses of its constituents) or idiomatic (as it is a fixed expression with lexicalized figurative sense).

Much effort has been spent on the detection of metaphors, idioms, and general non-literal language use (Shutova, 2015). However, because of the named vague and subjective nature of these phenomena, a multitude of datasets using differing definitions has emerged in the process. Even when datasets address the same aspect of non-literality, they may use diverging or underspecified definitions; compare, e.g., the guidelines for annotating metaphors of Tsvetkov et al. (2014) ("[...] all words that, in your opinion, are used non-literally [...]") and Mohammad et al. (2016) ("more complex; more distant from our senses; more abstract; more vague; ...").

The fuzziness of non-literality has two natural consequences: (1) training data is sparse, because different researchers may use diverging definitions, and hence may annotate different things rather than extend "the same story"; (2) high-quality training data is costly to obtain because there may be considerable disagreement among crowd-workers and even trained experts regarding the labels for different instances of (non-)literality.

In this work, we address two research questions:

[1] https://github.com/UKPLab/coling2018-nonliteral-mtl

[2] VUAMC (Steen et al., 2010)

Proceedings of the 27th International Conference on Computational Linguistics, pages 1558–1569
Santa Fe, New Mexico, USA, August 20-26, 2018.

- (how) can we leverage existing datasets for non-literality, possibly using diverging definitions and addressing different aspects of non-literality, to bootstrap classifiers on new sparse data? This question is particularly relevant for non-literal language detection due to problem (2) above;

- do existing datasets for non-literality share common ground in the first place or are many of them using arbitrary and mutually exclusive definitions? If the answer to this question is "yes", then this would call for a re-thinking of a whole computational research area, and a return to safe grounds.

To address our research questions, we apply *multi-task learning* (MTL) to four non-literal language datasets. Introduced by Caruana (1993), MTL has recently been used to improve a variety of NLP tasks with the help of other, auxiliary tasks. This includes chunking (Søgaard and Goldberg, 2016), using POS tagging, and spelling normalization (Bollmann and Søgaard, 2016), using orthographic data from other domains, but also semantic tasks like entailment (Hashimoto et al., 2017) or argument mining (Schulz et al., 2018). The underlying idea of MTL is that it is beneficial to learn several tasks jointly because of "spill-over" effects. Some researchers have claimed that a requirement for success in MTL is task relatedness. If this is true, then MTL is a formidable testbed for *both* of our research questions.

We aim at **four birds**, namely: We consider detection of non-literal phenomena in four different datasets, regarding each as a separate task. These are (A) *metaphor detection in content tokens*, (B) *classification of metaphorical adjective-noun constructions*, (C) *detection of idiomatic use of infinitive-verb compounds*, and (D) *non-literal usage of particle verbs*. Two of the datasets comprise English data, the other two consist of German data.

We throw **two stones** at them, namely: (i) an MTL sequence tagging framework using hard-parameter sharing (Kahse, 2017) and (ii) Sluice Networks (Ruder et al., 2017), for which sharing of information is not hard-wired, but can adjust softly. Both frameworks yield different insights because the first has to make use of all available data, while the second can freely decide if other tasks contain relevant information and if so, how much sharing to enable.

This work is structured as follows. We first ground our motivation to tackle four non-literal language tasks in Section 2. There, we also discuss applications of MTL, from pure syntactic to higher-level, semantic tasks. In Section 3, we describe the two systems that we compare in our experiments. We specify the used datasets and describe their differences in Section 4. In Section 5, we discuss our experiments and results. Finally, we conclude with an outlook on possible future work in Section 6.

2 Related Work

Work in non-literal or figurative language classification usually revolves around one specific phenomenon, be it metaphor, idiom or also metonymy detection. While many approaches are monolingual, some explore cross-lingual non-literal language classification. Tsvetkov et al. (2014) train models separately on English adjective-noun and subject-verb-object metaphors using random forests and a variety of semantic features, including supersenses and concreteness values. The models are then used to classify metaphors in similarly annotated Spanish, Russian, and Farsi test sets.

To the best of our knowledge, a combined detection of multiple non-literal phenomena has not been conducted before. This is surprising because common semantic features have already been used to classify different kinds of non-literal language.

One such typical feature in non-literal language classification is the violation of selectional preferences (Wilks, 1978). It is used, e.g., in *met** (Fass, 1991) to classify metaphors and metonyms. While the system distinguishes between both phenomena, it does so only after using the selectional preference information. In a related task, Horbach et al. (2016) employ this information for classifying idiomatic uses of infinitive verb compounds. Another feature used across different non-literal language detection tasks is topic information. While the work by Horbach et al. (2016) includes this feature for idiom detection, Beigman Klebanov et al. (2014) utilize it to classify metaphorically used tokens. Additionally, they make use of concreteness ratings, grounded in the Conceptual Metaphor Theory (Lakoff and Johnson, 1980). However, as argued in our introduction, concreteness is also useful for the detection of other kinds of non-literal language. For example, Zhang and Gelernter (2015) utilize such ratings to detect

metonymy. Further, supersenses are employed to detect metaphors (Tsvetkov et al., 2014) or non-literal language in general (Köper and Schulte im Walde, 2017). One more feature that is often integrated is textual cohesion, e.g., in metaphor (Schulder and Hovy, 2014) and idiom detection (Sporleder and Li, 2009). The use of such common features suggests that different aspects of non-literality require similar information and that representation sharing may thus turn out beneficial.

Introduced in the early nineties (Caruana, 1993), multi-task learning (MTL) has been more widely and successfully used in NLP recently (Ruder, 2017). MTL denotes a machine learning technique in which multiple tasks are trained in parallel in the same system, using a shared representation. The goal is to take advantage of commonalities between the different tasks. Bollmann and Søgaard (2016) use multi-task learning for historical spelling normalization. They employ texts from different domains as main respectively auxiliary tasks and improve upon a CRF baseline. Søgaard and Goldberg (2016) show that task supervision at lower layers for lower-level syntactic tasks like POS-tagging is beneficial to higher-level syntactic tasks such as chunking and CCG supertagging. Since their experiments with semantic tasks (NER, supersense tagging) on the higher levels show no improvement, they conclude that tasks need to be "sufficiently similar, e.g., all of syntactic nature" for multi-task learning to increase performance. Their conclusion is challenged by Hashimoto et al. (2017), who create a similar multi-task learning network in which lower layers predict syntactic tasks, while higher layers predict sentential relatedness and entailment. Their semantic tasks also improve when introducing *shortcut connections*, i.e., feeding the word representations into all layers of their network. In contrast, Alonso and Plank (2017) find generally mixed performance of MTL for semantic tasks. They also use syntactic tasks as low-level auxiliary tasks, but cannot improve performance over a single-task learning baseline for three out of five investigated semantic tasks (NER, supersense classification, frame identification). Schulz et al. (2018) apply MTL to another semantic task, argumentation mining. Instead of syntactic tasks as auxiliaries, they use diverse argumentation mining datasets from different domains. Similar to our tasks, annotation and labels vary across their different tasks due to inherent subjectivity and vagueness of argumentation mining (as for non-literal language detection). Experimenting with artificially downsized datasets, they show that—especially when data for the main task is sparse—MTL improves sequence tagging results for argumentation mining, even when the tasks cover different domains. In contrast, we also investigate the effect of auxiliary tasks with small datasets on a large-data main task.

3 System Descriptions

We conduct our multi-task learning experiments using two different architectures: a sequence tagging framework (MTL-SEQ) (Kahse, 2017), and Sluice Networks (SLUICE) (Ruder et al., 2017).

We adapt both systems to our datasets, which only have labels for few tokens in a sentence. Thus, overfitting on the missing/"empty" labels seems probable, and is confirmed by preliminary experiments. To alleviate this issue, we exclude the loss on the tokens with empty labels from the total loss calculation, so that they do not influence weight updates.

Multi-Task Learning Sequence Tagging Framework (MTL-SEQ) We employ the system by Kahse (2017), a framework for multi-task learning sequence tagging generalizing the model of Søgaard and Goldberg (2016). An example of a two-task setup is shown in Figure 1. It uses English metaphor classification on a token level as the main task, and English metaphor detection in adjective-noun constructions as an auxiliary task (both described in Section 4).

After an input layer that reads in word embeddings, there are multiple shared, bi-directional LSTM layers, thus implementing hard parameter sharing. The shared layers are followed by a number of fully connected task-specific layers (Peng et al., 2017), storing private information for each task. At their end, a softmax classifier predicts labels for each input token.

In addition to using pre-trained word embeddings, the architecture incorporates character-level information to improve handling of out-of-vocabulary words. The framework can further be configured to terminate different tasks at different layers. We set this option to randomly use one of two scenarios: either all tasks use all BiLSTM layers, or all auxiliary tasks terminate one layer before the main task.

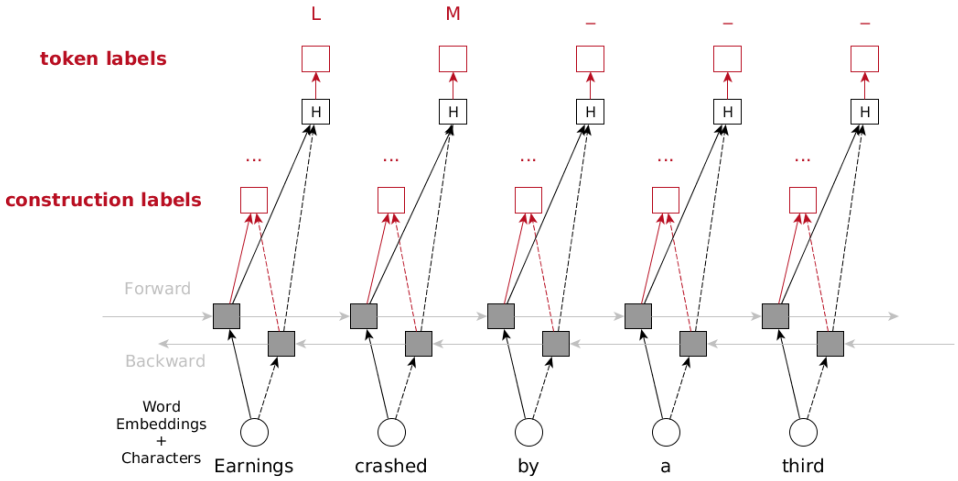

Figure 1: Example setup for the sequence tagging MTL framework (Kahse, 2017). It shows auxiliary task `adj-noun-met` and main task `tok-met`. Gray blocks represent shared BiLSTM units. In this example, both tasks are terminated after one shared BiLSTM and multiple private fully connected layers (white *H* blocks). The input is task-specific and only evaluated for the respective task; pictured is input for `tok-met`. "Earnings" is labeled as literal, "crashed" is labeled as a metaphor; the remaining tokens have no label and their loss is excluded from the total loss calculation.

We optimize over several hyper-parameters, which include the number of task-specific fully connected layers, the layer at which tasks should terminate, and word dropout rate. An overview of the hyper-parameters and the range from which we randomly sample their values is shown in Table 1.

Sluice Networks (SLUICE) Ruder et al. (2017) introduced *sluice networks* as a generalization and combination of various MTL architectures that use different information transfer techniques. Thus, it can emulate, e.g., hard parameter sharing (Caruana, 1993), where the same layer weights (i.e., the same layers) are used for different tasks, and cross-stitch networks (Alonso and Plank, 2017), in which trainable parameters decide the amount of shared information between layers of separate networks. A generic example is given in Figure 2.

The system first reads input in an embedding layer, and combines the word embeddings with character-level embeddings (produced by a BiLSTM). This representation is passed to task-specific BiLSTM networks, which learn to share parts of their layer outputs, i.e., activations, in the following way. Each layer contains two different subspaces, to store both task-specific, and shared representations. Trainable parameters α determine the amount of sharing between the subspaces of the task BiLSTMs. Parameters β decide to which degree the output of the BiLSTM layers should be used for the task-specific classifier (a multilayer perceptron). This way, they allow for hierarchical relations.

Most hyper-parameters regarding information and weight sharing are encoded into trainable parameters for sluice networks. Thus, the most important hyper-parameters are the number of BiLSTM layers in the network, the way layer output is combined, and constraints on the subspaces (see Table 2).

Hyper-parameter	value range
number of of shared BiLSTM layers	{1, 2, 3}
number of task specific fully connected layers	{0, 2}
Word dropout	[0.0, 0.5]
Dropout	[0.0, 0.5]
Activation function for fully connected layers	{tanh, relu}
Output layer	{0, 1, 2}

Table 1: Hyper-parameters for the multi-task learning sequence tagging framework (Kahse, 2017).

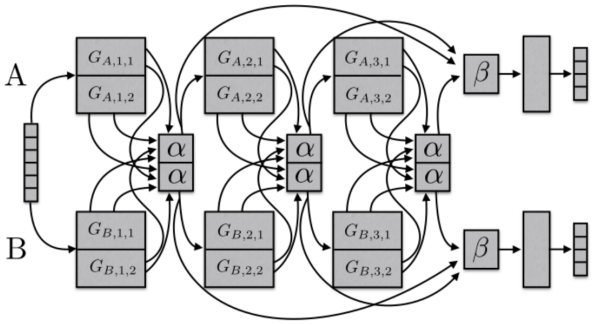

Figure 2: Example for sluice networks (Ruder et al., 2017). A single input representation is passed into task networks A and B. Both of the two networks i have three RNN layers j, consisting of two subspaces $G_{i,j,k}$ each. For each layer output, α determines the amount of sharing between the layers of different tasks while β controls the layer at which a task network terminates.

Conceptually, the largest difference between both systems is the following: MTL-SEQ implements hard parameter sharing, i.e., the layer weights are the same for all tasks, and the structure of the network is predefined; in particular, at which layer a task should terminate. Essentially, this amounts to using one network for multiple tasks, trained jointly. In contrast, SLUICE has separate layers for each task, and learns parameters which control the information flow between those task-specific layers. Further, the level at which task predictions take place is also learned for each task. This means that two networks are trained in parallel, that share a learnable amount of information. Comparing both approaches, we can analyze which tasks profit from which degree of information sharing.

Hyper-parameter	value range	notes
number of BiLSTM layers	{2, 3}	
layer connections	{stitch, skip}	*stitch* denotes learnable β parameters, while *skip* only uses the last BiLSTM layer as classification input
subspace constraint weights	{0.1, 0.2}	

Table 2: Hyper-parameters for the sluice networks.

