COLING 2018

The 27th International Conference on Computational Linguistics

Proceedings of the Conference

August 20-26, 2018
Santa Fe, New Mexico, USA

ISBN 978-1-948087-50-6

Preface: General Chair

On behalf of the International Committee on Computational Linguistics, I am thrilled to welcome you all to the 27th International Conference on Computational Linguistics (COLING 2018) here in Santa Fe, New-Mexico. Many of you are too young to remember the last COLING that took place in North America: it was actually the Montreal 1998 joint COLING-ACL conference. And indeed, most of you are too young to remember the last COLING in the U.S.A. which (would you believe?) was held as far back as 1984, also as a joint COLING-ACL conference. Moreover, the only other COLING that took place in the U.S.A. was the very first one, chaired by David G. Hays back in 1965. It gave rise to the oldest publication you can currently read in the ACL anthology. Whatever the reasons for the rarity COLING in the USA, we are very proud to bring you the present one and our team has worked very hard to make it a memorable event.

Over the last 18 months, a tremendous amount of work has been carried out by the COLING 2018 organizing committee. Please join me in thanking Sergei Nirenburg (Local Organizer), Emily Bender and Leon Derczynski (Program Chairs), Tim Baldwin, Yoav Goldberg and Jin Jiang (Workshop Chairs), Donia Scott, Pascale Fung and Marilyn Walker (Tutorial Chairs), Dongyan Zhao (Demonstration Chair), Xiaodan Zhu and Zhiyuan Liu (Publications Chairs), Yuji Matsumoto and Hiroshi Noji (Publicity Chairs), Qian Chen and Christine Tang (Webmasters) and last but not least, Leo Wanner, Soo-Min Pantel, Satoshi Sekine and Le Sun (Sponsorship Chairs).

I hope that you will enjoy the special atmosphere and the spectacular scenery offered by Santa Fe, the convenience of our meeting site as well as the social events and excursions carefully arranged by our Local Organizing Committee.

Most importantly, I hope that you will love the content of our conference. I trust that the COLING difference will be unmistakable. While paying due tribute to the hottest methods and trends of the times, we will also offer you a more diversified intellectual menu. Our Program Chairs deserve highly special thanks for their truly remarkable work in setting up a program that comprises some 331 papers which, in addition to the ubiquitous type of scientific contribution these days ("NLP engineering experiment"), accommodates a variety of other worthwhile kinds of contributions, each with appropriate evaluation criteria. This emphasis on diversity is also visible in their choice of our four outstanding invited speakers: Fabiola Henri, James Pustejovsky, Min-Yen Kan and Hannah Rohde. Throughout their program development work, Emily and Leon have made sure to engage our community on all aspects of their decision-making through a lively blog. And as if this wasn't enough, they also found the energy to setup a highly successful mentoring program for authors. Our scientific program also includes 35 system demonstrations, seven enticing tutorials, and twelve different workshops.

I would like to thanks our generous COLING 2018 sponsors:

Amazon Alexa, Baidu, Disney Research, the Linguist List, Lenovo, Brandeis University, the University of Washington and the University of Colorado. And last but not least, I offer my sincere thanks to all those who have submitted papers and demos to COLING 2018 as well as to all those who have served as area chairs, reviewers or helped our organizing committee in any other way.

I wish you all a pleasant and fruitful conference.

Pierre Isabelle (National Research Council, Canada)
COLING 2018 General Chair

Preface: Program Chairs

COLING is the oldest Computational Linguistics conference, from its first instance fifty-three years ago in 1965, held in New York. This year marks its third visit to the USA, after the second in 1984 at Stanford. COLING remains the strongest conference in the field that is beyond the ACL, instead organised by the ICCL. The ICCL and COLING hold ideals of being a conference for all, originally to bring together both NATO and Soviet scientists without an overseeing US-based organization. These are values that we have constantly held in mind with our construction of COLING 2018, in Santa Fe, and we are honored to have had so much support in doing so.

As we began the process of constructing the program for COLING 2018, we started by identifying our goals. These were set on our PC blog in a post in August 2017. They are: (1) to create a program of high quality papers which represent diverse approaches to and applications of computational linguistics, written and presented by researchers from throughout our international community; (2) to facilitate thoughtful reviewing which is both informative to ACs (and to us as PC co-chairs), and helpful to authors; and (3) to ensure that the results published at COLING 2018 are as reproducible as possible.

To give a bit more detail on the first goal, by diverse approaches/applications, we mean that we aimed to attract (in the tradition of COLING):

- papers which develop linguistic insight as well as papers which deepen our understanding of how machine learning can be applied to NLP—and papers that do both!
- research on a broad variety of languages and genres
- many different types of research contributions (application papers, resource papers, methodology papers, position papers, reproduction papers. . .)

We had the challenge and the privilege of taking on this role at a time when our field is growing tremendously quickly. We seized the opportunity to advance the way our conferences work by trying new things and improving the experience from all sides. To this end, while ever-mindful of author, reviewer and chair workload, we took specific actions.

Paper types

We reasoned that one cause of a lack of diversity of type of papers is that the typical review form in our field is primarily designed for the dominant type (which we dubbed 'NLP engineering experiment paper'), and that this makes it harder for other paper types to receive positive reviews. We decided to address this by identifying a small range of paper types and creating specialized review forms for each one. We developed an initial set, then solicited community feedback via a PC blog post (of 17 August 2017), then refined the types based on that input. A second function of the paper types was to explicitly elicit submissions of non-standard format. The paper types defined are (in order of number of submissions we received in each type): NLP engineering experiment paper, computer assisted linguistic analysis paper, resource paper, reproduction paper, position paper, and survey paper. Though the NLP engineering experiment paper type remains dominant, we are pleased at how the process has led to the diverse range of papers appearing in this volume. Submission and acceptance numbers for each type are given in Table 1.

Type	Submitted	Withdrawn	Accepted	Acceptance rate
NLPEE	657	85	217	37.94%
CALA	163	28	45	33.33%
Resource	106	7	32	32.32%
Reproduction	35	0	17	48.57%
Position	31	6	8	32.00%
Survey	25	3	12	54.55%
Overall	1017	129	331	37.27%

Table 1: Submission and acceptance, by paper type

Mentoring

One of our strategies for achieving goal (1) given above was to create a writing mentoring program, which took place before the reviewing stage. This optional program focused on helping those who perhaps aren't used to publishing in the field of computational linguistics, are early in their careers, and so on. We see mentoring as a tool that makes a conference accessible for a broader range of high-quality ideas. In other words, this isn't about pushing borderline papers into acceptance but rather alleviating presentational problems with papers that, in their underlying research quality, easily make the high required standard.

The response from mentors was very enthusiastic—over 100 people volunteered! We see this as a good indication of the long-term viability of mentoring programs. There were fewer papers submitted for mentoring than available mentors, but still a strong number: 56. We asked authors seeking mentoring to submit an abstract 4 weeks ahead of the deadline and a draft for feedback 3 weeks ahead. We asked mentors to bid on abstracts once they were received and to provide feedback on papers within one week (leaving 2 weeks for mentees to revise their submissions based on that feedback). We also provided a structured mentoring form. Of the 56 papers receiving mentoring, 47 were ultimately submitted to the conference, 3 subsequently withdrawn, and 14 accepted. We see value in the mentoring of all of these papers, both those that ultimate ended up in this volume and those that did not. The authors received valuable feedback from their mentors which can inform their future work, both on the mentored papers specifically and more generally.

Real double-blind

We know that non-blind peer review favors work by well-recognised authors or from well-recognised institutions (Tomkins et al. 2017, Laband and Piette 2014, Peters and Ceci 1982). This has two unfavorable impacts: first, substandard work may be presented as more worthy of reader and audience time than it is; secondly, when presentation slots are limited, substandard work will displace excellent work from beyond well-recognised institutions or authors. We took steps at every point of COLING 2018's review process to reduce or remove this bias.

Firstly, unlike the majority of conferences in the field, we hid author identities from area chairs, who are those making the primary recommendation about paper acceptance. We also hid reviewer identities from each other, thinking that reviewers may be inadvertently swayed by comments from a well-known reviewer, or afraid to contradict e.g. a potential future employer.[1] We also took pains to hide author identities from ourselves as PC co-chairs in making our final decisions. In addition, we hid authors

[1] We did set things up so that reviewer identities were revealed to co-reviewers at the end of the process, and announced this to reviewers. The goal here was to promote civility in reviews.

from the best paper committee; this involved withholding the "Accepted Papers" list until the best paper awards had been nominated and fixed. Finally, we followed ACL policy on preprints, blocking from consideration non-blind papers that had been published within the month before the deadline. We made one mistake in this process, where we asked authors to contact their ACs about belated author responses; this leaked author identity in a handful of cases (fewer than ten submissions).

To avoid the second unfavorable impact, we were lucky enough to have a venue of size such that we did not need to limit the number of accepted papers. Poster and oral presentation are of identical standard and receive the same treatment in the proceedings, which helped with this space limit. Having sufficient room meant that the acceptance of a substandard paper based on its author's name or institution did not lead to another, better paper being displaced. Additionally, we did not impose a maximum acceptance rate. Fixed acceptance rates under non-blind review lead to good borderline papers being lost in favor of weaker papers from well-recognized origins. Fixed acceptance rates also risk that some excellent work will be missed (Church 2005).

Reviewing quality

It is important to maintain consistency, good standards, and to be responsive. To achieve this, we had at least two people involved at every step in the program selection process. The PC chairs were co-chairs; each area had two chairs, who were both in the same coarse-grained geographic region for all but one area; all papers were reviewed by many people; and then to ensure this continued, there were Special Circumstances ACs who filled in AC gaps, and the General Chair would stand in when a PC co-chair couldn't.

We know that reviewing in computer science can be a little harsher than in general (Meyer 2011). Reviewers are not as kind to authors, or to each other. Malicious or unconstructive reviews hurt quality. So, we asked ACs to specifically look out for this kind of behavior and to ask reviewers to edit their reviews for tone where necessary, and we discounted malicious reviews when making acceptance decisions. Reviews tend to be of better tone and more constructive when signed by the author, so we gave the option for reviewers to add their names to their reviews. This couldn't be compulsory: this might risk reviewers disagreeing by name with e.g. their later bosses, which is too much to ask of the generally young CL reviewing pool.

Review quality also suffers when area chairs' jobs are too difficult. This can be addressed by reducing area chair load. To enable flexible load management, we provided information as early as possible, helped ACs move unrelated papers out of their areas, gave rapid responses during the critical period (being nine hours apart enabled an almost 24h availability), and critically, kept area size limited. This meant that there was, for example, no one area for machine translation—this would have been unmanageable and have had unacceptably low reviewing quality. Instead, papers with facets that placed them in very large areas were placed based on their other features. For example, papers on MT in low-resourced languages might be put together; those on MT for dialogue would also be grouped, but in a separate area. This way, load was managed and the risk of unreliable (and so unfair) review reduced.

Broader recognition

In keeping with building a diverse program that brings together excellent work in all aspects of our field, we wanted to make sure that our awards also recognized the many kinds of excellence to be found in work on computational linguistics. To this end, we enumerated 10 awards, of which 9 were ultimately given. We received 44 nominations for best papers over these categories, and conferred best paper awards in the categories as follows:

- Best error analysis: 'SGM: Sequence Generation Model for Multi-label Classification', by Pengcheng Yang, Xu Sun, Wei Li, Shuming Ma, Wei Wu and Houfeng Wang.
- Best evaluation: 'SGM: Sequence Generation Model for Multi-label Classification', by Pengcheng Yang, Xu Sun, Wei Li, Shuming Ma, Wei Wu and Houfeng Wang.
- Best linguistic analysis: 'Distinguishing affixoid formations from compounds', by Josef Ruppenhofer, Michael Wiegand, Rebecca Wilm and Katja Markert
- Best NLP engineering experiment: 'Authorless Topic Models: Biasing Models Away from Known Structure', by Laure Thompson and David Mimno
- Best position paper: 'Arguments and Adjuncts in Universal Dependencies', by Adam Przepiórkowski and Agnieszka Patejuk
- Best reproduction paper: 'Neural Network Models for Paraphrase Identification, Semantic Textual Similarity, Natural Language Inference, and Question Answering', by Wuwei Lan and Wei Xu
- Best resource paper: 'AnlamVer: Semantic Model Evaluation Dataset for Turkish—Word Similarity and Relatedness', by Gökhan Ercan and Olcay Taner Yıldız
- Best survey paper: 'A Survey on Open Information Extraction', by Christina Niklaus, Matthias Cetto, André Freitas and Siegfried Handschuh
- Most reproducible: 'Design Challenges and Misconceptions in Neural Sequence Labeling', by Jie Yang, Shuailong Liang and Yue Zhang

The lack of an award in the "Best challenge" category (for a paper that sets a new challenge) may reflect one of two things. On the one hand, reviewers and ACs may not have been on the look-out for this kind of excellence. On the other, there may not have been any papers with this particular strength at COLING 2018.

We also used the best paper awards to further our goal of promoting reproducibility. Specifically, we required that, in order to be eligible for one of the above awards, any code/resources associated with the research reported be publicly available by camera ready time. This encouraged all authors (not just those of nominated papers) to be sure their code/resources were available.

A team effort

In total, we relied upon and COLING was excellently supported by 76 area chairs, 1029 reviewers, and 11 best paper committee members, all of whom we thank profusely for an excellent iteration of the International Conference on Computational Linguistics.

Emily M. Bender (University of Washington)
Leon Derczynski (IT University of Copenhagen)

Choi, Joachim Bingel, Joakim Nivre, Jodi Schneider, Joel Tetreault, Joern Wuebker, Johan Bos, Johann Petrak, Johanna Monti, Johannes Bjerva, Johannes Welbl, John Chen, John Hale, John Wieting, John Philip McCrae, Jojo Sze-Meng Wong, Jonathan Brennan, Jongbok Kim, Joonsuk Park, Jordi Atserias Batalla, Jorge Gracia, Josef Ruppenhofer, Joseph Le Roux, Josiah Wang, Joyce Chai, Juan Soler, Judith Eckle-Kohler, Juergen Trouvain, Julian Hough, Julian Michael, Julian Richardson, Julie Weeds, Jun Araki, Jun Zhao, Junqiu Wei, Junwei Bao, Junyi Jessy Li, Jörg Tiedemann, Jürgen Wedekind, Kai Zhao, Kalika Bali, Kalina Bontcheva, Kalliopi Zervanou, Kallirroi Georgila, Karin Verspoor, Karl Pichotta, Karl Stratos, Karën Fort, Kasia Hitczenko, Katerina Frantzi, Katharina Kann, Kathy Lee, Katrin Erk, Katsuhito Sudoh, Kazunori Komatani, Keelan Evanini, Keh-Yih Su, Keisuke Sakaguchi, Keith VanderLinden, Kellie Webster, Kemal Oflazer, Kenji Sagae, Kenneth Church, Kenneth Heafield, Kentaro Inui, Kentaro Torisawa, Kevin Cohen, Kevin Duh, Kevin Scannell,

Kevin Seppi, Kevin Small, Khalid Al Khatib, Kilian Evang, Kim Anh Nguyen, Kiril Simov, Kirk Roberts, Koji Mineshima, Koji Murakami, Koldo Gojenola, Kris Cao, Kristen Howell, Krister Lindén, Kristina Striegnitz, Kuang-hua Chen, Kumiko Tanaka-Ishii, Kun Xu, L. Alfonso Urena Lopez, Lan Du, Lane Schwartz, Larry Moss, Laurel Perkins, Laurent Besacier, Laurette Pretorius, Lawrence Cavedon, Leanne Rolston, Lei He, Lei Zhang, Leila Kosseim, Lemao Liu, Lena Jäger, Leon Bergen, Leonel Figueiredo de Alencar, Li Dong, Liang-Chih Yu, Lianhui Qin, Libby Barak, Lifeng Jin, Lili Mou, Liling Tan, Lin Yang, Linfeng Song, Lionel Nicolas, Long Duong, Long Zhou, Lonneke van der Plas, Lori Levin, Luciana Benotti, Lucy Vanderwende, Lucy H. Lin, Luheng He, Luis Espinosa Anke, Lun-Wei Ku, Maciej Piasecki, Maja Miličević, Makoto Miwa, Malvina Nissim, Mamoru Komachi, Manex Agirrezabal, Manfred Sailer, Manfred Stede, Manikandan R, Mans Hulden, Manuel Ciosici, Maofu Liu, Marcel Bollmann, Marcelo Luis Errecalde, Marco Basaldella, Marco Idiart, Marco Turchi, Mareike Hartmann, Marek Rei, Maria Barrett, Maria Liakata, Maria Nadejde, Mariana Neves, Marianna Apidianaki, Mariano Felice, Marie Candito, Marie-Catherine de Marneffe, Marie-Francine Moens, Marina Sokolova, Marine Carpuat, Marion Weller-Di Marco, Mark Carman, Mark Dras, Mark Finlayson, Mark Fishel, Mark Greenwood, Mark Hasegawa-Johnson, Mark Last, Mark Sammons, Mark Stevenson, Mark-Jan Nederhof, Markus Egg, Markus Freitag, Markus Saers, Markus Zopf, Marta Recasens, Marta Tatu, Marta R. Costa-jussà, Marten Postma, Marten van Schijndel, Martha Palmer, Martin Benjamin, Martin Potthast, Martin Reynaert, Martin Riedl, Marzieh Saeidi, Masaaki Nagata, Masoud Jalili Sabet, Massimo Poesio, Mathieu Roche, Matko Bošnjak, Matt Gardner, Matteo Negri, Matthew Purver, Matthias Gallé, Matthias Hartung, Matthias Huck, Matthieu Constant, Maud Ehrmann, Mauro Cettolo, Max Kisselew, Maxwell Forbes, Maya Ramanath, Mayank Singh, Md Arafat Sultan, Md Shad Akhtar, Meishan Zhang, Meliha Yetisgen, Memduh Gokirmak, Menno van Zaanen, Meriem Beloucif, Michael Becker, Michael Denkowski, Michael Elhadad, Michael Maxwell, Michael Roth, Michael Wiegand, Michael Zock, Michael Wayne Goodman, Michael Yoshitaka Erlewine, Michal Lukasik, Michel Gagnon, Michel Simard, Mihaela Vela, Mike Tian-Jian Jiang, Mikhail Kozhevnikov, Milan Dojchinovski, Milica Gasic, Miloslav Konopik, Miloš Stanojević, Min-Yen Kan, Min-Yuh Day, Mingbo Ma, Mingxuan Wang, Minjoon Seo, Minlie Huang, Mireia Farrús, Miriam R L Petruck, Miryam de Lhoneux, Mo Yu, Mohamed Yahya, Mohammad Ebrahimi, Mohammad Shahed Sorower, Mohammad Taher Pilehvar, Mohit Bansal, Mohsen Mesgar, Monica Dominguez, Monojit Choudhury, Montserrat Marimon, Moreno Coco, Morgan Sonderegger, Muntsa Padró, Na-Rae Han, Nadir Durrani, Nancy Ide, Nanyun Peng, Naoaki Okazaki, Naoki Yoshinaga, Naomi Tachikawa Shapiro, Naoya Inoue, Nasredine Semmar, Nazneen Fatema Rajani, Ni Lao, Nicoletta Calzolari, Nikhil Londhe, Nikola Ljubešić, Nikolaos Aletras, Nils Reiter, Nina Dethlefs, Nina Zhou, Niranjan Balasubramanian, Nitish Gupta, Niyati Chhaya, Nizar Habash, Octavia-Maria Şulea, Oier Lopez de Lacalle, Oladimeji Farri, Olga Uryupina, Olga Zamaraeva, Oliver Hellwig, Olivier Ferret, Omer Levy, Omri Abend, Ondřej Dušek, Or Biran, Oren Melamud, Orphee De Clercq, Oscar Täckström, Ozan Arkan Can, Pablo Gamallo, Pamela Shapiro, Paolo Rosso, Paramita Mirza, Parisa Kordjamshidi, Pascual Martínez-Gómez, Pasquale Minervini, Patrick Ehlen, Patrick Littell, Patrick Paroubek, Paul Buitelaar, Paul Piwek, Paul Reisert, Pavel Braslavski, Pavel Logacev, Pawan Goyal, Pei-Hao Su, Penny Labropoulou, Peter Dirix, Peter Jansen, Peter Ljunglöf, Petya Osenova, Philipp Cimiano, Philipp Koehn, Philippe Muller, Philippe Thomas, Phivos Mylonas, Phoebe Mulcaire, Phong Le, Piek Vossen, Pierre Lison, Pierre Nugues, Pierre Zweigenbaum, Ping Jian, Pontus Stenetorp, Pranava Swaroop Madhyastha, Prerana Singhal, Preslav Nakov, Prokopis Prokopidis, Pushpak Bhattacharyya, Qi Zhang, Qian Chen, Qian Yang, Qin Lu, Qinlan Shen, Quan Liu, Qun Liu, Quynh Ngoc Thi Do, Rabih Zbib, Rachael Tatman, Rachele Sprugnoli, Radu Florian, Rafael E. Banchs, Raffaella Bernardi, Raghav Goyal, Rami Al-Rfou, Ramy Eskander, Ramón Astudillo, Raphael Rubino, Raquel Fernández, Raquel Martínez, Renfen Hu, Richard Eckart de Castilho, Richard Evans, Richard Futrell, Richard Tzong-Han Tsai, Richong Zhang, Rik Koncel-Kedziorski, Rob Malouf, Rob Voigt, Robert Daland, Robert Frank, Robert Östling, Roberto Basili, Robin Cooper, Rodrigo Wilkens, Roland Kuhn, Roland

Roller, Ron Artstein, Rong Xiang, Roser Morante, Roxana Girju, Roy Bar-Haim, Rui Chaves, Rui Wang, Ruifeng Xu, Ruihong Huang, Ruiji Fu, Ruobing Xie, Ruochen Xu, Ryan Cotterell, Ryan Georgi, Ryu Iida, Ryuichiro Higashinaka, Sabine Bergler, Sadao Kurohashi, Saif Mohammad, Salah Ait-Mokhtar, Salvatore Romeo, Sameer Singh, Samuel Bowman, Sanda Harabagiu, Sander Wubben, Sandesh Swamy, Sandra Kübler, Sang Phan, Sanghoun Song, Sanja Štajner, Santanu Pal, Sapna Negi, Sara Stymne, Sara Tonelli, Sascha Rothe, Satoshi Sekine, Sean MacAvaney, Sebastian Krause, Sebastian Nordhoff, Sebastian Schuster, Seong-Bae Park, Sergio Jimenez, Sergiu Nisioi, Shachar Mirkin, Shalom Lappin, Shammur Absar Chowdhury, Shaolei Wang, Shaonan Wang, Shashi Narayan, Sheila Castilho, Shervin Malmasi, Shih-Hung Wu, Shizhu He, Sho Hoshino, Shoaib Jameel, Shuhan Wang, Shujian Huang, Shuohang Wang, Siddharth Patwardhan, Silvio Cordeiro, Simon Baker, Simon Keizer, Simon Kocbek, Simon Mille, Simone Paolo Ponzetto, Sina Zarrieß, Siqi Bao, Siva Reddy, Sorcha Gilroy, Soujanya Poria, Stanislau Semeniuta, Stasinos Konstantopoulos, Stefania Degaetano-Ortlieb, Stefano Menini, Steffen Eger, Stella Frank, Stephen McGregor, Stephen Wan, Stergios Chatzikyriakidis, Stergos Afantenos, Steven Moran, Suchet Chachra, Sudha Rao, Sudip Kumar Naskar, Sujan Perera, Sujay Kumar Jauhar, Sumeet Agarwal, Sunayana Sitaram, Suncong Zheng, Sunghwan Mac Kim, Susanne Burger, Suzan Verberne, Svetla Koeva, Svetlana Stoyanchev, Svitlana Volkova, Swabha Swayamdipta, Tadashi Nomoto, Taesung Lee, Takenobu Tokunaga, Takuya Matsuzaki, Tanel Alumäe, Tanja Samardzic, Taraka Rama, Tatjana Scheffler, Taylor Mahler, Ted Pedersen, Tejaswini Deoskar, Teresa Lynn, Tetsuji Nakagawa, Thamar Solorio, Thiago Pardo, Thien Huu Nguyen, Thierry Declerck, Thierry Hamon, Thomas Francois, Thomas Schatz, Thomas Wasow, Tim Hunter, Tim Van de Cruys, Timo Baumann, Timothy Baldwin, Timothy Dozat, Timothy Miller, Ting Liu, Ting Qian, Tobias Horsmann, Tommaso Pasini, Tomáš Brychcín, Tomáš Hercig, Torsten Zesch, Tracy Holloway King, Tristan Miller, Tsung-Hsien Wen, Tyler Baldwin, Valeria dePaiva, Valerio Basile, Vasileios Lampos, Veno Pachovski, Verena Lyding, Verónica Pérez-Rosas, Victoria Yaneva, Victoria Zayats, Viet-An Nguyen, Vikramjit Mitra, Vincent Claveau, Vincent Ng, Vincent Vandeghinste, Vinodkumar Prabhakaran, Virach Sornlertlamvanich, Vishrawas Gopalakrishnan, Vivek Datla, Vivek Kulkarni, Vivek Srikumar, Vivek Kumar Rangarajan Sridhar, Viviane Moreira, Volkan Cirik, Vuk Batanović, Wei Li, Wei Lu, Wei Song, Wei-Fan Chen, Wei-Ning Hsu, Weinan Zhang, Weiwei Sun, Weiwei Yang, Wen-wai Yim, Wencan Luo, Wenduan Xu, Wenjie Li, Wenliang Chen, Wenpeng Yin, William Schuler, William Yang Wang, Wolfgang Maier, Woodley Packard, Wuwei Lan, Xavier Tannier, Xi Victoria Lin, Xian-Ling Mao, Xianpei Han, Xiao Ling, Xiao Sun, Xiaochang Peng, Xiaodong Liu, Xiaofeng He, Xiaoman Pan, Ximing Li, Xing Wang, Xingyi Song, Xiujun Li, Xu Sun, Xuanjing Huang, Yaakov HaCohen-Kerner, Yadollah Yaghoobzadeh, Yael Netzer, Yan Shao, Yan Song, Yang Liu, Yangfeng Ji, Yankai Lin, Yannis Korkontzelos, Yannis Papanikolaou, Yanqing He, Yanran Li, Yansong Feng, Ye Tian, Yi Luan, Yimai Fang, Yiming Cui, Yiping Song, Yogarshi Vyas, Yonatan Belinkov, Yong Cheng, Yoong Keok Lee, Yoshihiko Hayashi, Yoshinori Sagisaka, Young-Suk Lee, Yu Wu, Yu Zhang, Yuan Cao, Yuan Ling, Yuanfeng Song, Yubo Chen, Yufan Guo, Yufang Hou, Yugo Murawaki, Yuhang Guo, Yuhao Zhang, Yuichiroh Matsubayashi, Yulan He, Yulia Tsvetkov, Yunfei Long, Yung-Chun Chang, Yusuke Oda, Yuta Tsuboi, Yutaka Sasaki, Yuval Pinter, Yvette Graham, Yvonne Adesam, Zdenka Uresova, Zeerak Waseem, Zhao Yan, Zhe Zhao, Zhengxian Gong, Zhiguo Wang, Zhiting Hu, Zhiyang Su, Zhiyang Teng, Zhiyuan Chen, Zhongqing Wang, Zhongyu Wei, Zhunchen Luo, Ziqiang Cao, Zongyang Ma, Çağrı Çöltekin, and Özlem Çetinoğlu

Outstanding Paper Mentors

Kevin Cohen, Carla Parra Escartín, David Mimno, Emily Morgan, Irina Temnikova, and Jennifer Williams

Paper Mentors

Aditya Joshi, Ahmed Abdelali, Alexandra Balahur, Alexandre Rademaker, Arkaitz Zubiaga, Arpit

Mittal, Carla Parra Escartín, Christian Retore, Christina Bergmann, Christos Christodoulopoulos, Constantin Orasan, Daniel Cer, David Chiang, David Mimno, Devamanyu Hazarika, Donia Scott, Ekaterina Vylomova, Emily Morgan, Francis Tyers, Guy Emerson, Helen O'Horan, Heng Yu, Hiram Calvo, Irina Temnikova, Ivan Vladimir Meza Ruiz, Jen-Tzung Chien, Jennifer Williams, Junwei Zhou, Kenneth Church, Kevin Cohen, Lei Zhang, Lili Mou, Linfeng Song, Luis Espinosa Anke, Marek Rei, Mariana Neves, Milan Dojchinovski, Mireia Farrús, Octavia-Maria Şulea, Parisa Kordjamshidi, Prerana Singhal, Ramón Astudillo, Raphael Rubino, Rik Koncel-Kedziorski, Rui Wang, Shervin Malmasi, Siddharth Patwardhan, Taraka Rama, Tracy Holloway King, Victoria Yaneva, Xiaofeng He, Yuan Ling, and Zhongqing Wang

Invited Speakers

Fabiola Henri, University of Kentucky, USA
Hannah Rohde, University of Edinburgh, UK
James Pustejovsky, Brandeis University, USA
Min-Yen Kan, National University of Singapore, Singapore

Table of Contents

Conference Program

Tuesday 21st August

9:00–9:30 Opening ceremony

9:30–10:30 Invited talk: James Pustejovsky

10:30–11:00 Refreshment break

11:00–12:20 Session 1-1-a: Co-reference

A New Approach to Animacy Detection
Labiba Jahan, Geeticka Chauhan and Mark Finlayson

Zero Pronoun Resolution with Attention-based Neural Network
Qingyu Yin, Yu Zhang, Weinan Zhang, Ting Liu and William Yang Wang

They Exist! Introducing Plural Mentions to Coreference Resolution and Entity Linking
Ethan Zhou and Jinho D. Choi

Triad-based Neural Network for Coreference Resolution
Yuanliang Meng and Anna Rumshisky

Tuesday 21st August (continued)

11:00–12:20 Session 1-1-b: Low-resource languages

Unsupervised Morphology Learning with Statistical Paradigms
Hongzhi Xu, Mitchell Marcus, Charles Yang and Lyle Ungar

Challenges of language technologies for the indigenous languages of the Americas
Manuel Mager, Ximena Gutierrez-Vasques, Gerardo Sierra and Ivan Meza-Ruiz

Low-resource Cross-lingual Event Type Detection via Distant Supervision with Minimal Effort
Aldrian Obaja Muis, Naoki Otani, Nidhi Vyas, Ruochen Xu, Yiming Yang, Teruko Mitamura and Eduard Hovy

Neural Transition-based String Transduction for Limited-Resource Setting in Morphology
Peter Makarov and Simon Clematide

11:00–12:20 Session 1-1-c: Parsing

Distance-Free Modeling of Multi-Predicate Interactions in End-to-End Japanese Predicate-Argument Structure Analysis
Yuichiroh Matsubayashi and Kentaro Inui

Sprucing up the trees – Error detection in treebanks
Ines Rehbein and Josef Ruppenhofer

Two Local Models for Neural Constituent Parsing
Zhiyang Teng and Yue Zhang

RNN Simulations of Grammaticality Judgments on Long-distance Dependencies
Shammur Absar Chowdhury and Roberto Zamparelli

Tuesday 21st August (continued)

11:00–12:20 Session 1-1-posters: Application, extraction and knowledge

How Predictable is Your State? Leveraging Lexical and Contextual Information for Predicting Legislative Floor Action at the State Level
Vladimir Eidelman, Anastassia Kornilova and Daniel Argyle

Learning to Search in Long Documents Using Document Structure
Mor Geva and Jonathan Berant

Incorporating Image Matching Into Knowledge Acquisition for Event-Oriented Relation Recognition
Yu Hong, Yang Xu, Huibin Ruan, Bowei Zou, Jianmin Yao and Guodong Zhou

Representation Learning of Entities and Documents from Knowledge Base Descriptions
Ikuya Yamada, Hiroyuki Shindo and Yoshiyasu Takefuji

Simple Neologism Based Domain Independent Models to Predict Year of Authorship
Vivek Kulkarni, Yingtao Tian, Parth Dandiwala and Steve Skiena

Neural Math Word Problem Solver with Reinforcement Learning
Danqing Huang, Jing Liu, Chin-Yew Lin and Jian Yin

Personalizing Lexical Simplification
John Lee and Chak Yan Yeung

From Text to Lexicon: Bridging the Gap between Word Embeddings and Lexical Resources
Ilia Kuznetsov and Iryna Gurevych

Lexi: A tool for adaptive, personalized text simplification
Joachim Bingel, Gustavo Paetzold and Anders Søgaard

Identifying Emergent Research Trends by Key Authors and Phrases
Shenhao Jiang, Animesh Prasad, Min-Yen Kan and Kazunari Sugiyama

Embedding WordNet Knowledge for Textual Entailment
Yunshi Lan and Jing Jiang

Tuesday 21st August (continued)

Attributed and Predictive Entity Embedding for Fine-Grained Entity Typing in Knowledge Bases
Hailong Jin, Lei Hou, Juanzi Li and Tiansi Dong

Joint Learning from Labeled and Unlabeled Data for Information Retrieval
Bo Li, Ping Cheng and Le Jia

Modeling the Readability of German Targeting Adults and Children: An empirically broad analysis and its cross-corpus validation
Zarah Weiß and Detmar Meurers

Automatic Assessment of Conceptual Text Complexity Using Knowledge Graphs
Sanja Štajner and Ioana Hulpus

Par4Sim – Adaptive Paraphrasing for Text Simplification
Seid Muhie Yimam and Chris Biemann

Topic or Style? Exploring the Most Useful Features for Authorship Attribution
Yunita Sari, Mark Stevenson and Andreas Vlachos

A Deep Dive into Word Sense Disambiguation with LSTM
Minh Le, Marten Postma, Jacopo Urbani and Piek Vossen

Enriching Word Embeddings with Domain Knowledge for Readability Assessment
Zhiwei Jiang, Qing Gu, Yafeng Yin and Daoxu Chen

WikiRef: Wikilinks as a route to recommending appropriate references for scientific Wikipedia pages
Abhik Jana, Pranjal Kanojiya, Pawan Goyal and Animesh Mukherjee

Authorship Identification for Literary Book Recommendations
Haifa Alharthi, Diana Inkpen and Stan Szpakowicz

A Nontrivial Sentence Corpus for the Task of Sentence Readability Assessment in Portuguese
Sidney Evaldo Leal, Magali Sanches Duran and Sandra Maria Aluísio

Adopting the Word-Pair-Dependency-Triplets with Individual Comparison for Natural Language Inference
Qianlong Du, Chengqing Zong and Keh-Yih Su

Cooperative Denoising for Distantly Supervised Relation Extraction
Kai Lei, Daoyuan Chen, Yaliang Li, Nan Du, Min Yang, Wei Fan and Ying Shen

Adversarial Feature Adaptation for Cross-lingual Relation Classification
Bowei Zou, Zengzhuang Xu, Yu Hong and Guodong Zhou

One-shot Learning for Question-Answering in Gaokao History Challenge
Zhuosheng Zhang and Hai Zhao

Dynamic Multi-Level Multi-Task Learning for Sentence Simplification
Han Guo, Ramakanth Pasunuru and Mohit Bansal

Interpretation of Implicit Conditions in Database Search Dialogues
Shunya Fukunaga, Hitoshi Nishikawa, Takenobu Tokunaga, Hikaru Yokono and Tetsuro Takahashi

Few-Shot Charge Prediction with Discriminative Legal Attributes
Zikun Hu, Xiang Li, Cunchao Tu, Zhiyuan Liu and Maosong Sun

Can Taxonomy Help? Improving Semantic Question Matching using Question Taxonomy
Deepak Gupta, Rajkumar Pujari, Asif Ekbal, Pushpak Bhattacharyya, Anutosh Maitra, Tom Jain and Shubhashis Sengupta

Natural Language Interface for Databases Using a Dual-Encoder Model
Ionel Alexandru Hosu, Radu Cristian Alexandru Iacob, Florin Brad, Stefan Ruseti and Traian Rebedea

Tuesday 21st August (continued)

12:20–13:50 Lunch

13:50–15:50 Session 1-2-a: Discourse relations

Employing Text Matching Network to Recognise Nuclearity in Chinese Discourse
Sheng Xu, Peifeng Li, Guodong Zhou and Qiaoming Zhu

Joint Modeling of Structure Identification and Nuclearity Recognition in Macro Chinese Discourse Treebank
Xiaomin Chu, Feng Jiang, Yi Zhou, Guodong Zhou and Qiaoming Zhu

Implicit Discourse Relation Recognition using Neural Tensor Network with Interactive Attention and Sparse Learning
Fengyu Guo, Ruifang He, Di Jin, Jianwu Dang, Longbiao Wang and Xiangang Li

Transition-based Neural RST Parsing with Implicit Syntax Features
Nan Yu, Meishan Zhang and Guohong Fu

Deep Enhanced Representation for Implicit Discourse Relation Recognition
Hongxiao Bai and Hai Zhao

A Knowledge-Augmented Neural Network Model for Implicit Discourse Relation Classification
Yudai Kishimoto, Yugo Murawaki and Sadao Kurohashi

Tuesday 21st August (continued)

13:50–15:50 Session 1-2-b: Machine translation

Modeling Coherence for Neural Machine Translation with Dynamic and Topic Caches
Shaohui Kuang, Deyi Xiong, Weihua Luo and Guodong Zhou

Fusing Recency into Neural Machine Translation with an Inter-Sentence Gate Model
Shaohui Kuang and Deyi Xiong

Improving Neural Machine Translation by Incorporating Hierarchical Subword Features
Makoto Morishita, Jun Suzuki and Masaaki Nagata

Design Challenges in Named Entity Transliteration
Yuval Merhav and Stephen Ash

A Comparison of Transformer and Recurrent Neural Networks on Multilingual Neural Machine Translation
Surafel Melaku Lakew, Mauro Cettolo and Marcello Federico

On Adversarial Examples for Character-Level Neural Machine Translation
Javid Ebrahimi, Daniel Lowd and Dejing Dou

13:50–15:50 Session 1-2-c: Named entities

Systematic Study of Long Tail Phenomena in Entity Linking
Filip Ilievski, Piek Vossen and Stefan Schlobach

Neural Collective Entity Linking
Yixin Cao, Lei Hou, Juanzi Li and Zhiyuan Liu

Exploiting Structure in Representation of Named Entities using Active Learning
Nikita Bhutani, Kun Qian, Yunyao Li, H. V. Jagadish, Mauricio Hernandez and Mitesh Vasa

A Practical Incremental Learning Framework For Sparse Entity Extraction
Hussein Al-Olimat, Steven Gustafson, Jason Mackay, Krishnaprasad Thirunarayan and Amit Sheth

Tuesday 21st August (continued)

An Empirical Study on Fine-Grained Named Entity Recognition
Khai Mai, Thai-Hoang Pham, Minh Trung Nguyen, Nguyen Tuan Duc, Danushka Bollegala, Ryohei Sasano and Satoshi Sekine

Does Higher Order LSTM Have Better Accuracy for Segmenting and Labeling Sequence Data?
Yi Zhang, Xu Sun, Shuming Ma, Yang Yang and Xuancheng Ren

13:50–15:50 Session 1-2-posters: Sentiment, NLG, understanding

Ant Colony System for Multi-Document Summarization
Asma Al-Saleh and Mohamed El Bachir Menai

Multi-task dialog act and sentiment recognition on Mastodon
Christophe Cerisara, Somayeh Jafaritazehjani, Adedayo Oluokun and Hoa T. Le

RuSentiment: An Enriched Sentiment Analysis Dataset for Social Media in Russian
Anna Rogers, Alexey Romanov, Anna Rumshisky, Svitlana Volkova, Mikhail Gronas and Alex Gribov

Self-Normalization Properties of Language Modeling
Jacob Goldberger and Oren Melamud

A Position-aware Bidirectional Attention Network for Aspect-level Sentiment Analysis
Shuqin Gu, Lipeng Zhang, Yuexian Hou and Yin Song

Dynamic Feature Selection with Attention in Incremental Parsing
Ryosuke Kohita, Hiroshi Noji and Yuji Matsumoto

Vocabulary Tailored Summary Generation
Kundan Krishna, Aniket Murhekar, Saumitra Sharma and Balaji Vasan Srinivasan

Reading Comprehension with Graph-based Temporal-Casual Reasoning
Yawei Sun, Gong Cheng and Yuzhong Qu

Projecting Embeddings for Domain Adaption: Joint Modeling of Sentiment Analysis in Diverse Domains
Jeremy Barnes, Roman Klinger and Sabine Schulte im Walde

Tuesday 21st August (continued)

Cross-lingual Argumentation Mining: Machine Translation (and a bit of Projection) is All You Need!
Steffen Eger, Johannes Daxenberger, Christian Stab and Iryna Gurevych

HL-EncDec: A Hybrid-Level Encoder-Decoder for Neural Response Generation
Sixing Wu, Dawei Zhang, Ying Li, Xing Xie and Zhonghai Wu

Multi-Perspective Context Aggregation for Semi-supervised Cloze-style Reading Comprehension
Liang Wang, Sujian Li, Wei Zhao, Kewei Shen, Meng Sun, Ruoyu Jia and Jingming Liu

A Lexicon-Based Supervised Attention Model for Neural Sentiment Analysis
Yicheng Zou, Tao Gui, Qi Zhang and Xuanjing Huang

Open-Domain Event Detection using Distant Supervision
Jun Araki and Teruko Mitamura

Semi-Supervised Lexicon Learning for Wide-Coverage Semantic Parsing
Bo Chen, Bo An, Le Sun and Xianpei Han

Summarization Evaluation in the Absence of Human Model Summaries Using the Compositionality of Word Embeddings
Elaheh ShafieiBavani, Mohammad Ebrahimi, Raymond Wong and Fang Chen

A review of Spanish corpora annotated with negation
Salud María Jiménez-Zafra, Roser Morante, Maite Martin and L. Alfonso Urena Lopez

Document-level Multi-aspect Sentiment Classification by Jointly Modeling Users, Aspects, and Overall Ratings
Junjie Li, Haitong Yang and Chengqing Zong

Leveraging Meta-Embeddings for Bilingual Lexicon Extraction from Specialized Comparable Corpora
Amir Hazem and Emmanuel Morin

Learning Emotion-enriched Word Representations
Ameeta Agrawal, Aijun An and Manos Papagelis

Evaluating the text quality, human likeness and tailoring component of PASS: A Dutch data-to-text system for soccer
Chris van der Lee, Bart Verduijn, Emiel Krahmer and Sander Wubben

Tuesday 21st August (continued)

Answerable or Not: Devising a Dataset for Extending Machine Reading Comprehension
Mao Nakanishi, Tetsunori Kobayashi and Yoshihiko Hayashi

Style Obfuscation by Invariance
Chris Emmery, Enrique Manjavacas Arevalo and Grzegorz Chrupała

Encoding Sentiment Information into Word Vectors for Sentiment Analysis
Zhe Ye, Fang Li and Timothy Baldwin

Multi-Task Neural Models for Translating Between Styles Within and Across Languages
Xing Niu, Sudha Rao and Marine Carpuat

Towards a Language for Natural Language Treebank Transductions
Carlos A. Prolo

Generating Reasonable and Diversified Story Ending Using Sequence to Sequence Model with Adversarial Training
Zhongyang Li, Xiao Ding and Ting Liu

Point Precisely: Towards Ensuring the Precision of Data in Generated Texts Using Delayed Copy Mechanism
Liunian Li and Xiaojun Wan

Enhancing General Sentiment Lexicons for Domain-Specific Use
Tim Kreutz and Walter Daelemans

An Operation Network for Abstractive Sentence Compression
Naitong Yu, Jie Zhang, Minlie Huang and Xiaoyan Zhu

Enhanced Aspect Level Sentiment Classification with Auxiliary Memory
Peisong Zhu and Tieyun Qian

Tuesday 21st August (continued)

15:50–16:20 Refreshment break

16:20–18:00 Session 1-3-a: Aspect-based sentiment, Ethics

Author Profiling for Abuse Detection
Pushkar Mishra, Marco Del Tredici, Helen Yannakoudakis and Ekaterina Shutova

Automated Scoring: Beyond Natural Language Processing
Nitin Madnani and Aoife Cahill

Aspect and Sentiment Aware Abstractive Review Summarization
Min Yang, Qiang Qu, Ying Shen, Qiao Liu, Wei Zhao and Jia Zhu

Effective Attention Modeling for Aspect-Level Sentiment Classification
Ruidan He, Wee Sun Lee, Hwee Tou Ng and Daniel Dahlmeier

Bringing replication and reproduction together with generalisability in NLP: Three reproduction studies for Target Dependent Sentiment Analysis
Andrew Moore and Paul Rayson

16:20–18:00 Session 1-3-b: Relation extraction, Summarization

Multilevel Heuristics for Rationale-Based Entity Relation Classification in Sentences
Shiou Tian Hsu, Mandar Chaudhary and Nagiza Samatova

Adversarial Multi-lingual Neural Relation Extraction
Xiaozhi Wang, Xu Han, Yankai Lin, Zhiyuan Liu and Maosong Sun

Neural Relation Classification with Text Descriptions
Feiliang Ren, Di Zhou, Zhihui Liu, Yongcheng Li, Rongsheng Zhao, Yongkang Liu and Xiaobo Liang

Abstract Meaning Representation for Multi-Document Summarization
Kexin Liao, Logan Lebanoff and Fei Liu

Abstractive Unsupervised Multi-Document Summarization using Paraphrastic Sentence Fusion
Mir Tafseer Nayeem, Tanvir Ahmed Fuad and Yllias Chali

16:20–18:00 Session 1-3-c: Dialogue systems

Adversarial Domain Adaptation for Variational Neural Language Generation in Dialogue Systems
Van-Khanh Tran and Le-Minh Nguyen

Ask No More: Deciding when to guess in referential visual dialogue
Ravi Shekhar, Tim Baumgärtner, Aashish Venkatesh, Elia Bruni, Raffaella Bernardi and Raquel Fernández

Sequence-to-Sequence Data Augmentation for Dialogue Language Understanding
Yutai Hou, Yijia Liu, Wanxiang Che and Ting Liu

Dialogue-act-driven Conversation Model : An Experimental Study
Harshit Kumar, Arvind Agarwal and Sachindra Joshi

Structured Dialogue Policy with Graph Neural Networks
Lu Chen, Bowen Tan, Sishan Long and Kai Yu

16:20–18:00 Session 1-3-posters: Translation, Variation

JTAV: Jointly Learning Social Media Content Representation by Fusing Textual, Acoustic, and Visual Features
Hongru Liang, Haozheng Wang, Jun Wang, Shaodi You, Zhe Sun, Jin-Mao Wei and Zhenglu Yang

MEMD: A Diversity-Promoting Learning Framework for Short-Text Conversation
Meng Zou, Xihan Li, Haokun Liu and Zhihong Deng

Refining Source Representations with Relation Networks for Neural Machine Translation
Wen Zhang, Jiawei Hu, Yang Feng and Qun Liu

A Survey of Domain Adaptation for Neural Machine Translation
Chenhui Chu and Rui Wang

An Evaluation of Neural Machine Translation Models on Historical Spelling Normalization
Gongbo Tang, Fabienne Cap, Eva Pettersson and Joakim Nivre

Fine-Grained Arabic Dialect Identification
Mohammad Salameh and Houda Bouamor

Who Feels What and Why? Annotation of a Literature Corpus with Semantic Roles of Emotions
Evgeny Kim and Roman Klinger

Local String Transduction as Sequence Labeling
Joana Ribeiro, Shashi Narayan, Shay B. Cohen and Xavier Carreras

Deep Neural Networks at the Service of Multilingual Parallel Sentence Extraction
Ahmad Aghaebrahimian

Diachronic word embeddings and semantic shifts: a survey
Andrey Kutuzov, Lilja Øvrelid, Terrence Szymanski and Erik Velldal

Interaction-Aware Topic Model for Microblog Conversations through Network Embedding and User Attention
Ruifang He, Xuefei Zhang, Di Jin, Longbiao Wang, Jianwu Dang and Xiangang Li

Cross-media User Profiling with Joint Textual and Social User Embedding
Jingjing Wang, Shoushan Li, Mingqi Jiang, Hanqian Wu and Guodong Zhou

Incorporating Syntactic Uncertainty in Neural Machine Translation with a Forest-to-Sequence Model
Poorya Zaremoodi and Gholamreza Haffari

Ensure the Correctness of the Summary: Incorporate Entailment Knowledge into Abstractive Sentence Summarization
Haoran Li, Junnan Zhu, Jiajun Zhang and Chengqing Zong

Extracting Parallel Sentences with Bidirectional Recurrent Neural Networks to Improve Machine Translation
Francis Grégoire and Philippe Langlais

Fast and Accurate Reordering with ITG Transition RNN
Hao Zhang, Axel Ng and Richard Sproat

Tuesday 21st August (continued)

Neural Machine Translation with Decoding History Enhanced Attention
Mingxuan Wang, Jun Xie, Zhixing Tan, Jinsong Su, Deyi Xiong and Chao Bian

Transfer Learning for a Letter-Ngrams to Word Decoder in the Context of Historical Handwriting Recognition with Scarce Resources
Adeline Granet, Emmanuel Morin, Harold Mouchère, Solen Quiniou and Christian Viard-Gaudin

SMHD: a Large-Scale Resource for Exploring Online Language Usage for Multiple Mental Health Conditions
Arman Cohan, Bart Desmet, Andrew Yates, Luca Soldaini, Sean MacAvaney and Nazli Goharian

Crowdsourcing a Large Corpus of Clickbait on Twitter
Martin Potthast, Tim Gollub, Kristof Komlossy, Sebastian Schuster, Matti Wiegmann, Erika Patricia Garces Fernandez, Matthias Hagen and Benno Stein

Cross-lingual Knowledge Projection Using Machine Translation and Target-side Knowledge Base Completion
Naoki Otani, Hirokazu Kiyomaru, Daisuke Kawahara and Sadao Kurohashi

Assessing Quality Estimation Models for Sentence-Level Prediction
Hoang Cuong and Jia Xu

User-Level Race and Ethnicity Predictors from Twitter Text
Daniel Preoţiuc-Pietro and Lyle Ungar

Multi-Source Multi-Class Fake News Detection
Hamid Karimi, Proteek Roy, Sari Saba-Sadiya and Jiliang Tang

Killing Four Birds with Two Stones: Multi-Task Learning for Non-Literal Language Detection
Erik-Lân Do Dinh, Steffen Eger and Iryna Gurevych

Twitter corpus of Resource-Scarce Languages for Sentiment Analysis and Multilingual Emoji Prediction
Nurendra Choudhary, Rajat Singh, Vijjini Anvesh Rao and Manish Shrivastava

Wednesday 22nd August

09:00–10:00 Invited talk: Fabiola Henri

10:00–10:30 Refreshment break

10:30–11:50 Session 2-1-a: Language change, Historical linguistics

Towards identifying the optimal datasize for lexically-based Bayesian inference of linguistic phylogenies
Taraka Rama and Søren Wichmann

The Road to Success: Assessing the Fate of Linguistic Innovations in Online Communities
Marco Del Tredici and Raquel Fernández

Ab Initio: Automatic Latin Proto-word Reconstruction
Alina Maria Ciobanu and Liviu P. Dinu

A Computational Model for the Linguistic Notion of Morphological Paradigm
Miikka Silfverberg, Ling Liu and Mans Hulden

10:30–11:50 Session 2-1-b: Embedding creation

Relation Induction in Word Embeddings Revisited
Zied Bouraoui, Shoaib Jameel and Steven Schockaert

Contextual String Embeddings for Sequence Labeling
Alan Akbik, Duncan Blythe and Roland Vollgraf

Learning Word Meta-Embeddings by Autoencoding
Danushka Bollegala and Cong Bao

GenSense: A Generalized Sense Retrofitting Model
Yang-Yin Lee, Ting-Yu Yen, Hen-Hsen Huang, Yow-Ting Shiue and Hsin-Hsi Chen

Wednesday 22nd August (continued)

10:30–11:50 Session 2-1-c: ML methods

Variational Attention for Sequence-to-Sequence Models
Hareesh Bahuleyan, Lili Mou, Olga Vechtomova and Pascal Poupart

A New Concept of Deep Reinforcement Learning based Augmented General Tagging System
Yu Wang, Abhishek Patel and Hongxia Jin

Learning from Measurements in Crowdsourcing Models: Inferring Ground Truth from Diverse Annotation Types
Paul Felt, Eric Ringger, Jordan Boyd-Graber and Kevin Seppi

Reproducing and Regularizing the SCRN Model
Olzhas Kabdolov, Zhenisbek Assylbekov and Rustem Takhanov

12:00 Lunch and excursion

Thursday 23rd August

09:00–10:00 Invited talk: Hannah Rohde

10:00–10:30 Refreshment break

Thursday 23rd August (continued)

10:30–12:10 Session 3-1-a: Generation

Structure-Infused Copy Mechanisms for Abstractive Summarization
Kaiqiang Song, Lin Zhao and Fei Liu

Measuring the Diversity of Automatic Image Descriptions
Emiel van Miltenburg, Desmond Elliott and Piek Vossen

Extractive Headline Generation Based on Learning to Rank for Community Question Answering
Tatsuru Higurashi, Hayato Kobayashi, Takeshi Masuyama and Kazuma Murao

A Multi-Attention based Neural Network with External Knowledge for Story Ending Predicting Task
Qian Li, Ziwei Li, Jin-Mao Wei, Yanhui Gu, Adam Jatowt and Zhenglu Yang

A Reinforcement Learning Framework for Natural Question Generation using Bi-discriminators
Zhihao Fan, Zhongyu Wei, Siyuan Wang, Yang Liu and Xuanjing Huang

10:30–12:10 Session 3-1-b: Embedding creation

Embedding Words as Distributions with a Bayesian Skip-gram Model
Arthur Bražinskas, Serhii Havrylov and Ivan Titov

Assessing Composition in Sentence Vector Representations
Allyson Ettinger, Ahmed Elgohary, Colin Phillips and Philip Resnik

Subword-augmented Embedding for Cloze Reading Comprehension
Zhuosheng Zhang, Yafang Huang and Hai Zhao

Enhancing Sentence Embedding with Generalized Pooling
Qian Chen, Zhen-Hua Ling and Xiaodan Zhu

Treat us like the sequences we are: Prepositional Paraphrasing of Noun Compounds using LSTM
Girishkumar Ponkiya, Kevin Patel, Pushpak Bhattacharyya and Girish Palshikar

Thursday 23rd August (continued)

10:30–12:10 Session 3-1-c: Humor, rumor, sarcasm and spam

CASCADE: Contextual Sarcasm Detection in Online Discussion Forums
Devamanyu Hazarika, Soujanya Poria, Sruthi Gorantla, Erik Cambria, Roger Zimmermann and Rada Mihalcea

Recognizing Humour using Word Associations and Humour Anchor Extraction
Andrew Cattle and Xiaojuan Ma

A Retrospective Analysis of the Fake News Challenge Stance-Detection Task
Andreas Hanselowski, Avinesh PVS, Benjamin Schiller, Felix Caspelherr, Debanjan Chaudhuri, Christian M. Meyer and Iryna Gurevych

Exploiting Syntactic Structures for Humor Recognition
Lizhen Liu, Donghai Zhang and Wei Song

An Attribute Enhanced Domain Adaptive Model for Cold-Start Spam Review Detection
Zhenni You, Tieyun Qian and Bing Liu

10:30–12:10 Session 3-1-posters: Entities, QA and classification

Robust Lexical Features for Improved Neural Network Named-Entity Recognition
Abbas Ghaddar and Phillippe Langlais

A Pseudo Label based Dataless Naive Bayes Algorithm for Text Classification with Seed Words
Ximing Li and Bo Yang

Visual Question Answering Dataset for Bilingual Image Understanding: A Study of Cross-Lingual Transfer Using Attention Maps
Nobuyuki Shimizu, Na Rong and Takashi Miyazaki

Style Detection for Free Verse Poetry from Text and Speech
Timo Baumann, Hussein Hussein and Burkhard Meyer-Sickendiek

A Neural Question Answering Model Based on Semi-Structured Tables
Hao Wang, Xiaodong Zhang, Shuming Ma, Xu Sun, Houfeng Wang and Mengxiang Wang

Thursday 23rd August (continued)

LCQMC:A Large-scale Chinese Question Matching Corpus
Xin Liu, Qingcai Chen, Chong Deng, Huajun Zeng, Jing Chen, Dongfang Li and Buzhou Tang

Genre Identification and the Compositional Effect of Genre in Literature
Joseph Worsham and Jugal Kalita

Transfer Learning for Entity Recognition of Novel Classes
Juan Diego Rodriguez, Adam Caldwell and Alexander Liu

Location Name Extraction from Targeted Text Streams using Gazetteer-based Statistical Language Models
Hussein Al-Olimat, Krishnaprasad Thirunarayan, Valerie Shalin and Amit Sheth

The APVA-TURBO Approach To Question Answering in Knowledge Base
Yue Wang, Richong Zhang, Cheng Xu and Yongyi Mao

An Interpretable Reasoning Network for Multi-Relation Question Answering
Mantong Zhou, Minlie Huang and Xiaoyan Zhu

Task-oriented Word Embedding for Text Classification
Qian Liu, Heyan Huang, Yang Gao, Xiaochi Wei, Yuxin Tian and Luyang Liu

Adaptive Learning of Local Semantic and Global Structure Representations for Text Classification
Jianyu Zhao, Zhiqiang Zhan, Qichuan Yang, Yang Zhang, Changjian Hu, Zhensheng Li, Liuxin Zhang and Zhiqiang He

Lyrics Segmentation: Textual Macrostructure Detection using Convolutions
Michael Fell, Yaroslav Nechaev, Elena Cabrio and Fabien Gandon

Learning What to Share: Leaky Multi-Task Network for Text Classification
Liqiang Xiao, Honglun Zhang, Wenqing Chen, Yongkun Wang and Yaohui Jin

Towards an argumentative content search engine using weak supervision
Ran Levy, Ben Bogin, Shai Gretz, Ranit Aharonov and Noam Slonim

Improving Named Entity Recognition by Jointly Learning to Disambiguate Morphological Tags
Onur Gungor, Suzan Uskudarli and Tunga Gungor

Thursday 23rd August (continued)

Farewell Freebase: Migrating the SimpleQuestions Dataset to DBpedia
Michael Azmy, Peng Shi, Jimmy Lin and Ihab Ilyas

An Analysis of Annotated Corpora for Emotion Classification in Text
Laura Ana Maria Bostan and Roman Klinger

Investigating the Working of Text Classifiers
Devendra Sachan, Manzil Zaheer and Ruslan Salakhutdinov

A Review on Deep Learning Techniques Applied to Answer Selection
Tuan Manh Lai, Trung Bui and Sheng Li

A Survey on Recent Advances in Named Entity Recognition from Deep Learning models
Vikas Yadav and Steven Bethard

Distantly Supervised NER with Partial Annotation Learning and Reinforcement Learning
Yaosheng Yang, Wenliang Chen, Zhenghua Li, Zhengqiu He and Min Zhang

Joint Neural Entity Disambiguation with Output Space Search
Hamed Shahbazi, Xiaoli Fern, Reza Ghaeini, Chao Ma, Rasha Mohammad Obeidat and Prasad Tadepalli

Learning to Progressively Recognize New Named Entities with Sequence to Sequence Models
Lingzhen Chen and Alessandro Moschitti

Responding E-commerce Product Questions via Exploiting QA Collections and Reviews
Qian Yu, Wai Lam and Zihao Wang

Thursday 23rd August (continued)

12:10–13:40 Lunch

13:40–15:20 Session 3-2-a: Sentiment

Aff2Vec: Affect–Enriched Distributional Word Representations
Sopan Khosla, Niyati Chhaya and Kushal Chawla

Aspect-based summarization of pros and cons in unstructured product reviews
Florian Kunneman, Sander Wubben, Antal van den Bosch and Emiel Krahmer

Learning Sentiment Composition from Sentiment Lexicons
Orith Toledo-Ronen, Roy Bar-Haim, Alon Halfon, Charles Jochim, Amir Menczel, Ranit Aharonov and Noam Slonim

Representations and Architectures in Neural Sentiment Analysis for Morphologically Rich Languages: A Case Study from Modern Hebrew
Adam Amram, Anat Ben-David and Reut Tsarfaty

Scoring and Classifying Implicit Positive Interpretations: A Challenge of Class Imbalance
Chantal van Son, Roser Morante, Lora Aroyo and Piek Vossen

13:40–15:20 Session 3-2-b: IE

Exploratory Neural Relation Classification for Domain Knowledge Acquisition
Yan Fan, Chengyu Wang and Xiaofeng He

Who is Killed by Police: Introducing Supervised Attention for Hierarchical LSTMs
Minh Nguyen and Thien Nguyen

Open Information Extraction from Conjunctive Sentences
Swarnadeep Saha and Mausam -

Graphene: Semantically-Linked Propositions in Open Information Extraction
Matthias Cetto, Christina Niklaus, André Freitas and Siegfried Handschuh

Thursday 23rd August (continued)

An Exploration of Three Lightly-supervised Representation Learning Approaches for Named Entity Classification
Ajay Nagesh and Mihai Surdeanu

13:40–15:20 Session 3-2-c: Multimodal processing, ASR, NLI

Multimodal Grounding for Language Processing
Lisa Beinborn, Teresa Botschen and Iryna Gurevych

Stress Test Evaluation for Natural Language Inference
Aakanksha Naik, Abhilasha Ravichander, Norman Sadeh, Carolyn Rose and Graham Neubig

Grounded Textual Entailment
Hoa Vu, Claudio Greco, Aliia Erofeeva, Somayeh Jafaritazehjan, Guido Linders, Marc Tanti, Alberto Testoni, Raffaella Bernardi and Albert Gatt

Recurrent One-Hop Predictions for Reasoning over Knowledge Graphs
Wenpeng Yin, Yadollah Yaghoobzadeh and Hinrich Schütze

Hybrid Attention based Multimodal Network for Spoken Language Classification
Yue Gu, Kangning Yang, Shiyu Fu, Shuhong Chen, Xinyu Li and Ivan Marsic

13:40–15:20 Session 3-2-posters: Distributional information

Exploring the Influence of Spelling Errors on Lexical Variation Measures
Ryo Nagata, Taisei Sato and Hiroya Takamura

Stance Detection with Hierarchical Attention Network
Qingying Sun, Zhongqing Wang, Qiaoming Zhu and Guodong Zhou

Correcting Chinese Word Usage Errors for Learning Chinese as a Second Language
Yow-Ting Shiue, Hen-Hsen Huang and Hsin-Hsi Chen

Retrofitting Distributional Embeddings to Knowledge Graphs with Functional Relations
Ben Lengerich, Andrew Maas and Christopher Potts

Context-Sensitive Generation of Open-Domain Conversational Responses
Weinan Zhang, Yiming Cui, Yifa Wang, Qingfu Zhu, Lingzhi Li, Lianqiang Zhou and Ting Liu

A LSTM Approach with Sub-Word Embeddings for Mongolian Phrase Break Prediction
Rui Liu, Feilong Bao, Guanglai Gao, Hui Zhang and Yonghe Wang

Synonymy in Bilingual Context: The CzEngClass Lexicon
Zdenka Uresova, Eva Fucikova, Eva Hajicova and Jan Hajic

Convolutional Neural Network for Universal Sentence Embeddings
Xiaoqi Jiao, Fang Wang and Dan Feng

Rich Character-Level Information for Korean Morphological Analysis and Part-of-Speech Tagging
Andrew Matteson, Chanhee Lee, Youngbum Kim and Heuiseok Lim

Why does PairDiff work? - A Mathematical Analysis of Bilinear Relational Compositional Operators for Analogy Detection
Huda Hakami, Kohei Hayashi and Danushka Bollegala

Real-time Change Point Detection using On-line Topic Models
Yunli Wang and Cyril Goutte

Automatically Creating a Lexicon of Verbal Polarity Shifters: Mono- and Cross-lingual Methods for German
Marc Schulder, Michael Wiegand and Josef Ruppenhofer

Part-of-Speech Tagging on an Endangered Language: a Parallel Griko-Italian Resource
Antonios Anastasopoulos, Marika Lekakou, Josep Quer, Eleni Zimianiti, Justin DeBenedetto and David Chiang

One vs. Many QA Matching with both Word-level and Sentence-level Attention Network
Lu Wang, Shoushan Li, Changlong Sun, Luo Si, Xiaozhong Liu, Min Zhang and Guodong Zhou

Learning to Generate Word Representations using Subword Information
Yeachan Kim, Kang-Min Kim, Ji-Min Lee and SangKeun Lee

Urdu Word Segmentation using Conditional Random Fields (CRFs)
Haris Bin Zia, Agha Ali Raza and Awais Athar

Thursday 23rd August (continued)

ReSyf: a French lexicon with ranked synonyms
Mokhtar Boumedyen BILLAMI, Thomas François and Nuria Gala

If you've seen some, you've seen them all: Identifying variants of multiword expressions
Caroline Pasquer, Agata Savary, Carlos Ramisch and Jean-Yves Antoine

Learning Multilingual Topics from Incomparable Corpora
Shudong Hao and Michael J. Paul

Using Word Embeddings for Unsupervised Acronym Disambiguation
Jean Charbonnier and Christian Wartena

Indigenous language technologies in Canada: Assessment, challenges, and successes
Patrick Littell, Anna Kazantseva, Roland Kuhn, Aidan Pine, Antti Arppe, Christopher Cox and Marie-Odile Junker

Pluralizing Nouns across Agglutinating Bantu Languages
Joan Byamugisha, C. Maria Keet and Brian DeRenzi

Automatically Extracting Qualia Relations for the Rich Event Ontology
Ghazaleh Kazeminejad, Claire Bonial, Susan Windisch Brown and Martha Palmer

SeVeN: Augmenting Word Embeddings with Unsupervised Relation Vectors
Luis Espinosa Anke and Steven Schockaert

Evaluation of Unsupervised Compositional Representations
Hanan Aldarmaki and Mona Diab

Using Formulaic Expressions in Writing Assistance Systems
Kenichi Iwatsuki and Akiko Aizawa

What's in Your Embedding, And How It Predicts Task Performance
Anna Rogers, Shashwath Hosur Ananthakrishna and Anna Rumshisky

Word Sense Disambiguation Based on Word Similarity Calculation Using Word Vector Representation from a Knowledge-based Graph
Dongsuk O, Sunjae Kwon, Kyungsun Kim and Youngjoong Ko

Thursday 23rd August (continued)

Learning Semantic Sentence Embeddings using Sequential Pair-wise Discriminator
Badri Narayana Patro, Vinod Kumar Kurmi, Sandeep Kumar and Vinay Namboodiri

A Reassessment of Reference-Based Grammatical Error Correction Metrics
Shamil Chollampatt and Hwee Tou Ng

Information Aggregation via Dynamic Routing for Sequence Encoding
Jingjing Gong, Xipeng Qiu, Shaojing Wang and Xuanjing Huang

A Full End-to-End Semantic Role Labeler, Syntactic-agnostic Over Syntactic-aware?
Jiaxun Cai, Shexia He, Zuchao Li and Hai Zhao

15:20–15:50 Refreshment break

15:50–17:30 Session 3-3-a: Applications

Authorship Attribution By Consensus Among Multiple Features
Jagadeesh Patchala and Raj Bhatnagar

Modeling with Recurrent Neural Networks for Open Vocabulary Slots
Jun-Seong Kim, Junghoe Kim, SeungUn Park, Kwangyong Lee and Yoonju Lee

Challenges and Opportunities of Applying Natural Language Processing in Business Process Management
Han Van der Aa, Josep Carmona, Henrik Leopold, Jan Mendling and Lluís Padró

Novelty Goes Deep. A Deep Neural Solution To Document Level Novelty Detection
Tirthankar Ghosal, Vignesh Edithal, Asif Ekbal, Pushpak Bhattacharyya, George Tsatsaronis and Srinivasa Satya Sameer Kumar Chivukula

What represents "style" in authorship attribution?
Kalaivani Sundararajan and Damon Woodard

15:50–17:30 Session 3-3-b: Distributional semantics

Learning Target-Specific Representations of Financial News Documents For Cumulative Abnormal Return Prediction
Junwen Duan, Yue Zhang, Xiao Ding, Ching-Yun Chang and Ting Liu

Model-Free Context-Aware Word Composition
Bo An, Xianpei Han and Le Sun

Learning Features from Co-occurrences: A Theoretical Analysis
Yanpeng Li

Towards a unified framework for bilingual terminology extraction of single-word and multi-word terms
Jingshu Liu, Emmanuel Morin and Peña Saldarriaga

Neural Activation Semantic Models: Computational lexical semantic models of localized neural activations
Nikos Athanasiou, Elias Iosif and Alexandros Potamianos

15:50–17:30 Session 3-3-c: Emotion

Folksonomication: Predicting Tags for Movies from Plot Synopses using Emotion Flow Encoded Neural Network
Sudipta Kar, Suraj Maharjan and Thamar Solorio

Emotion Representation Mapping for Automatic Lexicon Construction (Mostly) Performs on Human Level
Sven Buechel and Udo Hahn

Emotion Detection and Classification in a Multigenre Corpus with Joint Multi-Task Deep Learning
Shabnam Tafreshi and Mona Diab

How emotional are you? Neural Architectures for Emotion Intensity Prediction in Microblogs
Devang Kulshreshtha, Pranav Goel and Anil Kumar Singh

Expressively vulgar: The socio-dynamics of vulgarity and its effects on sentiment analysis in social media
Isabel Cachola, Eric Holgate, Daniel Preoţiuc-Pietro and Junyi Jessy Li

15:50–17:30 Session 3-3-posters: ML, parsing, MT

Clausal Modifiers in the Grammar Matrix
Kristen Howell and Olga Zamaraeva

Sliced Recurrent Neural Networks
Zeping Yu and Gongshen Liu

Multi-Task Learning for Sequence Tagging: An Empirical Study
Soravit Changpinyo, Hexiang Hu and Fei Sha

Sepideh Sadeghi and Matthias Scheutz

Sentence Weighting for Neural Machine Translation Domain Adaptation
Shiqi Zhang and Deyi Xiong

Quantifying training challenges of dependency parsers
Lauriane Aufrant, Guillaume Wisniewski and François Yvon

Seq2seq Dependency Parsing
Zuchao Li, Jiaxun Cai, Shexia He and Hai Zhao

Thursday 23rd August (continued)

Revisiting the Hierarchical Multiscale LSTM
Ákos Kádár, Marc-Alexandre Côté, Grzegorz Chrupała and Afra Alishahi

Character-Level Feature Extraction with Densely Connected Networks
Chanhee Lee, Young-Bum Kim, Dongyub Lee and Heuiseok Lim

Neural Machine Translation Incorporating Named Entity
Arata Ugawa, Akihiro Tamura, Takashi Ninomiya, Hiroya Takamura and Manabu Okumura

Semantic Parsing for Technical Support Questions
Abhirut Gupta, Anupama Ray, Gargi Dasgupta, Gautam Singh, Pooja Aggarwal and Prateeti Mohapatra

Deconvolution-Based Global Decoding for Neural Machine Translation
Junyang Lin, Xu Sun, Xuancheng Ren, Shuming Ma, Jinsong Su and Qi Su

Friday 24th August

09:00–10:00 Invited talk: Min-Yen Kan

10:00–10:30 Refreshment break

10:30–12:30 Session 4-1-a: Question answering

Pattern-revising Enhanced Simple Question Answering over Knowledge Bases
Yanchao Hao, Hao Liu, Shizhu He, Kang Liu and Jun Zhao

Integrating Question Classification and Deep Learning for improved Answer Selection
Harish Tayyar Madabushi, Mark Lee and John Barnden

Knowledge as A Bridge: Improving Cross-domain Answer Selection with External Knowledge
Yang Deng, Ying Shen, Min Yang, Yaliang Li, Nan Du, Wei Fan and Kai Lei

Modeling Semantics with Gated Graph Neural Networks for Knowledge Base Question Answering
Daniil Sorokin and Iryna Gurevych

Friday 24th August (continued)

Rethinking the Agreement in Human Evaluation Tasks
Jacopo Amidei, Paul Piwek and Alistair Willis

Dependent Gated Reading for Cloze-Style Question Answering
Reza Ghaeini, Xiaoli Fern, Hamed Shahbazi and Prasad Tadepalli

10:30–12:30 Session 4-1-b: Rumor

Automated Fact Checking: Task Formulations, Methods and Future Directions
James Thorne and Andreas Vlachos

Can Rumour Stance Alone Predict Veracity?
Sebastian Dungs, Ahmet Aker, Norbert Fuhr and Kalina Bontcheva

Attending Sentences to detect Satirical Fake News
Sohan De Sarkar, Fan Yang and Arjun Mukherjee

Predicting Stances from Social Media Posts using Factorization Machines
Akira Sasaki, Kazuaki Hanawa, Naoaki Okazaki and Kentaro Inui

Automatic Detection of Fake News
Verónica Pérez-Rosas, Bennett Kleinberg, Alexandra Lefevre and Rada Mihalcea

All-in-one: Multi-task Learning for Rumour Verification
Elena Kochkina, Maria Liakata and Arkaitz Zubiaga

Friday 24th August (continued)

10:30–12:30 Session 4-1-c: Second language, Biomedical

Open Information Extraction on Scientific Text: An Evaluation
Paul Groth, Mike Lauruhn, Antony Scerri and Ron Daniel, Jr.

Simple Algorithms For Sentiment Analysis On Sentiment Rich, Data Poor Domains.
Prathusha K Sarma and William Sethares

Word-Level Loss Extensions for Neural Temporal Relation Classification
Artuur Leeuwenberg and Marie-Francine Moens

Personalized Text Retrieval for Learners of Chinese as a Foreign Language
Chak Yan Yeung and John Lee

Punctuation as Native Language Interference
Ilia Markov, Vivi Nastase and Carlo Strapparava

Investigating Productive and Receptive Knowledge: A Profile for Second Language Learning
Leonardo Zilio, Rodrigo Wilkens and Cédrick Fairon

10:30–12:30 Session 4-1-posters: Dialog, discourse, argumentation and applications

iParaphrasing: Extracting Visually Grounded Paraphrases via an Image
Chenhui Chu, Mayu Otani and Yuta Nakashima

MCDTB: A Macro-level Chinese Discourse TreeBank
Feng Jiang, Sheng Xu, Xiaomin Chu, Peifeng Li, Qiaoming Zhu and Guodong Zhou

Corpus-based Content Construction
Balaji Vasan Srinivasan, Pranav Maneriker, Kundan Krishna and Natwar Modani

Bridging resolution: Task definition, corpus resources and rule-based experiments
Ina Roesiger, Arndt Riester and Jonas Kuhn

Friday 24th August (continued)

Semi-Supervised Disfluency Detection

A New Approach to Animacy Detection

Labiba Jahan[1], **Geeticka Chauhan**[2], **Mark A. Finlayson**[1]

Abstract

Animacy is a necessary property for a referent to be an agent, and thus animacy detection is useful for a variety of natural language processing tasks, including word sense disambiguation, co-reference resolution, semantic role labeling, and others. Prior work treated animacy as a word-level property, and has developed statistical classifiers to classify words as either animate or inanimate. We discuss why this approach to the problem is ill-posed, and present a new approach based on classifying the animacy of co-reference chains. We show that simple voting approaches to inferring the animacy of a chain from its constituent words perform relatively poorly, and then present a hybrid system merging supervised machine learning (ML) and a small number of hand-built rules to compute the animacy of referring expressions and co-reference chains. This method achieves state of the art performance. The supervised ML component leverages features such as word embeddings over referring expressions, parts of speech, and grammatical and semantic roles. The rules take into consideration parts of speech and the hypernymy structure encoded in WordNet. The system achieves an F_1 of 0.88 for classifying the animacy of referring expressions, which is comparable to state of the art results for classifying the animacy of words, and achieves an F_1 of 0.75 for classifying the animacy of coreference chains themselves. We release our training and test dataset, which includes 142 texts (all narratives) comprising 156,154 words, 34,698 referring expressions, and 10,941 co-reference chains. We test the method on a subset of the OntoNotes dataset, showing using manual sampling that animacy classification is 90%$\pm$2% accurate for coreference chains, and 92%$\pm$1% for referring expressions. The data also contains 46 folktales, which present an interesting challenge because they often involve characters who are members of traditionally inanimate classes (e.g., stoves that walk, trees that talk). We show that our system is able to detect the animacy of these unusual referents with an F_1 of 0.95.

1 Introduction

Animacy is the characteristic of being able to independently carry out actions (e.g., movement, communication, etc.). For example, a person or a bird is animate because they move or communicate under their own power. On the other hand, a chair or a book is inanimate because they do not perform any kind of independent action.

Animacy is a useful semantic property for different NLP systems, including word sense disambiguation (WSD), semantic role labeling (SRL), coreference resolution, among many others. Animacy can be used to distinguish different senses and thus help a WSD systems assign senses to different words. As an example, animacy has been applied in grouping senses from WordNet (Palmer et al., 2004; Palmer et al., 2007). Animacy can also be used directly in a WSD system to decide thematic assignment, which is useful for assigning senses: for example, Carlson and Tanenhaus (1988) used the presence of an animate subject in a sentence to determine if a the verb is transitive, which is a useful for thematic role assignment. Another task where animacy can play an important role is semantic role labeling (SRL). Agentive

Proceedings of the 27th International Conference on Computational Linguistics, pages 1–12
Santa Fe, New Mexico, USA, August 20-26, 2018.