4 Datasets and Tasks

In our experiments, we consider four different non-literal language tasks (Table 3). Specifically, we include two metaphor detection tasks, with data being annotated on a token and on a construction level (i.e., grammatical constructions that share one label). We further include data from two tasks classifying idiomatic language use. The latter two tasks use German data, while the metaphor task datasets are in English. While those tasks all cover distinct, or at least distinctly annotated, non-literal language phenomena, on a textual level they all are examples of irregular polysemy. Thus, in many feature-based detection systems similar or even the same features and resources are used to classify these phenomena.

Token-level Metaphor Classification We consider metaphor detection on a token level, i.e., each (content) token should be classified as belonging to a metaphor or not. We employ the *VU Amsterdam Metaphor Corpus* (Steen et al., 2010), short *VUAMC*, for our experiments. It is the largest available resource in which each token is specifically annotated as being used metaphorically or literally, and comprises four genres: *academic*, *conversation*, *fiction*, and *news* texts.

The VUAMC is annotated using very rigid annotation guidelines, *MIPVU* (Steen et al., 2010). In short, each token that is not used in its most basic (i.e., most concrete, body-related, historically oldest) sense is labeled as metaphoric. Unclear cases are resolved using specified online dictionaries. These guidelines lead to a high inter-annotator agreement of 0.84 Fleiss' κ. At the same time, they introduce the problem of very commonly used word senses being annotated as metaphoric. For example, prepositions such

Task	dataset	size	M	lang	example
Token-level metaphor detection	VUAMC	103,865	15%	en	"Along with Sir James he **found** the US much more **attractive**, [...]"
Construction level metaphor detection	Tsvetkov et al., (2014)	1,738	47%	en	Wind and wave power providing the **green energy** of the future.
Classification of idiomatically used verb compounds	Horbach et al., (2016)	5,249	64%	de	"Auch eine Uhr, die **stehen geblieben** ist, geht zweimal am Tag richtig", sagt er. ("A clock that has **stopped running**, is correct two times a day, too," he says.)
Classification of non-literally used particle verbs	Köper and Schulte im Walde (2016)	6,436	35%	de	Auf Decken sitzt man ums Feuer und lässt den ereignisreichen Tag **nachklingen**. (You sit around the fire on blankets and let the day **linger on** [lit.: ring on].)

Table 3: Investigated tasks and datasets. *Size* describes labeled tokens in case of token-level metaphor detection (content tokens), and labeled constructions for the other tasks respectively, *M* denotes percentage of non-literal labels. Non-literal use of tokens/constructions in the examples is marked bold.

as *on* are labeled as metaphoric when not being used in their positional sense. We partially avoid this problem by filtering out non-content words and auxiliary verbs. Dataset statistics are given in Table 3.

Construction-level Metaphor Classification Many datasets in metaphor detection tasks label *grammatical constructions* instead of tokens, prominently, e.g., adjective-noun compounds or subject-verb/verb-object compounds. We use the adjective-noun dataset by Tsvetkov et al. (2014). Their training set was created by two annotators and later curated, while the test set—comprised of sentences from the TenTen web corpus (Jakubíček et al., 2013)—was annotated by five annotators. Fleiss' κ for the latter is reported as 0.74.

Compared to the VUAMC, the guidelines for this dataset are substantially less specific, appealing to the intuition of the annotators (in fact, annotators were asked to mark all *non-literally* used words). Due to this difference in guidelines and the focus on adjective-noun metaphors, the resulting annotations also differ from the VUAMC, which is why we consider this a different task.

For the test set, the original 200 sentences containing the construction are available. We automatically crawl large corpora[3] to obtain sentences for the constructions in the training set. Note that both training and test sets are substantially smaller than those of the VUAMC (Table 3), by a factor of 50.

Classification of idiomatically used infinitive-verb compounds In contrast to the metaphor datasets which can also include more novel meanings of the annotated words, e.g., "spot of information", Horbach et al. (2016) focus on idiomatic usage of verb compounds. This means they consider only conventionalized figurative meanings, i.e., compounds whose figurative sense is already lexicalized. They create a corpus of literal and idiomatic uses of six German infinitive-verb compounds (e.g., *sitzen lassen—to leave sitting/abandon*). Thus, this dataset contains considerably more samples for a specific compound (up to 1,000 for each) compared to the previous two datasets. Genres covered are newspaper and magazine articles published from 1993–2013.

Two lexicographers were tasked to annotate occurrences of the compounds within a three-sentence

[3]ukWac (Baroni et al., 2009), British National Corpus (BNC Consortium, 2007)

context as *literal* or *idiomatic*, but were given no further guidelines. Still, they achieve an inter-annotator agreement of 0.72 Cohen's κ. The dataset contains the unanimously labeled instances and a portion of adjudicated ambiguous cases.

Classification of non-literally used particle verbs Similar to the infinitive-verb compound dataset, Köper and Schulte im Walde (2016) investigate pre-set constructions, specifically 165 different German particle verbs. For each particle verb, they selected up to 50 sentences containing *literal* and *non-literal* uses from a German web corpus, *DECOW14AX* (Schäfer and Bildhauer, 2012; Schäfer, 2015); however, they do not discuss the types of non-literality covered. Annotation was conducted by three German speakers with "linguistic background" on a 6-point scale; guidelines are not disclosed. Köper and Schulte im Walde (2016) report an inter-annotator agreement of 0.70 Fleiss' κ after mapping the 6-point scale to a binary annotation.

5 Experiments

We conduct three types of experiments for MTL-SEQ and SLUICE:

- a regular single-task learning baseline *(STL)*
- a combined-data single-task learning baseline *(MERGED)*, where we merge the training data of the different tasks
- a multi-task learning setup *(MTL-all)*, where one main task is supported by three auxiliary tasks

The MERGED baseline allows us to differentiate between causes for possible improvements, since we want to investigate in which way additional tasks and data can influence performance. We further partition our MTL experiments along languages, i.e., we carry out additional experiments separately for German *(MTL-de)* and English *(MTL-en)* tasks. Those mono-lingual setups thus only include one auxiliary task.

Setup We use the same train and test split as in Tsvetkov et al. (2014) for `adj-noun-met`. Thus, we use 11% of the data as test data and the remainder as training data. We use 20% of the training data as development data. For `tok-met`, we use a split of 70%/20%/10%. For the two German idiom datasets, we use a training/development/test set split of roughly 80%/10%/10%.

As input to both neural networks we use 100-dimensional, bilingual word embeddings trained using bivec (Luong et al., 2015) on a parallel (en-de) version of the Europarl corpus (Koehn, 2005).

Results We report test set results for the best performing system configurations on the development sets and use macro F_1-score to compare our results. We first analyze the results of the different architectures separately, before comparing both approaches.

Task type	`tok-met`	`adj-noun-met`	`inf-verb`	`part-verb`
STL	0.4399	0.5172	0.8507	0.7037
MERGED	0.4600	0.5976	0.8405	0.6875
MTL-all	**0.4897**	**0.6705**	**0.8602**	**0.7083**
MTL-en	0.4277	0.5357	–	–
MTL-de	–	–	0.8519	0.7065

Table 4: **MTL-SEQ** F_1-scores on the test sets for the different tasks and experiment types. *MTL-all* specifies that the respectively remaining three tasks are used as auxiliary tasks. *MTL-en* and *MTL-de* stand for mono-lingual experiments, i.e., containing only one auxiliary task.

Task type	tok-met	adj-noun-met	inf-verb	part-verb
STL	0.4833	0.5487	0.8609	0.7894
MERGED	0.4570	0.5143	0.8401	0.7965
MTL (all)	**0.5604**	**0.6333**	0.8763	0.8007
MTL (en)	0.5467	0.6207	–	–
MTL (de)	–	–	**0.8833**	**0.8146**

Table 5: **SLUICE** F_1-scores on the test sets for all four tasks and experiment types.

MTL-SEQ Our results for MTL-SEQ are given in Table 4.

For tok-met, MERGED already improves over the STL baseline. MTL-all further improves upon the two. In contrast, including only adj-noun-met as auxiliary task (MTL-en) performs even worse than STL.

For adj-noun-met, the pattern is identical except that MTL-en slightly outperforms STL. Comparing MERGED with MTL-all we see that the performance difference is mainly due to MTL-all introducing fewer new classification errors over the STL baseline.

In other words: both metaphor tasks, where training (and evaluation) data for a particular token or construction is sparse, profit heavily from inclusion of the idiom datasets. In contrast, using only the respective other English metaphor dataset does not help. Here, the difference between STL and MTL-en is not statistically significant (McNemar's Test, $p = 0.22$). It is notable that the German idiom datasets improve the English metaphor tasks by jointly fitting the same network.

The results for inf-verb and part-verb display a different pattern. MERGED performs worse than STL and even though MTL-all improves over both baselines, the difference is not significant. Unlike for the English datasets, MTL-de performs better than STL. The network can better fit to the datasets which are designed to contain many instances of a particular token or construction (inf-verb and part-verb). This is evidenced by the large differences in F_1-scores between the tasks. But these idiom datasets also substantially improve classification for the English metaphors, regardless of differences in language and annotated phenomenon.

SLUICE Results for SLUICE are found in Table 5.

For tok-met, the MERGED baseline performs weaker than STL. In contrast, both MTL approaches improve substantially over the baselines, by more than 6 percentage points over STL. Further, MTL-all outperforms MTL-en, although not significantly so.

Similar to tok-met, for adj-noun-met MTL-all improves significantly over STL. The performance drop from STL to MERGED is similarly large. Also, MTL-all outperforms MTL-en here, even though not significantly. Even though the difference in F_1-score between MTL-all and MTL-en is small, they make considerably different predictions. 16 instances were labeled correctly using MTL-all, but misclassified by MTL-en; and the same number vice versa. Thus, 16% of all 200 test instances were classified differently by the MTL setups. This means that adding the additional idiom tasks does indeed add further information that is helpful for some instances, but detrimental to others—more so than for tok-met.

For inf-verb, STL again outperforms MERGED. MTL-all and MTL-de marginally improve upon the baselines, with the latter performing best, though slightly. Again, both MTL setups show differences in the correctly labeled instances, albeit less than it was the case for adj-noun-met (12%). These differences are distributed similarly over the six compounds. An exception is *sitzen bleiben (to stay seated/to be stuck with something)*, which is considerably better classified using MTL-de than MTL-all.

Results for part-verb differ from the previous tasks, as the MERGED baseline actually perform better than STL. Still, MTL-all and MTL-de improve upon both baselines, with the mono-lingual approach again performing slightly better.

STL		actual

predicted	M	2,119	1,467
	L	1,857	20,220

Table 7: `tok-met`: Confusion matrices for SLUICE.

Analysis For both MTL-SEQ and SLUICE, the MTL-all approach outperforms both STL and MERGED baselines. Contrary to MTL-SEQ, SLUICE performs worse on the MERGED baseline than STL for the English tasks.

Consistent between both architectures is that they show significant—and indeed, very substantial—performance gains using MTL for the metaphor datasets. For the idiom and non-literal language datasets, while also improving using MTL, increases are smaller. We attribute this to the nature of the datasets `inf-verb` and `part-verb`, as both comprise multiple annotated instances of few particular compounds/verbs. Thus, the STL approach already yields good performance, and adding the more unstructured information of the metaphor datasets does not improve the MTL settings.

An important difference can be observed in the specific MTL setups. While MTL-SEQ fails to profit from just one (in-language) auxiliary task, SLUICE improves significantly over STL even in this lower-resource setup. Adding more auxiliary tasks boosts MTL-SEQ, but does not change SLUICE performance significantly. For MTL-SEQ, this indicates that including information from just one auxiliary task skews the main task too much in one direction, due to hard parameter sharing, while including multiple auxiliary tasks appears to better "balance" the architecture. In contrast, SLUICE can choose to only share the information necessary to improve the tasks, and thus already profits heavily from one auxiliary task. While we expected an increase in performance for the small-data task `adj-noun-met` using more data-heavy auxiliary tasks, it is interesting that `tok-met` also yields better results when including `adj-noun-met` as auxiliary. We attribute this to the network successfully learning a common representation.

We investigate the improvements of MTL-all over STL on the `tok-met` task, using the confusion matrices of MTL-SEQ (Table 6) and SLUICE (Table 7). For both networks, the increase in F_1-score mainly arises due to an increase in recall. This advantage, especially the increase in correctly labeled metaphoric instances, is comparable between SLUICE and MTL-SEQ. For example, "covering" in "So who's covering tomorrow?" is wrongly classified as literal by both STL approaches, but correctly labeled as metaphoric by both MTL-all configurations, i.e., with the help of auxiliary tasks. However, most of the newly identified metaphors (i.e., found by MTL-all but not by STL) differ between the approaches. So, in contrast to the first example, "sweet" in "That's a sweet little village" is misclassified by both networks in STL configuration, but correctly labeled as metaphoric only using SLUICE in the MTL-all setting.

Finally, we compare to the state-of-the-art (SOA) on our chosen tasks. We note that such a comparison with SOA is difficult for most tasks due to non-described test splits or usage of cross validation. The latter was too costly in terms of computation time for our tested architectures. Nonetheless, we include reference numbers for an approximate comparison. `adj-noun-met` is the only dataset for which we have the original test split. Here, the original feature based implementation of Tsvetkov et al. (2014) ($F_1 = 0.85$) outperforms our approach (MTL: 0.63) by a large margin. We attribute this to heavy feature-engineering on their part, using supersenses and concreteness information. In contrast, we perform on par with the state-of-the-art on `tok-met` (Do Dinh and Gurevych (2016): $F_1 = 0.56$, our system:

$F_1 = 0.56$). They implement a simple MLP, incorporating also POS tags and concreteness features. Their test set is similarly large as ours. Horbach et al. (2016) report only accuracy (A = 0.86) for their cross validation experiments on `inf-verb`. Our system results are comparable to their approach, albeit in a different setup using a dedicated test set (A = 0.85 for MTL-de). However, as described in Section 2, Horbach et al. (2016) employ a multitude of semantic features, including selectional preferences and topic information. For `part-verb`, we do not reach the results of Köper and Schulte im Walde (2017). They attain $F_1 = 0.88$ using multi-sense embeddings with Multinomial Naive Bayes in a cross validation setting (vs. our $F_1 = 0.81$ on a test set). Since the multi-sense embeddings vastly outperform their own single-sense baseline, it would be interesting for future work to also include this approach into our model.

6 Conclusion

To the best of our knowledge, we are the first to abstract from related non-literal language detection tasks metaphor and idiom classification to a more general model, using multi-task learning. To this end, we presented an evaluation of two different multi-task learning models on four related semantic, non-literal language tasks in English and German: detection of metaphoric tokens, classification of metaphoric adjective-noun constructions, classification of idiomatic use of infinitive-verb compounds, and non-literal particle verbs. We compared both performances to respective single-task learning baselines, and baselines which use merged training data. While results for the latter systems are mixed, the multi-task learning setups improved performance over the baselines in all cases. Especially the metaphor datasets profit substantially from the multi-task setups, and the inclusion of auxiliary tasks—in the case of hard parameter sharing even for out-of-language idiom tasks.

For all but the smallest dataset, soft parameter sharing and learned architecture outperformed hard parameter sharing. However, the latter approach could benefit from more information (using all related tasks as auxiliary tasks), while the former performed best in a mono-lingual setting. In both cases, data from related non-literal language tasks increase classifier performance, which means that a common representation within the network could be established.

Future work could explore more specifically which non-literal language tasks benefit from the inclusion of which auxiliary tasks. Further, it could be investigated how classic features such as the concreteness or supersenses can increase performance when viewed as lower-level semantic auxiliary tasks.

Abstract

In this paper, we leverage social media platforms such as twitter for developing corpus across multiple languages. The corpus creation methodology is applicable for resource-scarce languages provided the speakers of that particular language are active users on social media platforms. We present an approach to extract social media microblogs such as tweets (Twitter). In this paper, we create corpus for multilingual sentiment analysis and emoji prediction in Hindi, Bengali and Telugu. Further, we perform and analyze multiple NLP tasks utilizing the corpus to get interesting observations.

1 Introduction

Twitter has become a valuable source of data for various NLP studies such as sentiment analysis, polarity detection and emoji prediction. Although, copious amount of research studies have been conducted on twitter data, a majority of them deal with English tweets. This is due to several factors. First, English dominates in the mix of languages on Twitter. According to (Hong et al., 2011), more than 50% of tweets are in English. Outside of the largest five Twitter languages (given in Figure 1), other languages represent just under 1% of Twitter traffic each. We primarily focus on collecting data for sentiment analysis. Additionally, taking the premise that social media devices like emojis convey sentiment of their respective tweet, we provide a methodology for collecting tweets with emojis for any language irrespective of its resource availability. Going beyond sentiment analysis, we also collect data without any preconditions on presence or absence of emojis in the tweets which could be used to draw interesting social media analytics both within and across languages or linguistic communities.

We discuss, specifically, about resource-poor languages because such discourse is available on resource-rich languages like English and Spanish, whereas resource-poor languages are largely ignored. For such resource-poor, but yet widely spoken, languages (especially in multilingual communities that have their predominant literature in a language other than their native tongue), we observe social media as a good data source. In this paper, we look at Twitter to collect data in Telugu, Hindi and Bengali, predominantly spoken in the Indian subcontinent. In these regions, English is the language of administration and is increasingly becoming the lingua franca. This, also, explains the lack of sizable corpora despite the relatively large number of speakers.

2 Related Work

Sharing of corpora or resources is important for researchers to compare results with each other, pushing the boundaries of the state-of-the-art model. Openly available corpora reduce the efforts of researchers in constructing the same corpus others developed merely for comparison. However, Twitter's terms of service, under which sharing of aggregated resources (tweets) is barred, prove an unnecessary obstacle in this regard. For example, the Edinburgh Twitter corpus (Petrovic et

Proceedings of the 27th International Conference on Computational Linguistics, pages 1570–1577
Santa Fe, New Mexico, USA, August 20-26, 2018.

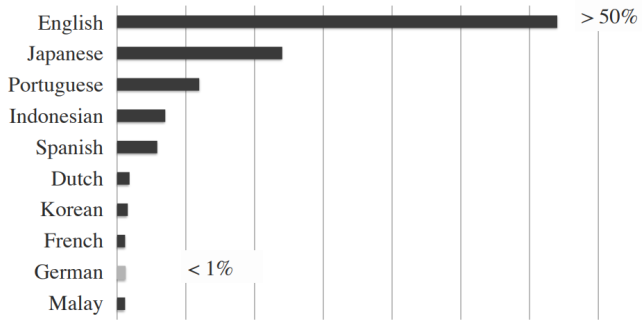

Figure 1: Top ten languages on Twitter. Data from (Hong et al., 2011)

al., 2010) was dissolved as a result of their policies. However, researchers found certain routes to progress even with such issues, following are some examples:

1. Distribution of only lists of tweet IDs, e.g.; in this TREC 2011 microblog task [1]

2. Distribution of the derivatives of data, e.g.; sharing n-gram counts, instead of the original tweets (Herdağdelen, 2013).

However, the second method loses important information about the data such as word order and limits the analyses of experiments. For example, in (Herdağdelen, 2013), the analysis in section 4 would require more than just n-gram counts since the model deals with tweets per day of the week. Hence, primary metadata regarding the tweets is required.

Twitter provides a streaming API under a public "gardenhouse" setting to build corpora. For example, the Edinburgh corpus (Petrovic et al., 2010), the Tweets2011 corpus from the TREC microblog shared task, and the Rovereto n-gram corpus (Herdağdelen, 2013). In this method, a considerably small fraction of tweets, over a time period are collected. However, the way in which Twitter makes these set of tweets is unclear, inducing a possible bias. Even after these restrictions, the corpora that exist are predominantly in English, hence extracting twitter for resource-scarce languages is necessary.

In their attempt to construct language specific corpora, some approaches choose certain sites to crawl based on results from using medium frequency terms of the language as search terms (Baroni and Bernardini, 2004; Schäfer and Bildhauer, 2012). Following a similar approach, we employ the top most frequent words of the required language as keywords. (Rehbein et al., 2013) proposes an efficient approach to collect German tweets using geolocation features with language filter. However, the data encounters certain biases:

1. Only a fraction of users have GPS access while tweeting. These tweets are included whereas other kinds of users' tweets are completely ignored. Hence, the collected data is not a representative of the larger sample.

2. Tweets that do not originate from devices with geolocation features like smartphones are also completely excluded. Curated content or in-depth political discussions are not necessarily tweeted from a smartphone.

Similarly, (Scheffler, 2014) have created a German twitter corpus using Twitter APIs.

(Cui et al., 2011) analyze emotion tokens, including emotion symbols (e.g. emoticons) for sentiment analysis and emotion analysis of Twitter snapshots. (Barbieri et al., 2017) established a sentiment analysis architecture for Twitter and released a data set for the same in English. They released the data set of roughly 500K tweets for English with emojis as labels. On a

[1] `http://trec.nist.gov/data/tweets`

similar track, our work focuses on resource-poor languages. Here, the architecture addresses sentiment analysis as a supervised multi class classification problem where each English tweet is "annotated" with its emoji. Hence their data consists of tweets with exactly a single emoji which later is treated as the sentiment label of the tweet, while the tweet itself is striped of the emoji.

We continue their task and collect data on the same lines i.e. we collect Tweets with exactly one emoji in the given aforementioned Languages and more.

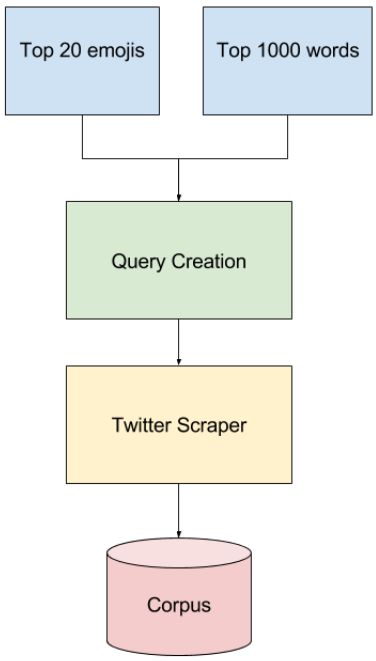

Figure 2: Corpus creation pipeline.

3 Building the corpus

While the previous work for gathering the tweets has been restricted to using twitter search APIs [2], the free usage is limited to only a history of 7 days of tweets. Therefore, we use twitter scraper for no limits with respect to temporal history, as it scraps the web search results of the given query and returns tweets from them. We attempt to scrap tweets using prominent keywords of particular language. Our methodology which is both efficient in time and memory, can easily be extended to any other language irrespective of Resource availability. Following is the description of our methodology to collect tweets with emojis for emoji prediction tasks (Barbieri et al., 2017) which can be extended to collecting just the tweets irrespective of emojis for various other NLP tasks:

3.1 Keywords Extraction

First, we get 1000 most frequent words of the target language for which we want to create the corpus. There are various websites which showcase most frequent used words in a particular language. We use 1000mostcommonwords.com [3] for this project. The most common words usually contain stop words and commonly occuring verbs of the language.

[2] `https://developer.twitter.com/en/docs/tweets/search/overview`
[3] `http://1000mostcommonwords.com/`

Language	Without Emojis	With Emojis as classes	Total
Hindi	194,063	202,415	396,478
Telugu	161,851	16,990	178,841
Bengali	78,308	59,528	137,836
Total	434,222	278,933	**713,155**

Table 1: Total Number of Collected Tweets

3.2 Query creation

To create a search query for the scraper, in preparing corpus for emoji prediction task. we use an emoji and one of the most frequent words of the language for eg.< ❤️,की >. For creating a general twitter corpus irrespective of emojis, we just drop the emoji from the search query.

3.3 Scraper

We then scrap tweets using the Python package *twitterscraper* (Taspinar, 2016 2017) [4]. Our corpus collection pipeline is shown in Figure 2. The scraper returns tweets for the given query based on the condition that the tweet contains the query keyword. We also keep two hashmaps, for tweet id and tweet text's initial 30 characters. These hashmaps are used to remove repetition in incoming tweet results. Every time a tweet is processed, its availability in previously appeared tweets that are already present in corpus is checked, this ensures data is enough diverse and we avoid duplicate entries. Spam or automated tweets from bots, or tweets feed on a celebrity's birthday will be overflowing with very similar tweets like: "जन्मदिन पर बहुत बहुत शुभकामनाएँ बच्चन जी", (Huge Wishes on your Birthday Bacchan sir) and "जन्मदिन पर बहुत शुभकामनाएं अमिताभ जी (Huge Wishes on your Birthday Amitabh sir)" etc. will be avoided in this method.
Collecting such tweets as separate entries is only going to deplete the quality of our data as the later tweet doesn't give much information which the first won't. Any kind of learning on such a data, is only going to reinforce a specific data point rather than giving diversity in label or dataset.
We, also, store a preprocessed version of the collected data by removing mentions and urls because they do not carry significant information for some major tasks such as sentiment analysis and emoji prediction.

4 Corpus Analysis

In total we collected 713,155 tweets in three languages, 396K in Hindi, 178K in Telugu and 137K in Bengali (Table 1) out of which 279K tweets are with emojis as labels and remaining we collected irrespective of emojis. In both the cases we maintain two distinct versions of the data: Cleaned and Uncleaned. Where Cleaning is done with the emoji prediction task in consideration, the changes made include:

1. Trailing symbols removed, for example "????" becomes "?" or "...." becomes ".".

2. Words and symbols which are foreign to the language of the tweet are removed, for example "मुर्गी के अंडे और पा जी के फंडे रोके नही रुकते Just #ViruPanti #INDvAUS" will be cleaned to "मुर्गी के अंडे और पा जी के फंडे रोके नही रुकते"

However, As we maintain an uncleaned raw version too, depending on the application, data can be used accordingly.

The most frequent emojis in Telugu, Hindi and Bengali can be found in Table 2 , Table 3, Table 4 respectively.

4.1 Relationship between emojis and Sentiments

A random sampling of 500 tweets of each language, from the extracted tweets with emojis, are manually annotated into three sentiment classes: Positive, Negative, and Neutral to study a relationship between emojis and annotated sentiments. Results shown in Table 5.

The tabulated statistics suggest that sentiments and emojis in most of the cases share a strong correlation, which further reinforces the idea of using emoji as a sentiment label. Furthermore, we note from Tables 5,6 and 7 that even across languages the annotation of different emoji tweets into the three sentiment classes is similar, indicating that the sentiment or emoji's semantic value is preserved across languages till a large extent.

5 Applications

The entire corpus has been hosted on the link given in the footnote [5]. Potential use of the corpus can be really varied:

- `Sentiment Analysis:` As discussed in related work, we built a Sentiment Analysis tool. The emoji data be used as label for Sentiment Analysis, where we could go one step further and predict emoji for the emoji-less data we collected.

- `Enrich Resource-scarce Language:` Siamese network based approaches (Choudhary et al., 2018b; Choudhary et al., 2018c; Choudhary et al., 2018a) are capable of utilizing these emojis of resource-poor language concurrently with emojis of resource-rich languages to enhance the overall performance of both resource-poor and resource-rich languages.

- `Social Media Analytics:` Beyond Sentiment Analysis too, We could learn a lot, especially in Topic modeling across languages for example, what domain do most Telugu tweets belong to. Are Telugu tweets more about Movies than say Bengali tweets which might be into Politics. Social Media is always heavy with Demographic trends which can be analyzed.

6 Limitations and Future Work

Certain issues with our data which require further investigation would include

- Code Mixed Data: Because we only look for just one word to decide the language of the tweet, It's possible we may take a lot of code mixed data as compared to a corpus which is exclusively in one language, for example
  - "तू कल भी दिल में थी... और आज भी है...बस कल तक favorite list मे थी...आज block list मे है... ", (*You were in my heart till yesterday and so today too, but yesterday you were in my favorite list and today in block list*)
  - "#Sun #Pagli.... अगर तू #doll है तो में #Dollar... अगर तू #Brand है तो में #Branded हु ", (*Listen, O mad woman, If you are a doll, then I am Dollar, if you are a brand, then I am branded*)

  Such tweets may also get included in our data, even though the amount of Hindi information they have is minimal

- In any data Noise is unfavorable, Noise in such social media platforms could be
  - "सिर्फ $attitude होने से कुछ नही होता #smile ऐसी दो की हर एक #लोग बोल पड़े ", (*only having $attitude won't do anything, give a #smile which will make #people talk*)
  - "####french_fries....!!! : तले भुने आलू सदा सुखी रहो ", (*####french_fries....!!!* .. semantically non compliant)

  Such a noise will corrupt any learning to be performed on this data.

- Twitter like any other social media is a live, thriving platform, taking a snapshot at one time and presuming it to work forever is not a sound judgment. Which is why such data needs to be updated regularly.