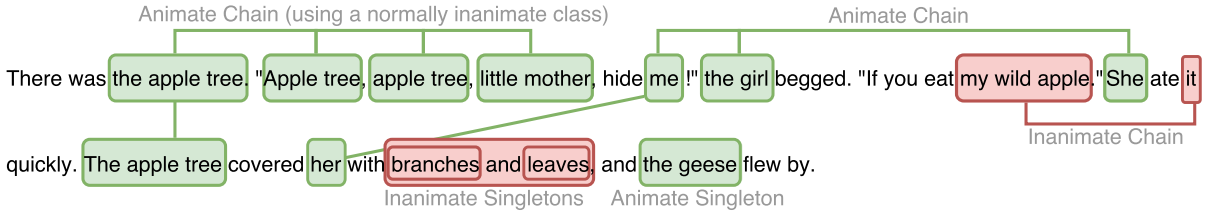

Figure 1: Example text containing animate and inanimate coreference chains. Colored boxes represent referring expressions, while links between them signify coreference. Animate chains are green, while inanimate chains are red. The text is drawn from Story #113 *The Magic Swan Geese* (Guterman, 1975, p. 350) and has been slightly modified for clarity. The figure is adapted from (Jahan et al., 2017).

or semantic subject roles must often be filled by animate entities, whereas goal, theme, patient, instrument and location roles are often filled by inanimate entities (Kittila et al., 2011). In some works (Connor et al., 2013; Kittilä, 2006, for example), animacy is used as a feature that helps to identify agents, and Ferreira (1994) showed how knowing the animacy of roles allows one to better identify the passive voice. In many coreference resolution systems (Raghunathan et al., 2010; Iida et al., 2003; Cardie and Wagstaf, 1999, for example) animacy is used as an semantic feature to determine co-referents of an expression.

In addition to these broad uses of animacy, our own research group is particularly interested in detecting animacy with a view toward identifying characters in stories. Most definitions of narrative acknowledge the central role of character, for example: "a representation of a possible world . . . at whose centre there are one or several protagonists of an *anthropomorphic* nature . . . who (mostly) perform goal-directed actions . . . " *(emphasis ours)* (Fludernik, 2009, p. 6). If we are to achieve the long-term goal of automatic story understanding, it is critical that we be able to automatically identify a story's characters, distinguishing them from non-character entities. All characters are necessarily animate—although not all animate things are necessarily characters—and so detecting animacy will immediately narrow the set of possibilities for character detection.

Prior work treated animacy as a word-level phenomenon, marking animacy as an independent feature on individual words (Orăsan and Evans, 2007; Bowman and Chopra, 2012; Karsdorp et al., 2015). But word-level animacy is not always sufficient to identify an animate or an inanimate object. For example, *horse* is normally animate, but a *dead horse* is obviously inanimate. On the other hand, *tree* is an inanimate word but a *talking tree* is definitely an animate thing. So, assigning animacy at the word level confuses the issue and makes it more difficult classify these type of complex cases.

Furthermore, referents are expressed in texts as coreference chains comprised of referring expressions, and so conceiving of animacy as a word-level phenomenon requires an additional method for computing chain animacy from word animacy. One way to do this is to combine word-level animacy markings—say, using majority vote—into referring expressions animacy and then coreference chains. As it turns out, this does not work all that well and we used this method as our baseline. Alternatively, we can attempt to compute animacy directly on the referring expressions and then use majority vote of referring-expression-level animacy to compute animacy of coreference chains, the approach we pursue here.

Although detecting animacy might seem to be straightforward, it presents a number of subtleties. For example, some theorists have proposed closed lists of linguistic expressions that should be automatically considered animate entities, such as titles, animals, or personal pronouns (Quirk et al., 1985; Yamamoto, 1999). However, texts, especially stories about unreal worlds, can arbitrarily introduce characters that would not be animate in real life, for example, walking stoves or talking trees. Figure 1 shows an example sentence from a Russian fairytale which contains three animate chains, one of which is a tree that talks: trees would not be normally be considered animate according to canonical lists of animate entities. Therefore some context sensitivity in detection is needed.

In our work, we compute animacy directly on referring expressions, and transfer those markings up to the coreference chain level, to get a direct classification of the animacy of the whole chain. We present a hybrid system combining statistical machine learning (ML) and hand-built rules for classifying the

Text Types	# Texts	# Tokens	# Referring Expressions	# Coref. Chains
Russian Folktales	46	109,120	20,391	4,950
Islamist Extremist Texts	32	26,557	8,041	3,684
Islamic Hadiths	64	20,477	6,266	2,307

Table 1: Counts of various text types in the corpus.

animacy of referring expression, and also present a voting model to identify the animacy of coreference chains based on the animacy of the chain's constituent referring expressions. The paper proceeds as follows. First we discuss our data sources and annotation procedures (§2). Next we discuss the experimental setup including the ML features, rules, and classification models (§3), and then describe our results (§4). We analyze the error patterns of the system and mention potential future work (§5), and also discuss work that is related to this study (§6). We finish with a discussion of the contributions of the paper (§7).

2 Data

We started this project seeking to use existing data annotated for animacy, as there have been a number of studies on animacy detection already (as we discuss in §6). However, no prior data in English was readily available to use; the best performing prior work on word-level animacy was done on a corpus of 74 stories comprising 74,504 words in Dutch (Karsdorp et al., 2015). Orăsan and Evans (2007) did their work in English but their data was not available. Therefore we sought other data (specifically stories, because of our interest in story understanding), and our annotated data was a corpus comprising a variety of Russian folktales, Islamist Extremist stories, and Islamic Hadiths that are freely available and assembled for other work, and had been annotated for referring expressions and coreference chains (Finlayson, 2017; Finlayson et al., 2014). The composition of the corpus is shown in Table 1.

The corpus contains 46 Russian folktales, originally collected in Russian in the late 1800's but translated into English in the mid-twentieth century (Finlayson, 2017). The other portion (the N2 corpus) contains 96 stories of relevance to Islamist Extremists (Finlayson et al., 2014). All but 31 of the texts in the corpus already contained gold-standard annotations for token and sentence boundaries, parts of speech, referring expressions, and coreference chains (as well as other layers of annotation. We processed these 31 un-annotated texts using the Stanford CoreNLP suite (Manning et al., 2014), automatically generating tokens, sentences, parts of speech, referring expressions, and coreference chains.

We annotated the whole corpus for animacy of coreference chains, and the first fifteen stories for animacy at the word level. We propagated the animacy annotations from the chains to their constituent referring expressions to generate animacy annotations at that level. Because we had to automatically compute referring expression and coreference chains on 31 of the texts, and the CoreNLP coreference resolution is somewhat noisy, we hand-corrected the chains. We did this hand-correction using the Story Workbench annotation tool (Finlayson, 2008; Finlayson, 2011) that allows for the manipulation and correction of referring expression and coreference chains.

The annotation of the animacy of coreference chains and referring expressions for the first fifteen stories was performed by the first two co-authors. Disagreements were discussed and corrected to generate a gold-standard annotation. Agreement for the coreference-level was 0.99 F_1 and 0.99 Cohen's kappa coefficient (κ), which represents near-perfect overall agreement (Landis and Koch, 1977). The annotation of the rest of the stories was performed by only the first author.

We also annotated first fifteen Russian tales for word-level animacy so that we could test via reimplementation the existing best performing word animacy model (Karsdorp et al., 2015). This annotation was done under the following guidelines. First, all nouns that would refer to animate entities in real life, such humans or animals, as discussed in (Quirk et al., 1985, pp. 314 & 345) were marked animate. We marked gendered pronouns as animate, e.g., *he*, *she*, *his*, *hers*, etc. We also marked adjectives suggesting animacy as animate, e.g., *alive*, *vital*, *kindlier*, etc., whereas adjectives implying inanimacy, such as

	Total entity	Animate entity	Inanimate entity	Unique Animate	Unique Inanimate
Token (15 stories)	23,291	3,896	19,395	291	2,221
Referring Expression (142 stories)	34,698	22,052	12,646	1,104	2,249
Coreference-chain (142 stories)	10,941	3,832	7,109	-	-

Table 2: Total number of animate and inanimate tokens, referring expressions, and coreference chains, with breakdowns of number of unique items in each class.

Referring Expression	**Class**	**Explanation**
Muslims, the dragon, Abu Bakr	Animate	Normally animate entities
walking stove, talking tree	Animate	Normally inanimate but are animate in context
"those who do not know what it is"	Inanimate	Discourse acts, when marked as referents
the mosque, this world, every house	Inanimate	Normally inanimate objects
dead horse	Inanimate	Normally animate but are inanimate in context
her eyes, his hands , horse tail	Inanimate	Inanimate parts of animate entities
Word		
princess, dragon, Abdullah	Animate	Nouns denoting animate entities
he, she, his, her	Animate	Personal pronouns referring to animate objects
kind [prophet], stronger [dragon]	Animate	Adjectives that suggest animacy
Morning, Evening, [talking] stove	Animate	Usually inanimate but are animate in context
Kiev, world, mosque	Inanimate	Nouns denoting inanimate entities
it, that, this	Inanimate	Personal pronouns referring to inanimate objects

Table 3: Examples of annotation of coreference- and word-level animacy. At the word level, only an adjectives suggesting animacy or nouns referring to an animate object are marked animate. Everything else (including verbs, adverbs, determiners, and so forth) are marked inanimate.

dead in the noun phrase *dead horse*, were marked inanimate. Second, we marked as animate any words directly referring to entities that acted animately in a story, regardless of the default inanimacy of the words. For example, we marked *stove* animate in the case of a walking stove, or *tree* animate in the case of a talking tree. This also covered proper names that might normally be marked as inanimate because of their ostensible class, such as those underlined in the next example:

> *All of them were born in one night—the eldest in the evening, the second at midnight, and the youngest in the early dawn, and therefore they were called Evening, Midnight, and Dawn. (Guterman, 1975, Tale #140, p. 458)*

The word-level annotation was done by the first two co-authors. Disagreements were discussed and corrected to generate a gold-standard annotation. We annotated every word in the corpus for animacy directly (marking each word as either animate or not). Agreement was 0.97 F_1 and 0.97 Cohen's kappa coefficient (κ), which represents near-perfect overall agreement (Landis and Koch, 1977).

A summary of the counts of animate and inanimate words, referring expressions, and coreference chains is given in Table 2. Examples of animate and inanimate words are given in Table 3. The data is included in the supplementary materials archive for the paper, which is publicly available[1].

3 Approach

Our hybrid system comprises two parts: a rule-based classifier that can mark the animacy of roughly 50% of the referring expressions, followed by a statistical classifier trained on the annotated data that can be

[1] https://dspace.mit.edu/handle/1721.1/116172

applied to the remaining referring expressions. Once all referring expressions are marked for animacy, the animacy of a coreference chain is inferred from the animacy of its constituent referring expression.

3.1 Rules

We implemented five rules that considered semantic subjects parsed from the semantic role labeler associated with the Story Workbench annotation tool (Finlayson, 2008; Finlayson, 2011), the named entities computed using the classic API of Stanford dependency parse (Manning et al., 2014, v3.7.0), and knowledge from WordNet (Fellbaum, 1998). These rules were inspired by existing rule-based animacy systems. We also considered the last word of a referring expression in most of the rules because it helps to mark quotes as inanimate, as well as to detect the regular animate and inanimate referring expression.

1. If the last word of a referring expression is a gendered personal, reflexive, or possessive pronoun (i.e., excluding *it*, *its*, *itself*, etc.), we marked it animate.
2. If the last word of a referring expression is the semantic subject to a verb, we marked it animate.
3. If a referring expression contains a proper noun we marked it animate. We excluded anything tagged as *location*, *organization*, or *money*, as determined by the Stanford CoreNLP NER system.
4. If the last word of a referring expression is a descendant of *living_being* in WordNet, we marked it animate.
5. If the last word of a referring expression is a descendant of *entity* WordNet, we marked it inanimate.

3.2 Features

We explored seven different binary and vector features to train the statistical classification model, some of which are drawn from prior work.

1. **Word Embeddings (WE)**: We computed pre-trained word embeddings in 300 dimensions for all the words in the stories using the skip-gram architecture algorithm (Mikolov et al., 2013). We used the DeepLearning4J library (Deeplearning4j Development Team, 2017), and configured the built-in skip-gram model with a minimum word frequency of 3, layer width (dimensions) of 300, a window size of 5, and trained for 10 iterations. We explored a few different combinations of these parameters, but found that these settings produced the best results. This is a vector feature drawn from (Karsdorp et al., 2015), and is primarily relevant to classifying word-level animacy. We ran this model on each word of our data and used the output vector as a feature.

2. **Word Embeddings on Referring Expressions (WER)**: We calculated pre-trained word embeddings in 450 dimensions for just the words within the referring expressions, again using the skip-gram approach as above, except with a minimum word frequency of 1. Again, this is a vector feature. 450 dimensions worked better for this feature (rather than 300), which we discovered after doing a small amount of parameter exploration. We ran this model on each referring expression of our data used the output vector as a feature.

3. **Composite Word Embedding (CWE)**: We computed a composite pre-trained word embedding for the neighborhood of each word, adding together the word embedding vectors for three words before and three words after the target word (excluding the target). This is also a vector feature, and is again partially drawn from (Karsdorp et al., 2015). The idea of this feature is that it estimates the similarities of the context among all animate words (or all inanimate words) as well as the dissimilarities of animate from inanimate, and vice versa.

4. **Parts of Speech (POS)**: By analogy with the other embeddings, we computed an embedding over part of speech tags in 300 dimensions, with the same settings as in feature #1 (WE). This feature models the tendency of nouns, pronouns, and adjectives to refer to animate entities.

5. **Noun (N)**: We checked whether a given referring expression contained a noun and encoded this as a boolean feature because we observed that in the first 15 stories 43% of nouns are animate. Thus this feature explicitly captures the tendency of nouns to refer to animate entities. We used dependency parses generated by the classic API of Stanford dependency parser (Manning et al., 2014, v3.7.0).

6. **Grammatical Subject (GS)**: Animate references tend to appear as the grammatical subjects of verbs (Ovrelid, 2005). We used dependency parses generated by the classic API of Stanford dependency parser (Manning et al., 2014, v3.7.0) to check if the last word of a given referring expression was used as a grammatical subject relative to any verb in the sentence, and encoded this as a boolean feature.

7. **Semantic Subject (SS)**: We also computed whether or not a referring expression appeared as a semantic subject to a verb. We used the semantic role labeler associated with the Story Workbench annotation tool (Finlayson, 2008; Finlayson, 2011) to compute semantic roles for all the verbs in the stories. We then checked whether the last word of a given referring expression contained an ARG0 for a verb (an exact match was not required), and encoded this as a boolean feature.

3.3 Classification Models

We implemented our classification models using SVM (Chang and Lin, 2011), with a Radial Basis Function Kernel. The features used to train the different models are shown in Table 4. We trained each model using cross validation, and report macroaverages across the performance on test folds.

We have three models for animacy: referring expressions, coreference chains, and words. For our referring expression animacy model, we implemented two approaches. The first is a ML-only approach, in which we explored different combinations of features: word embedding over referring expressions (WER), noun (N), grammatical subject (GS), and semantic subject (SS). We configured the SVM with $\gamma = 1, C = 0.5$ and $p = 1$. We measured the performance of the classifier using 10-fold cross validation. The second approach is the hybrid system where we we first applied the rules, then applied the ML classifier for referring expressions not covered by the rules. In our prior work we only implemented the first approach (Jahan et al., 2017) on a small data set.

For the coreference chain animacy model, we implemented a majority voting approach for combining the results of the referring expression animacy model to obtain a coreference animacy prediction. In the case of ties, the chain was marked inanimate.

To compare with prior work, we also implemented a word animacy model, adapting an existing system with the best performance (Karsdorp et al., 2015). That model used features based on word N-grams, parts of speech, and word embeddings. Similarly, we implemented our classifier using word embeddings over words (WE), combined word embeddings (CWE), and parts of speech (POS). The SVM was configured with $\gamma = 5, C = 5000$ and $p = 1$, and we measured the performance with 20-fold cross validation. This model performed very close to the prior state of the art with our small data set of 15 stories.

4 Results & Discussion

We calculated two baselines for referring expression animacy. The first baseline is to choose the majority class (animate). The second baseline combines word-level animacy predictions generated by our word animacy model via a majority vote; we measured the upper bound for this over the 15 texts for which we have gold-standard word animacy annotations.

We evaluated our models by measuring accuracy, precision, recall, F_1, and Cohen's kappa (κ) compared to the gold-standard annotations. Table 4 shows the results for both classes. Our word animacy model achieved an F_1 of 0.98, whereas the prior state of the art achieved F_1 of 0.99 for marking inanimacy. On the other hand, for marking animacy our model achieved F_1 of 0.90 where the state of the art achieved F_1 of 0.93. For referring expression animacy we varied the features to determine the optimal set. We obtained the best result (F_1 of 0.84) using different combinations of three features: noun (N), grammatical subject (GS) and semantic subject (SS). Our hybrid model for referring expression animacy performed better (F_1 of 0.88) than the statistical model (F_1 of 0.84). The rule-based model achieved 0.88 F_1 when we applied the rules first, and marked any remaining referring expressions as majority class. Our rule based model performed similarly to the hybrid model, but the hybrid model is more consistent.

For the coreference animacy model, we implemented the majority vote approach to detect animacy of coreference chain using the best output of referring expression model. Majority vote resulted in an overall F_1 of 0.75, which substantially outperforms the result from our prior work of 0.61 F_1. Around 3% of coreference chains resulted in a tied vote, and these were marked as inanimate (the majority class).

Model	Feature Set	Acc.	Inanimate				Animate			
			κ	Prec.	Rec.	$\mathbf{F_1}$	κ	Prec.	Rec.	$\mathbf{F_1}$
Word	(Karsdorp et al., 2015)	-	-	0.98	0.99	0.99	-	0.94	0.91	0.93

	Random Sampling	90%†	0.80	0.86	0.98	0.92	**0.80**	**0.97**	**0.81**	**0.88**

Table 4: Result of different Animacy Models (Bolded according to when our F_1 measure is higher). MFC stands for "Most Frequent Class", and the other abbreviations stand for features as indicated in the text. *Estimated $\pm 2\%$ with 95% confidence. †Estimated $\pm 1\%$ with 95% confidence.

We also evaluated our model using direct sampling (Saunders et al., 2009). We ran our hybrid model over 200 news articles from the OntoNotes (Hovy et al., 2006) data set containing 46,088 referring expressions and 7,836 coreference chains. We randomly sampled 558 coreference chains and checked their animacy markings by hand, resulting in a estimated accuracy of 90% $\pm 2\%$ at a 95% confidence level, as well as estimated precision, recall, and F_1 listed in Table 4. Those coreference chains contained 3,543 referring expressions, which allowed us to estimate the accuracy of the referring expression model at 92% $\pm 1\%$ at a 95% confidence level.

The data contains 46 folktales, which have 142 mentions of 12 characters who are members of traditionally inanimate classes (e.g., stoves that walk, trees that talk). We manually identified those 12 characters and evaluated our model's performance on them. Our system is able to detect the animacy of these unusual referents with an F_1 of 0.95. Conversely, there was only one mention of a normally animate class that was inanimate in context ("dead horse"), and this was correctly marked by the system.

5 Error Analysis & Future Work

A detailed error analysis of the results revealed at least two major problems for the hybrid model that we will focus on in future work: short chains, quotes, and exceptions to the rules.

Determining the animacy of short coreference chains was challenging for our system: approximately 11% of short chains are incorrectly marked. As the length of a chain tends toward a single referring expression, the coreference classifier should converge to the referring expression classifier performance. However, for chains between two and four referring expressions long, the majority voting approach seems to fall short. We suspect this is because many referring expressions are themselves quite short, and can contain false alarms: e.g., our system classifies "his hands" as animate because of the animate word "his" in the expression. We believe another approach to solving this problem is to generate new rules in our hybrid model so that it can handle these type of special cases.

Second, many quotes are full of animate words, e.g., "the fate of the tsar's daughter to go to the dragon" is a phrase that is itself a referring expression in one story, and should be inanimate according

to our animacy annotation rule. However, the classifier marks the quote as animate because it finds three animate words: *tsar*, *daughter*, and *dragon*. In our data, approximately 2.5% of quotes that are referring expressions are incorrectly marked, and handling this likely will require rule-based processing.

Finally, a common error type was exceptions to the rules. In the hybrid system we combined together a large number of similar referring expressions under one rule so that we can handle them under a similar animacy class. But there are always exceptions for every rule: for example, we define "it" as inanimate but of course sometimes "it" can refer to an animate object. For the most part these individual instances will be out-voted by animate referring expressions in long chains, so it is a relatively small problem. One approach to solving this would to implement the idea of Orăsan and Evans (2001; 2007) to use supervised machine learning to mark unseen WordNet senses by their animacy rather using specific rules.

6 Related Work

We divide the related work into two sections: first animacy detection in English, followed by animacy detection in other languages. The work reported here is in English (thus the related work of the first section), but the material covered in non-English second section makes clear both that our approach had not attempt before in any language, and also that no language-specific features have been used in any prior work. There have been both rule-based and machine learning methods to classify the animacy of words, but to the best of our knowledge, no one has combined both techniques, and no one has tackled animacy classification at the referring expression or coreference level.

6.1 Animacy Detection in English

Evans and Orăsan (2000) performed animacy classification to improve anaphora resolution using a rule-based method to identify animate WordNet hypernym branches. In later work they used supervised machine learning to mark unseen WordNet senses for their animacy (Orăsan and Evans, 2001; Orăsan and Evans, 2007). The rule-based method uses the unique beginners in WordNet for classification of sense animacy using a statistical chi-squared method, while the machine learning method uses k-nearest neighbors in a multi-step procedure, along with careful feature engineering, to determine noun animacy. They achieved an F_1 of 0.94 for animacy, and also performed an extrinsic evaluation using the MARS anaphora resolution system and a word sense disambiguation algorithm. Similarly, Moore et al. (2013) combined a majority vote model using rule-based methods, features from WordNet, and a SVM to achieve an accuracy of 89% for majority voting and 95% for SVM (no F_1 score was reported).

Bowman and Chopra (2012) used a maximum entropy classifier to predict multiple classes for noun phrases as *human*, *vehicle*, *time*, *animal*, etc., with an overall accuracy of 85%. A binary animacy classification could be derived from each of these classes, with a performance of 94% accuracy.

Additionally, there are others that have used pure rule-based and pattern matching methods. Ji and Lin (2009) generate n-grams and performed pattern matching using the Google n-gram corpus to label gender and animacy properties for words for to assist in person mention detection. With these gender and animacy markings, they applied a confidence estimation which is compared against the test document using fuzzy matching. The highest F_1 they achieved for animacy was 0.67, with an F_1 of 0.46 for gender.

Declerck et al. (2012) used an ontology-based method to detect characters in folktales. Their ontology consists of family relations as well as elements of folktales such as supernatural entities. After looking at the heads of noun phrases and comparing them with labels in the ontology, they added the noun phrase to the ontology as a potential character if a match was found. Then, they applied inference rules to the candidate characters in order to find two strings in the text that refer to the same character. They discarded strings that are related to a potential character only once and are not involved in an action. They obtained an accuracy of 79%, a precision of 0.88, a recall 0.73, and an F_1 of 0.80.

Wiseman et al. (2015) used a mention-ranking approach for coreference resolution, using animacy as a feature, derived from the Stanford Coreference System (Lee et al., 2013). The Stanford Coreference System set animacy attributes using a static list for pronouns, named entity labels, and a dictionary.

Finally, a marginally related rule-based system was implemented by Goh et al. (2012) using verbs and WordNet in order to determine the protagonists in fairy tales (where protagonists must of necessity be

animate). They used the Stanford parser's phrase structure trees to obtain the subjects and objects of the verbs and used the dependency structure to obtain the head noun of compound phrases. Additionally, they used WordNet's *derivationally_related* relation to find verb associated with a particular nominal action. They achieved a precision of 0.69, a recall of 0.75, and an F_1 of 0.67.

6.2 Animacy Detection in Other Languages

Nøklestad (2009) implemented animacy detection for Norwegian nouns, using this along with Named Entity Recognition to improve the performance of anaphora resolution. They explored various pattern matching methods, using web data to extract lists of animate nouns as well as to check the animacy of a particular noun. For example, if a noun co-referred frequently with *han* (he) or *hun* (she), then it was characterized as animate. This method achieved an accuracy of 93%. The main problem here, from our point of view, is that using data from the web makes the problem too general: you only measure the typicality of animacy, not the animacy of an item in context. In the case of folktales, we have unusual animate entities (e.g., talking stoves) that will on the whole be seen by the web as inanimate.

Bloem and Bouma (2013) developed an automatic animacy classifier for Dutch nouns by dividing them into *Human*, *Nonhuman* and *Inanimate* classes. They use the k-nearest neighbor algorithm with distributional lexical features—e.g., how frequently the noun occurs as a subject of the verb "to think" in a corpus—to decide whether the noun was predominantly animate. Prediction of the *Human* category achieved 87% accuracy, and the large inanimate class was predicted correctly 98% of the time. But, again, this work focuses on individual noun phrases, not coreference chains, and is concerned with the default animacy of the expression, not its animacy in context.

Another implementation of word-level animacy for Dutch was performed by Karsdorp et al. (2015) on folktale texts. Because this work was the highest performing word-level system, many of our features were inspired by their approach. They used lexical features (word forms and lemmas), syntactic features (dependency parses to check which word is a subject or an object), part of speech tags, and semantic features (word embedding using a skip-gram model to vectorize each word). They implemented a Maximum Entropy Classifier to classify words according to their animacy and obtained a good result of 0.93 F_1 for the animate class, by just using the words, parts of speech, and embedding features.

Baker and Brew (2010) performed animacy classification on a multilingual dataset containing English and Japanese. They used Bayesian logistic regression with morphological features, WordNet semantic categories, and frequency counts of verb-argument relations. They obtained 95% classification accuracy. In sum, all the prior work has been for word-level animacy (usually nouns, sometimes noun phrases). In contrast, we focus on characterizing the animacy of referring expressions and coreference chains.

7 Contributions

This paper makes four major contributions. First, we have redefined the problem of animacy classification as one of marking animacy on coreference chains, in contrast to all prior work that seeks to mark the animacy at the world level. Second, we have presented a hybrid system merging an SVM classifier and hand-built rules to predict the animacy of referring expressions directly, achieving performance of 0.90 F_1, which is comparable to the state of the art for word-level animacy detection. Third, we used a majority voting approach to obtain the animacy of coreference chains. The overall performance of this approach is substantially improved in comparison with our prior work. Our error analysis further suggests several potentially profitable ways forward to improving the performance. Finally, we provide 15 texts annotated for word-level animacy and 142 texts annotated for coreference chain animacy, as well as the code reproducing the results, in the supplementary materials archive[2].

Abstract

Recent neural network methods for zero pronoun resolution explore multiple models for generating representation vectors for zero pronouns and their candidate antecedents. Typically, contextual information is utilized to encode the zero pronouns since they are simply gaps that contain no actual content. To better utilize contexts of the zero pronouns, we here introduce the self-attention mechanism for encoding zero pronouns. With the help of the multiple hops of attention, our model is able to focus on some informative parts of the associated texts and therefore produces an efficient way of encoding the zero pronouns. In addition, an attention-based recurrent neural network is proposed for encoding candidate antecedents by their contents. Experiment results are encouraging: our proposed attention-based model gains the best performance on the Chinese portion of the OntoNotes corpus, substantially surpasses existing Chinese zero pronoun resolution baseline systems.

Title and Abstract in Chinese

基于注意力神经网络模型的零指代消解研究

传统的关于零指代的方法提出了多种关于先行语和零代词的表示模型。这些模型中，研究者们用零代词的上下文信息来帮助表示缺省的信息。为了更好的帮助建模零代词，我们提出了一种基于注意力机制的神经网络模型，通过注意力模型来获取更有表示性信息的上下文信息。实验结果表明：我们的方法能够有效提升效果，并在中文OntoNotes 5.0数据集上取得了最好的结果，超越了现有的基准系统。

1 Introduction

In natural languages, expressions that can be deduced contextually by people are frequently omitted in texts. This is special the case in pro-dropped languages, such as Chinese, where a kind of anaphoric expression is frequently eliminated. A zero pronoun is a gap in the sentence that is found when a phonetically null form is used to refer to a real-world entity (Chen and Ng, 2016). We here show a case of zero pronouns from the OntoNotes-5.0 dataset.

> 这 次 地震 ϕ_1 有 一些 房屋 塌 的 , 这 里面 如果 有 建房 的 质量 问题 ， ϕ_2 是 要 追究 责任 的 。
>
> In this earthquck ϕ_1 some rooms collapsed, if there exsit some room quality issues, ϕ_2 will need to call to account.

We use ϕ to represent the zero pronouns in this example. Among these zero anaphoras, we can assign the mention "政府/the government" that appears in leading text, to be the antecedent of ϕ_2 while there are no such mentions for ϕ_1. Hence, ϕ_2 is an anaphoric zero pronoun, and ϕ_1 is the un-anaphoric case.

With the fact that zero pronouns are gaps that have no text, it is almost impracticable to representant the zero pronouns by themselves. This issue has received increasingly attention. In recent time, deep neural network methods for Chinese zero pronoun resolution (Chen and Ng, 2016; Yin et al., 2017a; Yin et al., 2017b) have been proposed and are intended to encode zero pronouns into the vector-space semantic by additional elements. Chen and Ng (2016) propose a neural network model that learns to encode the anaphoric zero pronoun by using the leading word and governing verb, which leads to the insufficient text issue. To better use associated text information for expressing zero pronouns, Yin et al. (2017a) present the ZP-centered-LSTM architecture that learns to encode zero pronouns by their text words. However, it could bring with some defects: their model regards all the words in the sentence equally, thus fails in capturing informative parts of the sentence. As described in (Chen and Ng, 2016), the clause information of a zero anaphora is very important in explaining these gaps, it is a natural way of modeling zero pronoun by focusing on some important texts. For instance, in sentence "two trains in ten weeks ago ϕ crashed in their way to the southern German countryside", "crashed in their way" is an important clue for the zero pronoun but "several weeks ago" is not. Under this consideration, a systematic solution that can encode zero pronouns by focusing on informative parts of associate texts is the better choice. Besides, another important issue for the task of zero pronoun resolution is modeling candidates. Recent researches use context and content words to encode candidates (Yin et al., 2017a; Yin et al., 2017b). Typically, these words are modeled in a sequential way by recurrent neural networks. We argue that some of the words in noun phrases contains more important information than others, a need that leads to the usage of attention mechanism.

To alleviate the above-mentioned issues, in this paper, we propose a novel attention-based neural network model to deal with the task. Following existing neural network work for Chinese zero pronoun resolution (Chen and Ng, 2016; Yin et al., 2017a; Yin et al., 2017b), we focus on anaphoric zero pronoun resolution task, introducing a pair-wise model to resolve anaphoric zero pronouns. For some natural language processing tasks (Mnih et al., 2014; Tang et al., 2016), people investigate to apply attention mechanism on top of the convolutional neural network or recurrent neural network to introduce an extra source of information to guide the modeling of useful information. However, since zero pronouns are simple gaps that have no such kind of extra information, the above-mentioned attention mechanism can rarely be directly practiced for modeling these gaps. Inspired by (Lin et al., 2017), we here investigate the usage of a self-attentive mechanism for encoding the zero anaphoras. With the help of self-attentive mechanism, our model is able to effectively focus on informative texts of the zero pronouns and therefore captures essential information on encoding the zero pronouns. In addition, on purpose of modeling informative texts of mentions (noun phrases), we propose an attention-based recurrent neural network to build the mention encoder. With the help of representative vector of zero anaphoras, our model is able to effectively focus on important parts of mentions and therefore brings an efficient way of expressing candidates at the semantic level. Empirically, we show that our method has brought performance gains in baselines, achieving great performance on the widely used OntoNotes-5.0 dataset. Our contributions are three-fold:

- By utilizing the self-attention mechanism, our model is able to focus on informative parts of associate texts when modeling zero pronouns, leading to an effective way of capturing useful information for interpreting the zero pronouns;

- Our model is capable of modeling candidate antecedents by their informative words with the help of zero pronouns, which in return brings a better way of explaining candidate antecedents;

- We show that our model substantially surpasses all baseline systems, gains state-of-the-art performance on the benchmark dataset.

In Section 2, we will discuss related work on zero pronoun resolution. Next, we will intorduce our attention-based neural network model in Section 3. In Section 4, empirical evaluation results are shown. And finally, we conclude in Section 5.

2 Related Work

In this section, we give a brief summary of early efforts for zero pronoun resolution both for Chinese and other languages.

2.1 Zero Pronoun Resolution for Chinese

Converse (2006) is the first rule-based study that integrate Hobbs-algorithm into the resolution of zero pronoun in the Chinese Treebank (Xue et al., 2005). After that, a variety of learning-based methods have been investigated. Zhao and Ng (2007) use the learning-based model to locate and resolve zero anaphoras. They investigate a serious of features and apply the decision-tree algorithm to train the classifier. To better capture the syntactic-level information, Kong and Zhou (2010) introduce the context sensitive tree-kernel unified framework for zero anaphor resolution. On the base of Zhao and Ng (2007), Chen and Ng (2013) further investigate their model, introducing two extensions to the resolver, namely, novel features and zero pronoun links. However, these work deeply rely on annotation dataset. To alleviate this issue, Chen and Ng (2014) present the first unsupervised model that first convert zero anaphoras into ten pre-defined pronouns and then apply a ranking-based pronoun resolution model to select antecedent mentions. Chen and Ng (2015) build a discourse-aware model that can jointly locate and resolve zero anaphoras.

More recently, with the advance of neural network techniques, deep-learning-based methods are introduced and have been demonstrated to be effective for this task. Chen and Ng (2016) first introduce a feed-forward neural network framework, where zero anaphoras are encoded by its previous word and headword. However, their model overlooks context of a zero anaphora, which inevitably misses some valuable information. Naturally, some works try to alleviate this issue by investigating information from associate texts. Yin et al. (2017a) introduce a novel memory-based network neural network model that learns to encode zero anaphoras by its texts and antecedent mentions. They take advantage of multi-hops architecture, producing abstract information from external-memories as hints for explaining zero anaphoras. Yin et al. (2017b) focus on encoding global-information for candidates, where a hierarchical candidate encoder is introduced that learns to model the candidates. Liu et al. (2017) investigate the issue of generating pseudo training-data for the task of zero anaphora resolution. They use a novelty two-step training strategy that helps to overcome the diversity between the generated pseudo training-data and the real one. Even though these above-mentioned methods can reveal the semantic of zero anaphoras by its context, they regard all the words equally, overlooking the diversity of different words. In this paper, we focus on exploring an effective way of modeling zero pronoun by using the associated texts. More specifically, we integrate a novel self-attentive mechanism, which provides our model an ability to focus on multi-aspects text, benefiting the encodings of zero anaphoras. In addition, by employing an attention-based technique for modeling candidates, our model learns to encode more informative parts of the mentions. All these bring advantages to the resolution of zero pronouns.

2.2 Zero Pronoun Resolution for other Languages

There has been a variety of work on zero pronoun resolution for other languages besides Chinese, such as Korean and Japanese. These methods could be categorized as rule-based and learning-based. Ferrández and Peral (2000) investigate a rule-based method that can encode preferences for candidates for resolving zero anaphoras in Spanish. In recent time, learning-based methods (Han, 2006; Iida and Poesio, 2011; Isozaki and Hirao, 2003; Iida et al., 2006; Iida et al., 2007; Sasano and Kurohashi, 2011; Iida and Poesio, 2011; Iida et al., 2015; Iida et al., 2016) have been well studied. Iida et al. (2016) present a novel CNN-based deep neural network model for intrasentential subjective zero anaphora resolution in Japanese. As clues, they use both the surface-word and the dependency tree-structure of a sentence. Their model gains higher precision, which is needed for real-world natural language processing (NLP) applications.

3 Methodology

We introduce an attention-based neural network model for anaphoric zero pronoun resolution. Compared to the prior studies that have the underutilized context of zero pronouns, we investigate an attention

mechanism that helps to effectively capture useful information from associate texts. We here present the methodology in details, which include the preliminary, the architecture of proposed attention-based neural network and training objective of the model.

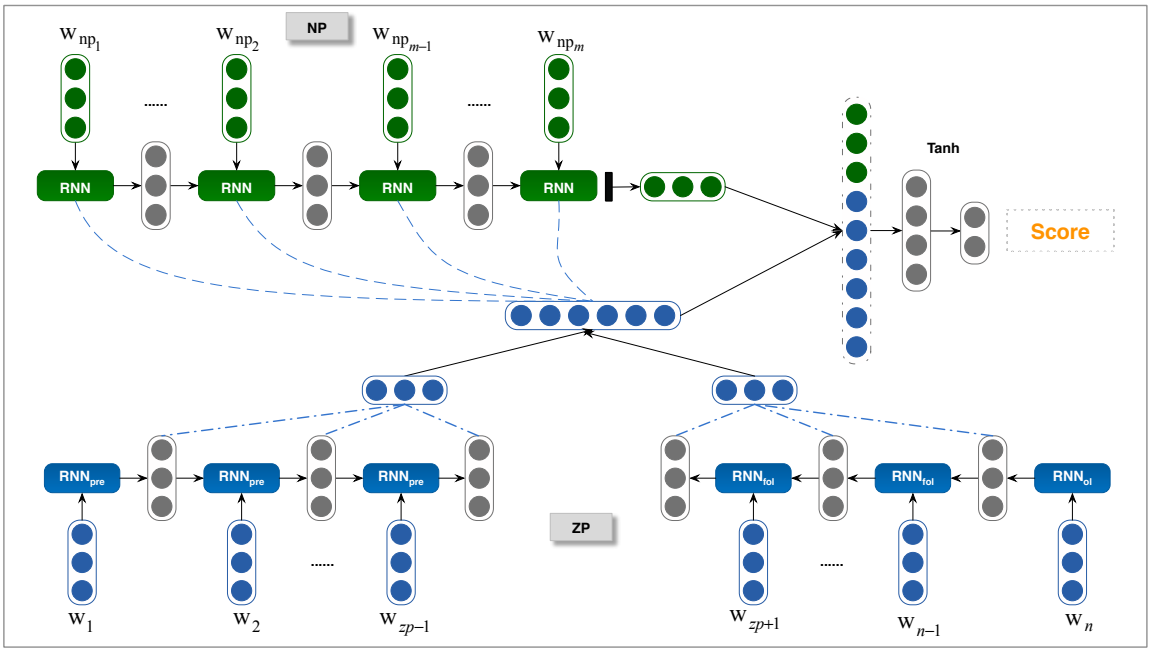

Figure 1: Framework of the proposed attention-based neural network for zero pronoun resolution. The w_i for zero pronoun part means the i-th word in the associated sentence, w_{zp-i} is the i-th word before the zero pronoun and w_{zp+i} is the i-th word behind the zero pronoun. w_{np_i} is the i-th word of the noun phrase. After generating the representative vector of zero pronoun and candidate mention, we generate its resolution score by going through two $tanh$ layers.

3.1 Preliminary

In the first place, we select its candidate mentions from the associated texts. More specifically, we choose the noun phrases that appear within two sentences from the zero anaphora to be the candidates. In addition, we choose the strategy used in prior approaches (Chen and Ng, 2016; Yin et al., 2017a) for Chinese zero pronoun resolution, reserving those mentions that are max noun phrases or modifier noun phrases as candidates. By doing so, we can recall most (about 98%) of the antecedents with a small loss. Then, what we desire the resolver to do is to accurately recognize antecedents for zp from its candidates list $NP = \{np_1, np_2, ..., np_n\}$.

Our model is basically a pair-wise model (Zhao and Ng, 2007; Chen and Ng, 2016; Yin et al., 2017b). For each candidate mention of zp, we classify it into two classifications, namely, "corefer" that means the candidate is the antecedent of the zero pronoun; or otherwise, "un-corefer". We build the classifier by applying the attention-based techniques. More specifically, an attention-based neural network model is utilized that generates the coreference score of each zero pronoun-candidate antecedent pair.

3.2 Attention-based Neural Network Model

In this part, we introduce our attention-based neural network for anaphoric zero pronoun resolution in detail. The architecture of our model is shown in Figure 1. For an anaphoric zero pronoun zp, we convert the input instances into real-valued vectors by using its context words. With the help of the self-attentive mechanism, our model learns to represent zero pronouns by focusing on different parts of contexts. In this way, we generate the representative vector of zp as v_{zp}. In addition, when dealing with candidate mentions, our model learns to encode the candidate mentions by using its informative content words. We here manipulate the v_{zp} as an external vector to attend to the informative parts of its candidate mentions.

By doing so, our model captures the important information of each candidate according to the zp. After that, we generate the representative vectors of candidates as $\{v_{np_1}, v_{np_2}, ..., v_{np_n}\}$. Lastly, we feed the representative vectors of the candidate and zero pronoun to a two-layer neural network, generating the resolution score for each zero pronoun-candidate antecedent pair. After that, we obtain the resolution probability for each candidate. The candidate mention with the biggest probability is regarded as the final result. Basically, our model involves three modules, namely, a zero pronoun encoder; a candidate antecedent encoder; and a feed-forward neural network that learns to score each candidate antecedent.

3.2.1 Modeling Zero Pronoun

Inspired by Lin et al. (2017), we investigate the self-attention mechanism when modeling zero anaphoras. In practice, we use two recurrent neural networks (RNNs) to encode the preceding and following texts of the zero anaphora (Yin et al., 2017a). The last hidden vectors of these two RNNs are concatenated as the vector-space semantic of the zero pronoun. On top of the employed recurrent neural network architecture, we apply the proposed attention technique that helps the model to capture the informative parts of associated texts.

Especially, our self-attention mechanism provides the attention-weight vectors for hidden states of the employed RNN architectures. We then dot these attention-weight vectors with counterpart hidden states and use the weighted summation vector as the representative vector for the zero pronoun. For a zero pronoun, we map its associated text words as sequential embeddings.

$$Context_{precedding} = (w_1, w_2, ..., w_{zp-1}) \tag{1}$$

$$Context_{following} = (w_{zp+1}, w_{zp+2}, ..., w_n) \tag{2}$$

where w_i is a d dimensional embedding for the ith word in the sentence. After that, we generate the representative vector of the preceding and the following text by using two separate RNNs:

$$h_t^{pre} = RNN_{pre}(w_t, h_{t-1}^{pre}) \tag{3}$$

$$h_t^{fol} = RNN_{fol}(w_t, h_{t-1}^{fol}) \tag{4}$$

where RNN_{pre} and RNN_{fol} are two employed RNNs that model the precedding and following context of the zero pronoun independently. After that, we get the hiddent vector for each word, which has the dimension of u. We represent all the hidden states of RNN_{pre} and RNN_{fol} as $H_{pre} \in \mathbb{R}^{n_{pre} \times u}$ and $H_{fol} \in \mathbb{R}^{n_{flo} \times u}$, seperately:

$$H_{pre} = \{h_1^{pre}, h_2^{pre}, ..., h_{n_{pre}}^{pre}\} \tag{5}$$

$$H_{fol} = \{h_1^{fol}, h_2^{fol}, ..., h_{n_{fol}}^{fol}\} \tag{6}$$

We then apply the self-attention mechanism, which computes linear-combinations of the hidden vectors in H_{pre} and H_{fol}. The attention mechanism takes H_{pre} (or H_{fol}) as the inputs and produces a matrix of attention-weight A_{pre} (A_{fol}):

$$A_{pre} = softmax(W_2^{pre} tanh(W_1^{pre} H_{pre}^T)) \tag{7}$$

$$A_{fol} = softmax(W_2^{fol} tanh(W_1^{fol} H_{fol}^T)) \tag{8}$$

where W_1 is a weight matrix with a shape of d_a-by-u and W_2 is in shape of r-by-d_a; r represents the number of hops of attention we choose. The $softmax()$ is performed along the second dimension of its input. In this way, the attention matrix A could be seen as a multi-hope attention matrix. Comparing with the single-attention matrix, such a mechanism enables our model to focus on different parts of the contexts, bringing a more efficient way of modeling sentence-level information for the zero pronoun at the semantic level.

We get the r weighted sums by multiplying the attention matrix A and hidden states H, regarding the resulting matrix as the representative vector of the zero pronoun's preceding and following texts:

$$M_{pre} = A_{pre} H_{pre} \tag{9}$$

$$M_{fol} = A_{fol} H_{fol} \tag{10}$$

Subsequently, we obtain the representative vectors of the associated text of the zero pronoun by averaging the row vectors in each representative matrix (namely, M_{pre} and M_{fol}). After that, these two vectors are concatenated as the representative vector of the zero pronoun. Our experiments show that the attention-based model leads to a considerable improvement from the non-attentive model, indicating that the self-attention mechanism can help to better encode the zero pronoun, focusing on informative parts of the associated texts.

3.2.2 Modeling Candidate Antecedent

We here build the candidate antecedent encoder by using an RNN architecture, whose input is comprised by the words in the candidate antecedent. In an effort to better align the more informative parts of phrases to the anaphoric zero pronoun, we here integrate an attention technique into our model. In this work, we use a gating-function as our attention mechanism. Especially, given the representative vector of the anaphoric zero pronoun $v^{(zp)}$, the output vector and input embedding vector of RNN in the candidate mention part at time t, $h_t^{(np)}$ and e_t, the attention mechanism computes a gate as: $attention_t = att(e_t, h_t^{(np)}, v^{(zp)})$, where att is defined as:

$$s_t = tanh(W^{(att)} \cdot [e_t; h_t^{(np)}; v^{(zp)}] + b^{(att)}) \tag{11}$$

$$attention_t = \frac{exp(s_t)}{\sum_{t'=1}^{m} exp(s_{t'})} \tag{12}$$

where $W^{(att)}$ and $b^{(att)}$ are parameters to be learned, m is the number of words in the mention. After that, we regard the averaged attention-hidden vector as the vector-space semantic of the candidate antecedent, which takes considerations of a hierarchy of historical semantic:

$$\tilde{v}_{np} = \sum_{i=1}^{m} h_i^{(np)} * attention_i \tag{13}$$

3.2.3 Calculating Resolution Scores

After generating the representive vector of zero pronoun, v_{zp} and vectors of its candidates $\{\tilde{v}_{np1}, \tilde{v}_{np2}, ..., \tilde{v}_{npn}\}$, we calcualte the resolution score for each zero pronoun-candidate antecedent by using a two-layers feed-forwd nerual network. Taking v_{zp} and its i-th candidate mention v_{np_i} as inputs, our model calcuate the resolution score by going through two $tanh$ layers:

$$s_j = tanh(W_i^{(s)} \cdot s_{j-1} + b_j^{(s)}) \tag{14}$$

where $s_0 = [v(zp); v(np_i); v_i^{(fe)}]$, $W^{(s)}$ and $b^{(s)}$ are the parameters of this feed-forward neural network. In addition, to better capture the syntactics, position and other relations between an anaphoric zero pronoun and its candidates, we encode hand crafted features ($v^{(fe)}$) as inputs to our neural network model. We utilize the features from exsiting work on zero anaphora resolution (Chen and Ng, 2013; Chen and Ng, 2016), map them into vectors to estimate the resolution score for the zero pronoun-candidate mention pair as:

$$score_i = W^{(sco)} \cdot s_{-1} + b^{(sco)} \tag{15}$$

where $score_i$ denotes the probability of the i-th candidate mention (np_i) being predicted to be the antecedent, and s_{-1} is the output vector of the second hidden layer. After that, we obtain the resolution scores for all the candidates $\{score_1, score_2, ..., score_n\}$. The candidate mention with the biggest score is eventually selected to be the antecedent of the anaphoric zero pronoun.

3.3 Training Objective

Same as Yin et al. (2017b), we train our model by minimizing the cross entropy error of coreference classification. The training objective is defined as:

$$loss = -\sum_{t \in T} \sum_{np \in NP} \delta(zp, np) \log(P(zp, np)) \tag{16}$$

where T represents all training instances, NP is the candidate-set of the anaphoric zero pronoun zp; $\delta(zp, np)$ represents the coreference of zp and its candidate mention np: if they are coreference, $\delta(zp, np) = 1$ or otherwise, $\delta(zp, np) = 0$.

4 Experiments

4.1 Experiment Setup

4.1.1 Evaluation Metrics

Same as early work on Chinese zero pronoun resolution (Zhao and Ng, 2007; Chen and Ng, 2016; Yin et al., 2017a; Yin et al., 2017b), we manipulate to evaluate the quality of our model by Recall, Precision and F-score (denoted as F). More specifically, recall and precision are defined as:

$$Recall_{Res} = \frac{\#\ Res\ Hit}{\#\ AZP\ in\ Key} \tag{17}$$

$$Precision_{Res} = \frac{\#\ Res\ Hit}{\#\ AZP\ in\ Predictions} \tag{18}$$

where a "Res Hit" means that the anaphoric zero pronoun is successfully identified and successfully resolved to a candidate mention that is in the same coreference chain as in the golden answer key annotated in the dataset.

4.1.2 Experiment Settings

Same to existing work on Chinese zero pronoun resolution (Chen and Ng, 2016; Yin et al., 2017a; Yin et al., 2017b), we run experiments on the Chinese part of the OntoNotes-5.0 dataset[1] used in the Conll-2012 task. Because zero pronoun coreferences are only annotated in the training and development set, we thus train our model on the training dataset and evaluate the model on the development dataset. Table 1 is the statistics of our dataset.

	Documents	Sentences	Words	Anaphoric Zero Pronouns
Training	1,391	36,487	756K	12,111
Test	172	6,083	110K	1,713

Table 1: Statistics on the training and test dataset.

We use the recent zero pronoun resolution systems for Chinese as our baselines, namely, a learning-based model (Zhao and Ng, 2007); an unsupervised method (Chen and Ng, 2015); and others are deep-learning-based methods (Chen and Ng, 2016; Liu et al., 2017; Yin et al., 2017a; Yin et al., 2017b). As we are focusing on the anaphoric zero pronoun resolution, we run experiments by directly employing golden parse tree and golden anaphoric zero pronouns that are annotated in the dataset. In addition, documents in the datasets are from 6 sources: **BN** (Broadcast News), **NW** (Newswire), **BC** (Broadcast Conversation), **WB** (Web Blog), **TC** (Telephone Conversation) and **MZ** (Magazine). We report the overall results on the complete test dataset and also the result from the different source of the dataset.

[1] `http://catalog.ldc.upenn.edu/LDC2013T19`

	NW (84)	MZ (162)	WB (284)	BN (390)	BC (510)	TC (283)	**Overall**
Zhao and Ng (2007)	40.5	28.4	40.1	43.1	44.7	42.8	41.5
Chen and Ng (2015)	46.4	39.0	51.8	53.8	49.4	52.7	50.2
Chen and Ng (2016)	48.8	41.5	56.3	55.4	50.8	53.1	52.2
Yin et al. (2017b)	50.0	45.0	55.9	53.3	55.3	54.4	53.6
Yin et al. (2017a)	48.8	46.3	59.8	58.4	53.2	**54.8**	54.9
Liu et al. (2017)	59.2	51.3	60.5	53.9	55.5	52.9	55.3
Our model	**64.3**	**52.5**	**62.0**	**58.5**	**57.6**	53.2	**57.3**

Table 2: Experiment results on the test dataset, including the results on the overall dataset and different sources of the dataset. The first six columns show the results on the different source of documents and the last is the overall result. The strongest F-score in each row is in **bold**. The parenthesized number beside a source's name is the number of anaphoric zero pronouns in that source.

4.2 Hyperparameter

To tune the hyperparameters of our model, 20% of the training dataset are reserved as a held out development set. Such a strategy is also utilized in the baseline systems (Chen and Ng, 2016; Yin et al., 2017a). We randomly initialize the parameters and minimize the loss-function by Adagrad (Duchi et al., 2011) with learning-rate 0.003. The input embedding vector dimension is 100, the dimension of hidden layer of RNNs (namely, the u) is 256 and d_a is 128. Besides, we fix the dimensions of two hidden layer of the feed-forward neural network to 256 and 512. We add the dropout (Hinton et al., 2012) with a probability of 50% on the output of each layer. The code for this work is released in `https://github.com/qyyin/AttentionZP.git`.

4.3 Experiment Results

We report the experiment results (F-score) of our model and the baselines in Table 2. The number of hops of attention is fixed to be 2 ($r = 2$), where we gain the best result. We report the overall results on the complete test dataset and also the results for each source of documents. As we can observe that our model gains 57.3% in overall F-score, which significantly beats the best baseline system (Liu et al., 2017) by 2.0%. In addition, we run experiments on different sources of test corpus, as shown in the first six columns Table 2. The parenthesized number beside a source's name represents the number of anaphoric zero pronouns in that source. We can observe that our model improves performance significantly in 5 of 6 sources of the dataset. More specifically, our model beats the best baseline (Liu et al., 2017) on all documents in F-score: by 5.1% (source NW), 1.2% (source MZ), 1.5% (source WB), 4.6% (source BN), 2.1% (source BC) and 0.3% (source TC). The main reason why our model gains worse performance on source "TC" lie in the short length of text in this source, which makes our model hard to learn to capture useful information for expressing the zero pronouns. Besides, there are full of numerous verbose words such as "呃/Er", "哟/Yo", which brings difficulties for our model to accurately encode a zero pronoun by focusing on its informative contexts. More efforts could be performed in order to encode the associated text of a zero pronoun in a more efficient way, modeling word-sequences beyond the sentence boundary, for instance.

We show in Figure 2 the learning curve of our model on the development dataset. As we can observe, after the first epoch, the F-score on the test dataset is about 46%, and it gradually grows to 52% after about 30 iterations when performance starts to plateau. It is well accepted that modeling useful parts of associated text play an important role in encoding the zero pronouns. By applying the self-attentive mechanism, our model learns to focus on important parts of the contexts, revealing multi-aspect sentence-level information in a more efficient way than those without attention. On the other side, by assigning different attention to the words in a candidate mention with respect to the information of the counterpart zero pronoun, our model learns to encode candidate mentions in a more natural way. Hence, both of them bring benefit to selecting accurate antecedents, leading to better performance.

In addition, having multi-aspect sentence-level information is expected to afford more abundant in-

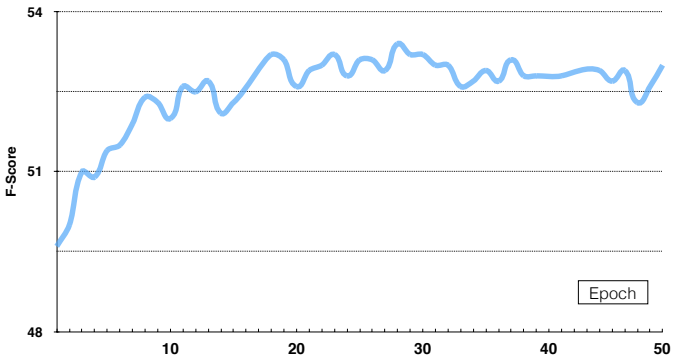

Figure 2: Learning curve of our model on the development dataset.

formation about the encoded zero pronoun, we thus evaluate how the improvement can be brought by tuning r in the self-attentive mechanism. We vary r from 2 to 6, as is shown in Figure3. We can observe that the best performance is reached when $r = 2$. The results are not confusing because we are tried to focus on the informative part for zero pronouns, and we cut the sentence into two separate parts that are zero pronoun-centric, when $r = 2$ means to attend on totally 4 parts of the sentence, thus our model performances well in this situation.

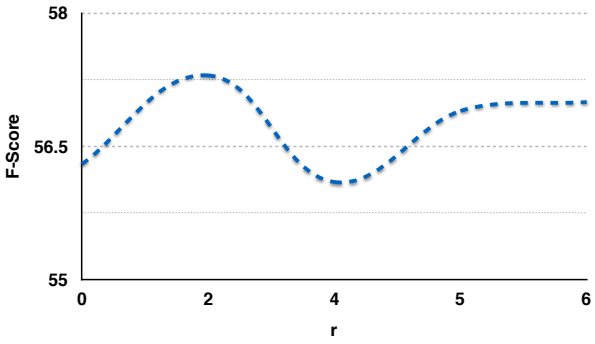

Figure 3: Effect of tuning r for encoding zero pronouns.

For illustrating the effect of the proposed attention mechanism for zero pronoun and candidate mentions, we also run an experiment without applying the attention mechanism for both zero pronouns and candidates, which is $r = 0$ in Figure 3. As we can observe that the performance drops by removing the attention mechanism. For the model without the attentive mechanism, the performance drops by 0.9% in F-score compared with that of the full model. Because that the proposed self-attentive mechanism for zero pronoun brings our model an ability to access multi-aspect sentence-level information, removing such an architecture unsurprising influences the results significantly. With an inspiration that not all the words are equally important for explaining the mention, the performance of removing the attention for candidate mentions is reasonable weak. All these show the benefit of our attention-based model.

Lastly, we give a case study to illustrate the power of our self-attentive mechanism, as is shown in Figure 4. From the figure, we can tell that the model successfully focuses on informative parts of the texts. Though there are redundancies between different hops of attention, our model can capture useful information for explaining the zero pronoun (denoted as "*pro*" in the picture). Our model learns to focus on the informative words such as "数字证书/digital certificate", which is essential for expressing the zero pronoun.

Figure 4: Heat maps of our attention-based model. In this case, we show the detailed attention weight taken by the attention matrix taken by the attention matrix ($r = 2$). Darker color means higher weight.

5 Conclusion

We proposed a novel attention-based neural network model for Chinese zero pronoun resolution. Using recent advances in attention mechanism, we developed a self-attentive architecture for modeling zero pronouns, which enables our model to focus on parts of the associated texts. In addition, we also investigated an attention-based candidate antecedent encoder that learns to model important parts of the noun phrases with respect to the representative vector of zero anaphoras. Our experiments demonstrated that our method significantly surpasses the state-of-the-art on a benchmark dataset for anaphoric zero pronoun resolution. Future work will evaluate our model on other natural language processing problems, such as anaphora resolution for Chinese and English. We also plan to investigate training the anaphora-specific embedding that could better reveal the descriptive attribute for the zero anaphoras.

Abstract

This paper analyzes arguably the most challenging yet under-explored aspect of resolution tasks such as coreference resolution and entity linking, that is the resolution of plural mentions. Unlike singular mentions each of which represents one entity, plural mentions stand for multiple entities. To tackle this aspect, we take the character identification corpus from the SemEval 2018 shared task that consists of entity annotation for singular mentions, and expand it by adding annotation for plural mentions. We then introduce a novel coreference resolution algorithm that selectively creates clusters to handle both singular and plural mentions, and also a deep learning-based entity linking model that jointly handles both types of mentions through multi-task learning. Adjusted evaluation metrics are proposed for these tasks as well to handle the uniqueness of plural mentions. Our experiments show that the new coreference resolution and entity linking models significantly outperform traditional models designed only for singular mentions. To the best of our knowledge, this is the first time that plural mentions are thoroughly analyzed for these two resolution tasks.

1 Introduction

Resolution tasks such as coreference resolution and entity linking are challenging because they require a holistic view of a document (or across multiple documents) to find correct entities. Although many models have been proposed for these tasks (Clark and Manning, 2016; Francis-Landau et al., 2016; Wiseman et al., 2016; Gupta et al., 2017; Lee et al., 2017), most of them are focused on singular mentions such that they are insufficient for resolving the other type of mentions, plural, although the amount of plural mentions is not negligible in practice.[1] Table 1 illustrates how mentions are annotated for coreference resolution by the CoNLL'12 shared task (Pradhan et al., 2012) and our proposed work. In the CoNLL'12 annotation, the plural mention *They*$_8$ is grouped with the noun phrase [*Mary*$_1$ and *John*$_2$]$_3$; however, the other plural mention *We*$_7$ becomes a singleton because there is no noun phrase representing such an entity. Since CoNLL'12 limits each plural mention to be linked to a single noun phrase, it loses connections to individual entities that exist within the document but not grouped as a noun phrase.

Document	[*Mary*$_1$ and *John*$_2$]$_3$ came to see *me*$_4$ yesterday. *She*$_5$ looked happy, and so did *he*$_6$. *We*$_7$ had a great time together. *They*$_8$ left around noon.
CoNLL'12	{*Mary*$_1$, *She*$_5$}, {*John*$_2$, *he*$_6$}, {[*Mary*$_1$ and *John*$_2$]$_3$, *They*$_8$}, {*me*$_4$}, {*We*$_7$}
Our Work	{*Mary*$_1$, *She*$_5$, *We*$_7$, *They*$_8$}, {*John*$_2$, *he*$_6$, *We*$_7$, *They*$_8$}, {*me*$_4$, *We*$_7$}

Table 1: Snippets of how mentions are annotated by the CoNLL'12 shared task and our work.

In our work, the plural mentions *We*$_7$ and *They*$_8$ are linked to multiple entities that those mentions refer to. This allows higher-level NLP tasks such as question answering or machine translation to reason more explicitly about those entities while adding another level of challenges to the resolution tasks. In this paper, we first present the annotation scheme for resolving plural mentions that is used to expand the corpus

[1] A singular mention is a noun phrase that refers to exactly one entity while a plural mention is one that refers to multiple entities.

Proceedings of the 27th International Conference on Computational Linguistics, pages 24–34
Santa Fe, New Mexico, USA, August 20-26, 2018.

provided by the Character Mining project (Section 3). We then introduce a novel algorithm for coreference resolution that selectively creates clusters for singular and plural mentions, as well as evaluation metrics to handle plural mentions for coreference resolution (Section 4). We also present a new deep learning-based entity linking model that jointly identifies both singular and plural mentions (Section 5). All models are evaluated on our dataset (Section 6); the experiments reveal significant improvement from our new models compared to the previous state-of-the-art models dedicated for singular mentions. As far as we can tell, this is the first time that such annotation for plural mentions is provided in a large enough scale that deep learning models can be trained on, at the same time, machine learning models are developed to achieve promising results for the resolution of plural mentions.

2 Related Work

Chen and Choi (2016) were the first to introduce the task of character identification and provided a new corpus based on TV show transcripts. Given a dialogue transcribed in text where all mentions are detected, character identification aims to find the entity for each personal mention, who may or may not be active in the dialogue. Unlike most other entity linking tasks focusing on Wikification, this task is challenging because it is dialogue-based where the entities are general characters in the show. This corpus was later expanded by Chen et al. (2017) who added annotation for the ambiguous entity types. In this work, we expanded the corpus further by doubling the size of the annotation and adding new annotation for plurals.

The character identification corpus can be used for both coreference resolution and entity linking tasks. Our approach to coreference resolution was partially motivated by the previous works, Clark and Manning (2016) and Durrett et al. (2013), who tackled the general cases of coreference resolution including plurals; however, since their approaches were based on the annotation provided by CoNLL'12, they did not handle plural mentions to our satisfaction (Table 1). Jain et al. (2004) presented a rule-based system for resolving plural mentions, which was limited to unambiguous plural types. Our work is distinguished because we handle both ambiguous and unambiguous types of plural mentions, which makes it more challenging. Chen et al. (2017) presented an entity linking model that identified the real entity of each singular mention, which we adapted to develop a new multi-task learning model that jointly handles singulars and plurals.

3 Corpus

3.1 Annotation

The Character Mining project provides transcripts from the TV show *Friends* for all ten seasons in JSON.[2] A subset of the first two seasons of this show was annotated for the task of character identification by Chen et al. (2017), who made it publicly available through the International Workshop on Semantic Evaluation (SemEval 2018).[3] Given this annotation, we expanded the corpus as follows:

1. We realized that about 20% of the first two seasons were not covered by the previous annotation. Following the annotation guidelines suggested by Chen et al. (2017), we completed the annotation for the first two seasons and further annotated two more seasons. As a result, the first four seasons are completely annotated for character identification in our corpus.

2. There were quite a few mismatches among the speaker and the entity labels in the previous annotation. For instance, while mentions were annotated by the entity's full name such as `Monica_Geller`, some utterances were paired with speaker labels represented by only the first name, `Monica`, which could cause confusions for machine learning models. We manually went through the entire annotation and made sure the speaker and the entity labels were coherent across all seasons.

3. The previous annotation consisted of only singular mentions such that each mention was guaranteed to be linked to exactly one entity. We annotated plural mentions for the first four seasons through crowdsourcing. Unlike singular mentions that were automatically recognized by the heuristic-based

[2]Character Mining: `https://github.com/emorynlp/character-mining`
[3]SemEval 2018 Task 4: `https://competitions.codalab.org/competitions/17310`

mention detector (Chen and Choi, 2016), plural mentions in our corpus were manually detected by the crowd workers who were also asked to link each plural mention to a set of its referent entities.

The annotation guidelines used for singular mentions are adapted to annotate plural mentions as well such that the only difference in annotation between these two types of mentions is the number of entities to which the mentions refer. Formally, each mention m is annotated with a set of entities E, where each element in E belongs to one of the following four groups:

1. Known entities: include all the primary and secondary characters recurring in the show.
2. `GENERIC`: indicates actual characters in the show whose identities are unknown across the show: e.g., That *waitress* is really cute, I am going to ask *her* out.
3. `GENERAL`: indicates mentions referring to a general case rather than a specific entity: e.g., The ideal *guy* you look for doesn't exist.
4. `OTHER`: indicates actual characters in the show whose identities are unknown in this dialogue but revealed in some other dialogue.

The `COLLECTIVE` type, used to distinguish the plural usage of the pronoun *you* in the previous annotation, is discarded in our annotation because each *you* is now annotated with a set of entities such that the plural usage can be deterministically distinguished by the size of its entity set.

Speaker	**Utterance**
Jack	And I_1 read about these *women*$_2$ trying it all, and I_3 thank God '*Our*$_4$ *Harmonica*$_5$' doesn't have this problem.
Monica	So, *Ross*$_6$, what's going on with *you*$_7$ two? Any stories? No little anecdotes to share with *mom*$_8$ and *dad*$_9$?
Ross	Okay, I_{10} just got this from the *guy*$_{11}$ next to *me*$_{12}$. *He*$_{13}$ was selling a whole bunch of stuff.

$\{I_1, I_3, Our_4, dad_9\} \rightarrow$ `Jack` $\{Our_4, mom_8\} \rightarrow$ `Judy`, $\{Harmonica_5\} \rightarrow$ `Monica`, $\{Ross_6, you_7, I_{10}, me_{12}\} \rightarrow$ `Ross`, $\{women_2\} \rightarrow$ `GENERAL`, $\{you_7\} \rightarrow$ `OTHER`, $\{guy_{11}, He_{13}\} \rightarrow$ `MAN_1`

Table 2: An example of entity annotation in our corpus, where *Our*$_4$ and *you*$_7$ are the plural mentions.

Table 2 shows examples of all types of entities for both singular and plural mentions. The mention *women*$_2$ does not refer to any specific character so it is identified as `GENERAL`. Both the mentions *guy*$_{11}$ and *He*$_{13}$ refer to a specific person whose identity is never revealed so it is annotated with the generic type, `MAN_1`. There are two plural mentions, *Our*$_4$ and *you*$_7$, which are handled differently. All entities of *Our*$_4$ can be identified from the context of this dialogue so it is annotated with the known entities `Jack` and `Judy`. However, only one of *you*$_7$ can be identified in this context so it is annotated with the known entity `Ross` and also `OTHER`, implying that it refers to some other entity that can be identified in a separate dialogue. This method is used to distinguish non-immediately identifiable entities from the generic case of `MAN_1` whose identity is unknown across the entire show.

3.2 Analytics

Table 3 shows the statistics of our corpus. Compared to the previous annotation including 18,608 mentions, our corpus is comprised of 47,367 annotated mentions, which is 2.5 times larger. Plural mentions together compose about 9% of the entire dataset, which is significant enough to make a difference in resolution. Each cluster contains about 6 mentions on average when each scene is treated as an independent dialogue.

All mentions were double-annotated by crowd workers. From this double-annotation, Cohen's kappa score of 56.88% was achieved for plural mentions, which was about 20% lower than the one achieved for singular mentions (Chen and Choi, 2016). The lower inter-annotator agreement was expected due to the high complexity of this task. A subset of the disagreed annotation was manually adjudicated by experts, from which we found that taking the union of the entity sets annotated by two workers would effectively give the correct set of entities for each of those disagreed plural mentions. Thus, a vast amount of plural mentions were pseudo-adjudicated by taking their unions of double-annotation.

Season	General				Mention			Entity	
	Episode	Scene	Utterance	Speaker	Singular	Plural	Total	Cluster	Type
1	24	326	5,968	107	10,313	1,147	11,460	2,162	270
2	24	293	5,747	107	10,521	1,156	11,677	1,934	285
3	25	348	6,495	108	11,458	907	12,365	1,925	230
4	24	334	6,318	100	10,726	1,139	11,865	1,881	175
Total	97	1,301	24,528	331	43,018	4,349	47,367	7,902	781

Table 3: The overall statistics of our corpus. All columns show raw counts except that the speaker column and the type column in the entity section give the set counts of all speakers and entities, respectively.

Table 4 shows the distributions of entity types. The primary characters compose about 67% of all mentions whereas the ambiguous types together compose about 8.6%, which implies that the majority of mentions can be linked to known entities. Notice that the total count of `GENERAL` increases by 554 from Seasons 1-2 to 3-4, whereas the total count of `OTHER` decreases by 654 for those seasons; these two ambiguous entity types are easily confused because they do not refer to any specific entity within the dialogue. Considering that annotation tasks for the first two seasons were mostly conducted by Chen et al. (2017) whereas the next two seasons were conducted by us, it is possible that our crowdsourcing instructions were more biased towards `GENERAL` than `OTHER`, which we will analyze in the future.

Season	Known Entities		Ambiguous Entities			Total
	Primary	Secondary	`GENERIC`	`GENERAL`	`OTHER`	
1	9,247	3,616	214	641	463	14,181
2	9,591	3,704	184	598	455	14,532
3	9,491	3,512	200	896	136	14,235
4	9,807	3,181	112	897	128	14,125
Total	38,136	14,013	710	3,032	1,182	57,073

Table 4: The distributions of entity types. Each column shows the number of mentions annotated with the corresponding entity type. Note that the total number of mentions here is different from the one in Table 3 (57,073 vs. 47,367) because each plural mention is counted more than once in this table.

4 Coreference Resolution

The presence of plural mentions brings up several challenges for coreference resolution. First, the search scope becomes broader. For each mention m_j, a typical coreference resolution system would find another mention m_i that is referent to m_j, and assigns m_j to the cluster C_i that m_i belongs to if it exists; otherwise, creates a new cluster and assigns both m_i and m_j to that cluster.[4] As soon as m_j is assigned, the search can stop for m_j. This strategy works for singular mentions but fails with plural mentions because they can be assigned to more than one cluster. Second, the referent relations are no longer transitive. Let $m_i \leftarrow m_j$, $m_i \rightarrow m_j$, $m_i \leftrightarrows m_j$ stand for referent relations such that m_j is referent to m_i, m_i is referent to m_j, m_i is coreferent to m_j, respectively. Then, $m_i \leftrightarrows m_j$ and $m_j \leftrightarrows m_k$ would imply $m_i \leftrightarrows m_k$ for singular mentions, but this transitivity fails with plural mentions when m_j belongs to two different clusters $C_i = \{m_i, m_j\}$ and $C_k = \{m_j, m_k\}$ such that m_i and m_k have no referent relation. Third, some of the popular evaluation metrics for coreference resolution such as B^3 (Bagga and Baldwin, 1998) are not necessarily designed for plural mentions such that they need to be revisited.

Section 4.1 introduces our new coreference resolution algorithm that selectively creates clusters with respect to different mention types. This algorithm ensures singular mentions representing different entities get assigned to separate clusters. For example, let m_p be a plural mention and m_i be a singular mention such that $m_p \rightarrow m_i$. When the referent relation is found, the cluster C_i is created and both m_p and m_i are assigned to C_i. Let m_j be another singular mention such that $m_p \rightarrow m_j$. Now, the algorithm must decide

[4]The term 'cluster' indicates a group of mentions that refer to the same entity within a document such that each cluster represents a distinct entity although a cluster in one document can represent the same entity as another cluster in a different document.

whether to assign m_j to C_i or create another cluster C_j for m_j. If $m_i \leftrightarrows m_j$, m_j should be assigned to C_i; otherwise to C_j. Our algorithm allows a model to learn this decision during training so that the clusters can be created accordingly during decoding. Section 4.3 describes how existing evaluation metrics can be adjusted to evaluate both singular and plural mentions for coreference resolution, which is the first time that these metrics are adapted for plural mentions linked to multiple entities.

4.1 Algorithm

For each mention m_j, our algorithm compares it against all of the preceding mentions m_i to determine whether or not they are referent, where i and j are the ordered indices such that $0 < i < j$. Additionally, two more mentions, m_g and m_o, are compared to m_j that represent the `GENERAL` and the `OTHER` types, respectively (Section 3.1). For each mention pair (m_i, m_j), the algorithm assigns one of the following three labels for multi-classification:

1. `N`: m_i is not referent to m_j.
2. `L`: m_j gets assigned to the cluster that m_i belongs to. If m_i does not yet belong to any cluster, a new cluster C_i is created and both m_i and m_j are assigned to C_i.
3. `R`: m_i gets assigned to the cluster that m_j belongs to. If m_j does not yet belong to any cluster, a new cluster C_j is created and both m_i and m_j are assigned to C_j.

During training, labels are determined by consulting the oracle. `L` is labeled if m_i is a singular mention. `R` is labeled if m_i is plural and m_j is singular. `N` is labeled for all the other cases. Notice that this algorithm does not allow any plural mention to be directly linked to another plural mention; in other words, it does not create any cluster consisting of only plural mentions. Plural mentions can still be indirectly linked through clusters created for singular mentions. The creation of clusters comprising only plural mentions would not help identifying the known entities of those mentions, which defeats the purpose of character identification. It is possible to link plural mentions directly by using the `GENERIC` type (Section 3.1), which is not adapted to annotate entities for plural mentions in the current annotation scheme.

$[m_i] \rightarrow \{$**N, L, R**$\}$	m_j	**Clusters**
[G, O] → N	1	$\emptyset_g, \emptyset_o$
[O, 1] → N, [G] → L	2	$\{2\}_g, \emptyset_o$

Table 5: A demonstration of our algorithm using the example in Table 2. The m_j column indicates the index of m_j that the algorithm is currently processing. The first column shows the labels generated for all mention pairs (m_i, m_j), where the indices of m_i are indicated inside the square brackets (e.g, [O, 1] stands for m_o and m_1) and the labels are indicated next to the right arrows (e.g., → L). The clusters column shows the list of entity sets created by taking the labeling information from the first column.

Table 5 depicts how this algorithm finds the referent relations for all the mentions in Table 2. Note that the special mentions m_g and m_o are considered singular and placed prior to any other mention here. The algorithm labels `L` for (m_g, m_2), which makes *women*$_2 \in C_g$ representing `GENERAL`. For m_4, it labels `L`

for m_1 and m_2, which makes *Our*$_4$ $\in C_1$ representing JACK; although *Our*$_4$ is a plural mention, it gets assigned to only one cluster at the moment since the other entity has yet been revealed. For m_7, it labels L for both m_o and m_6, which makes *you*$_7$ $\in C_o$ representing OTHER and $\in C_6$ representing Ross. For (m_4, m_8), it labels R because m_4 is plural and m_8 is singular, which creates a new cluster C_8 and assigns both *Our*$_4$ and *mom*$_8$ to C_8. Once all mention pairs are compared, the algorithm collects mentions that are not assigned to any cluster, and makes them singletons such that *Harmonica*$_5$ becomes the singleton C_5. Furthermore, every mention that belongs to either C_g or C_o gets turned into a singleton such that C_2 and C_7 are created at the end. This is because mentions assigned to those ambiguous types are not referent to one another, if they were, they would have been assigned to GENERIC instead.

4.2 Learning Model

Our learning model uses a modified version of the Agglomerative Convolutional Neural Networks (ACNN) introduced by Chen et al. (2017). This architecture incorporates multiple sets of features and learns the most optimized feature combination at each convolution layer. It also allows the model to dynamically accumulate the most salient features for eventual inclusion in the mention and mention pair embeddings. ACNN takes a mention pair (m_i, m_j), performs multiple convolutions to extract features from different groups (CONV$_1$), combines the extracted features among groups using more convolutions (CONV$_2$), and generates mention embeddings $r_s(m_i)$ and $r_s(m_j)$. These mention embeddings are then concatenated with discrete features $\phi_d(m)$ and combined through convolutions to generate a mention-pair embedding $r_p(m_i, m_j)$. The mention-pair embedding together with pairwise features $\phi_p(m_i, m_j)$ are used to make a binary classification for m_i and m_j being referent or not.