7 Conclusion

In this paper, we present a twitter corpora for Telugu, Bengali and Hindi along with a methodology which is scalable across languages. A data which could be used for tasks like Sentiment Analysis,often done on Resource heavy languages only. Along with it we also release a regular data which can be used for tasks beyond. In addition to this, we further present that such a data provides more information than already present in the field, by providing its use for some applications. We hope this corpus can serve as a basis for more work to be done upon such Resource Scarce languages.

Towards identifying the optimal datasize for lexically-based Bayesian inference of linguistic phylogenies

Abstract

Bayesian linguistic phylogenies are standardly based on cognate matrices for words referring to a fix set of meanings—typically around 100-200. To this day there has not been any empirical investigation into which datasize is optimal. Here we determine, across a set of language families, the optimal number of meanings required for the best performance in Bayesian phylogenetic inference. We rank meanings by stability, infer phylogenetic trees using first the most stable meaning, then the two most stable meanings, and so on, computing the quartet distance of the resulting tree to the tree proposed by language family experts at each step of datasize increase. When a gold standard tree is not available we propose to instead compute the quartet distance between the tree based on the n-most stable meaning and the one based on the $n+1$-most stable meanings, increasing n from 1 to $N-1$, where N is the total number of meanings. The assumption here is that the value of n for which the quartet distance begins to stabilize is also the value at which the quality of the tree ceases to improve. We show that this assumption is borne out. The results of the two methods vary across families, and the optimal number of meanings appears to correlate with the number of languages under consideration.

1 Introduction

Phylogenetic methods—both distance-based and character-based methods (specifically Bayesian phylogenetic inference)—from computational biology are being widely used in historical linguistics and typology, for phylogenetic inference, for triangulating homelands of proto-languages (Wichmann et al., 2010b), for investigating rates of lexical change (Greenhill et al., 2017), dating and spread of language families (Gray et al., 2009; Holman et al., 2011; Bouckaert et al., 2012), reconstruction of proto-languages (Bouchard-Côté et al., 2013), and for investigating typological universals (Dunn et al., 2011).

Most of the above studies require cognate matrices based on wordlists annotated by experts for cognacy. Each column in such a matrix represents a *cognate class*, with 1's and 0's indicating whether or not a form in the shared ancestral language has a reflex in the descendant languages with a given predefined meaning pertaining to the fixed list of meanings. Such cognate matrices are fed to Bayesian phylogenetic software such as MrBayes (Ronquist et al., 2012b), BEAST (Drummond et al., 2012) or BayesPhylogenies (Pagel and Meade, 2004). An alternative approach is to apply distance-based methods (Wichmann et al., 2010a; Jäger, 2013; Rama and Borin, 2015). Such methods have the advantage that they do not necessarily require labor-intensive cognate identification or the assumption which goes with cognate identification, namely that the languages analyzed are actually related. Instead, an aggregate phonetic distance can be computed. As in biology, the most popular algorithm for inferring phylogenies from linguistic distance data has been Neighbor-Joining (Saitou and Nei, 1987). All the above methods have typically been applied using variants of Swadesh meaning lists (Swadesh, 1952), sometimes adapted for the language family in focus.

Some information is already available concerning the optimal word list size for distance-based linguistic phylogenetic inference. The pertinent literature is reviewed in the next section. As for

Proceedings of the 27th International Conference on Computational Linguistics, pages 1578–1590
Santa Fe, New Mexico, USA, August 20-26, 2018.

character-based methods, such as Bayesian ones, there is no study investigating the optimal meaning list length when inferring linguistic phylogenies. One reason for this could be the computational costs involved in inferring millions of trees for each of the cumulative meaning lists. To the best of our knowledge the present paper represents the first known computationally intensive study in this direction. We infer trees for eleven language families (a total of 313 languages) using Bayesian phylogenetic inference procedure and apply two methods to determine whether the quality of trees stops changing as the size of the word list increases. The first method requires expert phylogenetic trees for validation. It is similar in nature to one applied by Holman et al. (2008), described in the next section. The second method is entirely novel and does not require expert trees. Both methods are applied to the five language families in our sample for which reasonably reliable expert trees were available, and we show that the results are similar. Thus support is found for also including results for the second method, which does not require expert trees. Thereby results could be added the remaining six language families and more reliable statistics was obtained.

In this paper, we ask the following research questions:

- Is there any optimal list length after which there is no improvement in the trees inferred from Bayesian phylogenetic inference procedure?
- Is there any procedure to determine the optimal list length when there is sparse historical linguistic research regarding the genetic tree for a language family?

The structure of the paper is as follows. We discuss some work related to determining ranks of item stability in section 2. The problem and our approach are described in section 3. Section 4 presents the datasets and outlines how Bayesian phylogenetic inference is applied. Section 5 presents and discusses the implications of our results and is followed by conclusion in section 6.

2 Related work

Holman et al. (2008) used 245 100-item word lists from languages of 69 families previously compiled for another paper (Brown et al., 2008) and then devised a stability measure quantifying the resistance of a meaning to undergo lexical replacement. The authors ranked the 100 meanings by the order of stability and then created lists consisting of the 5, 6 ... 100 most stable meanings. They then proceeded to infer linguistic trees from the meaning lists, computing the fit of the trees to expert trees. The authors found that the quality of the trees ceased to improve when using more than the 40 most stable meanings (and subsequently 40-item lists were collected for as many languages of the world as possible, ultimate leading to the so-called ASJP database of Wichmann et al. (2018), covering more than two thirds of the world's languages). Evaluation studies (Wichmann et al., 2010a; Pompei et al., 2011; Jäger, 2013; Rama and Borin, 2015) have suggested that the quality of the phylogenetic trees inferred from 40-item word lists is quite high when compared to gold standard phylogenetic trees.

Another investigation of the effect of the number of meanings on the quality of a phylogeny is represented by Petroni and Serva (2010). The authors rank 200-item meaning lists of 50 Austronesian and 50 Indo-European languages through a stability measure derived from the Levenshtein distance between synonyms across word lists. They then infer a distance-based tree for each cumulative meaning list and compare the tree with the Levenshtein distance tree inferred from the full dataset using the Robinson-Foulds distance (Robinson and Foulds, 1979). The authors observe that the Robinson-Foulds distance drops as the length of meaning list changes from 1 to 200. The authors do not compare the inferred trees from subsets to the gold standard family tree. Neither do the authors use the cognate information to infer trees. Instead, the distance between two languages is based on aggregate Levenshtein distance computed between synonyms in the word lists.

In another work, Rama and Borin (2013) computed phoneme n-gram entropy for synonyms belonging the 100-item meaning lists from 245 languages used by Holman et al. (2008). Then they rank the meanings in order of increasing entropy. The meaning with the lowest entropy is the most stable item.

The authors find that the entropy-ordered meaning lists' ranks correlate highly with the order inferred by Holman et al. (2008).

In a related work, which uses Bayesian inference, Pagel and Meade (2006) employ a Bayesian phylogenetic inference model where each meaning is treated as a separate partition within the complete dataset (cf. table 2). Each partition or meaning has a separate weight that contributes to the likelihood calculation. The weight for each meaning is inferred through an MCMC procedure (cf. section 4.2 for details on Bayesian phylogenetic inference procedure). Then the authors correlated the mean weight for each meaning estimated from the posterior samples with the number of cognate classes in the meaning for 87 Indo-European languages and 95 Bantu languages. The authors find a positive correlation ($r > 0.6$) between the mean weights and the number of cognate classes for both language families.

In a follow-up paper, the same authors Pagel et al. (2007) interpreted the inferred weight from posterior samples as an index for lexical replacement and found a negative correlation with corpus-based estimates of the frequency of words representing the different meanings. In essence, meanings with low frequency undergo lexical replacement more easily than meanings with high frequency. In the present paper, we also apply Bayesian inference procedure to cumulative datasets ranked by the diachronic lexical stability.

3 Problem and approach

To investigate the influence of the datasize on the quality of a Bayesian phylogeny, word lists of different sizes must be produced. In doing so, it is necessary to take the differential stabilities of the words corresponding to different meanings into account, because more stable items are expected to lead to better phylogenies and the influence of stability can thus mask the influence of the number of items. It is well known that the words for some meanings tend to be more quickly replaced than words for some other meanings.

Different methods and datasets discussed in section 2 lead to somewhat different assessments of relative stabilities, but not to such a degree that any major controversies have arisen. The measure of stability used in the present paper is based on the simple and quite old idea idea (cf. Thomas (1960), Kroeber (1963), and Oswalt (1970)) that words for more stable items can be identified by their greater tendency to yield cognates within groups of closely related languages than words for less stable items. Here we use the number of cognate classes as a measure of stability: the smaller the number of cognate classes found for a given meaning is, the fewer word substitutions there would have been, and thus the greater the stability. Having ranked the meanings in this way for a given language family we can go on to define word lists of different sizes, n, each consisting of words for the n-most stable meanings. As a note, in case of ties—two or more equally stable meanings—these meanings will be arbitrarily ranked.

We propose two tests for comparing the quality of trees based on two meaning lists differing by the number of items they contain. In the first test, for each of the two meaning lists, we report the average of the generalized quartet distances (GQD) between the posterior tree distribution and a gold standard tree. We hypothesize that after reaching a certain size, n, of meaning list, the difference between the average GQD distance between the list having n meanings and the one having $n + 1$ meanings will stabilize. This first test is designed for cases where the gold standard family tree is reasonably well established and uncontroversial. This is not always the case, since the amount of historical linguistic work dedicated to language families throughout the world varies greatly (Campbell and Poser, 2008). For cases where expert classifications are lacking or not very trustworthy we propose a second test that does not depend on the gold standard tree. This test consists in computing the GQD's between trees inferred from meaning lists of size n and $n + 1$, where n ranges from 1 to the next to largest number of meanings covered in the dataset used, and then plot the average quartet distance for each such pair. Our hypothesis is that after a point, the difference of average quartet distances will begin to stabilize.

4 Materials and Methods

In this section, we describe the datasets, tree inference procedure, and the evaluation procedure.

Family	Languages	Meanings	Sources
Austronesian	96	210	Gray et al. (2009)
Mayan	30	100	Wichmann and Holman (2013)
Mixe-Zoque	10	100	Cysouw et al. (2006)
Indo-European	52	208	Dunn (2012)
Uto-Aztecan	31	100	Miller (1984)
Afro-Asiatic	25	100	Militarev (2000)
Bai	9	110	Wang (2006)
Chinese	18	180	Dàxué (1964)
Mon-Khmer	16	100	Peiros (1998)
Ob-Ugrian	21	110	Zhivlov (2011)
Tujia	5	109	Starostin (2013)

Table 1: Number of languages, meanings, and sources for each dataset.

4.1 Datasets

The experiments involving expert trees are performed on datasets belonging to five different language families: Austronesian, Mayan, Mixe-Zoque, Indo-European, and Uto-Aztecan. In addition to this dataset we draw on another six language families or subfamilies: Afro-Asiatic, Bai, Chinese, Mon-Khmer, Ob-Ugrian, and Tujia. The number of languages, number of meanings, and sources for each dataset is given in Table 1. In case of Austronesian and Indo-European, we use a subset of languages provided in Jäger et al. (2017).

Each of the above datasets is a multilingual word list with expert annotated cognate judgments concerning the words representing each meaning. An excerpt of a multilingual word list from Indo-European is shown in table 2a. The meanings are ordered by the number of cognate classes. We also show the corresponding binary matrix in table 2b. The binary matrix has 2 columns and 3 columns for the meanings ALL and AND since there are, respectively, two and three cognate classes for the meanings ALL and AND. In contrast, the meaning NAIL, for instance, has only one cognate class since all the daughter languages show words that can be traced back to the Proto-Indo-European stage. The meanings are accumulated at each rank and converted to a binary matrix of dimensions $L \times C$ where L is the number of languages and C is the number of cognate sets in the list of meanings accumulated. We explain the Bayesian phylogenetic inference and the tree evaluation algorithms below.

Language	ALL	AND	...
English	ɔːl^1	aɛnd^1	...
German	alə^1	ʊnt^1	...
French	tu^2	e^2	...
Spanish	toðo^2	i^2	...
Swedish	ˈalːa^1	ɔkɾ^3	...

(a) Forms and cognate classes

Language	ALL		AND		
English	1	0	1	0	0
German	1	0	1	0	0
French	0	1	0	1	0
Spanish	0	1	0	1	0
Swedish	1	0	0	0	1

(b) Binary Matrix

Table 2: Excerpt from meaning list showing cognate classes (table 2a) and the binary cognate matrix (table 2b) for ALL and AND in Germanic and Romance subfamilies of Indo-European. The superscript indicates words that are cognate.

The meanings ranked by the number of cognate classes in each of the five families for which we make use of expert trees are provided below. A number in a square bracket introduces meanings for which there are as many cognate classes as the number indicates. The lists have some interest in their own right since they contribute to the available empirical data on word stabilities across different language families. For reasons of page limitations we do not include the remaining six families.

Austronesian : [1] fifty, [2] twenty, six, [3] stickwood, seven, louse, five, [4] to yawn, breast, ten, eye, [5] two, that, to die/be dead, three, fruit, eight, nine, [6] one thousand, father, [7] liver, [8] we, to vomit, they, new, four, i, to pound/beat, [9] thou, who, one hundred, [10] name, to dig, to choose, stone, he/she, branch, when, to come, above, [11] thin, what, wife, mother, to hide, to grow, one, to buy, [12] dust, worm/earthworm, root, star, salt, toeat, [13] person/human being, in/inside, this, to drink, leaf, woman/female, feather, needle, to dream, [14] fog, head, where, lake, bird, rain, ear, thick, to hear, if, to fear, bad/evil, road/path, [15] fire, to sleep, right, blood, hair, tongue, to climb, sky, moon, to chew, [16] to kill, you, to shoot, to burn, man/male, to throw, child, and, to steal, thatch/roof, house, ash, [17] shoulder, how, night, tail, to cry, bone, to blow, nose, spider, other, shy/ashamed, tooth, to open/uncover, year, [18] flower, to swell, to think, to say, water, below, sea, to bite, to hunt, to count, to swim, to walk, to plant, [19] to suck, fish, old, back, egg, rope, dry, to stand, narrow, to flow, heavy, day, all, [20] to see, far, mosquito, to cook, painful/sick, wide, black, dull/blunt, snake, to spit, fat/grease, skin, green, [21] rat, sand, hand, intestines, to sew, at, to live/be alive, to turn, cold, white, to fall, to split, [22] correct/true, warm, wet, sharp, to squeeze, to hold, smoke, leg/foot, grass, [23] to sniff/smell, to lie down, to scratch, left, near, woods/forest, to stab/pierce, earth/soil, husband, [24] short, no/not, to hit, to cut/hack, wing, mouth, dog, [25] to work, lightning, meat/flesh, wind, small, to laugh, to fly, cloud, [26] to tie up/fasten, red, yellow, [27] big, neck, belly, to breathe, to sit, [28] rotten, long, [29] to know/be knowledgeable, good, [30] dirty, thunder.