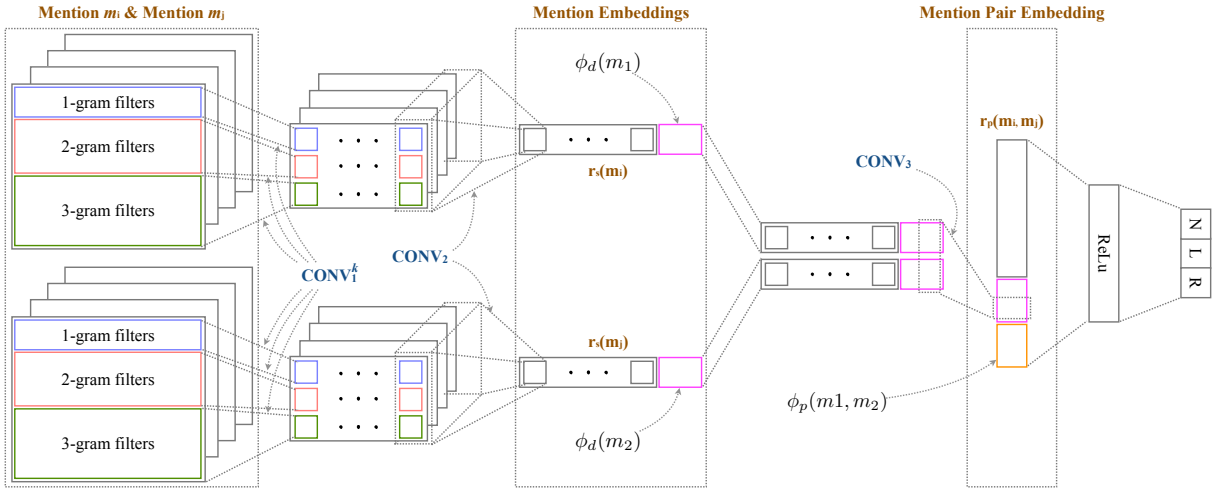

Figure 1: The overview of our coreference resolution model using the multi-class ACNN.

To be adapted to our coreference resolution algorithm in Section 4.1, ACNN is modified at the output layer to include three labels, N, L, and R, such that it is optimized for multi-class instead of binary classification. The modified ACNN, called the multi-class ACNN, generates mention embeddings, $r_s(m_i)$ and $r_s(m_j)$, as well as mention pair embeddings, $r_p(m_i, m_j)$, which are used to create cluster embeddings and fed as input to our entity linking model in Section 5.1.

4.3 Evaluation Metrics

Three metrics proposed by the CoNLL'12 shared task (Pradhan et al., 2012), B^3, CEAF$_{\phi_4}$, and BLANC, are used to evaluate our coreference resolution models. B^3 (Bagga and Baldwin, 1998) is a mention-based metric that measures precision (P) and recall (R) as follows (D: a set of documents, N: the total number of mentions in D, $C_m^{s/o}$: the cluster from the system (s) or the oracle (o) that the mention m belongs to):

$$P = \frac{1}{N} \sum_{d \in D} \sum_{m \in d} \frac{|C_m^s \cap C_m^o|}{|C_m^s|} \qquad R = \frac{1}{N} \sum_{d \in D} \sum_{m \in d} \frac{|C_m^s \cap C_m^o|}{|C_m^o|}$$

In our case, each mention can be assigned to more than one cluster; thus, C^*_m is replaced by the union of all clusters that the mention m belongs to, which enables this metric to evaluate plural mentions.

CEAF$_{\phi_4}$ (Luo, 2005) is an entity-based metric that first creates a similarity matrix $M \in \mathbb{R}^{|S|\times|O|}$ where S and O are the sets of clusters produced by the system and the oracle, respectively. It then measures the similarity between every pair of clusters $(C^s, C^o) \in S \times O$ where $s \in [1, |S|]$ and $o \in [1, |O|]$ such that:

$$M_{s,o} = \frac{2 \times |C^s \cap C^o|}{|C^s| + |C^o|}$$

Given this similarity matrix, the Hungarian algorithm is used to find the list $\mathcal{H}$ that contains similarity scores from the most similar matching pairs of clusters $(C^s, C^o) \in S \times O$ such that $|\mathcal{H}| = \min(|S|, |O|)$. Finally, the overall similarity between S and O is measured as $\Phi = \sum_{\phi\in\mathcal{H}} \phi$, and precision and recall are measured as $P = \Phi/|S|$ and $R = \Phi/|O|$, respectively. Since CEAF$_{\phi_4}$ is entity-based, the metric can be used to evaluate plural mentions without any modification. The potential pitfall is that certain clusters may include a greater number of plural mentions than singular mentions, in which case, distinct clusters with similar sets of plural mentions may yield a high similarity score. However, plural mentions make up less than 10% of the dataset, so we are not concerned about these plural-majority clusters, since most if not all clusters would be dominated by singular mentions.

BLANC (Recasens and Hovy, 2011) is a link-based metric. Let L_s and L_o be the sets of links generated by the system (s) and the oracle (o), respectively. Let G be the set of all possible links between every pair of mentions whether or not they are referent. This metric first creates a confusion matrix $B \in \mathbb{R}^{2\times2}$ such that $B_{0,0} = |L_s \cap L_o|$, $B_{0,1} = |L_o - L_s|$, $B_{1,0} = |L_s - L_o|$, and $B_{1,1} = |(G - L_s) \cap (G - L_o)|$. It then measures precision and recall for referent links (P_c and R_c) and also for non-referent links (P_n and R_n):

$$P_c = \frac{B[0,0]}{B[0,0] + B[1,0]} \quad R_c = \frac{B[0,0]}{B[0,0] + B[0,1]} \quad P_n = \frac{B[1,1]}{B[1,1] + B[0,1]} \quad R_n = \frac{B[1,1]}{B[1,1] + B[1,0]}$$

$$F1_c = \frac{2 \times P_c \cdot R_c}{P_c + R_c} \qquad F1_n = \frac{2 \times P_n \cdot R_n}{P_n + R_n}$$

Finally, precision, recall, and F$_1$-score are measured as $P = {}^{P_c+P_n}/_2$, $R = {}^{r_c+r_n}/_2$, and $F_1 = {}^{F1_c+F1_n}/_2$. Note that we decide to replace MUC (Vilain et al., 1995), another popular metric used by the CoNLL'12 shared task, with BLANC because both are link-based and BLANC takes singletons into consideration, which consume a large portion of our dataset (over 20%), whereas MUC does not so that BLANC is more appropriate for our case. It is worth mentioning that a separate confusion matrix B_d is constructed for each document d such that $B = \sum_{d\in D} B_d$ where B_d is based on links only in d. This prevents potential inflation of $B[1, 1]$, which could become huge if it were to be measured across the entire dataset. BLANC can also be used to evaluate plural mentions without any modification because each link is treated independently regardless of its mention type in this metric.

5 Entity Linking

5.1 Multi-Task Learning

The task of character identification requires each mention to be identified by the names of actual characters (e.g., `Monica`, `Ross` in Table 2). Figure 2 gives the overview of our entity linking model, which adapts the underlying architecture from the entity linking model proposed by Chen et al. (2017) and generalizes it to jointly handle singular and plural mentions. It assumes the output from ACNN in Section 4.2 such that for each mention m_i, the embedding of that mention and the set of clusters $\{C_1, \ldots, C_k\}$ that m_i belongs to are taken. For each cluster C_a, ACNN gives the list of mention pair embeddings $m^{C_a}_{i,j}$, where $m_i, m_j \in C_a$. Similarly to the previous model, the cluster embedding and the cluster pair embedding are created. Unlike the previous model, our model creates multiple cluster and cluster pair embeddings when m is assigned to more than one cluster during coreference resolution so that the average vectors of those embeddings are generated, which get concatenated with the mention embedding of m_i and passed onto the fully-connected layers for prediction.

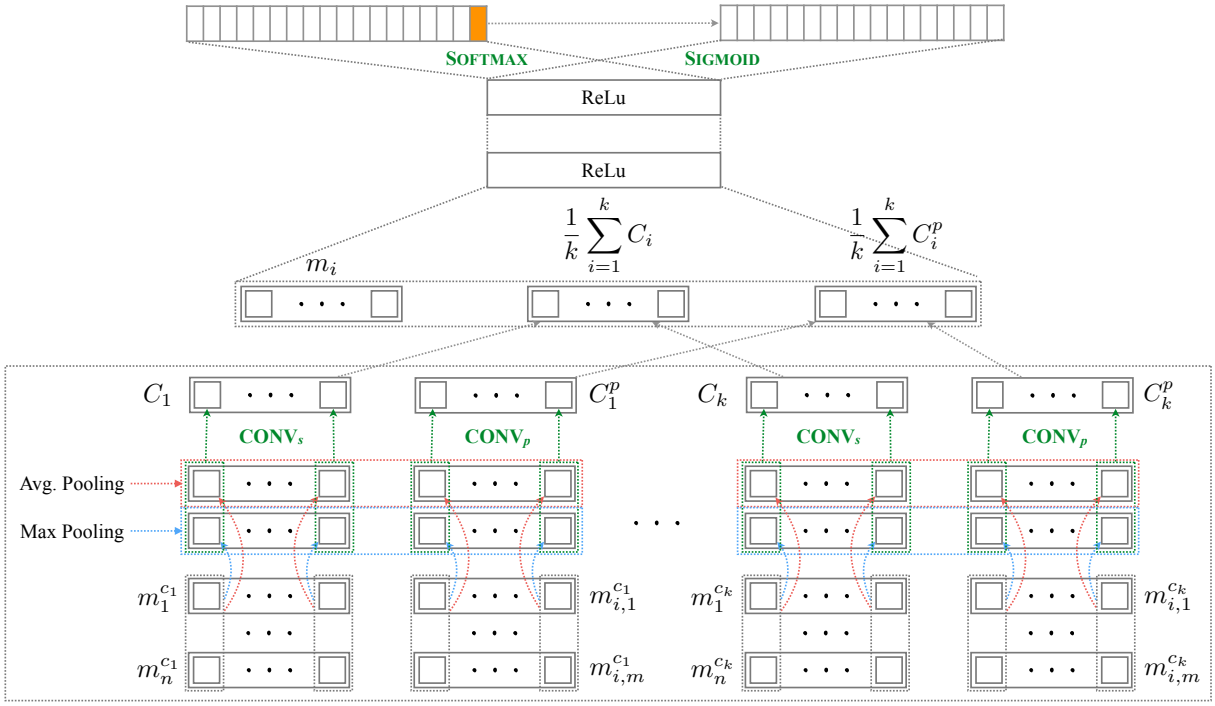

Figure 2: The overview of our entity linking model using multi-task learning.

The final `ReLu` layer is fed to two output layers optimized by softmax and sigmoid functions, respectively. The dimension of the output layer from softmax is $|E| + 1$ where E is the set of all entities such that each cell represents an entity and the extra cell gives an indication of m being plural. When this extra cell is predicted, the output layer from sigmoid is used, whose dimension is $|E|$, to predict multiple entities for m. Since the sigmoid function optimizes each cell to be between 0 and 1, any entity whose score is greater than 0.5 is taken. These two output layers are optimized jointly, treating the resolution of singular and plural mentions as multi-task learning.

5.2 Evaluation Metrics

Two metrics are used to evaluate the entity linking models. One is the micro-average F1 score whose precision (P) and recall (R) are measured as follows (D: a set of documents, $E_m^{s/o}$: the set of entities found for m by the system (s) or the oracle (o)):

$$P = \frac{\sum_{d \in D} \sum_{m \in d} |E_m^s \cap E_m^o|}{\sum_{d \in D} \sum_{m \in d} |E_m^s|} \qquad R = \frac{\sum_{d \in D} \sum_{m \in d} |E_m^s \cap E_m^o|}{\sum_{d \in D} \sum_{m \in d} |E_m^o|}$$

The micro-average F1 tends to weigh more on frequently occurring entities so it is useful if you need to know the raw prediction power of your model. The other is macro-average F1 score that measures the micro-average F1 for each entity e, say F_1^e, and takes the average, that is $1/|E| \sum_{e \in E} F_1^e$ where E is the set of all entities. The macro-average F1 treats all entities evenly so it is useful if you need to optimize your model to make correct predictions for as many entities as possible.

6 Experiments

6.1 Configuration

Experiments are conducted on two tasks, coreference resolution and entity linking. For both tasks, models from Chen et al. (2017) are used to establish strong baseline (CZC). Since they take only singular mentions, a pseudo-singular dataset is created where exactly one entity is chosen for each plural mention based on the closest matching previous speaker or if there is none, chosen randomly. Thus, the models trained on this pseudo-singular dataset always predicts one entity per mention. These models are compared to our

models described in Sections 4 and 5 (Ours). Additionally, CZC models are evaluated on the singular-only dataset (S-only) where all plural mentions are filtered out, which should give an intuition of how much impact the addition of plural mentions has on the predictions for singular mentions. All results reported from these experiments are averages of three randomly initialized trials. The corpus in Section 3 is split into training, development, and evaluation sets, where all models are tuned on the development set and the best models are tested on the evaluation set. Episodes 1–19, 20–21, and the rest from each season are used to generate the training, development, and evaluation sets, respectively.

6.2 Coreference Resolution

Table 6 shows that our coreference model is capable of learning to handle plural mentions effectively while significantly outperforms the CZC model. The CZC model is trained on the pseudo-singular dataset but evaluated on the full dataset by the metrics adjusted for plurals (Section 4.3) such that it is penalized for not predicting multiple entities for plural mentions. Both the B^3 and BLANC metrics show a similar trend that the CZC and our models achieve higher precision and recall, respectively, whereas our model dominates both precision and recall for the $CEAF_{\phi_4}$ metric. The remarkable gap in performance between these two models signals that our model finds referents for plural mentions well without compromising its ability to find referents for singular mentions. The S-only model gives comparable performance as the one reported by Chen et al. (2017), ensuring that our implementation of the CZC model is robust.

	B^3			**$CEAF_{\phi_4}$**			**BLANC**		
	P	**R**	**F1**	**P**	**R**	**F1**	**P**	**R**	**F1**
CZC	**84.5±0.6**	60.7±0.2	70.6±0.3	49.0±0.8	63.7±0.3	55.4±0.6	**81.2±1.0**	73.3±0.4	75.9±0.5
Ours	83.8±1.5	**67.0±2.7**	**74.4±1.1**	**52.1±1.2**	**68.0±0.6**	**59.0±0.5**	80.4±0.8	**76.5±1.2**	**78.0±0.6**
S-only	84.3±1.2	71.9±1.4	77.6±1.0	54.5±1.3	71.8±1.0	62.0±0.6	84.3±1.6	80.4±1.1	82.1±1.3

Table 6: Coreference resolution results on the evaluation set (±: standard deviation).

6.3 Entity Linking

Tables 7 and 8 show the micro and macro average scores achieved by all models. For the micro average, the trend is clear across all types of mentions such that the CZC and our models achieve higher precision and recall, respectively. The precision gap for micro average is quite small, signaling that there is no significant loss of ability in entity resolution for singular mentions in our model. For the macro average, our model completely dominates except for the precision of plural mentions, which implies that our model is more generalizable across different entities regardless of their frequency rates in the training set. The recall of micro-average for plural mentions shows relatively high standard deviations for our model. We expect that running more trials of experiments potentially mitigates this variance, which we will explore. It is expected for the micro average scores to be higher than the macro average scores because the micro average favors frequently appearing entities such that it is possible to achieve high micro average scores without handling infrequent entities well, whereas that is not the case for the macro average.

	Singular			**Plural**			**All**		
	P	**R**	**F1**	**P**	**R**	**F1**	**P**	**R**	**F1**
CZC	**72.8±0.5**	72.8±0.5	72.8±0.5	**60.8±2.4**	19.7±0.8	29.8±1.2	**71.8±0.4**	61.4±0.4	66.2±0.4

S-only	73.7±0.6	73.7±0.6	73.7±0.6						

Table 7: Micro-average scores for entity linking on the evaluation set (±: standard deviation).

Table 9 shows the micro average F1 score for each entity. The top-15 frequently appearing characters are considered to be known entities, whereas all the other secondary characters are considered `OTHER`, which composes about 26.8%. Our model dominates all the main characters (the first six entities) and `OTHER`, together of which gives about 90% of the entire annotation. Given that these results are achieved by using automatically generated clusters from our coreference resolution models, they are encouraging.

7 Conclusion

In this paper, we explore a new paradigm for handling plural mentions in two resolution tasks, coreference resolution and entity linking, on multiparty dialogue. We address this challenge by showing the inadequacy of traditional approaches in handling plural mentions, and present an innovative approach to overcome the shortcomings of existing methods for these tasks at hand. For resource creation, we expand upon the Character Identification corpus and augment it with the manual annotation of plural mentions (Section 3). For linguistic analysis, we propose a novel transition-based algorithm and evaluation metrics to process different types of mentions for coreference resolution (Section 4). For NLP engineering, we introduce a neural-based entity linking model using multi-task learning that comprehensively handles plural mentions (Section 5). The results of our models demonstrate significant improvements on these tasks, implying the feasibility of our approach to handle plural mentions (Section 6).

To the best of our knowledge, this paper provides the first extensive framework for resolving referents for plural mentions, which is a critical problem in any resolution task. Further work includes improving the quality of the dataset as well as expansion of its size, and addressing the issue of extracting global and external features for complete coreference and entity resolution for both singular and plural mentions. All resources including the annotated corpus and source codes are publicly available through the Character Identification project: `https://github.com/emorynlp/character-identification`.[5]

Abstract

We propose a triad-based neural network system that generates affinity scores between entity mentions for coreference resolution. The system simultaneously accepts three mentions as input, taking mutual dependency and logical constraints of all three mentions into account, and thus makes more accurate predictions than the traditional pairwise approach. Depending on system choices, the affinity scores can be further used in clustering or mention ranking. Our experiments show that a standard hierarchical clustering using the scores produces state-of-art results with MUC and B^3 metrics on the English portion of CoNLL 2012 Shared Task. The model does not rely on many handcrafted features and is easy to train and use. The triads can also be easily extended to polyads of higher orders. To our knowledge, this is the first neural network system to model mutual dependency of more than two members at mention level.

1 Introduction

Entity coreference resolution aims to identify mentions that refer to the same entity. A mention is a piece of text, usually a noun, a pronoun, or a nominal phrase. Resolving coreference often requires understanding the full context, and sometimes also world knowledge not provided in the text. Generally speaking, three types of models have been used for coreference resolution: pairwise models, mention ranking models, and entity-mention models. The first two are more common in literature, and the third one is somewhat less studied.

Pairwise models a.k.a. mention pair models build a binary classifier over pairs of mentions (Soon et al., 2001; McCallum and Wellner, 2003). If all the pairs are classified correctly, then all coreferent mentions are identified. The mention ranking models do not rely on the full pairwise classification, but rather compare each mention to its possible antecedents in order to determine whether the mention might refer to an existing antecedent or starts a new coreference chain (Durrett and Klein, 2013; Wiseman et al., 2016; Clark and Manning, 2016). The entity-mention models try constructing representations of discourse entities, and associating different mentions with the entity representations (Luo et al., 2004).

However, none of these model types consider more than two mentions together at the low level. By low level here, we mean the processing of input mention features, as opposed to processing of constructed representations. Pairwise models and mention ranking models make low-level decisions on mention pairs only. Some further processing may be applied to reconcile global scope conflicts, but this process no longer relies directly on mention features.

This paper proposes a neural network model which works on triads of mentions directly. Each time, the system takes three mentions as input, and decisions on their coreference relations are made while taking into account all mutual dependencies. Inferences drawn from three mentions, if correctly modeled, should be more reliable than those from two mentions, simply because entities in a text tend to have multiple mutual dependencies. Firstly, coreference relation is transitive, and transitivity can be revealed only by 3 or more participants. Secondly, mutual dependencies are not just at the level of transitivity,

Proceedings of the 27th International Conference on Computational Linguistics, pages 35–43
Santa Fe, New Mexico, USA, August 20-26, 2018.

but can occur among lexical items, syntactic structures, or discourse information. Modeling dependency at these lower levels can therefore be helpful for coreference resolution. We believe it is also a closer approximation of humans' cognitive process. When we read text, we often look in two or more places (including not only mentions, but also their context) to decide what a pronoun might refers to. Therefore it is reasonable to account for it at an early stage of system design.

We show that the decisions made by the triad model are more accurate than those made by the dyad model. Such decisions can be further used in mention ranking, or simply followed up by clustering or graph partitioning as in the canonical mention pair models. The triad system can be easily extended to higher order polyads, if necessary. In this paper, we only consider triads, and dyads (pairs) are used for comparison. We use the English portion of CoNLL 2012 Shared Task dataset for training and evaluation. Our experiments show that a standard hierarchical clustering algorithm using the triad model output achieves state-of-art performance under several evaluation measures.[1]

2 Related Work

Before the neural network models became popular in coreference resolution tasks, graphical models had often been used to capture dependencies. McCallum and Wellner (2003) described a system which draws pairwise inferences but also accounts for transitivity constraints. Essentially, their model can be summarized as in equation

$$P(\mathbf{y}|\mathbf{x}) = \frac{1}{Z_x} \exp\left(\sum_{i,j,l} \lambda_l f_l(x_i, x_j, y_{ij}) + \sum_{i,j,k,l'} \lambda_{l'} f_{l'}(y_{ij}, y_{jk}, y_{ik})\right) \quad (1)$$

The first term describes the potential function of a mention pair x_i, x_j as well as their label y_{ij}. For instance, $y_{ij} = 1$ if x_i and x_j belong to the same entity. The second term adds constraints on the labels to assure logical consistency. A particular assignment of values to x_i, x_j does not only affect the potential function involving these two nodes, but also other potential functions involving one of them. This makes the variables (mentions, in this case) dependent on each other. Exact algorithms to solve such problems are NP-hard, and some approximation techniques are often applied.

Our proposed model can be viewed as constructing potential functions over three variables x_i, x_j and x_k. However, we do not look to optimize the product of all the potential functions. Instead, we train a neural network model to assign labels to all edges within a triad locally. Note that the label y_{ij} for a given mention pair x_i, x_j may have different optimal values when different x_k's are used to construct a triad. The final assignment is determined by computing the average of y_{ij}'s. Moreover, our input features are mainly series of word embeddings and part of speech (POS) embeddings, encoding rich context information. The conventional algorithms used in graphical models cannot deal with such high dimensional features.

Graphical neural network (GNN) models have recently been used to process graphs (Duvenaud et al., 2015; Santoro et al., 2017; Kipf et al., 2018). For example, the graph convolutional networks (GCN) (Kipf and Welling, 2016; Defferrard et al., 2016) take graphs as input. Each node of the graph contains features, and a matrix represents their mutual relations. The features and the relation matrix are both used as input. Some filter layers, often shared by all nodes, process the features. The output of the filters and the relation matrix are further processed by other layers. The final output is new representations of nodes, which can be labels.

Our model shares some characteristics with GCNs. The triad input can be viewed as a basic graph: triangle, and each node is a mention. The features we used (word embeddings, POS embeddings, speaker identity, mention distance) are all associated with a node or a pair of nodes (edges). The three nodes share recurrent neural network layers. Because the output of such layers are used together, higher layers in the system have access to information from all the nodes. The output is a 3 dimensional binary vector, which can be considered a graphical representation too. However, our goal here is to find pairwise relations, and the triangle graphs are employed only to model (partial) mutual dependency among three mentions.

[1] Our source code is freely available here: `https://github.com/text-machine-lab/entity-coref`

In contrast, CGNs are capable of generating new complex representations for the nodes and they rely on the structure of the input graph, both of which are not applicable in our case.

3 System

The system consists of two major parts: the triad-based neural network model to compute mutual distances and a model to perform clustering. These two stages are not clearly divided, since defining mutual distances affects the clustering strategy.

3.1 Input Features

Our input is triads of entity mentions. The triads have mutual (joint) features and individual features as input. Speaker identity and mention distance are mutual features. The files in the CoNLL 2012 dataset are largely transcripts of broadcast news and conversations, which typically involve several speakers. We use a binary feature to indicate whether two mentions are from utterances of the same speaker (1) or not (0). Mention distance indicates how far apart two mentions are in the text. If they are next to each other, the distance is 1; if there is another mention in between, the distance is 2, and so on. We only count the mentions in between, regardless the number of the words or sentences in between.

Individual features are word tokens and POS tokens for each entity mention. The word tokens include the mentions themselves, as well as their 5 preceding tokens and 5 succeeding tokens. We also design two special tokens to mark the beginning and end of each mention. Similarly, the POS tokens include the POS tags of the mentions, as well as the POS tags of 5 preceding and 5 succeeding tokens. Two other special tags are used to mark the beginning and end of the mentions for POS tokens too.

Each word token is represented by a 300-dimensional vector. We use glove.840B.300d word vectors[2] to initialize them, and they are updated in the training process. Each POS token is represented by a one-hot vector, and updated during training too. This enables the model to learn the similarities between different POS tags (such as NNPS and NNS, for example). Table 1 gives a summary of input features.

Feature	Description
Word tokens	word embeddings of the mentions, and of 5 words before and after
POS tokens	part-of-speech tag embeddings
Speaker identity	whether two mentions are from the same speaker
Mention distance	how many other mentions are between them

Table 1: Input features

3.2 Triad Neural Network

Word embeddings are fed into a bidirectional LSTM layer, which generates a representation for each mention. The three members of the triad share the same LSTM layer. Similarly, POS embeddings are fed into a shared bidirectional LSTM layer.

$$h_i^{word} = \text{Word-LSTM}(X_i^{word}) \tag{2}$$

$$h_i^{pos} = \text{POS-LSTM}(X_i^{pos}) \tag{3}$$

where $i = 0, 1, 2$ is the index of the three mentions, X_i^{word} is the sequence of word embeddings used to represent mention i, and X_i^{pos} is the corresponding sequence of POS embeddings. Word-LSTM and POS-LSTM are both bidirectional, and shared by all input mentions. For each pair in the triad, the LSTM outputs for the two entities are concatenated with their joint features:

$$h_{ij} = f(X_{ij}^{speaker}, X_{ij}^{distance}, h_i^{word}, h_j^{word}, h_i^{pos}, h_j^{pos}) \tag{4}$$

[2]https://nlp.stanford.edu/projects/glove/

where $X_{ij}^{speaker}$ is a binary speaker identity feature for the mentions i and j, $X_{ij}^{distance}$ is the positive integer feature tracking the distance between them, and f represents several fully connected layer(s), shared by the three pairs. Our implementation uses two layers, with dropout between them.

While h_{ij} represents the relation between i and j, the other triad member needs taken into account as well. We achieve this by constructing a shared context h_{ijk}:

$$h_{ijk} = g(h_{ij} \bigoplus h_{jk} \bigoplus h_{ki}) \tag{5}$$

where g is another fully connected layer. Operator $\bigoplus$ means elementwise vector summation. Now, we can have a decoder layer d_{ij} for each of the pairwise relations.

$$d_{ij} = f_d(h_{ij}, h_{ijk}) \tag{6}$$

Function f_d is another fully connected layer. The three decoders work together to generate a 3D binary vector, as in equation 7. Each element represents whether the mention pair refers to the same entity (0 or 1).

$$\mathbf{y} = \text{sigmoid}(W(d_{ij}, d_{jk}, d_{ki}) + b) \tag{7}$$

where W and b are the weights and bias to be trained. The output $\mathbf{y}$ is a 1×3 vector. As we can see, the three decoders do not make decisions independently, but rather, "consult" with each other, as in equation 7. Each decoder also uses the shared context h_{ijk} at a lower level, as seen in equation 6.

3.3 Triads Generation

For n mentions in the text, there can be $\binom{N}{3}$ triads. In most cases, we have dozens of mentions in an article, which is not an issue. However, some long articles have hundreds of mentions, so generating all triads is unpractical and unnecessary. For instance, for 500 mentions, the total number of triads would be 20,708,500!

During the training process, we use only the mentions within the distance of 15 or less. In other words, we consider the pairs with 14 or fewer mentions between them. For testing, we consider the mentions with distances up to 40. However, this does not mean the long-distance coreference can never be detected. Often, coreferent mentions in-between the distant ones may serve as bridges, and our clustering algorithm is able to put them together. That being said, it is also true that long-distance mention pairs are less likely to corefer than those in closer proximity. Training with triads that include very distant pairs could also have the harmful effect of introducing too many negative samples.

3.4 Dyad Baseline System

To demonstrate that triads have advantages over a strictly pairwise approach, we also build a neural network model which takes mention pairs as input, and make binary decisions on the pairs only. The input features are the same as in the triad model, and the architecture can be considered a reduced triad system. Now there is no context information shared by three entities. The pair representation is directly connected to the output layer.

4 Entity Clustering

After the likelihood of pairwise coreference between all mentions has been determined, we use a clustering algorithm to group them. At the end of this process, each entity is represented by a mention cluster.

For every triad a, b and c, the system will produce three real values between [0,1] to represent the "probability" of a coreference link. We will refer to them as affinity scores. The higher the score, the more likely a pair of mentions refers to the same entity. The affinity score over a pair is computed as the average of their scores in all triads, as shown in equation 8.

$$\Phi(a, b) = \frac{1}{N} \sum_{c \in W(a,b)} \Phi(a, b; c) \tag{8}$$

Here, N is the total number of triads containing (a, b), $\Phi(a, b)$ is the affinity score of a and b, and $\Phi(a, b; c)$ is the affinity score of a and b when another mention c is in the triad. $W(a, b)$ represents the set of mentions within the distance window of a or b. We have experimented with other methods besides averaging, including taking the maximum, or the average of several top candidates. We found that the average produces better results.

The mutual distance between a and b is defined as the reciprocal of the affinity score, except we set the maximum value to be 10. Since the maximum value of $\Phi(a, b)$ is 1, the minimum value of $d(a, b)$ is also 1 according to equation 9. In principle, we would like distance metrics to have 0 as the minimum, which can be achieved by subtracting 1. However, for the purpose of clustering, it is not necessary.

$$d(a, b) = min\{\frac{1}{\Phi(a, b)}, 10\} \tag{9}$$

Recall that our system does not consider mention pairs too far apart in the text. For evaluation, the maximum distance for consideration is 40 (i.e. they may have up to 39 other mentions in between). We set the mutual distance between out-of-window mentions as 10, the maximal distance. As mentioned before, this does not mean they can never be clustered together. The result depends on the choice of linkage, and whether there is any coreferent entities in-between.

We use the hierarchical clustering function provided by SciPy library to build the sets of coreferent entities. Other than the customized distance metric, we used the default settings, opting for the $distance$, rather than $inconsistent$ cutoff criterion. When the clusters are built hierarchically, those with distances lower than a threshold are joined. Presumably, the threshold t should be lower than 2, which corresponds to affinity score higher than 0.5. The higher the threshold, the fewer clusters will be produced at the end. Preliminary experiments showed that the results are not affected very much when t is between 1.5$\sim$2.0. We used the $t = 1.7$, which corresponds to affinity score of 0.59.

The choice of linkage has a major impact on the results. We found the $single$ linkage produces the best results. Intuitively, it also makes sense. In a text, coreference among a group of mentions can only be recognized via one or several bridging mentions. In this case, the $single$ linkage can best represent the relation, while the $average$ and other linkages tend to overestimate the distances between clusters.

5 Experiments

For all the experiments, hyperparameters were tuned with the development set only. We use Adam optimizer with binary cross-entropy loss. The learning rate is initially set as 10^{-3}, then 5×10^{-4} after 100 sub-epochs, and 10^{-4} after 100 sub-epochs. We use the term "sub-epoch" to refer to training on 50 files, rather than the whole training set. The training set is relatively big, so we implemented a data generator with multiple subprocesses with a shared output queue. There are 1940 training files in total, so roughly all training files can be consumed in 40 sub-epochs, although smaller files may be used more frequently due to the nature of multiprocessing. The training completed in 300 sub-epochs. We use input dropout ratio 0.5 for word embeddings and POS embeddings. The last layer of each pair representations has dropout ratio 0.3. The bidirectional LSTMs use the average output of two directions.

For the baseline dyad model, the settings are similar. We also use 300 sub-epochs, but here it refers to training on 100 files, not 50.

5.1 Results of Triad Model

Table 2 shows the results of our triad system, compared to other systems in literature. All results are on the CoNLL 2012 English test data. As we can see, all the recent system have pretty much the same average F1 scores over the three metrics. Likely, they all capture the relatively easy cases, and the difficult ones remain to be tackled. Compared to other systems, ours has a very different distribution of scores across the three metrics, which suggests our results are quite different. Our system performs by far the best with the MUC evaluation metric, and is also the best with B^3 metric, measured with F1 score. However, the performance is quite low from the $CEAF_{\phi 4}$ metric. To understand the discrepancies, we need to analyze not only the nature of our system but also the nature of the metrics.

	MUC			B^3			$CEAF_{\phi4}$			
	Prec.	Rec.	F1	Prec.	Rec.	F1	Prec.	Rec.	F1	Avg. F1
Wiseman et al. (2016)	77.49	69.75	73.42	66.83	56.95	61.50	62.14	53.85	57.70	64.21

Triad	**84.93**	**77.26**	**80.92**	60.35	**71.77**	**65.65**	44.43	**59.20**	50.76	**65.78**

Table 2: Results of coreference resolution systems on the ConLL 2012 English test data. Our model (Triad) was trained on triads with the maximum distance of 15, making predictions on the triads with the maximum distance of 40. All other results are copied from Clark and Manning (2016).

MUC (Vilain et al., 1995) is a link-based metric. Mentions in the same entity/cluster are considered "linked". MUC penalizes the missing links and incorrect links, each with the same weight. It has been noted that MUC prefers over-merging entities (Luo, 2005) over under-merging. Incorrectly merging two entities is penalized less than incorrectly splitting an entity. Since we chose the $single$ linkage in our clustering algorithm, it is likely to over-merge sometimes.

B^3 (Bagga and Baldwin, 1998) is a mention-based metric. The evaluation score depends on the fraction of the correct mentions included in the response entities (i.e. entities created by the system). If a system does not make any decision and leaves every mention as singletons (i.e. no coreference at all), it will get a perfect precision score. Luo (2005) indicates that the B^3 precision score prefers no decision. On the other hand, the recall prefers over-merging entities. We have a high B^3 recall and relatively low precision, which reflects our results in MUC.

We manually spot-checked our results and the over-merging suggested by our MUC and B^3 scores appears to be true. Figure 1 provides an example to illustrate this. The top subfigure is the true clusters of entities, and the bottom shows the predictions. As we can see, the mentions are mostly grouped correctly, but there is a very large cluster (red) on the right, which basically merges two big ground truth clusters (light blue and yellow).

$CEAF_{\phi4}$ (Luo, 2005) assumes each key entity should only be mapped to **one** response entity, and vice versa. It aligns the key entities (clusters) with the response entities in the best way, and compute scores from that alignment. However, a major disadvantage of this approach is that the **unaligned responses are totally ignored**, even if they are legitimate clusters. Moosavi and Strube (2016) used an example to illustrate the problem. From a text, system $cr1$ identifies two entities $\{the\ American\ administration, it_1, it_2, it_3\}$ and $\{they_1, they_2, them, their\}$. However, it misses the fact that the two are actually the same entity. As we know, relatively few entities can be referred by both it and $they$, as $administration$ can. Another system $cr2$ only identifies the fist cluster, and misses all of the second cluster. Our intuition is $cr1$ does a better job, because it resolves much more coreference relations. However, $CEAF_{\phi4}$ will score $cr2$ higher. This is what happens to our system. There are 4217 true coreference entities from the test set. However, our system generated 5619 entities, or 33% more. Note our $CEAF_{\phi4}$ recall score is also 33% higher than $CEAF_{\phi4}$ precision score, which is related to their definitions. As a result, our system identifies a lot of small subsets of entities, but may miss some crucial links in between. MUC and B^3 will give partial credits to it, but $CEAF_{\phi4}$ completely ignores the efforts and only picks one subset for the best alignment.

In order to understand the distribution of entity/cluster sizes, we collected all the entities from test data and from our system response. Figure 2 shows the distribution of entities with respect to their size. As we can see, our system generates some very large entities, quite a few bigger than 100. This is evidence of over-merging. On the other hand, the system also generates many small entities, as shown by the left-most green bar. Note the y-axis there is in log scale, so the difference is not proportionally visualized. Figure 1 also shows that there are 13 true entities in the file, but the system finds 17. On the one hand, it merges two major entities; but on the other hand, it breaks down some small entities.

Different evaluation metrics help to diagnose different problems, and every system, as well as every

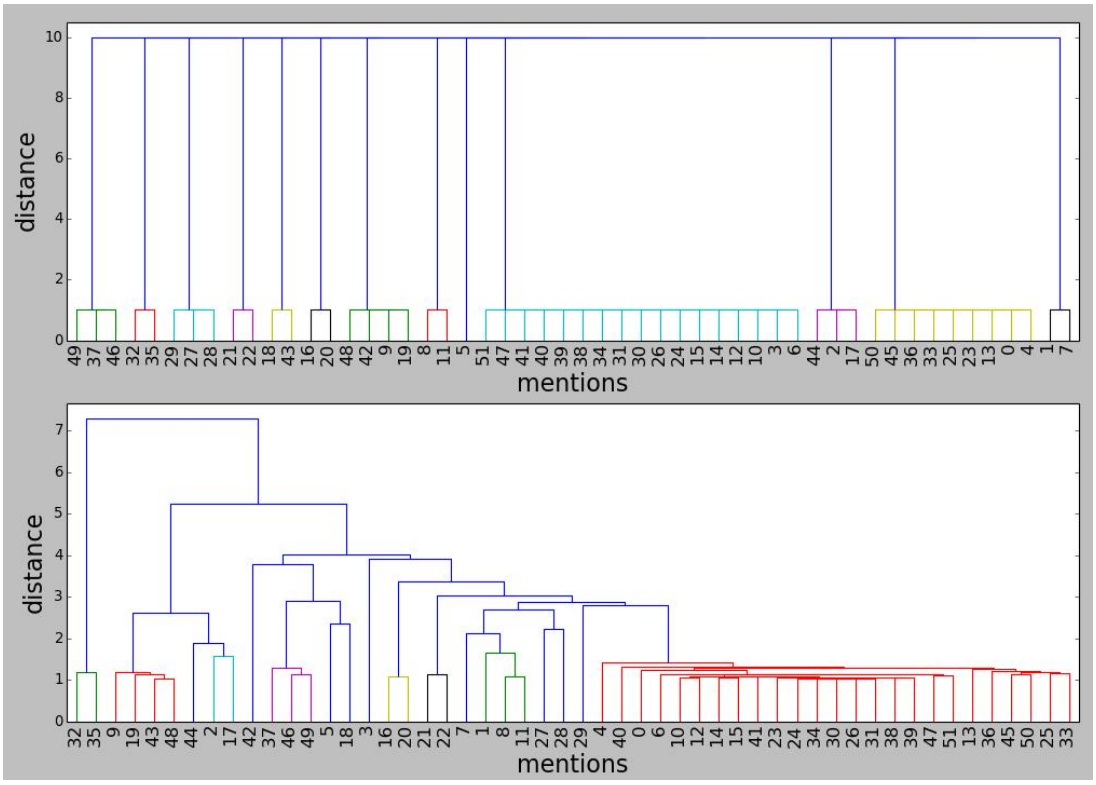

Figure 1: Clustering results from the test file voa_0049. Top subfigure is the true clusters. Bottom is the predicted results. Mentions with the same color are in the same cluster. The cutoff threshold is 1.7.

metric, would have its strength and weakness. In practice, what is needed depends on the purpose. CoNLL 2012 Shared Task uses the average of the three metrics to rank systems. Even though our system shows the best performance, the average here may not be very meaningful, given that our system has a very different distribution of scores from the others.

5.2 Results of Dyads Model

The results of the dyad system are shown in Table 3. As we can see, the triad system has a big advantage over the dyad system. Although we use maximum mention distance 15 for training, for prediction, it is beneficial to allow larger distances in the triad model. However, even in prediction, it is difficult to increase the distance beyond a certain point, since the number of triads increases very fast when the allowed distance becomes larger. Below, we show the results of both dyad and triad systems using the distance of up to 15 and up to 40 at test time.

	MUC			**B^3**			**$CEAF_{\phi4}$**			
	Prec.	Rec.	F1	Prec.	Rec.	F1	Prec.	Rec.	F1	Avg. F1
Dyad, max distance 15	76.83	78.16	77.49	46.03	70.59	55.73	44.43	41.58	42.96	58.73
Dyad, max distance 40	77.80	**82.84**	80.24	37.65	**77.86**	50.76	**47.99**	36.49	41.46	57.48
Triad, max distance 15	84.48	75.26	79.60	**62.36**	68.30	65.20	42.78	**59.98**	49.94	64.91
Triad, max distance 40	**84.93**	77.26	**80.92**	60.35	71.77	**65.65**	44.43	59.20	**50.76**	**65.78**

Table 3: Results of the dyad model compared to the triad model. Two maximum mention distances are tested: 15 and 40. They are all trained with maximum distance 15.

Generally, we found that dyad-based system generates more entities (less coreference) than the triad system. For test data, we had 11,299 entities from the dyad-based model, but only 5,619 from the triad-based model.

Triad model can also support additional restrictions. For example, we can require at least one pair in a

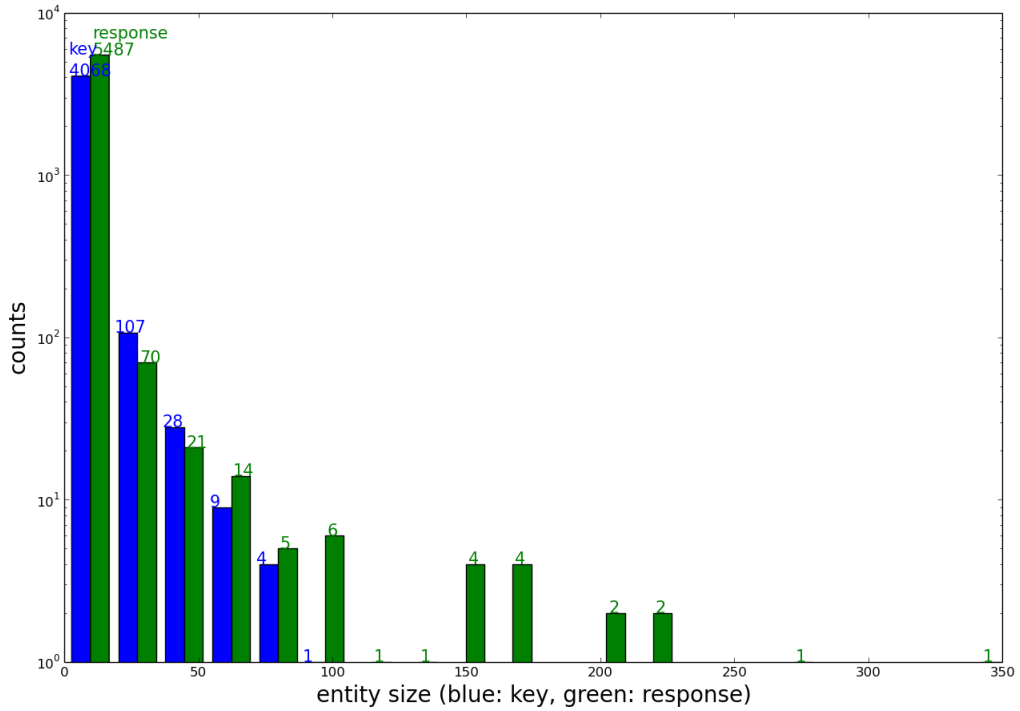

Figure 2: Entity sizes (number of mentions). Horizontal axis is the size of entities. Blue/left bars are the true counts from test set. Green/right bars are the counts from system response. Note the vertical axis is drawn in log scale. Compared to the truth, our system produces more extreme cases i.e. entities with very small number of mentions, or very big number of mentions.

triad to have a smaller distance. The point of allowing longer distances between mentions is to identify coreferent mentions that are far apart in text. However, it is typically fairly rare to have mentions that are far away refer to the same entity. We do not have to allow all sides of a triangle to be big, and imposing this restriction may improve the overall quality of the response entities.

Note that this system can be easily extended from triads to tetrads (union of four mentions) and higher polyads. Sometimes we may want to look at two more other places to determine whether a coreference relation is present. Ideally, the larger the polyad, the better we can capture mutual dependencies. However, since the number of polyads grows fast with the polyad order, the computation may quickly become intractable for larger texts.

6 Conclusion

We developed a triad-based neural network model that assigns affinity scores to mention pairs. A standard clustering algorithm using the resulting scores produces state-of-art performance on MUC and B^3 metrics. Our system appears to behave quite differently from others, judging by its performance on different metrics. A dyad-based baseline model has substantially lower performance, suggesting that using triads plays an important role. Note that approaches other than clustering, such as the mention ranking models, can easily be used with our output as well, and we expect some of them would work better than the simple agglomerative clustering.

Mutual dependencies among multiple mentions are important in coreference resolution tasks, but it is often ignored. Our triad-based model addresses this gap. This model can be additionally constrained to improve performance, and if necessary, easily extended from triads to polyads with higher order.

Abstract

This paper describes an unsupervised model for morphological segmentation that exploits the notion of *paradigms*, which are sets of morphological categories (e.g., suffixes) that can be applied to a homogeneous set of words (e.g., nouns or verbs). Our algorithm identifies statistically reliable paradigms from the morphological segmentation result of a probabilistic model, and chooses reliable suffixes from them. The new suffixes can be fed back iteratively to improve the accuracy of the probabilistic model. Finally, the unreliable paradigms are subjected to pruning to eliminate unreliable morphological relations between words. The paradigm-based algorithm significantly improves segmentation accuracy. Our method achieves state-of-the-art results on experiments using the Morpho-Challenge data, including English, Turkish, and Finnish. [1]

1 Introduction

Morphological learning aims to automatically uncover constitutive units of words. It is an especially important task for many NLP applications such as language generation, information retrieval etc. (Sproat, 1992). Morphology analyzing is non-trivial especially for morphologically rich languages such as Turkish where the word formation process is extremely productive and can create in principle tens of billions of word forms. The identification of morphological relations between words provides a basis for uncovering their syntactic and semantic relations, which in turn can be exploited by downstream NLP applications.

Most unsupervised models of morphological segmentation (Virpioja et al., 2013; Goldwater and Johnson, 2004; Creutz and Lagus, 2005; Creutz and Lagus, 2007; Lignos, 2010; Poon et al., 2009; Snyder and Barzilay, 2008) treat words as concatenation of morphemes. In some models, the dependencies between morphemes (e.g., the English suffix *-es* often follows a verbal stem with *y* changed to *i*, as in *carries*) are recognized (Narasimhan et al., 2015), making use of transformations akin to rewrite rules (Goldwater and Johnson, 2004; Lignos et al., 2010). In all these approaches, the dependency between morphemes is generally local, and the overall distribution of the underlying paradigms implied by the segmentation result is not explored.

In this paper, we propose to exploit the notion of the *paradigm*, a global property of morphological systems, for the task of unsupervised morphological segmentation (Parkes et al., 1998; Goldsmith, 2001; Chan, 2006). The idea of using paradigm to describe the morphological structure of a language can be traced back to a long time ago, and has been widely adopted in modern linguistic studies, starting from Ferdinand de Saussure. A paradigm refers to a set of morphological categories such as suffixes that can be can be applied to a homogeneous class of words. For instance, the paradigm (*NULL, -er, -est, -ly*) is defined over English adjectives (e.g., *high, higher, highest, highly*), the paradigm (*NULL, -ing, -ed, -s, -er*) is defined over English verbs (e.g, *walk, walking, walked, walks, walker*), etc. In essence, a paradigm establishes an equivalence class for word formation such that a word realized in one of the categories in a paradigm can be expected to appear in all the categories in the paradigm.

Proceedings of the 27th International Conference on Computational Linguistics, pages 44–54
Santa Fe, New Mexico, USA, August 20-26, 2018.

The advantages of using paradigms in morphological learning are manifold. On the one hand, paradigms provide a principled strategy for tackling the data sparsity problem. Not all morphologically possible forms of a word will be attested (Chan, 2006) and in a morphologically rich language such as Turkish, only a small fraction will be attested even in very large corpora. Paradigms can extend the attested morphological forms from few but high frequency words to low frequency words, likely the majority, for which there is little data. On the other hand, high quality paradigms may prove effective at detecting spurious morphological relations between words that have plagued many previous models. For instance, it is not uncommon for unsupervised morphological segmentation models to produce segmentations such as *with-in*, *with-out*, and *with-er*, where *with* is an attested word and *-in*, *-out*, and especially *-er*, are highly plausible suffixes (or more generally, morphemes). From the perspective of the paradigm, a global property defined over all words that take the suffix set (*-in, -er, -out*), it is clear that such a paradigm is very poorly supported—in fact by only one stem, namely, *with*, rather than a substantial set. This suffix set, then, is very unlikely to be a true paradigm and will be discarded, thereby eliminating segmentation errors such as *with-er*.

In this paper, we show that high quality morphological paradigms can be automatically constructed, resulting in considerable improvement in unsupervised morphological segmentation accuracy. Section 2 provides a review of previous and related work. Section 3 describes the general framework of our approach. Section 4 describes how to use linguistically-motivated language-independent heuristics to generate candidate segmentations with transformation rules for each word. Section 5 describes a probabilistic model of morphological learning that provides an initial segmentation including the identification of potential suffixes. Section 6 lays out the details of constructing morphological paradigms and a pruning process that eliminates spurious morphological relations. Section 7 reports the results of our experiments on Morpho-Challenge data including English, Turkish, and Finnish in comparison with previous models. Section 8 concludes with a discussion of future research.

2 Related Work

The Morpho-Challenge, held from 2005 to 2010, led to many successful morphology learning models. The Morfessor baseline system (Creutz and Lagus, 2002; Virpioja et al., 2013) provides a framework that maximizes the likelihood of the observation under the MDL principle. Creutz and Lagus (2005; 2007) extend the model with the maximum a posteriori (MAP) on both observed data and the model. Semi-supervised models have shown to be effective on morphological segmentation (Kohonen et al., 2010; Spiegler et al., 2010). In this paper, we focus on unsupervised learning of language morphologies, based on the consideration that constructing annotating data is expensive, especially for low-resource languages.

Narasimhan et al. (2015) adopt a log-linear model with semantic similarity measures obtained from word embedding to identify morphologically related word pairs (Schone and Jurafsky, 2001) and achieve impressive segmentation results on the Morpho-Challenge data. Such semantically based model, however, requires a large corpus to train reliable word embeddings, which renders the method unsuitable for low-resource languages.

The idea of paradigms has been explored in previous studies (Parkes et al., 1998; Goldsmith, 2001; Dreyer and Eisner, 2011; Ahlberg et al., 2014). Parkes et al. (1998) propose a model that learns neat inflectional paradigms only for English verbs from a corpus. Goldsmith (2001; 2006) uses heuristic rules with the MDL principle to greedily search morphological patterns (signatures). But the performance of rule-based search methods is crucially determined by the heuristic rules, and transformation rules are difficult to incorporate. Dreyer and Eisner (2011) proposed a log-linear model to identify paradigms. However, their method requires a number of seed paradigms for training. In morphologically rich languages such as Turkish, where one paradigm can be extremely large, this method requires considerable human annotation effort. Ahlberg et al. (2014) use a semi-supervised approach to learn abstract paradigms from a given inflection table. However, the task is different from what we discuss here, which somehow discovers inflection tables as an intermediate step.

In the paper, instead of constructing paradigms as a goal, we select statistically reliable paradigms from

the initial segmentation generated from a simple probabilistic model, and then use the reliable paradigms for pruning the unreliable ones, which we refer to paradigm pruning. The advantage of the proposed model is that it mathematically maximizes the likelihood of the observed data through the probabilistic model as well as maintains the global morphological structure in terms of paradigms. As will be demonstrated later, our method produces state-of-the-art results for morphological segmentation. It also provides a promising approach to unsupervised morphological learning for low-resource languages for which there is no sufficient quantity of data to enable embedding methods.

3 Our Method

We now formally describe our model. We write $w = (r, s, t)$ for a word w that consists of a root r, a suffix s, and a transformation rule t which captures stem changes in morphological processes. A morphologically simple word is treated as taking an empty suffix *NULL* without transformation rules. For example, the word *realizing* can be analyzed as deleting the last letter *e* from the word *realize* and adding suffix *-ing*, i.e. (*realize, -ing, DEL-e*). To deal with words with multiple suffixes is trivial. If $w = (r, s, t)$ and $r = (r', s', t')$, then $w = ((r', s', t'), s, t)$. Here, we call r the *immediate root* of w. If the word has itself as immediate root, i.e. taking a *NULL* suffix, it is called *atomic*. If r' is atomic, it is called the *final* root of w, otherwise, it is called an *intermediate* root of w. For example, the word *realizing* can be represented as ((*real, -ize, NULL*), *-ing*, *DEL-e*), where (*real, -ize, NULL*) represents the word *realize*. So, the final root of *realizing* is *real*, and the word *realize* is an intermediate root. Finally, the task of morphological segmentation for a word is to recursively find immediate root until its final root is found.

3.1 Modeling Transformation Rules

We model three stem changes, called transformation rules, namely *deletion*, *substitution*, and *duplication*, similarly to (Narasimhan et al., 2015). These three transformation rules were mainly designed to capture stem changes that are involved in suffixation. All transformation rules are represented with the specific characters involved in changes. The definitions of the three transformation rules are as follows.

1. **Deletion** (DEL) of the end letter of the root. For example, the word *using* can be analyzed as (*use, -ing, DEL-e*).

2. **Substitution** (SUB) of the end letter of the root with another. For example, the word *carries* can be analyzed as (*carry, -es, SUB-y+i*)

3. **Duplication** (DUP) of the end letter of the root. For example, the word *stopped* can be analyzed as (*stop, -ed, DUP+p*).

We note, however, that certain morphological phenomena do not readily yield to the transformation-based approach here. Infixation and templatic morphology are obvious examples. Even agglutinative systems, which at first glance appear suitable for transformation rules that operate at word edges, may still prove problematic when more global morphological processes are at play. For instance, the Turkish suffixes *-lar* and *-ler* will fall under two distinct transformational rules but are in fact one morpheme that is realized differently due to vowel harmony. This problem does not pose insurmountable problems for the purpose of morphological segmentation since both *-lar* and *-ler* are relatively frequent and can be identified as genuine (and distinct) suffixes, but clearly a more robust representation of morphological processes will be necessary to account for the full range of languages. We leave this problem for future research.

3.2 Morphological Segmentation Framework

Our method is schematically described in Algorithm 1. It has several major components. The GETPRIOR function sets the prior of the model parameters by assigning each candidate segmentation (r, s, t) of a word w equal probability. The function GENSEG generates candidate segmentations, (r, s, t), for each word w. A probabilistic model is then used to compute the probability of each candidate, i.e. $P(r, s, t)$

based on the parameters estimated by the function ESTIMATE. Then the segmentation with the maximum probability is chosen. The final segmentation (e.g. words with multiple suffixes) can be constructed recursively as described in the beginning of this section.

After that, the function PARADIGMS reorganizes the segmented words into paradigms. The function RELIABLE then selects a set of statistically reliable paradigms. The function ESTIMATE estimates the model parameters based on the segmentation result derived from reliable paradigms. Then the new parameters are used by the probabilistic model to get better segmentation result. The procedure iterates for several times. Here, we let the algorithm iterate twice as we find it sufficient to produce high quality segmentations. The function PRUNE prunes the unreliable paradigms. The final result is generated based on the reliable paradigms and the pruned ones with function SEGMENTATION. The following sections describe each component in details.

Algorithm 1 The main procedure

```
1: procedure MAIN(WordList D)
2:     {P(r, s, t)} ← GETPRIOR(D)
3:     while iter < maxIter do
4:         morph ← {}
5:         for all w in D do
6:             segs ← GENSEG(w)
7:             seg ← arg max_{(r,s,t)∈segs} P(r, s, t)
8:             morph ← morph + (w, seg)
9:         pdgs ← PARADIGMS(morph)
10:        pdgs_reliable, pdgs_unreliable ← RELIABLE(pdgs)
11:        {P(r, s, t)} ← ESTIMATE(pdgs_reliable)
12:    pdgs_pruned ← PRUNE(pdgs_unreliable)
13:    return SEGMENTATION(pdgs_pruned + pdgs_reliable)
```

4 Generating Candidate Segmentations

4.1 Selecting Candidate Suffixes

To obtain a working set of suffixes, we first adopt a simple method from previous studies: given a word pair (w_1, w_2), if $w_2 = w_1 + s$, then s is a candidate suffix (Keshava and Pitler, 2006; Dasgupta and Ng, 2007). By comparing all possible word pairs, we can generate a set of candidate suffixes with their counted frequencies. The more frequent a candidate is, the more likely it is to be a real suffix. In our system, we only keep candidate suffixes that are at most six character long and appear at least three times in the word list. If applied naively, this method produces many short, spurious suffixes that are frequently occurring substrings in words, e.g. (*for, fore*), (*are, area*), (*not, note*), (*she, shed*) etc. The problem can be overcome by imposing a minimum length on words that are subject to candidate suffix generation. In practice, we find that a minimum word length of four characters works well, which partially reflects the prosodic constraints on minimal words from the linguistic literature (McCarthy and Prince, 1999).

In addition, if a candidate suffix can be taken by words of various lengths, it is more likely to be a real one; if a candidate suffix can only be taken by short words, it is likely to be a false one. To further utilize this information, we use the following equation to calculate the confidence value (conf) of a candidate suffix.

$$conf(s) = \log(1 + |W_s|) \times \frac{1}{|W_s|} \times \sum_{w \in W_s} len(w) \quad (1)$$

where W_s is the set of words that can take the candidate suffix s and form a new word, and $len(w)$ is the length of word w. Finally, we can select the top N candidates.

4.2 Generating Candidate Segmentations with Transformation Rules

The procedure for generating a candidate segmentation of target word w begins by stripping a possible suffix s from the word. If the remaining part r is a valid word, then (r, s, *NULL*) is a possible candidate. If r is not a word, but there exists a word r'=r+c and $c \neq s$, then (r', s, *DEL-c*) is a candidate. If r is in

the form r'+c, and r' is a valid word also ending with c, then (r', s, *DUP-c*) is a candidate. If r is in the form r'+c, r' is not a word, but there exist another word w'=r'+c' and $c' \neq c$, then (w', s, *SUB-c+c'*) is a candidate. If no possible suffix s could be found, then add (w, *NULL*, *NULL*) as a candidate.

We apply the transformation rule types in the following ordering: (*NULL, duplication*, *deletion*, *substitution*). A candidate with a transformation rule is generated only if no candidate could be found with a previous type. The ordering reflects the linguistic approaches to morphology where suffixation applies to the stem changes, and the changes take place at morpheme boundaries before affecting the rest of the words on either side (Halle and Marantz, 1993). The linguistic reality of these processes, once more widespread in English, is now only latently reflected in modern English orthography but can be transparently observed in other languages.

5 A Probabilistic Model for Morphological Segmentation

We evaluate the conditional probability of a segmentation (r, s, t) given a word w. Since each triple (r, s, t) is uniquely associated with a single word w, denoted as $(r, s, t) = w$, for all (r, s, t), $P(r, s, t|w) = 0$ if $(r, s, t) \neq w$. Otherwise, we use the following formula to calculate this probability.

$$P(r, s, t|w) = \frac{P(r, s, t)}{\sum_{(r', s', t')=w} P(r', s', t')} \tag{2}$$

To compute $P(r, s, t)$, we assume that r is independent of s, and that t depends on both r and s. Taking into account that the transformation rules are not word form specific, but rather follow some constraints based on the phonological structures of the word and the suffix. We assume that the transformation rule t is dependent on feature extracted from r and s, denoted by $f(r, s)$. Thus, $P(r, s, t)$ can be decomposed as follows.

$$P(r, s, t) = P(r) \times P(s) \times P(t|f(r, s)) \tag{3}$$

In our implementation, we assume that t depends on the last character of the root r ($end(r)$) and the initial character of the suffix s ($init(s)$), i.e. $f(r, s) = end(r)$-$init(s)$. For example, the probability of the segmentation (*carry, -es, SUB-y-i*) for the word *carries* can be calculated by multiplying P(*carry*), P(*-es*), and P(*SUB-y+i|f*), where *f* is *y-e*. Again, this is an approximation of the morpho-phonological properties of language but one which nevertheless proves effective for morphological segmentation.

Finally, the segmentation of a word w can be predicted by choosing the segmentation (r, s, t) that maximizes $P(r, s, t)$ as follows.

$$seg(w) = \underset{(r,s,t)=w}{\operatorname{argmax}} P(r, s, t) \tag{4}$$

5.1 Parameter Estimation

To estimate the parameters $P(r)$, $P(s)$, $P(t|f)$, we initially assume that each candidate segmentation of a word has equal probability because the unsupervised model has no access to gold data. Each (r, s, t) of all possible segmentations seg of a word w then obtains $1/|seg|$ weight. After that, the probabilities $P(r)$, $P(s)$, and $P(t|f)$ can be easily computed based on the frequencies of r, s, f, and (t, f). This first estimation of the parameters $P(r)$, $P(s)$, $P(t|f)$ is the prior returned by the function GETPRIOR in Algorithm 1.

Consequently, the probability of a segmentation (r, s, t) of a word w can be computed using Formula 3, and select the segmentation with the maximum probability. Here, EM can also be used for estimating parameters, but we found that this simple method works very well. After the first round, the parameters can be re-estimated by only using the predicted segmentation of each word, with the function ESTIMATE in Algorithm 1.

As discussed above, the reliability of a candidate suffix is also related to the length of words that can take the suffix. So, another way of estimating $P(s)$ is to use the confidence value calculated with Equation 1. We will show that the method gives better results.

Table 1: Examples of paradigm suffix sets and their supports of English, Turkish, and Finnish.

6 Paradigm Construction and Pruning

In this section, we discuss how to perform a post-pruning with a paradigm-based algorithm to exclude noisy segmentations. We define a paradigm formally as follows.

- **Paradigm** $p = S \times R$ is a Cartesian product of a set of suffix $S = \{s_i\}$ and a set of roots $R = \{r_i\}$, such that for any suffix $s \in S$ and root $r \in R$, r can take s to form a valid word w by applying a transformation rule t [2].

With this definition, the larger the cardinality $|R|$ is, the more reliable a paradigm p is. On the other hand, it is not always true that the larger $|S|$ is, the more reliable a paradigm is. An extreme case occurs when there is only one root in the paradigm, i.e. $|R| = 1$. For example, the root *the* forms a paradigm with 42 possible suffixes and all of them are false. We therefore define the support of a paradigm as follows.

- **Support** (SUP) of the a paradigm $p = S \times R$ is $|R|$, the cardinality of the root set R.

6.1 Constructing Paradigms

After we get the segmentation (r, s, t) for each word w, the paradigms can be easily obtained by grouping together the words that share the same immediate root r, regardless of the transformation rules that are involved. For example, the words *reporting*, *reported*, and *reports* are segmented as (*report, -ed, NULL*), (*report, -ing, NULL*), and (*report, s, NULL*) respectively, and the words *baked*, *baking*, *bakes* are segmented as (*bake, -ed, DEL-e*), (*bake, -ing, DEL-e*), and (*bake, -s, NULL*). Then we can construct a paradigm based on these two words as {*-ed, -ing, -s*} × {*report, bake*}.

6.2 Paradigm Pruning

We crucially assume that even though the segmentation result given by the initial model is not highly accurate, the distribution of paradigms constructed will provide clear evidence of whether they are reliable. Table 1 shows some examples of paradigms with more than one suffix, and these are indeed consistent with the morphological structures of the languages.

The paradigms with more than one suffix and with support value larger than 1 are selected as the reliable ones, the same strategy used by Goldsmith (2001) for filtering when constructing candidate paradigms. The method has two consequences. First, we exclude a large proportion of suffixes that only appear in unreliable paradigms so that the frequency of suffixes be estimated based on the reliable paradigms. Second, we can use the reliable paradigms as references for pruning the unreliable ones.

The basic idea of pruning unreliable paradigms with reliable ones is to take the intersection of the suffix set of a paradigm to be pruned and that of any of the reliable ones and to choose the one that achieves the best score. The score of a set of suffixes is calculated according to the following equation.

[2]Transformation rules (or stem changes) are not considered a part of the paradigms, because they are usually not directly driven by morphological processes but rather some phonological rules or others

	English	Turkish	Finnish
Training (MC:10)	878,036	617,298	2,928,030
Test (MC:05-10)	2,218	2,534	2,495

Table 2: Data Set. MC:10 is the Morpho-Challenge 2010 and MC:05-10 is the combined data of Morpho-Challenge 2005-2010.

$$score(S) = \sum_{s \in S} conf(s) \tag{5}$$

For instance, suppose we have an unreliable paradigm {*-ed, -ing, -s, -se*} × {*appear*} [3], which only has support value 1, and there are two reliable paradigms with suffix sets (*-ed, -ing, -s*) and (*-ed, -ing*) respectively. Then, the pruning algorithm calculates the intersection of the unreliable one and each of the reliable ones, resulting in (*-ed, -ing, -s*) and (*-ed, -ing*). According to Equation 5, the former one will be kept since it has a higher score. Thus, the original paradigm is pruned to {*-ed, -ing, -s*} × {*appear*}, and consequently, the false morphological relation between *appease* and *appear* (by *-se*) is filtered out.

7 Experiments

7.1 Experiment Setting

7.1.1 Data

We ran experiments on a combined version of the Morpho-Challenge 2005-2010 data sets including English, Turkish, and Finnish, the same setup as Narasimhan et al. (2015). In our experiments, testing words are included in the training set since the method is unsupervised. A statistical description of the data is shown in Table 2.

As in previous work on unsupervised morphological learning, we use a frequency-based filtering method to reduce noise in the data. This is necessary because the word list provided by Morpho-Challenge 2010 is generated by lower-casing all running tokens in the corpora including abbreviations and proper nouns. Many of these are three characters words. We use the following conditions to select reliable roots: 1) $freq \geq 2000$ if $len(word) \leq 3$; 2) $freq \geq 200$ if $len(word) \leq 4$; 3) $freq \geq 20$ if $len(word) \leq 5$; 4) $freq \geq 3$ else. The motivation is that short words are expected to be more frequent; rare short words are likely to be abbreviations or noise.

7.1.2 Compounding

We also add a compound inference module, which simply splits a word w before generating candidate segmentations if it is composed of w_1 and w_2. If there is more than one possible segmentation, then we choose the one with maximum length of w_1. The candidate segmentations are then generated for w_1 and w_2 separately. The final segmentation result is obtained by combining the segmentation results of w_1 and w_2.

7.1.3 Evaluation

Following (Narasimhan et al., 2015), we measure the performance of our model with segmentation points, i.e. the boundaries between morphemes in words. The precision, recall and F1 values on the identification of segmentation points are reported.

7.2 Experiment Results

7.2.1 Ablation test

We first test five different variations of our model. The first one is the baseline system (Base) which only uses the probabilistic Model without transformation rules. The second one (+Trans) is the baseline plus transformation rules. The third one (+Comp) is the second one plus the compounding inference module. The fourth one (+Prune) is the third one plus the paradigm pruning algorithm. The fifth one (+Conf) is

[3]The word *appear* takes suffix *-se* to form *appease* through a transformation rule *DEL-r*.

Our model	0.810	0.787	**0.798**	0.600	0.746	**0.665**	0.824	0.452	**0.584**

Table 4: Comparison of our model with others. The numbers for Finnish are obtained by running the systems by ourselves. The other numbers are from (Narasimhan et al., 2015).

the same as the fourth one except that the estimation of $P(s)$ is based on the confidence value calculated through Equation 1. In order to achieve the best performance, if a feature harms the performance, it will be removed in the next round.

The results are shown in Table 3. Firstly, we can see that incorporating of transformation rules improves the performance for all the three languages with 7.6%, 3.2%, and 3.0% improvements of F1 measure respectively. After adding the compounding analysis module, the performance is significantly improved on Finnish, with 11.1% improvement of F1 measure. The paradigm pruning algorithm significantly improves the performance on English and Finnish, with 15.7% and 6.0% of F1 measure, and improves precision of the model on Turkish, although the overall performance decreases. Finally, by using confidence based estimation of $P(s)$, the performance is improved further on all the three languages, achieving the best result for English and Turkish. For Finnish, the best result is actually achieved without transformation rules, namely 0.824, 0.452, and 0.584 in Precision, Recall, and F1 respectively.

7.2.2 Comparison with other models

We compare our model with three systems including the Morfessor Baseline system (Morf-Base) (Virpioja et al., 2013), Morfessor CatMAP (Morf-Cat), and the Log-linear model with full features (LogLinear-Full) and the model without semantic similarity (LogLinear-C) in (Narasimhan et al., 2015). Besides English and Turkish as used in (Narasimhan et al., 2015), we also add Finnish for experiments. For training word embeddings which will be in LogLinear-Full model, we use a corpus created in the DARPA LORELEI [4] project, which contains about 101 million tokens.

The result is shown in Table 4. The numbers for English and Turkish are from (Narasimhan et al., 2015). We can see that our model achieves the best performance in all the three languages. The LogLinear-Full model is the second best model on English and Turkish. However, it is worth noting that that model is based on semantic similarity features which requires training word vectors on independent corpora. Our model, on the other hand, only uses a list of words. The word frequencies are only used to filter noise. Our model is significantly better than the (Narasimhan et al., 2015) model without semantic embedding (i.e. LogLinear-C), with 20.1% relative improvement of F1 on English and 12.8% relative improvement on Turkish. For Finnish, the Morfessor CatMAP model has similar result as ours. The semantic similarity information harms the LogLinear-Full model. We think that this is due to the data sparseness problem as Finnish is a highly synthetic language, which then requires a larger corpus for training effective word embeddings.

[4] https://www.darpa.mil/program/low-resource-languages-for-emergent-incidents

7.3 Error Analysis and Discussion

Morphology learning systems in general suffer from two major problems, namely over-segmentation and under-segmentation. Over-segmentation is usually caused by spurious roots, either intermediate or final, such as the over-segmented words caused by the short frequent words, e.g. *the, with*, etc. Under-segmentation is usually caused by unseen intermediate roots or unidentified real suffixes. In morphologically rich languages like Turkish and Finnish where a root can take multiple suffixes, this problem is more serious.

Firstly, we can see from Table 3 that the use of transformation rules significantly reduces the under-segmentation problem in all the three languages as indicated by the increased recall rates. For English, the transformation rules also reduce the over-segmentation problem. This is due to fact that the transformation rules can well capture the morphology of English and thus significantly increase the true positive segmentations. On the other hand, the transformation rules increase the over-segmentation problem for Turkish and Finnish as indicated by the decreased precisions. For Finnish, the best performance of the system is achieved without transformation rules. That is due to the fact that Finnish morphology involves a large number of vowel changes, e.g. lengthening and shortening at non-boundary positions, which cannot be captured by the current transformation rules. However, the transformation rules we use introduce a large number of false stem changes which then causes the over-segmentation problem increased. We will address this problem in our future research.

Secondly, the compounding module can further improve the recall rates and thus decrease the under-segmentation problem for English and Finnish. This also reflects the compounding nature of the languages and also the distribution of the test set.

Finally, the pruning algorithm significantly reduces over-segmentations for all three languages as indicated by the increased precision values. However, the under-segmentation problem is also increased. This is due to the identification of incomplete paradigms which is then caused by data sparseness problem. For Turkish, the problem is even more serious. Pruning with incomplete paradigms will falsely exclude real suffixes from an unreliable paradigm. This problem can be potentially addressed by merging proper paradigms to identify the maximal suffix sets (complete paradigms). This will be in our future research.

8 Conclusion and Future Work

In this paper, we propose an unsupervised model of morphology learning which outperforms the state-of-the-art systems, using only orthographic information from a word list. Our contribution also lies in providing a new method of using automatically learned paradigms to fine tune the morphological segmentation results produced by a simple probabilistic model. This method is effective in eliminating spurious segmentations and improving the segmentation accuracy. Finally, we also use the word length information to select good candidate suffixes and estimate the suffix probabilities, which can further improve the performance of the model. In addition, combining our model and semantics based systems can potentially yield better result since they use different kinds of information and complement each other.

We believe that our approach of using paradigms provides a foundation for dealing with other morphological types such as prefixes, infixes, reduplication etc. In detail, the notation of the suffix variable s can be generalized to f, a morphological function that takes a root as input and produces the derived form. Correspondingly, the definition of paradigms could be easily revised as a set of morphological functions that can take a set of words and generate their derived forms. We will work on extending our system to process other types of morphologies in our future research.

Acknowledgements

We thank the rest of the University of Pennsylvanias LORELEI research team for the helpful discussions. We also thank the anonymous reviewers who have given valuable and constructive comments as well as insightful suggestions for improving our system. This research was funded by the DARPA LORELEI program under Agreement No. HR0011-15-2-0023.

Abstract

Indigenous languages of the American continent are highly diverse. However, they have received little attention from the technological perspective. In this paper, we review the research, the digital resources and the available NLP systems that focus on these languages. We present the main challenges and research questions that arise when distant languages and low-resource scenarios are faced. We would like to encourage NLP research in linguistically rich and diverse areas like the Americas.

1 Introduction

The American continent is linguistically diverse, it comprises many indigenous languages that are nowadays spoken from North to South America. There is a wide range of linguistic families and they exhibit linguistic phenomena that are different from the most common languages usually studied in Natural Language Processing (NLP). There are approximately 28 million[1] people who self identify as members of an indigenous group (Wagner, 2016) and they speak around 900[2] native or indigenous languages. This represents an important cultural and linguistic richness. This richness was captured by the following quote from McQuown (1955) "in one small portion of the area, in Mexico just north of the Isthmus of Tehuantepec, one finds a diversity of linguistic type hard to match on an entire continent in the Old World". In spite of this, few language technologies have been developed for these languages, moreover, many of the indigenous languages spoken in the Americas face a risk of language extinction.

The aim of this work is to explore the research in the NLP field for the indigenous languages spoken in the American continent and to encourage research for these languages. We stress the need of developing language resources and NLP tools for these languages and we point out some of the challenges that arise

[1] Each country has its own methodology and criteria to estimate the amount of speakers. This is the sum of all estimations.

[2] This number varies depending on the classification criteria used on different studies.

Proceedings of the 27th International Conference on Computational Linguistics, pages 55–69
Santa Fe, New Mexico, USA, August 20-26, 2018.

when working on this field. Since indigenous languages are digitally scarce, developing technologies can have a positive social impact for the communities which depend on these languages. The great diversity of these languages posses interesting scientific challenges, e.g., adapting well established approaches, creation of new methods, collecting new data. Tackling these challenges contributes to building more general computational models of language, and to get a deeper insight into human language understanding. Moreover, many statistical NLP methods seek to achieve language independence, however they often lack of linguistic knowledge or they do not cover the broad diversity of languages (Bender, 2011). In this sense, it is important to acknowledge the characteristics of the indigenous languages of the Americas as a way of complementing the current NLP methods.

Contributions. To sum up, we made the following contributions: (i) we gave a brief introduction into the diverse language space of the indigenous languages of the American continent; (ii) we provide an overview of the existing digital corpora and language sytems that have been developed for some of the languages spoken in the Americas; (iii) and we discusses the advances, used methodologies, challenges and open questions for the most researched NLP tasks in these languages.

In order to maintain the information of this paper updated of the computer readable resources, developed systems and scientific research we made a public available list[3] with the latest advances for the Indigenous Languages of the Americas.

1.1 Languages overview

Linguistic typology is a field that studies the different languages of the world and tries to establish the relationships among them. This is not an easy task since there is still limited knowledge about many languages, specially in highly diverse regions. However, according to several linguistic atlas[4], there are around 140 linguistic families in the world, from these linguistic families almost 40% are native to the Americas. Nowadays, approximately 900 different indigenous languages are spoken of this region, making this continent a linguistically diverse territory.

Americas native languages can exhibit very different linguistic phenomena, these typological features are important to be taken into account when developing language technologies (O'Horan et al., 2016). It would be hard to provide a general description of all the languages spoken in the Americas, however, we would like to highlight some of the linguistic features that usually represent a challenge when doing NLP.

Many languages in North America tend to have a high degree of morphological synthesis, i.e., many morphemes per word (Mithun, 2017). For instance, languages that belong to the Eskimo-Aleut family (native to Canada, Alaska, Greenland and Siberia) are highly polysynthetic suffixing languages. Languages from other linguistic families spoken in North America also show specific degrees of agglutination, polysynthesis, and they have morphemes that express a wide range of functions and nuances of space or direction (Mithun, 2001). Languages with this type of phenomena usually have compact word constructions that are equivalent to whole sentences in other languages like English.

Another linguistic phenomena that is found in many languages spoken in the Americas is the tone, i.e., languages where the pitch is important to distinguish one word from another (the tone can express lexical meaning and grammatical function). Some linguistics families like Oto-manguean (spoken in Mexico) have languages with many types of tones. The orthography of these languages need to mark the wide range of tones, however, many indigenous languages face a lack of orthographic normalization. This can be specially problematic when trying to do NLP and processing text documents.

In general, the native languages of the Americas have a limited digital text production, in some cases they may have a strong oral tradition but not a written one. Due to social and political reasons, alphabetization and education programs are not always available for native speakers. Details about the languages families for which we were able to identify digital and technological resources, are given in Appendix A

[3]Updated list of resources for Indigenous languages of the Americas: `https://github.com/pywirrarika/naki`

[4]Based on Ethnologue (Simons and Fennig, 2017), Glottolog(Nordhoff et al., 2013), WALS (Dryer and Haspelmath, 2013).

2 Corpus and digital resources

Most of the current state of the art methods in NLP are data-driven approaches that require vast amounts of corpora in order to achieve good performance. Widely popular machine learning methods and vector space representations, e.g., neural networks and word embeddings, often rely in big monolingual corpora.

Annotated and unannotated corpora are required for several NLP tasks. For instance, parallel corpora are essential for building statistical machine translation (MT) systems, while morphological annotated data is essential for POS (Part-of-Speech) taggers and morphological analyzers, just to name a few.

In the case of MT, the most common sources for gathering large amounts of parallel data include specific domain texts such as parliamentary proceedings, religious texts, and software manuals that are translated into several languages. Additionally, the World Wide Web represents a good and typical source for finding large-size and balanced parallel and monolingual text (Resnik and Smith, 2003). However, many of the world languages do not have readily available digital corpora. Indigenous languages of the Americas do not have a web presence or text production comparable to richer resourced languages and it is difficult to find websites that offer their content the native languages.

We explored the resources that are digitally available for some of the native languages spoken in the Americas. Regarding parallel corpora, the bible is a common source that contains translations to many of these languages, although it is not always straightforward to extract the content in a digital format. On the other hand, there are some projects that offer parallel content through a web search interface, e.g., Axolotl (Spanish-Nahuatl parallel corpus) that was mainly gathered from non-digital sources (books from several domains), the documents have dialectal, diachronic and orthographic variation (Gutierrez-Vasques et al., 2016). Nahuatl is a Uto-Aztecan language spoken in Mexico (approx. 1.5M speakers) that lack of an orthographic normalization. In fact, this is the case for many languages spoken the Americas: large dialectal variation, and missing standardization.

Also for the same language (Nahuatl), a comprehensive digital dictionary has been collected with information from five previous dictionaries (Thouvenot, 2005), these dictionaries date from 16th to 21st Century (de Olmos et al., 2002; Walters et al., 2002). The query interface of this resource is available online[5].

Another language that belongs to the Uto-Aztecan family is Wixarika or Huichol (approx. 45K speakers). For this language, there is a parallel corpus (Wixarika-Spanish) that gathers translations of classic Hans Christian Andersen's literature (Mager et al., 2018). In this case, the translations belong to one specific dialect (Nayarit). This resource can be fully downloaded from the web [6].

The Shipibo-konibo language (approx. $26,000$ speakers) belongs to the Panoan language family, it is spoken in the Amazon region of Peru and Brazil. Several types of digital resources are available for this language. A parallel corpus between Spanish and this language was constructed using educational and religious documents (Galarreta et al., 2017). Moreover, Shipibo-konibo language has a POS tagged corpus, a set of words and its lemmas and an online-dictionary that has been recently released by Pereira-Noriega et al. (2017).

Also spoken in South America, the Guarani language (approx. 8M speakers) belongs to the Tupi-Guarani family. Abdelali et al. (2006) developed software for collecting Guarani resources from speakers, from this gathering they were able to construct a parallel corpus (Spanish-English-Guarani) and a monolingual corpus. There is also a digital Guarani dictionary (Ramírez and Wolf, 1996) available online[7].

Quechua is one of the most spoken language families on the continent (approx. 9M speakers) but there is scarceness of corpora and language technologies. Espichán-Linares and Oncevay-Marcos (2017) released monolingual corpora in 16 Peruvian languages that belong to different linguistic families (including Quechua).

Regarding speech resources, Guarani has a spoken corpus comprised by $1,000$ phrases from 110 different speakers, it was collected through a web interface (Maldonado et al., 2016), however, this dataset

[5] www.gdn.unam.mx

[6] https://github.com/pywirrarika/wixarikacorpora

[7] https://www.uni-mainz.de/cgi-bin/guarani2/dictionary.pl

has not been publicly released. The Chatino language (approx. 45K speakers) is an Oto-Manguean language spoken in southern Mexico, recently a language documentation and revitalization project has been developed. They use automatic speech recognition and forced alignment tools to time align transcriptions. Parts of this resource are freely available (Cavar et al., 2016).

There are some other types of datasets that are useful for developing language technologies, e.g., morphological annotated data. The CoNLL-SIGMORPHON 2017 Shared Task (Cotterell et al., 2017) released a large morphological database with inflection information of 52 languages, including Haida (7,040 words), Navajo (12,000 words), and Quechua (12,000 words), all of these are indigenous languages spoken in the Americas. In the same way, there is a Oto-manguean inflectional class database which contains over 13,000 verbal entries from twenty Oto-Manguean languages spoken in Mexico, along with information about each verb's inflectional class membership (Palancar and Feist, 2015). For morphological segmentation a data set of four Uto-Aztecan languages[8] were used and released by Kann et al. (2018) (4,468 segmented words from the Mexicanero, Nahutal, Wixarika and Yorem Nokki languages). The UQAILAUT Project contains roots, lexicalized words, infixes, noun and verb endings for the Inuktitut language[9] (Farley, 2012). Plain Cree language, spoken in North America (Algic language family) has also a lexicon databases (16,452 words) collected by Walters et al. (2002) and Wolfart and Pardo (1973).

To improve the data recollection, Dunham et al. (2014) developed tools for annotation of text and audio for Blackfoot, Gitksan, Okanagan, Tlingit, Plains Cree, Coeur d'Alene and Kwak'wala. With these tool they gather 19,187 word forms, 324 texts and 18.8 GB of audio.

A collection of datasets have been developed for the Mapudungun or Mapuche language spoken mainly in Chile (Araucanian language family) (Huenchullan, 2000; Monson et al., 2004). An audio dataset with 170 hours of spoken Mapudungun, that covers three dialects (120 hours of Nguluche, 30 hours of Lafkenche and 20 hours of Pewenche) has been released. This resource contains a word list with the 70,000 most frequent full form words (stem plus inflections) to support a spelling checker for Mapudungun. Also a bilingual Mapudungun-Spanish lexicon was included, containing sample entries 1,600.

Annotated data corresponding to higher linguistic levels is harder to find. For instance, almost no treebanks have been developed for the indigenous languages of the Americas. To our knowledge, the only available dataset is a parallel aligned treebank between Quechua and Spanish (Rios et al., 2008) with 2,000 annotated sentences.

It is important to mention that many of the languages spoken in the Americas have a Wikipedia's set of articles available[10]. This is useful for building monolingual and comparable corpora. Furthermore, Wikipedia can be a helpful resource to predict Part-of-Speech (POS) tags for low resource languages and other tasks (Hoenen, 2016). In any case, one common limitation of the digital resources for these languages is the lack of orthographic standardization and difficulties for processing certain types of characters. Table 1 summarizes the above-mentioned resources.

3 Morphological segmentation and analyses

Morphology has been studied in NLP field focusing mainly on the following tasks: lemmatization, stemming, segmentation, analysis and inflection/reinfection. These tasks serve to other higher level tasks such as machine translation. On this regard, there have been several studies which have been applied to the Americas languages.

In NLP, lemmatization and stemming methods are used to reduce the morphological variation by converting words forms to a standard form, i.e., a lemma or a stem. However, most of these technologies are focused in a reduced set of languages. For languages like English there are plenty of resources, however, this is not the case for all the languages. Specially for languages in the Americas with rich

morphological phenomena, and not always suffixal, where it is not enough to remove inflectional endings in order to obtain a stem.

Morphological segmentation is the task of splitting a word into the surface forms of its smallest meaning-bearing units, its *morphemes*. On the other hand, Morphological analysis not only focuses in the segmentation of words, but also in assigning tags to each part of the word. There are several approaches to do these tasks, i.e., rule-based, semi-supervised and unsupervised (Goldsmith, 2001; Creutz and Lagus, 2002; Kohonen et al., 2010). Some examples of rule-based methods applied to the Americas languages are the Finite State approaches to model the morphology of a language: plains Cree (Arppe et al., 2017; Harrigan et al., 2017; Wolfart and Pardo, 1973; Snoek et al., 2014), East Cree (Arppe et al., 2017) , for the East Odawa dialect of Ojibwe (Bowers et al., 2017), for Mohawk (Iroquoian language family) (Assini, 2014), for the Bribri (Chibchense language family) (Solórzano, 2017) using the FOMA tool (Hulden, 2009), Quechua (Vilca et al., 2012; Monson et al., 2006), Mapudungun (Monson et al., 2006), and the Argentinian branch of Quechua and Toba (Porta, 2010). More recently a new hybrid ap-

proach of finite-state transducer (FST) with statistical inference is part of the *Basic Language Technology Toolkit for Quechua* (Rios, 2016).

For Uto-Aztecan languages, there exists a computational tool called "*chachalaca*" that performs morphological analysis (Thouvenot, 2011) of Nahuatl. This is a rule-based software focused on Classical Nahuatl, it is able to generate more than one morphological analysis candidate per word. It is based on grammars that describe most of the 16th-century-word constructions. Additionally, Mager et al. (2018) propose a morphological segmentation tool for the Wixarika language, with a supervised approach, using previous given morphological tables and a probabilistic model to infer the inherent morphological rules.

Regarding to unsupervised methods, neural methods have been used to tackle the rich morphology of the languages of the continent. Micher (2017) propose a Segmental Recurrent Neural Network (RNN) for segmenting and tagging Inuktitut. Kann et al. (2018) used a set of extensions to the Encoder-Decoder RNN architecture with Gated Recurrent Units (GRU) for automatically segmenting four Uto-Aztecan languages (Mexicanero, Nahuatl, Wixarika and Yorem Nokki). Semisupervised segmentation approaches like Morfessor have also been successfully applied to Nahuatl (Gutierrez-Vasques, 2017). For the Uto-Aztecan language Tarahumara and the Mayan language Chuj, there are works that try to automatically discover affixes through unsupervised approaches (Medina-Urrea, 2007; Medina-Urrea, 2008; Medina Urrea and García, 2006).

Lately, there has been interest in the reinflection task, i.e., generating an inflected form for a given target tag and lemma. The CoNLL-SIGMORPHON Shared Task (Cotterell et al., 2016; Cotterell et al., 2017) released a dataset for reinflection of 52 languages, including 3 Native American languages. The systems that got the best performance (Kann and Schütze, 2016; Kann and Schütze, 2017; Makarov et al., 2017).

In some cases it is difficult to disambiguate between homonym morphs. To deal with this problem, Rios et al. (2008) used Conditional Random Fields (CRFs) (Lafferty et al., 2001).

Most of the methods that we found that deal with morphology are based on FST. However, the indigenous languages of the continent are far too diverse, it would be expensive to build such analyzers with expert knowledge for each language, besides the fact that the analyzers need to be constantly updated to cope with language change (Creutz and Lagus, 2005).

4 Machine Translation

Machine Translation is a natural task for indigenous languages, since it might provide a communication window with more popular languages. The development of MT systems for indigenous languages have follow the trends in the field, from rule-based, to statistical and neural based approaches.

Rule-Based Machine Translation (RBMT) approaches are sometimes suitable for low resource languages since they do not require aligned parallel corpora. However. In recent years, research on data-driven approaches has increased, with the aim to overcome the scarcity of data using different methods. In any case, translation of low-resource languages represents an interesting and active research problem in the NLP field.

In the case of native American languages, there have been some efforts in building rule-based systems. The Apertium system (Tyers et al., 2009; Forcada et al., 2011) is a big help for this approach, and at least two languages has translation teams working with it. This is the case of Quechua (Eastern Apurimac Quechua and Cusco Quechua)-Spanish (Cavero and Madariaga, 2007) and Spanish-Wayuunaiki (Spoken in Venezuela and Colombia) (Fernández et al., 2013). Other RBMT systems were created for Aymara-Spanish (spoken in Peru) (Coler and Homola, 2014) Wayuunaki-Spanish, Quechua-Spanish and Mapuche-Spanish (Monson et al., 2006). For the latter a web available translator[11](González Hernández, 2016) is available. We found that there are mobile apps for translating indigenous languages, this is the case of Zapotec-Spanish language pair (spoken in Mexico from the Oto-Manguean family)[12].

All of this RBMT systems have a set of shortcomings. The majority is not able to translate complex constructions, specially when the languages are distant from each other, which increases the complexity

[11] `http://142.4.219.173/wt/`

[12] `https://play.google.com/store/apps/details?id=com.SimplesoftMx.Didxazapp&hl=es`

of the machine translation rules. One way to overcome this is to include linguistic information, e.g., morphology, syntax. However, this kind of knowledge or linguistic tools is not always available, especially for low-resource languages. Experiments using the Example Based Machine Translation (EBMT) methodology are not common, we only found the work of Llitjós et al. (2005) and Monson et al. (2006) for the Mapuche-Spanish pair.

Statistical Machine Translation (SMT) Systems are data-driven since they use vast amounts of parallel corpora to model the translations between sentences or subunits. Their performance is highly dependent on the number of training data; they represent a challenge when low resource conditions are faced. In the case of the native languages of the Americas, they tend to be morphologically rich and this must be taken into account to improve the translation and reduce the data sparseness. An example of this is the Wixarika-Spanish SMT system that aligns Wixarika morphemes with Spanish words or tokens (Mager Hois et al., 2016; Mager Hois, 2017)[13]. A similar case can be found for the Nahuatl-Spanish pair. Uto-Aztecan languages can be highly agglutinative with the polysynthetic tendency, Gutierrez-Vasques (2015) extracts bilingual correspondences from a parallel corpus, by aligning the Nahuatl non-grammatical morphs to Spanish words. Another example was collected for the pair Mixteco-Spanish (Santiago, 2017). The same trend can be observed in SMT for Shipibo-konibo (Galarreta et al., 2017).

Regarding commercial systems, Microsoft has targeted some languages spoken in Mexico, Mayan and Otomi (Queretaro variant)[14]. SMT was also applied for the Guarani, it translates to Spanish, but also to English, French, Italian, German and Portuguese[15].

Recently, there has been an increasing interest in Neural Machine Translation (NMT) models, which are also statistical based, but they use neural networks architectures that are feed with very big amounts of parallel corpora. Mager and Meza (2018) showed that in such low-resource scenarios, translating from Mexicanero, Nahuatl, Purepecha, Wixarika and Yorem-Nokki to Spanish, SMT systems achieve better performance than NMT. Even though these architectures are not suitable for low-resource settings, there have been some recent efforts to adapt them. Soriano (2018) experimented with the Mexican Purepecha (an isolated language with about 140 thousand speakers) using the OpenNMT toolkit (Klein et al.,). Tiedemann (2018) took the massive bible corpus (Mayer and Cysouw, 2014) and trained a multilingual NMT model to improve overall translation performance. Experiments included Oto-manguean, Quechua and Mayan families. Moreover, empirical results (Vania and Lopez, 2017) show that problem of data sparsity of rich morphological languages can be handled with subword models: the usage of character level NMT improve performance over token level translation and unsupervised morphological segmentation (Creutz and Lagus, 2002). But their experiment also conclude that a canonical segmentation enhances character level translation.

In order to alleviate the lack of resources automatic data recollection has been proposed, this has been tried for Guarani language (Abdelali et al., 2006). Moreover, it would be very useful to have big repositories of translated texts. One alternative is to create parallel corpora between many languages using manual translations (controlled elicitation) as described for the Mapudungun (Mapuche) language (Probst et al., 2001).

In any case, SMT and NMT systems should be adapted to deal with the scarcity, of the sparseness of word forms and the rich morphology of languages. Although there are works that try to deal with morphology (Virpioja et al., 2007; Popovic and Ney, 2004; Costa-jussà and Fonollosa, 2016; Sennrich et al., 2016; Dalvi et al., 2017), they are rarely applied to Native American languages.

5 Other studies and tools

5.1 Multilinguality and Code-Switching

Most native speakers of indigenous languages are at least bilingual, they have to communicate using the primary or official language of their own country, i.e., Spanish, Portuguese, French or English. Only few

[13] Available at `http://turing.iimas.unam.mx/wix`

[14] `https://www.microsoft.com/en-us/translator/languages.aspx`

[15] `http://www.iguarani.com/?p=traductor`

communities remain completely monolingual in their native language, moreover, modern migrations and the use of social networks contribute to bilingualism and code-switching.

Code-switching occurs when a speaker alternates between two or more languages in a conversation. This adds a challenge when doing NLP for this kind of data. Code-switching is not a new phenomenon, it can be found in historical documents, Garrette and Alpert-Abrams (2016) proposes an unsupervised approach of paired encoding (words and characters) to improve language modeling (Latin, Spanish and Nahuatl) in an Optical character recognition (OCR) task. King and Abney (2013) applies weakly supervised methods for labeling the language of each word in documents that can have many mixed languages. The targeted languages are 30, including Chippewa, Nahuatl, and Ojibwa.

Being able to automatically detect Code-switching could be useful when doing NLP for minority languages, for instance to use the web as a source for a corpus.

From the quantitative linguistics perspective, parallel corpora of an outstanding number of languages have been extracted from the Bible and used to perform typological studies in many languages, included native languages of the Americas. For instance, exploring the tense behavior (Asgari and Schütze, 2017), contrasting the morphological complexity in many languages (Bentz et al., 2016; Kettunen, 2014) just to mention some.

5.2 Language Tools

For some rich resource languages, there are already available NLP tools that deal with several phenomena and linguistics levels of processing. However, for low resource languages, there is still much work to do. In this section we summarize some of the works related with POS Tagging, OCR, Parsing, Spell Checking, Language Identification and other tasks, that we have found for the languages of the Americas.

Speech synthesis and recognition has made some progress for the Raramuri language (Urrea et al., 2009), using a unit selection approach based on function words, suffix sequences and diphones of the language. For speech recognition, Maldonado et al. (2016) applied on Guarani a Hidden Markov Model (HMM) with the CMU Sphinx toolkit (Lamere et al., 2003). Coto-Solano and Solórzano (2016) proposes an automatic aligner of text and voice for the indigenous language Bribri of Costa Rica.

Part-of-Speech (POS) tagging assigns a category from a given symbol set to each token in an input string. It is used as a prepossessing step that serves as input for other tasks or for higher level NLP task. POS Tagging was also incorporated into the Peruvian Shipibo-konibo NLP toolkit (Pereira-Noriega et al., 2017).

Spell checking is not a trivial task for highly agglutinative and polysynthetic languages, that can't rely on a token based evaluation, and need sub-word level models. We found only two tools that handle this issue: Monson et al. (2006) build a dictionary based tool for Quechua and Alva and Oncevay (2017) for Shipibo-Konibo used rule-based analysis and dictionaries.

Another field that is crucial to increase the amount of digitized data for other tasks is **Optic Character Recognizing** (OCR). Maxwell and Bills (2017) studied the challenges regarding the digitalization of Tzeltal-Spanish, Muinane-Spanish, Cubeo-Spanish dictionaries. Garrette and Alpert-Abrams (2016) developed an unsupervised transcription model for dealing with orthographic variation in digitized historical documents, some of them were written in Nahuatl.

In the context of indigenous **Language Identification** (LID), Espichán-Linares and Oncevay-Marcos (2017) studied LID on 17 languages from the Arawak, Aru, Jíbaro, Pano and Quechua linguistic families. The proposed models were flexible enough to handle the lack of orthographic standardization of the language.

Another important NLP task is **parsing**. The research in this area is also weak, however, the Quechua-Spanish Treebank helped to perform some experiments in this topic (Bresnan et al., 2015; Rios, 2016). For other languages parsing experiments were performed on Ayamara (Homola, 2011) using Lexical-Functional Grammar (LFG).

6 Discussion

Study of the languages of the Americas has increased in the recent years, in both the linguistic and the language technology fields. Many factors have contributed to this, such as speakers self-awareness about the importance of their languages and digital inclusion. Figure 1 shows that many of the papers that we reviewed, were published from year 2000 to present day, with a notable increase in the activity in the last five years. The most studied NLP tasks are Machine Translation and Morphology, however, from 2013 upon now, other tasks, e.g., POS-tagging, parsing, speech, spell correction, also received attention.

Despite the fact that we found NLP contributions for around 35 languages, this is still a small number if we take into account the big diversity and number of languages that exist in the continent. Table 2 showed that some linguistic families have concentrated the attention, but even for these languages the developed technology is not enough. We noticed that North American languages are the most studied, despite some of them don't have a big number of speakers compared to other indigenous languages, e.g., Navajo, Haida, Cree, Chippewa, Ojibwa, Blackfoot, Nata, Gitksan, Okanagan, Tlingit, Plains Cree, Ktunaxa, Coeur d'Alene, Kwak'wala, and Inuktitut. Uto-Aztecan language family that includes languages like Raramuri, Nahuatl, Wixarika, Yorem Nokki, Mexicanero (spoken mainly in Mexico) have also received attention from the NLP community. Regarding to South America, the most spoken native languages, Quechua, Mapuche, Guarani and Ayamara, have several resources available. Surprisingly, languages with less speakers such as Shipibo-konibo, Arawak, Aru, Jíbaro, Pano and Wayuunaki have been also studied.

The diversity in the linguistic phenomena of these languages makes developing language technologies a challenging task. In recent years, NLP and Machine Learning fields have paid attention to low resource settings, organizing workshops and special tracks to tackle this issue. Indigenous languages could be greatly benefit from this kind of research in the future. In particular, American languages with rich morphology, e.g., agglutinative and polysyntehthic, seems to benefit from approaches that take into account the morphology and sub-word modeling.

We also noticed that some NLP tasks that are considered almost solved for languages like English, need to be adapted or started from scratch when applied to the languages of the American continent. Moreover, fields like machine translation could enable in the future the creation of multilingual technologies for all of the languages in the world that face a similar situation, this could have a great impact in these communities.

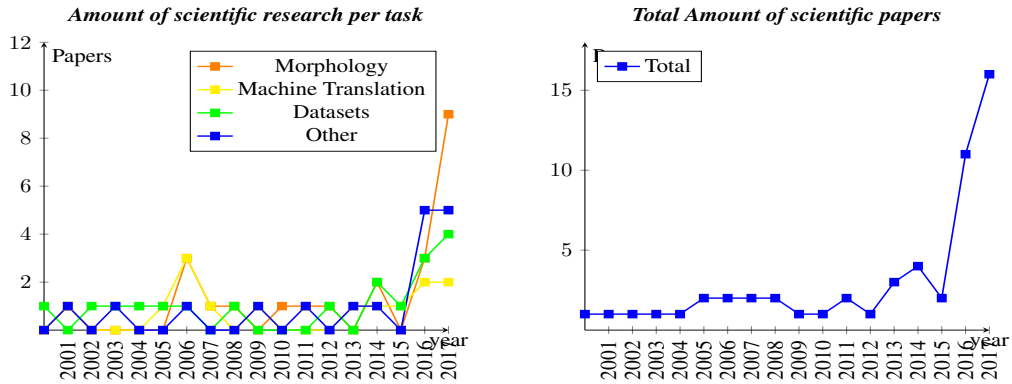

Figure 1: NLP papers and digital resources that contain any indigenous language of the Americas (between 2000 and 2017)

7 Conclusions

In this work, we presented a review of NLP research focused on Indigenous Languages of the Americas. We showed which languages have available digital resources and their related tools. Research has focused in tasks like morphology and machine translation, however, there is still a lot of work to be done since these languages exhibit a wide range of linguistic phenomena while resources are scarce.

Through this work, we discussed some of the challenges that must be taken into account, e.g., small datasets, high dialectal variation, rich morphology, lack of orthographic normalization, scarcity of linguistic preprocessing tools.

NLP research for these languages can broad the understanding of human language structures and help to build more general computational models. Moreover, the development of language technologies can have a positive social impact for the speakers of the indigenous languages, helping to maintain the living cultural heritage that each language represents.

Appendix A. Language Families

Table 2 summarizes the language families for which we were able to identify some digital and technological resources during this research. We distinguish among only two geographical macroareas: North America (it includes Central America) and South America (Dryer and Haspelmath, 2013).

L. Family	Macroarea	Papers	L. Family	Macroarea	Papers
Uto-Aztecan	North A.	16	Mayan	North A.	4
Oto-Manguean	North A.	3	Arawakan	South A.	3
Haida	North A.	4	Ayamaran	South A.	2
Na-Dene	North A.	5	Aru	South A.	1
Eskimo-Aleut	North A.	2	Jibaro	South A.	1
Algic	North A.	8	Bora–Witóto	South A.	1
Tsimshianic	North A.	1	Tucanoan	South A.	1
Penutian	North A.	1	Araucanian	South A.	7
Salishan	North A.	2	Panoan	South A.	4
Wakashan	North A.	1	Tupian	South A.	5
Iroquoian	North A.	1	Quechuan	South A.	15
Chibchan	North A.	2	Guaicuruan	South A.	1

Table 2: Language families (L. Family) for which some technology was found, and the number of NLP/Computer Linguistic papers referring to each (one paper can reference more than one languages). North A. stands for North America and South A. for South America.

Low-resource Cross-lingual Event Type Detection in Documents via Distant Supervision with Minimal Effort

Abstract

The use of machine learning for NLP generally requires resources for training. Tasks performed in a low-resource language usually rely on labeled data in another, typically resource-rich, language. However, there might not be enough labeled data even in a resource-rich language such as English. In such cases, one approach is to use a hand-crafted approach that utilizes only a small bilingual dictionary with minimal manual verification to create distantly supervised data. Another is to explore typical machine learning techniques, for example adversarial training of bilingual word representations. We find that in event-type detection task—the task to classify [parts of] documents into a fixed set of labels—they give about the same performance. We explore ways in which the two methods can be complementary and also see how to best utilize a limited budget for manual annotation to maximize performance gain.

1 Introduction

For most languages of the world, few or no language processing tools or resources exist (Baumann and Pierrehumbert, 2014). This hinders efforts to apply certain language technologies enjoyed by languages like English, in which much current research is done.

To perform natural language processing tasks in resource-poor languages, one way to overcome data scarcity is to tap on resources from another resource-rich language. Assuming that there are already good resources and tools to solve the same tasks in the more resource-rich language (henceforth, *auxiliary language*), the only remaining challenge is to transfer the learning process into the resource-poor language (henceforth, *target language*) and adapt it to the specifics of that language. One way to do this is to build a shared word representation across the two languages and train an NL engine on this shared representation, perhaps using an adversarial domain adaptation approach to handle the domain (language) shift (Chen et al., 2017). Usually, these approaches assume the availability of large labeled data in the auxiliary language, on the order of hundred thousands to millions.

However, for some more complex or specialized tasks, there might not be enough available training data even in a resource-rich language such as English. A case in point is the event-type classification task over the publicly available datasets, such as ACE 2005[1] and TAC KBP [2] datasets, which usually contain only a few hundred to a few thousand documents. The situation frame (SF) detection task is one example of event-type classification task, where the objective is to extract from each document one or more *situation frames* with their corresponding arguments. A situation frame (SF) is either an *issue* being described in the articles, such as civil unrest or terrorism, or a *need* situation such as the need for water or medical aid. In our task there are 11 situation frame types, each associated with a set of arguments, namely the location, status, relief, and urgency. For example, an article titled "Millions of people are at the risk of starvation due to the food shortage in South Sudan", with content describing the details and the cause of the food shortage, including a mention of difficulty accessing certain regions, can be classified as describing a *food need* and an *infrastructure need*.

Proceedings of the 27th International Conference on Computational Linguistics, pages 70–82
Santa Fe, New Mexico, USA, August 20-26, 2018.

As described below, we have tried two approaches: (1) a simple keyword-matching system utilizing only a small bilingual dictionary and minimal manual verification and (2) a sophisticated neural adversarial network that learns bilingual word representations for cross-lingual transfer. We find that the methods have similar performance. We therefore explore ways in which few keyword-based models can create additional, distantly supervised data to improve the performance of a neural cross-lingual event type detection system. Our contributions are: (1) an evaluation of a state-of-the-art method in a different task showing its similar result against a simple baseline, (2) ways to improve performance of such models, and (3) an analysis of the result, with insights to practitioners as to where to focus the available, yet limited, budget for manual annotation work.

This paper is organized as follows: we first describe the related work on cross-lingual NLP tasks in low-resource settings, specifically how the available resources are used. Based on previous work, we then apply our proposed training data augmentation methods and run experiments to show the effectiveness of our methods. We then analyze the results, and follow with a few suggestions on how to best utilize the available annotation effort for maximum gain.

2 Related Work

Keyword-based Models A keyword-based heuristic model is a simple yet effective approach to extract specific information such as events (Keane et al., 2015), because keywords often indicate a strong presence of important information contained in documents (Marujo et al., 2015). Such methods have been used in different tasks like text categorization (Özgür et al., 2005) and information retrieval (Marujo et al., 2013) to extract the required information. Keyword heuristics have also been used to overcome language and domain barriers using bilingual dictionaries (Szarvas, 2008; Tran et al., 2013). However, a weak bilingual dictionary could result in low coverage with this method. Hence, to overcome the limiting bilingual dictionary people employ bootstrapping methods to improve the coverage (Knopp, 2011; Ebrahimi et al., 2016).

Cross-Lingual Text Classification Cross-lingual event type detection is closely related to cross-lingual text classification (CLTC), which aims to classify text in a target language using training data from an auxiliary language (Bel et al., 2003).

To bridge the language gap, early approaches of CLTC relied on a comprehensive bilingual dictionary to translate documents between languages (Bel et al., 2003; Shi et al., 2010; Mihalcea et al., 2007). However, in resource-poor languages, bilingual dictionaries may be small and sparse. Therefore, the performance of direct word translation will be unsatisfactory. Some researchers utilized the bilingual dictionary to translate the models instead (Xu et al., 2016; Littell et al., 2017).

Another line of work focuses on the use of automatic machine translation as an oracle. The various learning algorithms treated the translations as a second view of document and facilitate cross-lingual learning with co-training (Wan, 2009), majority learning (Amini et al., 2009), matrix completion (Xiao and Guo, 2013) and multi-view co-regularization (Guo and Xiao, 2012a).

Instead of word-level or sentence-level translation, various other approaches seek some cross-lingual mapping between document representation (Littman et al., 1998; Vinokourov et al., 2002; Platt et al., 2010; Jagarlamudi et al., 2011; De Smet et al., 2011; Guo and Xiao, 2012b; Zhou et al., 2015; Zhou et al., 2016a; Zhou et al., 2016b; Chen et al., 2017) or label distribution (Xu and Yang, 2017).

Bilingual Word Embedding The most recent method for sharing document representation between languages is bilingual word embedding (Mikolov et al., 2013a; Faruqui and Dyer, 2014; Luong et al., 2015). The goal is to learn a shared embedding space between words in two languages. With the shared embedding, we are able to project all documents into a shared space. The model trained in one language can, therefore, be used in the other language.

3 Models

To see how well recent state-of-the-art methods for CLTC work in our task, we implemented a convolutional neural classifier. We compare this against a simple keyword-based method.

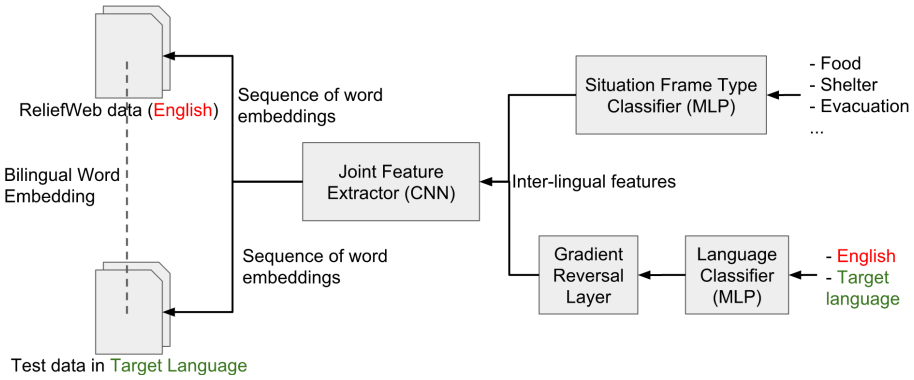

Figure 1: Architecture of the neural classifier with adversarial domain (language) adaptation by Ganin and Lempitsky (2015). Arrows show the flow of gradient.

3.1 Adversarial Convolutional Network

The first step is to train a bilingual word embedding as a shared feature representation space between the two languages. We trained our bilingual word embedding for English and the incident language using the method proposed in XlingualEmb (Duong et al., 2016). This method is a cross-lingual extension from word2vec model (Mikolov et al., 2013b) to bilingual text using two large monolingual corpora and a bilingual dictionary.

Based on the shared representation, we then used a convolutional neural network (CNN) (Kim, 2014) to perform the classification. There are two main advantages of choosing a deep neural classifier over a shallow one. First, CNN outperforms shallow models like SVM or Logistic Regression in various text classification benchmark datasets (Kim, 2014; Lai et al., 2015; Johnson and Zhang, 2015; Xu and Yang, 2017). Second, CNN takes dense word vector representations as input, allowing one to incorporate the state-of-the-art bilingual word embedding methods into the pipeline.

The CNN model takes a sequence of word embeddings as input and applies 1-D convolutional operation on the input to extract semantic features. The features are then passed through a fully-connected layer before reaching the final soft-max layer. The model is trained in English using the ReliefWeb dataset (Littell et al., 2017, Sec 2.3), which is annotated at sentence level with disaster relief needs and emergency situations. Thanks to the bilingual word embedding, which maps the words from the two languages to the same distributional semantic space, the model trained in English can be applied to documents in the target language.

Ideally, if the bilingual word embedding captures the ground-truth mapping between two languages, a classifier learned from English training documents should generalize well on the target language. However, in practice, we can observe obvious domain gaps between documents in different languages when we represent them with bilingual word embeddings. In order to close the domain (language) gap between training and testing, we adapt our learned model in English to the target language with similar adversarial training techniques used in (Xu and Yang, 2017; Chen et al., 2017). In order to alleviate the domain mismatch, we are essentially looking for a feature extractor that only captures the semantics of the event types but not the difference in language usage between English and the target language. In other words, we want the features captured by CNN to be informative for the event type classification and to be language-invariant at the same time. To achieve this goal, we include an auxiliary classifier that takes the features extracted by CNN and predicts the language that the input belongs to. During training, we update our parameter to simultaneously minimize the loss of the event type classification and maximize the loss of language classification through Gradient Reversal Layer (Ganin and Lempitsky, 2015).

3.2 Keyword-based Model

As mentioned previously, a keyword-based model is a simple, quick, yet effective approach to perform text classification without much training data. In our case, we do this in two steps: (1) build a list of keywords for each SF type in English, then (2) translate the keywords into the target language automatically

Table 1: Statistics of the various sources of training data. Eng-Orig and Eng-KW refer to training data in English described in Littell et al. (2017, Sec 2.3) and from our English keyword model's output on ReliefWeb corpus, respectively, while Tgt-Boot and Tgt-Ann refer to training data in the target language obtained from bootstrapped keyword-spotting and from annotation, respectively. The "none" class signifies negative examples in the data. The last column shows a visualization of the SF types, excluding "none". Note: for Test Data, the instances refer to documents, while for the rest, instances refer to sentences.

using a bilingual dictionary. We also asked native speakers of the target language to refine the translation, especially for domain-specific keywords which are not adequately captured by the bilingual dictionary.[3]

Building English keywords is again a two-step process. First, we use the ReliefWeb dataset to generate a list of 100 candidate keywords for each class by taking the top-100 words with the highest TF.IDF scores. Similar to the keyword generation method described by Littell et al. (2017), we manually refined the keyword list by pruning based on world knowledge. For each candidate keyword, we added 30 most similar words using the English word2vec model trained on the Google News corpus[4]. We retained only the words that have cosine-similarity greater than 70%. For each candidate keyword in this extended list, we computed a label affinity score with each SF class label (e.g., *water*, *evacuation*) using cosine-similarity between their word2vec embeddings. Candidate keywords with similarity above a certain threshold th_1 were retained and used as keywords for the corresponding classes[5].

4 Method: Training Data Augmentation

Chen et al. (2017) assumed the auxiliary language contains a large amount of labeled data for the task, about 700k Yelp reviews. For our case, the original training data, which was built semi-automatically by Littell et al. (2017, Sec 2.3), contains only about 80k sentences (Table 1, first row). To improve the performance of the neural model, therefore, we propose to utilize the keyword-based system to automatically augment the original training data. We also explore using additional training data obtained via manual annotation for comparison.

Figure 2 is a summary of the various training data sources we compare in this paper: the original training data (Ⓞ), keyword-spotting in the auxiliary language (Ⓔ), keyword-spotting with bootstrapping in the target language (Ⓣ), and annotated data in the target language (Ⓐ). The additional training data from keyword-spotting in English (Ⓔ) can be directly obtained by using the keyword list in English that we used for the keyword model (Section 3.2) to label a larger ReliefWeb corpus. We describe the other two ways (Ⓣ and Ⓐ) to obtain additional training data in the following sections.

[3]We showed the native speakers translation pairs obtained through the bilingual dictionary, and asked them to verify the translation as acceptable, or to supply a better translation.

[4]https://code.google.com/archive/p/word2vec/

[5]Threshold $th_1 = 0.9$ was determined by a grid search on a held-out English dataset.

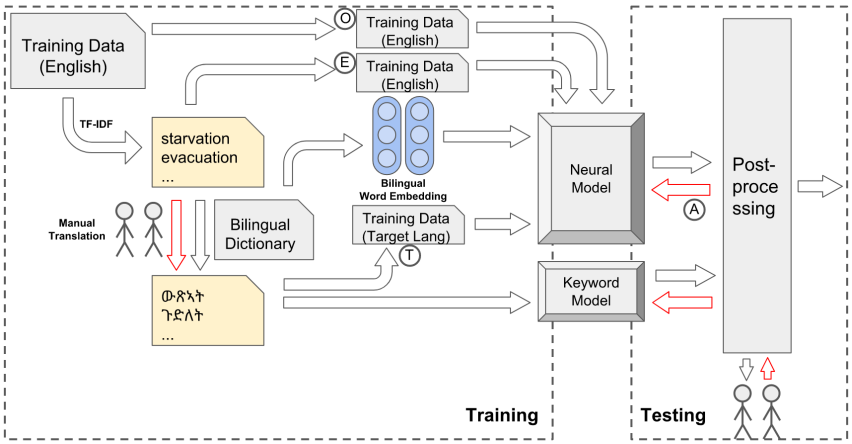

Figure 2: A summary of the various training data sources that we compare in this paper (Ⓞ, Ⓔ, Ⓣ, Ⓐ).

4.1 Bootstrapping Language-specific Keywords

We note that using simple keyword matching can result in low coverage due to missing keywords in the bilingual dictionary or word-variations in the target language. To overcome this, we developed an iterative bootstrapping algorithm that takes into account the newly labeled documents from keyword-spotting and generates additional language-specific keywords in a two-step process (Ⓣ in Figure 2).

Clustering: In the first step, we collected labeled documents from each class, and generated clusters for them ($D = \{D_{c_1},..,D_{c_m}\}$, where D_{c_p} is the cluster of the class c_p). For each cluster D_{c_p} and non-keyword w_i in it, we then computed the label affinity score $S_p(w_i)$, defined as follows:

$$S_p(w_i) = tfidf(w_i) + \frac{\sum_{w_j \in W_p} cos(w_i, w_j)}{|W_p|}$$

where W_p was the set of keywords present in D_{c_p}. We then appended the words which exceed a certain threshold th_2 to the keywords list of class c_p.

The rationale for this step is that the keywords that were missed in the initial keyword list (due to an incomplete bilingual dictionary, the keywords being language-specific, or incident-specific) may appear more frequently in the document cluster, and the second term in $S_p(w_i)$ will capture this.

Labeling: With the updated set of keywords for each class, we relabeled the documents to obtain a new set of labeled documents and again executed the clustering step to get more keywords. We can repeat this two-step process n times until we have the desired coverage or until this process no longer gives useful new keywords. In our experiments, we found that $n = 10$ generally gives good coverage. To generate the training data, we ran this procedure on the test set and took the top-100 most confident predictions.[6]

4.2 Annotation in Target Language

When we have the budget and annotators to do so, we can also annotate documents in the target language with class labels of interest. Given the limited budget and the rarity of documents with SFs (14-18% in our dataset), however, one question remains: how to best pick the documents to be annotated to maximize the gain from the additional training data? Seeing that the number of documents with at least one positive class is much less common compared to the number of documents without any positive class (see Table 1), simply taking a randomly sampled document from the unlabeled documents will likely give a document with no class, which is less useful compared to document with at least one positive class. Thus, we opt for a simpler method of asking annotators to make a binary decision on a

[6] As explained below, we used sentences as our training data, by taking the sentences which contain the keywords found.

	Tigrinya	Oromo
#Documents	2,991 (100%)	2,810 (100%)
– single sentence	2,508 (83.9%)	2,432 (86.6%)
– with 0 SFs	2,565 (85.7%)	2,307 (82.1%)
– with 1 SF	295 (9.9%)	361 (12.9%)
– with 2 SFs	95 (3.2%)	99 (3.5%)
– with 3 SFs	26 (0.9%)	26 (0.9%)
#Sentences	9,412	11,905
#SFs	612	721

Table 2: Data statistics for Situation Frame (SF) type extraction task in Tigrinya and Oromo dataset.

subset of our model's output on a separate dataset, different from the test set. We obtained 653 annotated sentences in Tigrinya this way (and 652 in Oromo). In addition to the native speakers, we also had non-speaker linguists annotate another separate (359) sentences in Tigrinya, assisted by grapheme-to-phoneme conversion, morphological glossing, and machine translation (MT) output.[7] This results in 1,012 sentences annotated in Tigrinya (Ⓐ in Figure 2 and Table 1). Overall, we spent less than 12 man-hours with native speakers of the target language to do the keyword translation and the annotation, with the larger amount of time spent on keyword translation.

5 Experiments

5.1 Dataset

For the purpose of the experiments and analysis, we used the dataset from the LoReHLT 2017[8] shared task, which consists of news articles in two Ethiopian languages: Tigrinya and Oromo.[9] The statistics of the dataset is shown in Table 2.

The available resources that we used for this experiment consist of:

1. Monolingual articles in Tigrinya and Oromo in various genres (news, discussion, social media).
2. Bilingual word dictionary (English-Tigrinya and English-Oromo).
3. A few hours of interaction with volunteers who are native speakers of Tigrinya or Oromo.
4. English documents about disaster recovery from ReliefWeb[10] and CrisisNet[11] annotated semi-automatically with disaster type and theme (Littell et al., 2017, Sec 2.3).[12]

5.2 Setup

We summarize more details about the experiment setup.

Sentence-level prediction: Although the model we used can be applied to produce document-level predictions directly, working at sentence-level provided more training data for the model and made it easier to train. Doing so also enabled some insight on which sentences contain the information about the document-level predictions.

Document-level aggregation: We then aggregate sentence-level predictions to a document-level prediction by assigning to each SF type the maximum confidence score of that type across all sentences in the document. Based on these scores, we calculate the mean confidence score μ_{c_p} of each SF type c_p. We then took the top-k ($k = 3$ in our experiments) SF types as our document-level prediction and filter out the predicted SF types which have confidence scores below μ_{c_p}. In the absence

[7] The MT model was also trained in a low-resource setting, with BLEU score around 12 for Tigrinya.

[8] https://www.nist.gov/itl/iad/mig/lorehlt-evaluations#lorehlt17

[9] For Oromo, the original dataset includes one annotator (out of 4) which annotated most of the documents with a single class. We did not consider this outlier annotator in our experiments.

Table 3: Performance of the neural model (NN) with various sources of training data. Ⓞ is the original training data, Ⓔ is the additional training data in English from keyword-spotting, Ⓣ is the additional training data in target language from bootstrapping, and Ⓐ is the additional training data in target language from annotation. The result on keyword model (KW) is also shown for comparison.

of labeled data in the target language to be used as development set, this is one method that we can use without much tuning. In later sections we show how different document-level aggregation procedures may affect the performance.

Metric: We followed the metric defined in LoReHLT 2017 guidelines[13], which is *occurrence-weighted scores*, defined as follows:

$$P_{occ} = \frac{\sum \alpha_{tp}}{\sum \alpha_{tp} + \sum \alpha_{fp}}, \qquad R_{occ} = \frac{\sum \alpha_{tp}}{\sum \alpha_{tp} + \sum \alpha_{fn}}, \qquad F_{occ} = \frac{2 \cdot P_{occ} \cdot R_{occ}}{P_{occ} + R_{occ}}$$

where $\sum \alpha_{tp}$ is the number of true positives, weighted with the number of annotators that agree with it. $\sum \alpha_{fp}$ and $\sum \alpha_{fn}$ are similarly defined for false positives and false negatives. False negatives always have weight 1. For brevity, we drop the occ subscript when referring to these scores.

Model hyperparameters: In our neural CNN model, we used filter lengths of $\{3, 4, 5\}$ and 300 filters for each length. We also applied dropout on the extracted feature by CNN at a rate of 0.2. The model was optimized in mini-batches of size 128 by Adam (Kingma and Ba, 2014) optimizer at the learning rate of 0.001. The optimization was terminated after 30 epochs or a convergence criteria was satisfied on the held-out training data.

5.3 Results

Table 3 shows the results in Tigrinya and Oromo with the varying training data described in Section 4.

First, the keyword model (KW) gave results comparable to the neural model (NN Ⓞ), even outperforming it in Oromo. This suggests that in a low-resource setting, a keyword-based model can be used as a way to quickly get a working classifier, without the hassle of training a machine learning classifier or getting a large additional training data.

Next, the additional training data did help to significantly improve the performance of the baseline neural model in both languages. The large additional English data (+Ⓔ) provided a large boost both in Tigrinya (+6.8) and Oromo (+4.7). Interestingly, with only about 900 examples in the target language, the additional annotation in the target language (+Ⓐ) gave about the same improvements in F_1-score in Tigrinya, and even 1.4 points higher in Oromo compared to the large additional training data in English. Recall that the annotation was done on a subset of the neural model's output (trained on Ⓞ). This suggests that when an annotation budget is available, using that to verify the output of a model is a good investment.

It is interesting to note that each source of additional training data improved a different aspect of the model. The additional training data in English (Ⓞ+Ⓔ) seemed to improve precision more, while the

[13] https://goo.gl/FwRCwj

additional training data in target language from annotation seemed to improve recall more (Ⓞ+Ⓐ), and combining both (Ⓞ+Ⓔ+Ⓐ) provided the best of both worlds, especially in Oromo.

When we included the training data in target language from the keyword model with bootstrapping together with all other training data (Ⓞ+Ⓔ+Ⓣ+Ⓐ), it further improved the result in Tigrinya, but not in Oromo, although when it was used alone (Ⓞ+Ⓣ) it still gave some improvements. This could be due to the lower quality of the keyword system in Oromo. Recall that it was created by taking the top-100 most confident predictions of the keyword model. This set of predictions gave 75.9% precision in Tigrinya and 47.1% precision in Oromo. This lower quality of Oromo bootstrapping method can also be seen in the diverging SF Type distribution, as can be seen in Table 1.

The best overall improvement was more pronounced in Oromo (+14.99 points in F_1 for Ⓞ+Ⓔ+Ⓐ) than in Tigrinya (+7.90 points in F_1 for Ⓞ+Ⓔ+Ⓣ+Ⓐ). This could be related to the fact that the baseline score was much lower in Oromo than in Tigrinya to begin with.

For completeness, we also compare the results of the keyword model (KW) in target language without and with bootstrapping in the first two rows of Table 3. As anticipated, the bootstrapping process increased recall significantly, almost doubling the recall in Oromo. Although the precision was slightly reduced, it still resulted in an overall improvement in F_1-score for both languages.

In summary, there are four main observations:

1. The Neural model (NN Ⓞ) gave similar performance to the keyword (KW) model in Tigrinya and lower performance in Oromo, although the keyword model was a much simpler system.
2. With large additional training data in English (+Ⓔ), we obtained large improvements both in Tigrinya (+6.8) and Oromo (+4.7).
3. With only small additional annotations in target language (+Ⓐ) we obtained similar performance to using large English training data in Tigrinya, and even better in Oromo.
4. Getting additional training data in the target language through the keyword model can help if the quality of the keyword model is good enough.

6 Discussion

We hypothesize that the focused improvements on precision when using additional training data in English (Ⓔ) could be attributed to the similarity of the SF distribution to the original training data, since both are in English. This causes the model to be more confident in its prediction, at the expense of diverging away from the true distribution of SF types in the target language. In contrast, the annotated dataset in the target language (Ⓐ) has similar distribution to the true distribution, making the model able to rank correct SF types higher. We can see this from the SF type distribution shown in Table 1 by comparing the visualization at the last column.

Another explanation for the higher recall when adding annotated data in the target language is word coverage. The other two additional sources of data rely on keywords, and although bootstrapping helps improve coverage, the annotated data in the target language will cover more subtle correlations between word forms and class labels.

To analyze the differences between the various source of additional training data, we plot the co-occurrence of classes on the Tigrinya dataset in Figure 3. Each row describes the percentage of a particular SF type co-occurring with other SF types in the same document (recall that each document might be labeled with multiple SF types), including none, in which the SF type is the single label for that document. The numbers in a row sums to unity.

As can be seen, predictions of the NN system trained on the additional English data (Figure 3b) and target language data (Figure 3c) have different co-occurrence patterns. The additional English data apparently allowed the NN to find a strong correlation between the *crime violence* class and the *terrorism* and *regime change* classes, which is consistent with our intuition. On the other hand, the NN fine-tuned on the Tigrinya annotations apparently found the *terrorism* and *regime change* classes tend to occur alone.

There is also an interesting phenomenon that arises from the correlation between keywords and class labels. We found that the SF type *terrorism* is associated with the keyword "መንእሰይ" which means

Table 4: Impact of various aggregation strategy to the performance.

"youth" or "juvenile", as in the example sentence (English translation, the word recognized as keyword in the original language underlined) "According to the information, the Eritrean girls killed in the incident hide near the tyre of a car and was hot by the Sudanese soldiers." Examining the various examples in the dataset, we found that the violence inherent in terrorism is often depicted with youths as the victims. This could be related to the tendency of news outlets to focus on the suffering experienced by young people to make more emotional appeal.

6.1 Impact of Document-level Aggregation Strategy

In Section 5.2 we showed one heuristic to do document-level aggregation. One might wonder whether one can do better in the classification performance by using another aggregation strategy, such as filtering out classes with confidence scores under certain threshold, or using different k when taking top-k classes. In this section, we explore the impact of different aggregation strategies on the performance under different conditions. Assuming the more realistic case of having no development set to prefer one strategy over another, we can use the top-k strategy like we did in our experiments, or set a fixed threshold on the confidence score based on the average confidence score of each type across all documents in the test set. We also show the result when we set the threshold based on the reference annotation, to show how well the result can be in the case that we have a development set to find the best threshold. The result is shown in Table 4.

The significant gap of performance between the one tuned on the reference annotation and the rest suggests that if additional training data can be obtained in the target language, independently from the model's predictions, we should allocate a portion of them to be used for validation, since there are still large room for improvements just from tuning the thresholds (3-4% in Tigrinya and over 12% in Oromo). Note that in our experiments, since the annotation was done on the output of our neural model, we cannot use them as validation set, as it is biased towards the output of our model. So there is a trade-off between ease of annotation process and the amount of data that can be used as validation set.

7 Conclusion and Future Work

In this paper we tackled the problem of event type detection and classification in low-resource setting. We found that a neural model with adversarial training compared about the same as a simple keyword-based model using a small bilingual dictionary. Given that the problem lies with the limited amount of training data available, we proposed and compared methods to increase the amount of training data: to get significant gain in performance one can either use a very large additional semi-automatically labeled dataset in a resource-rich language, or annotate a small amount of documents in the target resource-poor language. We also showed how investing in a development set for tuning might also be a good strategy when there is a limited budget for annotation, after allocating some of them for keyword translation and additional training data.

One possible direction for future work is to address the mismatch of distribution of the classes between the additional training data and the actual test data as we see in Oromo. One way to mitigate the mismatch would be to make the classifier itself less prone to overfitting. In Section 6.1 we have shown how the document-level aggregation strategy may significantly affect the final result. Thus, exploring ways to effectively select the thresholds might be worthwhile. We could also incorporate the correlation between classes as evident from Figure 3, which has proven useful in multi-label classification (Zhang and Zhang, 2010).

Acknowledgments

We acknowledge NIST for coordinating the SF type evaluation and providing the test data. NIST serves to coordinate the evaluations in order to support research and to help advance the state-of-the-art. NIST evaluations are not viewed as a competition, and such results reported by NIST are not to be construed, or represented, as endorsements of any participants system, or as official findings on the part of NIST or the U.S. Government. Neural Transition-based String Transduction for Limited-Resource Setting in Morphology

Peter Makarov **Simon Clematide**
Institute of Computational Linguistics
University of Zurich, Switzerland
makarov@cl.uzh.ch simon.clematide@cl.uzh.ch

Abstract

We present a neural transition-based model that uses a simple set of edit actions (copy, delete, insert) for morphological transduction tasks such as inflection generation, lemmatization, and reinflection. In a large-scale evaluation on four datasets and dozens of languages, our approach consistently outperforms state-of-the-art systems on low and medium training-set sizes and is competitive in the high-resource setting. Learning to apply a generic copy action enables our approach to generalize quickly from a few data points. We successfully leverage minimum risk training to compensate for the weaknesses of MLE parameter learning and neutralize the negative effects of training a pipeline with a separate character aligner.

1 Introduction

Morphological string transduction involves mapping one word form into another, possibly given a feature specification for the mapping, and comprises such inflectional morphology tasks as reinflection and lemmatization (Figure 1), and related problems such as normalization of historical texts. Traditionally, this task has been solved with weighted finite state transducers (Mohri, 2004; Eisner, 2002, WFST). Recently, it has been approached with neural sequence-to-sequence (seq2seq) methods (Faruqui et al., 2016; Kann and Schütze, 2016), inspired by the advances in neural machine translation (Sutskever et al., 2014; Bahdanau et al., 2014). Albeit offering a general solution to a special case of the string-to-string mapping problem, seq2seq models are highly data-intensive. The long tradition of modeling for morphology offers insights into the specifics of the task, suggesting models that would exploit inductive biases and thereby attain lower sample complexity. Recent works in seq2seq morphology model full input string context and unbounded dependencies in the output, but also propose conditioning generation on the context-enriched representation of one input character at a time (Aharoni and Goldberg, 2017; Yu et al., 2016). This and constraining character alignment to be monotonic bring this line of work close to traditional WFST approaches, which monotonically modify a string by performing local changes.

Figure 1: Morphological inflection generation in German (left). Lemmatization in Irish (right).

Having as our starting point the hard monotonic attention model of Aharoni and Goldberg (2017, HA), our goal is to improve seq2seq morphological processing by explicitly modeling local string edits commonly studied in traditional approaches. Our contributions are as follows:

- First, we explain HA as a neural transition-based system over edit actions. Alternative models are then available, differing in the choice of edit actions. We argue that extending HA with the COPY

Proceedings of the 27th International Conference on Computational Linguistics, pages 83–93
Santa Fe, New Mexico, USA, August 20-26, 2018.

edit action is crucial and supported by the nature of the problem, accounting for large performance gains especially in the low-resource setting.

- Second, trained with the original MLE procedure, HA relies on gold action sequences computed by a separate character aligner. As a result, the overall approach is a pipeline. We propose enabling exploration at training (e.g. via expected risk minimization (MRT) or reinforcement learning-style training), thereby allowing the model to prefer alternative actions that also lead to the correct output sequence and neutralizing negative effects of the pipelined architecture. Additionally, this approach benefits from directly optimizing a sequence-level performance metric.

- Third, we conduct extensive experiments on the morphological inflection generation, reinflection and lemmatization tasks, showing that our approaches come near to or improve on the state-of-the-art results. We make our code and model predictions publicly available.[1]

2 Model Description

In our approach, we seek the most probable sequence of edit actions for a given input string and an optional feature specification for the transduction. Unlike traditional WFST approaches to this problem, we abandon the explicit modeling of all possible edit sequences via latent alignments in favor of a greedy, representationally rich RNN-powered transition-based architecture. When training with the MLE criterion following Aharoni and Goldberg (2017), our overall set-up is a pipeline of a character aligner followed by a greedy neural string transducer. Character alignments generated by the aligner are mapped to gold action sequences, whose conditional likelihood the neural transducer then learns to maximize. Under training with exploration, the neural transducer no longer relies on gold action sequences. Instead, the parameters are adjusted to directly maximize the model's accuracy of producing training-set output sequences.

Let Σ_x, Σ_y, and Σ_a be alphabets of input characters, output characters, and edit actions, respectively. Let $\mathbf{x} = x_1, \ldots, x_n$, $x_i \in \Sigma_x$ denote an input sequence, $\mathbf{y} = y_1, \ldots, y_p$, $y_j \in \Sigma_y$ an output sequence, and $\mathbf{a} = a_1, \ldots, a_m$, $a_t \in \Sigma_a$ an action sequence. Let $\{f_h\}_{h=1}^{H}$ be the set of morpho-syntactic features.

seq2seq state-transition system We build a greedy transition-based string transducer that uses a seq2seq neural network to model arbitrary dependencies in the input sequence, the unbounded action history, and the non-deterministic choice of the next action. The system operates a buffer filled with RNN-encoded input characters, and a decoder RNN, which implements a push-only stack. The configuration of the system is given by the decoder state. Transitions are scored based on the output of the decoder, which takes as input the encoded character from the top of the buffer. Here, we elaborate on the model architecture.

We encode input sequence $\mathbf{x}$ with a bidirectional LSTM (Graves and Schmidhuber, 2005)

$$\mathbf{h}_1, \ldots, \mathbf{h}_n = \text{BiLSTM}(E(x_1), \ldots, E(x_n)), \tag{1}$$

where E returns the embedding for x_i. Vector $\mathbf{h}_i$ is thus the representation of x_i in the context of the entire sequence $\mathbf{x}$. We push $\mathbf{h}_1, \ldots, \mathbf{h}_n$ in reversed order into the buffer. Transduction begins with the full buffer and the empty decoder state.

The decoder LSTM keeps track of the past actions and—through conditioning at each step on $\mathbf{h}_i$—knows of character x_i at the top of the buffer and the full contents of the buffer. From the latest state of the decoder $\mathbf{c}_{t-1}$, we compute the configuration of the system:

$$\mathbf{s}_t = \text{LSTM}(\mathbf{c}_{t-1},\ [A(a_{t-1})\ ;\ \mathbf{h}_i\ ;\ \mathbf{f}]), \tag{2}$$

where the input is the concatenation of (i) the embedding of the previous action (given by A), (ii) $\mathbf{h}_i$ from the top of the buffer indicating the current position in $\mathbf{x}$, and—optionally—(iii) feature vector $\mathbf{f}$,

which is the concatenation of the embedded morpho-syntactic features $\phi \subseteq \{f_h\}_{h=1}^{H}$ associated with this transduction: $\mathbf{f} = [F(f_1)\ ;\ \cdots\ ;\ F(f_H)]$ and $F(f_h) = F(0)$ if $f_h \notin \phi$.

To compute probabilities of transitions $\mathbf{a}_t$, we feed $\mathbf{s}_t$ through a softmax classifier:

$$P(a_t = k \mid \mathbf{a}_{<t}, \mathbf{x}, \Theta) = \text{softmax}_k(\mathbf{W} \cdot \mathbf{s}_t + \mathbf{b}) \tag{3}$$

Model parameters Θ include softmax classifier parameters $\mathbf{W}$ and $\mathbf{b}$, the embedding parameters, and the parameters of the encoder and decoder.

Edit actions Traditional transducers edit input sequence $\mathbf{x}$ into output sequence $\mathbf{y}$ by a sequence of single-character edit actions from the following set (Cotterell et al., 2014):

- DELETE: Read x_i and write nothing.
- INSERT(c) for $c \in \Sigma_y$: Write c and read nothing.
- SUBST(c) for $c \in \Sigma_y$: Read x_i and write c.
- COPY: Read x_i and write x_i.

Let INSERTS$_y$ be the set of all insertions with respect to Σ_y. We consider the following two action alphabets: $\Sigma_a^{HA} = \text{INSERTS}_y \cup \{\text{DELETE}\}$ and $\Sigma_a^{CA} = \Sigma_a^{HA} \cup \{\text{COPY}\}$.

Alphabet Σ_a^{HA} is from Aharoni and Goldberg (2017) and includes only the INSERT and DELETE actions. Both substitution and copying of c are expressed as an INSERT(c) followed by a DELETE.

Alphabet Σ_a^{CA} adds a designated COPY action to Σ_a^{HA}. Thus, copying x_i to the output sequence can be executed by one single action. This results in shorter and simpler action sequences dominated by COPY actions, following the observation that inflectional changes are typically small and most of $\mathbf{x}$ is preserved in $\mathbf{y}$.[2]

Action execution Operationally, reading x_i corresponds to popping its representation $\mathbf{h}_i$ from the top of the buffer. The transducer terminates when the buffer is empty and the latest action a_t is INSERT(EOS), where EOS is the end-of-sequence character. If we constrain the number of successive insertions to at most q, the transducer runs in $O(n)$ time, where n is the length of input $\mathbf{x}$.[3]

[2]We also experimented with extending Σ_a^{HA} and Σ_a^{CA} with actions for character substitutions. The resulting models perform similarly to models without substitutions, and so we do not report them here.

[3]In practice, we simply cap the number of actions at 150.

f	l	i	e	g	e	n
|	|	|	|	|	|	|
f	l	o	g	ϵ	ϵ	ϵ

f	l	i	e	g	e	n
|	|	|	|	|	|	|
f	l	o	ϵ	g	ϵ	ϵ

Figure 3: Longest Common Substring (LCS, left) and Chinese Restaurant Process (CRP, right) character alignments for the same $\mathbf{x}$ and $\mathbf{y}$. Input sequence $\mathbf{x}$ is at the top, output sequence $\mathbf{y}$ at the bottom. A CRP aligner recovers this alignment given sufficient training data and number of iterations.

MLE training The model is trained to maximize the conditional log-likelihood of the data $D = \{(\mathbf{x}^{(l)}, \mathbf{a}^{(l)})\}_{l=1}^{N}$, which is an everywhere differentiable function of parameters Θ:

$$\mathcal{L}(D, \Theta) = \sum_{l=1}^{N} \sum_{t=1}^{m} \log P(a_t^{(l)} \mid \mathbf{a}_{<t}^{(l)}, \mathbf{x}^{(l)}, \Theta) \tag{4}$$

The gold action sequences $\mathbf{a}^{(l)}$ are computed by a deterministic algorithm from some character alignment: $\mathbf{a}^{(l)} = C_{\Sigma_a}^{Align}(\mathbf{x}^{(l)}, \mathbf{y}^{(l)})$. Figure 3 illustrates different character alignment algorithms that we use in our experiments. A simple procedure for the generation of gold actions from alphabet Σ_a^{CA} would call the following subroutine d on each pair of character alignment $(b_1, c_1), \ldots, (b_r, c_r)$ between input $\mathbf{x}$ and output $\mathbf{y}$, where $b_k \in \Sigma_x \cup \{\epsilon\}$ and $c_k \in \Sigma_y \cup \{\epsilon\}$ but not $b_k = c_k = \epsilon$:

$$d(b, c) = \begin{cases} \text{COPY}, & \text{if } b = c, \\ \text{DELETE}, & \text{if } c = \epsilon, \\ \text{INSERT(c)}, & \text{if } b = \epsilon, \\ \text{DELETE, INSERT(c)} & \text{otherwise} \quad \% \textit{ substitution} \end{cases}$$

Applying this procedure to e.g. the CRP alignment from Figure 3, we obtain the following gold action sequence: COPY, COPY, DELETE, INSERT(o), DELETE, COPY, DELETE, DELETE.

Learning with exploration Training with MLE comes with a number of limitations. First, the model is not exposed to its own errors at training time: It makes predictions conditioned on gold-action histories, which is at odds with test time when the model has to condition on predicted actions. Second, MLE training increases the model's per-action likelihood, although at test time, the model's performance is assessed with sequence-level accuracy or edit distance. Both constitute well-known MLE training biases—the exposure bias and the loss-evaluation mismatch (Wiseman and Rush, 2016). Finally, we would like the model to be less dependent on the gold actions generated by the aligner, which is uninformed of the downstream task, and that at training, the model can choose alternative action sequences leading to correct predictions, if that helps it generalize.

To address all these issues at once, we train the model by minimizing the expected risk (Och, 2003; Smith and Eisner, 2006) of the actual training data $T = \{(\mathbf{x}^{(l)}, \mathbf{y}^{(l)})\}_{l=1}^{N}$:

$$\mathcal{R}(T, \Theta) = \sum_{l=1}^{N} \mathbb{E}_{\mathbf{a}|\mathbf{x}^{(l)};\Theta} \left[\Delta(\mathbf{y}, \mathbf{y}^{(l)}) \right], \tag{5}$$

where $\mathbf{y}$ is computed from $\mathbf{a}$ and $\mathbf{x}$, and the risk is given by a combination of normalized Levenshtein distance (NLD) and accuracy:

$$\Delta(\mathbf{y}, \mathbf{y}^{(l)}) = \text{NLD}(\mathbf{y}, \mathbf{y}^{(l)}) - \mathbb{1}\{\mathbf{y} = \mathbf{y}^{(l)}\} \tag{6}$$

Thus, an action sequence $\mathbf{a}$ attains the lowest risk of -1 if its corresponding output sequence $\mathbf{y}$ is identical to $\mathbf{y}^{(l)}$ of the training sample and the highest risk of $+1$ if the number of edits from $\mathbf{y}$ to $\mathbf{y}^{(l)}$ equals the maximum of their lengths.

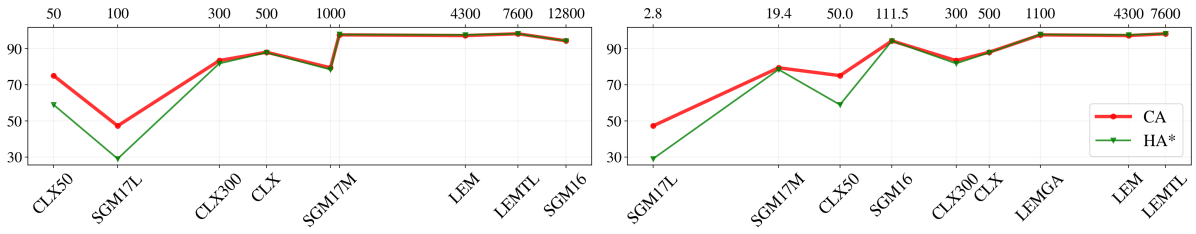

Figure 4: Accuracy as a function of dataset size (left) and the ratio of dataset size to the number of unique transformations (right) for selected experiments. A log scale is used for the X axis. CLX50/CLX300=average scores on CELEX with 50/300 samples (Figure 5), SGM16 =SIGMORPHON2016, SGM17L/SGM17M=SIGMORPHON2017-low/medium, LEM=average scores on lemmatization, LEMGA/LEMTL=lemmatization Irish/Tagalog.

Following Shen et al. (2016), we approximate the expectation under the posterior distribution $P(\mathbf{a} \mid \mathbf{x}^{(l)}; \Theta)$ with ancestral sampling from the model and re-normalize the sampled probability scores to get a new distribution Q:

$$\mathcal{R}(D, \Theta) \approx \sum_{l=1}^{N} \sum_{\mathbf{a} \in S(\mathbf{x}^{(l)})} Q(\mathbf{a} \mid \mathbf{x}^{(l)}; \Theta, \alpha)\ \Delta(\mathbf{y}, \mathbf{y}^{(l)}) \tag{7}$$

$$Q(\mathbf{a} \mid \mathbf{x}^{(l)}; \Theta, \alpha) = \frac{P(\mathbf{a} \mid \mathbf{x}^{(l)}; \Theta)^{\alpha}}{\sum_{\mathbf{a}' \in S(\mathbf{x}^{(l)})} P(\mathbf{a}' \mid \mathbf{x}^{(l)}; \Theta)^{\alpha}} \tag{8}$$

Here, $S(\mathbf{x}^{(l)})$ denotes the set of samples from $P(\mathbf{a} \mid \mathbf{x}^{(l)}; \Theta)$ and $\alpha \in \mathbb{R}$ is a hyper-parameter that controls for the peakedness of the new distribution Q.

3 Experiments

In the following experiments, we evaluate the performance of our model with an explicit copy action (referred to as CA) and show how it further improves with exploration training (-MRT).

Unless stated otherwise, our MLE models are trained on gold actions computed using Mans Hulden's Chinese Restaurant Process string-pair aligner (indicated as CRP)[4] and decoded with beam search. On some problems, we find a simple strategy, which heuristically maximizes the number of COPY actions, to work surprisingly well: The Longest Common Substring aligner (LCS) first aligns the longest common substring of $\mathbf{x}$ and $\mathbf{y}$ and then pads both strings to the same length.

MRT models are initialized with the corresponding MLE models and decoded with beam search. We found the best value of $\alpha = 1$ from $\{1, 0.1, 0.05\}$ on the CELEX-ALL task (§ 3.1) and used that for all other datasets as well.

We use the same embedding parameters for characters and insertion actions (i.e. $A(\text{INSERT}(b)) = E(b)$) to match closely the set-up of Aharoni and Goldberg (2017). In all our systems, the dimension of the character and action embeddings is 100, LSTM hidden layers are of size 200, and all LSTMs are single-layer. We use LSTMs with peephole connections and coupled input and forget gates (Greff et al., 2016). We optimize with ADADELTA (Zeiler, 2012) and update parameters at a single training sample (=batch size 1) during MLE training. For MRT, we build sets $S(\mathbf{x}^{(l)})$ by drawing twenty samples per training example. We mini-batch using these sets as batches. We include the gold action sequence (generated for MLE training) into the batch. We implement our models using DyNet (Neubig et al., 2017).

All experiments report exact accuracies. They are mean accuracies over single runs with different initializations, unless the model is an ensemble (marked with an -E suffix). The ensembles are built with majority voting over differently initialized runs of the same model.

Table 1: Results on the CELEX dataset.

We evaluate our approaches on four standard morphological datasets and compare to the following published systems: (HA) the ensemble of five MLE models over Σ_a^{HA} of Aharoni and Goldberg (2017) as well as our re-implementation of a single model marked as HA*; (MED) the ensemble of five soft-attentional models of Kann and Schütze (2016) and an alternative implementation of the soft-attention approach, SOFT, by Aharoni and Goldberg (2017); (NWFST) the neural WFST model of Rastogi et al. (2016) and (LAT) the non-neural WFST with latent variables of Dreyer et al. (2008).

3.1 Morphological reinflection

The task is to map an inflected form $\mathbf{x}$ into another form $\mathbf{y}$ of that word given a feature specification ϕ for this transformation.

CELEX This dataset of German verbal morphology transformations was compiled by Dreyer et al. (2008) from the CELEX database (Baayen et al., 1993). It comprises four transformations (13SIA↦13SKE, 2PIE↦13PKE, 2PKE↦z, rP↦pA),[5] featuring such morphological phenomena as circumfixation, infixation, and irregular stem changes. The data are split into five folds, each with 500 training samples per transformation. We conduct two types of evaluation on these data. In the original experiment, which we call CELEX-BY-TASK, models are trained on each transformation separately, and scores are averaged over the folds. In the second experiment, CELEX-ALL, five single models are trained on all the 2,000 samples of one fold and then ensembled. Again, scores are averaged over the folds. As part of CELEX-BY-TASK, we additionally evaluate how our models perform on even fewer—50, 100, and 300—training samples on two tasks, 2PKE and 13SIA. CELEX could be considered a relatively simple dataset as the ratio of the number of training samples to the number of unique transformations is high, even though the overall training-data size is modest. On the other hand, most CELEX tasks require learning complex lexical properties such as the distinction between strong and weak verbs or prefix types.

3.2 Morphological inflection generation

Given a feature specification ϕ and a base form $\mathbf{x}$, the task is to generate the corresponding inflected form $\mathbf{y}$.

Sigmorphon 2017 The low (100 training samples) and medium (1,000 training samples) settings of the SIGMORPHON 2017 shared task data (Cotterell et al., 2017) feature fifty-two languages. The datasets contain extremely diverse language material and morphological transformations. Unlike CELEX, input $\mathbf{x}$ is always a dictionary form, however morphological changes are unrestricted. The low setting constitutes a very hard learning problem, with the ratio of training samples to unique transformations being 2.8 on

average (SD $= 2.9$). In the medium setting, the mean number of unique transformations rises to 19.8 (SD $= 29.3$), with a minimum of 1.4 observed for Basque and a maximum of 200 for English.

For this dataset, we also show the results for the official baseline, a ruled-based system that is particularly strong in the low setting,[6] and the best systems of the shared task (Makarov et al., 2017).

Sigmorphon 2016 The SIGMORPHON 2016 shared task dataset (Cotterell et al., 2016) is the largest dataset. It comprises ten languages with about 12,800 training examples on average. The number of samples per transformation varies from 6 for Maltese to 198 for Hungarian, being 112 samples per transformation on average (SD $= 51.3$). In both SIGMORPHONS, we train five single models for each language.

3.3 Lemmatization

Given an inflected word form $\mathbf{x}$ (without any feature specification), the task is to predict the correct dictionary form $\mathbf{y}$. Following Dreyer (2011) and Rastogi et al. (2016), we evaluate our approach on a subset of the dataset by Wicentowski (2002). The data, split into ten folds, comprise four languages, with per-fold training sizes ranging on average from 1,100 for Irish to 7,635 for Tagalog. For each language, we train a separate model for each fold and then average the scores over the folds.

4 Results and Discussion

Generally, comparing the performance of CA and HA (or HA*), we observe that CA achieves great performance gains on small-sized problems while matching HA in the higher-resource setting (Figure 4).

4.1 Morphological reinflection

CA is a very competitive model on both CELEX-BY-TASK and CELEX-ALL, and adding exploration (CA-MRT) results in the strongest performance in both evaluations (Table 1). In contrast to HA*, in very low settings (Figure 5), CA performs not much worse than the only non-neural model, LAT. HA* and NWFST need around 300 training examples to start catching up, and the extremely low-resource conditions (50, 100) on 13SIA are especially troublesome for HA*. On CELEX-ALL, even with more training data, soft-attentional ensemble MED is typically much weaker, including tasks with infixation (2PKE) and circumfixation (rP).

Advancing further on most CELEX tasks is difficult due to morphological irregularities. As an example, examining the predictions of CA-MRT on one fold of the rP task reveals that the system largely fails to predict strong-verb participles (71% of the errors), conjugating 67% of them as if they were regular.

4.2 Morphological inflection generation

Table 2 summarizes the results on the SIGMORPHON 2017 dataset. In the low setting, CA easily beats the baseline system, whereas HA* fails to do so. Our simple majority-vote ensemble CA-MRT-E over five models comes very close to the complex 15-strong ensemble HA[EC]M-E15 of Makarov et al. (2017), the best system of the shared task. Under a paired permutation test, the latter system is statistically significantly better ($p < 0.05$) on only twenty one languages.

In the medium setting, CA maintains the advantage, although the performance gap from HA* is much smaller. CA-MRT-E even outperforms the shared task's best system, although the gain is statistically significant for only ten languages. In both settings, MRT consistently improves the performance of both the HA* and CA models.

In the high-resource scenario of SIGMORPHON 2016 (Table 3), HA* and CA attain virtually identical results, occasionally outperforming the soft-attentional ensembles. Unlike HA, we use the same set of hyper-parameters (the dimension of embeddings, the number of hidden LSTM layers, etc.) for all of our experiments, which might explain that both our reimplementation HA* and CA perform less strongly here. Due to computational restrictions, we could not apply MRT to this dataset.

4.3 Lemmatization

On the lemmatization task (Table 4), CA strongly outperforms WFST models LAT and NWFST on average. Yet, the HA* reimplementation consistently delivers the best results on every language. The error analysis for English in Rastogi et al. (2016) mentions the tendency of their system, NWFST, to simply copy the inflected word over, which accounts for 25% of English-language errors. Given that CA also has a dedicated copy action, one might suspect that the inferior performance of CA compared to HA* for English and Basque would be due to excessive copying. An inspection of the incorrectly predicted lemmas reveals that both systems produce virtually the same number of copy errors. The difference in error counts is actually due to cases where the system modifies the inflected word form. For English, errors typically occur in strong verbs and verbs with graphemic alternations, as e.g. "oozing" gets incorrectly lemmatized as "ooz". The scores of over 97% on every language and the kind of unsolved cases, likely requiring external resources, suggest that this task should be considered solved.

As a final remark, we note that with the datasets at hand, performance attribution is often hampered by the lack of explicit characterization of morphological phenomena or lexical properties at the example level (we have derived some of these meta-data for the CELEX rP task). Given the difficulties interpreting neural models, computational morphology could arguably profit from challenge sets that have recently been gaining popularity in machine translation (Sennrich, 2017; Avramidis et al., 2018).

5 Related Work

Traditional models for morphological string transduction are discriminatively trained WFSTs (Cotterell et al., 2014; Dreyer et al., 2008; Eisner, 2002). The transducer defines eligible edit sequences for $\mathbf{x}$ (each implying a different monotonic character alignment), and its weights are expressed in terms of hand-crafted features. Rastogi et al. (2016) employ RNNs to parametrize the weights of a globally normalized

WFST, thereby conditioning on global context. The powerful approach of Dreyer et al. (2008) adds latent variables to a globally normalized log-linear WFST to learn task-specific properties: a word's paradigm class and approximate morphological segmentation.

Enabling soft character alignment via a deterministic function of inputs (Kann and Schütze, 2016) has proven crucial to the success of seq2seq models first proposed for this task in Faruqui et al. (2016). In line with the traditional simplification of the task, other neural-network approaches treat hard monotone character alignment as a latent variable that the model marginalizes out using dynamic programming, while enabling unbounded dependencies in the output and permitting online generation (Yu et al., 2016; Graves, 2012). An appealing alternative to latent alignment is to learn from supervised alignment, an idea explored to train soft-attention models (Mi et al., 2016). For hard-attention models (Aharoni and Goldberg, 2017), training with an observed alignment is particularly simple as it results in learning from a single gold action sequence.