Mayan: [1] green, white, tail, two, water, [2] tongue, path, die, yellow, bone, rain, tree, red, [3] name, tooth, mouth, mountain, hand, one, louse, sleep, foot, dry, [4] person, fire, ash, [5] claw, flesh, heart, blood, dog, sun, [6] neck, black, ear, fish, moon, I, [7] smoke, walk, see, earth, seed, breasts, man, skin, drink, [8] we, grease, kill, night, nose, cloud, leaf, hair, [9] head, star, stone, say, horn, woman, come, give, [10] sand, hot, cold, hear, full, [11] eat, egg, you, feather, new, bird, fly, stand, [12] bark, big, bite, eye, [13] not, [14] liver, this, burn, belly, good, swim, long, [15] know, knee, [16] round, who, [17] many, [18] all, root, [19] that, [20] lie, small, [21] what, [24] sit.

Mixe-Zoque: [1] ear, tooth, green, see, star, yellow, earth, stone, what, blood, bone, rain, white, leaf, thou, hair, drink, road/path, dry, water, red, [2] name, black, eat, head, person, bark, ashes, tongue, feather, walk, mountain, die, night, liver, new, moon, I, hand, tree, louse, hear, one, come, sun, tail, skin, good, no, clawnail, stand, [3] we, neck, sand, fire, smoke, mouth, kill, horn, knee, seed, round, give, eye, who, two, meat, root, [4] egg, fish, big, know, heart, say, bird, this, nose, fly, woman, sleep, man, [5] warm, sit, breast, belly, cloud, long, [6] cold, bite, that, dog, full, small, swim, many, [7] fat, foot, [8] lie, all, burn.

Indo-European: [1] name, four, three, fingernail, five, two, [2] we, what, I, who, tongue, when, ant, [3] how, new, egg, sun, tooth, one, [4] where, give, heart, thou, mother, full, drink, [5] sit, die, night, ear, not, star, horn, salt, day, [6] you, spit, root, snow, father, knee, [7] know, fish, this, seed, flower, eye, sew, water, long, foot, [8] warm, there, nose, other, dry, hear, sleep, [9] fly, sand, hand, bone, wind, leaf, stand, he, feather, right side, [10] eat, ice, far, old, that, liver, louse, sing, swim, with, smoke, wing, sea, moon, live, suck, [11] head, they, fire, all, rain, small, flow, blow, some, wash, dog, skin, grass, here, [12] lake, freeze, blood, bird, see, hold, red, cold, bark, laugh, green, and, breathe, lie, snake, year, meat, [13] rub, dig, sharp, tie, man, person, heavy, fall, sky, yellow, worm, cloud, straight, [14] burn, thin, short, stone, round, river, black, mouth, animal, think, fruit, in, come, [15] few, bite, neck, leg, breast, tree, play, left, guts, earth, woman, white, [16] fog, count, big, rotten, float, dust, hair, wide, thick, narrow, near, say, mountain, ashes, [17] wet, smooth, fear, pull, smell, cut, vomit, [18] right, turn, at, split, many, [19] road, belly, hunt, good, [20] fat, back, kill, hit, wipe, if, [21] stab, scratch, walk, dull, wife, [24] tail, swell, throw, woods, stick, [25] rope, fight, [26] child, [28] squeeze, husband, [29] dirty, [32] bad, push, [37] because.

lie, feather, vomit, sing, man, many, red, [13] skin, walk, rain, [14] burn, green, yellow, new, fly, [15] year, cloud, small, [16] bird, [17] woman, good, [18] old, come, [19] rope.

4.2 Phylogenetic inference

The Bayesian phylogenetic inference (Ronquist and Huelsenbeck, 2003) is based on the following Bayes rule:

$$f(\tau, \mathbf{T}, \theta|X) = \frac{f(X|\tau, \mathbf{T}, \theta) f(\tau, \mathbf{T}, \theta)}{f(X)}, \tag{1}$$

where X is the binary data matrix of dimensions $L \times C$, τ is the tree topology, θ is the substitution model parameters, $\mathbf{T}$ is the branch length vector of the tree. The posterior distribution $f(\tau, \mathbf{T}, \theta|X)$ is difficult to calculate analytically since one has to sum over all the possible rooted topologies ($\frac{(2L-3)!}{2^{L-2}(L-2)!}$). Therefore, Markov Chain Monte Carlo (MCMC) methods are used to calculate the posterior probability of the parameters $\tau, \mathbf{T}, \theta$. The Metropolis-Hastings algorithm (a MCMC algorithm) is used to sample the parameters from the posterior distribution. This algorithm constructs a Markov chain by proposing change to one or a block of parameters and then accepts the proposal with the following probability:

$$r = \frac{f(X|\tau, t^*, \theta)}{f(X|\tau, t, \theta)} \frac{f(t^*)}{f(t)} \frac{q(t|t^*)}{q(t^*|t)} \tag{2}$$

We assume that the parameters $\tau, \mathbf{T}, \theta$ are independent of each other. Therefore, the joint prior probability $f(\tau, \mathbf{T}, \theta)$ can be decomposed into $f(\tau) f(\mathbf{T}) f(\theta)$. In equation 2, the inference program proposes a change to a branch length t to generate a new branch length t^*. Subsequently, the likelihood of the data to the new parameters is computed using the pruning algorithm (Felsenstein, 2004), which is a special case of the Sum-Product algorithm (Jordan, 2004).

All our Bayesian analyses use binary datasets with states 0 and 1 (cf. table 2b). We employ the Generalized Time Reversible Model (Yang, 2014) for computing the transition probabilities between individual states. The rate variation across sites is modeled using a four category discrete Γ distribution (Yang, 1994). We follow Lewis (2001) and Felsenstein (1992) in correcting the likelihood calculation for ascertainment bias resulting from unobserved 0 patterns. We used a uniform tree prior (Ronquist et al., 2012a) in all our analyses which constructs a rooted tree and draws internal node heights from a uniform distribution. All our experiments are performed using MrBayes 3.2.6 (Zhang et al., 2015).

A Markov chain is initiated at a random starting point which consists of random tree, random branch lengths, and random substitution model parameters. In our experiments, we run two independent chains and sample every thousandth state in the chain and write it to the file. The runs are stopped until the average standard deviation of split (unique bipartition in a tree) frequencies does not differ beyond a threshold of 0.01. The size of the dataset influences the number of states needed for convergence. The tree space required to explore grows factorially with the number of languages whereas the cost of likelihood calculation increases linearly with the number of languages. In the case of Austronesian, we run the analysis for fifty million states; in the case of Indo-European and Uto-Aztecan, we run the analysis for ten million and five million states respectively. For the rest of the datasets, we run the Markov chains for two million states.

The Bayesian phylogenetic inference is performed on each meaning list's binary matrix. Each meaning list is processed cumulatively and the phylogenetic trees are stored to disk. In summary, each language family has binary matrices equal to the number of meanings in the family. Once the inference is finished, we proceed to evaluate the phylogenetic trees as described in the next subsection. For the evaluation we discarded the initial 25% of the trees as part of burnin and used the rest of the trees for evaluation.

4.3 Evaluation of inferred trees

The quality of inferred phylogenetic trees is evaluated using the quartet distance (Christiansen et al., 2006). The quartet distance measures the distance between two trees in terms of the number of different quartets. A quartet is a subtree consisting of four languages. A quartet for languages a, b, c, d can either be a *star* quartet when there is no internal branch separating the leaves or a *butterfly* quartet when there is an internal branch separating any two leaves from the two other leaves. The quartet distance measures the total number of different butterflies and star quartets divided by the total number of possible quartets in the tree. However, this definition of quartet distance does not work well when the gold standard tree is unresolved and has non-binary internal nodes. Expert linguistic phylogenies often have unresolved internal nodes due to lack of detailed knowledge causing the splits. In such a case the quartet distance penalizes the inferred tree because a butterfly quartet in the inferred tree is a star quartet in the gold standard tree and the former will be counted as erroneous. To remedy this, Pompei et al. (2011) proposed an extension to quartet distance known as Generalized Quartet Distance (GQD), which measures the distance between a binary tree and the gold standard tree as the number of different butterflies divided by the number of butterflies in the gold standard tree. We extract the gold standard trees from Glottolog (Hammarström et al., 2017)—a publicly available repository of language references and phylogenetic trees.

5 Results and Discussion

5.1 Comparison with gold standard trees

The results of the first test are given in Figure 1. Here, we plot the GQD as a function of number of meanings in each meaning list. Each point in the graph presents the GQD score for each meaning list. We fit a LOESS curve for each language family.[1] For all families but Austronesian the most drastic effect of list length size is seen for the first 50 or so items. For Mayan and Uto-Aztecan the GQDs appear to fluctuate not far after this point, whereas for Indo-European the drop continues to somewhat beyond 100 items. For Austronesian the regime with the most drastic drop is for the first 100 or so items, and then a slower drop sets in, continuing for the remainder of the curve.

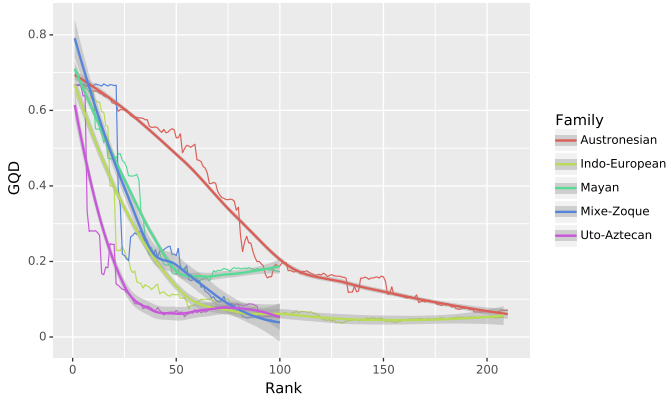

Figure 1: Lineplot of GQD of meaning lists sorted by the number of cognate classes when compared with gold standard trees. The trendlines are drawn using LOESS smoothing.

5.2 Comparison between successive trees

The second method is designed for related languages where the gold standard tree is not determined to the fullest satisfaction of the language family experts. Following this method, we compute the GQD between the inferred trees from successive meaning lists and then plot the GQD. The results, shown in Figure 2 are remarkably similar to the ones making reference to a gold standard tree, displayed in Figure

[1] All the plots are generated using `plotnine` python library available at `http://plotnine.readthedocs.io/en/stable/index.html`.

1. The visual impression of similarities in the shape of the curves is supported by Pearson correlations, which all lie in the range $0.890 > R^2 > 0.967$.

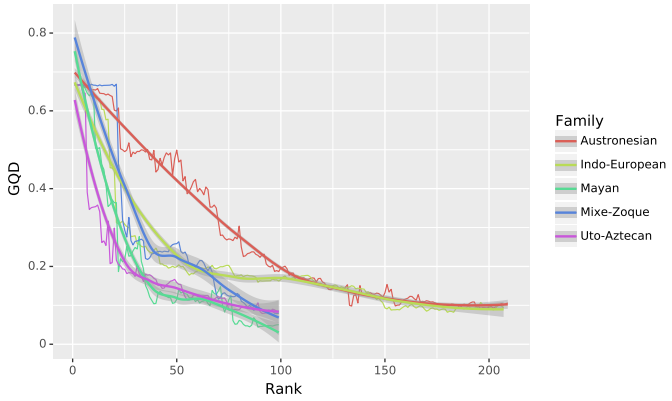

Figure 2: Lineplot of GQD between two successive meaning lists. We show the LOESS fit for each family.

Finally, we provide Figure 3, which shows plots for the remaining six language groups in our sample for which expert trees are generally absent or less reliable.

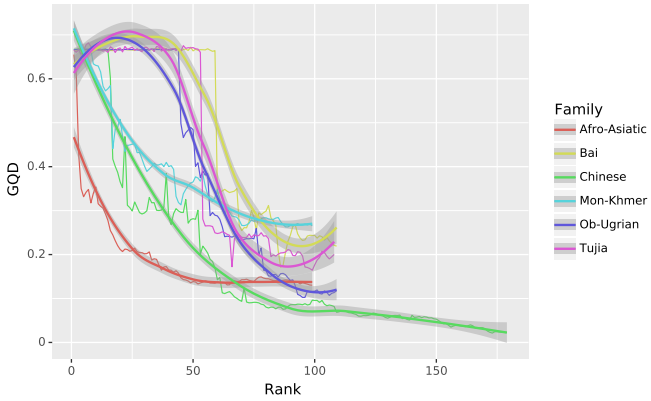

Figure 3: Lineplot of GQD between two successive meaning lists for the remaining language groups in our sample. We show the LOESS fit for each family.

5.3 Analyzing the results

In order to replace eye-balling with a more consistent identification of the cut-off between the approximately monotonic regime of each curve and the regime (if any) where fluctuations set in, we tested two different approaches. The first approach, inspired by Grieve et al. (2017), was as follows. We compute the Spearman rank correlation between the mean GQDs in each segment of the left tail with the corresponding numbers of meaning items, increasing the size of the segment in steps of one datapoint from 2 to the maximal number of meanings. For instance, for a segment of the curve corresponding to rank 1-10 we correlate the 10 GQD values with the series of numbers 1-10. As long as the result continues to be a strong negative correlation one could consider the curve to be approximately monotonically falling. Here we experimented with different cut-offs, including $\rho = -0.96$. If the increase of a segment of the curve by one meaning results in a weaker correlation than the cut-off, this point could then be considered to pertain to the fluctuating regime. As it turned out, there was no sensible way of defining a cut-off that would work across all eleven cases. Moreover, this method was too sensible to local fluctuations. Instead we applied a second and much simpler approach, which is to assume that the relevant point identifying the point where the GQD ceases to drop as simply the minimum. Table 3 summarizes the results.