A state-transition system is an elegant, linear-time model for morphological string transduction, in which eligible monotonic edit sequences are implied by the semantics of the actions. As demonstrated on other tasks (Dyer et al., 2015; Andor et al., 2016), when provided with global context via RNNs, the model overcomes the limitations of a locally normalized conditional distribution, while retaining computational efficiency.

Using a single designated copy action in not new in morphological string transduction, e.g. the SIGMORPHON 2016 feature-based state-transition baseline uses COPY$[n]$, where n is the number of characters to copy. Biasing towards copy edits is crucial to the performance of the model of Rastogi et al. (2016). An alternative to the copy action is to introduce a binary latent variable that signals whether y_i is copied from x_i or generated (Gu et al., 2016; Gulcehre et al., 2016; See et al., 2017). Extending models with alignment variables with such a copying mechanism is simple as the the choice of which x_i has to be copied need not be modeled (Makarov et al., 2017): The copy variable points to the x_i that y_j is aligned with. This alternative requires learning additional model parameters, which could explain its somewhat worse performance on smaller-sized problems.

Minimum risk training (Smith and Eisner, 2006; Och, 2003) is one simple solution enabling exploration and addressing the loss-evaluation mismatch. The approach of Shen et al. (2016) closely relates to classical policy gradient methods in reinforcement learning (Edunov et al., 2018). A number of alternative methods have recently been proposed to address the MLE training biases in the context of seq2seq models (Andor et al., 2016; Wiseman and Rush, 2016; Ranzato et al., 2016; Rennie et al., 2017).

6 Conclusion

In a large-scale evaluation on different morphological tasks and languages, we show that a neural transition-based system over edit actions consistently outperforms state-of-the-art systems on morphological string transduction tasks in low- and medium-resource settings and is competitive on large training sets. Crucially, adding a designated action to copy the input character over to the output string helps the transition model generalize quickly from very few data points. Using a training procedure that enables exploration of the action space (e.g. minimum risk training) consistently improves the performance of our models as they are exposed to action sequences other than those proposed by the character aligner underlying the static oracle in the MLE training procedure.

Abstract

Capturing interactions among multiple predicate-argument structures (PASs) is a crucial issue in the task of analyzing PAS in Japanese. In this paper, we propose new Japanese PAS analysis models that integrate the label prediction information of arguments in multiple PASs by extending the input and last layers of a standard deep bidirectional recurrent neural network (bi-RNN) model. In these models, using the mechanisms of pooling and attention, we aim to directly capture the potential interactions among multiple PASs, without being disturbed by the word order and distance. Our experiments show that the proposed models improve the prediction accuracy specifically for cases where the predicate and argument are in an indirect dependency relation and achieve a new state of the art in the overall F_1 on a standard benchmark corpus.

1 Introduction

A predicate-argument structure (PAS) is a structure that represents the relationships between a predicate and its arguments. Identifying PASs in Japanese text is a long-standing challenge chiefly due to the abundance of omitted (elliptical) arguments. In the example in Figure 1, the dative relation between *answer* and *reporters* is not explicitly indicated by the syntactic structure of the sentence. We regard such arguments as elliptical and call those argument slots *Zero* cases. 25% of the obligatory arguments in Japanese newspaper articles are reported to be elliptical.[1] The accuracy of identifying the fillers of such Zero cases remains only around 50% in terms of F_1 even if the task is restricted to the identification of intra-sentential predicate-argument relations (Matsubayashi and Inui, 2017).

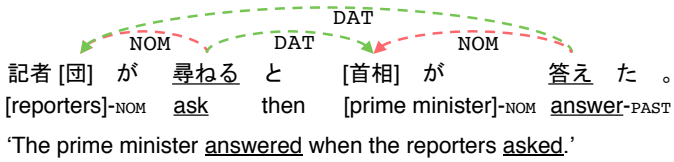

Figure 1: Example of PAS analysis. The dashed lines represent the predicate-argument relations. "[reporters]-NOM ask then" constitutes a subordinate clause and "[prime minister]-NOM answer-PAST" constitutes a matrix clause.

One promising approach for addressing this problem is to model argument sharing across multiple predicates (Iida et al., 2015; Ouchi et al., 2015; Ouchi et al., 2017). In Figure 1, for example, one can find very limited syntactic clues for predicting the long-distance dative relation between *answer* and *reporters*. However, the relation must be easy to identify for human readers who know that *the person who asks a question is likely to be answered*; namely, the nominative argument of *ask* is likely to be shared with the dative argument of *answer*. Capturing such inter-predicative dependencies has, therefore, been considered crucial of Japanese PAS analysis.

(a) Base model (b) Proposed models

Figure 2: Network structures of the base and proposed models.

With this goal in mind, Iida et al. (2015) constructed a *subject-shared predicate network* with an accurate recognizer of subject-sharing relations and deterministically propagated the predicted subjects to the other predicates in the graph. However, this method is applied only to subject sharing, so it cannot take into account the relationships among multiple argument labels.

More recently, as an end-to-end model considering multi-predicate dependencies, Ouchi et al. (2017) used Grid RNN to incorporate intermediate representations of the prediction for one predicate generated by an RNN layer into the inputs of the RNN layer for another predicate. However, in this model, since the information of multiple predicates also propagates through the RNNs, the integration of the prediction information is influenced by word order and distance, which is not necessarily important for aspects of syntactic and semantic relations. Consequently, there might be information loss caused by the surface distances of words, as previous work had pointed out for RNN language models (Linzen et al., 2016).

In this study, we propose new Japanese PAS analysis models that integrate the prediction information of arguments in multiple predicates. We extend a standard end-to-end style deep bi-RNN model (Figure 2a) and introduce components that consider the multiple predicate interactions into both the input and last layers (Figures 2b and 3). In contrast to Grid RNN, our extended models stack the extra layers using pooling and attention mechanisms on top of a deep bi-RNN so that they can directly associate the label prediction information for a target (predicate, word) pair with the predictions for words strongly related to the target pair. Through experiments, we show that the proposed models improve argument prediction accuracy, especially for the *Zero* cases, and achieve a new state-of-the-art performance in the overall F_1 on a standard benchmark corpus.

2 Task

In this paper, we employ a task definition based on the NAIST Text Corpus (NTC) (Iida et al., 2010; Iida et al., 2017), a commonly used benchmark corpus annotated with nominative (NOM), accusative (ACC), and dative (DAT) arguments for predicates. Given a tokenized sentence $\mathrm{w} = w_1, ..., w_n$ and its predicate positions $\mathrm{p} = p_1, ..., p_q$, our task is to identify at most one head of the filler tokens for each argument slot of each predicate. In this study, we follow the setting of Iida et al. (2015), Ouchi et al. (2017), and Matsubayashi and Inui (2017), and focus only on analyzing arguments in a target sentence. In addition, we exclude argument instances that are in the same *bunsetsu*, a base phrase unit in Japanese, as the target predicate, following Ouchi et al. (2017), which we will compare with the results in experiments.

The semantic labels used in NTC may seem to be rather syntactic as they are named nominative, accusative, etc. However, this annotation task markedly differs from shallow syntactic parsing and is, in fact, more like a semantic role labeling (SRL) task including implicit argument prediction. First, the semantic labels in NTC generalize case alteration caused by voice alteration and thus represent semantic roles analogous to ARG0, ARG1, etc. in the PropBank-style annotation (Palmer et al., 2005). Second,

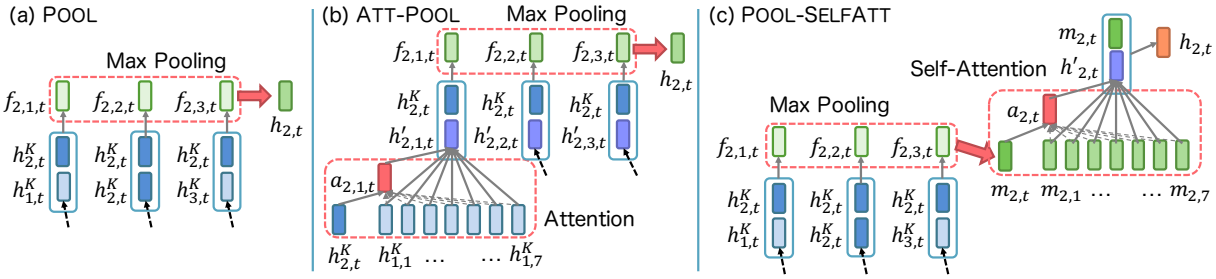

Figure 3: Three variants of interaction layers.

in the corpus, when an argument is omitted (i.e., zero-anaphora), the antecedent is identified with an appropriate semantic role, which is a prominent problem in Japanese semantic analysis and is the primary target of this study.

3 Base Model

Our proposed models extend end-to-end style SRL systems using deep bi-RNN (Zhou and Xu, 2015; He et al., 2017; Ouchi et al., 2017) to combine mechanisms that consider multiple predicate interactions. Figure 2a shows the network of our base model. Formally, given a word sequence $\mathrm{w} = w_1, ..., w_n$ and a target predicate position p_i in p, the model outputs a label probability for each word position: $p(c_{i,1}|i, \mathrm{p}, \mathrm{w}), ..., p(c_{i,n}|i, \mathrm{p}, \mathrm{w})$. Here, $c_{i,t} \in \{\texttt{NOM}, \texttt{ACC}, \texttt{DAT}, \texttt{NONE}\}$ represents the argument label of the word w_t for the target predicate w_{p_i}.

The input layer creates a vector $h^0_{i,t} \in \mathbb{R}^{d_w+1}$ for each pair of a predicate w_{p_i} and a word w_t by concatenating a word embedding $e(w_t) \in \mathbb{R}^{d_w}$ and a binary value representing the target predicate position in a method similar to that of He et al. (2017). The obtained vectors are then input into the deep bi-RNN, where the directions of the layers alternate (Zhou and Xu, 2015):

$$h^1_{i,t} = r^1(h^0_{i,t}, h^1_{i,t-1}), \quad h^k_{i,t} = \begin{cases} h^{k-1}_{i,t} + r^k(h^{k-1}_{i,t}, h^k_{i,t-1}) & (k \text{ is odd}) \\ h^{k-1}_{i,t} + r^k(h^{k-1}_{i,t}, h^k_{i,t+1}) & (k \text{ is even}) \end{cases} (k \geq 2). \tag{1}$$

Here, $h^k_{i,t} \in \mathbb{R}^{d_r}$ is the output of the k-th RNN layer for a pair (w_{p_i}, w_t), and r^k is a function representing the k-th RNN layer. We employ gated recurrent units (GRUs) (Cho et al., 2014) for the RNNs. In addition, we use the residual connections (He et al., 2016) following Ouchi et al. (2017). Then, a four-dimensional vector representing a probability $p(c_{i,t}|i, \mathrm{p}, \mathrm{w})$ is obtained by applying a softmax layer to each output of the last RNN layer $h^K_{i,t}$. For each argument label c of each predicate, we eventually select a word with the maximum probability that exceeds an output threshold θ_c.

4 Proposed Models

Our base model independently predicts the arguments of each predicate. In order to capture dependencies between the arguments of multiple predicates, we apply two extensions to our base model: a *multi-predicate input layer* and three variants of *interaction layers* on top of the deep bi-RNNs. Figures 2b and 3 show the network structures of the extended models.

In contrast to the Grid RNN model of Ouchi et al. (2017), where the information of multiple predicates propagates through the RNNs, our interaction layers use pooling and attention mechanisms to directly associate the label prediction information for a target (predicate, word) pair with that for words strongly related to the target pair, without being disturbed by word order and distance.

4.1 Interaction Layers

Pooling (POOL) Argument sharing across multiple predicates can be captured with both syntactic and semantic clues. At the syntactic level, we want to capture tendencies that, for example, the subject of the predicate of a matrix clause is likely to fill argument slots of other predicates in the same sentence.

At the semantic level, we want to model semantic dependencies between neighboring events such as *the person who asks a question is likely to be answered*, as in Figure 1. Our proposal is to capture both types of clues by incorporating a max pooling layer on top of the base model.

Specifically, as illustrated in Figure 3a, for each word w_t, we integrate the intermediate representation of label prediction for each predicate $h^K_{i,t}$ by applying max pooling to the vectors that represent pairs of prediction information for two predicates $h^K_{i,t}$ and $h^K_{j,t}$ (including the case $i = j$):

$$h_{i,t} = \mathrm{maxpool}_j(f_{i,j,t}), \quad \text{where} \quad f_{i,j,t} = \mathrm{ReLU}(W_f[h^K_{i,t}, h^K_{j,t}] + b_f). \tag{2}$$

In this equation, $\mathrm{maxpool}_j(f_{i,j,t})$ is an operation to extract the maximum value of each dimension in $\{f_{i,1,t}, ..., f_{i,q,t}\}$. The newly obtained vector $h_{i,t}$ for w_{p_i} and w_t is input into the softmax layer in the same manner as in the base model.

Attention-then-Pooling (ATT-POOL) Besides the argument sharing across multiple predicates, we would also like to capture dependencies between different arguments of a single predicate (and potentially, arguments of multiple predicates). For example, syntactically, two distinct argument slots of a single predicate are unlikely to share the same filler. Semantically, the subject of a predicate *take* is likely to be a person when its object is *a bread*, but is likely to be a company if the object is *a new employee*.

To capture such dependencies, we integrate the intermediate label prediction $h^K_{j,t'}$ of $w_{t'}$ for an arbitrary predicate w_{p_j} (including the case $i = j$) into the prediction of w_t for a target predicate w_{p_i}. In the integration, we aim to weigh the prediction information for $(w_{p_j}, w_{t'})$ based on its relatedness to the target pair (w_{p_i}, w_t) using the attention mechanism (Bahdanau et al., 2015). As in Figure 3b, we calculate a weight $a_{i,j,t}(t') \in \mathbb{R}$ for each of $h^K_{j,1}, ..., h^K_{j,n}$ on the basis of the prediction $h^K_{i,t}$ for the target pair and we obtain a weighted sum of $h^K_{j,t'}$ as a summary of the argument information of w_{p_j}, which is expected to be useful for the label prediction of (w_{p_i}, w_t):

$$h'_{i,j,t} = \textstyle\sum_{t'} a_{i,j,t}(t') \cdot h^K_{j,t'}, \quad \text{where} \quad a_{i,j,t}(t') = \frac{\exp(W_a g_{i,j,t,t'} + b_a)}{\sum_{t''} \exp(W_a g_{i,j,t,t''} + b_a)}, \tag{3}$$

$$g_{i,j,t,t'} = \tanh(W_g[h^K_{i,t}, h^K_{j,t'}] + b_g). \tag{4}$$

The obtained $h'_{i,j,t}$ are concatenated with the prediction for the target pair $h^K_{i,t}$ and linearly transformed with the ReLU activation. Max pooling is then applied to these vectors to combine the predictions for multiple predicates.

$$h_{i,t} = \mathrm{maxpool}_j(f_{i,j,t}), \quad \text{where} \quad f_{i,j,t} = \mathrm{ReLU}(W_f[h^K_{i,t}, h'_{i,j,t}] + b_f) \tag{5}$$

Pooling-then-Self-Attention (POOL-SELFATT) The ATT-POOL model involves a high computational cost because it must compute nq^2 different attentions regarding the number of words n and the number of predicates q in a sentence. Therefore, as illustrated in Figure 3c, in this model, we first apply the max pooling that we applied in the POOL model to reduce the sequences for which attentions must be computed by integrating the label predictions of w_t for all the other predicates in advance.

$$m_{i,t} = \mathrm{maxpool}_j(f_{i,j,t}), \quad \text{where} \quad f_{i,j,t} = \mathrm{ReLU}(W_f[h^K_{i,t}, h^K_{j,t}] + b_f) \tag{6}$$

Then, we combine the information in the obtained sequence $m_{i,1}, ..., m_{i,n}$ in a similar manner as in the ATT-POOL model using the attention mechanism, but this time, with self-attention, that is, computing the weights of the elements in the sequence based on the relatedness to the element inside the sequence.

$$h_{i,t} = \mathrm{ReLU}(W_h[m_{i,t}, h'_{i,t}] + b_h) \tag{7}$$

$$h'_{i,t} = \textstyle\sum_{t'} a_{i,t}(t') \cdot m_{i,t'}, \quad \text{where} \quad a_{i,t}(t') = \frac{\exp(W_a g_{i,t,t'} + b_a)}{\sum_{t''} \exp(W_a g_{i,t,t''} + b_a)} \tag{8}$$

$$g_{i,t,t'} = \tanh(W_g[m_{i,t}, m_{i,t'}] + b_g) \tag{9}$$

Consequently, the number of attentions that must be computed is reduced to nq.

Self-Attention (SELFATT) To conduct ablation tests to assess the impact of the proposed extensions, we also implemented a model only with self-attention. This model explicitly considers the relationships between arguments of a single predicate, but not arguments across multiple predicates.

$$h_{i,t} = \mathrm{ReLU}(W_h[h^K_{i,t}, h'_{i,t}] + b_h) \tag{10}$$

$$h'_{i,t} = \textstyle\sum_{t'} a_{i,t}(t') \cdot h^K_{i,t'}, \quad \text{where} \quad a_{i,t}(t') = \frac{\exp(W_a g_{i,t,t'} + b_a)}{\sum_{t''} \exp(W_a g_{i,t,t''} + b_a)} \tag{11}$$

$$g_{i,t,t'} = \tanh(W_g[h^K_{i,t}, h^K_{i,t'}] + b_g) \tag{12}$$

4.2 Multi-Predicate Input Layer (MP)

In addition, we add a simple but effective extension to the input layer. As He et al. (2016) reported, the information of the target predicate w_{p_i} propagates to the intermediate prediction $h^K_{i,t}$ of the candidate argument w_t through the deep bi-RNN by just adding a binary value representing the predicate position. Inspired by this finding, as shown in Figure 2b, in the input layer, we add another binary value that represents all the predicate positions to $h^0_{i,t}$, aiming to propagate multiple predicate information.

5 Experiments

We evaluated the impacts of our extensions and compared their performances to those of previous studies. Our main hypothesis is that the pooling and attention mechanisms are both useful for capturing different types of argument interactions as we explained in Section 4 and do work complementarily of each other to improve the prediction accuracy, especially for arguments in a long-distance dependency.

5.1 Settings

5.2 Dataset and Implementation Details

The experiments were performed on NTC 1.5. We divided the corpus into the commonly used divisions of training, development, and test sets (Taira et al., 2008), each of which includes 24,283, 4,833, and 9,284 sentences, respectively. NTC represents each argument of a predicate by indicating a coreference cluster in a text. For each given predicate-argument slot, we count a system's output as correct if the output token is included in the coreference cluster corresponding to the slot fillers. The evaluation is performed on the basis of the precision, recall, and F_1 score.

The hyperparameters were selected to obtain a maximum F_1 on the development set. The details of the hyperparameter selection and preprocessing are described in the supplemental material. In the following experiments, we train each model 10 times with the same training data and hyperparameters and then show the average scores.

5.3 Grid RNN Baseline (GRID)

In order to strictly compare the impact of our extensions to the method used for integrating multiple pieces of predicate information in the state-of-the-art end-to-end model, in addition to our base model, we replicated the method of Ouchi et al. (2017) by modifying Equations (1) of our base model as follows:

$$h^1_{i,t} = r^1([h^0_{i,t}, h^1_{i-1,t}], h^1_{i,t-1}), \quad h^k_{i,t} = h^{k-1}_{i,t} + \begin{cases} r^k([h^{k-1}_{i,t}, h^k_{i-1,t}], h^k_{i,t-1}) & (k \text{ is odd}) \\ r^k([h^{k-1}_{i,t}, h^k_{i+1,t}], h^k_{i,t+1}) & (k \text{ is even}) \end{cases} (k \geq 2), \tag{13}$$

if $1 \leq i \leq q$; otherwise, $h^k_{i,t} = \mathbf{0}$. The performance of this replicated model may not be strictly the same as that reported in Ouchi et al. (2017) due to discrepancies in the embeddings of inputs, hyperparameters (a training batch size, a hidden unit size, etc.), and training strategy (an optimizing algorithm, a regularization method, an early stopping method, etc.). The predicate positions $\mathrm{p} = p_1, ..., p_q$ are arranged in ascending order.

5.4 Results

Impact of Extensions

The first two sets of rows in Table 1 compare the impact of each component of our extension. The effects of incorporating the interaction layer can be seen in the comparisons of the BASE model with the SELFATT, POOL, ATT-POOL, and POOL-SELFATT models. Among the four proposed extensions, POOL-SELFATT, an integration of POOL and SELFATT, achieved the best performance (83.76 in F_1), gaining 0.37 points in overall F_1 from BASE. Also, the significance tests in Table 2 show that the POOL and SELFATT models significantly outperform the BASE model, and the POOL-SELFATT model makes a further significant gain from the POOL and SELFATT models. This indicates that POOL and SELFATT work complementarily with each other, and combining them makes a further improvement from each individual extension. Recall that SELFATT is designed to capture long-distance dependencies over a single predicate-argument structure, whereas POOL is expected to capture argument sharing across multiple predicates. These results provide empirical support to the hypotheses behind our design of the interaction layer.

The MP model, where the input layer is extended to represent the positions of all the predicates in a sentence, significantly outperforms the BASE model by 0.28 points in overall F_1. This result suggests the importance of position information regarding the neighboring predicates in identifying the arguments of a given predicate. Furthermore, the MP-POOL-SELFATT model, which is a combination of MP and POOL-SELFATT, resulted in a further 0.27-point improvement and consequently achieved the best overall F_1 of 83.94 as a single model.

Following Matsubayashi and Inui (2017), we also assess F_1 values at different dependency distances. The results are shown in the right half of Table 1. From the table, we can see that MP-POOL-SELFATT

improves F_1 from BASE by 0.9–1.4 points consistently across all the distance categories other than *Dep*.

Comparison to Related Work

The third set of rows in Table 1 shows the reported performance of related studies. Grid RNN of Ouchi et al. (2017) is a state-of-the-art end-to-end model, designed to capture interactions among multiple predicate-argument relations. A comparison between their model and the proposed models was somewhat tricky because our replication of Grid RNN did not reproduce the reported performance on the same dataset (see the row of GRID in Table 1). Unlike the results reported in Ouchi et al. (2017), the GRID model in our experiment did not clearly outperform the model without the grid architecture, i.e., the Base model. We first suspected that this might have resulted from the difference in dimensionality d_r of RNN hidden states: $d_r = 32$ in Ouchi et al. (2017), whereas $d_r = 256$ in our experiments. Specifically, we speculated that the base model with a low dimensionality left a larger margin for improvement and incorporating the Grid architecture derived positive effects. We thus trained our GRID model with Ouchi et al. (2017)'s settings ($d_r = 32$ and $K = 8$) and the best performing hyperparameters; however, we were not able to reproduce the reported gain from Grid RNN (see the row of "GRID ($d_r = 32$, $K = 8$)" in Table 1).[2] This might be an indication of the difficulty in capturing multi-predicate interactions by threading deep bi-RNNs with RNNs, as we discussed in Section 1.

Another previous state-of-the-art model was proposed by Matsubayashi and Inui (2017) (M&I 2017). This model extends a feedforward NN with dependency path embeddings and other new features to capture long-distance dependencies in a single PAS. The row "M&I 2017" in Table 1 shows the reported performance of their model.[3] The performance of M&I 2017 is comparable with the performance of our SELFATT model. This result provides another piece of empirical evidence that the self-attention mechanism has a comparably positive effect in incorporating dependency path information for capturing long-distance dependencies in a single PAS.

Overall, the proposed methods of using the pooling and attention mechanisms for capturing interactions across predicates and arguments gained considerable improvement and achieved state-of-the-art accuracy, significantly outperforming the previous state-of-the-art models. The last set of rows in Table 1 shows the results of the ensemble models. A model that predicts arguments with the average score of the 10 MP-POOL-ATT models further improves the overall F_1 by 1.4 points from that of a single model, achieving state-of-the-art accuracy for NTC 1.5.

Table 3 shows the F_1 score for each case label. In a comparison of the single models, although our MP-POOL-ATT model slightly degrades the scores of NOM and ACC on the *Dep* cases compared to the state-of-the-art model (M&I 2017), it greatly improves the scores for DAT and the *Zero* cases. Regarding the ensemble models, MP-POOL-ATT improves the scores for all cases.

Iida et al. (2015) and Iida et al. (2016) report Japanese subject anaphora resolution systems, designed to predict only *Zero* NOM arguments. It is not straightforward to directly compare their results with ours due to the differences in the experimental settings. However, our best performing model outperforms the

[2]We discussed this negative result, including the implementation details, with one of the authors of Ouchi et al. (2017). However, we could not find a plausible reason for the results.

[3]For the purpose of a strict comparison with Ouchi et al. (2017), we re-evaluate the model of Matsubayashi and Inui (2017) by excluding the instances for which the argument is in the same *bunsetsu* phrase as the predicate; this is the same setting as that in Ouchi et al. (2017). We have reported the new results in Tables 1 and 3.

model of Ouchi et al. (2015), which is then reported to outperform both Iida et al. (2015) and Iida et al. (2016) in their experimental settings.

5.5 Detailed Analysis

To analyze the behavior of our proposed models in detail, we show some prediction examples of the SELFATT, MP-SELFATT, and MP-POOL-ATT models in the development set with the weights in the attention layers in Figures 4-7.

In Figure 4, Examples (1) and (2) are the instances for which only SELFATT failed to predict the answer and for which only MP-POOL-SELFATT correctly predicted the answer, respectively. For these examples, the weights in the attention layers behave similarly. Figure 5 shows the weights for Example (1). In this sentence, the correct NOM of *stretch*, *Tanigawa*, is also NOM of *respond*, which is relatively easy to predict. SELFATT, which is designed to capture dependencies over a single predicate-argument structure, failed to predict NOM of *stretch* most likely because the answer *Tanigawa* is distant from the target predicate with its limited syntactic clues. Conversely, MP-POOL-SELFATT and MP-SELFATT successfully predicted the answer by taking the answer token *Tanigawa* into account when computing the

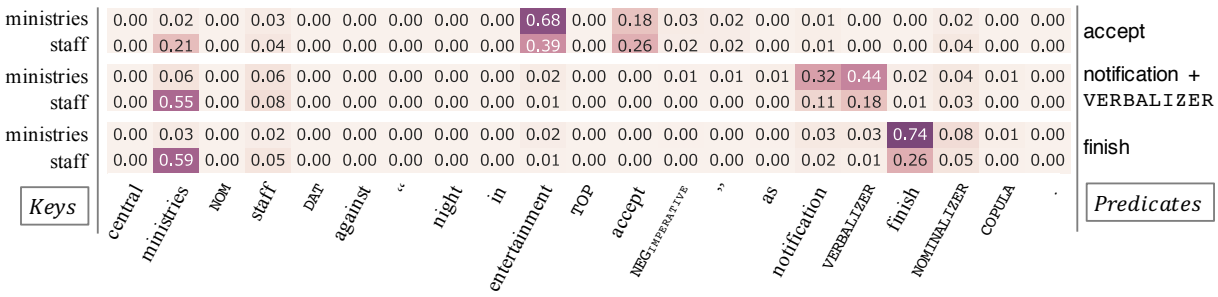

Figure 6: Attention weights of MP-POOL-SELFATT for Example (3).

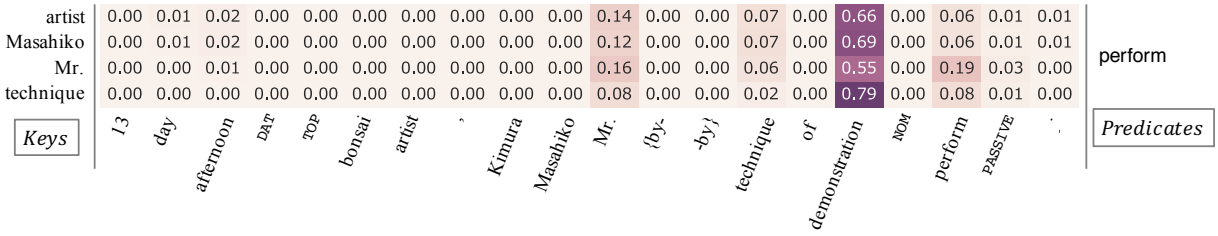

Figure 7: Attention weights of MP-POOL-SELFATT for Example (4).

score of the counter candidate *thinking*. MP-SELFATT, the model that incorporates the other predicate positions into SELFATT, significantly increases the weight for the answer token. MP-POOL-SELFATT, which explicitly integrates the predictions for the other predicates, further increases the weight for the answer token. This example demonstrates that the proposed extensions successfully predict a correct argument by considering the relation to the argument in another predicate where the syntactic relation between the predicate and argument is much clearer and thus the argument relation is relatively easy to predict. Due to space limitations, we cannot show the weights for Example (2), but the same also holds for that example. MP-POOL-SELFATT focuses on professors, which is the "easy-to-predict" NOM argument of dive, when the model computes the scores of this token for *take* and, consequently, *support*. SELFATT and MP-SELFATT assign smaller weights to that token for *take* and even smaller weights for *support*, which is far from the answer token.

Examples (3) and (4) are the instances where all the three models failed to predict the answers. Figure 6 illustrates the attention weights in MP-POOL-SELFATT for Example (3). To solve this example, the model is expected to understand that NOM of *accept* should be the same as the persons who received the order from the *ministries*. However, MP-POOL-SELFATT could not acquire this kind of dialog-level knowledge and pays little attention to the correct argument *staff* when the model computes the score of the wrong answer *ministries* for NOM of *accept*.

In Example (4), NOM of the nominal predicate *demonstration* can be a clue for predicting NOM of *perform*. However, the models currently do not predict the arguments of nominal predicates and therefore cannot capture the relationships between these two sufficiently (Figure 7). This example suggests one of our future directions: the joint prediction of verbal and nominal predicates.

6 Related Work

End-to-End Models in SRL End-to-end approaches to SRL have been widely explored recently, and many state-of-the-art results have been achieved (Zhou and Xu, 2015; He et al., 2017; Marcheggiani and Titov, 2017; Tan et al., 2018). Following these advanced models, we adopted a stacked bi-RNN as our base model.

Methods for Dealing with Long-Distance Dependencies in End-to-End Models In SRL studies, Marcheggiani and Titov (2017) proposed a variant of deep bi-RNN models that connects the intermediate representations of the predictions for the words in syntactic dependency relations on top of the deep RNN.

Very recently, aiming to directly connect the related words, Tan et al. (2018) stacked self-attention layers, each of which followed a feedforward layer, in a manner similar to the method of Vaswani et al. (2017), which was originally applied to an encoder-decoder model.

Self-attention has been successfully applied to several NLP tasks, including textual entailment, sentiment analysis, summarization, machine translation, and language understanding (Paulus et al., 2017; Shen et al., 2018; Lin et al., 2017; Vaswani et al., 2017). Techniques using pooling have been applied to merge intermediate expressions in predictions in the tasks where related tokens are often at long distance such as coreference resolution and machine reading (Clark and Manning, 2016; Kobayashi et al., 2016). One major contribution of this study is its novel idea of using these techniques for capturing long-distance dependencies for modeling interactions among multiple predicate-argument relations.

Approaches to Capturing Multi-Predicate Interactions For Japanese, Ouchi et al. (2015) jointly identified arguments of multiple predicates by modeling argument interactions with a bipartite graph. Iida et al. (2015) constructed a *subject-shared predicate network* and deterministically propagated the predicted subjects to other predicates. Shibata et al. (2016) adapted a NN framework to Ouchi et al. (2015)'s model using a feedforward network. For an end-to-end neural model, Ouchi et al. (2017) used a Grid RNN to capture multiple predicate interactions. Through experiments, we demonstrated that our proposed models outperformed these models in terms of the overall F_1 on a standard benchmark corpus.[4]

To the best of our knowledge, there are few previous studies related to SRL considering multiple predicate interactions for languages other than Japanese. Yang and Zong (2014) performed a discriminative reranking in the role classification of shared arguments. Lei et al. (2015) proposed an SRL model based on the dimensionality reduction on a tensor representation to capture meaningful interactions between the argument, predicate, corresponding features, and role label. It is not straightforward to compare these methods with our models; however, it is an intriguing future issue to consider how well the techniques devised for Japanese PAS analysis work for other languages.

Other Approaches to Argument Omission In order to perform robust prediction for arguments with fewer syntactic clues, several previous studies have explored various types of selectional preference scores that consider the semantic relations between a predicate and its arguments (Iida et al., 2007; Imamura et al., 2009; Komachi et al., 2010; Sasano and Kurohashi, 2011; Shibata et al., 2016). This direction of research is orthogonal to our approach, suggesting that the models could be further improved by being combined with these extra features.

7 Conclusion

In this study, we have proposed new Japanese PAS analysis models that integrate prediction information of arguments in multiple predicates. We extended the end-to-end style model using a deep bi-RNN and introduced the components that consider the multiple predicate interactions into the input and last layers. As a result, we achieved a new state-of-the-art accuracy on the standard benchmark data.

Our detailed analysis showed that the proposed models successfully predict the correct arguments by using the information of the *"easy-to-predict"* arguments in other predicates. In addition, the error analysis suggests that jointly predicting the arguments of verbal and nominal predicates may further improve the performance. An intriguing issue we plan to address next is how to extend the proposed interaction layer to cross-sentential interactions of PASs.

Appendix A: Implementation Details

Hyperparameters The hyperparameters were selected to obtain a maximum F_1 on the development set. The dimension of the word embeddings d_w was set to 256. The dimension of the hidden state of the GRUs d_r was set to 256 from $\{128, 256, 512\}$ and the number of the GRU layers was set to 10 from $\{6, 8, 10, 12\}$. The dropout rate of the GRUs was set to 0.1 from $\{0.0, 0.1, 0.2\}$. The dimensions of the outputs of the nonlinear transformations f, g and $h_{i,t}$ were set to 1024 from $\{512, 768, 1024\}$. We set the batch size of the training data as the number of predicates in each sentence. We employed the negative log likelihood as the training loss and an Adam optimizer with $\beta_1 = 0.9$, $\beta_2 = 0.999$, and $\epsilon = 1e-08$. During the training, we halved the learning rate when the F_1 score on the development set did not improve after four epochs, and restarted training with the parameters that obtained the maximum F_1 score. We repeated this process and terminated the training when the new learning rate was less than 1/16 of the initial value. The initial learning rate of each model was selected from $\{0.00002, 0.00005, 0.0001, 0.0002, 0.0005\}$. The output threshold for each label $\theta_c \in [0.0, 1.0]$ was searched in increments of 0.01 to maximize the F_1 score in the training data.

Preprocessing As initial word embeddings, we used vectors obtained via the same procedure as the one proposed by Matsubayashi and Inui (2017) using Japanese Wikipedia articles. These vectors were fine-tuned in the training. Following their approach, we used part of speech (PoS) vectors for words that were not contained in the lexicon of the Wikipedia articles. We used the CaboCha parser v0.68 [5] with the JUMAN dictionary for word segmentation and PoS tagging of NTC.

Abstract

We present a method for detecting annotation errors in manually *and* automatically annotated dependency parse trees, based on ensemble parsing in combination with Bayesian inference, guided by active learning. We evaluate our method in different scenarios: (i) for error detection in dependency treebanks and (ii) for improving parsing accuracy on in- and out-of-domain data.

1 Introduction

Structural syntactic information is an important ingredient for many NLP applications. In recent years, the Universal Dependencies (UD) framework (Nivre et al., 2016) has become increasingly popular as a source for syntactically annotated training data, mainly for two reasons. First, the UD project provides a unified framework for multilingual applications and second, its annotation scheme encodes semantic information in a more transparent way, yielding better support for semantic applications.

The project already provides treebanks for over 60 languages, some of them, however, rather small. To obtain high parsing accuracies, a sufficient amount of training data is needed, preferably from different genres and domains. Since treebanking is a notoriously time-consuming task, most of the UD treebanks have been automatically converted from other frameworks and thus include some noise introduced in the conversion, in addition to the usual annotation noise that stems from inconsistencies in the human annotations. Due to limited funding, a full manual quality check is often not feasible. Therefore, methods that are able to detect errors in automatically predicted parse trees are of great value for data clean-up and might also be of use for domain adaptation settings and when dealing with low-resource languages.

We present such a method, aimed at the detection of parser errors in manually *and* automatically predicted parse trees. We evaluate our approach in two different scenarios, i) in an active learning (AL) setup where we try to detect and manually correct errors in existing treebanks, and ii) in a domain adaptation setting where we automatically improve parsing performance without manual correction. We make an implementation of our approach publically available.[1]

2 Model

Our error detection model is an adaptation and substantial extension of MACE-AL (Rehbein and Ruppenhofer, 2017) which combines a generative, unsupervised method for estimating annotator reliability (MACE) (Hovy et al., 2013) with active learning for the task of error detection in *automatically* annotated data. MACE-AL can be applied to any classification task and has been tested in two applications, POS tagging and Named Entity Recognition (NER) (Rehbein and Ruppenhofer, 2017). The model is, however, not applicable to tasks with structured output such as trees or graphs. In contrast to POS tagging or NER where we try to detect annotation errors in the predicted labels for individual tokens, when looking for errors in parse trees we have to deal with directed, labelled relations between nodes, and changing the relation or label between two nodes in the tree usually requires the adjustment of other attachment and labelling decisions in the same tree.

[1] MACE-AL-TREE can be downloaded from http://www.cl.uni-heidelberg.de/research/downloads/

Proceedings of the 27th International Conference on Computational Linguistics, pages 107–118
Santa Fe, New Mexico, USA, August 20-26, 2018.

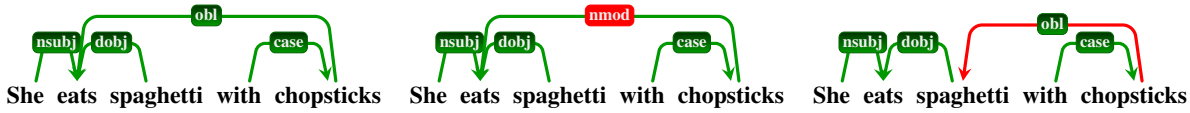

Figure 1: Correct tree (left), tree with label error (center) and tree with attachment error (right).

A high-precision method for error detection in automatically predicted trees, however, would be of tremendous use for many treebanking projects. Below, we first describe the approach of Hovy et al. (2013) and Rehbein and Ruppenhofer (2017) for unstructured data (§2.1) and then our extension of the model for the purpose of error detection in tree structures (§2.2).

2.1 MACE-AL: Error detection in unstructured data

MACE-AL combines variational inference (VI) with active learning (AL) to model the reliability of *automatically* predicted annotations. As input, it takes the output of a committee of classifiers (e.g. the output of N POS taggers) and uses *Bayesian inference* to learn which taggers' predictions are more trustworthy than others. The method is unsupervised, meaning that the distribution of the true labels $Y = \{y_1, y_2, ..., y_n\}$ is unknown. Instead, the model tries to approximate the posterior distribution over the set of unobserved random variables Y by a variational distribution $Q(Y)$, based on the observed data X (the predictions made by the classifier committee).

MACE-AL is based on MACE (Hovy et al., 2013), a tool for estimating annotator reliability in a crowdsourcing setting. MACE implements a simple graphical model where the observed annotations A are generated as follows. The (unobserved) "true" label T_i is sampled from a uniform prior, based on the assumption that the annotators always try to predict the correct label and thus the majority of the annotations should, more often than not, be correct. To model each annotator's behaviour, a binary variable S_{ij} (also unobserved) is drawn from a Bernoulli distribution that describes whether annotator j is trying to predict the correct label for instance i or whether s/he is just spamming (a behaviour not uncommon in crowdsourcing settings). If S_{ij} is 0, the "true" label T_i is used to generate the annotation A_{ij}. If S_{ij} is 1, the predicted label A_{ij} for instance i comes from a multinomial distribution with parameter vector ξ_j.

Rehbein and Ruppenhofer (2017) showed that MACE, while highly successful when applied to human annotations from crowdsourcing, is not able to outperform the majority baseline when the predictions have been generated *automatically* by a classifier committee. MACE-AL, however, addresses this shortcoming by combining variational inference with human feedback from active learning. Active learning is an approach to minimise human annotation effort by only selecting instances for labelling that provide useful information to the classifier. It has been shown that annotating only a small set of carefully selected instances not only reduces manual annotation effort but can yield the same accuracy as when training on a larger set of randomly selected instances (Settles, 2009).

The extended model, guided by human feedback, is now able to pick up on the signal and significantly outperforms the majority baseline as well as a query by committee strategy for error detection where the next instance for manual inspection is selected based on the entropy in the classifiers' predictions.

2.2 MACE-AL-TREE – An extension to structured data

To be able to apply the model to tree structures, we need to solve the following two problems. First, we need to track two different types of errors, namely *labelling* errors and *attachment* errors, and encode them in a meaningful way so that the variational model is able to learn from the data. Second, we need to collect the local predictions from the variational model and translate them back into a tree structure.

Error encoding We need to track *labelling* errors where a directed arc has been assigned the wrong label (Figure 1 (center)), and *attachment* errors where the relation between two nodes has been predicted incorrectly (Figure 1 (right)). We do this by training two separate variational models, one for the labelling decisions and the other one for the attachment relations between nodes.[2]

[2]Combining both into one model would blow up the number of possible labels and thus make the model unnecessarily hard to learn, and would also take too much time for training to be used in an active learning scenario.

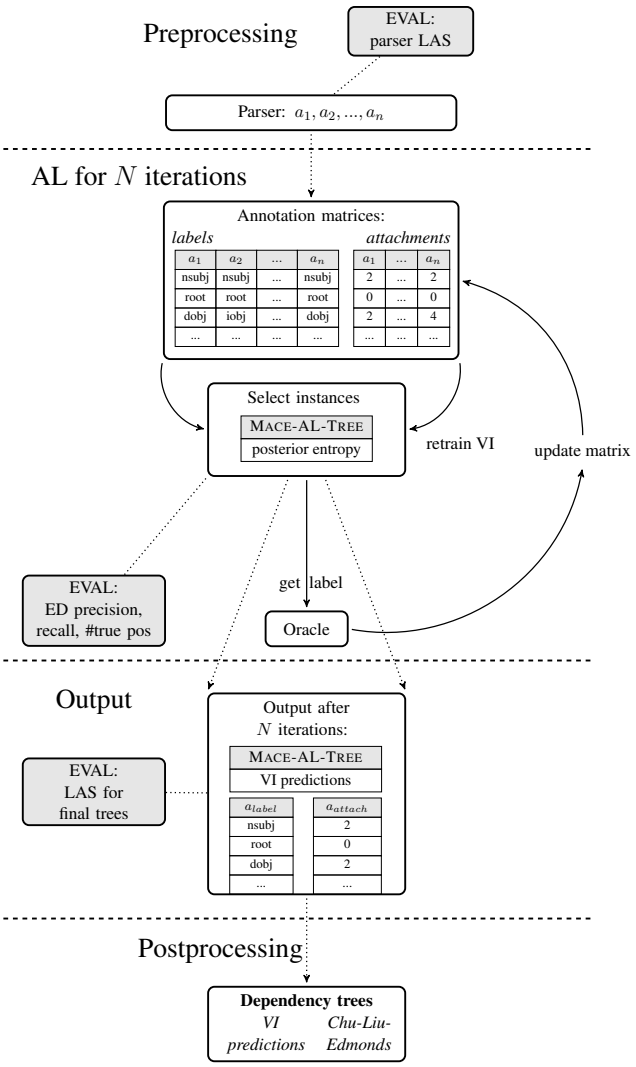

Figure 2: Error detection model with VI and AL (Error Detection (ED) precision: no. of True Positives / total no. of instances selected for error correction; True Positives: no. of instances selected for correction that are true errors; Recall: correctly identified errors / total no. of errors in the corpus).

Let's assume we have a dependency tree forest where each tree consists of a set of nodes V, one for each word in the sentence, and of a set of edge labels R that hold between the nodes. Let $L = l_1, l_2, ..., l_m$ be the set of all possible edge labels. $A = a_1, ..., a_n$ is the set of annotators, in our case the committee of dependency parsers used for obtaining the predicted parse trees. We then train two variational models where the first model aims at learning the reliability of each annotator with regard to the edge label predictions, and the second model learns the reliability of the attachment decisions for each of the parsers. The input to the *labelling* model for MACE-AL-TREE is a matrix with all labels predicted by the annotators (parsers) A_{1-n}, and the MACE-AL-TREE *attachment* model takes a matrix with the head information for each token, extracted from the parser output of the different annotators A_{1-n}.

After preprocessing the data to obtain the parser output trees, we transform the predicted trees as described above and train the variational inference model of MACE-AL-TREE separately on the label and attachment encodings (Figure 2). After training, each model outputs the posterior entropies for its respective decisions about the preprocessed input. We then alternate in extracting the label and attachment decisions with the highest posterior entropy, according to the variational model. The intuition behind this is simple: The labels or attachments with the highest entropy are most likely incorrect.

We either present the selected instances to the human annotator and request the correct annotation or, in a simulation, we extract the correct annotation from the gold tree. In the first setting, the human annotator is shown the sentence with the token in question highlighted in blue while and all the nodes that are predicted as potential heads of the token by any of the parsers are highlighted in red. The annotator

then enters the correct label *and* head for this token. The information is used to update both the label and attachment matrices by randomly selecting one of the annotators and replacing the predictions of that annotator for the instance in question with the new prediction.[3] Note that the update does not necessarily result in an increase in accuracy (or decrease in the number of errors) because the prediction may already have been correct to start with. After updating the annotation matrices, we start over and retrain the variational model on the updated annotations. To save time, we alternate in retraining the models so that each model is retrained after every other iteration. We can repeat this process as many times as we like.

Generating trees Once we are done with error correction, we want to output the trees. However, what we get from the variational model are local decisions for individual labels and edges, and it is not straight-forward to generate connected trees based on these decisions. We test two different methods for generating the output trees. In the first setting, MACE-AL-TREE, we simply use the final predictions of the variational inference model to select the most trustworthy labels and edges and combine those in a final tree. Please note that this does not necessarily result in a fully connected tree, a problem that also affects the output of many local, greedy parsers. Our second approach uses the Chu-Liu-Edmonds (CLE) algorithm (Chu and Liu, 1965; Edmonds, 1967) to select the highest scoring, well-formed tree from a weight matrix, where the weights are based on the votes from the parser committee, weighted by the competence estimates learned by the variational inference model (MACE-AL-TREE-CLE).

Overall workflow Figure 2 illustrates the workflow of our error detection model. During preprocessing, we collect parse predictions from a committee of N dependency parsers. Based on these predictions, we create the two input matrices, one for dependency labels and one for attachments, that we use to train the two variational inference models. Based on the posterior entropy from the variational inference model, we select the next instances to be annotated during active learning. After the instances have been corrected, we alternately retrain the variational inference model: in even iterations we retrain the labeling model and in odd runs the attachment model. This saves time over retraining both models in each iteration. We do, however, update both matrices in each iteration, based on the attachment and label annotations we get from the human annotator (the oracle).

Once we are done with active learning, we collect the annotations for the labels and the attachments and generate the output trees, either based on the predictions from the variational inference model (MACE-AL-TREE) or on the output from the Chu-Liu-Edmonds algorithm (MACE-AL-TREE-CLE).

A key advantage of our model is that, while making use of the feedback from active learning, we do not have to retrain the parsers after each iteration, which would be infeasible due to the time requirements. Instead, we only train the parsers once, for offline preprocessing, before active learning starts.

3 Experiments

In our experiments, we use five different dependency parsers for preprocessing to predict the parse trees. We employ the neural BiLSTM parser (BIST$_{Graph}$) of Kiperwasser and Goldberg (2016) and the RBG parser (Lei et al., 2014), both graph-based, as well as the transition-based IMSTrans parser (Björkelund and Nivre, 2015) and the slightly outdated Malt parser (Nivre et al., 2006).[4] As the fifth model, we use our in-house implementation of the head-selection parser of Zhang et al. (2017) which also employs bidirectional LSTMs (Hochreiter and Schmidhuber, 1997) for learning the feature representations. We chose the parsers so that they cover a range of different parsing algorithms and approaches, as it has been shown before that the parsers' predictions, due to the inductive biases of the algorithms involved, can complement each other (McDonald and Nivre, 2007). All parsers use default settings as reported in the literature. For the BIST$_{Graph}$ parser, we selected the model with the highest LAS on the development set after 10 training iterations.[5] We run the Malt parser with the settings *arc-eager, liblinear* without any further optimisation. For all experiments, we remove the language-specific extended labels and only train the parsers on the universal dependency relations.

[3] Other update strategies such as always updating the predictions of the annotator with the lowest performance, or updating the predictions of all annotators did not yield the same increase in results.

[4] It has been shown that the most important success criterion for ensemble parsing is the diversity of the base parsers rather than model complexity or a high accuracy for the individual parsers (Surdeanu and Manning, 2010).

[5] We started with 30 iterations but noticed no further increase in LAS after the first 10 iterations.

3.1 Error detection with active learning for manually annotated trees

The first experiment focusses on error detection in the German UD treebank which includes newswire, reviews and text from Wikipedia. Our goal is to test our error detection method in a realistic setup where we want to improve the quality of an existing dataset with minimal manual effort.

We run the task as an active learning experiment with a real human annotator in the loop who provides the correct labels for the selected error candidates. The annotator is a trained linguist with experience in linguistic annotation. The annotation task, however, is not easy due to the non-canonicity of the web data which includes many ungrammatical structures and does not conform to standard spelling conventions. Therefore, we asked a second trained linguist to adjudicate the disagreements between the original treebank annotations and the modifications carried out by the first annotator, using MaltEval (Nilsson and Nivre, 2008) to visualise the trees.

For preprocessing, we split the training part of the treebank into two sections and trained the five parsers on each section. Then we used the parsing models to predict the trees for the test set. Splitting the training data has the advantage that we now have 10 different versions of the test set (5 parsers x 2 training sets) that we can use to extract the input matrices for the active learning approach. A systematic and principled evaluation of the impact of data size and the number of annotators for the error detection approach is still outstanding.[6] Here we start with a set of 7 annotators (parsing models) for preprocessing as this setup yielded good results for POS tagging and NER (Rehbein and Ruppenhofer, 2017).[7]

Then we run 200 iterations of active learning where in each iteration the human judge had to assign the correct dependency label and head for the next token selected for annotation. After 200 iterations, we generated the parse trees for the corrected instances using the CLE algorithm weighted by the competence scores from the VI model (see §2.2) and compared them to the original treebank annotations.

The evaluation shows that out of the 200 instances from the test set inspected by the first annotator, the annotator did not agree with the original treebank annotation in 96 cases. Our second annotator agreed with the first judge on 71 of the 96 instances. For 15 instances, the annotator prefered the original annotations and for 8 instances, the second judge would have chosen a label or attachment different from the original treebank and from the first judge. This corresponds to an error detection precision of 35.5% (71/200) which should be considered as a *lower bound* as the instances where the second judge did neither agree with the first annotator nor with the original annotations might also be errors.

3.2 Error detection with AL on out-of-domain data

After validating our approach on the task of identifying errors in manually annotated trees, we now present an AL simulation study where we try to detect errors in *automatically* predicted parse trees. For this, we use the data from the English web treebank (Linguistic Data Consortium release LDC2012T13), originally annotated with constituency trees (Bies, 2012) and automatically converted to universal dependencies. The treebank includes data from five different web genres (reviews, weblogs, answers, emails, newsgroups) and provides us with a good test bed for error detection in a domain adaptation scenario. The simulation study also allows us to systematically evaluate different parameters in a controlled setting, without the need to employ human annotators.

[6] Preliminary experiments on English showed the same results with a smaller number of annotators for some datasets while for others a higher number of annotators was crucial to obtain a high error detection precision.

[7] To obtain a diverse parser committee, we selected the BIST and Dense models trained on the first section of the treebank, the Malt parser (arc-eager, lib-linear) trained on the second section, and both models for the RBG and IMSTrans parsers.

Table 2: Performance for individual parsers and parse combinations based on the predictions of the VI model with AL (MACE-AL-TREE) and with CLE (MACE-AL-TREE-CLE) for generating the trees (simulation study; Labelled attachment score (LAS) and error detection (ED) precision)

We preprocess the data as follows. First, we separate the data according to the five web genres and put all the trees for each genre into a genre-specific test set, pretending that no annotated trees for this genre are available for training. Instead, we use all remaining genres as training data. We further split the available test data for each genre into a development set, using the first 1,000 trees of each genre, and a test set including all the remaining trees (Table 1).

Table 2 (lines 1-5) shows the results for the individual baseline parsers on the different web genres. Please note that we did not optimise the parsers on the data and thus the comparison should be taken with a grain of salt. However, it is interesting to see that there is not one best parser but that the different parsers (excluding the 'vintage' Malt system) all yield results in the same range and the best performing parser varies depending on the dataset.[8]

Then we run an AL simulation for 1,000 iterations, where in each iteration one instance is selected according to our error detection model and the correct label and attachment decision is retrieved from the gold standard. Table 2 (lines 6-16) shows the parsing accuracies after increasing iterations of error correction (from 0-1000 where 0 is the output of MACE-AL-TREE with 0 iterations of active learning).

We first compare the results for MACE-AL-TREE with the ones for the best individual parser and observe an increase in LAS between 0.6% (for reviews) and more than 2% (for newsgroups and weblogs). This increase was obtained *without* any manual error correction. Using MACE-AL-TREE in this particular setup can be seen as a form of ensemble parsing where we use the predictions of the variational inference model to select the edges and labels of the parser output trees to be included in the final tree.

Now we want to evaluate the precision of the error detection method after increasing iterations of error correction via active learning. We calculate *error detection (ED) precision* as the number of error candidates that are real errors, divided by the number of instances selected for error detection.

Table 2 (lines 6-16) shows the LAS and ED precision for the different web genres. In the beginning, ED precision is quite high (between 78-92%) for nearly all genres, with the exception of the reviews.

[8]The results are not directly comparable to the ones from the SANCL shared task where the parsers were trained on the PTB while we use the data from the other web genres as training data.

line no.	*# iterations*	**ED prec**	**LAS**	*line no.*	*# iterations*	**ED prec**	**LAS**

Table 3: Results for error detection on data from the German TiGer treebank for increasing iterations of AL; trees generated with MACE-AL-TREE-CLE (simulation study; ED prec: error detection precision).

Here we start with an ED precision of 49% after 100 iterations. While for the other genres it becomes slightly harder with increasing numbers of iterations to detect new errors and ED precision slowly decreases, for the reviews the picture is rather mixed. After inspecting 1,000 instances we have a higher precision than in the beginning. We can only suspect that this might be an artefact of either idiosyncracies in the data or inconsistencies in the gold annotations.

While precision for error detection is high for all genres, the increase in LAS seems to vary across individual genres. This is because the number of tokens in the test sets also varies. The inspected 1,000 tokens correspond to 2,6% of the answers data, 2.2% for emails, 3,9% for newsgroups, 2,4% for reviews and 4.4% for the weblogs data. This means that we examined between 2.2 to 4.4% of the tokens in the data which resulted in an increase in labelled accuracy (LAS) in the range of 2 to 5%, which seems like a very good trade-off between time investment and reward in terms of data quality.[9]

Next, we compare the two different methods for generating the final parse trees. The first methods simply uses the predictions of the variational inference model (MACE-AL-TREE) and combines the highest-ranked labels and attachments into a tree. Our second method uses the Chu-Liu-Edmonds algorithm to generate well-formed trees (MACE-AL-TREE-CLE) that also allow for non-projectivity. Interestingly, as shown in Table 2 (lines 17-19), we notice only very small differences between the two methods and it is hard to say which method is superior as the differences in results might also be an effect of different initialisations of the variational inference model.[10] This observation is in line with the results from Zhang et al. (2017) who compared the output of their greedy local bi-LSTM parser with the same trees that had undergone additional postprocessing with the CLE algorithm. The authors also report only insignificant improvements for postprocessing German and Czech parser output.

Finally, we want to evaluate the importance of the generative unsupervised model as a component in our error detection model. Surdeanu and Manning (2010) emphasize that the most important success criterion for ensemble parsing is not the complexity of the model but the diversity of the baseline parsers. Therefore it is conceivable that we could get similar results using a simpler model, based merely on the predictions of the parsers *without* the variational inference model. To test this, we run 1,000 iterations of AL but select the next instance based on the entropy in the predictions of the baseline parsers instead of using the posterior entropy from the VI model (Table 2, lines 20-22) and generate the final trees running the CLE algorithm on the unweighted votes of the parser ensemble.

Table 2 shows that for 4 out of 5 genres we get substantially higher results using MACE-AL-TREE. After 1,000 iterations our model shows an increase in LAS that is between 1-2% higher than the one for the simpler model (lines 16, 19 and 22). The only outlier is the reviews subcorpus which also seemed to behave differently from the other genres with regard to error detection precision.[11]

[9] Improvements in LAS over the best individual parser after correcting 1,000 instances: answers 3.6%, emails 2.9%, newsgroup 4.8%, reviews 2.0%, weblogs 5.0%.

[10] As we use the model in an active learning setup where we need to keep the time requirements for training as small as possible, we only initialise the model once. The original model of Hovy et al. (2013) (MACE) allows for a higher number of restarts with random initialisation and then selects the best model.

[11] The lower error detection precision for the reviews in combination with higher LAS (line 22: ED: 35.8%, LAS: 88.91% after 1,000 iterations) is due to the fact that the initial predictions for the reviews based on the majority vote of the baseline parsers yielded a higher accuracy, which means that we start with a smaller amount of errors in the data. As ED precision is based on the overall number of errors in the set, we obtain a lower precision even though the model was able to detect more errors than MACE-AL-TREE.

3.3 Error detection with AL on in-domain data

We showed that our approach yields high error detection precision in out-of-domain scenarios. We now want to test whether our method is also suited for in-domain settings where we start with a higher parser output quality, which means that errors in the data might be harder to find.

Again, we run a simulation study, but this time on German newspaper text from the TiGer treebank (Brants et al., 2002). We use the version from the SPRML 2014 shared task (Seddah et al., 2014) with 40,472 sentences in the training set and 5000 sentences for testing. We train five parsers[12] on the training portion of the data and predict parse trees for the automatically tagged test file provided by the shared task organisers. Parsing accuracies for the individual parsers on our testset with automatically predicted POS and morphological tags are in the range of 84.2-90.3% UAS and of 81.1-87.6% LAS.

We then run an AL simulation on the first 500 sentences in the testset, with 1000 iterations of active learning. In each iteration we select one instance and replace its head and label with the gold information. Again, it is not guaranteed that each modification will improve results as we might select instances which, according to the VI model, are already predicted correctly. Table 3 shows results for increasing iterations of error correction with AL, and error detection (ED) precision and LAS.

We can observe the same trend on the German in-domain data as we saw for the English out-of-domain data. LAS for the generated output trees based on the predictions of the parser ensemble with CLE (Table 3, line 1), weighted by the competence score from the VI model, is significantly higher with 88.9% than the score for the best individual parser (87.6% LAS). Looking at increasing numbers of AL iterations (lines 2-11), we also see a high error detection (ED) precision, starting with 70% and slowly decreasing as it gets harder to find new errors. After 1000 iterations, we still have an error detection precision of $> 50\%$, meaning that every second instance that we inspect is a real error. In terms of accuracy, running 1000 iterations of error correction on the TiGer subcorpus translates into an increase in LAS from 88.8% to 94.6% while keeping the number of instances for manual correction reasonably low.

3.4 Error analysis

Having established that our model is able to detect errors in manually and automatically annotated parse trees on in-domain and out-of-domain data, we would now like to learn more about the types of errors our model is able to detect. We thus evaluate the output trees generated from the German newspaper corpus (Section 3.3) *before* and *after* running 1000 iterations of AL for error correction.

Overall, our error correction resulted in 385 changed attachment decisions and in 298 modified dependency labels. In 167 cases, both label and attachment have been changed. Looking only at the label errors, we can see that the errors are distributed over 25 different dependency labels. The most frequent ones concern labels for core arguments (subject (SB), direct and indirect object (OA/DA), predicate (PD) and genitive attributes (AG/PG)) that are, due to the semi-free German word order and ambiguity arising through case syncretism, one of the major sources for parsing errors.

Other frequent labelling errors include the distinction between verb and noun attachment for PPs (modifier (MO)/noun modifier to the right (MNR)). The distinction between modifying (MO) and obligatory PPs (OP) is another frequent error that the model was able to detect. Our model also finds errors concerning coordination (CJ, CD) and clause structure, such as relative clauses (RC), parenthesis (PAR), clausal objects (OC), repeated element (RE) and reported speech (RS).

[12]For German, we used the IMSTrans parser, the head-selection parser and the BIST$_{Graph}$ parser that we also used in the previous set of experiments. In addition, we also use the transition-based biLSTM parser of (Kiperwasser and Goldberg, 2016) (BIST$_{Trans}$) and the RBG parser (Lei et al., 2014).

# unlabelled sentences	**LAS answer**	**LAS email**	**LAS newsgroup**	**LAS reviews**	**LAS weblog**
Results without self-training (best individual parser)					
	85.03	82.81	83.53	86.73	84.93

Table 5: Baselines and results for self-training on the different web genres.

Looking at the attachment errors that have been detected by our model (Table 4, right), we find that the most frequent head types that have been re-attached are modifiers (MO, MNR). This not only includes PPs but also adverbal and adjectival modification. The next frequent error type are incorrectly attached punctuations. This, however, is not an error type we are concerned with and it might make sense to exclude punctuation from the error correction.[13] More interesting attachment errors include coordination (CJ, CD), parenthesis (PAR), apposition (APP) and again the core arguments (OA, AG, DA, SB, PD).

This shows that our model is not biased toward a small set of specific error types but is able to detect frequent parsing errors that are well-known from the literature (Kummerfeld et al., 2012).

3.5 Domain adaptation with self-training

In the final set of experiments we want to test whether we can use our method to automatically correct parser output for self-training, to improve parsing accuracy for out-of-domain data. As before, we use the English web treebank, split into different genres as described above. Again, we pretend that no annotated training data for the different genres are available. This time, however, we make use of the supplementary raw text data for the five web genres (Table 1) that were provided for the SANCL shared task (Petrov and McDonald, 2012). The data is segmented into sentences and pre-tokenised. For preprocessing, we use UDPipe (Straka and Straková, 2017) with the pretrained models from the CoNLL-2017 shared task.[14] We also remove unlabelled sentences with a length > 60 tokens.[15]

We parse the additional data using the following settings. As our first baseline, we use the parser that achieved the best LAS on this particular genre for preprocessing. For our second baseline, we apply the best two parsers for each genre to parse the raw text and then select only those trees for self-training where the two parsers agree (excluding punctuation). In the last setting, we use MACE-AL-TREE (but without active learning) to generate the parse trees for each bin of automatically parsed text, based on the predictions of the parser ensemble.

We then use the output of each setting and combine the bins with the original training data for each genre, resulting in new training sets of increasing sizes. Then we train the BIST$_{Graph}$ parser on the new data and select the best model, based on the results on the development set after 10 iterations of training.

[13] In the original constituency-based TiGer treebank, all punctuation marks are attached to a virtual root node and have been reattached during the conversion to dependencies. This results in many arbitrary attachment decisions which makes it hard for the parser to learn these attachments.

[14] The models are available from `https://lindat.mff.cuni.cz/repository/xmlui/handle/11234/1-1990`.

[15] For the answers where we only have 27,274 raw sentences, this results in only 4 samples after removing long sentences, and only one sample for the agreement-based self-training (baseline 2).

Table 5 reports results for the three different settings. Looking at the self-training results where we retrain the BIST$_{Graph}$ parser on the predictions of the best individual parser, we can see mostly small improvements but sometimes also a decrease in LAS. The results for baseline 2 are also a bit mixed. When adding only 5,000 additional sentences, we obtain slightly higher results as compared to baseline 1. When adding more data, however, it shows that this improvement is not stable and sometimes results are lower than for the first baseline. A possible explanation is that the agreement-based selection strategy favors shorter sentences (as those are the ones where the two parsers tend to agree more often), and that we thus only add less complex structures that are not very informative for the parser. In addition, we introduce a bias in the training set that also might have a negative effect on results.

The third setting, however, clearly outperforms our baselines and shows a significant increase in parsing accuracy. Nonetheless, when comparing the results for MACE-AL-TREE *with* self-training to the results *without* self-training we see that our self-training approach fails to beat the results obtained on the original data on three web genres. We only observe improved results on the emails and on the reviews. These two genres are also the ones that have the largest amount of unknown words which might explain why self-training is more promising for emails and reviews than for the other three genres, as Reichart and Rappoport (2007) have shown that the number of unknown words can be a good indicator for the potential benefit from self-training.

4 Related work

Most studies on error detection in treebanks have focussed on finding errors in manual annotations (Dickinson and Meurers, 2003; Ule and Simov, 2004; van Noord, 2004; Dickinson and Meurers, 2005; Agrawal et al., 2013). Dickinson and Meurers (2003; 2005) proposed the use of *variation n-grams* to detect inconsistencies in manually annotated constituency treebanks and Boyd et al. (2008) extend this line of work to dependency trees. This approach, however, only works for manually annotated treebanks while for automatic parses where the errors are consistent and systematic, looking for variation in the predictions will not be very helpful. Volokh and Neumann (2011) address the latter problem and use two different parsing models to reproduce the annotations in the *training data*. They consider an instance to be erroneous if the two parsers agree in their predictions for the attachment of the token but disagree with the gold standard. The authors report a high precision for automatic error correction. However, their method only addresses attachment errors but does not handle label errors.

Work on predicting *automatic* parser errors includes Dickinson and Smith (2011) who develop a grammar-based method for error detection. They use ngrams extracted from automatic parses and weigh them by comparing them to the rules in a small gold grammar. Follow-up work (Dickinson and Smith, 2017) builds on this approach and uses parse simulations to extend the training grammar.

Relevant for our work are also studies on parse accuracy prediction. Ravi et al. (2008) predict parser performance for data from new domains. Our error detection method can be applied to automatic parses in a domain adaptation setting and can not only predict the accuracy of the parses but also improve the accuracy of the parser output. Our work can be seen as a combination of semi-supervised and ensemble-based methods and is thus similar in spirit to Søgaard and Rishøj (2010) who use tri-training in combination with self-training for dependency parsing and report an increase in labelled attachment score (LAS) for different languages in the range of 1.4 to 2.6%. Their self-training experiments, however, were based on a much larger amount of additional data (100,000 sentences vs. up to 25,000 sentences in our self-training experiments). It would be interesting to see whether more unlabelled data can further improve results, as suggested by the results for MACE-AL-TREE with self-training.

5 Conclusions

We presented a method for error detection in treebanks, based on the combination of (i) ensemble parsing, (ii) an unsupervised generative inference model, and (iii) human guidance from active learning. We validated our model on the task of error detection in manual and automatic annotations using active learning and showed that we can identify parse errors with precisions in the range of 35% to over 90%. Our approach can also be used to improve the quality of automatic annotations on out-of-domain data, without any human feedback, where we obtained gains in accuracy of up to 2% and more.

Two Local Models for Neural Constituent Parsing

Zhiyang Teng and **Yue Zhang**
Singapore University of Technology and Design
zhiyang_teng@mymail.sutd.edu.sg
yue_zhang@sutd.edu.sg

Non-local features have been exploited by syntactic parsers for capturing dependencies between sub output structures. Such features have been a key to the success of state-of-the-art statistical parsers. With the rise of deep learning, however, it has been shown that local output decisions can give highly competitive accuracies, thanks to the power of dense neural input representations that embody global syntactic information. We investigate two conceptually simple local neural models for constituent parsing, which make local decisions to constituent spans and CFG rules, respectively. Consistent with previous findings along the line, our best model gives highly competitive results, achieving the labeled bracketing F1 scores of 92.4% on PTB and 87.3% on CTB 5.1.

1 Introduction

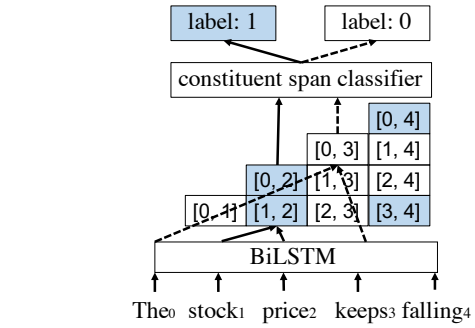
Non-local features have been shown crucial for statistical parsing (Huang, 2008a; Zhang and Nivre, 2011). For dependency parsing, High-order dynamic programs (Koo and Collins, 2010), integer linear programming (Martins et al., 2010) and dual decomposition (Koo et al., 2010) techniques have been exploited by graph-based parser to integrate non-local features. Transition-based parsers (Nivre, 2003; Nivre, 2008; Zhang and Nivre, 2011; Bohnet, 2010; Huang et al., 2012) are also known for leveraging non-local features for achieving high accuracies. For most state-of-the-art statistical parsers, a global training objective over the entire parse tree has been defined to avoid label bias (Lafferty et al., 2001).

For neural parsing, on the other hand, local models have been shown to give highly competitive accuracies (Cross and Huang, 2016b; Stern et al., 2017) as compared to those that employ long-range features (Watanabe and Sumita, 2015; Zhou et al., 2015; Andor et al., 2016; Durrett and Klein, 2015). Highly local features have been used in recent state-of-the-art models (Stern et al., 2017; Dozat and Manning, 2016; Shi et al., 2017). In particular, Dozat and Manning (2016) show that a locally trained arc-factored model can give the best reported accuracies on dependency parsing. The surprising result has been largely attributed to the representation power of long short-term memory (LSTM) encoders (Kiperwasser and Goldberg, 2016).

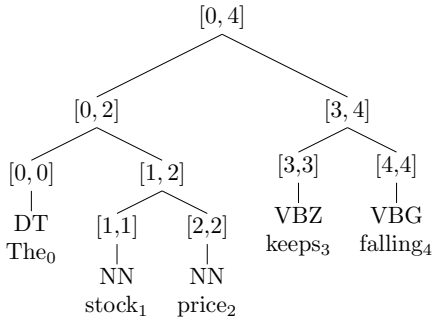
An interesting research question is to what extent the encoding power can be leveraged for constituent parsing. We investigate the problem by building a chart-based model that is local to unlabeled constituent spans (Abney, 1991) and CFG-rules, which have been explored by early PCFG models (Collins, 2003; Klein and Manning, 2003). In particular, our models first predict unlabeled CFG trees leveraging bi-affine modelling (Dozat and Manning, 2016). Then, constituent labels are assigned on unlabeled trees by using a tree-LSTM to encode the syntactic structure, and a LSTM decoder for yielding label sequences on each node, which can include unary rules.

Experiments show that our conceptually simple models give highly competitive performances compared with the state-of-the-art. Our best models give labeled bracketing F1 scores of 92.4% on PTB and 87.3% on CTB 5.1 test sets, without reranking, ensembling and external parses. We release our code at

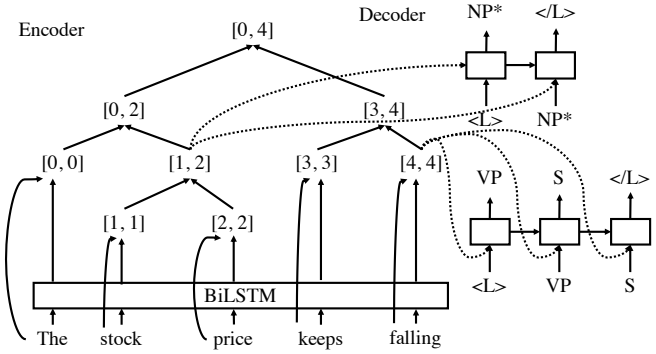
Proceedings of the 27th International Conference on Computational Linguistics, pages 119–132
Santa Fe, New Mexico, USA, August 20-26, 2018.



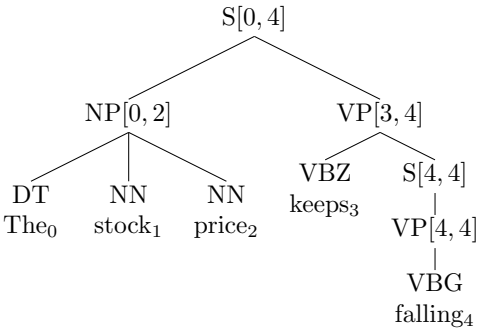
(a) BiLSTM based constituent span classifier.



(b) unlabeled binarized parse tree.



(c) Label generator for two example spans. **NP*** is an intermediate constituent label.



(d) Final example parse tree.

Figure 1: An example workflow of our parsers for the sentence "The stock price keeps falling". We annotate every non-terminal span with its covered span range. Figure 1a shows constituent span classifiers making 0/1 decisions for all possible spans. Based on the local classification probabilities, we obtain an unlabeled binarized parse tree (Figure 1b) using binary CKY parsing algorithms. We then hierarchically generate labels for each span (Figure 1c) using encoder-decoder models. Figure 1d shows the final output parse tree after debinarization.

`https://github.com/zeeeyang/two-local-neural-conparsers`.

2 Model

Our models consist of an unlabeled binarized tree parser and a label generator. Figure 1 shows a running example of our parsing model. The unlabeled parser (Figure 1a, 1b) learns an unlabeled parse tree using simple BiLSTM encoders (Hochreiter and Schmidhuber, 1997). The label generator (Figure 1c, 1d) predicts constituent labels for each span in the unlabeled tree using tree-LSTM models.

In particular, we design two different classification models for unlabeled parsing: the **span model** (Section 2.1) and the **rule model** (Section 2.2). The span model identifies the probability of an arbitrary span being a constituent span. For example, the span $[1, 2]$ in Figure 1a belongs to the correct parse tree (Figure 1d). Ideally, our model assigns a high probability to this span. In contrast, the span $[0, 3]$ is not a valid constituent span and our model labels it with 0. Different from the span model, the rule model considers the probability $P([i, j] \rightarrow [i, k][k + 1, j]|S)$ for the production rule that the span $[i, j]$ is composed by two children spans $[i, k]$ and $[k + 1, j]$, where $i \leq k < j$. For example, in Figure 1a, the rule model assigns high probability to the rule $[0, 2] \rightarrow [0, 0][1, 2]$ instead of the rule $[0, 2] \rightarrow [0, 1][2, 2]$. Given the local probabilities, we use CKY algorithm to find the unlabeled binarized parses.

The label generator encodes a binarized unlabeled tree and to predict constituent labels for every span. The encoder is a binary tree-LSTM (Tai et al., 2015; Zhu et al., 2015), which recursively composes the representation vectors for tree nodes bottom-up. Based on the representation vector of a constituent span, a LSTM decoder (Cho et al., 2014; Sutskever et al., 2014) generates chains of constituent labels, which

can represent unary rules. For example, the decoder outputs "VP →S→ </L>" for the span [4, 4] and "NP→ </L>" for the span [0,2] in Figure 1c where </L> is a stopping symbol.

2.1 Span Model

Given an unlabeled binarized tree T_{ub} for the sentence S, $S = w_0, w_1 \dots w_{n-1}$, the span model trains a neural network model $P(Y_{[i,j]}|S, \Theta)$ to distinguish constituent spans from non-constituent spans, where $0 \leq i \leq n-2$, $1 \leq j < n$, $i < j$. $Y_{[i,j]} = 1$ indicates the span [i, j] is a constituent span ($[i, j] \in T_{ub}$), and $Y_{[i,j]} = 0$ for otherwise, Θ are model parameters. We do not model spans with length 1 since the span $[i, i]$ always belongs to T_{ub}.

Network Structure. Figure 2a shows the neural network structures for the binary classification model. In the bottom, a bidirectional LSTM layer encodes the input sentence to extract non-local features. In particular, we append a starting symbol <s> and an ending symbol </s> to the left-to-right LSTM and the right-to-left LSTM, respectively. We denote the output hidden vectors of the left-to-right LSTM and the right-to-left LSTM for $w_0, w_1, \dots, w_{n-1}$ is $\mathbf{f}_1, \mathbf{f}_2, \dots, \mathbf{f}_n$ and $\mathbf{r}_0, \mathbf{r}_1, \dots, \mathbf{r}_{n-1}$, respectively. We obtain the representation vector $\mathbf{v}[i, j]$ of the span $[i, j]$ by simply concatenating the bidirectional output vectors at the input word i and the input word j,

$$\mathbf{v}[i, j] = [\mathbf{f}_{i+1}; \mathbf{r}_i; \mathbf{f}_{j+1}; \mathbf{r}_j]. \tag{1}$$

$\mathbf{v}[i, j]$ is then passed through a nonlinear transformation layer and the probability distribution $P(Y_{[i,j]}|S, \Theta)$ is given by

$$\mathbf{o}[i, j] = \tanh(\mathbf{W}_o\mathbf{v}[i, j] + \mathbf{b}_o), \;\; \mathbf{u}[i, j] = \mathbf{W}_u\mathbf{o}[i, j] + \mathbf{b}_u, \;\; P(Y_{[i,j]}|S, \Theta) = \text{softmax}(\mathbf{u}[i, j]), \tag{2}$$

where $\mathbf{W}_o, \mathbf{b}_o, \mathbf{W}_u$ and $\mathbf{b}_u$ are model parameters.

Input Representation. Words and part-of-speech (POS) tags are integrated to obtain the input representation vectors. Given a word w, its corresponding characters $c_0, \dots, c_{|w|-1}$ and POS tag t, first, we obtain the word embedding $\mathbf{E}^w_{word}$, character embeddings $\mathbf{E}^{c_0}_{char}, \dots, \mathbf{E}^{c_{|w|-1}}_{char}$, and POS tag embedding $\mathbf{E}^t_{pos}$ using lookup operations. Then a bidirectional LSTM is used to extract character-level features. Suppose that the last output vectors of the left-to-right and right-to-left LSTMs are $\mathbf{h}^f_{char}$ and $\mathbf{h}^r_{char}$, respectively. The final input vector $\mathbf{x}_{input}$ is given by

$$\mathbf{x}_{char} = \tanh(\mathbf{W}^l_{char}\mathbf{h}^l_{char} + \mathbf{W}^r_{char}\mathbf{h}^r_{char} + \mathbf{b}_{char}), \;\; \mathbf{x}_{input} = [\mathbf{E}^w_{word} + \mathbf{x}_{char}; \mathbf{E}^t_{pos}], \tag{3}$$

where $\mathbf{W}^l_{char}$, $\mathbf{W}^r_{char}$ and $\mathbf{b}_{char}$ are model parameters.

Training objective. The training objective is to maximize the probabilities of $P(Y_{[i,j]} = 1|S, \Theta)$ for spans $[i, j] \in T_{ub}$ and minimize the probabilities of $P(Y_{[i,j]} = 1|S, \Theta)$ for spans $[i, j] \notin T_{ub}$ at the same time. Formally, the training loss for binary span classification $\mathcal{L}_{\text{binary}}$ is given by

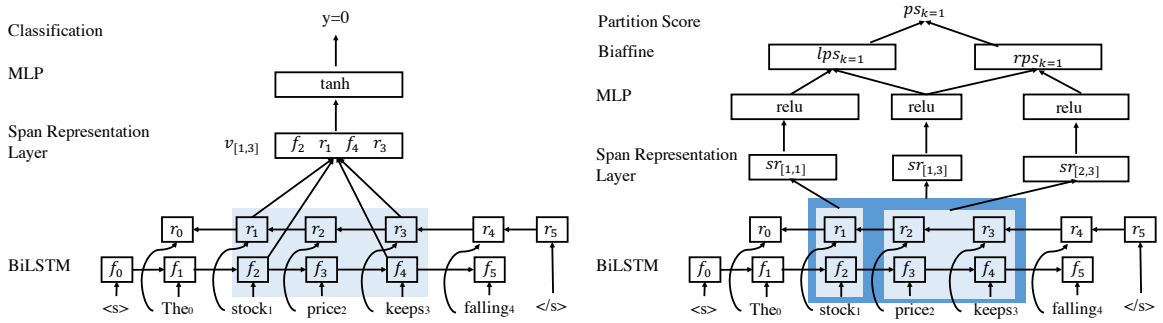
$$\mathcal{L}_{\text{binary}} = -\sum_{[i,j]\in T_{ub}} \log P(Y_{[i,j]} = 1|S, \Theta) - \sum_{[i,j]\notin T_{ub}} \log P(Y_{[i,j]} = 0|S, \Theta), \\ (0 \leq i \leq n-2, 1 \leq j < n, i < j) \tag{4}$$

For a sentence with length n, there are $\frac{n(n-1)}{2}$ terms in total in Eq 4.

Neural CKY algorithm. The unlabeled production probability for the rule $r : [i, j] \rightarrow [i, k][k + 1, j]$ given by the binary classification model is,

$$P(r|S, \Theta) = P(Y_{[i,k]} = 1|S, \Theta)P(Y_{[k+1,j]} = 1|S, \Theta).$$

During decoding, we find the optimal parse tree T^*_{ub} using the CKY algorithm. Note that our CKY algorithm is different from the standard CKY algorithm mainly in that there is no explicit phrase rule probabilities being involved. Hence our model can be regarded as a zero-order constituent tree model, which is the most *local*. All structural relations in a constituent tree must be implicitly captured by the BiLSTM encoder over the sentence alone.



(a) Span model. (b) Rule model.

Figure 2: Neural network structures for span and rule models using BiLSTM encoders.

Multi-class Span Classification Model. The previous model preforms binary classifications to identify constituent spans. In this way, the classification model only captures the existence of constituent labels but does not leverage constituent label type information. In order to incorporate the syntactic label information into the span model, we use a multi-class classification model $P(Y_{[i,j]} = c|S, \Theta)$ to describe the probability that c is a constituent label for span $[i, j]$. The network structure is the same as the binary span classification model except the last layer. For the last layer, given $\mathbf{o}_{[i,j]}$ in Eq 2, $P(Y_{[i,j]} = c|S, \Theta)$ is calculated by,

$$\mathbf{m}[i, j] = \mathbf{W}_m \mathbf{o}[i, j] + \mathbf{b}_m, \ P(Y_{[i,j]} = c|S, \Theta) = \text{softmax}(\mathbf{m}[i, j])_{[c]}. \tag{5}$$

Here $\mathbf{W}_m, \mathbf{b}_m, \mathbf{W}_m$ and $\mathbf{b}_m$ are model parameters. The subscript $[c]$ is to pick the probability for the label c. The training loss is,

$$\mathcal{L}_{\text{multi}} = -\sum_{[i,j]\in T_{ub}} \sum_{c\in[i,j], c\neq</L>} \log P(Y_{[i,j]} = c|S, \Theta) - \sum_{[i,j]\notin T_{ub}} \log P(Y_{[i,j]} = </L>|S, \Theta), \tag{6}$$
$$(0 \leq i \leq n-2, 1 \leq j < n, i < j)$$

Note that there is an additional sum inside the first term in Eq 6, which is different from the first term in Eq 4. This is to say that we treat all constituent labels equally of a unary chain. For example, suppose there is a unary chain S→VP in span [4,4]. For this span, we hypothesize that both labels are plausible answers and pay equal attentions to VP and S during training. For the second term in Eq 6, we maximize the probability of the ending label for non-constituent spans.

For decoding, we transform the multi-class probability distribution into a binary probability distribution by using,

$$P(Y_{[i,j]} = 1|S, \Theta) = \sum_{c, c\neq</L>} P(Y_{[i,j]} = c|S, \Theta), \ \ P(Y_{[i,j]} = 0|S, \Theta) = P(Y_{[i,j]} = </L>|S, \Theta)$$

In this way, the probability of a span being a constituent span takes all possible syntactic labels into considerations.

2.2 Rule Model

The rule model directly calculates the probabilities of all possible splitting points k $(i \leq k < j)$ for the span $[i, j]$. Suppose the partition score of splitting point k is ps_k. The unlabeled production probability for the rule $r : [i, j] \rightarrow [i, k][k + 1, j]$ is given by a softmax distribution,

$$P([i, j] \rightarrow [i, k][k + 1, j]|S, \Theta) = \frac{\exp(ps_k)}{\sum_{k'=i}^{j-1} \exp(ps_{k'})}.$$

The training objective is to minimize the log probability loss of all unlabeled production rules.

$$\mathcal{L}_{\text{rule}} = -\sum_{r \in T_{ub}} \log P(r : [i,j] \rightarrow [i,k][k+1,j] | S, \Theta)$$

The decoding algorithm is the standard CKY algorithm, which we omit here. The rule model can be regarded as a first-order constituent model, with the probability of each phrase rule being modeled. However, unlike structured learning algorithms (Finkel et al., 2008; Carreras et al., 2008), which use a global score for each tree, our model learns each production rule probability individually. Such local learning has traditionally been found subjective to label bias (Lafferty et al., 2001). Our model relies on input representations solely for resolving this issue.

Span Representation. Figure 2b shows one possible network architecture for the rule model by taking the partition point $k = 1$ for the span $[1, 3]$ as an example. The BiLSTM encoder layer in the bottom is the same as that of the previous span classification model. We obtain the span representation vectors using difference vectors (Wang and Chang, 2016; Cross and Huang, 2016b). Formally, the span representation vector $\mathbf{sr}[i,j]$ is given by,

$$\begin{aligned} \mathbf{s}[i,j] &= [\mathbf{f}_{j+1} - \mathbf{f}_i; \mathbf{r}_i - \mathbf{r}_{j+1}], \\ \mathbf{sr}[i,j] &= [\mathbf{s}[0,i-1]; \mathbf{s}[i,j]; \mathbf{s}[j+1,n-1]]. \end{aligned} \tag{7}$$

We first combine the difference vectors $(\mathbf{f}_{j+1} - \mathbf{f}_i)$ and $(\mathbf{r}_i - \mathbf{r}_{j+1})$ to obtain a simple span representation vector $\mathbf{s}[i,j]$. In order to take more contextual information such as $\mathbf{f}_p$ where $p > j+1$ and $\mathbf{r}_q$ where $q < i$, we concatenate $\mathbf{s}[0,i-1]$, $\mathbf{s}[i,j]$, and $\mathbf{s}[j+1,n-1]$ to produce the final span representation vector $\mathbf{sr}[i,j]$. We then transform $\mathbf{sr}[i,j]$ to an output vector $\mathbf{r}[i,j]$ using an activation function ϕ,

$$\mathbf{r}[i,j] = \phi(\mathbf{W}_r^M \mathbf{sr}[i,j] + \mathbf{b}_r^M), \tag{8}$$

where $\mathbf{W}_r^M$ and $\mathbf{b}_r^M$ and model parameters, and M is a parameter set index. We use separate parameters for the nonlinear transforming layer. $M \in \{P, L, R\}$ are for the parent span $[i,j]$, the left child span $[i,k]$ and the right child span $[k+1,j]$, respectively.

After obtaining the span representation vectors, we use these vectors to calculate the partition score ps_k. In particular, we investigate two scoring methods.

Linear Model. In the linear model, the partition score is calculated by a linear affine transformation. For the splitting point k,

$$ps_k = \mathbf{w}_{ll,k}^T \mathbf{r}[i,k] + \mathbf{w}_{lr,k}^T \mathbf{r}[k+1,j] + b_{ll,k}$$

where $\mathbf{w}_{ll,k}^T$ and $\mathbf{w}_{ll,k}^T$ are two vectors, and $b_{ll,k}$ is a size 1 parameter.

Biaffine model. Since the possible splitting points for spans are varied with the length of span, we also try a biaffine scoring model (as shown in Figure 2b), which is good at handling variable-sized classification problems (Dozat and Manning, 2016; Ma and Hovy, 2017). The biaffine model produces the score lps_k between the parent span $[i,j]$ and the left child span $[i,k]$ using a biaffine scorer

$$lps_k = (\mathbf{r}[i,j] \oplus 1)^T \mathbf{W}_{pl} (\mathbf{r}[i,k] \oplus 1) \tag{9}$$

where $\mathbf{W}_{pl}$ is model parameters. Similarly, we calculate the score rps_k between the parent span $[i,j]$ and the right child span $[k+1,j]$ using $\mathbf{W}_{pr}$ and $\mathbf{b}_{pr}$ as parameters. The overall partition score ps_k is therefore given by

$$ps_k = lps_k + rps_k.$$

2.3 Label Generator

Lexicalized Tree-LSTM Encoder. Shown in Figure 1c, we use lexicalized tree LSTM (Teng and Zhang, 2016) for encoding, which shows good representation abilities for unlabeled trees. The encoder first propagates lexical information from two children spans to their parent using a lexical gate, then it produces the representation vectors of the parent span by composing the vectors of children spans using a

binarized tree-LSTM (Tai et al., 2015; Zhu et al., 2015). Formally, the lexical vector $\mathbf{tx}[i,j]$ for the span $[i,j]$ with the partition point at k is defined by:

$$\mathbf{i}^{lex}_{[i,j]} = \sigma(\mathbf{W}^{lex}_{l}\mathbf{tx}[i,k] + \mathbf{W}^{lex}_{r}\mathbf{tx}[k+1,j] + \mathbf{W}^{lex}_{lh}\mathbf{h}_{[i,k]} + \mathbf{W}^{lex}_{rh}\mathbf{h}_{[k+1,j]} + \mathbf{b}_{lex})$$
$$\mathbf{tx}[i,j] = \mathbf{i}^{lex}_{[i,j]} \odot \mathbf{tx}[i,k] + (\mathbf{1.0} - \mathbf{i}^{lex}_{[i,j]}) \odot \mathbf{tx}[k+1,j],$$

where $\mathbf{W}^{lex}_{l}$, $\mathbf{W}^{lex}_{r}$ and $\mathbf{b}_{lex}$ are model parameters, $\odot$ is element-wise multiplication and σ is the logistic function. The lexical vector $\mathbf{tx}[i,i]$ for the leaf node i is the concatenate of the output vectors of the BiLSTM encoder and the input representation $\mathbf{x}_{\textbf{input}}[i]$ (Eq 3), as shown in Figure 1c.

The output state vector $\mathbf{h}[i,j]$ of the span $[i,j]$ given by a binary tree LSTM encoder is,

$$\mathbf{i}_p = \sigma(\mathbf{W}_1\mathbf{tx}_p + \mathbf{W}_2\mathbf{h}_l + \mathbf{W}_3\mathbf{c}_l + \mathbf{W}_4\mathbf{h}_r + \mathbf{W}_5\mathbf{c}_r + \mathbf{b}_1),$$
$$\mathbf{f}^l_p = \sigma(\mathbf{W}_6\mathbf{tx}_p + \mathbf{W}_7\mathbf{h}_l + \mathbf{W}_8\mathbf{c}_l + \mathbf{W}_9\mathbf{h}_r + \mathbf{W}_{10}\mathbf{c}_r + \mathbf{b}_2),$$
$$\mathbf{f}^r_p = \sigma(\mathbf{W}_{11}\mathbf{tx}_p + \mathbf{W}_{12}\mathbf{h}_r + \mathbf{W}_{13}\mathbf{c}_l + \mathbf{W}_{14}\mathbf{h}_r + \mathbf{W}_{15}\mathbf{c}_r + \mathbf{b}_3),$$
$$\mathbf{g}_p = \tanh(\mathbf{W}_{16}\mathbf{tx}_p + \mathbf{W}_{17}\mathbf{h}_l + \mathbf{W}_{18}\mathbf{h}_r + \mathbf{b}_4),$$
$$\mathbf{c}_p = \mathbf{f}^l_p \odot \mathbf{c}_l + \mathbf{f}^r_p \odot \mathbf{c}_r + \mathbf{i}_p \odot \mathbf{g}_p,$$
$$\mathbf{o}_p = \sigma(\mathbf{W}_{19}\mathbf{tx}_p + \mathbf{W}_{20}\mathbf{h}_p + \mathbf{W}_{21}\mathbf{h}_r + \mathbf{W}_{22}\mathbf{c}_p + \mathbf{b}_5), \;\; \mathbf{h}_p = \mathbf{o}_p \odot \tanh(\mathbf{c}_p).$$

Here the subscripts p, l and r denote $[i,j]$, $[i,k]$ and $[k+1,j]$, respectively.

Label Decoder. Suppose that the constituent label chain for the span $[i,j]$ is $(\mathrm{YL}^0_{[i,j]}, \mathrm{YL}^1_{[i,j]}, \ldots, \mathrm{YL}^m_{[i,j]})$. The decoder for the span $[i,j]$ learns a conditional language model depending on the output vector $\mathbf{h}[i,j]$ from the tree LSTM encoder. Formally, the probability distribution of generating the label at time step z is given by,

$$P(\mathrm{YL}^z_{[i,j]}|T_{ub}, \mathrm{YL}^{z<m}_{[i,j]}) = \mathrm{softmax}\Big(g(\mathbf{h}[i,j], \mathbf{E}_{label}(\mathrm{YL}^{z-1}_{[i,j]}), \mathbf{d}_{z-1})\Big),$$

where $\mathrm{YL}^{z<m}_{[i,j]}$ is the decoding prefix, $\mathbf{d}_{z-1}$ is the state vector of the decoder LSTM and $\mathbf{E}_{label}(\mathrm{YL}^{z-1}_{[i,j]})$ is the embedding of the previous output label.

The training objective is to minimize the negative log-likelihood of the label generation distribution,

$$\mathcal{L}_{\text{label}}[i,j] = -\sum_{z=0}^{m} \log P(\mathrm{YL}^z_{[i,j]}|T_{ub}, \mathrm{YL}^{z<m}_{[i,j]}),$$
$$\mathcal{L}_{\text{label}} = \sum_{[i,j]\in T_{ub}} \mathcal{L}_{\text{label}}[i,j].$$

2.4 Joint training

In conclusion, each model contains an unlabeled structure predictor and a label generator. The latter is the same for all models. All the span models perform binary classification. The difference is that BinarySpan doesn't consider label information for unlabeled tree prediction. While MultiSpan guides unlabeled tree prediction with such information, simulating binary classifications. The unlabeled parser and the label generator share parts of the network components, such as word embeddings, char embeddings, POS embeddings and the BiLSTM encoding layer. We jointly train the unlabeled parser and the label generator for each model by minimizing the overall loss

$$\mathcal{L}_{\text{total}} = \mathcal{L}_{\text{parser}} + \mathcal{L}_{\text{label}} + \frac{\lambda}{2}||\Theta||^2,$$

where λ is a regularization hyper-parameter. We set $\mathcal{L}_{\text{parser}} = \mathcal{L}_{\text{binary}}$ or $\mathcal{L}_{\text{parser}} = \mathcal{L}_{\text{multi}}$ and $\mathcal{L}_{\text{parser}} = \mathcal{L}_{\text{rule}}$ when using the binary span classification model, the multi-class model and the rule model, respectively.

hyper-parameter	value	hyper-parameter	value

Table 1: Hyper-parameters for training.

3 Experiments

3.1 Experimental Settings

Data. We perform experiments for both English and Chinese. Following standard conventions, our English data are obtained from the Wall Street Journal (WSJ) of the Penn Treebank (PTB) (Marcus et al., 1993). Sections 02-21, section 22 and section 23 are used for training, development and test sets, respectively. Our Chinese data are the version 5.1 of the Penn Chinese Treebank (CTB) (Xue et al., 2005). The training set consists of articles 001-270 and 440-1151, the development set contains articles 301-325 and the test set includes articles 271-300. We use automatically reassigned POS tags in the same way as Cross and Huang (2016b) for English and Dyer et al. (2016) for Chinese.

We use ZPar (Zhang and Clark, 2011)[1] to binarize both English and Chinese data with the head rules of Collins (2003). The head directions of the binarization results are ignored during training. The types of English and Chinese constituent span labels after binarization are 52 and 56, respectively. The maximum number of greedy decoding steps for generating consecutive constituent labels is limited to 4 for both English and Chinese. We evaluate parsing performance in terms of both unlabeled bracketing metrics and labeled bracketing metrics including unlabeled F1 (UF)[2], labeled precision (LP), labeled recall (LR) and labeled bracketing F1 (LF) after debinarization using EVALB[3].

Unknown words. For English, we combine the methods of Dyer et al. (2016) and Cross and Huang (2016b) to handle unknown words. In particular, we first map all words (not just singleton words) in the training corpus into unknown word classes using the same rule as Dyer et al. (2016). During each training epoch, every word w in the training corpus is stochastically mapped into its corresponding unknown word class unk_w with probability $P(w \rightarrow unk_w) = \frac{\gamma}{\gamma + \#w}$, where $\#w$ is the frequency count and γ is a control parameter. Intuitively, the more times a word appears, the less opportunity it will be mapped into its unknown word type. There are 54 unknown word types for English. Following Cross and Huang (2016b), $\gamma = 0.8375$. For Chinese, we simply use one unknown word type to dynamically replace singletons words with a probability of 0.5.

Hyper-parameters. Table 1 shows all hyper-parameters. These values are tuned using the corresponding development sets. We optimize our models with stochastic gradient descent (SGD). The initial learning rate is 0.1. Our model are initialized with pretrained word embeddings both for English and Chinese. The pretrained word embeddings are the same as those used in Dyer et al. (2016). The other parameters are initialized according to the default settings of DyNet (Neubig et al., 2017). We apply dropout (Srivastava et al., 2014) to the inputs of every LSTM layer, including the word LSTM layers, the character LSTM layers, the tree-structured LSTM layers and the constituent label LSTM layers. For Chinese, we find that 0.3 is a good choice for the dropout probability. The number of training epochs is decided by the evaluation performances on development set. In particular, we perform evaluations on development set for every 10,000 examples. The training procedure stops when the results of next 20 evaluations do not become better than the previous best record.

[1] https://github.com/SUTDNLP/ZPar

[2] For UF, we exclude the sentence span [0,n-1] and all spans with length 1.

BiaffineRule	**92.49**	92.23	92.36	91.31	**91.28**	91.29

Table 3: Main development results.

3.2 Development Results

We study the two span representation methods, namely the simple concatenating representation $\mathbf{v}[i,j]$ (Eq 1) and the combining of three difference vectors $\mathbf{sr}[i,j]$ (Eq 7), and the two representative models, i.e, the binary span classification model (**BinarySpan**) and the biaffine rule model (**BiaffineRule**). We investigate appropriate representations for different models on the English dev dataset. Table 2 shows the effects of different span representation methods, where $\mathbf{v}[i,j]$ is better for `BinarySpan` and $\mathbf{sr}[i,j]$ is better for `BiaffineRule`. When using $\mathbf{sr}[i,j]$ for `BinarySpan`, the performance drops greatly ($92.17 \rightarrow 91.80$). Similar observations can be found when replacing $\mathbf{sr}[i,j]$ with $\mathbf{v}[i,j]$ for `BiaffineRule`. Therefore, we use $\mathbf{v}[i,j]$ for the span models and $\mathbf{sr}[i,j]$ for the rule models in latter experiments.

Table 3 shows the main results on the English and Chinese dev sets. For English, `BinarySpan` acheives 92.17 LF score. The multi-class span classifier (**MultiSpan**) is much better than `BinarySpan` due to the awareness of label information. Similar phenomenon can be observed on the Chinese dataset. We also test the linear rule (**LinearRule**) methods. For English, `LinearRule` obtains 92.03 LF score, which is much worse than `BiaffineRule`. In general, the performances of `BiaffineRule` and `MultiSpan` are quite close both for English and Chinese.

For `MultiSpan`, both the first stage (unlabeled tree prediction) and the second stage (label generation) exploit constituent types. We design three development experiments to answer what the accuracy would be like of the predicted labels of the first stage were directly used in the second stage. The first one doesn't include the label probabilities of the first stage for the second stage. For the second experiment, we directly use the model output from the first setting for decoding, summing up the label classification probabilities of the first stage and the label generation probabilities of the second stage in order to make label decisions. For the third setting, we do the sum-up of label probabilities for the second stage both during training and decoding. These settings give LF scores of 92.44, 92.49 and 92.44, respectively, which are very similar. We choose the first one due to its simplicity.

3.3 Main Results

English. Table 4 summarizes the performances of various constituent parsers on PTB test set. `BinarySpan` achieves 92.1 LF score, outperforming the neural CKY parsing models (Durrett and Klein, 2015) and the top-down neural parser (Stern et al., 2017). `MultiSpan` and `BiaffineRule` obtain similar performances. Both are better than `BianrySpan`. `MultiSpan` obtains 92.4 LF score, which is very close to the state-of-the-art result when no external parses are included. An interesting observation is that the model of Stern et al. (2017) show higher LP score than our models (93.2 v.s 92.6), while our model gives better LR scores (90.4 v.s. 93.2). This potentially suggests that the global constraints such as structured label loss used in (Stern et al., 2017) helps make careful decisions. Our local models are likely to gain a better balance between bold guesses and accurate scoring of constituent spans. Table 7 shows the unlabeled parsing accuracies on PTB test set. `MultiSpan` performs the best, showing 92.50 UF score. When the unlabeled parser is 100% correct, `BiaffineRule` are better than the other two, producing an oracle LF score of 97.12%, which shows the robustness of our label generator. The decoding speeds of `BinarySpan` and `MutliSpan` are similar, reaching about 21 sentences per second. `BiaffineRule` is much slower than the span models.

Chinese. Table 5 shows the parsing performance on CTB 5.1 test set. Under the same settings, all the three models outperform the state-of-the-art neural model (Dyer et al., 2016; Liu and Zhang, 2017a).

Liu and Zhang (2017a)			86.1	**BiaffineRule**	87.1	87.5	**87.3**

Table 5: Results on the Chinese Treebank 5.1 test set.

Compared with the in-order transition-based parser, our best model improves the labeled F1 score by 1.2 (86.1 $\rightarrow$ 87.3). In addition, `MultiSpan` and `BiaffineRule` achieve better performance than the reranking system using recurrent neural network grammars (Dyer et al., 2016) and methods that do joint POS tagging and parsing (Wang and Xue, 2014; Wang et al., 2015).

4 Analysis

Constituent label. Table 6 shows the LF scores for eight major constituent labels on PTB test set. `BinarySpan` consistently underperforms to the other two models. The error distribution of `MultiSpan` and `BiaffineRule` are different. For constituent labels including SBAR, WHNP and QP, `BiaffineRule` is the winner. This is likely because the partition point distribution of these labels are less trivial than other labels. For NP, PP, ADVP and ADJP, `MultiSpan` obtains better scores than `BiaffineRule`, showing the importance of the explicit type information for correctly identifying these labels. In addition, the three models give similar performances of VP and S, indicating that simple local classifiers might be sufficient enough for these two labels.

LF v.s. Length. Figure 3 and Figure 4 show the LF score distributions against sentence length and span length on the PTB test set, respectively. We also include the output of the previous state-of-the-art top-down neural parser (Stern et al., 2017) and the reranking results of transition-based neural generative parser (RNNG) (Dyer et al., 2016), which represents models that can access more global information. For sentence length, the overall trends of the five models are similar. The LF score decreases as the length increases, but there is no salient difference in the downing rate (also true for span length $\leq$6), demonstrating our local models can alleviate the label bias problem. `BiaffineRule` outperforms the other three models (except RNNG) when the sentence length less than 30 or the span length less than 4. This suggests that when the length is short, the rule model can easily recognize the partition point. When the sentence length greater than 30 or the span length greater than 10, `MultiSpan` becomes the best option (except RNNG), showing that for long spans, the constituent label information are useful.

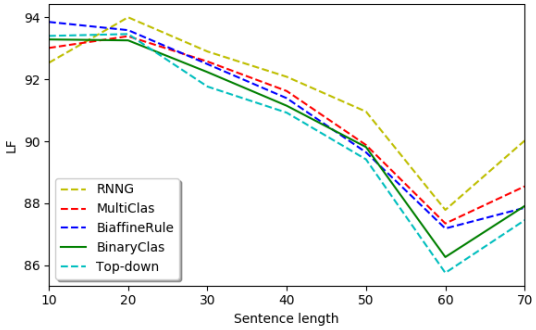

Figure 3: Sentence length v.s LF scores.

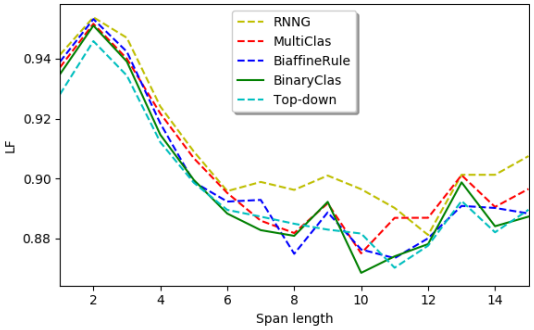

Figure 4: Span length v.s LF scores.

Model	NP	VP	S	PP	SBAR	ADVP	ADJP	WHNP	QP
BinarySpan	93.35	93.26	92.55	89.58	88.59	85.85	76.86	95.87	89.57
MultiSpan	**93.61**	93.41	92.76	**89.96**	89.16	**86.39**	**78.21**	95.98	89.51
BiaffineRule	93.53	**93.46**	**92.78**	89.30	**89.56**	85.89	77.47	**96.66**	**90.31**

Table 6: LF scores for major constituent labels.

Model	UF	LF	Speed(sents/s)
BinarySpan	92.16	96.79	22.12
MultiSpan	92.50	97.03	21.55
BiaffineRule	92.22	97.12	6.00

5 Related Work

Globally trained discriminative models have given highly competitive accuracies on graph-based constituent parsing. The key is to explicitly consider connections between output substructures in order to avoid label bias. State-of-the-art statistical methods use a single model to score a feature representation for all phrase-structure rules in a parse tree (Taskar et al., 2004; Finkel et al., 2008; Carreras et al., 2008). More sophisticated features that span over more than one rule have been used for reranking (Huang, 2008b). Durrett and Klein (2015) used neural networks to augment manual indicator features for CRF parsing. Structured learning has been used for transition-based constituent parsing also (Sagae and Lavie, 2005; Zhang and Clark, 2009; Zhang and Clark, 2011; Zhu et al., 2013), and neural network models have been used to substitute indicator features for transition-based parsing (Watanabe and Sumita, 2015; Dyer et al., 2016; Goldberg et al., 2014; Kiperwasser and Goldberg, 2016; Cross and Huang, 2016a; Coavoux and Crabbé, 2016; Shi et al., 2017).

Compared to the above methods on constituent parsing, our method does not use global structured learning, but instead learns local constituent patterns, relying on a bi-directional LSTM encoder for capturing non-local structural relations in the input. Our work is inspired by the biaffine dependency parser of Dozat and Manning (2016). Similar to our work, Stern et al. (2017) show that a model that bi-partitions spans locally can give high accuracies under a highly-supervised setting. Compared to their model, we build direct local span classification and CFG rule classification models instead of using span labeling and splitting features to learn a margin-based objective. Our results are better although our models are simple. In addition, they collapse unary chains as fixed patterns while we handle them with an encoder-decoder model.

6 Conclusion

We investigated two locally trained span-level constituent parsers using BiLSTM encoders, demonstrating empirically the strength of the local models on learning syntactic structures. On standard evaluation, our models give the best results among existing neural constituent parsers without external parses.

RNN Simulations of Grammaticality Judgments on Long-distance Dependencies

Shammur Absar Chowdhury and Roberto Zamparelli
CIMeC: Center for Mind/Brain Sciences
University of Trento
{shammur.chowdhury, roberto.zamparelli}@unitn.it

Abstract

The paper explores the ability of LSTM networks trained on a language modeling task to detect linguistic structures which are ungrammatical due to extraction violations (extra arguments and subject-relative clause island violations), and considers its implications for the debate on language innatism. The results show that the current RNN model can correctly classify (un)grammatical sentences, in certain conditions, but it is sensitive to linguistic processing factors and probably ultimately unable to induce a more abstract notion of grammaticality, at least in the domain we tested.

Title and Abstract in Italian

RNN Simulazioni di giudizi di grammaticità sulle dipendenze a distanza

L'articolo studia la capacità delle reti neurali LSTM addestrate su un compito di modellazione linguistica di rilevare strutture linguistiche che sono agrammaticali a causa di violazioni nella estrazione di argomenti (dovute alla presenza di argomenti di troppo, o alla presenza di isole del soggetto e delle frasi relative), esplorando le implicazioni per il dibattito sull'innatismo linguistico. I risultati mostrano che l'attuale modello RNN può classificare correttamente frasi grammaticali, in certe condizioni, ma è eccessivamente sensibile a fattori di elaborazione linguistica e probabilmente non in grado di indurre una nozione più astratta di grammaticalità, almeno nel dominio da noi testato.

1 Introduction

Native speaker intuitions about the meaning and grammaticality of linguistic expressions have been the key methodology in theoretical linguistics since at least Chomsky (1957), and are widely seen as a crucial window on the internalized linguistic competence which theoretical linguistics aims to study. Despite lively discussions on the limits of the methodology (see Cowart, 1997; Sprouse and Almeida, 2012; Sprouse *et al.*, 2013, 2016), the availability of very large corpora has not replaced in linguistics the need for judgments on artificially constructed cases whenever theoretical points hinge on the status of very rare or complex constructions, concern languages or dialects for which large corpora do not exist, or involve semantic intuitions that have no easily detectable correlates in corpora (e.g. semantic scope alternations).

Due to its scarce practical applications, modeling grammaticality judgments with computers has never been a typical NLP task, but it can be an important testbed for theories of language processing and grammatical competence. In particular, judgments on syntactic well-formedness require a sensitivity to long-distance structural cues which is a crucial aspect of language competence (Everaert *et al.*, 2015). Elman's (1991) pioneering work on the application of simple recurrent neural network (RNN, Elman 1990) to linguistic sequences showed that such networks could indeed learn some linguistic structures, but had a tendency to forget important linguistic features (e.g. the presence of a Wh-element) as new

Proceedings of the 27th International Conference on Computational Linguistics, pages 133–144
Santa Fe, New Mexico, USA, August 20-26, 2018.

material arrived. However, more recent network architectures, like Long-Short Term Memory Network (LSTMs, Hochreiter and Schmidhuber 1997) or Gated Recurrent Networks (GRU, Chung *et al.* 2014) incorporate memory-management systems which yield much better performances. The seminal work of Linzen *et al.* (2016) and other recent papers (Bernardy and Lappin, 2017; Gulordava *et al.*, 2018) have shown these networks to be capable, in certain conditions, to approximate human levels in a subject-verb number agreement task, even across intervening nouns and verb (e.g. *The boy**s** [that the girl has seen] **are/*is**...*).

These advances raise the question whether similar models, trained on corpora of naturally occurring sentences, could come to approximate the full range of human grammaticality judgments, including judgments on structures which, unlike agreement, are virtually non-existent in the training input. The ability to do so would have implications for the debate on language innatism (Christiansen and Kirby, 2003; Sprouse *et al.*, 2013): a generalist (R)NN has no language-specific learning skills, no innate linguistic parameters to set (Chomsky and Lasnik, 1993; Baker, 2001); if such a device could manage to replicate fine-grained human intuitions inducing them from the raw training input this would be evidence that exposure to language structures (albeit in an amount orders of magnitude larger than the one a child receives, and without a connection to the non-linguistic context of utterance) should in principle be sufficient to derive a syntactic competence, against the innatist hypothesis. Suppose on the other hand that NNs could approximate human intuitions on some linguistic phenomena but not on others, despite similar statistical distributions in the training input: this would now count as strong evidence that the 'unlearnable' phenomena tap on aspects of the grammar faculty that have limited representations in normal language samples, and are good candidates for being innate.

This paper is a step in the direction of this research program. We trained two types of RNNs (GRU and LSTM) on a large corpus of English (Wikipedia and parts of UKWAC, Ferraresi *et al.* 2008), then tested their performances or a range of artificially constructed language structures, contrasting grammatical and ungrammatical examples. Unlike Lau *et al.* (2017), who use LSTM to prove that they can learn the *graded* nature of human grammaticality, we only look at long distance dependencies (the relation between a dislocated element like a Wh-nominal or the head of a relative clause and its gap). As a preliminary task (Task A), we check whether the network is sensitive to the difference in processing complexity between subject and object relatives, a much-studied domain in the psycholinguistic literature; next, we turn to two cases of ungrammaticality, one due to a violation of the principle of Full Interpretation (Chomsky, 1986a, p.98-99) (Task B), one to extraction out of "strong" syntactic islands (Ross, 1982), specifically, subject and relative clause islands (Task C). Violations of these types have been regarded as sharp both in the theoretical (Szabolcsi and den Dikken, 1999) and the experimental literature (Sorace and Keller, 2005; Cowart, 1997; Sprouse *et al.*, 2013).

Our preliminary conclusions are that while the models are able to catch a surprising range of subtle differences in Task A and to correctly classify grammatical and ungrammatical cases in Task B, their performances are highly sensitive to processing factors (esp. sentence length, sentence complexity), a fact which becomes particularly evident in Task C. Two possible conclusions can be drawn: either the NN has troubles disentangling processing and grammaticality, or the most obvious ways for detecting this distinction are not effective for this target.

In the following sections, we first present a brief overview of the methodology used in this study (Section 2), followed by the a detailed task description in Section 3. The results and observation of the network behavior is presented in Section 4; we conclude the study and discuss future directions in Section 5.

2 Methodology

The use of RNN for the evaluation of grammaticality can already be found in Tomida and Utsumi (2013) (a reply to a non-NN learning model in Pearl and Sprouse 2013). However, their RNN (a Jordan RNN, Jordan 1997) worked on abstract data (it was trained on preassigned constituent labels and had to generate other label sequences), a choice that in our opinion requires too many underlying assumptions. RNN trained on raw textual input are first found in Linzen *et al.* (2016), who achieve a very high score (<1%

error rate) in the subject-verb number agreement task. However, they specifically train an LSMN classifier on this task alone. This is fine as a demonstration that the input contains enough network-accessible information to make the correct choice, but it puts the network at an unfair advantage over humans, since giving explicit grammaticality judgment is a rather marginal and non-natural linguistic task (though we make use of *implicit* judgments when we decide if someone is a native speaker, we choose the best wording in a text, etc.). Moreover, it is a task which arguably plays no role in language acquisition. While there are of course immense quantitative and qualitative differences between the language learning process in humans and NNs, we believe that a comparison between their final states can still make sense, under two conditions: (i) that the comparison is not directly between humans and NN judgments, but rather between task-dependent judgment differences, i.e. minimal task-pairs which are very similar for the machine but very different for humans, or vice versa; (ii) that the NN has **not** been specifically trained on this tasks. When Linzen et al. (2016) trained their LSTM on a general task (language modeling: predicting the following word, arguably a more natural task, see van Berkum 2010) and tried to use the resulting network for the judgment task, the error rate increased to around 7% error rate. More recently, a group including Linzen himself (Gulordava *et al.*, 2018) has shown that, with better tuning, a different LSTM trained on a language modeling task is in fact capable of performances comparable to those of the classifier in Linzen *et al.* (2016), even in the absence of any semantic information (a potential confound in Linzen *et al.* 2016).

Assessing grammaticality judgments in a task which is not binary like number agreement raises important methodological questions. We want the network to discriminate between (1a) and (1b). The acceptable Wh-question in (1a) might end with a question mark right at the gap (the object position of *catch*), but also continue with an adverbial, or even (at the coast of decreasing acceptability) a nominal containing a gap (*the tail of*). The ungrammatical case (1b) ends with a normal verb argument (*the tail*).

(1) a. Which mouse did the cat catch {? / last night ? / the tail of ? }
b. *Which mouse did the cat catch the tail?

The question is which NN measure best corresponds to the speaker's perception of ungrammaticality in (1b), keeping into account that even in the theoretical and psycholinguistic literature there are no established metrics to measure 'degrees of ungrammaticality' (see Cowart 1997; Sorace and Keller 2005 for discussion).

2.1 Evaluation Measures

We explored various possibilities, from *global* measures like *perplexity* (PPL) and non-normalized sentence cross-entropy loss (CEL), to *local* measures like the normalized log probability of a full stop $LogP_n(FS)$ or question mark $LogP_n(QM)$ after the current word.

Cross-entropy loss (CEL) measures the distance between the output distribution predicted by the model and one-hot vector representing the target word (t_i). The loss for the test sentence can therefore be described as an approximation of the equation $CEL = \sum_{i=1}^{n} \ln P(t_i)$, where $P(t_i)$ is the probability given by the model to the i^{th} target word in the sentence of length n. In our analysis, we mostly use the averaged CEL (ACEL) while comparing each particular set of cases. Note that (A)CEL is not normalized by sentence length. Perplexity measures how many equally probable words can follow a point in the text; as the sentence grows longer and more information accumulates, the options for the following word decrease. Perplexity is calculated by $PPL = e^{-\frac{TCEL}{N}}$, where the total cross-entropy loss ($TCEL = \sum CEL$) is computed for the sub-dataset and the total number of words, N, in the corresponding dataset. Both measures are based on the intuition that an ungrammatical sentence should 'confuse' the NN more than a corresponding grammatical one, and that this confusion will translate in a decreased ability to make correct predictions.

As for the local measure, normalized log probability of the full stop and question mark is calculated as $LogP_n(QM/FS) = log(\frac{p_m(\Im)}{p_u(\Im)})$ where $p_m(\Im)$ is the probability of the symbol, $\Im$, at a given position given by the model; $p_u(\Im)$ is the unigram probability of the $\Im$.

As it turns out, neither PPL or CEL are perfect ways to evaluate a language model for ungrammatical-

ity, since they do not locate it at a specific point in the sentences. Yet, this could also be an advantage, since global measures like PPL/CEL can potentially catch parsing problems that arise earlier than expected, and record a perturbation in the NN's later predictions as it recovers from an ungrammatical point earlier in the text. Therefore, these methods seem appropriate for a first exploration of this task.

On the other hand, the advantage of the local measure used in this study (P(FS/QM), i.e. the confidence that the sentence is about to end) is that it can give precise information about the point at which ungrammaticality is detected (e.g. after *catch* in (1)), or can be used to track the NN expectations through time, as we do in Figure 1. The disadvantage is that, as example (1a) shows, a sentence can always continue in unexpected ways. Moreover, in some cases of ungrammaticality the presence of individual words might not be a significant predictor.

2.2 RNN Architecture

In order to simulate an "unbiased learner" that tries to model human grammatical intuitions, inducing them from the raw training input, we designed a RNN-based language model. A language model is often defined as a model learning the conditional probability over words, given a historical context. The model includes a vocabulary V of size $|V|$; when learning a training sentence, each word is represented by a one-hot encoding vector, $x \in \mathbb{R}^{|V|}$, with a corresponding index in V.

For this study we used two successful variant of simple RNN – long-short term memory (LSTM) and gated recurrent unit (GRU) models. GRU is basically an LSTM without the output gate; the content of the memory cell is copied into the network at each time steps. We trained the models varying the number of hidden units (u=$\{$100, 1500$\}$). For our datasets we observed that the un-tuned LSTM (u=100) performed slightly better than the GRU architecture with same parameters. Though it is possible that with better tuning the GRU could outperform LSTM, for the purpose of this study we present data from just the LSTM model tuned only for number of hidden units $u = 1500$, $layer = 2$ and embedding dimension, $e = 256$. To avoid over-fitting the model on the training data we also applied dropout — a regularization technique — in different layers. For training the model, we used a PyTorch RNN implementation with an SGD optimizer. We have not tuned the models for different dropout or learning rate parameters, and we used a fixed batch size of 80.

To train the RNN model we used an English corpus extracted from Wikipedia plus a small subset of UKWaC ($\approx$ 0.32% of the training data), crawled from *.uk* domain. For the Wikipedia data, we downloaded the WikiText-103 raw data containing the original case, punctuation and numbers. We then tokenized both datasets, removing urls, email addresses, emoticons and text enclosed in any form of brackets ({.},(.), [.]). We replaced rare words (tokens with frequency $\leq$10) with *<unk>* token along with its signatures (e.g. *-ed, -ing, -ly* etc.) to represent every possible out-of-vocabulary (OOV) words. We also replaced numbers (exponential, comma separated etc) with a *<NUM>* tag. After these preprocessing steps, our training data consisted of $\approx 136M$ words, with a vocabulary of size $|V| = 0.1M$. It is to be noted that the style of the texts selected to train the language model is mostly encyclopedic, due to the prevalence of Wikipedia over other web corpus data. This is of course not representative of the typical registers of English language, but it does give us a good proportion of complex embedded sentences, which match some of the deeply embedded constructions present in the task set. Recall, moreover, that the measures in this study are always relative, i.e. they contrast minimally different inputs within the same language model. Thus, any imbalance in the training data should not be expected to make a large difference in the global results.

3 Task Description

In order to filter out the effect of words which could affect the network performance in ways orthogonal to the structures at issue, we opted to increase the number of sentences to evaluate by building them as *sentence schemata*, (e.g. (2) for the subject relative Task A), which were expanded automatically to generate all the possible ways of picking one of the expressions within {}. Note that some of the variable were experimental conditions (e.g. the presence of *that* or *who* in (2)), others were added just to increase variety at the level of the content lexicon, so as to minimize possible effects of collocations or sentences

the network might have encountered in the training phase. The results we present are averaged across all the sentences that express the same experimental condition.

(2) { The / A / Every / Some } { student / man / professor / driver } { that / who } had { seen / spoken with / interviewed / mentioned / approached / met / lived with }{ her / Mary / the woman } gave a brief speech.

The phenomena[1] we tested are the following:

A. SUBJECT VS. OBJECT RELATIVE CLAUSES: Much psycholinguistic literature since Gibson (1998); Gordon *et al.* (2001) has shown that object relatives such as (3a) are harder to parse than subject relatives (3b) (in terms of time, accuracy, etc.), and that the presence of certain material intervening between the head (*boy*) and the gap (indicate with an underscore) can affect reaction times (Gordon *et al.*, 2002, 2004). While this is not a contrast in grammaticality (both structures are clearly acceptable for adults, Adani *et al.* 2010), we designed this preliminary task to check if the network was sensitive to the position of the gap and to the type of intervening subject: a pronoun, a proper name or a full noun phrase. According to Rizzi's Featural Relativized Minimality (Friedmann *et al.*, 2009; Adani *et al.*, 2010), an intervener with many grammatical features in common with the moved element can make the extraction harder, or even ungrammatical (see esp. Villata *et al.* 2016 for the case of 'weak islands').

(3) a. The boy that Mary has invited __ *object extraction*
b. The boy that __ invited Mary *subject extraction*

A second variable was the relative pronoun, which could be *that*, *who* or null (in object relatives: *The girl Anna saw*). This test set comprised 1680 expanded sentences.

B. WH EXTRACTIONS: A second test set involves cases of Wh-extraction where the gap position could be empty (4a) or filled by an overt element (4b) (a personal pronoun, an indefinite pronoun, a demonstrative NP).

(4) a. Which candidate/issue should the students discuss ?
b. *Which candidate/issue should the students discuss {him / it / something else / this candidate / this issue}

(4b) is a very strong semantic/syntactic violation, since either the Wh or the final nominal cannot be connected to the verb, violating the principle of Full Interpretation (Chomsky, 1986b). However, certain uses of pronouns are standardly treated as bound variables in formal semantics (and there are languages, e.g. Hebrew or Welsh, which use so-called *resumptive* pronouns in place of gaps at least in relative clauses), so we expected that filling the gap with pronouns might be better than filling it with full noun phrases. If the NN is able to carry over semantic information from the Wh-phrase to the gap position, we also expected that gap-fillers that match in animacy (*which candidate . . . him/this candidate*) should be better than non matching cases (*which issue . . . him/this candidate*). The sentences were generated at 0, 1 or 2 levels of embedding (e.g. *Who did John claim [that the professor assumed [that the students should discuss (it)]]?* is level 2), to see if distance makes the network 'forget' the Wh or its features.

All the Wh cases above were contrasted with corresponding affirmative sentences. In this case, however, the gap is the ungrammatical case (5a), while the gap fillers we see in (5b) all yield grammatical sentences. The pre-gap verbs, *discuss, mention, describe, write about, worry about, address, promote, consider* were chosen not to easily allow intransitive counterparts.

(5) a. *The student should consider .

[1]The expanded test sets for each task can be found in
https://github.com/LiCo-TREiL/Computational-Ungrammaticality.

b. The student should consider {him / it / something else / this candidate / this issue}

This allows us to directly compare the interrogative and affirmative case. What makes this task particularly interesting is the fact that, locally, the beginning and the end of each sentence is perfectly grammatical; they become strongly ungrammatical only when seen together, possibly at a distance which is rarely (if ever) attested in corpora. When fully expanded, this test set contains 72720 sentences.

C. SUBJECT AND RELATIVE ISLAND VIOLATIONS: While the previous test measures the ability of the network to carry information from the Wh phrase across the whole sentence, the last test set pitches them against the phenomenon of *syntactic islands* (Ross, 1967). Descriptively, a *subject island* blocks a dependency whose gap is *inside* (hence the tag 'subextraction') a nominal subject (6a), as opposed to a nominal object (6b); a *relative clause island* bars gaps inside relatives (7). Note that (7b) combines the two types of islands, and should be worse if the effect of multiple violations is cumulative.

(6) a. *Who did [a classmate of __] ruin John ?
b. ?Who did John see of [a classmate of __]?

(7) a. *Which girl did John see [the person that dated __]?
b. **Which girl did [the person that dated __] see John ?

Despite decades of research, there is no established functional explanations why islands exist (though see Szabolcsi and Zwarts 1990; Sprouse *et al.* 2012 for some approaches). Thus, they represent a good starting point to verify the limits of NN performance. In this case, we provided Y/N question and affirmative counterparts for each of the Wh-interrogatives, as a point of reference.

4 Results and Discussion

Task A. Subject vs. Object Relative Clauses: Tables 1-2 contains the results of the Subject *vs.* Object Relative Task. As it can be observed, the network is better (both in terms of PPL and CEL) at dealing with subject than object relatives, thus indicating a sensitivity for the position of the gap which corresponds to the preference found in humans, and especially children (Adani *et al.*, 2010). Moreover, the network loss (Avg. CEL) improves (i.e. it is lower) when the other nominal inside the RC is a pronoun (recall that in *object* relatives the non-gapped nominal intervenes between the Wh-element and the gap): the pronoun improves by ≈ 2.83 over (proper name) PN and ≈ 2.94 over the (noun phrase) NP in subject RC, by ≈ 5.55 and ≈ 5.93 respectively in object relative; there is no significant difference in loss between PNs and full NPs. The fact that the pronoun effect is larger in subject position is particularly noteworthy. It could be due to the greater frequency of pronouns in subject than object position reported in Gordon *et al.* (2001), but this tendency is also in line with the Featural Relativized Minimality approach of Friedmann *et al.* (2009); Villata *et al.* (2016): in object RC the RC-internal nominal intervenes between the relative head and its gap; the more features the head and the nominal have in common, the more the connection between head and gap is disrupted; pronouns have fewer features in common with the relative head (*boy* in (3)) than other nominals (e.g. no +N(oun)), so they interfere less.

With respect to relative pronoun type, Table 2 shows a significant preference for *that* over *who* in Subject RC, and a preference for null relative pronouns over overt ones in object RC (i.e. *the boy Mary saw* > *the boy that/who Mary saw*, ">" = easier for the NN), in terms of ACEL. This seems in line with corpus frequencies measured on UKWAC01, where **Det NP** *that* is about 4 times more frequent than **Det NP** *who*.

Cases	**PPL**	**ACEL** ($\pm std$)	**#**
Subj-relatives	84.52	55.99 ($\pm$3.60)	672
Obj-relatives	105.59	57.25 ($\pm$4.23)	1008

Table 1: Task A Results: Subject vs. Object RC. # represents the number of instances in that sub-data

Nom-Rel	Subj-R	Obj-R	Rel-Pronoun	Subj-R	Obj-R
	ACEL	*ACEL*		*ACEL*	*ACEL*
pronoun	54.07	53.42	*that*	57.7	57.4
proper name	56.9	58.97	*who*	54.28	58.25
full Noun Phrase	57.01	59.35	*no Rel Pron.*	–	56.09

Table 2: Task A Results: Nom-Rel represents Nominal inside Relative clause and Rel-Pronoun represents Relative Pronouns.

Task B. Wh extractions and FI violations: To analyze the Task B dataset we initially divided it into four cases: [WH. . . GAP], [AFF(ERMATIVE). . . NOGAP] (both grammatical) and [WH. . . NOGAP], [AFF. . . GAP] (both ungrammatical). We studied the overall network perplexity (PPL) and the ACEL loss for the sentence given by the NN. We observed that the PPL is 106.10 overall for the grammatical sets, 151.57 for the ungrammatical ones. When we keep Wh and affirmative cases apart, [AFF. . . NOGAP] have PPL = 67.72 (calculated over 11640 instances), which is as expected lower than [AFF. . . GAP], PPL = 76.63 (calculated over 2940 instances). However, the perplexity given by grammatical [WH...GAP] (163.16, with 11616 instances) is higher than that of the ungrammatical [WH...NOGAP]-sentences (PPL = 156.42, 46560 instances).

Options to Select from	CEL	Comments
O1: What should Mary discuss? *Gramm.*	**29.14**	
O2: What should Mary discuss it?	32.79	
O3: What should Mary discuss him?	34.32	CEL(O1) <CEL(O2-6)
O4: What should Mary discuss something else?	39.63	Correct if O1 is chosen
O5: What should Mary discuss this topic?	40.22	
O6: What should Mary discuss this candidate?	42.37	
O1: The professor has said that Mary should consider. *UnGramm.*	**48.40**	
O2: The professor has said that Mary should consider it.	49.15	CEL(O1) <CEL(O2-5)
O3: The professor has said that Mary should consider something else.	55.53	Correct if any of O2-O5
O4: The professor has said that Mary should consider this topic.	56.87	is chosen
O5: The professor has said that Mary should consider this candidate.	58.40	

Table 3: Example of Gramm. vs UnGramm. classification task by RNN using ACEL as a measure. Lower values are better.

To explore this further, we designed a simple classification task where each sentence was presented with 5 or 6 possible alternatives in the gap position, as shown in Table 3. The NN's choice was correct if the CEL for the correct option was the lowest. The experiment included a total of 14520 instances containing Wh and affirmative sentences and had an accuracy of 91.45%, indicating that the RNN network is largely able to pick the correct option for Wh (99.1% out of 11616 instances) and for Aff (60.7% out of 2904 instances). The very different margins of the two effects, which probably account for the WH/AFF PPL difference above, are actually not unexpected, as it is probably easier to accommodate the existence of an intransitive version of a transitive verb than to explain away an extra argument.

Since all the sentences in Task B could potentially end at the (filled) gap, we decided to investigate the effect of sentence type on the network's perception that the sentence is about to end. Figure 1 tracks the NN expectation that the following word is going to be a full stop (P(FS)), or a question mark (P(QM)). The results are intriguing: in general, an end-of-sentence (EOS) is least expected after an auxiliary or modal; in affirmatives "." is unlikely after the final verb, very likely after the object. Interestingly, the possibility of a question mark (i.e. a question marked by intonation alone) is always present in affirmatives. Wh-sentences are dominated by the expectation of a gap (whose proxy is "?"), peaking at the first verb and decreasing slowly. The unexpected arrival of the object seems to convince the NN that the sentence is after all not a direct interrogative ("." higher than "?").

Turning to an analysis of the impact of each filled overt element in the Wh-extraction dataset, Table 3 shows that when the gap is filled by a personal pronoun (Pro, e.g. *it, him*), the overall PPL, of such set, is much better than when the gap filled by an indefinite pronoun (IndPro, *something else*) or a demonstrative NP (a 10 point difference). A similar pattern obtains with ACEL: Pro $>$ IndPro $>$ DemNP. The ability of the NN to track semantic information (specifically, animacy) from the Wh to the gap (i.e. *which candidate . . . this candidate* and *which issue . . . this topic*) was also confirmed: the global PPL of the cases with a match in animacy is lower ($PPL = 220.05$) than the unmatched cases ($PPL = 223.89$),

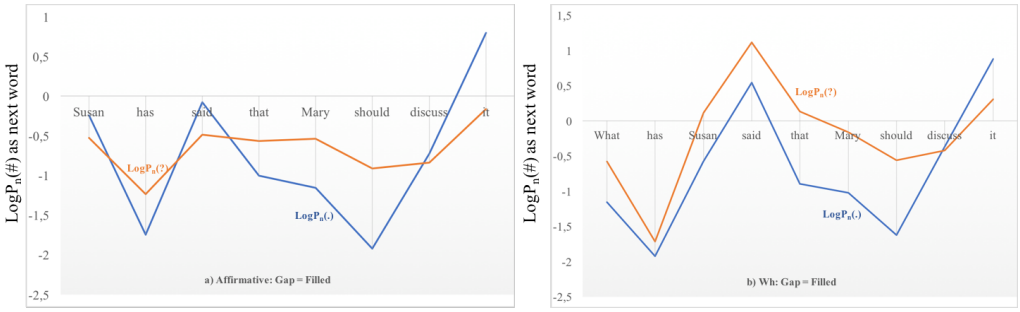

Figure 1: The EOS expectations for different types of sentences. Log Probability that the next word is a "?" (red) or a "." (blue), according to the LSTM model. The sentence is an example for the whole category.

but by only 3 points; once again, a similar pattern with a minor difference of 0.31 obtains using average CEL.

In Figure 2, we presents the effect of different levels of embedding between the wh-element and the gap position in cases where the gap is filled (Ungrammatical cases) or empty (Grammatical). Our findings suggests that in all our scenarios (grammatical and ungrammatical, Wh and affirmatives) an increase in the level of embedding increases the average CEL very significantly. A similar pattern is observed with affirmative sentences.

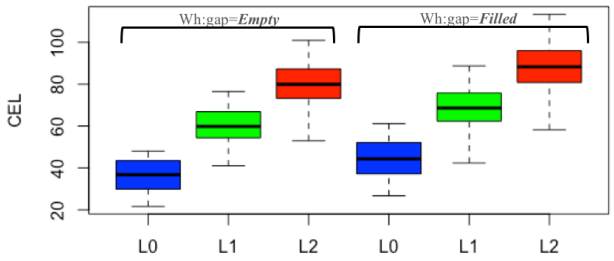

Figure 2: Variation of CEL for different level of embedding; Wh cases with gap empty or filled.

Task C. Subject and Relative Island Violations: So far we have seen that the RNN model was able to distinguish grammatical from ungrammatical pairs with some success, but also to capture a number of interesting effect from the psycholinguistic literature: in Task A, the preference for subject relatives and the effect of intervening pronouns vs. full DPs (see Table 2); in Task B, the almost acceptability of Wh-resumptive pronouns vs. indefinites vs. the fully ungrammatical demonstrative fillers (Table 3), the matching animacy, and the shifting preferences for full stops or question marks (Figure 1). However, in many of these cases the margin of success was small with respective to others; for instance, only 3 ACEL points divide *What should Mary discuss* from *What should Mary discuss it*, but the ACEL distance between e.g. *What should Mary discuss* and *What has she said that Mary should discuss* is over 20 ACEL points.

We now turn to see how the model performs on the typically syntactic Task C. The overall results for subject (S) and object (O) position are presented in Table 4. Since many of the gaps are non final we do not employ the local P(FS/QM) measure and only present the two global measures. At a first glance, the network seems to have been able to capture the facts with exactly the right progression: in the ACEL measure object subextractions are best, followed at an 8 ACEL point distance by subextractions from subjects, subject of passives, relatives in object position and relatives in subject position. The PPL facts are harder to fit, especially for the passive (NSp: 95.64). It should be noted, however, that NSp could be interpreted as a *parasitic gap* construction (Ross, 1967; Engdahl, 1985), which is normally judged fairly acceptable (*Who was a portrait of __ painted by __ ?*), plus a spurious *Tim* filling the second gap, as in Task B.

Has our model learned syntactic islands from Wikipedia? It would appear so, down to the fact that the

Cases		PPL	ACEL ($\pm std$)	#
OBJ NP extraction (NO):	*Who has Tim seen a portrait of __?*	95.87	43.50 ($\pm$8.32)	480
SUBJ NP extraction (NS):	*Who has a portrait of __ scared Tim?*	159.78	48.37 ($\pm$7.30)	480
SUBJ NP extr. from pass. (NSp):	*Who was a portrait of __ painted by Tim?*	95.64	49.75 ($\pm$5.95)	480
OBJ RC extraction (RO):	*Who has Tim seen a portrait that showed __ ?*	131.75	51.64 ($\pm$8.76)	768
SUBJ RC extraction (RS):	*Who has a portrait that showed __ scared Tim?*	181.87	56.11 ($\pm$6.90)	960

Table 4: Overall results of Task C: Subject and Relative Clause (RC) island violations, where overall PPL represents the perplexity on the sub-dataset, ACEL represents the average cross-entropy loss given by the network and # represents the number of instances in that sub-data set. The losses differ from each other significantly, p-value < 0.05.

Cases	Wh-interrogatives	Y/N interrogatives	Affirmatives	Ratio PPL	Ratio CEL
	ACEL	ACEL	ACEL	(Wh-/YN), (Wh-/Aff)	(Who/YN), (Who/Aff)
OBJ pos. extraction (NO)	**51.26**	**45.81**	**36.4**	(1.57, 2.78)	(1.12, 1.42)
SUBJ. pos. extraction (NS)	54.32	51.05	41.73	(1.27, 2.03)	(1.06, 1.30)
SUBJ. Pos. extr. + Passive (NSp)	53.51	51.92	45.08	(1.07, 2.01)	(1.03, 1.19)
OBJ. RC (RO)	59.11	54.35	43.95	(1.43, 2.46)	(1.09, 1.34)
SUBJ. RC (RS)	60.76	58.54	50.57	(1.12, 1.47)	(1.04, 1.20)

Table 5: Results of Task C: Subject and Relative Island Violations, divided in to *wh- interrogatives*; *Y/N interrogatives* and *affirmatives*. ACEL represents the average cross-entropy loss given by the network and #, the number of instances in that sub-data set. For ACEL the lower the value the better. The losses we obtain differ from each other significantly, p-value < 0.05.

last case, RS extraction, is the worst because, arguably, it is the sum of two distinct islands — relative and subject. However, a look at the performance of the model on a set of parallel cases shows that the interpretation of these facts should probably be quite different. Recall that for each Wh case, our Task C test set contains the corresponding Y/N and affirmative sentences (8):

(8) a. Who did John see the person that dated __?
b. Did John see the person that dated Mary?
c. John saw the person that dated Mary.

Table 5 shows the ACEL scores for all three types, as well as the ratio between the scores given to the sentence types. One remarkable aspect is that the Wh cases have a much higher (i.e. worse) score than the corresponding affirmative; even more remarkable, however, is the fact that Y/N questions are also very far from assertions, much closer in fact to their Wh counterparts. But Y/N questions have no Wh gap, hence no island effects. Equally remarkably, Y/N-questions and assertions follow a progression which is almost identical to the one of Wh-cases: NO>NS>NSp>RO>RS. This is quite visible from the ratios, which remain very stable under ACEL, and taper down slightly in PPL.

This data shows that the increased perplexity with Wh cases has nothing to do with island effects, or we would not find it in Yes/No questions and assertions. Our hypothesis is that it is rather the cumulative effect of increasing syntactic complexity, plus position. Suppose that an NP such as *a classmate of John* is more complex than *John*, *a classmate* and possibly *John's classmate*, thus potentially more ambiguous. Suppose further that relative clauses are even more complex/ambiguous. Ambiguity leads to uncertainty, so by increasing it we increase perplexity as well, yielding the difference between NO,NS>RO,RS.

This does not yet explain why NO>NS and RO>RS (recall that they are made of the same words, just in different orders). This, we hypothesize, is the effect of position. A complex structure at the beginning of a sentence (subject position) can be more damaging than one at the end (object position), probably since it can lead the intermediate network units into a "wrong" state of activation, which will be fed back to the RNN as the next word enters, generating additional perplexity. To test this hypothesis, we placed other types of complex nominals (NP conjunctions, NPs containing adjectival and PP modifiers in both subject ((9a), (9c)) and object position (e.g. (9b), (9d)) in Y/N-interrogatives and in the corresponding affirmative sentences. We observed that the PPL/ACEL for sentences with complex subjects was 154.79/73.01, vs. 99.70/66.64 with complex objects. The pattern was similar in Y/N-interrogatives

and affirmatives, and across the two different types of complex nominals.

(9) a. Did [the publisher, the journalist and their families] meet Mary?
b. Did Mary meet [the man, the woman and their families]?
c. Did [a well built, blond-haired man with a large, heavy backpack] meet Mary ?
d. Did Mary meet [a well built, blond-haired man with a large, heavy backpack]?

In addition, all things being equal, a Wh might generate additional perplexity, since it leads the model to expect a gap at multiple points (cf. Figure 1b). Putting these factors together, it is not strange that the RS case (relative complexity + subject position + Wh perplexity) might come out with the highest score.

5 Conclusions and future work

Our work builds on Linzen *et al.* (2016); Gulordava *et al.* (2018); Bernardy and Lappin (2017), but with a difference goal: the possibility for an RNN to learn to classify sentences by grammaticality, focusing on two specific long-distance effects: the presence of an extra argument (Task B) and the island effects in extraction (Task C). The results showed, first of all, that our NN model was good at capturing known effects in the processing of relatives (subject/object preferences, effect of interveners), and good at spotting the selective need for a final argument (Task B). The fact that the ungrammatical cases were graded, with pronouns next best after gaps (see Table 3) shows that the network wasn't just using the simple rule "If it starts with Wh*, pick the version with fewer words, if not, don't". On the other hand, the overwhelming effect of processing factors like the level of embedding (Figure 2), and the fact that the apparent success of the NN in the island task in not based on the island extraction effect itself cast doubts on the idea that the NN is using an abstract dimension of 'grammaticality'.

It could be tempting to take this as a cue that even human ungrammaticality should be reduced to processing (see Villata *et al.* 2016 for discussion in the domain of *weak islands*, which we did not test here), but there are reasons to believe that, while processing might play a role, it cannot be the whole story. As is well-known to anyone who has practiced a musical instrument, pronounced tongue-twisters or read centrally-embedded sentences, processing difficulties improve a lot with practice. However, multiple repetitions of *Who did John see Mary?* by humans are not likely to make it better.

The study raises several methodological issues, first and foremost in the choice of measures. Perplexity seems to be an obvious first choice for a language model, but even when it is normalized by the number of words in the sentence it is sensitive to contrasting effects: longer sentences are more predictable, but recursively embedded sentences are less. Moreover, complex structures increase perplexity more when they are at the beginning of a sentence than at the end (see our discussion of Task C results). In future work we plan to explore variations of these measures with different properties, and use *bidirectional* LSTMs to mitigate the latter effect. Local prediction tracking as in Figure 1, on the other hand, seems to be a promising, intuitive tool to see what the NN is "thinking" throughout a parse, but it is not always applicable. This is related to a final point. Grammaticality is typically judged relative to a (grammatical) point of comparison. Thus, *Who did a portrait that showed scared Tim?* is truly awful if judged as the RC+Subj extraction from *The portrait that showed **who** scared Bill?*, but what if the NN takes it as a variant of a structure such as *[(the person) who has a dress that (really) showed] scared Tim*? Humans can be given minimal pairs to make the difference clear. Learning how to do this with NN remains for future work. Only after these issues have been resolved and a performance plateau has been reached we will be in a position to go back to the original question: are (R)NN feasible models of innate-grammar-free language learners? Which abstract properties can they learn from the input?

Abstract

Modeling U.S. Congressional legislation and roll-call votes has received significant attention in previous literature. However, while legislators across 50 state governments and D.C. propose over 100,000 bills each year, and on average enact over 30% of them, state level analysis has received relatively less attention due in part to the difficulty in obtaining the necessary data. Since each state legislature is guided by their own procedures, politics and issues, however, it is difficult to qualitatively asses the factors that affect the likelihood of a legislative initiative succeeding. Herein, we present several methods for modeling the likelihood of a bill receiving floor action across all 50 states and D.C. We utilize the lexical content of over 1 million bills, along with contextual legislature and legislator derived features to build our predictive models, allowing a comparison of the factors that are important to the lawmaking process. Furthermore, we show that these signals hold complementary predictive power, together achieving an average improvement in accuracy of 18% over state specific baselines.

1 Introduction

Federal institutions in the U.S., like Congress and the Supreme Court, play a significant role in lawmaking, and in many observable ways define our legal system. Thus, as data and computational resources have become more readily available, political scientists have increasingly been adopting quantitative methods focused on understanding these entities and the role they play in our society (Katz et al., 2017; Poole and Rosenthal, 2007; Slapin and Proksch, 2008; Lauderdale and Clark, 2014).

Although many issues are legislated and regulated primarily at the federal level, state governments have significant power over certain areas. An increasing number of important issues are being decided at the state or local levels, especially in emerging industries and technologies, such as the gig economy and autonomous vehicles (Hedge, 1998). Moreover, there are 535 members of Congress who introduce over 10,000 pieces of legislation a session,[1] of which less than 5% is enacted. Similar dynamics exist at the state level, except on a much broader scale. There are over 7,000 state legislators, in aggregate introducing over 100,000 pieces of legislation, with over 30% being enacted. In order to be enacted, every bill must pass through one or more legislative committees and be considered on the chamber floor, a process we refer to as receiving floor action. This process is one of the most pivotal steps during lawmaking (Rosenthal, 1974; Hamm, 1980; Francis, 1989; Rakoff and Sarner, 1975), as on average, only 41% of bills receive floor action, with most legislation languishing in the committees.

Legislative policymaking decisions are extremely complex, and are influenced by a myriad of factors, ranging from the content of the legislation, to legislators' personal characteristics, such as profession, religion, and party and ideological affiliations, to their constituents' demographics, to governor agendas, to interest group activities, and to world events (Canfield-Davis et al., 2010; Hicks and Smith, 2009; Talbert and Potoski, 2002).

Despite this complexity, in this paper we present an approach to better understand state lawmaking dynamics and the legislative process by focusing on the task of predicting the likelihood that legislation

[1] A session is the period of time a legislative body is actively enacting legislation, usually one to two years.

Proceedings of the 27th International Conference on Computational Linguistics, pages 145–160
Santa Fe, New Mexico, USA, August 20-26, 2018.

will reach the floor in each state. As there are many dimensions underlying the content of the legislation, such as the policy area and ideology of the sponsor (Linder et al., 2018), that may affect the likelihood of floor action, in addition to text we examine several established contextual legislature and legislator derived features. To the best of our knowledge, this is the first work quantitatively modeling the floor action process across all 50 states and using the text of legislation alongside traditional contextual information.

2 Related Work

Much of the work analyzing the federal legislature is aimed at understanding legislator preferences through the use of voting patterns. One of the most popular techniques in political science is the application of spatial, or ideal point, models built from voting records (Poole and Rosenthal, 1985; Poole and Rosenthal, 2007), that is often used to represent unidimensional or multidimensional ideological stances (Clinton et al., 2004). However, there is also an increasing literature examining broader legislative dynamics, such as measuring legislative effectiveness (Harbridge, 2016), evaluating the impact of legislation on stock prices using legislators' constituents (Cohen et al., 2012), creating cosponsorship networks (Fowler, 2006), and examining the role of lobbying (Bertrand et al., 2018; Matthew et al., 2013),

In recent years a variety of primary and secondary textual legal data, such as legislation, floor debates, and committee transcripts, has become increasingly available, enabling the NLP community to create richer multidimensional ideal point estimation (Gerrish and Blei, 2011; Nguyen et al., 2015; Kornilova et al., 2018), and examine ideology detection from political speech (Iyyer et al., 2014), voting prediction from debates (Thomas et al., 2006), committee referral (Yano et al., 2012), and enactment (Nay, 2016).

While there is also an increasing amount of state legislative research, states have received significantly less attention (Hamm et al., 2014). One major reason for this is that quantitative methods require data, and the availability of data for Congress far exceeds that of states. In fact, Yano et al. (2012) noted "When we consider a larger goal of understanding legislative behavior across many legislative bodies (e.g., states in the U.S., other nations, or international bodies), the challenge of creating and maintaining such reliable, clean, and complete databases seems insurmountable." Thus, while there has been scholarship quantifying the role of committees, it has been limited in scope, to a few sessions or states, or reliant on survey data (Francis, 1989; Rakoff and Sarner, 1975; Rosenthal, 1974; Hamm, 1980). More recently, as different kinds of state data has become more accessible, it has enabled studying the affect of interest groups on legislative activity (Gray and Lowery, 1995), the application of spatial models (Shor et al., 2010; Shor and McCarty, 2011), and comparisons of textual similarity (Linder et al., 2018).

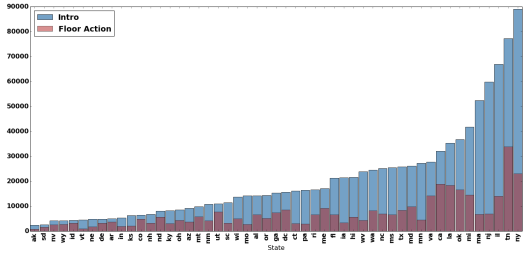
The contribution of this work is to continue building a broader understanding of state legislative dynamics by evaluating how predictable state lawmaking is, and what factors influence that process. We create a novel task, predicting the likelihood of legislation receiving floor action, and utilize a corpus of over 1 million bills to build computational models of all 50 states and D.C. We present several baseline models utilizing various features, and show that combining the legislative and legislator contextual information with the text content of bills consistently provides the best predictions. Our analysis considers various factors and their respective importance in the predictive models across the states, showing that although there are some consistent patterns, there are many variations and differences in what affects the likelihood in each state.

3 Data

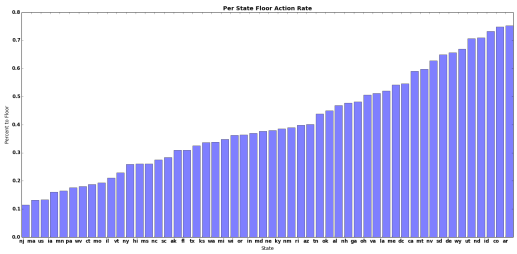
There is state-to-state variation in the legislative procedure of how a bill becomes law, but the path is largely similar. Legislation is introduced by one or more members of the legislature in their respective chamber,[2] and assigned to one or more standing subject committees.[3] Committees are made up of a subset of members of their respective chamber, and are chaired by the majority party. Once in committee,

[2] All legislatures are bicameral, with either a House or Assembly as the lower chamber, and the Senate as the upper chamber, except D.C. and Nebraska, which are unicameral.

[3] Depending on the state, other groups can introduce legislation, including legislative committees, legislative delegations, the governor, or non-elected individuals. For the purpose of this work we focus on legislator sponsored legislation.



(a) Number of bills introduced and receiving floor action for each state.



(b) Percent of bills reaching floor per state.

Figure 1: Dataset characteristics.

legislation is subject to debate and amendment only by the committee members, with the successful outcome being a favorable referral, or a recommendation, to be considered by the full chamber on the floor.

The primary data we use to model floor action was scraped directly from each state legislatures' website. For each state, we downloaded legislation, committee, and legislator pages for all sessions that were publicly accessible. Legislation pages were automatically parsed to determine legislative contextual metadata, which includes bill text versions, sponsors, committee assignments, and the timeline of actions. Legislator pages were parsed to obtain sponsor contextual metadata, which includes party affiliation, committee assignments, and committee roles.

As states demarcate legislative status in the timeline of actions differently, we automatically map and normalize all textual descriptions of legislative actions to a finite set of statuses.[4] These statuses are used to determine whether a piece of legislation survived committee and received a floor action, or consideration on the floor. All bills having a status of passed in their introductory chamber, or having had a recorded floor vote are treated as positive examples, while any status prior to passed is considered failed, including legislation that was reported out of committee but not considered on the floor.

Finally, since each state follows their own conventions with regard to classifying the type of legislation, we normalize all legislation across states to two types: resolutions and bills.[5]

Figure 1a shows the total number of bills introduced and receiving floor action for each state. In total, our dataset consists of 1.3 million pieces of state legislation, broken into 1 million bills, with 360k receiving floor action, at an average rate across states of 41%, and 275k resolutions, with 210k receiving floor action. On average, we have 10 legislative sessions of data per state.[6] As bills represent substantive legislation, with a much lower floor action rate, while resolutions are much more likely to receive floor action, for the rest of this paper we focus on bills only, and refer to bills and legislation interchangeably. We include 15 sessions of U.S federal legislation in our data for comparative purposes, with 23k of 172k bills receiving floor action.

Figure 1b presents the percent of bills receiving floor action. It is interesting to note the difference in difficulty for legislation to receive floor action in different states. For example, in New Jersey and Massachusetts, fewer than 15% of bills reach the floor, whereas 75% do in Colorado and Arkansas.[7]

4 Methods

4.1 Models

In order to not only be able to predict, but also examine the importance of features to our prediction, we chose three relatively interpretable models for our modeling framework. Formally, let our training

[4]The normalized statuses include introduced, assigned to committee, reported from committee, and passed.

[5]Resolutions are pieces of legislation of type appointment, resolution, joint resolution, concurrent resolution, joint memorial, memorial, proclamation, nomination. Bills are those of type bill, amendment, urgency, appropriation, tax levy, or constitutional amendment.

[6]Full data statistics are given in Table 7 in Appendix A.

[7]Our average across states, chambers, and sessions is in line with previous single state and session findings; in examining five states Rosenthal (1974) found between 34% and 73% of legislation did not survive committee.

data $(\boldsymbol{X}, \boldsymbol{Y})$ consist of n pairs $(\boldsymbol{x}_i, y_i)_{i=1}^n$ where, each $\boldsymbol{x}_i$ is a bill and y_i a binary indicator of whether $\boldsymbol{x}_i$ received floor action. Let $\mathbf{f}(\boldsymbol{x}_i)$ be a feature vector representation of $\boldsymbol{x}_i$, and $\mathbf{w}$ the parameter vector indicating the weight of each feature learned by the model.

The first two models are linear classifiers, where the prediction of floor action, $\hat{y}_i$, is given by $\texttt{sign}(\mathbf{w}^\top \mathbf{f}(\boldsymbol{x}))$. The first is a regularized conditional log-linear model $p_{\mathbf{w}}(y \mid \boldsymbol{x})$:

$$p_{\mathbf{w}}(y \mid \boldsymbol{x}) = \frac{\exp\left\{\mathbf{w}^\top \mathbf{f}(\boldsymbol{x})\right\}}{Z(\boldsymbol{x})} \tag{1}$$

where $Z(\boldsymbol{x})$ is the partition function given by $\sum_y \exp\left\{\mathbf{w}^\top \mathbf{f}(\boldsymbol{x})\right\}$. The model optimizes $\mathbf{w}$ according to

$$\min_{\mathbf{w}} \sum_{i}^{n} -\log p_{\mathbf{w}}(y_i \mid \boldsymbol{x}_i) + \lambda ||\mathbf{w}|| \tag{2}$$

The second model is NBSVM (Wang and Manning, 2012), an interpolation between multinomial Naive Bayes and a support vector machine, which optimizes $\mathbf{w}$ according to:

$$\min_{\mathbf{w}} C \sum_{i}^{n} \max(0, 1 - y_i(\mathbf{w}^\top(\mathbf{f}(\boldsymbol{x}_i) \circ \mathbf{r})))^2 + ||\mathbf{w}||^2 \tag{3}$$

where $\mathbf{r}$ is the log-count ratio of features occurring in positive and negative examples. The third model is non-linear, in the form of a tree-based gradient boosted machine (Friedman, 2000), which optimizes $\mathbf{w}$ according to:

$$\min_{\mathbf{w}} \sum_{i}^{n} l(y_i, \hat{y}_i) + \sum_{k=1}^{K} \Omega(\mathbf{t}_k) \tag{4}$$

where K is the number of trees, l is the loss function, typically binomial deviance, and $\hat{y}_i$ is given by $\sum_{k=1}^{K} \mathbf{t}_k(\boldsymbol{x}_i)$ where $\mathbf{t}_k$ is a tree.