Family	Lgs.	Meanings	Min (gold)	CC (gold)	Min (consec.)	CC (consec.)
Austronesian	96	210	203	3251	197	3091
Mayan	30	100	61	310	90	655
Mixe-Zoque	10	100	100+	300+	99	292
Indo-European	52	208	130	1078	181	1883
Uto-Aztecan	31	100	100+	846+	92	711
Afro-Asiatic	25	100			100+	1273+
Bai	9	110			87	137
Chinese	18	180			174	1115
Mon-Khmer	16	100			90	606
Ob-Ugrian	21	110			96	172
Tujia	5	109			100	152

Table 3: The information on languages and total meanings from Table 1 is repeated, and in addition the last four columns indicate the point where the curves reach their minimum ("Min"), and the corresponding number of cognate classes ("CC") for respectively the method using a gold standard ("gold") and the one using comparisons between consecutive size-increased meaning lists ("consec."). A plus sign following a number indicates that the minimum is reached when all items are used, such that we can suspect, although we cannot know for certain, that adding some more items (also implying more cognate classes) would continue to bring improvements.

The results in Table 3 suggest the existence of a linear correlation between the optimal number of meanings and the number of languages to be classified for the gold standard method. The correlation is strong ($R^2 = 0.786$) but only barely below the 0.05 significance level ($p = 0.0452$). As just mentioned, however, the real impact should come not from the mere number of items, but from the number of cognate classes they produce. Thus, not unexpectedly, the correlation is stronger yet between the optimal number of cognate classes and the number of languages ($R^2 = 0.923$) and also significant ($p = 0.0094$). For the method using consecutive datasets for eleven language families and groups the correlation between the number of meanings and the number of languages is weak albeit significant ($R^2 = 0.537$, $p = 0.010$); but again the situation radically improves when the number of languages is correlated with the number of cognate classes ($R^2 = 0.876$, $p < 0.0001$).

The linear model for the optimal number of cognate classes as a function of the number of languages intercepts at -11.24. Since to classify zero languages zero cognate classes are needed the intercept can be set at zero, something which only requires a small adjustment, and the slope of the resulting function will then be 32.397, indicating that ∼33 cognate classes per language classified is optimal. The gold standard results from the smaller set of five families gives us a slope of 29.297 when the intercept is at zero, indicating that ∼30 cognate classes is optimal. We choose to place more weight on the more conservative of these estimates.

Our result should be highly useful in the design of future studies in Bayesian phylogenetics. The initial decision on how many items to include in a lexical dataset can be difficult since the amount of resulting cognate classes may be unknown, but across our case studies the number of items required was always at least 87. Thus, for a small or medium-sized family (∼30 languages or less) the researcher could initially aim at 100 items, but for larger families this will clearly not suffice. For around 31-100 languages 200 items may be needed, and for yet larger families more than that. Counting cognate classes will yield a much more precise estimate of the adequacy of the sample. As an example, a recent study of Dravidian languages (Kolipakam et al., 2018) reports that 778 cognate classes were used for inferring a phylogeny for 20 languages. Since $20 \times 33 = 660$, we now have reasons to believe that this is an adequate sample. The sample of 20 languages, however, only contains around one fourth of the total set of Dravidian languages (Hammarström et al., 2017), so a future investigation may be directed at extending the phylogeny. In that case it can be anticipated that it will not suffice to add data for the list

of meanings used in Kolipakam et al. (2018)—rather, new items may have to be added.

6 Conclusion

This paper has, for the first time, addressed the question of the size of meaning lists required for the optimal Bayesian-based inferencing of linguistic phylogenies. In our search for this optimum, that is, the point where Bayesian inference stops improving, we find the following:

- Bayesian inference does not necessarily improve when given more cognate classes. In fact, more data can reduce the fit with expert trees, as is seen in the case of the Mayan family. Such a situation can be explained by a high level of borrowing where less stable words are exchanged more among lineages than more stable words, such that including these less stable words is not necessarily advantageous. (Indeed, Mayan languages are known to borrow heavily from one another, cf. Wichmann and Brown (2003)).

- The curves representing fits with gold standard trees and the ones representing fits between trees produced by successively adding items in descending order of stability are highly similar, so the latter can be used as a proxy for the former in order to increase the number of families sampled for the purpose of determining the optimal list size.

- The optimal list size for Bayesian phylogenetic inference depends on the number of cognate classes represented by the words corresponding to the items on the meaning list, and the number of cognate classes, in turn, is strongly correlated with the number of languages under investigation. Our results indicate that the optimal list size is one that produces around 33 cognate classes times the number of languages to be classified.

The Road to Success: Assessing the Fate of Linguistic Innovations in Online Communities

Marco Del Tredici and **Raquel Fernández**
Institute for Logic, Language and Computation
University of Amsterdam
{m.deltredici|raquel.fernandez}@uva.nl

Abstract

We investigate the birth and diffusion of lexical innovations in a large dataset of online social communities. We build on sociolinguistic theories and focus on the relation between the spread of a novel term and the social role of the individuals who use it, uncovering characteristics of innovators and adopters. Finally, we perform a prediction task that allows us to anticipate whether an innovation will successfully spread within a community.

1 Introduction

Language is an incessantly evolving system, and linguistic innovations of different kind are continuously created. New variants originate in concrete communicative situations with particular speakers. After being introduced, some of them are adopted by other speakers belonging to the same community and possibly spread until they become community norms. In contrast, other innovations do not manage to make their way into the community conventions and just disappear after a certain period of time. This process raises many intriguing questions, which have been the focus of attention in Sociolinguistics since the late 1960's (Weinreich et al., 1968; Chambers and Schilling, 2013). For example, at what linguistic levels (phonology, lexicon, syntax) do innovations arise and succeed? Who are the leaders of change and what are their social characteristics? In this paper, we investigate lexical innovation in online communities, focusing on the latter type of question, by means of a large-scale data-driven approach.

We study the interplay between the birth and spread of new terms and users' social standing in large online social communities, taking as starting point hypotheses put forward in the Sociolinguistics literature (see Section 2). We present a longitudinal study on a large social media dataset, including 20 online forums and around 10 million users overall. We consider each forum as an independent social network, and investigate how lexical innovations arise and spread within a forum. We analyse the fate of approximately 8 thousand innovations (focusing on acronyms such as *lol*, phonetic spellings such as *plis*, and other linguistic phenomena usually collected under the term of *Internet slang*), and relate their spread within a social network to the role of the individuals who use them. We characterise users' roles within a community by means of a novel, theoretically-motivated *tie-strength* measure, combined with well-known centrality measures.

We show that (1) innovators (users who introduce a new term) are central members of a community, connected to many other users but with relatively low tie-strength, and (2) strong-tie users (who belong to cliques or sub-groups within the community) effectively contribute to the dissemination of a new term. This pattern is surprisingly consistent across the 20 online communities under investigation. In addition, we show that, by solely using information on speakers' tie strength as predictor variable, we can anticipate whether an innovation will successfully spread within a community.

Our work yields new theoretical insights into the applicability of sociolinguistic theories to online settings. It also has practical significance for NLP systems encountering novel terms in social media: While new terms that do not succeed in becoming community norms may safely be treated as out-of-vocabulary words, a better understanding of the dissemination process of novel terms beyond their

Proceedings of the 27th International Conference on Computational Linguistics, pages 1591–1603
Santa Fe, New Mexico, USA, August 20-26, 2018.

frequency can help identify those innovations that a system should be able to deal with. Together with the in-depth analysis presented in the paper, we make available our dataset, which includes interactions scraped from 20 topic-based forums over a period of 4 to 8 years, as well as the code for preprocessing the data, extracting the dissemination trajectories of ∼8k internet slang terms, and computing the strength of the ties among users.[1]

2 Background

2.1 Sociolinguistic Theories

Our investigation of innovations in online social communities builds on Milroy's (1987) theory, according to which linguistic innovations propagate and become community norms when individuals with *strong ties* adopt them early on; however, it is usually individuals with only *weak ties* who are the actual *innovators*, i.e., those who introduce novel linguistic variants. Milroy's proposal is thus an application to Sociolinguistics of *The Strength of Weak Ties* theory put forward by Granovetter (1973) to explain the diffusion of innovations more broadly.

In Milroy's (1987) original study, the strength of a tie between two individuals is given by a combination of factors, such as the amount of time spent together, the level of intimacy, etc. As a result, strong ties are usually those connecting family members or close friends, while weak ties connect acquaintances. Individuals linked by strong ties form close-knit sub-communities or clusters, whereas weak ties act as bridges between these clusters. According to Milroy's theory, individuals without strong ties are more likely to innovate. Thanks to their bridging role, they can introduce an innovation into one or more close-knit clusters. Once introduced, the innovation can be adopted by closely connected individuals within a cluster, who quickly propagate it to others.

Milroy's theory has found confirmation both in small-scale sociolinguistic studies carried out in the protestant enclaves of Belfast (Milroy and Milroy, 1985; Milroy and Milroy, 1987) and in agent-based models with simulated data (Fagyal et al., 2010). However, it has not been tested at a large scale on actual linguistic data. Moreover, the theory contrasts with other well-established models regarding the source of novel variants, which casts some doubt on the generality of its application: Labov's studies on New York adolescent gangs and the neighbourhoods of Philadelphia (Labov, 1972; Labov, 2001) identified *leaders*, i.e., those who have strong networks and are the most popular in their communities, as the drivers of change. Similarly, Eckert's (2000) studies of adolescent groups in Detroit showed that language novelty and change is led by charismatic leaders with strong ties to the local community.

We assess the applicability of Milroy's theory to the emergence of lexical innovations in online social communities, where relationships between individuals and their exposure to new terms can only be modelled in terms of their directly observable linguistic interaction in online discussion threads.

2.2 Related Computational Work

Research on language change has recently experienced a boost within the NLP community (Hamilton et al., 2016; Frermann and Lapata, 2016). Here we focus on reviewing approaches that are directly related to the work we present in this paper, i.e., approaches that investigate linguistic innovation within relatively short time spans of a few years (rather than looking at historical time) and that do so by leveraging data from social media to create a graph of connected users. More general literature on graph modelling and innovation diffusion is out of the scope of our review.

Graphs representing social networks have been used to analyse the extralinguistic factors that drive diffusion, such as geographical (Eisenstein, 2015) and demographic variables (Eisenstein et al., 2014), as well as the position of individuals in the social network (Paolillo, 1999) and the kind of user interactions that foster the diffusion of the innovations. For example, Goel et al. (2016) and Paradowski and Jonak (2012) investigate the amount of interaction required to adopt an innovation, showing that while some innovations are adopted by a new user after multiple interactions, for others a single contact is sufficient. Rotabi et al. (2017a) relate the success of competing lexical variants to the seniority of the users who use them. This work is extended by Rotabi et al. (2017b), who introduce an inheritance graph

[1] https://github.com/marcodel13/The-Road-to-Success

to represent how speakers pass innovations (in this case called *practices*) on to others in time through real-life collaborations.

Perhaps the work that is most directly connected to ours is that of Rotabi and Kleinberg (2016), who investigate the diffusion patterns of words that experience a frequency burst at a given time, which the authors call *trends*, and analyse the level of activity of the users involved in the different phases of the diffusion process. While related, our work differs on key points: we focus on linguistic innovations rather than trends and characterise users in terms of tie strength rather than level of activity.

A parallel line of work has investigated linguistic diffusion in relation to social ties using agent-based computer simulations (Ke et al., 2008; Fagyal et al., 2010; Swarup et al., 2011). In particular, Fagyal et al. (2010) address questions similar to ours via simulated data and find that peripheral users are crucial in introducing new linguistic variants, which are then adopted and spread by central agents in the community. The current availability of large social media datasets containing real linguistic interactions allows us to study these questions with more ecological validity.

3 Methodology

We describe our dataset, the methodology we use to define the social network of a community and the social role of its members, and the procedure to identify linguistic innovations and characterise their diffusion.

3.1 Data

We use data from Reddit,[2] a popular website which includes around 1 million communities called *subreddits*. A subreddit is a topic-based forum where users can submit posts, comment on existing posts or score them. While in this paper we treat each forum independently (leaving the analysis of innovation diffusion across forums for future work), in order to conduct a large-scale analysis and draw conclusions that generalise across communities, we analyse 20 different forums that show substantial variability in terms of subject matter and size (see Table 1 for an overview). Despite their rich heterogeneity, all subreddits we consider share the following features, which are indicative of highly active and interconnected communities, where the spreading cascade process at the base of innovation diffusion finds a favourable environment (Hamilton et al., 2017; Guille et al., 2013):

- a topic that reflects a strong external interest, such as sport teams, videogames or TV series;
- small-to-medium size, which in contrast to very large subreddits such as r/news (15M users) or r/funny (18M), are less dispersive and favour tighter connections;
- high density, i.e., high ratio of existing connections over the number of potential connections;[3]

We downloaded the entire content of each subreddit from its first post to the end of 2016. We segment the data from each subreddit into consecutive time bins corresponding to one month.[4] We discard time bins with less than 200 active users, which are common during the first few months of a subreddit lifespan, and ignore any posts whose author is unknown.[5]

Next, we explain how we leverage this longitudinal data to extract information about the social role of forum members, as well as to detect linguistic innovations and characterise their diffusion.

3.2 Social Network

We create a graph representing a community's social network for each month t during the community lifespan. In these graphs, nodes are users and edges encode whether users have interacted. We consider two users to be connected by an edge if they comment within the same thread in close proximity.[6] Given

[2] `https://www.reddit.com`

[3] Hamilton et al. (2017) report density values in the range $[0.001 - 0.016]$ in their set of subreddits.

[4] We also experimented with smaller bins of one week, obtaining similar results.

[5] When users delete their account, the posts, comments, and messages submitted prior to the deletion are still visible to others, but information about the user is not available (see Reddit Privacy Policy at `https://www.redditinc.com/policies/privacy-policy`).

[6] In particular, if they are separated by at most two posts, as done e.g., by Hamilton et al. (2017).

subreddit	years	tokens	users	density	innovations
r/Android	7	158	1.03M	0.006	730
r/apple	8	89	580k	0.006	584
r/baseball	6	101	576k	0.014	520
r/beer	7	29	291k	0.008	360
r/boardgames	6	88	313k	0.004	380

r/running	6	56	279k	0.008	367
r/StarWars	6	56	542k	0.008	381
r/subaru	5	21	187k	0.005	340

Table 1: Statistics of the subreddits in our dataset, including: years of activity considered until end of 2016; total # of tokens (in millions); total # of active users (including users who may have left the community); average ratio of network ties over all possible ties computed over all the time bins (density); total # of linguistic innovations analysed.

that arguably lexical diffusion follows a simple "contagion" model whereby a single contact is sufficient for the spreading process (Goel et al., 2016), our graphs are undirected and unweighted.[7]

Milroy's (1987) theory relates the diffusion of a linguistic innovation to the local topology of individuals within a network, distinguishing between close-knit sub-groups and individuals outside of these groups. In line with other studies such as Weng et al. (2015) and Zhao et al. (2010), we build on a measure introduced by Onnela et al. (2007), which determines the strength of the edge between two individuals i and j in terms of the overlap O_{ij} of their adjacent neighbourhoods, as follows:

$$O_{ij} = \frac{n_{ij}}{(k_i - 1) + (k_j - 1) - n_{ij}} \quad [1]$$

where n_{ij} is the number of adjacent nodes between i and j, and k_i, k_j their respective degree, i.e., the number of edges incident to each of them. Possible values for O_{ij} are in the range $[0, 1]$, where 0 indicates no common neighbours (weakest possible connection between i and j) and 1 exactly the same adjacent neighbours (strongest possible connection between i and j).

We now leverage Equation [1] to characterize users given the strength of their connections. According to Milroy (1987), weak-tie individuals have only weak connections (are not part of close-knit clusters), while strong-tie individuals have strong connections with other users, but may also have weak connections if they are linked to weak-tie users. To capture this, we define the tie strength of each individual i as the highest value of her incident edges. That is, for all individuals j directly connected to i:

$$\textit{tie-strength}(i) := \max(O_{ij}) \quad [2]$$

Taking the maximum captures what we are after: A community member who only has weak connections will have low tie-strength and be considered a *weak-tie user*, while a member with either strong connections only or with both strong and weak connections will have high tie-strength and be considered a *strong-tie user*, who will be part of a local clique (Luce and Perry, 1949). Unlike mean or median values, which tend to be rather balanced and thus do not help to distinguish between innovators and non-innovators, taking the maximum is in line with Milroy's theory and captures the key difference between these two groups of users, as will be shown in the next section.

[7]The graphs are implemented with Python's package `networkx`.

Besides computing tie-strength as defined in Equation [2] for all users in our social graphs, we also compute their centrality values for three common measures of network centrality — degree, betweenness, and eigenvector — which are global indices of the importance of a node with respect to all other nodes in a graph (Newman, 2010).

3.3 Linguistic Innovations

We focus on *Internet slang*, a general term commonly used to refer to a range of linguistic phenomena such as abbreviations (*cu* for *see you*), acronyms (*IIRC* for *if I remember/recall correctly*) and phonetic spellings (*dat* for *that*). The motivation behind this choice is twofold: firstly, forms of this kind are very abundant and continuously introduced in online communication; and secondly, they are easier to identify and track than innovations at other levels, such as those related to meaning shift. In the present study, we do not focus on tracking the co-evolution of two variants (e.g., *dat* vs. *that*) that may be competing, but rather on analysing the emergence of new forms and their trajectories independently, in light of the tie-strength of the members who use them.

Our starting point are the terms in the dictionary available at `NoSlang.com`,[8] a comprehensive record of Internet slang that is constantly updated. After removing terms including non-alphabetic characters, we obtain a list of approximately 6k terms. For each subreddit, we only consider terms that:

- are used at least 10 times in the subreddit;
- are not present during the first 3 months of the community's existence; and
- are introduced within the initial quarter of the community lifespan.

That is, we restrict our analysis to *newly* introduced Internet slang terms that are not present from the very beginning of the community's activity, but are not introduced too late so as to be able to observe their trajectory for a substantial period of time.[9]

The number of innovations considered across all subreddits is 7962, while the number of unique innovations amounts to 1456. Most of the terms (around 76%) occur in more than one community, although no innovation is present in all the subreddits in our dataset. Thus, around 24% of innovations tracked occur in just one community — some of these are clearly topic-related, e.g., *pkemon* in /r/pokemon, while others are more general purpose abbreviations that, in principle, could appear in any community, such as *txs* (*thanks*, in /r/Android) or *omgz* (*oh my god/gosh*, in /r/subaru). Regarding frequency, while we set a minimum threshold of 10 occurrences, in practice 72% of terms occur at least 50 times on average.

Dissemination trajectory. Once introduced, innovations may have different fates: they can spread widely within the community, be used by just a small sub-group, or fail to make an impact and disappear altogether. We define the fate of a term as its *dissemination*, which we compute as the proportion of community members who use it at a given moment in time (Del Tredici and Fernández, 2017; Altmann et al., 2011). It should be stressed that dissemination differs from frequency. Although often they are highly correlated, in principle a term can have high relative frequency but low dissemination and vice versa. We quantify the diffusion of innovations in terms of their dissemination since this gives us a measure of their spread within a community. To this end, for each innovation we calculate its *dissemination trajectory* as the vector of its monthly dissemination values since the innovation was introduced.

Tie-strength trajectory. Similarly, we compute the *tie-strength trajectory* of each innovation as a vector whose features correspond to the maximum tie-strength value among the users that used it in the corresponding month. We choose the maximum value in order to test Milroy's (1987) hypothesis, according to which the crucial factor in the diffusion of an innovation is its adoption by strong-tie members (see Section 2). Considering only the maximum value provides a simple way to test whether any individual with high tie-strength has used the term in a given month.[10]

[8] `https://www.noslang.com/dictionary/`

[9] To assess whether ambiguity may be an issue, we checked whether the terms also appear in a standard English dictionary, PyDictionary. For example, the slang term *bra* for *brother* also has the standard meaning of *brasserie*. Given that under 2% of terms in our dataset could potentially be ambiguous, we decided to not treat them in any special way.

[10] The dissemination and the tie-strength vectors always have the same magnitude.

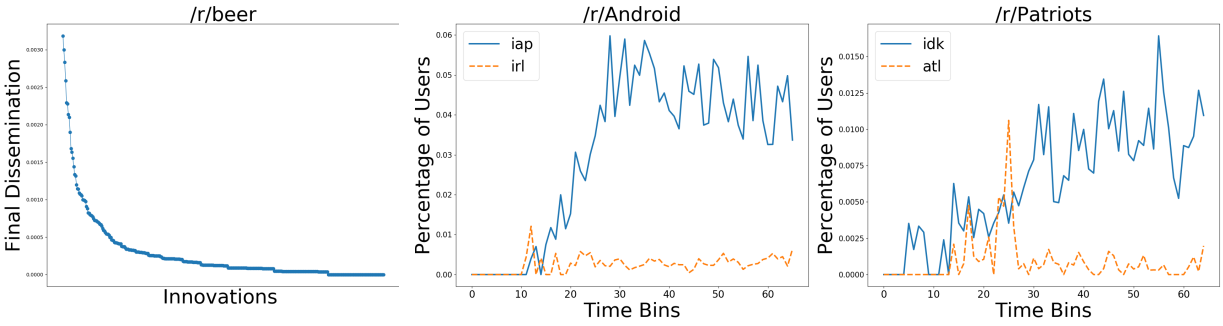

Figure 1: **Left**: Distribution of the final dissemination values in /r/beer. **Center/Right**: Examples of dissemination trajectories of *successful* (blue solid line) and *unsuccessful* (orange dashed line) innovations.

4 Empirical Observations

Our analysis reveals some patterns common to all communities, which we present in this section.

4.1 Linguistic Innovations

In order to explore the relative success of innovations, we consider the level of dissemination reached by an innovation to be the average dissemination value in the last six months.[11] Results show that the distribution of these final dissemination values is highly skewed for all the subreddits — see, for example, Figure 1 (left) for /r/beer. While a few innovations disseminate successfully (i.e., are adopted by a relatively high number of community members), most of them do not spread, and either disappear or barely appear in the last period.

In Figure 1 (center/right) we show examples of successful and unsuccessful innovations. Successful innovations such as *iap* (*In App Purchases*) and *idk* (*I don't know*) show a stable increase in dissemination after their introduction, which can reach a plateau at some point (*iap*) — thus showing the S-shaped curve typical of general processes of innovation adoption (Rogers, 2010) — or can still be ongoing at the end of the period covered by our analysis (*idk*). Unsuccessful innovations, in contrast, can either have a flat dissemination trajectory, as in the case of *irl* (*In Real Life*), indicating that the term has never experienced a spread in the community, or present a peak at some point, followed by a sudden decrease with no stable recovery, as for *atl* (*Atlanta*).

Given these observations, we formally define the classes of *successful* and *unsuccessful* innovations based on the dissemination *slope* of a term, computed as the difference between its average dissemination value in the first six months and in the last six months in the dissemination trajectory vector. We include in the *unsuccessful* class innovations with slope index ≤ 0, i.e., those with trajectories similar to the *irl* and *atl* examples in Figure 1 (center/right). In order to discard innovations with very low positive slope (i.e., those that do not disappear, but are only sporadically used) we only include in the *successful* class terms whose slope index is above the average value of the community.[12] We will make use of these two classes in the prediction experiment we present in Section 6.

4.2 Social Networks

Next, we analyse the distribution of users' tie-strength values in the social graphs derived for the communities in our dataset.[13] We find a clear pattern for all subreddits: the large majority of users have low tie-strength, with around 39% having values ≤ 0.05 and almost 50% having values ≤ 0.1; while, around 15 to 20% of users have strong tie-strength, with values ≥ 0.5. Figure 2 shows the average tie-strength value distribution computed over all the monthly graphs of all subreddits in the dataset, with probabilities calculated for bins of size 0.1 for illustration purposes.

[11] This makes our measurements more robust than taking only the very last bin.

[12] Average slope index is positive for all subreddits.

[13] A sample graph is available at `https://github.com/marcodel13/The-Road-to-Success`.

This distribution mirrors the typical power-law distribution observed for centrality measures in online communities (Mihalcea and Radev, 2011). The topological properties captured by our tie-strength measure (Equation [2]), however, are different from those captured by centrality, as already hinted at in Section 3.2. The three centrality measures considered (degree, betweenness, and eigenvector) correlate strongly with each other (Spearman's r in range 0.85–0.89).[14] But there is only a moderate correlation with tie-strength: r=0.63 degree, r=0.61 betweenness, and r=0.47 eigenvector. In addition, we observe that the three centrality measures correlate strongly with number of posts (r=[0.78–0.91]) in all subreddits, while we find low correlation between number of posts and tie-strength (r=0.31, std=0.08, $p < .05$).

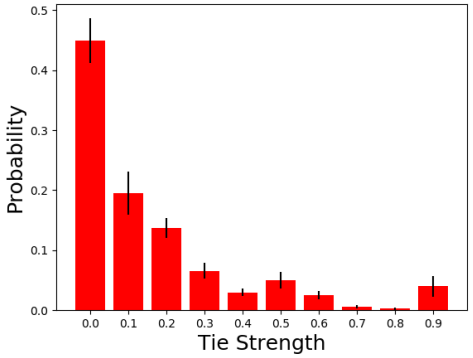

Figure 2: Average tie-strength distribution for all subreddits, with standard deviation.

These results confirm the difference between our tie-strength measure and centrality. While centrality values are *global* indices of the role of a node with respect to the entire graph (Newman, 2010), tie-strength captures the *local* topological information around a node. In the online social communities we investigate, individuals at the core of the social network, who interact with many other individuals and have high posting activity, receive high centrality values. In contrast, high tie-strength values are the signature of users who belong to small cliques, but who do not act as hubs for the entire network. We take this as confirmation that our tie-strength measure does capture key features of the social structures underpinning Milroy's (1987) theory. It remains to be seen, however, whether these social structures, as realised in large online social communities, lend support to the theory's main claims.

5 Assessing Sociolinguistic Claims

In this section, we uncover the features that characterise innovators and analyse the role of strong-tie users in the dissemination process.

5.1 Innovators

We consider *innovators* those members who introduce a new term, i.e., those who use it for the very first time in a community. In order to verify whether innovators are weak-tie users (as hypothesised by Milroy (1987)), we compare the distribution of the tie-strength values of innovators to the general tie-strength distribution in the community. Since innovations are introduced at different points in time, the general tie-strength distribution in the community is defined as the average of the months at which innovations were introduced. We compute Kullback-Leibler divergence (KL), which measures how similar the behaviour of two distributions is. We find KL values in the range 0.15–0.4, which indicates a moderate difference between the distributions. The source of this difference can be appreciated in Figure 3: the tie-strength values of innovators cluster around 0.1–0.3.[15] This contrasts with the overall tie-strength distribution: innovators tend to *not* be strong-tie users (lower blue than red bars for tie-strength ≥ 0.4 in Figure 3) and are far less likely to

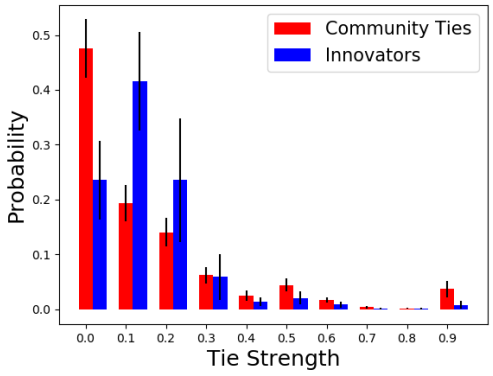

Figure 3: Comparison of the probability mass distribution of innovators' tie-strength values and avg. values of all users in all subreddits.

[14] All correlation coefficients reported are averages across time bins and subreddits and are all significant with $p < 0.05$.

[15] The same trend holds for all subreddits. Individual plots per subreddit can be found at `https://github.com/marcodel13/The-Road-to-Success`.

have very weak tie-strength than most users (lower blue than red bar for tie-strength < 0.1).

In addition to analysing tie-strength, we compare the centrality values and the posting activity of innovators and non-innovators. We observe that innovators are significantly more central than other users (for all measures considered: degree, betweenness and eigenvector) and are significantly more active in terms of number of posts than other individuals in the community (unpaired Welch's t-tests, all with $p < 0.05$).

Thus, a very robust pattern emerges across all subreddits, showing that innovators do have a particular profile in terms of their social standing: they do not belong to tightly connected cliques and occupy a central position in the network, as hubs with many connections of relatively low strength. On the one hand, this seems in line with Milroy's hypothesis, since it confirms that innovations do not arise within sub-communities that are close-knit. On the other hand, our results may also be interpreted as lending support to Labov's (1972; 2001) characterisation of innovators as *leaders*, since they occupy a core position in the network.