We use the `scikit-learn` (Pedregosa et al., 2011) implementation for the log-linear and gradient boosted models, and implemented NBSVM based on the interpolated version in Wang and Manning (2012).

As hyperparameters, such as learning rate and regularization, have a significant impact on model performance, we use Bayesian hyperparameter optimization (Bergstra et al., 2011) to select the optimal hyperparameters for each model on a held-out development set. We used the tree-structured Parzen Estimator (TPE) algorithm implemented in `hyperopt` for our sequential model-based optimization (Bergstra et al., 2013). After individually optimizing hyperparameters and training each of the three base models, we use their outputs to train a meta-ensemble model, a regularized conditional log-linear model, forming a linear combination over their predictions (Breiman, 1996).

As the lawmaking process in each state, and even within each chamber, is different, we divide the problem space by state and chamber, building separate models for each subset. Specifically, we consider each of these as separate problems: upper chamber bills and lower chamber bills. Thus, we have 2 predictions per state, and each prediction is comprised of 4 model outputs, three from the base models, and one from the meta-ensemble, resulting in 400 models.[8]

4.2 Features

As there are many dimensions underlying bills that may affect the likelihood of floor action, we compute and utilize several established contextual legislature and legislator derived features. Previous literature has proposed various factors that may affect legislation, including the content of bills,[9] number of and

[8] There are only upper chamber bills in D.C. and Nebraska, resulting in 49 states x 2 prediction types + 2 states x 1 prediction type) x 4 models = 400.

[9] In most previous literature the content is determined via a manual analysis of each bill to establish the scope of impact, the complexity, or the incremental nature.

Feature Type	Description
Sponsor	primary and cosponsor(s) identity, primary and cosponsors(s) party affiliation, number of primary and sponsors, number of Republicans, number of Democrats, sponsors bicameral, sponsors bipartisan, sponsor in majority/minority, majority party Republican or Democrat
Committee	identity of assigned committee(s), number of committee assignments, number of sponsors members of the committee, sponsor same party as committee chairman, sponsor role on the committee, referral rate of committee(s)
Bill	chamber, bill type, session, introductory date, companion bill(s) existence, companion(s) current status.

Table 1: Contextual feature types and descriptions.

identity of sponsors, extra-legislative forms of support, timing of introduction, leadership's position, seniority, identity of chairperson of the committee, identity of one's own party, and membership of the dominant faction (Hamm, 1980; Rakoff and Sarner, 1975; Harbridge, 2016; Yano et al., 2012).

In order to quantitatively evaluate these factors and establish a strong baseline from which to measure the affect of text, we include the contextual features shown in Table 1. These indicator features derived from the sponsors, committees, and bills are meant to capture many of the major factors that are proposed in the literature.[10] To strengthen the representation of legislators in our model beyond the basic features described above, we compute several measures of legislator effectiveness. The effectiveness score is calculated from the sponsoring and cosponsoring activity of each legislator, and meant to represent where they stand in relation to other legislators in successfully passing legislation.[11]

Similar to Harbridge (2016), the score we compute for each legislator is a combination of several partial scores, computed for each important stage of the legislative process. Each legislator gets a score for how many bills they sponsored, getting those bills out of committee, getting them to the floor, passing their own chamber, passing the legislature, and getting enacted. The score for each stage is further broken down by how many of those pieces of legislation were substantive, i.e. bills, attempting a meaningful legal change, versus non-substantive, i.e. resolutions. This results in 12 factors for each individual. To compute a score for each legislator's relative performance at each stage to the other members in the chamber, we create a weighted combination of that legislator's bills and resolutions, where bills get more weight, and compute the ratio based on the weighted contribution of the other members in the chamber. All the stage scores are then combined into a second weighted combination, where each successive stage in the process gets more weight, to get the final score. Finally, the scores are normalized to 0-10. In addition to using the effectiveness scores directly as features, we further compute and discretize several statistics derived from them, including ranks, percentiles, and deviations from the mean thereof.

To further enrich the bill representation beyond contextual information, we utilize the textual content of the bills. The legislation in our collection is comprised of long documents, with an average of 11 thousand words, often containing significant amounts of procedural language and pieces of extant statutes. As this can create additional challenges in identifying the salient points, for this work we chose to focus on a condensed amount of text, specifically the state provided title and description, that average 17 and 18 words, respectively.[12] Both are preprocessed by lowercasing and stemming. We compute the tf-idf weighting for n-grams of size (1,3) on the training data for each prediction task, and select the top 10k

[10]Each count based feature, such as number of sponsors, also spawns a number of discretized features, including ranks, percentiles, and deviations from the mean thereof. We automatically compute companion bills using a cosine-based lexical similarity.

[11]This is not a holistic representation of being an effective legislator, as someone may consider themselves effective by not passing anything, or preventing others from doing so. Members may also be highly influential and their support is needed behind the scenes but their names do not appear on the legislation. We can only account for recorded activity. Despite the limitations, we argue this is a fair, if incomplete, assessment of how well the legislator advances their agenda.

[12]Although this is a coarse approximation of the bill content, we believe it should capture the substantive aspects of the bill. Full details of the length of documents in each state are given in Table 7 in Appendix A.

Condition	Feature Set
`combined`	sponsor, committee, bill, text
`no_txt`	sponsor, committee, bill
`no_txt_spon`	committee, bill
`just_txt`	text
`just_spon`	sponsor

Table 2: The five feature settings with contextual and lexical features.

n-grams from the title and description separately.

While we would like to study the predictability of reaching the floor upon first introduction, bills often change after introduction and are updated with additional information. Thus, we limit our features to those available at the time of first introduction.

5 Results

In order to clarify the impact that each set of features described in Section 4.2 has on predictive performance, we create five different subsets of features described in Table 2, and train models on each one of them separately.

The first condition, `combined` contains all the contextual and text content features. The second condition, `no_txt`, removes text content, allowing us to study the importance of all contextual features, and by comparing `combined` to `no_txt` we can evaluate if text has any complementary information to contextual features. The third condition, `no_txt_spon` further removes sponsor features, essentially allowing us to study the importance of committee information. By comparing `no_txt` to `no_txt_spon` we can evaluate what sponsors contribute. The fourth and fifth conditions use only sponsor and only text features, respectively, to study the importance of each individually.

All models for a given condition are built from the same training data and feature space. We measure and report several performance metrics of our models using 10-fold cross validation. The baseline model represents guessing the majority class; for some states this means all fail, for others it is all receive floor action, based on the state specific rate.

Although accuracy is informative with respect to how many correct binary decisions the model made, as noted in Bradley (1997) for imbalanced problems such as this, where one class dominates, the baseline accuracy can be very high. As a supplement, it is useful to measure a probabilistic loss, where there is a cost associated with how correct the decision was. Thus, we move beyond pure predictive performance and consider the actual probability distributions created by our models under different conditions. The log-linear and gradient boosted models are probabilistic, while NBSVM is not, thus we train a probability transformation on top of NBSVM using Platts Scaling to obtain probability estimates.

In additional to accuracy, we measure model performance on log-loss and AUROC (area under the receiver operating characteristic curve) (Bradley, 1997). Log-loss, LL is defined as:

$$LL = -\frac{1}{n}\sum_{i=1}^{n} \mathbb{1}(y_i = \hat{y_i}) \log(p_i) + (1 - \mathbb{1}(y_i = \hat{y_i})) \log(1 - p_i) \tag{5}$$

where $\mathbb{1}(y_i = \hat{y_i})$ is an binary indicator function equaling 1 if the model prediction $\hat{y_i}$ was correct, and 0 otherwise. LL equals zero for a perfect classifier, and increases with worse probability estimates. Specifically, LL penalizes models more the more confident they are in an incorrect classification.

AUROC allows us to measure the relationship between a model's true positive (TP), how many floor action bills were correctly predicted as floor action, and false positive rate (FP), how many failed bills were predicted as floor action. It is defined by:

$$AUROC = \sum_{i=1}^{N} p(TP)\Delta p(FP) + \frac{1}{2}(\Delta p(TP)\Delta p(FP)) \tag{6}$$

Feature Set	Accuracy		Log-Loss		AUROC	
	Average	Std Dev	Average	Std Dev	Average	Std Dev
baseline	0.68	0.1	0.6	0.09	0.5	0
just_txt	0.732	0.09	0.53	0.14	0.7	0.14
just_spon	0.759	0.102	0.48	0.16	0.74	0.15
no_txt_spon	0.81	0.113	0.39	0.18	0.8	0.18
no_txt	0.846	0.098	0.32	0.18	0.82	0.21
combined	**0.859**	0.093	**0.31**	0.17	**0.85**	0.21

Table 3: Average and standard deviation across states on accuracy, log-loss, AUROC for bills on each feature set.

By considering the TP and FP at different values, we can construct an ROC curve. The area under that curve, AUROC, can be interpreted as the probability that the model will rank a uniformly selected positive instance (floor action) higher than a uniformly selected negative instance (failure), or in other words, the average rank of a positive example. A random model will have a AUROC of 0.5, and a 45-degree diagonal curve, while a perfect model will have an AUROC of 1, and be vertical, then horizontal.

Table 3 shows the average accuracy, LL, and AUROC with standard deviations for each of the five conditions. The `just_txt` model achieves an accuracy of 73%, outperforming the baseline by 5%, and notably, shows that there is a predictive signal even within the limited amount of text available in the title and descriptions.

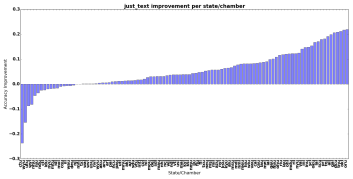
To examine where text content is most and least predictive on its own, we disentangle the average performance of the `just_txt` model in Figure 2a, showing the per state and chamber pair change from baseline. The states that improve the most over baseline, with 15% improvement or more using only textual features are Oregon, Oklahoma, Tennessee, D.C., South Carolina, Louisiana (lower), Georgia (lower), and Alabama (lower). On the other hand, text is least predictive in Connecticut, Wyoming, Idaho, New Jersey, Utah (upper), New Hampshire (upper), North Dakota (upper), all underperforming the baseline.

The relatively small improvement over baseline of `just_txt` provides insight into the lawmaking process, raising the possibility that other contextual factors, outside the subject matter of the legislation, such as who the sponsors are and what committee the bill is assigned to, are often more important than the subject of the legislation.

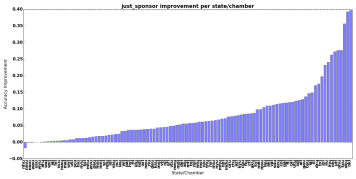
The `just_spon` model achieves an average accuracy of 76%, slightly outperforming `just_txt` with an improvement over baseline of 8%. This further indicates that knowing sponsor related information, without reference to the subject of the legislation, is itself highly predictive. In fact, Figure 2b shows that except for New Hampshire (upper), almost all states achieve gains using sponsor only information, with Oklahoma, Texas, and Ohio achieving gains of 30% or more. The committee information in `no_txt_spon`, which includes the sponsor committee positions, is even more predictive than sponsor and text only, and the addition of sponsors in `no_txt` improves performance by 3.5%.

Including text in the `combined` model further improves performance by 1.3% over `no_txt`, and 18% over the majority class baseline, showing the complementary effects of contextual and lexical information, as this model consistently outperforms all others. Figure 2c shows the per state and chamber pair `baseline` and `combined` model performance. The AUROC performance follows a very similar trajectory.

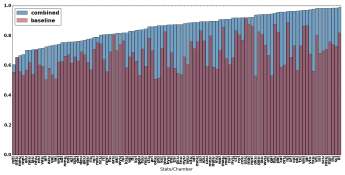
On LL, the model performance follows a similar path, with all models showing improvement in probability estimates from the baseline. LL almost doubles from the `combined` model's 0.31 to 0.6 on `baseline`. This reinforces that the `combined` model makes very confident correct predictions. Including text in the `combined` improves performance slightly over `no_txt`, while having just sponsors or just text decreases the LL to around 0.5.



(a) Change from baseline with text only features.



(b) Change from baseline with sponsor only features.



(c) Prediction accuracy on bills with combined model.

Figure 2: Performance improvements for text-only (2a) and sponsor-only models (2b), and combined performance (2c)

6 Analysis

All contextual and lexical features considered above are available upon the introduction of a bill, or shortly thereafter,[13] thus the evaluation above indicates how well floor action can be predicted from the day of introduction. However, after the bill is introduced, subsequent legislative actions indicate further contextual information about the legislative process. As it is reasonable to assume these actions carry relevant predictive information, we further examine subsequent events in the legislative process in the `combined+act` feature set. We include a binary feature for the occurrence of amendment introduction and outcomes, votes, committee referral outcomes and readings up to the point of floor action. By comparing `combined+act` to `combined` we can examine how important different events in the legislative procedure are to predicting floor action.

Table 4: Average accuracy, log-loss, AUROC for bills using legislative events post introduction.

Feature Set	Accuracy		Log-Loss		AUROC	
	Average	SD	Average	SD	Average	SD
`combined`	0.859	0.093	0.31	0.17	0.85	0.21
`combined+act`	**0.94**	0.059	**0.16**	0.12	**0.97**	0.04

Table 4 shows the results of the `combined+act` feature set. Accuracy improves to 0.94, while LL drops by half to 0.16, confirming that legislative events occurring up to the point point of floor action carry significant complementary information to other contextual factors and are highly indicative of floor action. While `combined+act` confirms the predictive power of procedural factors outside the legislative text, sponsor, and committee assignment, the `combined` model is arguably the most important result, as it indicates how well we can predict on features that are available upon introduction.

Beyond the predictions, we are interested in identifying the different features that contribute to legislative success across the states. As there are both a large number of models, and features in each model, in order to understand the relative predictive importance of contextual and legislature specific dynamics, we choose several previously proposed factors deemed to be important for floor action, and compare the rank and weight they received in each model.

We first examine the median rank and weight given to the following features in the `just_spon` condition across all states: bipartisan, sponsor in minority, sponsor in majority, and the number of sponsors. While many of these contextual features are highly ranked, there are many variations and differences across states. The top half of Table 5 shows the top ten states for which each feature was ranked among the top 20. For example, the bipartisan feature is ranked in the top 5 in Missouri, Virginia, Maine, and Mississippi, accounting for up to 6% of the explanatory power. As a comparison, in South Dakota, Hawaii, Minnesota, Wisconsin, and Pennsylvania, bipartisanship ranked lower than 200. Whether the sponsor is in the minority is important in the U.S. Congress, where it is ranked 6^{th}, along with Delaware, Tennessee, and West Virginia. Being in the majority accounts for 10% in Kentucky, and 7% in Wisconsin. This aligns with previous literature, as Wisconsin is known to have a strong party system (Hamm,

[13] Some states do not indicate committee assignment immediately, for those we include the first assignment after introduction.

Feature	Median	Top	Top States	Bottom States

Members	6	33	de,ct,me,sd,nc,nv,ok,ny,ga,il	hi,id,ia,ks,mt,oh,pa,tn,ut,wy

Table 5: Median ranking of across states for bipartisan, sponsor in minority, sponsor in majority, and number of sponsor features for sponsor only model, and having a ranking majority of the committee as a sponsor, not being a committee member as a sponsor, and being a member of the committee as a sponsor in the committee model. The top column indicates how many states have that feature ranked within the top 20 weighted features. The top states lists the ten states where each feature was ranked the highest and was one of the first 20 features. The bottom rows lists the ten states where each feature was ranked the worst.

1980), and indeed we find sponsor in majority and in minority features to be ranked 1^{st} and 9^{th}, respectively, while in Texas, which has a much weaker party system, those features are ranked among the lowest of all states.[14]

Similar ranking is presented for committee features in the bottom half of Table 5 in the `no_txt_spon` condition. The committee features play a similarly predictive role, with the sponsors holding membership positions on the committee accounting for over 10% of explanatory power in Delaware, Connecticut, Maine, and South Dakota.

To examine the difference in probability assigned by the models under different conditions, we chose a representative example where neither contextual nor lexical features dominate, as shown in Figure 2, and show the boxplots for Pennsylvania's lower chamber in Figure 3. Each subfigure shows the probability of floor action for legislation that received floor action (pass) and did not (failed). In all cases, the median of the probabilities on legislation that received floor action is higher than the median of the probabilities on legislation that failed. The `combined` models median and mean predictions on bills receiving action are above 90%, and it has the largest difference between the two cases. The `no_txt` model has a similar mean, but the probabilities become more distributed on both pass and fail. Removing sponsors significantly affects the distribution, and shifts the mean lower to 70%. `just_spon` and `just_text` both drop the mean to around 40%.

In addition, we show the calibration curves and distribution of predictions for the same settings in Figure 4 and ROC curves in Figure 5 in Appendix A. All models are well calibrated, closely following the diagonal line. The `combined` model is very confident in its predictions, resembling a bimodal distribution, placing most predictions close to either 0 or 1 probability. `just_spon` has the most distributed probability estimates, while `just_txt` moves the lower part of the distribution slightly forward. The `combined` model is quite accurate, with each subsequent model moving the ROC curve to the right, and thus allowing more false positives to reach the same true positive rate.[15]

Finally, we examine language ranked most and least predictive on the `just_txt` condition for New Mexico, Pennsylvania, and New York in Table 6.[16] Previous literature has proposed several theories on how content affects legislative passage, including that the more redistributive a policy is perceived, the higher in controversy, or the greater in scope, the lower the passage likelihood (Rakoff and Sarner, 1975; Hamm, 1980). While each state has a unique set of issues that are likely to be taken to the floor, and conversely, to be left in committee, there is also evident overlap. In the top phrases, several states contain

[14]Full rankings and weights are presented in Table 8 in Appendix A.

[15]For comparison to a state with a higher rate of floor action, we include analogous figures for California's lower chamber in Appendix A.

[16]Addition states are presented in Table 9 in Appendix A.

Table 6: Top and bottom ranked phrases for New Mexico, Pennsylvania, and New York.

budgetary issues, expressed with fiscal and appropriation language, as most states have to pass budgetary measures. We also see commendation and procedural language, which is often less contentious. In the bottom phrases, several states have tax related language, and several education related topics.

While outside the scope of this work, in future work we hope to explore the differing language identified by the model to help identify important questions about the policymaking process in each state, and allow comparison within states of what successful legislation contains, and across states, of how different issues take shape. In addition, as we only included a limited amount of text, we would like to explore how to incorporate the full body text of legislation effectively.

7 Conclusion

In this paper we explored the state legislative process by introducing the task of predicting floor action across all 50 states and D.C. We presented several baseline models and showed that combining contextual information about the legislators and legislatures with bill text consistently provides the best predictions, achieving an accuracy of 86% on which legislation will reach the floor upon first introduction. We further analyzed various factors and their respective importance in the predictive models across the states, gaining a broader understanding of state legislative dynamics. While the factors that influence legislative floor action success are diverse and understandably inconsistent among states, by examining them we can empirically help elucidate the similarities and differences of the policymaking processes.

Learning to Search in Long Documents Using Document Structure

Abstract

Reading comprehension models are based on recurrent neural networks that sequentially process the document tokens. As interest turns to answering more complex questions over longer documents, sequential reading of large portions of text becomes a substantial bottleneck. Inspired by how humans use document structure, we propose a novel framework for reading comprehension. We represent documents as trees, and model an agent that learns to interleave quick navigation through the document tree with more expensive answer extraction. To encourage exploration of the document tree, we propose a new algorithm, based on Deep Q-Network (DQN), which strategically samples tree nodes at training time. Empirically we find our algorithm improves question answering performance compared to DQN and a strong information-retrieval (IR) baseline, and that ensembling our model with the IR baseline results in further gains in performance.

1 Introduction

Reading comprehension (RC), the task of reading documents and answering questions about their content, has attracted immense attention recently. While early work focused on simple questions and short paragraphs (Hermann et al., 2015; Rajpurkar et al., 2016; Trischler et al., 2017; Onishi et al., 2016), current work is shifting towards more complex questions that require reasoning over long documents (Joshi et al., 2017; Hewlett et al., 2016; Welbl et al., 2017; Kočisky et al., 2017).

Long documents pose a challenge for current RC models, as they are dominated by recurrent neural networks (RNNs) (Chen et al., 2016; Kadlec et al., 2016; Xiong et al., 2017). RNNs process documents token-by-token, and thus using them for long documents is prohibitive. A common solution is to retrieve part of the document with an IR approach (Chen et al., 2017; Clark and Gardner, 2017) or a cheap model (Watanabe et al., 2017), and run an RNN over the retrieved excerpts. However, as documents become longer and questions become complex, two problems emerge: (a) retrieving all the necessary text with a one-shot IR method when performing complex reasoning becomes harder, and thus thousands of tokens are retrieved (Clark and Gardner, 2017). (b) Running even a cheap model over the document in its entirety becomes expensive (Choi et al., 2017).

Humans, in lieu of a mental inverted index, use document structure to guide their search for answers. E.g., the answer to *"What high school did Leonard Cohen go to?"* is likely to appear in *"Early life"*, while the answer to *"How hot is it in Melbourne in July?"* is likely to appear in *"Climate"*. In this work we investigate whether we can train a model to navigate through a document using its structure and find the answer, while reading only a small portion of the entire document.

We represent documents as trees and train an agent that navigates through the document tree until returning a final answer. Figure 1 illustrates this process. Our agent reads the question *"The vacation destinations of Pattaya and Phuket are in which country?"* and starts navigation at the title of the document. After reading a paragraph, and skipping *"History"*, it drills down to *"Geography"* until finally halting at a paragraph that specifies the answer (*"Thailand"*). The agent observes at each step only a glimpse of the local text to determine its next action, which can be movement to a tree node, answering

Proceedings of the 27th International Conference on Computational Linguistics, pages 161–176
Santa Fe, New Mexico, USA, August 20-26, 2018.

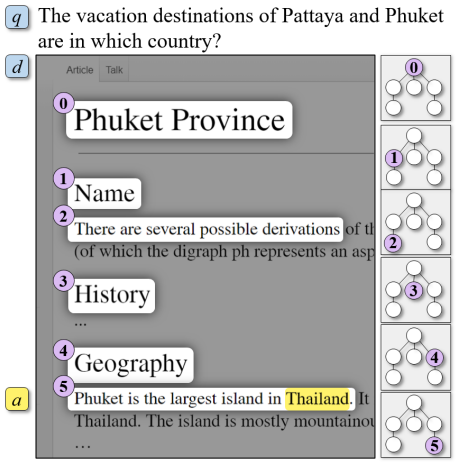

Figure 1: An overview of our framework: an agent answers the question q for a document d by starting at the title, performing navigation actions until reaching the relevant paragraph, extracting the answer a, and then stopping.

the question with a more expensive RC model, or terminating navigation. Thus, the agent consumes only a small fraction of the entire document.

Our training data is question-document-answer triplets, without gold navigation paths, and thus we train our model with the Deep Q-Network (DQN) algorithm. Because the dataset is biased towards answers appearing at the beginning of the document, the algorithm tends to stop early and does not explore the document well. To overcome this challenge, we propose DocQN: a variant of DQN for tree navigation that improves exploration by sampling nodes from multiple parts of the tree.

We evaluate the ability of our agent to navigate to paragraphs containing the answer on a variant of TriviaQA (Joshi et al., 2017) and find that: (a) DocQN navigates better than DQN in documents both quantitatively and qualitatively. (b) While DocQN observes only 6% of the document tokens, it outperforms an IR method in end-to-end QA performance. (c) An ensemble of DocQN and IR substantially improves both navigation and end-to-end QA performance over the ensemble components.

To summarize, in this paper we ask: can an agent use document structure and learn to find answers for complex questions in long documents? We propose a new model and training algorithm that overcomes an inherent bias in the data, answering the aforementioned question in the affirmative. Our code and dataset are available at `https://github.com/mega002/DocQN`.

2 Problem Overview

We work in the traditional RC setup, where we are given question-document-answer triplets $\{(q_i, d_i, a_i)\}_{i=1}^{N}$ as a training set, and aim to learn a function that finds the answer for an unseen question-document pair. Unlike prior work, we assume documents are trees, where every tree node u corresponds to a structural element and is labeled with text $l(u)$. Specifically, the root is labeled with the document title, sections and subsections are labeled by their title, and paragraphs and sentences are labeled by the text they contain. In addition, we order all non-sentence tree nodes by a pre-order traversal (which corresponds to the linear order of text in the document), and denote the index of a node u by $n(u)$. For sentence nodes, $n(u)$ is the index of their parent (a paragraph).

Figure 1 shows an example tree, where for each node we show the relevant structural element and index (sentence nodes are not shown in the figure).

With this document representation, answering questions can be viewed as a Markov Decision Process (MDP), where in each state the agent is located in a particular tree node, actions allow movement through the document tree, answering the question with a RC model, or stopping, and a reward is based on whether the agent locates a node that contains the answer.

Our agent interleaves actions that *navigate* in the document, with an action that runs an RC model in a certain document position and *extracts an answer*. Thus, the agent can decide to continue navigation after extracting a certain answer. This is strictly more expressive than existing approaches that combine

		TRIVIAQA	TRIVIAQA-NOP

	TRIVIAQA	TRIVIAQA-NOP
Questions	86.7%	83.8%
Question-document pairs	69.7%	66.9%

Table 3: Portion of answerable samples in a random subset of the training set, which contains 278 questions and 475 question-document pairs.

IR with RC, where some text is retrieved exactly once before applying an RC model. As RC shifts to reasoning over complex questions, navigating and reading multiple parts of the document will become necessary. We show in Section 5 this approach indeed improves QA performance.

3 Data

To test our framework, we capitalize on the recently-released TRIVIAQA dataset, which contains question-answer pairs, along with a small set of documents that (in almost all cases) contain the answer. TRIVIAQA is suitable for our purposes as it is a large scale dataset, where questions are relatively complex and documents are fairly long. The dataset includes only raw text, and thus for every evidence document, we built a tree representation by extracting the html metadata from the corresponding Wikipedia page, and constructing the document structure from it.

Because our goal is to investigate whether a model can learn to search through a document, it is important that a non-negligible fraction of the questions require navigation through the document. However, in Wikipedia each document starts with a preface that summarizes the document, and thus often contains the answer. Consequently, a model that ignores the question and document and always stops in the first paragraph is likely to obtain good performance. Figure 2 shows the distribution of the first answer occurrence (FAO) in a document in TRIVIAQA over the node indices $n(u)$ (x-axis), where all tree nodes, except sentences are considered (see Section 2). We find that in most question-document pairs the FAO is in the first few paragraphs, and that in 60% of the cases it is in the preface section.

To alleviate this heavy bias, we derive a new dataset, termed TRIVIAQA-NOP, where we remove the preface section from every document. After removing the preface, 2,144 out of 77,582 (2.8%) questions and 6,124 out of 138,537 (4.4%) question-document pairs are left without an answer and are removed. To further reduce the number of cases where an answer can not be inferred from a document, we drop question-document pairs where: (a) the answer appears only in titles; (b) the answer is a single-character; (c) the FAO node index is > 700 (in most cases the answer is an item in a list). Finally, the dataset includes 91.6% of the questions and 88.4% of the question-document pairs from the original dataset. We provide full statistics on the dataset in Tables 1 and 2.

To verify that questions remain answerable in TRIVIAQA-NOP after removing the preface, we perform manual analysis on a random sample of 278 questions and 475 documents from the training set (Table 3). We find that the portion of answerable questions and question-document pairs remains high and is reduced by less than 3% in comparison to TRIVIAQA . This demonstrates that indeed, for most questions and documents, the context necessary for answering the question also appears in the document body and not only in the preface.

Figure 2 shows the FAO node index distribution in TRIVIAQA-NOP. We observe, compared to TRIVIAQA, that the first occurrence of an answer is much more spread out across the document, and that the median increases from 3 to 14, which will require more navigation from the agent. However, even in TRIVIAQA-NOP answers tend to appear at the beginning of the document, because document content is usually organized by importance. This bias results in an exploration challenge for our training algorithm,

	Example
o	*"Phuket Province Name"*
ϕ_n^1: `height`	2
ϕ_n^2: `depth`	1
ϕ_n^3: `h_dist_start`	0
ϕ_n^4: `h_dist_end`	2
ϕ_n^5: `parent.h_dist_start`	0
ϕ_n^6: `parent.h_dist_end`	0
ϕ_n^7: `navigation step`	1

Table 4: An example observation o and list of navigation features ϕ_n for node 1 in Figure 1. The features `height` and `depth` correspond to distance from the farthest leaf and root, respectively (`height` is 2 since sentence nodes are omitted from the figure). `h_dist_start` and `h_dist_end` measure the horizontal distance from the first and last child of the node's parent. `navigation step` is a counter for the number of performed steps.

which we will address in Section 4.

4 Method

In this section, we describe a model for the agent and a training algorithm based on DQN (Mnih et al., 2015). Specifically, we introduce a tree-sampling strategy, which addresses the exploration challenge stemming from the bias towards answers early in the document.

4.1 Framework

We represent the MDP as a tuple $(\mathcal{S}, \mathcal{A}, R, T)$, where $\mathcal{S}$ is the state space, $\mathcal{A}$ is the action space, $R(s, a)$ is a reward function, and $T(s, a)$ is a deterministic transition function. Our model implements an action-value function $Q(s, a)$, which takes a state $s \in \mathcal{S}$ and returns a value for every action $a \in \mathcal{A}$. This function defines a policy $\pi(s) = \arg\max_{a \in \mathcal{A}} Q(s, a)$. We now describe the state space, actions and reward function.

States Given a tree node u, a state is a tuple $s^u = (q, o, z, \phi_n, \phi_z)$, where q is the question, o is an observation, z is an answer prediction, and ϕ_n, ϕ_z are navigation and answer prediction features. An observation $o = (o_1, \ldots, o_{|o|})$ is a sequence of tokens produced by recursively concatenating the first k tokens of text in the label $l(u)$ to the observation of u's parent. An answer prediction $z = (z_1, \ldots, z_{|z|})$ is the sequence of tokens that were extracted by an RC model, if an RC model was already run on $l(u)$ (and a null token otherwise). The answer prediction features $\phi_z = (z_e, z_l, z_n)$ provide information on the distribution over answer spans provided by the RC model, which reflects its confidence: z_e is the entropy of the distribution, z_l is the logit value for z, and z_n is the number of tokens in $l(u)$. Navigation features ϕ_n provide information on the relative location of u in the document. An example observation and full list of navigation features are given in Table 4.

Note that the state s does not depend on the history of visited tree nodes.[1] While incorporating history could be beneficial, a memory-less model enables us to explore tree-sampling strategies, which is important for training (Section 4.2).

Actions We define the following set of actions $\mathcal{A}$. Let u be a node with an ordered list of children (v_1, v_2, v_3), and w be a child of v_2. We define five movement actions (Figure 3), where DOWN moves from u to its first child v_1, RIGHT moves from v_2 to v_3, and LEFT moves from v_2 to v_1. Because moving upwards reaches a node we already visited, we define UPR, which moves from w to v_3, and UPL, which moves from w to v_1. If an illegal action is chosen (e.g., LEFT from v_1), then the agent stays in its current position. The action ANSWER returns an answer (and a distribution over spans) by running a RC model on $l(u)$, unless u is a sentence, in which case it is run on the paragraph containing u. After ANSWER, the agent can resume navigation. The action STOP also returns the answer given the current node u, but also terminates navigation.

Reward Our goal is to develop an agent that can navigate in the document, and thus we define the reward based on whether the agent stops in a node that contains the gold answer text (this is noisy,

[1] except for `navigation step`, which can be approximated by the shortest path from the root to any node.

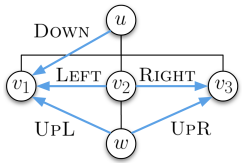

Figure 3: Movement actions in our environment.

because the answer might be there sporadically). While a simple reward would be an indicator for whether the agent stopped at a correct node, such a reward would not capture the proximity of the agent to the answer. Moreover, we would like to consider the overall document length, rewarding successful navigations in long documents. Therefore, we define the following reward:

$$r(s,a) = \begin{cases} 2 & a = \text{STOP}, |n(u) - n(u^*)| = 0 \\ 1 - \frac{|n(u)-n(u^*)|}{\max_u n(u)} & a = \text{STOP}, |n(u) - n(u^*)| > 0 \\ -0.06 & a = \text{ANSWER} \\ -0.02 & a \notin \{\text{ANSWER}, \text{STOP}\} \end{cases}$$

where u is the node where the agent is located and u^* is the closest tree node that contains the answer ($n(u)$ is the node index as defined above). Thus, when stopping, the reward is proportional to the distance to the closest answer location given the document length. An additional reward is given if navigation is successful, and a penalty is given for any other action, to encourage shorter trajectories. We further penalize the ANSWER action to discourage frequent usage of the RC model.

4.2 DOCQN: DQN with Tree Sampling

Training the navigation model is based on DQN (Mnih et al., 2015). In DQN, at every step an agent at state s_t selects an action a_t using ϵ-greedy policy, given the current action-value function $Q_\theta(s_t, a_t)$ parameterized by θ. The agent observes a reward r_t and a state $s_{t+1} = T(s_t, a_t)$ and adds a transition (s_t, a_t, r_t, s_{t+1}) to a replay memory buffer $\mathcal{D}$ that holds a large number of recent transitions. The parameters are then optimized so that the action-value function matches better the observed reward. This is done by sampling a batch of random transitions from $\mathcal{D}$ and minimizing the regression loss

$$(r_t + \gamma \max_{a'} Q_{\hat{\theta}}(s_{t+1}, a') - Q_\theta(s_t, a_t))^2, \tag{1}$$

where $\hat{\theta}$ are the parameters of a *target network*, which is a periodic copy of θ that is not optimized, and γ is a discount factor.

We also add some of the recent enhancements to DQN (Hessel et al., 2017), which have proved to be useful in our setup. Specifically we implement *Double Q-Learning* (van Hasselt et al., 2016), *Prioritized Experienced Replay* (Schaul et al., 2015), and *Dueling Networks* (Wang et al., 2016).

Reducing bias with DOCQN The DQN algorithm contains episodes, where in each episode the agent is placed at an initial state s_0, from which it starts taking actions. In our setup, this state corresponds to the root of the document tree. Because the data has a bias towards answers appearing at the beginning of the document, the agent learns that stopping early improves the reward and is stuck at a local minimum, where it ceases exploration. Examining Figures 2 and 8, we observe that DQN learns to stop very early in the document compared to the FAO node index distribution of TRIVIAQA-NOP, amplifying the bias in the data.

To address this issue, we suggest DOCQN, a variant of DQN aimed at increasing exploration when navigating in a document structure. DOCQN capitalized on two properties. First, DQN is an off-policy algorithm that trains from transitions (s_t, a_t, r_t, s_{t+1}). Second, our model is memory-less, and thus we can sample any node u and compute the corresponding state s^u. Therefore, we modify DQN, and instead of initializing every episode with s_0 and performing a sequence of actions, we sample states from distributions that explore the document better. By exploring transitions from across the document, the model learns from more distant parts of the document.

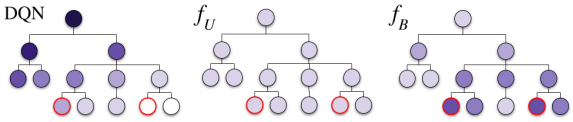

Figure 4: Illustration of the different state distributions for a specific documents tree. Nodes with darker color have higher sampling probability, and nodes marked in red are paragraph nodes containing the answer.

Algorithm 1: **DocQN**

1: Let f be a distribution over tree nodes
2: Initialize replay memory $\mathcal{D}$ and parameters $\theta, \hat{\theta}$
3: **for** episode $= 1, M$ **do**
4: **if** random() $< \varepsilon_s$ **then**
5: **for** $i = 1 \dots K$ **do**
6: sample node $u \sim f$ and generate s^u
7: sample action a from s^u (ϵ-greedily).
8: $r \leftarrow R(s^u, a), s' \leftarrow T(s^u, a)$
9: store (s^u, a, r, s') in $\mathcal{D}$
10: **else**
11: Initialize start state s_0
12: **for** $t = 0 \dots T-1$ **do**
13: sample action a from s_t (ϵ-greedily).
14: $r \leftarrow R(s_t, a), s_{t+1} \leftarrow T(s_t, a)$
15: store (s_t, a, r, s_{t+1}) in $\mathcal{D}$
16: UpdateParams$(\theta, \hat{\theta}, \mathcal{D})$ (Equation 1)

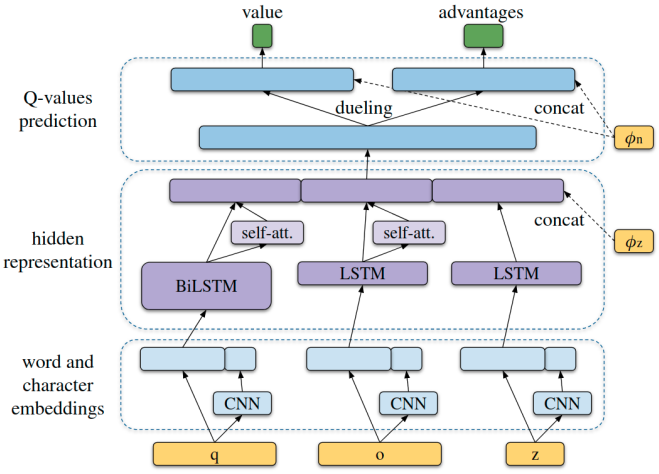

Figure 5: High-level overview of the network architecture.

Algorithm 1 provides the details of DocQN. The algorithm initializes the replay memory buffer, the model and target network parameters, and chooses a distribution f over tree nodes. At the beginning of every episode, with probability ϵ_s (line 4),[2] we sample K state transitions using f and store them in $\mathcal{D}$, and with probability $(1 - \epsilon_s)$ (line 10), we start at the initial state s_0 and sample a trajectory as in DQN. Parameters are updated as in DQN by sampling transitions from the replay buffer and minimizing Equation 1. If f samples nodes from various locations in the document, the algorithm will explore better and will not getting stuck at its beginning. We consider the following instantiations of f:

1. f_U: *Uniform sampling* over nodes, except we discourage sampling sentences by uniformly sampling with probability 0.2 a leaf (sentence), and probability 0.8 an inner node.
2. f_B: *Backward sampling*: We uniformly sample a paragraph node p that contains the gold answer, then uniformly a number of actions $B \in \{1, 2, 3\}$, and perform B random movement actions from p to output a node. This results in a node that is "close" to the answer a, and can be viewed as similar to bi-directional search or backward search (Lao et al., 2015).

Figure 4 shows the distribution over tree nodes for a specific document tree where the answer appears in two paragraph nodes (ignoring sentence nodes). We see that sequential sampling (as in DQN) puts most of the probability mass close to the root, uniform sampling is uniform (across paragraphs, as sentence nodes are omitted), and backward sampling is concentrated close to answer nodes. This illustrates how different distributions result in different exploration strategies.

Network Architecture We briefly describe the neural architecture (Figure 5) and provide full details in the supplementary material. As explained in Section 4.1, the input to the network is the state s, which comprises the question tokens q, observation tokens o, answer prediction tokens z and features ϕ_n, ϕ_z. The question, observation and answer prediction tokens are encoded with pre-trained word embeddings and trained character embeddings, where character embeddings are followed by a convolutional layer with max pooling, yielding a single vector per token. Each token is then represented by concatenating the word embedding with the character embedding.

Question tokens, observation tokens, and answer to are then fed into a BiLSTM and LSTM (Hochreiter and Schmidhuber, 1997) respectively and the LSTM outputs are compressed to a single vector through

[2] ϵ_s is annealed from 1 to 0.5 during training.

self attention (Cheng et al., 2016), resulting in one vector for q and one for o. Answer prediction tokens are fed into an LSTM, where the last hidden state is concatenated to the features ϕ_z, thus creating a third vector for the answer prediction.

We concatenate these three vectors, and pass them through a one layer feed-forward network that then branches to two networks according to the Dueling DQN architecture (Wang et al., 2016). In each branch we also concatenate the navigation features ϕ_n. One branch predicts the value of the state $V_\theta(s) \in \mathbb{R}$, and the other branch predicts the advantage of every action $A_\theta(s,a) \in \mathbb{R}$ for every possible action a. The output of the network is $Q_\theta(s,a) = V_\theta(s) + (A_\theta(s,a) - \frac{1}{\mathcal{A}} \sum_{a'} A_\theta(s,a'))$ as in Wang et al. (2016).

5 Experimental Evaluation

Our experimental evaluation aims to answer the following questions: (a) Can document structure be used to learn to navigate to an answer in a document? (b) How does DOCQN compare to DQN? (c) How does DOCQN compare to IR methods that observe the entire document?

5.1 Experimental Setup

We evaluate on TRIVIAQA-NOP. Because our focus is on the navigation ability of the agent, we train a single RC model and fix it in all experiments. Specifically, we download RASOR (Lee et al., 2017; Salant and Berant, 2018),[3] and exactly follow the procedure described by the authors of TRIVIAQA for training a RC model, i.e., we train RASOR on the first 400 tokens of each document in TRIVIAQA-NOP. As a sanity check for our RC model, we also train and evaluate RASOR on the original TRIVIAQA dataset. Indeed, RASOR obtains 48.6% EM and 53.4% F1, which is substantially higher than the baseline reported by Joshi et al. (2017).

Evaluation We use two metrics: First, we measure *navigation accuracy*, i.e., for a question-document pair, whether a method returns text containing a gold answer (if the agent stops at a sentence node we evaluate the encompassing paragraph). Because questions in TRIVIAQA-NOP often have more than one evidence document, we also measure *aggregated navigation accuracy*, where we give credit if the agent navigated correctly in any of the documents. This gives performance assuming an oracle that always chooses the best document for the question. Because the test set in TRIVIAQA is hidden, we evaluated navigation accuracy on the development set only.

In addition, we measure end-to-end QA performance with the official Exact Match (EM) and F1 metrics. The EM metric measures the percentage of predictions that match exactly any of the answer aliases, and the F1 metric measures the average overlap between the prediction and answer. To aggregate evidence from multiple documents we follow Joshi et al. (2017) and define the score of an answer to be the sum of probabilities for that answer across all documents.

Models We compare the following models:

- **DOCQN**: This is our main model, where we use the sampling distribution $f_{U+B} = \frac{1}{2} f_U + \frac{1}{2} f_B$.
- **DQN**: DQN algorithm without state sampling.
- {**DOCQN**|**DQN**}-**COUPLED**: A less expressive version of the model, where the actions ANSWER and STOP are coupled, i.e., the agent can use the RC model exactly once and then stops. This is similar to a setup where retrieval is performed once and not interleaved with navigation.
- **RANDOMWALK** An agent that selects an action at each step uniformly at random.
- **RANDOMPARA** An agent that randomly selects a non-sentence tree node.
- **DOC-TF-IDF**: An IR baseline, where a paragraph is selected based on its tf-idf score. We implement the tf-idf scheme of DOCQA (Clark and Gardner, 2017), which is a high-performing system on TRIVIAQA. Here, idf is computed for each paragraph in the context of the current document, and the paragraph with highest cosine similarity to the question is chosen. Note that DOC-TF-IDF processes the entire document (up to tens of thousands of tokens), while DOCQN processes only a small fraction.
- **TF-IDF**: Vanilla tf-idf, where the idf score is computed from all documents in TRIVIAQA-NOP.

[3] https://github.com/shimisalant/RaSoR

- **Ensemble**: We ensemble DocQN f_{U+B} with Doc-Tf-Idf in two ways: (1) for finding the final answer, we aggregate scores as described above, that is, we sum the probabilities from both models over all documents and choose the answer with highest score. (2) For navigation, we simply tune on the development set a threshold l, where we take the prediction of DocQN f_{U+B} if it stopped at a node with index $\leq l$ and use Doc-Tf-Idf otherwise.
- **ReadTop**: Following Joshi et al. (2017), a model that runs the RC model on the first 800 tokens of the document. Note that running the RC model on the text retrieved by DocQN involves consuming far fewer tokens, namely, RaSoR consumes only 160 tokens on average.

We report the value of all hyper-parameters in the supplementary material (all fixed without tuning).

5.2 Results

q: According to the rhyme, what is Wednesday's child? ***a:*** ['full of woe']

Step	Node	Observation Tokens	Answer	Action
0	0	['Wednesday']		DOWN
1	1	['Wednesday', 'Etymology']		DOWN

Figure 6: Navigation example of DocQN.

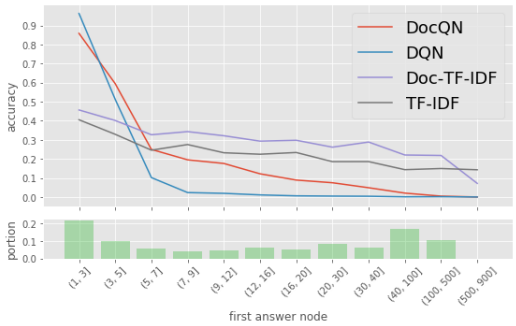

Figure 7: Model performance (top) and portion of samples in the development set (bottom) as functions of the node index of the FAO.

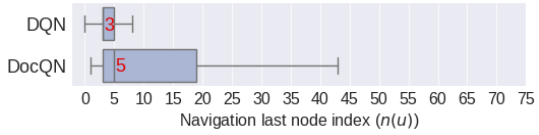

Figure 8: Distribution of node index at navigation stopping point (median value in red) for DQN and DocQN.

Tables 5 and 6 show the results of our experiments. Focusing on navigation accuracy, we see that randomly walking or choosing a paragraph yields low performance. Vanilla Tf-Idf performs considerably better than the random baselines, but is outperformed by all other models. Comparing DQN to DocQN, we see that DocQN outperforms DQN. Allowing DQN and DocQN to run the RC model during navigation improves their performance, but the accuracy gain is substantially higher for DocQN (2.3% accuracy and 3.1% aggregated accuracy) than for DQN (0.4% accuracy and 0.7% aggregated accuracy). Doc-Tf-Idf, which has access to the entire document outperforms DocQN, which consumes on average 6% of the entire document. Nonetheless, the two models obtain the same aggregated accuracy. This good performance of Doc-Tf-Idf shows that in TriviaQA-NoP answer paragraphs share a lot of lexical material with the question. Importantly, an ensemble of Doc-Tf-Idf with DocQN substantially improves the overall performance, reaching accuracy of 35% and aggregated accuracy of 48%. This is

	Dev.	Dev. Agg.
RANDOMWALK	1.8	3.1

Ensemble (threshold, $l = 5$)	26.8	32.0	24.2	29.4
Ensemble (answer)	**28.4**	**33.4**	**25.4**	**30.5**
READTOP	**32.5**	**36.7**	**28.1**	**32.4**

Table 6: End-to-end QA performance of all models on the development and test sets of TRIVIAQA-NOP. For the ensemble model, we choose the best threshold of $l = 5$.

	DQN	DOCQN
Path length	avg. 7.7, range [1,36]	avg. 15.2, range [3,100]
Answer predictions	avg. 2.8	avg. 4.1
Tokens consumed	3.4%	6.2%
Stopping node	0.5% title, 2.2% headline, 89.0% paragraph, 8.3% sentence	0% title, 0.4% headline, 75.1% paragraph, 24.5% sentence

Table 7: Comparing navigation properties of DQN and DOCQN on the development set. The average and range of navigation path length in steps, relative amount of consumed tokens, and distribution of stopping node types.

in sharp contrast to an ensemble with DQN, where for any value of l, DOC-TF-IDF performs better on its own.

Examining end-to-end performance, DOCQN again outperforms DQN, but DOCQN is now better than DOC-TF-IDF. This suggests that when DOC-TF-IDF selects a paragraph with the answer, it is often difficult to extract with the RC model. Again, the ensembles leads to a dramatic increase in performance, showing that DOC-TF-IDF and DOCQN are complementary. However, READTOP, which consumes the first 800 tokens of each document compared to ~ 160 for DOCQN, substantially outperforms all navigation models. This shows that the bias for answers at the beginning of documents is still strong in TRIVIAQA-NOP.

To further elucidate the differences between navigation models, Figure 7 shows navigation accuracy of different models and the proportion of samples for different node indices of the FAO. We see that DQN outperforms DOCQN when the answer is at the top of the document, but DOCQN dominates DQN when the answer is further down, showing that DOCQN learns to find answers deeper in the document. DOC-TF-IDF has a more balanced navigation accuracy across the document, which explains why an ensemble of DOC-TF-IDF with DOCQN works, as they are complementary to one another.

Analysis Figure 6 shows a navigation example, which includes the navigation step, node index, observation o, and the action a taken. For the observation we also highlight the attention distribution from the self-attention component. In this figure the question is about culture, and we see the agent going into multiple sections, reading them, running the RC model and continuing forward, until finally stopping at a paragraph that contains the answer. We provide many more examples in the supplementary material.

Table 7 highlights some differences between DQN and DOCQN. DOCQN has longer trajectories, and stops at sentence nodes more frequently, suggesting it reads the document at a finer granularity. Additionally, it leverages the RC model to collect more information and confidence during navigation, by choosing the action ANSWER more frequently. Both models consume less than 7% of the entire document. Figure 8 illustrates the navigation stopping point, and shows that DOCQN navigates deeper into the document.

6 Related Work

Handling the challenges of reasoning over multiple long documents is gaining fast momentum recently (Shen et al., 2017). As mentioned, some approaches use IR for reducing the amount of processed text (Chen et al., 2017; Clark and Gardner, 2017), while others use cheap or parallelizable models to handle long documents (Hewlett et al., 2017; Swayamdipta et al., 2018; Wang et al., 2018a). Searching for

answers while using a trained RC model as a black-box was also implemented recently in Wang et al. (2018b), for open-domain questions and multiple short evidence texts from the Web. Another thrust has focused on skimming text in a sequential manner (Yu et al., 2017), or designing recurrent architectures that can consume text quickly (Bradbury et al., 2017; Seo et al., 2018; Campos et al., 2018; Yu et al., 2018). However, to the best of our knowledge no work has previously applied these methods to long documents such as Wikipedia pages.

In this work we use TRIVIAQA-NOP for evaluation of our navigation based approach and comparison to an IR baseline. While there are various aspects to consider in such evaluation setup, our choice of data was derived mainly by the requirements for long and structured context. Recently, several new datasets such as WIKIHOP and NARRATIVEQA were published. These datasets try to focus on the tendency of RC models to match local context patterns, and are designed for multi-step reasoning. (Welbl et al., 2017; Wadhwa et al., 2018; Kočisky et al., 2017).

Our work is also related to several papers which model an agent that navigates in an environment to find objects in an image (Ba et al., 2015), relations in a knowledge-base (Das et al., 2018), or documents on the web (Nogueira and Cho, 2016).

7 Conclusions

We investigate whether document structure can be leveraged to train an agent that finds answers to questions in long documents while reading only a small fraction of it. We show that an agent that reads 6% of the document can improve QA performance compared to an IR method that utilizes the entire document, and that ensembling the two substantially improves performance. We also present DOCQN, an algorithm that promotes better exploration of the document, and show it outperforms DQN qualitatively and quantitatively.

Our approach represents a conceptual departure from previous methods for reading long documents, as it interleaves searching for an answer in the document with extracting the answer from a particular paragraph, which we show improves both navigation and QA performance. We expect that as RC models tackle longer documents that require reasoning and reading text that is spread in multiple parts of the document, models that can efficiently navigate and collect evidence will become more and more crucial. Our agent provides a first step in this important research direction.

Acknowledgments

We thank Eunsol Choi from Washington University for helpful discussions and comments on the paper. This research was partially supported by The Israel Science Foundation grant 942/16. This work was completed in partial fulfillment for the Ph.D degree of the first author.

A Supplementary Material

A.1 Network Architecture Details

Here, we elaborate on the network architecture, which was briefly described in the paper. Given an input state $s = (q, o, z, \phi_n, \phi_z)$, we denote by $q = (q_1, ..., q_n)$, $o = (o_1, ..., o_m)$ and $z = (z_1, ..., z_r)$ the question tokens, observation tokens and answer prediction tokens, respectively.

Word-level embedding For every $i = 1, ..., n$, every $j = 1, ..., m$ and every $k = 1, ..., r$, we create an embedding of the input tokens q_i, o_j, z_k in two steps. First, we embed every token with a pre-trained GloVe word embedding matrix W_w:

$$e^w_{q_i} = W_w \cdot q_i \quad ; \quad e^w_{o_j} = W_w \cdot o_j \quad ; \quad e^w_{z_k} = W_w \cdot z_k$$

Next, we apply character-level embeddings with a learned embedding matrix W_c. The embedded characters are then summarized with a max-pooling convolutional neural network:

$$\begin{aligned} e^c_{q_i} &= \mathrm{CNN}(\{W_c \cdot q_{ix}\}^{|q_i|}_{x=1}) \\ e^c_{o_j} &= \mathrm{CNN}(\{W_c \cdot o_{jx}\}^{|o_j|}_{x=1}) \\ e^c_{z_k} &= \mathrm{CNN}(\{W_c \cdot o_{kx}\}^{|z_k|}_{x=1}) \end{aligned}$$

Concatenation of the two components yields the final word-level embeddings:

$$e_{q_i} = [e^w_{q_i} \,;\, e^c_{q_i}] \quad ; \quad e_{o_j} = [e^w_{o_j} \,;\, e^c_{o_j}] \quad ; \quad e_{z_k} = [e^w_{z_k} \,;\, e^c_{z_k}]$$

Question sequence encoding The question is encoded with a BiLSTM, where for every timestamp i, the forward and backward outputs are concatenated:

$$\begin{aligned} \{u_{q_1}, ..., u_{q_n}\} &= \mathrm{BiLSTM}(e_{q_1}, ..., e_{q_n}) \\ u_{q_i} &:= [\overrightarrow{\mathrm{LSTM}}(\overrightarrow{h}_{q_{i-1}}, e_{q_i}) \,;\, \overleftarrow{\mathrm{LSTM}}(\overleftarrow{h}_{q_{i+1}}, e_{q_i})] \end{aligned}$$

The outputs are then summarized with a self-attention:

$$h_q = \sum_{i=1}^{n} \alpha_i u_{q_i}$$

where the coefficients $\alpha_1, ..., \alpha_n$ are obtained by feeding the outputs to a two-layer feed-forward network, and normalizing the output logits with softmax:

$$a_i = \mathrm{FFNN}(u_{q_i}) \quad ; \quad \alpha_i = \frac{e^{a_i}}{\sum_{k=1}^{n} e^{a_k}}$$

Observation sequence encoding The observation sequence encoding h_o is obtained in an analogous manner to h_q, except that we use a LSTM rather than a BiLSTM.

Answer prediction encoding The answer prediction encoding h_z is obtained by running the answer prediction tokens through a LSTM, and concatenating the last hidden state with the input feature vector ϕ_z:

$$\begin{aligned} \{u_{z_1}, ..., u_{z_r}\} &= \mathrm{LSTM}(e_{z_1}, ..., e_{z_r}) \\ u_{z_k} &:= \overrightarrow{\mathrm{LSTM}}(\overrightarrow{h}_{z_{k-1}}, e_{z_k}) \\ h_z &= [u_{z_r} \,;\, \phi_z] \end{aligned}$$

	Parameter	Value
Network	Maximum node observation length	20 tokens
	Maximum observation length	120 tokens

Table 8: DOCQN hyper-parameters

State representation The final state representation is formed by concatenating the encoded question h_q with the encoded observation h_o. Concretely:

$$h_s = [h_q \ ; \ h_o \ ; \ h_z]$$

The input node features ϕ_o are concatenated to an upper layer, as we describe next , to increase their weights in the final predictions. We have found that incorporation of these features in this way accelerates the navigation learning process.

Q-values prediction We implement a Dueling DQN architecture, where the final Q-values are composed of a state value $V(s)$ prediction and advantage predictions $A(s, a)$ for every possible action a. Denoting by FFNN a single-layer feed-forward neural network, predictions are derived as follows:

$$v_0 = \text{FFNN}(h_s)$$
$$v_1^V = \text{FFNN}(v_0) \ ; \ v_1^A = \text{FFNN}(v_0)$$
$$v_2^V = \text{FFNN}([v_1^V \ ; \ \phi_n]) \ ; \ v_2^A = \text{FFNN}([v_1^A \ ; \ \phi_n])$$

Where $v_2^V \in \mathbb{R}$, $v_2^A \in \mathbb{R}^{|\mathcal{A}|}$, and ϕ are the navigation features. The final Q-values prediction is obtained by averaging:

$$v^Q = v_2^V + \left(v_2^A - \frac{\sum_{i=1}^{|\mathcal{A}|} v_{2i}^A}{|\mathcal{A}|}\right)$$

A.2 Hyper Parameters

Table 8 summarizes the hyper-parameters used for building and training the DOCQN models.

A.3 Navigation Examples

Figures 9,10,11,12,13 show sample navigations, performed by the DOCQN model. In each example, q, a, n denote the question, answer aliases and answer node numbers. The observation tokens are highlighted according to the self-attention weights, given by the model. By choosing the action ANS, the agent executes the RC model to obtain an answer prediction, which is part of the observation in the next step.

q: How many legs does a ladybird have?
a: ['six', '6']
n: [2, 12, 14, 22, 46, 51, 60, 72, 74, 102, 150, 159, 163, 200]

Abstract

Event relation recognition is a challenging language processing task. It is required to determine the relation class of a pair of query events, such as causality, under the condition that there isn't any reliable clue for use. We follow the traditional statistical approach in this paper, speculating the relation class of the target events based on the relation-class distributions on the similar events. There is minimal supervision used during the speculation process. In particular, we incorporate image processing into the acquisition of similar event instances, including the utilization of images for visually representing event scenes, and the use of the neural network based image matching for approximate calculation between events. We test our method on the ACE-R2 corpus and compare it with the fully-supervised neural network models. Experimental results show that we achieve a comparable performance to CNN while slightly better than LSTM.

1 Introduction

Event relation recognition aims to predict the relationship between the query events. Here, an event is defined as a text span (sentence or clause) which describes the occurrence of a genuine event, such as "*The 2nd industrial revolution*". An event-oriented relation recogntion system is required to assign a relation type tag to a pair of query events, such as those defined in Hong et al (2016)'s natural event relation scheme, including causality, temporality, conditionality, etc. Listed below are a pair of related query events, along with the relation need to be predicted:

(1) **Event Instance 1** – *The 2nd industrial revolution* <Cause>
Event Instance 2 – *The killer fog that blanketed London* <Result>
Relation – `Causality` <Need to be predicted>

Recognizing event relations in an automatic way is a challenging task. It is because the query events are selected from different paragraphs in a document or even different documents, so that there is lack of explicit clue and shared context can be used for semantic relation analysis.

Statistics based inference is one of the promising solutions. It performs in a straight-forward manner: i) seeking for the similar events to the query events, ii) surveying the probability distribution of different types of relations over the similar events, and iii) assigning the most widely distributed relation to the query events. In order to fully implement the inference process, we need to address two crucial issues. One is to collect a large set of pairwise event instances whose relations are either previously known or explicitly signaled, such as the ones in (2). The other is to develop effective similarity measurement approaches, so as to retrieve the event instances similar to the query events.

(2) **Query Event 1** – *China's industrial development in the 21st century* <Cause>
Query Event 2 – *Heavy smog alerts issued for Beijing and other cities* <Result>
Relation – `Causality` <Previously Known>

Santa Fe, New Mexico, USA, August 20-26, 2018.

With regard to the first issue, we employ a connective based approach to collect explicitly related events. Current connective-based explicit relation recognition techniques (Pitler and Nenkova, 2009; Wu et al., 2017) have been proven effective in determining the explicit relations, with no less than 93% accuracy, for the sequential text structures connected by a connective. For example, a pair of clauses connected by the connective "*because*" can be determined to have a `causal` relation with a high level of confidence. This allows us to acquire numerous explicitly-related events from texts using a few carefully-selected connectives and simple patterns. Accordingly, we build a large-scale Textual Event Relation Bank (TERB) to support the relation inference.

We focus on the second issue in this paper, measuring the similarity between events. Recently, neural network has been successfully used in event-oriented semantic encoding to some extent (Nguyen and Grishman, 2016; Ghaeini et al., 2016; Feng et al., 2016; Peng et al., 2016; Liu et al., 2017; Chen et al., 2017), yielding substantial performance gains in the related information extraction tasks, such as event extraction (Doddington et al., 2004; Ahn, 2006) and nugget detection (Ellis et al., 2015). Semantic encoding enables the generation of a high-dimensional distributed representation for characterizing an event. So that it prompts semantic learning, computing and understanding at a very deep level. Undoubtedly, this can facilitate the acquisition of the "semantically-similar but pragmatically-different" event instances for the query events, such as those in (2).

Figure 1: Similar visual scenes

However, in our recent research on utilizing semantic similarity calculation, we fail to pass through a bottleneck that, for some query events, there doesn't exist any semantically-similar event instance in a finite dataset (e.g., TERB). It causes that the performance of the state-of-the-art approaches is actually far from what it should be. In order to overcome the problem, we propose to use visual scenes of events for similarity calculation. It is motivated by the fact that some semantically-dissimilar event instances may possess similar visual scenes with the query events. Figure 1 exhibits the scenes of the query events in (1) and that of the event instances in 3), where the visual scenes are similar (compared between the left and the right images), although the textual descriptions of the events are semantically different.

(3) **Event Instance 3** – *Pollution from steel mills blows over residential buildings* <Cause>
Event Instance 4 – *Mask wearing is in fashion* <Result>
Relation – `Causality` <Previously known>

In our experiments, images are taken as the visual scenes. On the basis, we introduce image captions into cross-media semantic matching, with the purpose of mining possible visual scenes by similarity measurement between query events and image captions. In addition, the Convolutional Neural Network (CNN) based image representation is utilized in visual scene matching. Over the ACE-R2, we compare our model with two fully-supervised discourse relation classification models, including Qin et al. (2016)'s CNN and Chen et al. (2016)'s Long-Short Term Memory (LSTM) based Recurrent Neural Network. Experimental results show that our minimally-supervised model slightly outperforms LSTM and obtain comparable performance with CNN.

In the rest of the paper, we overview the related work in section 2. And then we present the methodological framework in section 3, the caption based cross-media semantic matching in section 4 and image matching in section 5. Section 6 will give the TERB establishment method. In section 7, we evaluate the proposed method and analyze the experimental results. We conclude the paper in section 8.

2 Related Work

2.1 Causal and Temporal Event Relation Identification

So far, the study of event relation parsing mainly concentrates on identifying two kinds of relationships, causality and temporality respectively. The early work on causality identification can be traced back to

the use of lexical-syntactic patterns (Girju et al., 2002; Girju, 2003). Soon thereafter, Chang and Choi (2004) revise Girju et al. (2002)'s patterns using lexical pairs (LP) and cue phrases (e.g., *due to*). Besides they generalize the model for binary relation classification using the Bayes theorem. Abe et al. (2008) further use co-occurrence probability as the novel feature. Recently, scholars have made a great effort to model fine-grained causal relations (Inui et al., 2005), exploit the features for classification (Blanco et al., 2008), refine the patterns by syntactic and discourse parsing (Ittoo and Bouma, 2011; Do et al., 2011) and predict relations by semantic network (Radinsky et al., 2012).

Mani et al. (2006) and Lapata and Lascarides (2006) presented the first study on the temporal relation parsing. Both focus on the machine learning approaches. In the past decade, the SemEval (Verhagen et al., 2007; Pustejovsky and Verhagen, 2009) has promoted a great deal of experimental study, including on the grammatical, syntactic, semantic and ordering features (Bethard and Martin, 2007; Hepple et al., 2007; Puşcaşu, 2007; Bethard, 2013; Mirza and Minard, 2015; Caselli et al., 2015; Hashimoto et al., 2015). Meanwhile, temporal relation modeling has been implemented in different ways, such as sequence labeling, Markov logic networks and hybrid systems (Cheng et al., 2007; Min et al., 2007; Yoshikawa et al., 2009; UzZaman and Allen, 2010; Llorens et al., 2010; Velupillai et al., 2015).

2.2 Multi-class Discourse Relation Classification

In April 2006 (Prasad et al., 2007), the Penn Discourse Tree Bank (PDTB) was released as a corpus of discourse-level arguments as well as annotations of explicit and implicit relations. The PDTB relation scheme consists of 4 main relation classes and 16 sub-classes. Since it is released together with the corpus, a great deal of research has focused on the methodologies for multi-class relation classification.

Motivated by Marcu and Echihabi (2002)'s work, in the earlier study, both feature engineering and sophisticated machine learning dominated the field in a large region (Pitler and Nenkova, 2009; Lin et al., 2009; Louis et al., 2010; Park and Cardie, 2012; Rutherford and Xue, 2014).

Recently, it becomes increasingly popular to use neural networks for learning to classify discourse relations (Zhang et al., 2015; Qin et al., 2016; Chen et al., 2016; Qin et al., 2017; Liu and Li, 2016). Typically, Zhang et al (2015) propose a Shallow Convolutional Neural Network (SCNN) model, which is used by Ponti and Korhonen (2017) to identify contingent relation. Qin et al (2016) utilize CNN with a collaborative gated neural network (CGNN) for recognizing implicit relations. Chen et al (2016) develop a Gated Relevance Network (GRN) based on Bidirectional Long-Short Term Memory (Bi-LSTM) framework, combining bilinear model and single layer network for relevance measurement between arguments. Besides, the current work improves the classification performance of implicit relations by expanding the training data with connectives (Rutherford and Xue, 2015; Braud and Denis, 2016; Wu et al., 2017) or combining multiple corpora via multi-task learning (Liu et al., 2016).

3 Relation Inference Engine

In our statistical inference process, TERB is an indispensable knowledge base and needed to be build first. But in this section, we suppose that TERB has been established successfully, and focus on presenting the inference approach. TERB building will be treated as a separate work and presented in section 6.

3.1 Framework and Terminology

The input of the relation inference engine is a pair of query events, while the output is a relation type tag. The inference engine is constituted of three components, including Cross-Media Semantic Matching (CMSM), image matching and inference model (see the framework in Figure 2). In order to facilitate understanding of the following discussion, we first define the terminologies used as below.

Caption is the textual annotation of an image.

Mention is the textual description of an event.

Visual Scene is an image that best describes how an event happens as well as the surroundings. There is no regard to any concrete element or fact (such as who the participants are).

CMSM verifies whether an event mention has the consistent meaning with a scene, or in other word, the mention evokes the perception of the scene. In our method, CMSM plays an important role because

it helps transform the textual representation (i.e., mention) of an event to a visual version (scene), or vice versa. There are two CMSMs of different directions included in the inference process: forward CMSM and backward CMSM. They are methodologically the same, both measuring similarity between captions and mentions. The difference lies in the use of CMSM. The forward CMSM is used to transform mentions into scenes, while the backward CMSM is applied in a scene-to-mention direction.

Image Matching is put forth for calculating scene similarity. It is conducted between the scenes of the query events and that of the events in TERB. The events in TERB which have the similar scenes with the queries will be adopted, along with their explicit relations. They are used as the reference samples.

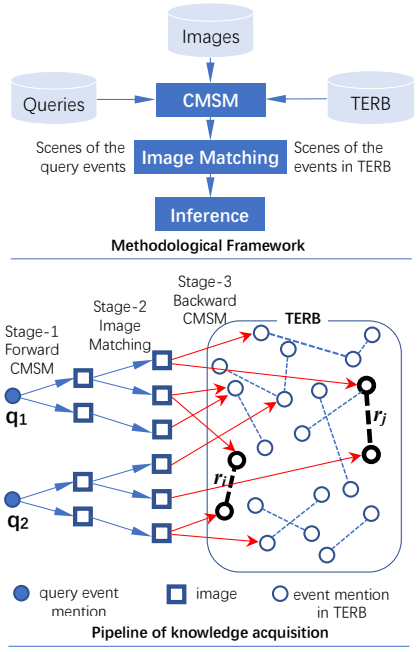

Figure 2: Framework and workflow

3.2 Pipeline for Reference Sample Acquisition

We acquire the reference samples by a three-stage information retrieval system, which consists of three successive one-to-many retrieval stages (see the pipeline in Figure 2):

Stage 1: Mention-to-Scene transformation

The forward CMSM is performed. It is used to retrieve top-n_1 most possible scenes of the query event in a large-scale image database. The images whose captions are most similar to the query event mention will be adopted. The image database (D) we use includes about 5 million images crawled from Wikipedia.

Stage 2: Scene-Scene matching

Each scene obtained in the first stage is used as a query of image search, where image matching is used. There are n_2 most similar images adopted from the image database D, and used as the similar scenes to that of the query event.

Stage 3: Scene-to-Mention transformation

The similar scenes are then used as queries. For each of them, the backward CMSM is performed, so as to acquire n_3 semantically-similar mentions in TERB.

By the knowledge acquisition, for a query event, we can obtain N (N=$n_1 \times n_2 \times n_3$) reference samples in TERB. Thus, given a pair of query events q_1 and q_2, we obtain a collection S of pairs of reference samples (in the size of $N \times N$). Most of the pairs have gone out of use in practice because they are irrelevant and fail to hold a relation. The rest will be reserved as the available reference samples. Their relations are named as reference relations (see r_i and r_j in Figure 2).

3.3 Statistical Inference

Given the set S of reference relations, we use the maximum likelihood estimation to speculate the relation r^* between the query events:

$$r^* = argmax\ p(r) \quad \exists r \in R \qquad p(r) = (\omega_r)^{-1} \times \frac{C(r)}{\sum_{r \in R} C(r)} \qquad \omega_r = \frac{\check{p}(r)}{\lambda_r} \tag{1}$$

where, R denotes all kinds of predefined relation types. We follow Hong et al. (2016)'s relation scheme to discrminate among different relation types. The function $C(r)$ computes the occurrence frequency of the relation r in S. The coefficient ω_r is prodced with a penalty factor λ_r and the prior probability $\check{p}(r)$ of r. The penalty λ_rs of different relation types are inconsistent and need to be fine-tuned on a development set. The prior probability $\check{p}(r)$ of every considered relation type need to be obtained on the training set beforehand. In this paper, we calculate $\check{p}(r)$ using the distribution of r in TERB.

4 Cross-Media Semantic Matching (CMSM)

We implement CMSM between a scene (image) and a mention as the semantic approximation calculation between the caption of the image and the mention. Thus it can be boiled down to a text matching problem.

Activation Function	Loss Function
$tanh_\theta(x) = \frac{e^{\theta^\top x} - e^{\theta^\top x}}{e^{\theta^\top x} + e^{\theta^\top x}}$	$L = -\sum_r y_r \cdot log(s_\theta(x)_r)$
Batch size: 256	**Epoch**: 5
Optimizer: Adadelta **Learning rate**: 10^{-3}	**Dropout ratio**: 0.5 (FC)

Table 1: Hyper-parameter settings for CMSM

Activation Function	Loss Function
$Relu_\theta(x) = ln(1 + e^{\theta^\top x})$	$L = -\sum_r y_r \cdot log(s_\theta(x)_r)$
Batch size: 256	**Epoch**: 74
Momentum: 0.9	**Padding**: 1 pixel
Optimizer: Adadelta **Learning rate**: 10^{-5}	**Dropout ratio**: 0.5 (FC1) **Dropout ratio**: 0.5 (FC2)

Table 2: Hyper-parameter settings for ConvNet

(Note: θ represents all the parameters and $s(*)$ is the ground truth (Vadapalli and Gangashetty, 2016))

For a caption and a mention, we encode each of them as a sentence-level embedding (Sen2vec). We calcualte the cosine similarity of the Sen2vecs and use it as the caption-mention approximation. CNN is utilized for generating the Sen2vecs. As usual, it produces the convolutional features on the concatenated word embeddings of the words in the input short text. There is only 1 hidden layer included in the network. Thus it fails to possess very deep-level perceptions of semantics. Undoubtedly, it can be enhanced by either adding more hidden layers to the network, or instead, using other state-of-the-art network models, such as attention based bidirectional LSTM (Zhou et al., 2016) or gated recurrent unit (Vadapalli and Gangashetty, 2016). In this paper, we choose to use a relatively simple model because we are more willing to verify the validity of the methodological framework.

The configuration of the employed CNN is presented as below: in the **input layer**, a short text (caption or mention) is represented as a fixed-size sequence of real numbers, involving 30 256-dimensional word embeddings. Zero padding is performed when the text length is smaller than 40, otherwise tail clipping. We follow Mikolov et al. (2013) to use skip-gram based word2vec to compute embeddings, and conduct training on the English articles in the latest 2015 Wikipedia dump (Dos Santos and Gatti, 2014). In the **hidden layer**, there are 128 (3×256) filters used for the convolutional computation with a stride of 1. This yields 28 128-dimensional feature vectors. Max pooling is then used to produce a lower dimensional (1×128) vector. As usual, we apply a dense layer to slightly increase the depth. And further, a dropout layer (rate=0.5) is used to produce a 64-dimensional vector. The vector produced in this way is specified as the semantic representation of the text. In the **output layer**, a fully-connected (FC) layer is used, followed by a 18-way softmax classification layer. We train the model on about 50 thousand short texts of 18 domains. Table 1 shows the parameter settings.

It is noteworthy that the domain classification has nothing to do with the task mentioned in this paper. What we really need in the training process is just the well-trained network. The network can be practically used to generate the sentence embeddings (i.e., the ones in FC layer) for captions and mentions.

5 Image Matching

Image matching is used to recognize similar visual scenes and thus enables the events of similar scenes to be acquired. Similarly, we apply the cosine similarity between image embeddings to align images. Simonyan and Zisserman (2014)'s ConvNet is employed to generate the image embeddings.

ConvNet provides an architecture for learning visual features. Each feature indicates a spatial concept of an image patch (only in the input layer) or a multiple-cell receptive field (in hidden layers), preserving the local information about the notions of left, right, top, down and center.

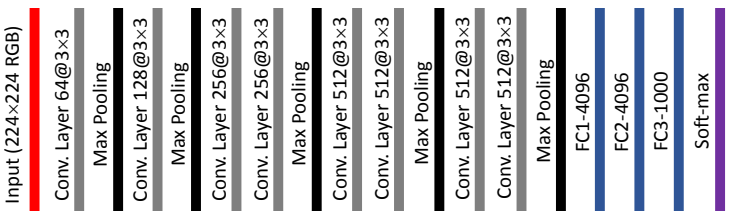

Figure 3: Structure of ImageNet (Plan-A)

In this paper, we follow Simonyan and Zisserman (2014)'s Plan-A, in which a relatively shallower ConvNet is established. The deeper versions in their other plans weren't taken into consideration. It is for the same reason that we mentioned earlier, evaluating the feasibility of our methodological framework when the models we use are weaker than the state of the art.

The ConvNet structure is presented as below and the parameter settings are listed in Table 2. In the **input layer**, a fixed-size 224×224 RGB image is input to the network. The preprocessing we do includes two aspects. One is to normalize images in batches by limiting the size of each to be uniformly 224×224 pixels. The other is to subtract the mean RGB value from each pixel. The mean RGB is computed on the training set. In the **hidden layers**, there are totally 8 convolutional layers deployed, along with 5 max-pooling layers. The number of filters in the convolutional layers is gradually increased (from 64 to 512) with depth. See the layout in Figure 3. In the **output layers**, there are 3 fully-connected (FC.) layers. The first two have 4,096 dimensions each. The third (FC3) is required to perform 1,000-way ILSVRC (Witten et al., 2016) classification during the training procedure and thus contains 1,000 dimensions. A non-linear softmax layer is deployed behind the FCs.

We train the network on ILSVRC-2012. There are about 5 million images used. In our experiments, we pass an image through the well-trained network and employ the FC3 layer as the image embedding. Instead of reproducing the network, we recommend the potential users to use the open source toolkit[1].

6 Textual Event Relation Bank (TERB)

TERB is an event and relation databank we build. There are about 0.74 million pairs of event mentions included in TERB. The mentions are automatically extracted in pairs from Gigaword corpus (Graff and Cieri, 2003). Each pair of events has been exclusively assigned with an exact relation. Below is a standard sample in TERB: <Event Instance 1: "*pollution emission level keeps rising*"> + **causal** relation + <Event Instance 2: "*mask wearing is in fashion*">.

We only take clause-level event mentions into consideration during the process of building TERB. And the eligible clauses for use are limited to the ones that contain a predicate. Syntactic parsing is used for clause segmentation and predicate identification (Björkelund et al., 2010).

There are three patterns used for pairwise mention extraction, including CEE, ECE and EEC, which are distinguishable by means of the position of a connective (C) relative to the neighbor event mentions (E). Below are the examples, where the words in bold font are connectives: $\{CEE-\textbf{\textit{Although}} < Clause1 > , < Clause2 >\}$; $\{ECE- < Clause1 >, \textbf{\textit{but}} < Clause2 >\}$; $\{EEC- < Clause1 >, < Clause2 >, \textbf{\textit{though}}\}$.