5.2 Strong-Tie Users and Innovation Spread

We consider strong-tie users those with a tie-strength value ≥ 0.5. By definition, these are users who are part of cliques or sub-communities within a subreddit. As mentioned in Section 4.2, strong-tie users constitute between 15 and 20% of the total number of community members. Thus, in contrast to the small scale social communities examined by Milroy and other sociolinguists, where most community members are part of some tight-knit sub-group (such as a family or a church congregation), in large online social networks strong-tie users are a minority. Despite this, strong-tie users are not isolated in remote cliques: Our analysis shows that, in all subreddits, strong-tie users are significantly more central (with respect to all, degree, betweenness, and eigenvector centrality) and have significantly more posting activity than users with weak tie-strength values ≤ 0.05, who make up the vast majority of community members — around 39% on average (unpaired Welch's t-test, $p < 0.05$). Thus, in terms of centrality, strong-tie members occupy an intermediate position in the social network, forming a loose ring around the core innovators and the majority of members, who are on the periphery and are characterised by very weak tie-strength.

To analyse the role of strong-tie users in the innovation diffusion process, we proceed as follows: We identify any time t_i in the tie-strength trajectory vector when the innovation is used by some strong-tie member for k consecutive months. We then check its average dissemination in the period up to time t_i and compare it to the average dissemination in the six months following t_{i+k-1}. We find that when $k = 1$ (i.e., when an innovation has been used by a strong-tie member only in one month) the probability that the dissemination increases in the next six months is around 50% for all subreddits — a value similar to the likelihood of dissemination increase after the usage by a weak-tie user. However, as k increases, and thus the adoption by strong-tie users becomes more stable, a future increase in dissemination becomes progressively more likely, for all the subreddits. Importantly, the same effect is not observed for weak-tie users, for whom, independently from the number of months, the probability of a future increase in dissemination is always approximately the same. Figure 4 shows examples of how the probability of dissemination changes after the adoption by either strong- or weak-tie users (see Appendix A for full results).

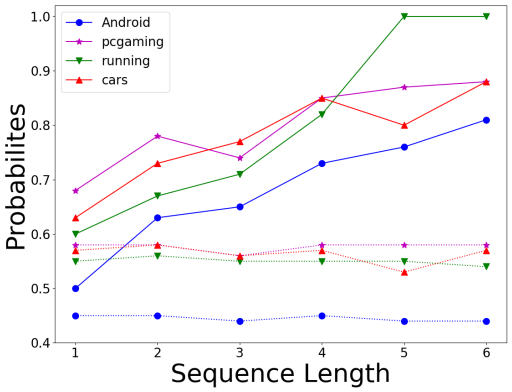

Figure 4: Probability of dissemination increase after a term is adopted by a strong-tie user (solid line) or by a weak-tie user (dotted line) for k consecutive months, computed for k in range $[1 - 6]$.

These results, thus, are consistent with Milroy's (1987) claims, and furthermore show that innovation diffusion is connected to *sustained* adoption by strong-tie community members.

6 Predicting Innovation Success

Most innovations do not succeed in becoming community norms, but some do. Here we assess whether information about the tie-strength of members who use an innovation in the first months after its introduction can predict whether it will be successful in the future. This provides further theoretical insight into the importance of tie-strength for innovation diffusion, and has practical significance by contributing to identifying new terms that NLP systems should be able to process. Our aim here is not to maximise prediction accuracy—which is likely to require taking into account several factors beyond users' tie-strength—but rather to explore whether the statistical effects we have uncovered are strong enough to have some predictive power.

We approach this as a binary classification task, making use of the distinction between *successful* and *unsuccessful* innovations defined in Section 4. We extract a subvector of length k from the tie-strength trajectory vector of innovations and use it as features for the prediction. For instance, with $k = 3$, we use the tie-strength information from the first three months of usage of a term to predict if it will be successful or not, leveraging subvectors of increasing magnitudes. We use Python's `scikit-learn` Random Forest classifier with default parameters[16] and perform 100-run cross-validation, using 90% of the data for training and 10% for testing. We compare our results against a *weighted baseline*, whereby the two labels (successful/unsuccessful) are randomly assigned taking into account their frequency in the training set. The classes are fairly balanced across subreddits, with an average proportion of 55% successful and 45% unsuccessful.

When leveraging tie-strength information from only the first 3 months of usage, we obtain F1 results that are significantly higher than the baseline for 12 out the 20 subreddits. But overall, performance remains rather low, with an average F1-score for the *successful* class of 0.62 vs. 0.58 for the baseline. Given that new terms are introduced by users with relatively low tie-strength (as shown in Section 5.1), arguably in the initial few months before a novel term is picked up by a strong-tie user, there is little difference between successful and unsuccessful innovations. With tie-strength information from the first 6 months of usage, we are able to make predictions with results significantly above baseline for 18 out 20 subreddits, with an average F1-score of 0.68. Not surprisingly, performance increases substantially when information for a longer period (first/second year of usage) is exploited, reaching an average F1-score of 0.76, significantly above the baseline for all communities. Detailed results, including precision, recall, and F1-score for each subreddit, can be found in Appendix B. In Figure 5 we graphically illustrate the results for a few subreddits, which are representative of the general trend observed.

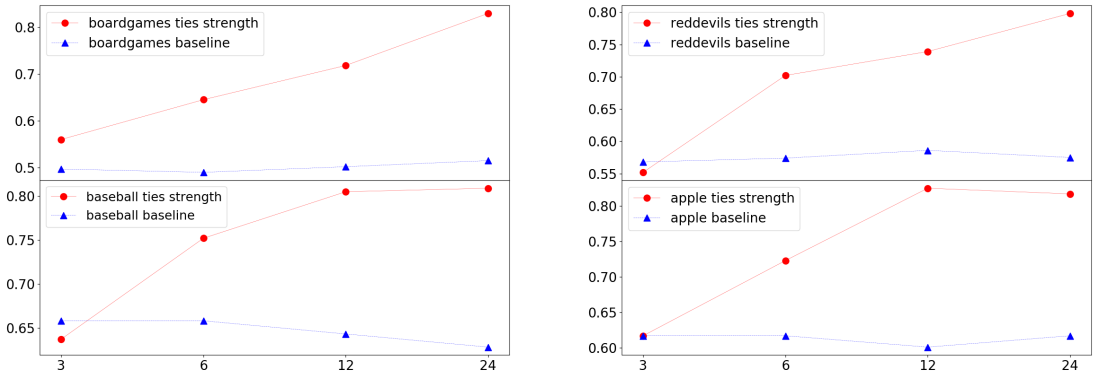

Figure 5: F-score (y-axis) for the successful class obtained with the ties-strength values of the first k months (x-axis) after the introduction of a term.

7 Conclusions

This work has provided a large-scale analysis of the interplay between the birth and spread of new terms and users' social standing in large online social communities. Building on sociolinguistic theories — in particular, Milroy's (1987) version of *The Strength of Weak Ties* theory — we have proposed a simple measure to quantify tie-strength in Milroy's sense and have used it in combination with common centrality measures to uncover the characteristics of innovators and to assess the role of strong-tie users in the dissemination process.

Regarding innovators, our results show that they are central community members, connected to many other users but with relatively low tie-strength. As for strong-tie users, we find that in online social networks they are a small proportion of community members, organised in small cliques, and that they do play an important role in the spread of an innovation, presumably by spreading new terms introduced by innovators into their sub-groups. The patterns we have revealed are surprisingly consistent across the 20 online communities we have investigated.

Our work opens a range of interesting questions. In particular, we are looking forward to investigating how the patterns we have observed are affected by users' membership in multiple forums and how these multi-community users transfer new terms between communities.

alina.ciobanu@my.fmi.unibuc.ro, ldinu@fmi.unibuc.ro

Abstract

Proto-word reconstruction is central to the study of language evolution. It consists of recreating the words in an ancient language from its modern daughter languages. In this paper we investigate automatic word form reconstruction for Latin proto-words. Having modern word forms in multiple Romance languages (French, Italian, Spanish, Portuguese and Romanian), we infer the form of their common Latin ancestors. Our approach relies on the regularities that occurred when the Latin words entered the modern languages. We leverage information from all modern languages, building an ensemble system for proto-word reconstruction. We use conditional random fields for sequence labeling, but we conduct preliminary experiments with recurrent neural networks as well. We apply our method on multiple datasets, showing that our method improves on previous results, having also the advantage of requiring less input data, which is essential in historical linguistics, where resources are generally scarce.

1 Introduction

Proto-language reconstruction is one of the main concerns of historical linguistics and is central to understanding the evolution of the world's languages. Reconstructing an ancestral language from the modern languages descending from it not only allows an analysis of language change across space and time, but also reveals information about the historical relationships between languages. The traditional process of reconstructing ancient languages is called the comparative method (Anttila, 1989) and relies on cognates (words in different languages descending from a common proto-word). The main idea of the comparative method is to perform a property-based comparison on multiple sister languages in order to infer properties of their common ancestor. For a long period, the comparative reconstruction has been a time-consuming manual process that required a large amount of intensive work. The first step of the process consists in identifying cognate pairs.

Identifying cognates and borrowings by means of computational approaches has attracted considerable attention in recent years (Hall and Klein, 2010; Tsvetkov et al., 2015; Ciobanu and Dinu, 2015). However, few studies went beyond this step, and beyond the comparative method, to automate the process of proto-language reconstruction (Oakes, 2000; Bouchard-Côté et al., 2013; Atkinson, 2013). Reconstructing proto-words is a challenging task. While the main hypothesis in this research problem is that there are regularities and patterns in how words evolved from the ancestor language to its modern daughter languages, there are also words which diverged significantly from their ancestor. Take, for example, the Latin word *umbilicu(lu)s*. It evolved into *buric* (Romanian), *nombril* (French), and *umbigo* (Portuguese).

One of the best approaches to proto-word reconstruction (Bouchard-Côté et al., 2013) relies on an analogy with reconstructing the genealogy of the species from genetic sequences in biology. This approach requires an existing phylogenetic tree and the phonetic transcripts of the words, to infer the ancient word forms based on probability estimates for all the possible sound changes on each branch of the tree.

Proceedings of the 27th International Conference on Computational Linguistics, pages 1604–1614
Santa Fe, New Mexico, USA, August 20-26, 2018.

Contributions of the present work. In this paper, we investigate proto-word reconstruction starting from modern word forms. The main goal of our study is to achieve state-of-the-art performance in proto-word reconstruction using less resources than in previous studies. We aim at providing a tool for linguists to use in their research on endangered and extinct languages. Our hypothesis is that orthographic changes represent sound correspondences to a large extent, and thus we attempt to reconstruct proto-words from the orthographic form of the modern words.

We address this problem in two steps. Firstly, given cognate pairs in multiple modern languages and their common ancestors, we apply a word production method based on sequence labeling for reconstructing proto-words. We apply the method on each modern language individually. Secondly, we propose several ensemble methods for combining information from multiple word production systems, with the purpose of joining the best productions from all modern languages. Through experiments, we show that our best ensemble system outperforms previous results (Bouchard-Côté et al., 2007). The novelty of our approach is enhancing the sequence alignment system with an additional step of reranking. We also compute the results of an oracle, which shows the potential of this approach. The proposed methods have the advantage of not requiring phonetic transcripts and other data besides the training word pairs (such as a corpus in the target language, as some of the existing methods require); external information regarding language evolution is difficult to obtain for some languages, and this method can be applied on low-resourced and endangered languages. Moreover, as opposed to previous methods, our system is able to reconstruct proto-words even from incomplete cognate sets (cognate pairs in multiple modern languages descending from a common proto-language).

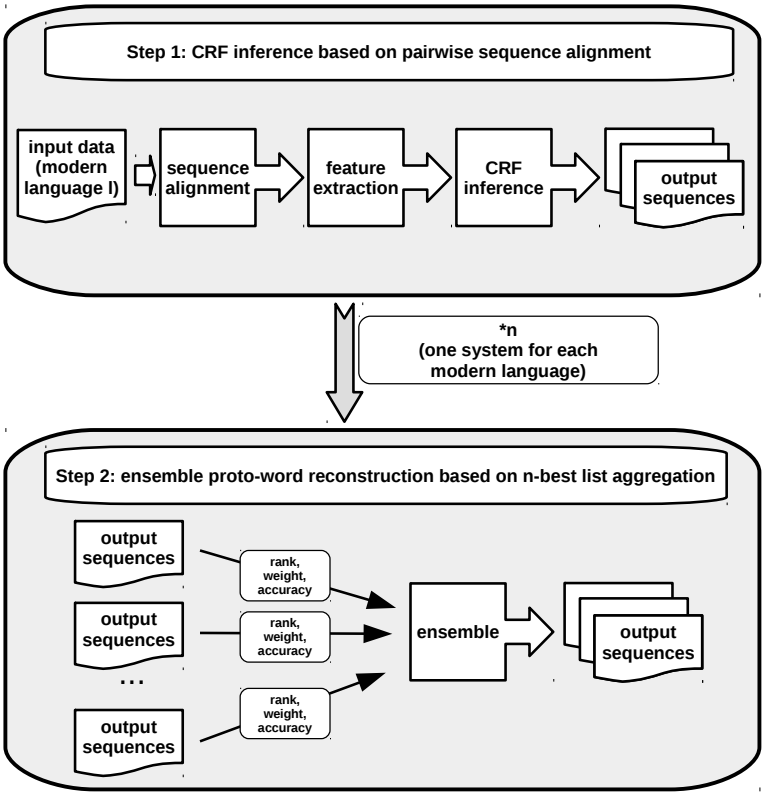

Figure 1: Methodology for proto-word reconstruction.

2 Methodology and Algorithm

In this section we introduce a new technique for proto-word reconstruction. Given cognate sets in several Romance languages, we infer the form of their common Latin ancestors. Our goal is to produce a tool that would provide support in historical linguistics, where the produced proto-words would be further analyzed by domain experts. We propose an approach based on conditional random fields. For each

modern language independently, we first apply a sequence labeling method that produces the form of the Latin ancestors. For this first step, we only require *(word, proto-word)* pairs (not cognate sets), as the input data is formed of modern word forms and their ancestors. Then we define several ensemble methods to take advantage of the information provided by all languages, in order to improve performance on Latin proto-word reconstruction. Our methodology is illustrated in Figure 1.

2.1 Conditional Random Fields

From the alignment of related words in the training set, the system learns orthographic patterns for the changes in spelling between each modern language and the proto-language. We apply a sequence labeling method to infer the form of the Latin proto-words for the modern words in the test set. The method that we employ is based on sequence labeling, an approach that has been proven useful in generating transliterations (Ganesh et al., 2008; Ammar et al., 2012) and in cognate production (Ciobanu, 2016).