The connectives are the words that structurally link sentence constituents. They have been widely used as the reliable clues for explicit semantic relation resolution between text spans. For example, the connective "*because*" frankly signals a causal relation. Nowadays, the utilization of connectives contributes to the high accuracy of explicit relation recognition, reaching a score more than 93% (Pitler and Nenkova, 2009; Wu et al., 2017). Thus, for a pair of event mentions extracted by the patterns, we determine their explicit relation by the one-to-one correspondence between connectives and relation types.

Relational Types	**Num**
Expansion.Conjunctive (Cnj.)	74
Contingency.Conditional (Cnd.)	180
Comparison.Concessive (Cnc.)	1
Temporality.before/after (Baf.)	919
Temporality.during (Dur.)	129
Expansion.Confirming (Cnf.)	19
Contingency.Causal (Cus.)	505
Comparison.Contrastive (Cnt.)	60
Temporality.Equal (Equ.)	107
Coreferential (Cre.)	277

Table 3: Relation scheme

We employ 50 connectives which are elaborately collected from the PDTB corpus (Prasad et al., 2007). The relations they signal have been manually annotated beforehand and double-checked. We filter some ambiguous connectives before use because they generally signal different types of relations. For example, "*since*" may signal a causal relation with the meaning of "*because*", while in some cases, it signals a temporal relation with the meaning of "*from then on*".

7 Experimentation

7.1 Corpus, Settings and Evaluation

Corpus— We use Hong et al. (2016)'s ACE-R2 corpus in our experiments. Table 3 shows the relation scheme, which consists of 5 main types and 10 subtypes. ACE-R2 contains 2,271 pairs of news events.

[1]https://github.com/BVLC/caffe

Each is annotated with a sole relation. The mentions are selected from the Automatic Content Extraction (ACE) corpus (Doddington et al., 2004).

Settings— Both the CNN models and the captioning model that we use in the experiment have been pretrained with external data. What we need to fine-tune is the number of the reference samples (section 3.2), i.e., N, which is produced by the parameters n_1, n_2 and n_3 (N=$n_1 \times n_2 \times n_3$) in the three-stage knowledge acquisition process. A larger value of N will introduce many noises in our inference process. By contrast, a smaller value causes the lack of reference samples and thus the statistical uncertainty.

Evaluation— The methods we concern are evaluated by the metrics of macro-average Precision (Mac-P), Recall (Mac-R) and F-score (Mac-F). For a particular type t, the positive examples are defined as the event pairs that hold the relation t. Thus for t, the precision score is calculated as the ratio of the positive examples in all the output examples of type t. The recall is defined as the ratio of the output positive examples in all the ground-truth ones.

7.2 Compared Methods

Based on the framework mentioned in section 3, we implement an event relation predictor, named as **Holmes**. For the purpose of validating statistically non-random effect, Holmes is compared with the weighted random sampling (**Baseline 1**). By the baseline method, a test sample is most probably determined to hold one of the widely-distributed relations (such as Temporality). The distribution is computed over the development set. Second, Holmes is required to compete with a pure text based approach (**Baseline 2**). In this approach, the statistical inference (section 3.3) is still followed, and similarly to Holmes, the CNN based Sen2vec (section 3) is involved, and devoted to representing the query event mentions and those in TERB. But unlike Holmes, it skips the steps of CMSM and image matching, and instead, directly acquires n_{bas} similar events from TERB by sentence-level embedding similarity.

In addition, we compare Holmes with two discourse classification models, which are based on more general models and trained in a fully supervised fashion. One is Qin et al. (2016)'s **CNN** model. The other is Chen et al. (2016)'s bidirectional LSTM (**Bi-LSTM**) based recurrent model. There are two kinds of performance of the competitors are reported. One is achieved by training the competitors over the standard PDTB corpus (sections 1-20), which is consisted of no more than 6,234 handmade sentence-level argument pairs and relations. The other is achieved by training the competitors over the TERB corpus, a large-scale set of automatically-extracted mentions and explicit relations.

Most of the relation types in PDTB are compatible with those in ACE-R2 and TERB. For example, the `Temporality` has been divided in two subtypes, `Synchronous` and `Asynchronous`, which are compatible with the `Temproality.Equal&During` and `Temporality.Before&After`. However PDTB fails to include the `Coreference` relation. Therefore, it isn't considered in the experiments. Besides, in ACE-R2, the numbers of available instances of the subtypes `Confirming` and `Concessive` are far from large (see Table 3). This makes it difficult to develop Holmes with a high-level confidence. Therefore, the two types aren't taken into consideration too. Thus the total number of available instances in ACE-R2 is 1,974. We use 1,579 as the development set, occupying about 80 percent of all, while the rest (395) for test. We run 5-fold cross validation and report the best performance, while the performance in every validation experiment will be presented in the discussion subsection.

7.3 Experimental Results

Knowledge Acquisition Performance — In the development process, we fine-tune the parameters n_1, n_2 and n_3 for Holmes, and the parameter n_{bas} for the Baseline 2. The NDCG@N metric is used to access the quality of the obtained reference samples (i.e., the retrieved similar events). For the image based retrieval approach in Holmes, N is the product of n_1, n_2 and n_3, while for the text based approach in Baseline 2, N equals to n_{bas}. The high value of NDCG@N implies that most of the N references highly ranked by similarity scores are reliable, holding the ground-truth relation of the query events.

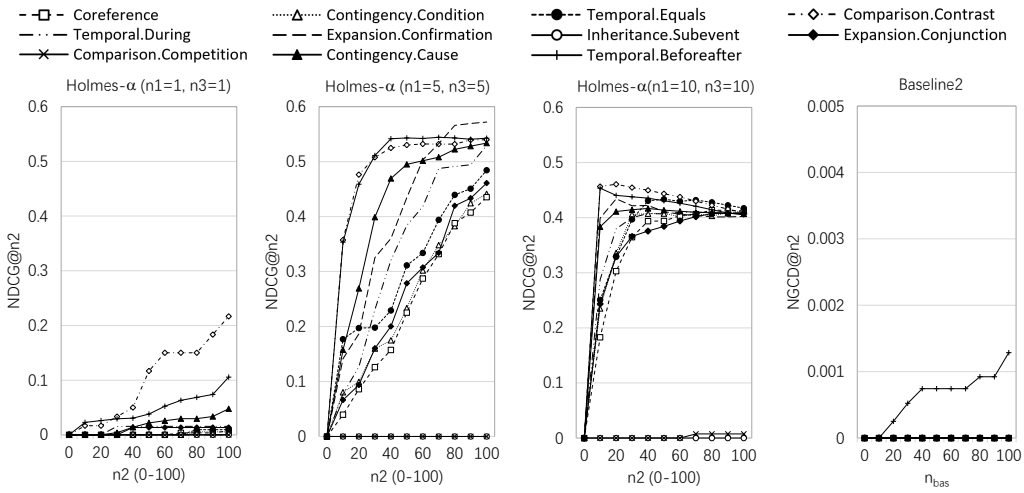

Figure 4: Partial development stages for Holmes-α

Type	Mac-P	Mac-R	Mac-F
Expansion	0.17	0.08	0.11
Contingency	0.82	0.80	0.81
Comparison	0.04	0.07	0.05

Table 4: Best Performance of Holmes for the three main relation types

Subtypes	Mac-P	Mac-R	Mac-F
Contingency.Cus	0.79	0.64	0.71
Contingency.Cnd	0.35	0.53	0.42

Table 5: Results on subtypes of `Contingency`

Subtypes	Mac-P	Mac-R	Mac-F
Temporality.Baf	0.79	0.97	0.87
Temporality.Equ&Dur	0.25	0.04	0.07

Table 6: Results on subtypes of `Temporality`

Figure 4 illustrates partial stages in the development process before the performance remains steady. For example, the subgraph 2 shows the changing tendency of NDCG when n_2 is gradually adjusted, and n_1 and n_3 are kept unchanged. It can be observed from the NDCG curves that the image based approach performs better than the text based (i.e., Baseline 2), obtaining more reliable reference samples. Using such samples, as presented below, we enable Holmes to achieve comparable performance to the sophisticated supervised learning models. It proves that the image based approach performs better than the text based approach in acquiring reference samples. Using such samples, as presented below, we enable the simple statistical inference to outperform some sophisticated supervised learning models.

On the basis, we fine-tune the penalty factor λ for different types of relations. In each-fold cross validation, the penalty factor of a particular relation type will be adopted if it effectively cooperates with the penalty factors of other relation types. The effectiveness is ensured by verifying whether the factors enable the recognizer to achieve the best performance on the development set. We have made the source codes, penalty factors and datasets publicly available[2], so as to enable the reproduction of the whole experiments.

Relation Recognition Performance — We test Holmes by setting the parameters n_1, n_2 and n_3 as 10, 85 and 10. Table 4 shows the performance for the three main relations `Contingency`, `Expansion` and `Comparison`. It is the best performance Holmes achieves in the 5-fold cross validations. Note that the performance for the `Temporal` relation type is evaluated separately and only a 2-way classification is conducted for its subtypes. It is because that every event pair can be regarded to be related temporally, although some of relations fail to be annotated in ACE-R2. The lack of annotations on `Temporality` definitely causes biased assertions on the performance of automated relation prediction.

Table 8: Evaluated by Average Macro-F

It is observed that Holmes precisely predicts the `Contingency` relation. Most of the contingently-related instances have been successfully recalled. By contrast, Holmes performs much worse for `Expansion` and `Comparison`. We overview the errors and analyze the reasons as below.

Due to the omission of `Expansion.Confirming`, the performance of Holmes on `Expansion` actually derives from that on `Expansion.Conjunctive`. In general, `Conjunction` appears as a rhetoric method. By `Conjunction`, a series of similar events can be enumerated, such as *earthquake*, *tsunami* and *storm*. Co-occurrence probabilities of such events play important roles for predicting `Conjunction`. However, there are few connectives can be used for pursuing the co-occurred events or they are extraordinarily general. For example, the connective "*and*" is frequently used to signal the co-occurred events, but frankly it nearly connects kinds of linguistic units or even acts as a pause from the perspective of mood. If we use "*and*" to collect sample events which hold conjunctive relations, TERB will be full of pseudo-instances, such as "*sunshine **and** beach*". This will reduce the precision more seriously. By contrast, if we neglect a connective "*and*", there will be lack of available sample events. This inevitably results in the incomplete statistics for the frequently-cooccurred events. We didn't overcome the bottleneck in this paper and use no more than 6 uncommon connectives to collect the sample events. Both the diversity and scale of the events are far from expectation. This makes it difficult to effectively recognize the `Conjunctive` relationship using a statistical approach.

We encounter a similar problem when treating with `Comparison`. A connective like "*than*" is effective to signal a pair of `Contrastive` events. However, due to the limitation of literal expression, in general, such event mentions aren't directly connected by "*than*", but instead the concrete elements in the events are. For example, in a story about *economic competition*, the contrastive events are introduced respectively in different sentences, on the contrary the *profit forecasts* in the events are connected by *than* in a sentence. The neglect of commonly-used connectives (e.g., "*than*") during TERB building causes the lack of sample events. Similarly, the statistic strategy we use fails to perform better under this condition.

Table 5 shows the performance of Holmes on the `Contingent` sub-type relations, i.e., `Cause` and `Condition`. It can be observed that Holmes is adept in predicting causal relations. Table 6 exhibits the performance on the `Temporal` sub-type relations, i.e., `Before&After` and `Equal&During`. It is illustrated that Holmes effectively predicts the synchronous events, though fails to infer the asynchronous.

7.4 Discussion

We carefully evaluate Holmes and the competitors with the general Macro F and average Macro F scores respectively. The former is calculated with the average Macro P and Macro R on the concerned relation types, while the latter is the average value of Macro F on the types. The average Macro F score plays a role of assistance because it is able to reveal the unbalance problem. If a system shows significantly different performance on different types of relations. the average Macro F will be substantially lower than the general. Tables 7 and 8 respectively exhibit the performance of the entrants for the 3 main relation types (3-way), `Temporal` subtypes (Temp) and `Contingent` subtypes (Cont). The tables only exhibit the best performance the competitors achieves through the 5-fold cross validations. The performance in every validation experiment is shown in Figure 5 and 6.

It can be observed that Holmes performs worse than CNN and LSTM for the 3-way main relation classification. Nevertheless, Holmes obtains a smaller gap between general and average Macro F scores. Besides, it achieves a comparable performance to the well-trained CNN and LSTM for the fine-grained sub-type relations. For the case of `Contingency`, Holmes reaches the top together with LSTM. Note

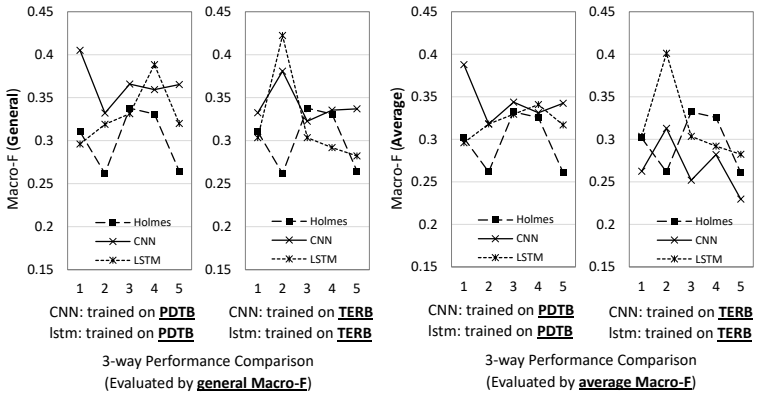

Figure 5: Cross validation for main relation types (`Contingency`, `Comparison` and `Expansion`)

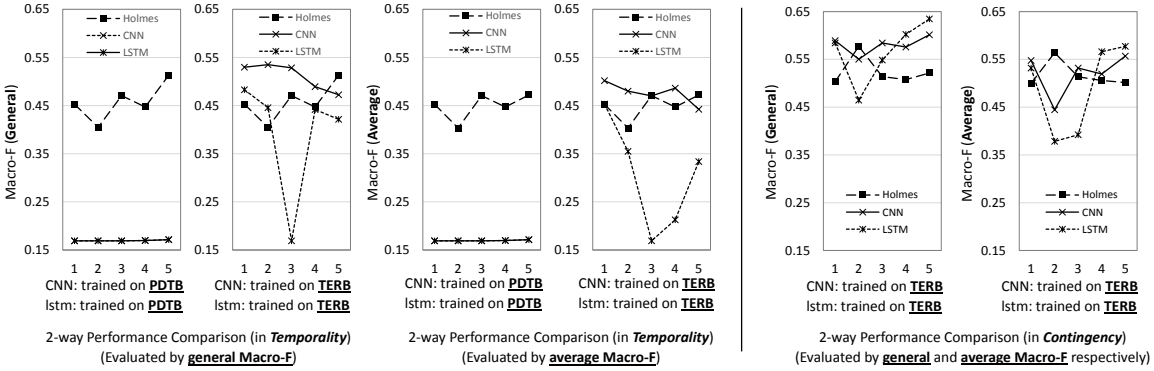

Figure 6: Cross validation for the subtypes in `Temporality` and `Contingency`

that CNN and LSTM fail to be trained on PDTB for classifying the `Contingent` sub-type relations. It is because PDTB contains only one implicit conditionally-related argument pair. The scale of training data and domain adaptation impose great influences on the performance. For example, for the subtypes, CNN and LSTM perform significantly worse than Holmes when trained on PDTB. In addition, Holmes outperforms Baseline 2. It demonstrates that, in TERB, there is lack of semantically-consistent events to the queries. Holmes bypasses the bottleneck, using CMSM and image matching to acquire visually-similar events. This contributes to the reference sample based statistical inference.

When we look through the 5-fold cross validation, we find that Holmes actually performs better than expectation. As shown in Figures 5 and 6, Holmes seldom shows an exceptionally high or an unusually low Marcro F score. And the mean level of Macro F scores of Holmes appears to be no less than that of LSTM for the subtypes of both `Temporality` and `Contingency`.

8 Conclusion

We demonstrate that the use of images also contributes to knowledge acquisition in the field of linguistic computing. By image matching, we open up a new perspective for the identification of similar events, i.e., measuring the similarity of visual scenes. On the basis, we have successfully acquired a variety of events which have comparable scenes with the queries. Using the obtained events and their explicit relations, we enable a simple statistical inference model to achieve competitive performance for event relation recognition. In the future we will introduce active learning into the refinement of the collected event instances, and expand the existing training data to strengthen the supervised classification models.

Abstract

In this paper, we describe *TextEnt*, a neural network model that learns distributed representations of entities and documents directly from a knowledge base (KB). Given a document in a KB consisting of words and entity annotations, we train our model to predict the entity that the document describes and map the document and its target entity close to each other in a continuous vector space. Our model is trained using a large number of documents extracted from Wikipedia. The performance of the proposed model is evaluated using two tasks, namely fine-grained entity typing and multiclass text classification. The results demonstrate that our model achieves state-of-the-art performance on both tasks. The code and the trained representations are made available online for further academic research.

1 Introduction

The problem of learning distributed representations (or embeddings) from a knowledge base (KB) has recently attracted considerable attention. These representations enable us to use the large-scale, human-edited information of a KB in machine learning models, and can be applied in various natural language tasks such as entity linking (Hu et al., 2015; Yamada et al., 2016; Yamada et al., 2017), entity search (Hu et al., 2015), and link prediction (Bordes et al., 2013; Wang et al., 2014).

In this paper, we describe *TextEnt*, a simple neural network model that learns distributed representations of entities and documents from a KB. Specifically, given a document in a KB consisting of words and *contextual* entities (i.e., entities referred from entity annotations in the document), our model predicts the *target* entity explained by the document (see Figure 1), and maps the document and its target entity close to each other in a continuous vector space. Here, words, contextual entities, and target entities are mapped into continuous vectors that are updated throughout the training. In this study, we train the model using documents retrieved from Wikipedia.

One key characteristic of our model is that it enables us to combine the semantic signals obtained from both words and entities in a straightforward manner. The main motivation for using entities in addition to words is to address the problems of ambiguity (i.e., the same words or phrases may have different meanings) and variety (i.e., the same meaning may be expressed using different words or phrases) in natural language. For example, the word *Washington* is ambiguous because it can refer to a US state, or the capital city of the US, or the first US president *George Washington*, and so on. Further, *New York* is sometimes referred to as *NY* or by its nickname, the *Big Apple*. Obviously, entities do not have these problems, because they are uniquely identified in the KB.

To evaluate our model, we address two important tasks using the proposed representations. Firstly, we consider a fine-grained entity typing task (Yaghoobzadeh and Schutze, 2015) to evaluate the quality of the learned entity representations. In this task, the aim is to infer one or more types of each entity (e.g., *athlete*, *airport*, *sports_team*) from a predefined type set. We perform this task using the simple multilayer perceptron (MLP) classifier with the learned entity representations as features. The results show that our method outperforms the state-of-the-art methods by a wide margin.

Proceedings of the 27th International Conference on Computational Linguistics, pages 190–201
Santa Fe, New Mexico, USA, August 20-26, 2018.

Saturn is the sixth planet from the Sun and the second-largest in the Solar System, after Jupiter. It is a gas giant with an average radius about nine times that of Earth.

Contextual entities: *Planet, Sun, Solar System, Jupiter, Gas giant, Earth*

Target entity: *Saturn*

Figure 1: Example of a KB document with entity annotations.

Secondly, we consider a multiclass text classification task, which aims to classify documents into a set of predefined classes. This task examines the ability of our model as a generic encoder of arbitrary documents. One important approach adopted here is that we automatically annotate entities appearing in the target documents using a publicly available entity linking system and encode the documents to the document representations in the same manner as the documents in the KB. For this task, the logistic regression classifier is applied to the document representations. Because of the quality of semantic signals obtained from the entities, our method outperforms strong state-of-the-art methods on two popular datasets (i.e., the 20 newsgroups dataset (Lang, 1995) and R8 dataset (Debole and Sebastiani, 2005)). To facilitate further research, our code and the trained representations are available online at `https://github.com/studio-ousia/textent/`.

Our contributions can be summarized as follows:

- We propose *TextEnt*, a simple neural network model that learns distributed representations of entities and documents from a KB. Given a document in a KB consisting of words and contextual entities, our model learns the representations by predicting the target entity explained by the document (see Figure 1). We train our model using large-scale documents extracted from Wikipedia.
- Our proposed model allows us to effectively combine the semantic signals retrieved from both words and entities in a straightforward manner. We demonstrate the effectiveness of this feature by addressing two important tasks: fine-grained entity typing and text classification. Despite the simplicity of our approach, we achieve state-of-the-art results in both tasks.
- We have published our code and the trained representations online to facilitate further academic research.

2 Our Method

In this section, we describe our approach of learning distributed representations of entities and documents from a KB.

2.1 Model

Given a document D in a KB consisting of a set of words $w_1, ..., w_N$ and a set of contextual entities $e_1, ..., e_K$, we train our model to predict the target entity that the document is explaining. We first derive two vector representations of document D: the word-based representation $\mathbf{v}_{D_w}$ and the contextual entity-based representation $\mathbf{v}_{D_e}$. For simplicity, we compute $\mathbf{v}_{D_w}$ and $\mathbf{v}_{D_e}$ by averaging the vector representations of words and those of contextual entities, respectively.

$$\mathbf{v}_{D_w} = \frac{1}{N}\sum_{n=1}^{N}\mathbf{a}_{w_n},\ \mathbf{v}_{D_e} = \frac{1}{K}\sum_{n=1}^{K}\mathbf{b}_{e_n}, \tag{1}$$

where $\mathbf{a}_w \in \mathbb{R}^d$ and $\mathbf{b}_e \in \mathbb{R}^d$ are the vector representations of words and contextual entities, respectively.

We define a probability that represents the likelihood of entity e_t being the target entity of document D as the following softmax function:

$$P(e_t|D) = \frac{\exp({\mathbf{c}_{e_t}}^{\top}\mathbf{v}_D)}{\sum_{e' \in E_{KB}}\exp({\mathbf{c}_{e'}}^{\top}\mathbf{v}_D)}, \tag{2}$$

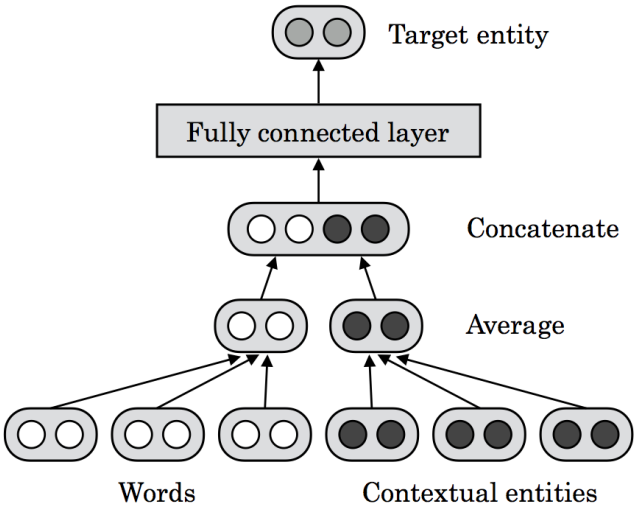

Figure 2: Model architecture of TextEnt.

where E_{KB} is a set of all entities in the KB, $\mathbf{c}_e \in \mathbb{R}^d$ denotes the vector representation of target entity e, and $\mathbf{v}_D \in \mathbb{R}^d$ is the vector representation of document D.

Here, $\mathbf{v}_D$ is computed using a fully connected hidden layer with $\mathbf{v}_{D_w}$ and $\mathbf{v}_{D_e}$ as inputs:

$$\mathbf{v}_D = \mathbf{W}[\mathbf{v}_{D_w}, \mathbf{v}_{D_e}] \tag{3}$$

where $\mathbf{W} \in \mathbb{R}^{d \times 2d}$ is a weight matrix, and $[\mathbf{v}_i, \mathbf{v}_j]$ is the concatenation of $\mathbf{v}_i$ and $\mathbf{v}_j$. This layer projects the input vector ($[\mathbf{v}_{D_w}, \mathbf{v}_{D_e}]$) down to d dimensions, and captures the interactions between $\mathbf{v}_{D_w}$ and $\mathbf{v}_{D_e}$.

We use the categorical cross-entropy loss to train the model:

$$\mathcal{L} = -\sum_{(D,e_t)\in\Gamma} \log P(e_t|D), \tag{4}$$

where Γ represents a set of pairs consisting of a document D and its target entity e_t in the KB.

When training our model, the denominator in Eq. (2) is computationally expensive because it involves summation over all KB entities. To address this, we use negative sampling (Mikolov et al., 2013b); specifically, we replace E_{KB} in Eq. (2) with a set consisting of the target entity e_t and k randomly chosen negative entities. Furthermore, to avoid overfitting, we use *word dropout* (Iyyer et al., 2015), which randomly excludes words and contextual entities with a probability p during the training.

We also test models trained using only words (denoted by *TextEnt-word*) and only contextual entities (denoted by *TextEnt-entity*) in our experiments. These variants are created by replacing $\mathbf{v}_D$ in Eq. (2) with $\mathbf{v}_{D_w}$ (*TextEnt-word*) and $\mathbf{v}_{D_e}$ (*TextEnt-entity*). Hereafter, our original model is referred to as *TextEnt-full*.

2.2 Dataset

We trained our model using documents obtained from the April 2016 version of the DBpedia NIF abstract dataset[1], which contains the texts and entity annotations in the first introductory sections of Wikipedia articles.

For computational efficiency, we limited the size of our dataset. In particular, we excluded documents with fewer than five incoming links from other documents if the corresponding entity of the document is not contained in the dataset used in our fine-grained entity typing experiments, presented in Section 3.1. As a result, the number of target documents was 702,388.

We also modified all words to lowercase, and excluded words that make fewer than five appearances and contextual entities that make fewer than three appearances in the documents. Thus, the final dataset contained 242,771 unique words and 327,263 unique contextual entities.

[1] `http://wiki.dbpedia.org`

2.3 Parameters

The parameters to be trained in our model are the weight matrix $\mathbf{W}$ in the fully connected layer and the vector representations of the words, contextual entities, and target entities. The weight matrix was initialized at random and the vector representations were initialized using pre-trained representations. The pre-trained representations of words and entities were learned jointly using the skip-gram model (Mikolov et al., 2013a; Mikolov et al., 2013b) with negative sampling[2]. The corpus was automatically generated by replacing the name of each entity annotation in the Wikipedia documents with a unique identifier of the entity corresponding to that annotation. Note that we used the same pre-trained entity representations to initialize the representations of the contextual entities and the target entities. Additionally, we used all Wikipedia documents obtained from the July 2016 version of Wikipedia dump[3] to build the corpus.

2.4 Implementation Details

The proposed model was implemented using PyTorch[4] and trained with mini-batch stochastic gradient descent (SGD). The mini-batch size was fixed at 100 and the learning rate was automatically controlled by Adadelta (Zeiler, 2012). We trained the model by iterating over the documents in the KB in random order for 50 epochs[5]. For computational efficiency, we used only the first 2,000 words and first 300 entities in the documents. The training took approximately 25 h on an NVIDIA GTX 1080 Ti GPU. Regarding the other hyper-parameters, the representations were set to have $d = 300$ dimensions, the size of the negative entities was $k = 100$, and the dropout probability was set to $p = 0.5$, as recommended in Srivastava et al. (2014)

3 Experiments

To evaluate the models described in the previous section, we conducted fine-grained entity typing and text classification tasks using the learned representations. A description of each task is given in the following subsections. Finally, we qualitatively analyze the learned representations.

3.1 Fine-grained Entity Typing

This section describes the task of fine-grained entity typing (Yaghoobzadeh and Schutze, 2015; Neelakantan and Chang, 2015; Yaghoobzadeh and Schütze, 2017) using the entity representations learned by our proposed models. The aim of this task is to assign each entity with one or more fine-grained types such as *musician* and *film*. Because an entity typing model is capable of predicting the entity types that are missing from the KB, this can be seen as a *knowledge base completion* problem. The task is important because entity type information is often missing from KBs, but is known to be beneficial for various downstream natural language tasks such as entity linking (Ling et al., 2015), coreference resolution (Hajishirzi et al., 2013), and semantic parsing (Liu et al., 2015).

Setup

Our experimental setup follows that of Yaghoobzadeh and Schutze (2015). In particular, we use their entity dataset of 201,933 Freebase[6] entities mapped to 102 entity types based on the FIGER type set (Ling and Weld, 2012). The dataset consists of a training set (50%), development set (20%), and test set (30%). Because the dataset is constructed based on Freebase, we preprocessed the data by mapping each entity to the corresponding entry in Wikipedia and excluded those entities that did not exist in Wikipedia.[7] As a result, we successfully mapped approximately 92% of the entities to Wikipedia, and obtained training,

[2]We used the skip-gram model implemented in the open-source Gensim library with $size = 300$, $window = 10$, $negative = 15$, $min\_count = 3$, and $iter = 5$. Default values were used for other parameters.

[3]We obtained the Wikipedia dump from Wikimedia Downloads: `https://dumps.wikimedia.org/`

[4]`http://pytorch.org`

[5]We experimented using 10, 20, 30, and 50 epochs. All numbers achieved similar performance in our experiments. We used the model trained for 50 epochs because it achieved the best P@1 performance in our fine-grained entity typing task.

[6]`https://developers.google.com/freebase/`

[7]We used the *wikipedia.en_title* property contained in the Freebase dump to create the mapping.

development, and test sets containing 93,350, 37,036, and 55,715 entities, respectively. We publicized the dataset and the code used to generate the dataset at `https://github.com/studio-ousia/textent/`.

Following Yaghoobzadeh and Schutze (2015), we evaluated the models using ranking and classification measures. The ranking measures test how well a model ranks entity types. In particular, we ranked the entity types based on the probabilities assigned by the model and evaluated the ranked list using the precision at 1 (P@1) and breakeven point (BEP)[8].

The classification measures evaluate the quality of the thresholded assignment decisions of a model. The assignment decisions are based on thresholding the probability assigned to each type. The threshold is selected per type by maximizing the F1 score of entities assigned to the type in the development set. We used the accuracy (an entity is correct if all its types and no incorrect types are assigned to it), micro-average F1 (F1 score of all type–entity assignment decisions), and macro-average F1 (F1 score of types assigned to an entity, averaged over entities). These ranking and classification measures are exactly the same as those used in Yaghoobzadeh and Schutze (2015).

Method

We used an MLP classifier with the entity representations as inputs to predict the probability of entity e being a member of type t in the set of possible types T. In particular, we used an MLP with a single hidden layer and the tanh activation function, and an output layer that contains, for each possible type $t \in T$, a logistic regression classifier that predicts the probability of t:

$$\big[P(t_1|e), ..., P(t_{|T|}|e)\big] = \sigma\big(\mathbf{W}_o \, tanh\,(\mathbf{W}_h \mathbf{c}_e)\big), \tag{5}$$

where $\mathbf{c}_e \in \mathbb{R}^d$ is the vector representation of entity e, σ is the sigmoid function, and $\mathbf{W}_h \in \mathbb{R}^{h \times d}$ and $\mathbf{W}_o \in \mathbb{R}^{|T| \times h}$ are the weight matrices corresponding to the hidden layer and the output layer, respectively. The model was trained to minimize the binary cross-entropy loss summed over all entities and types:

$$-\sum_e \sum_t \big(y_{e,t} \log p_{e,t} + (1 - y_{e,t}) \log(1 - p_{e,t})\big), \tag{6}$$

where $y_{e,t} \in \{0, 1\}$ and $p_{e,t}$ denote the ground-truth label and predicted probability, respectively, of entity e being type t. The parameters in $\mathbf{W}_h$ and $\mathbf{W}_o$ are updated in the training stage. Note that the model described here is equivalent to that proposed in Yaghoobzadeh and Schutze (2015).

The model was trained using mini-batch SGD, with the learning rate controlled by Adam (Kingma and Ba, 2014) and the mini-batch size set to 32. The model was trained using the training set and evaluated using the test set. Following Yaghoobzadeh and Schutze (2015), the number of hidden units was set to 200. We also measured P@1 on the development set to locate the best epoch for testing.

Baselines

The performance of our models is compared with that of the following three entity representation models.

- **Figment-GM** (Yaghoobzadeh and Schutze, 2015) is based on the skip-gram model (Mikolov et al., 2013a; Mikolov et al., 2013b) trained using a large corpus with automatically generated entity annotations (i.e., FACC1 (Gabrilovich et al., 2013)). In this experiment, we used the entity representations publicized by the authors[9].

- **Skip-Gram-Wiki** is equivalent to Figment-GM, except that Wikipedia is used as the entity-annotated corpus. This model is also the same as our pre-trained representations described in Section 2.3.

- **Wikipedia2Vec** (Yamada et al., 2016) extends the skip-gram model to learn entity representations based on the contextual words of link anchors in Wikipedia and the internal link structure

[8] BEP is the F1 score at the point in the ranked list at which the precision and recall have the same value.

Table 1: Results of the entity typing task.

of Wikipedia entities. We used the entity representations trained using the code publicized by the authors[10] and the Wikipedia dump used to train the Skip-Gram-Wiki model.[11]

We used the entity typing method presented above with the entity representations of each baseline model as inputs. Note that, because the Wikipedia2Vec and Skip-Gram-Wiki models were trained using the link anchors in Wikipedia, they do not contain entities that do not appear or are very rare as the link anchor destinations in Wikipedia. To address this, we evaluated these models in the following two settings: (1) using only the entities that exist in the model, and (2) using all entities, including non-existent ones. In the latter setting, we used the zero vector as the representation of non-existent entities. Similar to the latter setting, the former is not a fair comparison because it is typically more difficult to learn good entity representations of rare entities than those of popular entities (Yaghoobzadeh and Schutze, 2015).

Results

Table 1 compares the results of our models with those of the baseline models. Our TextEnt-full model outperforms the baseline models in all measures. In particular, the TextEnt-full model achieves a strong P@1 score of 93.2%, which clearly shows the effectiveness of our entity typing model for many downstream NLP tasks. Moreover, the TextEnt-full model generally performs better than both the TextEnt-word and TextEnt-entity models. This demonstrates the effectiveness of combining the semantic signals obtained from words and entities.

3.2 Multiclass Text Classification

This section describes the multiclass text classification task, which tests the ability of our proposed representations to encode arbitrary documents. Our key assumption here is that, because our proposed representations are trained to predict the corresponding entity of a given document in the KB, they can also classify non-KB documents into classes that are much more *coarse-grained* than entities.

Setup

Following Jin et al. (2016), we used two standard text classification datasets: the 20 newsgroups dataset[12] (denoted by 20NG) (Lang, 1995) and the R8 dataset (Debole and Sebastiani, 2005). The 20NG dataset consists of 11,314 training documents and 7,532 test documents retrieved from 20 different newsgroups. The documents are partitioned nearly equally across the classes. The R8 dataset contains documents from the eight most frequent classes of the Reuters-21578 corpus (Lewis, 1992), which consists of labeled news articles from the 1987 Reuters newswire. The R8 dataset contains 5,485 documents for training and 2,189 documents for testing. Unlike the 20NG dataset, the R8 dataset is imbalanced; the largest class contains 3,923 documents and the smallest class contains 51 documents. For both datasets, we report the

[10] `https://github.com/wikipedia2vec/wikipedia2vec`

[11] We trained the representations with $dim\_size = 300$, $window = 10$, $negative = 15$, $min\_entity\_count = 3$, and $iteration = 5$. Default values were used for other parameters.

[12] We used the *by-date* version of the dataset obtained from `http://qwone.com/~jason/20Newsgroups/`.

accuracy and macro-average F1 score. Furthermore, the development set was formed by selecting 10% of the documents in the training set at random for both datasets.

As preprocessing, we lowercased all words and removed words and entities appearing fewer than five times. Furthermore, we automatically annotated entity mentions in the documents using an entity linking system. In particular, we used TAGME[13] (Ferragina and Scaiella, 2010), a state-of-the-art entity linking system that is freely available and has been frequently used in recent studies (Xiong et al., 2016; Hasibi et al., 2016). However, TAGME returned many irrelevant entity mentions that would act as noise (e.g., *I like* refers to an entity *I Like (Keri Hilson song)*). Thus, we excluded mentions having relevance scores[14] of less than 0.05[15].

Method

For this task, we simply stacked a logistic regression layer onto our TextEnt model to classify documents into the predefined classes. First, we encoded each document (words with entity annotations) and used the resulting document representation (i.e., $\mathbf{v}_D$ in the TextEnt-full model, $\mathbf{v}_{D_w}$ in the TextEnt-word model, and $\mathbf{v}_{D_e}$ in the TextEnt-entity model) as the feature of the logistic regression classifier.

We trained the classifier using the training set of each dataset, and evaluated the classification performance using the corresponding test set. The classifier was trained using mini-batch SGD, with the learning rate controlled by Adam (Kingma and Ba, 2014) and the mini-batch size set to 32. The accuracy on the development set of each dataset was used to locate the best epoch for testing.

Baselines

We adopted the following state-of-the-art models as our baselines.

- **BoW-SVM** is based on a linear support vector machine (SVM) classifier with bag-of-words (BoW) features as inputs. This model outperforms the conventional naive Bayes model (Jin et al., 2016).

- **BoE** (Jin et al., 2016) is an extension of the skip-gram model that learns different word representations per target class. A linear model based on learned word representations was used to classify documents. This model achieves state-of-the-art results on both the 20NG and R8 datasets.

We also used the **Wikipedia2Vec** and **Skip-Gram-Wiki** models described in Section 3.1 as baselines. For this experiment, we simply input the representations of words and entities in these models to our text classification model described in the previous section.

Results

Table 2 compares the results of our proposed models with those of the baseline models. We obtained the BoW-SVM and BoE results from Jin et al. (2016). Our TextEnt-full model outperforms the state-of-the-art models in terms of accuracy and macro F1 score on both the 20NG and R8 datasets. Furthermore, similar to the results of our previous experiment, the TextEnt-full model generally performs better than both the TextEnt-word and TextEnt-entity models. This shows that combining semantic signals obtained from words and entities is also beneficial for text classification tasks.

Furthermore, we conducted a detailed comparison of the BoW-SVM model, BoE model, and TextEnt-full model using the class-level F1 scores on the 20NG dataset (Table 3) and the R8 dataset (Table 4). On the 20NG dataset, our model achieves the best scores in more than half of the classes and provides comparable performance in the other classes. Moreover, our model achieves strong performance in classes with relatively few documents on the R8 dataset. This is because our model successfully captures the strong semantic signals that can only be obtained from entities.

4 Qualitative Analysis

To investigate how our model encodes documents and entities into the same continuous vector space, we extracted five example sentences from the 20NG dataset and encoded each sentence into a vector using our model. The closest entities to this vector based on the cosine similarity are presented in Table 5. We automatically annotated the entity mentions using TAGME[16], and fed the words and detected entities into the TextEnt-full model. Table 5 presents the sentences, nearest entities, and their corresponding classes in the 20NG dataset. Our model successfully encodes the sentences into vectors that are close to their relevant entities. For example, all nearest entities of the first sentence "*At one time there was speculation that the first spacewalk (Alexei Leonov?) was a staged fake*" are strongly related to the historic Soviet space program. Similar results can be observed in the other four examples.

[13]We used the public Web API service available at `https://services.d4science.org/`.

[14]We used the ρ scores assigned by TAGME.

[15]Excluding entity mentions using the relevance scores is the recommended practice described in the documentation: `https://services.d4science.org/web/tagme/documentation`

[16]We used the same configuration as described in Section 3.2.

Class	Count	SVM	BoE	TextEnt

5 Related Work

In recent years, various models for computing distributed representations of text (e.g., sentences and documents) have been proposed (Le and Mikolov, 2014; Kiros et al., 2015; Wieting et al., 2016; Hill et al., 2016). These models typically use large, unstructured corpora for training; however, certain models attempt to learn text representations from structured data. For instance, Hill et al. (2016) proposed a neural network model that learns text representations from online public dictionaries by predicting each dictionary word from its description. Further, Wieting et al. (2016) used a large set of paraphrase pairs obtained from the Paraphrase Database (Ganitkevitch et al., 2013) to learn text representations.

A number of recent models have attempted to learn distributed representations of entities from a KB. For example, Hu et al. (2015) extended the skip-gram model (Mikolov et al., 2013a) to learn entity representations using the hierarchical structure of the KB, and Li et al. (2016) modified the model by Hu et al. to learn both the category representations and entity representations using the category information of the KB. Additionally, *relational embedding* models (Bordes et al., 2013; Wang et al., 2014; Lin et al., 2015) learn the entity representations for link prediction tasks.

Furthermore, some models learn the representations of both words and entities from the KB. A simple method reported in the literature (Yaghoobzadeh and Schutze, 2015; Yamada et al., 2017) is used to derive the pre-trained representations in this study (i.e., preprocessing an entity-annotated corpus by replacing the name of each annotation with the unique identifier of the entity and feeding the corpus into a word embedding model (e.g., skip-gram)). Yamada et al. (2016) proposed Wikipedia2Vec, which extends this idea by using neighboring entities in the internal link graph of the KB as additional contexts for training the model. Note that we used Wikipedia2Vec as a baseline method in the two experiments

conducted in this study. Similarly, in their subsequent work (Yamada et al., 2017), they proposed a neural network model that takes entity-annotated text as input and learns word and entity representations by predicting the annotated entities contained in each text. Furthermore, Mancini et al. (2017) proposed a model that maps words and entities in a lexical dictionary (i.e., BabelNet (Navigli and Ponzetto, 2012)) to a single vector space by extending the CBOW model. Unlike our proposed model, these models require users to design a composition function (e.g., vector averaging) to model the semantics of a document using words and entities in it. Moreover, we showed that our approach is highly effective for the two important tasks of fine-grained entity typing and multiclass text classification.

6 Conclusions

In this paper, we described *TextEnt*, a simple neural network model that learns distributed representations of entities and documents from large-scale KB descriptions. We evaluated the performance of the proposed model on fine-grained entity typing and text classification tasks, and achieved state-of-the-art results in both cases, which clearly demonstrates the effectiveness of our approach. In future work, we will explore the applicability of our model to broader NLP tasks such as entity search and KB-based question answering.

Abstract

We present domain independent models to date documents based only on neologism usage patterns. Our models capture patterns of neologism usage over time to date texts, provide insights into temporal locality of word usage over a span of 150 years, and generalize to various domains like News, Fiction, and Non-Fiction with competitive performance. Quite intriguingly, we show that by modeling only the distribution of usage counts over neologisms (the model being *agnostic* of the particular words themselves), we achieve competitive performance using several orders of magnitude fewer features (only 200 input features) compared to state of the art models some of which use 200K features.

1 Introduction

Determining when a document is written is an important task in historical linguistics and temporal information retrieval. For instance, several works attempt to date historical biblical texts like the *The Book of Isiah* (Rooker, 1996; Ehrensvärd, 1997; Hurvitz, 2000; Young and Rezetko, 2016) or ancient texts like *Beowoulf* (Chase, 1997). Likewise, in the field of information retrieval, establishing the dates of documents is an important pre-requisite to returning temporally relevant documents and provides important information for a large number of search tasks (Ostroumova Prokhorenkova et al., 2016; Efron, 2013).

Most efforts to automatically date texts adopt a learning based approach and rely on several linguistic features that are time-relevant (Garcia-Fernandez et al., 2011; Jatowt and Tanaka, 2012; Zampieri et al., 2015; Ostroumova Prokhorenkova et al., 2016). Such time-relevant features include neologisms/archaisms, political events, spelling variations, and the presence of named entities as well as external knowledge bases. In addition to the large input feature dimensionality (of the order of the input vocabulary), these approaches all focus on particular domains (for example, primarily News articles). While such feature rich models which are arguably domain specific perform very well, these features are rarely generalizable across domains (for example. models that use political events can perform very well when evaluated in the News domain, but do not necessarily generalize to Fiction). Developing models that generalize across domains without further fine tuning generally entails modeling linguistic cues that are stable across domains.[1]

Consequently, in this work, we propose the first set of models that effectively generalize across domains by leveraging insights into the temporal usage of language. Our models rely on a key insight which we term the **temporal locality of neologisms**: *Documents written at time t tend to use neologisms invented shortly before t.* By effectively modeling this usage of neologisms (as a feature class cumulatively) we propose models that not only reduce our input feature dimensionality by at-least an order of magnitude, but also effectively generalize across a variety of domains (Fiction, Non-Fiction, and News)

[1] It is worth noting that ultimately most domain adaptation techniques attempt to find such a general feature set by either attempting to map source domain features to the target domain or learning a more abstract feature set.

Proceedings of the 27th International Conference on Computational Linguistics, pages 202–212
Santa Fe, New Mexico, USA, August 20-26, 2018.

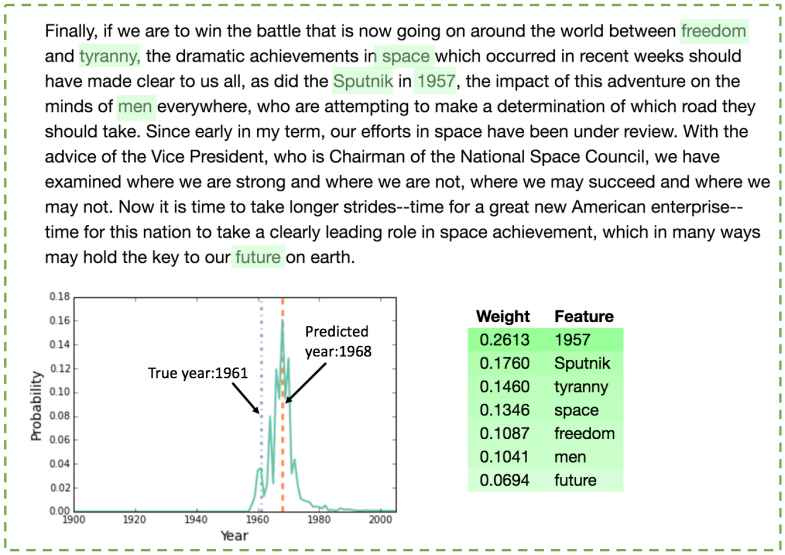

Figure 1: Sample output predictions of a Naïve Bayes model (NB) on a portion of a speech given by President John F.Kennedy in 1961. Note that this model outputs a probability distribution over years with a MAP estimate of year 1968. Note also that the model was trained *only using* Google Book Ngrams and not on the domain it is evaluated on. Finally, observe that words like `1957, Sputnik, tyranny and space` were most influential in this prediction thus providing insight into linguistic patterns the model has captured only from Google Book Ngrams. Moreover, the model is generic and can be applied to multiple domains like Fiction, News or Non Fiction. This motivates our hypothesis that neologisms can be effectively used to date documents across multiple domains.

without further tuning and perform competitively with more complex models that capture fine-grained linguistic cues. Intriguingly, we demonstrate that neologism-based models that use only ~ 200 features achieve a performance within 5 units of mean absolute error (21.58 on NonFiction) over the best Naïve Bayes model (18.25 on NonFiction) which uses more than 200K features.

In a nutshell, we make the following contributions:

- We propose domain independent models for the task of dating documents. We emphasize that our goal is not to necessarily outperform the state of the art domain specific models, but to demonstrate the effectiveness of simple models drawing on linguistic insights that generalize across domains.

- We leverage cumulative usage patterns of neologisms over time to propose the first set of simple generalizable models for this task while revealing insights into the cumulative usage patterns of neologisms over time.

- We empirically evaluate our models against several competing methods including neural models like LSTMs on three different domains (News, Fiction and Non Fiction).

2 Datasets

Here, we describe data-sets which we use for learning and evaluating our models.

Training Dataset We train all of our models using only the Google Book Ngrams dataset spanning the time $1850 - 2005$. Since the Google Book Ngrams spans multiple domains, we can capture domain agnostic linguistic cues to learn generalizable models for our task. Since our neologism models need only the frequency of occurrences, the Google Book Ngrams is an ideal dataset providing not only a large sample size for robust parameter estimation but also inherently spanning multiple domains.

Evaluation Datasets To evaluate our models, we consider the following datasets[2]:

- **NYTimes**: We consider a random sample of 10000 leading paragraphs of NEW YORK TIMES articles from the range $1850 - 2005$ constructed by scraping the New York Times website. Note that this dataset is primarily from the NEWS domain.
- **Corpus of Historical American English (COHA)**: We consider a random sample of 10000 articles from each genre, namely FICTION, NONFICTION, and NEWS from the COHA corpus (Davies, 2002). The COHA corpus is an ideal dataset to evaluate our models since it spans a wide time range, with multiple domains where the dates have been validated by human experts and is easily available for research purposes[3].

We emphasize that all of our models only use the Google Book Ngrams data to learn parameters. The models are then evaluated on the evaluation datasets which span multiple domains without any further fine-tuning.

3 Baselines

Before we describe our proposed models, we introduce two baseline methods to evaluate against on our task.

BOOKPROP We estimate the probability of a document written in a given year y, by computing the fraction of books written in year y over all books written in the time period under consideration. Formally, we estimate the following probability:

$$\mathsf{P}(Y = y) = \frac{\#(\text{books}, y)}{\sum_y \#(\text{books}, y)}$$

We estimate the number of books in English written in year y, as the number of distinct books the word `the` was mentioned in a given year y as per Google Book Ngrams (Michel and others, 2011) data. As expected, the distribution is skewed towards the right with more books written in the 20^{th} century than in the 18^{th} century (see Figure 2). Given a document to date, a random sample drawn from this distribution is then taken as the predicted estimate of the date of the document. A limitation of BOOKPROP is that it does not model language.

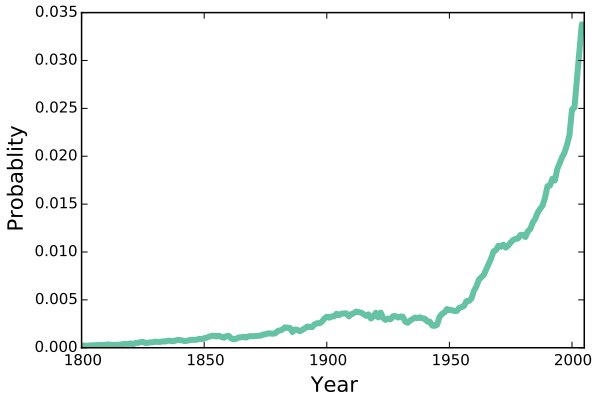

Figure 2: Estimate of the probability of English books being from a given year using the Google Book Ngrams data. As expected, the distribution is skewed towards the right with more books written in the 20^{th} century than in the 18^{th} century.

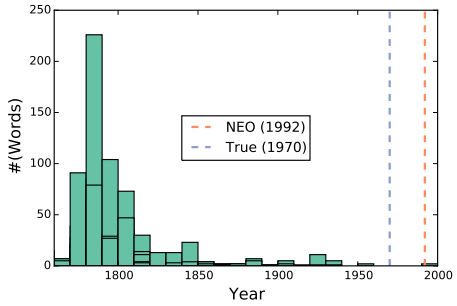
[2]While there has been work on dating documents (Zampieri et al., 2016; Kumar et al., 2012; Graliński et al., 2017), there are no standard publicly available evaluation datasets in the community for this task especially spanning multiple domains in English.

[3]We note that another option to construct such a dataset spanning multiple domains would be to use books from the HathiTrust. However, accessing a large clean dataset required institutional access unavailable to us at this point in time.

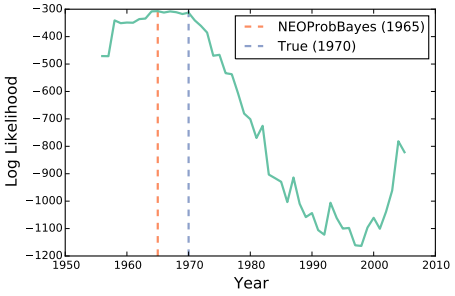
WORD	Estimated Year	Actual First Usage
HIV	1987	1986
Hitler	1933	1934
LSD	1955	1950
Obama	2007	2006
SARS	2003	2003
⋮	⋮	⋮

WORD	Estimated Year	Actual First Usage
Sputnik	1958	1957
electron	1905	1891
radio	1904	1907
television	1931	1907
transistor	1950	1948
walkman	1993	1979

Table 1: Example cases of estimated year of popular usage (MR) and actual year of first use (FU) obtained from `http://www.etymonline.com/` for different words from Google Book Ngrams data. Note that in the majority of these words, our estimated year is close to the year of first usage and shows a small lag from the year of first use as expected.



(a) NEO



(b) NEOProbBayes

Figure 3: Figure illustrating NEO and NEOPROBBAYES on the same document which was written in 1970. NEO is easily misled by outlier words and predicts the date to be 1992 ignoring other evidence like counts of other words. NEOPROBBAYES, in contrast incorporates all observed evidence to estimate more accurately that the document was written in 1965.

NEO A more sophisticated approach to assigning dates to documents is based on the following observation: If we observe a word which first came into popular usage in a year y, then the document is very likely written after year y. A simple model based on this hypothesis is to output the year of the most recent word found in the document. For example, in Figure 1, NEO estimates the date of a document to be 1958, since it is clear that `Sputnik`, the most recent word used in the document, sprung into popular use in 1958.

We estimate the year in which a word came into popular usage MR(w) from Google Book Ngrams as follows: (a) Compute the cumulative usage of a word w through every year in the Google Book Ngrams. (b) Compute the first year in which the cumulative usage of the word w exceeds a small fraction α (empirically set to $1/250.0$) of the total cumulative usage. As an example, our method estimates MR(`Obama`) $= 2007$ while the year of actual first usage is 2006. We validate our approach on a small set of manually curated words which we show in Table 1.

Observe that for the majority of these words, our estimated year is close to the year of first usage and shows a small lag, which is expected since we seek to estimate the year in which the word came into popular usage and not its year of first usage.

While NEO serves as a strong baseline, there are two limitations of this method: (a) The document could be written long after the time period corresponding to the most recent word observed in the document. (b) It ignores evidence of other words seen in the document and bases its decision on the occurrence of a single word.

Figure 3a illustrates these drawbacks. First, note that only one word `vinaya` with an MR(w) in the 1990's was observed in this document. NEO is easily misled by this single erroneous estimation of MR(`vinaya`) and estimates the date of this document to be 1992. It ignores other evidence that suggests that the document was written after 1940, but is unlikely to be written in the 1990's since words

with $\mathrm{MR}(w)$ a few decades before 1990's are not observed at all.

4 Proposed Neologism Based Model

We now describe a probabilistic model that effectively uses new words incorporated into popular usage to estimate when the document was written. In particular, our model computes the likelihood of observing a set of words that came into popular usage after year x given the document was written in year y to estimate when the document was written. Our method has two key steps:

1. **Ensemble Model Construction**: We construct an ensemble of probabilistic models where model M_i outputs $\mathsf{P}(y|X_i)$ and X_i is a discrete random variable counting the words observed in a document which came into popular usage after year i.
2. **Combining Ensemble Predictions**: Each model M_i outputs $\mathsf{P}(y|X_i)$, so we investigate multiple methods to combine predictions from individual models.

Ensemble Model Construction Let $\mathsf{F}(o, n)$ be the probability of observing a word that came into popular usage after year o in year n, where $n > o$. For every year pair (o, n), we estimate $\mathsf{F}(o, n)$ from the Google Books Ngrams Corpus by computing the fraction of words with $\mathrm{MR}(w) > o$ in the Google Book Ngrams of year n.

Given a text T of length N, let $N'(i)$ denote a realization of X_i in T. Each model M_i models the probability of T written in year y based on X_i as follows:

$$\mathsf{P}(y|X_i) \propto \begin{cases} \mathsf{P}(X_i|y)\mathsf{P}(y), & \text{if } i < y \\ 0, & \text{otherwise} \end{cases}$$

$\mathsf{P}(X_i|y)$ follows a binomial distribution with success probability $\mathsf{F}(i, y)$ which can be computed knowing the length of the document N and $N'(i)$ a realization of X_i. We assume the prior $\mathsf{P}(y)$ to be uniform.

Combining Ensemble Predictions Each model M_i computes a probability distribution over years, namely $\mathsf{P}(y|X_i)$. We now describe three methods to combine these individual model predictions to output a final prediction:

1. **NEOProbMean**: We output the mean of individual MAP predictions as the predicted year of authorship.
2. **NEOProbMedian**: We output the median of individual MAP predictions as the predicted year of authorship.
3. **NEOProbBayes**: We use a Bayesian scheme to incorporate all the observed evidence as follows: Let $\boldsymbol{X} = \{X_i \text{ for each year } i\}$. Specifically we compute the following:

$$\begin{aligned} \mathsf{P}(y|\boldsymbol{X}) &\propto \mathsf{P}(\boldsymbol{X}|y)\mathsf{P}(y) \\ &= \left(\prod_i \mathsf{P}(X_i|y)\right)\mathsf{P}(y) \end{aligned}$$

   where we make the *Naïve Bayes assumption* that each X_i is independent of any other X_j, when conditioned on the year y. We output the MAP estimate of $\mathsf{P}(y|\boldsymbol{X})$ as the final prediction.

Figure 3b shows this approach for a document and also contrasts it with the baseline NEO. Observe how NEOPROBBAYES enables a more accurate prediction by incorporating observed evidence ignored by NEO.

As we will show empirically, performance of each of the above methods is a function of the length of the document it is evaluated on since the accuracy of the individual probability estimates depends on the length. [4] While NEOPROBBAYES is better for large documents, it is quite sensitive to errors in estimates for small documents. Therefore, NEOPROBMEDIAN and NEOPROBMEAN which are less sensitive in the presence of outliers are better than NEOPROBBAYES for short documents (100 tokens) but are outperformed by NEOPROBBAYES for larger documents (2000 tokens) when individual model estimates are much more accurate.

[4] The larger the length, the more accurate the individual estimates.

5 Comparison to more Feature Rich Models

To place our models in the context of prior work which use a large set of linguistic features, we consider two linguistically feature rich models. Specifically, we consider a bag-of-words based Naïve Bayes' model as well as a neural network based model NEURALDATE for this task.

5.1 NAÏVEBAYES

We consider a simple, standard Multinomial Naïve Bayes classifier learned using Google Book Ngrams to date the year a document was written. We use unigram bag-of-words (we restrict our vocabulary to 200K tokens and discard out-of-vocabulary words) features and Laplace smoothing. It is worth noting that Naïve Bayes uses 200K features which is orders of magnitude higher than **NEO-Prob** approaches.

5.2 NEURALDATE

We propose a neural model NEURALDATE, to date texts. NEURALDATE operates on short sequences of words (n-grams), and outputs a probability distribution over years, $\mathsf{P}(y|\boldsymbol{x}_i)$ for each ngram $\boldsymbol{x}_i$ in the document $\boldsymbol{D}$,

Our model consists of a bi-directional LSTM with an embedding layer, two hidden layers and an output layer[5]. The embedding layer maps the input (one hot encoding of the word) to a dense embedding of size 200 dimensions. The implementation of the LSTM hidden layers are as described in (Graves and others, 2012) and therefore not described in this paper. The output layer is a soft-max layer over the years within the time-range considered. We use ADAM optimizer (Kingma and Ba, 2014) with a learning rate of $\eta = 0.001$.[6]

In order to date a document $\boldsymbol{D}$, we use the model to compute $\mathsf{P}(y|\boldsymbol{x}_i)$ for each n-gram (we use n=5) in $\boldsymbol{D}$. We then compute $\mathsf{P}(y|\boldsymbol{D})$ to be the mean of these individual probability distributions. Finally, we use the MAP estimate of $\mathsf{P}(y|\boldsymbol{D})$ as our point estimate of the year.

Autocorrelation Regularizer The model described above does not explicitly leverage structure of the label space, namely temporal structure (linear sequential structure). Observe the high variance in probability scores around the mode in Figure 4. Therefore, for a given n-gram $\boldsymbol{x}_i$ it would be preferable to learn model parameters such that $\mathsf{P}(y|\boldsymbol{x}_i)$ is "smooth" around any given label. This captures the insight that classes (years) in the neighborhood of a label l should be assigned probabilities similar to that assigned to l.[7]

We can formalize this notion of smoothness as follows: Let p_l be the probability assigned to label l. Given a neighborhood k, let $\boldsymbol{d}$ be the vector of first order differences: $p_i - p_{i+1}$ for $i \in [l-k \cdots l+k]$. We define the distribution to be L-smooth at l around neighborhood k if $\omega(\boldsymbol{d}) = \frac{\sigma(\boldsymbol{d})}{\text{mean}(|\boldsymbol{d}|)} \leq L$, for some small constant $L > 0$, where smaller values of L indicate smoother distributions.

We therefore propose to add the following cost to the original cost function:

$$\Omega(\boldsymbol{\theta}; \boldsymbol{X}^{\text{train}}) = \sum_j \omega\left(\boldsymbol{d}_j\right) ,$$

where $\boldsymbol{d}_j$ are differences between predicted probabilities for neighboring years for example j.

In summary, the final loss function including this regularization is $J(\boldsymbol{\theta}; \boldsymbol{X}^{\text{train}}, \boldsymbol{y}^{\text{train}}) + \alpha\Omega(\boldsymbol{\theta}; \boldsymbol{X}^{\text{train}})$, where $J(\boldsymbol{\theta}; \boldsymbol{X}^{\text{train}}, \boldsymbol{y}^{\text{train}})$ is the standard cross-entropy loss and α is a hyper-parameter weighing the regularization.

Figure 4 shows the effect of incorporating label smoothness constraints in the cost function for a sample n-gram. Note that incorporating the temporal structure of labels in the cost function produces markedly smoother and realistic distributions than a model not exploiting label structure.To investigate

[5]While more sophisticated and complex sequence models are being developed even as we write this paper, our goal here is only to place the performance of our proposed neologism models in context of other sophisticated methods. Therefore, Bidirectional LSTMs serve as a good lower bound for complex models.

[6]Hyper-parameter settings were chosen based on a validation set.

[7]We initially also experimented with using mean square loss and modeling this as a regression problem, but the resulting model did not perform well empirically.

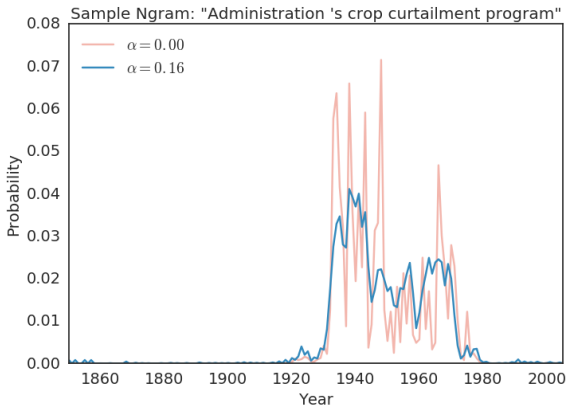


Figure 4: Predicted distribution over years for a given 5-gram (shown above the figure), motivating the need for the auto-correlation regularizer. Note that when $\alpha = 0$, the regularizer is disabled and the output probability distribution is very noisy and neighboring values have large variance. In contrast, when the regularizer is properly enabled ($\alpha = 0.16$), observe how the output probability distribution is much smoother and neighboring probability values are more similar.

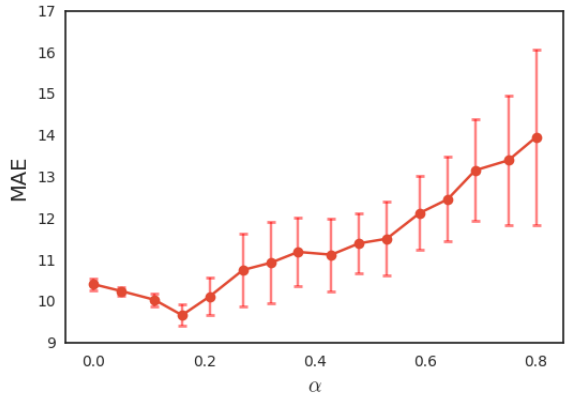

Figure 5: MAE from cross validation for candidates of α which controls the strength of the auto-correlation regularizer. The means and the standard deviations over 20 independent runs are shown. When the model is properly regularized ($\alpha = 0.16$), observe the improvements over model without regularization ($\alpha = 0$). Also, note that when the model is over-regularized ($\alpha > 0.25$), the performance is worse and demonstrates larger variance.

the effect of α, we measure the MAE (Mean Absolute Error) over n-grams and use cross-validation by selecting α from a set of candidates in $[0, 0.8]$ (see Figure 5). Based on these observations, we set α at 0.16 empirically for training our model.

6 Experiments

We evaluate all of our methods against several baselines on diverse data sets spanning multiple domains. We consider the time period of $1850 - 2005$ for the purpose of dating documents and evaluate our models on the evaluation data-sets described in Section 2. Since the tasks should get easier on long documents, we measure the performance of our models as a function of the length. Since the NYTIMES dataset only consists of the first paragraph of articles (about 100 tokens on average) we use the entire paragraph for evaluation on this dataset. Tables 2 and 3 show the Mean Absolute Error (MAE) over the NYTIMES and COHA datasets, from which we make the following observations:

- **Neologism Methods need relatively large documents to perform competitively**: Overall, the neologism based models perform competitively with Naïve Bayes using 1000 times fewer features (see

#(Tokens)	#(Features)	MAE
BOOKPROP	-	43.46
NEO	$\leq$ **200**	58.77
NEOPROBMEAN	$\leq$ **200**	27.55
NEOPROBMEDIAN	$\leq$ **200**	28.22
NEOPROBBAYES	$\leq$ **200**	67.14
NAÏVEBAYES	$\sim 200K$	23.69
NEURALDATE (w/o reg.)	1000	22.80
NEURALDATE	1000	**20.54**

Table 2: Mean Absolute Error on New York Times data. Note that neologism based methods (highlighted) whose feature set size is much smaller, perform competitively with NAÏVEBAYES with a feature space of dimension of 200K. NEURALDATE uses a 200 dimension embedding for each word in a 5-gram and so has an effective feature input size of 1000. It is worth noting that our neologism based models do not directly rely on the actual words themselves but on the number of neologisms used at a given time thus drastically reducing the feature size while yielding competitive performance.

Dataset	#(Tokens)	100	500	1000	2000
COHA-Fiction	BOOKPROP	44.57	44.54	43.95	44.21
	NEO	66.99	34.74	27.39	24.80
	NEOPROBMEAN	32.40	30.76	31.45	31.13

	NEOPROBBAYES	78.99	41.90	33.77	27.92
	NAÏVEBAYES	**26.61**	**23.98**	**22.62**	**21.93**
	NEURALDATE (w/o reg.)	37.56	30.71	28.96	27.97
	NEURALDATE	35.66	30.02	27.81	26.96
COHA-NonFiction	BOOKPROP	45.19	45.07	45.04	45.51
	NEO	57.99	30.75	24.84	22.86
	NEOPROBMEAN	31.13	26.90	26.02	25.39
	NEOPROBMEDIAN	30.68	26.60	25.73	25.13
	NEOPROBBAYES	56.58	30.73	25.46	21.58
	NAÏVEBAYES	**24.28**	**19.83**	**18.36**	**18.25**
	NEURALDATE (w/o reg.)	27.91	23.57	22.29	21.60
	NEURALDATE	25.21	20.07	20.38	20.09
COHA-News	BOOKPROP	44.97	45.34	44.99	45.02
	NEO	39.86	20.39	19.80	20.26
	NEOPROBMEAN	24.36	23.40	23.30	23.31
	NEOPROBMEDIAN	25.22	22.88	22.45	22.39
	NEOPROBBAYES	48.30	22.79	20.97	20.82
	NAÏVEBAYES	21.35	17.21	16.64	16.60
	NEURALDATE (w/o reg.)	20.40	16.04	15.43	15.34
	NEURALDATE	**19.30**	**15.33**	**14.72**	**14.59**

Table 3: Mean Absolute Error of different models on COHA datasets as a function of number of tokens used for evaluation in each document. Note that our proposed neologism based methods (highlighted) use a much smaller feature set, generalize across domains without any further fine-tuning, and perform competitively with feature rich models like NAÏVEBAYES and NEURALDATE for long documents (greater than 500 tokens).

Table 2) suggesting that effective usage of neologism usage patterns can serve as strong baselines.

Furthermore, from Table 3, the baseline NEO generally performs very poorly on short documents

(of length 100 tokens). For example, on the COHA-FICTION dataset using 100 tokens, the MAE is 66.99 compared to BOOKPROP which yields an MAE of 44.57. On short documents NEO is easily misled due to lack of effective sample size. In contrast, observe that as the length of the document increases NEO's error reduces significantly (note Table 3 that for 2000 word documents on COHA-FICTION the mean absolute error is now 24.80).

Finally, the probabilistic models we propose extending NEO also perform better than NEO especially on short documents (for example, on COHA-FICTION for documents with 100 tokens the MAE for NEOPROBMEAN is 32.40 compared to 66.99 for NEO). Similarly, NEOPROBMEAN and NEOPROBMEDIAN outperform NEOPROBBAYES on documents of up to 1000 tokens but NEOPROBBAYES almost always outperforms all of these on documents of length 2000, suggesting that NEOPROBBAYES needs a larger sample size to make effective predictions.

- **Deeper linguistic features boost performance**: We finally observe that including linguistic features like the words used in a simple Naïve Bayes classifier consistently outperforms methods relying solely on neologisms. Further, observe that the NEURALDATE with the auto-correlation regularizer demonstrates superior performance over NEURALDATE without regularization. Finally, note that NEURALDATE also performs competitively and sometimes out-performs Naïve Bayes.

Altogether, our proposed neologism based models generalize well across domains, reduce the input feature size significantly while performing competitively with more complex feature rich models.

7 Related Work

A large body of related work on the task of automatically dating texts exists in the field of temporal information retrieval (De Jong et al., 2005; Popescu and Strapparava, 2015; Kanhabua and Nørvåg, 2009; Garcia-Fernandez et al., 2011; Niculae et al., 2014; Zampieri et al., 2015; Zampieri et al., 2016; Bamman et al., 2017; Jatowt and others, 2017; Kumar et al., 2012; Kumar, 2013; Graliński et al., 2017). The community also has two shared tasks (Popescu and Strapparava, 2015) and (Graliński et al., 2017). However, both of these shared tasks differ from our setting. Popescu and Strapparava (2015) is a shared task for diachronic text evaluation but only focuses on the Newspaper domain in contrast to our work which focuses on generalizable models across domains. Graliński et al. (2017) is the most recent challenge on dating texts but it focuses on Polish texts. De Jong et al. (2005) proposed using temporal language models based on unigrams to date texts on Dutch newspaper articles. Several works incorporate additional features like lexical features, part-of-speech tagging, extraction of concepts and word sense disambiguation and use external knowledge bases (Kanhabua and Nørvåg, 2009; Garcia-Fernandez et al., 2011; Niculae et al., 2014; Zampieri et al., 2015; Zampieri et al., 2016). Recently Jatowt and others (2017) propose an interactive system to estimate the age of document using moment statistics of n-grams focusing on only a qualitative analysis.

Our work is most closely related to the works of (Kumar et al., 2012), (Garcia-Fernandez et al., 2011),(Zampieri et al., 2015) and (Bamman et al., 2017). Kumar et al. (2012) propose a model for predicting the dates of documents without explicit temporal cues. This model essentially learns temporal language models on the temporal corpus where explicit temporal expressions are removed. It then assesses the likelihood of a given document under each time point to make a prediction. It thus relies on implicit temporal cues and words and typically has an input feature dimensionality of the order of the vocabulary (in this case 300K words). Furthermore, this model has only been evaluated in different settings (like predicting the mid-point of an individual's lifetime using their Wikipedia biography). Garcia-Fernandez et al. (2011) develop a model to date documents using both chronological methods with external knowledge and classification methods like using an SVM to date documents on a French Newspaper corpus while Zampieri et al. (2015) propose a ranking based approach to temporal text classification. These methods learn models on the respective domains they are evaluated on. Bamman et al. (2017) proposed bag-of words based models (using Ridge Regression as well as Naïve Bayes) to predict the date of first publication over books obtained from the Hathi Trust.

Differing from these works, our proposed method seeks to learn a global model that can be applied across multiple domains without further tuning. We propose new probabilistic models to date texts by analyzing statistical patterns of the introduction of neologisms over time. Our models are simple, domain-independent, use several orders of magnitude fewer features and yet achieve competitive performance.

8 Conclusion

In this paper, we investigated the task of dating books on a large fine-grained time scale (spanning 150 years) through the lens of neologisms introduced over time. We propose probabilistic models that effectively analyze the usage of neologisms. We demonstrate that our methods perform competitively with models that use deeper linguistic cues (which could use a feature space of more than thousands of features). Furthermore, our models are learned using only the Google Book Ngrams, do not need any further tuning when evaluated on other domains and potentially enable researchers to obtain literary insights into the language of authors over time.

Abstract

Sequence-to-sequence model has been applied to solve math word problems. The model takes math problem descriptions as input and generates equations as output. The advantage of sequence-to-sequence model requires no feature engineering and can generate equations that do not exist in training data. However, our experimental analysis reveals that this model suffers from two shortcomings: (1) generate spurious numbers; (2) generate numbers at wrong positions. In this paper, we propose incorporating copy and alignment mechanism to the sequence-to-sequence model (namely CASS) to address these shortcomings. To train our model, we apply reinforcement learning to directly optimize the solution accuracy. It overcomes the "train-test discrepancy" issue of maximum likelihood estimation, which uses the surrogate objective of maximizing equation likelihood during training while the evaluation metric is solution accuracy (non-differentiable) at test time. Furthermore, to explore the effectiveness of our neural model, we use our model output as a feature and incorporate it into the feature-based model. Experimental results show that (1) The copy and alignment mechanism is effective to address the two issues; (2) Reinforcement learning leads to better performance than maximum likelihood on this task; (3) Our neural model is complementary to the feature-based model and their combination significantly outperforms the state-of-the-art results.

1 Introduction

The task of math word problem solving aims to automatically solve a math problem by reading the text description of the problem and generating the answer. This task requires the machine to have the ability of natural language understanding and reasoning.

In the past years, most of the proposed methods heavily rely on predefined rules or feature engineering. On one hand, the rule-based approaches (Bakman, 2007; Liguda and Pfeiffer, 2012; Shi et al., 2015) predefine a structured representation and maps the problem description into the structure by rules. These approaches usually accept only well-formed input and are difficult to scale to other problem types. On the other hand, the feature-based statistical learning approaches (Kushman et al., 2014; Roy and Roth, 2018) generate equation candidates and find the most probable equation by using predefined features. These approaches have two major drawbacks: (1) Their ability of equation generation is weak. An equation is generated by either replacing the numbers of existing equations in the training data, or enumerating possible combinations of math operators, numbers and variables, which leads to intractably huge search space. (2) They need manually designed features that are specific to math word problems.

Recent attempts (Ling et al., 2017; Wang et al., 2017) use sequence-to-sequence (seq2seq) model for math word problem solving and they have shown promising results. Wang et al. (2017) apply a standard seq2seq model to generate equations. They have shown that seq2seq models have the power to generate equations of which the problem types do not exist in the training data.

*Work was done at Microsoft Research.

Proceedings of the 27th International Conference on Computational Linguistics, pages 213–223
Santa Fe, New Mexico, USA, August 20-26, 2018.

However, we have observed two major shortcomings of the existing seq2seq model with attention mechanism. First, the model may generate spurious numbers, which are detrimental for math problem solving. As shown in Figure 1, the model generates a number "424" in the equation for *Problem 1*, which does not exist in the problem description. Since some of the numbers are unavoidably rare or do not appear in the training data, the existing models have difficulty generalizing to the long tail numbers. Second, the model is prone to generate numbers at wrong positions. In *Problem 2*, although the equation template is correctly generated by the model, the last token in the equation should be aligned to "1170" instead of "30" in the problem description. These two behaviors mentioned above are undesirable and will lead to wrong solutions.

In this paper, we focus on addressing the above two issues in the existing model (Wang et al., 2017) by incorporating Copy and Alignment mechanism to the seq2seq model (namely CASS). (1) Copy means directly copying the numbers in the problem description to the equations. In this way, we can avoid generating spurious numbers that are not in the problem description. (2) Alignment means that there is alignment information between the numbers in the equations and the numbers in the problem description. The model could learn the alignment in a supervised way.

Problem 1: Two busses leave Pleasant Grove High School at the same time going in opposite directions. One bus travels 43 mi/h and the other travels 57 mi/h. In how many hours will they be 350 miles apart?
Equation: (57 + 43) * x = 350
Baseline Seq2Seq + Attention: (424 + 43) * x = 350

Problem 2: A mortgage payment is $30 less than 3 times the property tax payment. The sum of the mortgage payment and the property tax payment is $1170. How much is the mortgage payment.
Equation: x = 3 * y – 30 ; x + y = 1170
Baseline Seq2Seq + Attention: x = 3* y - 30 ; x + y = 30

Figure 1: The baseline model generates a spurious number "*424*" in problem 1 and align numbers wrongly in problem 2.

When training the model, we adopt the reinforcement learning technique, specifically policy gradient. Because maximum likelihood estimation (MLE) suffers from the issue of "train-test discrepancy". It means that MLE uses a surrogate objective of maximizing equation likelihood during training, while the evaluation metric of the task is solution accuracy, which is non-differentiable. Therefore we use policy gradient to directly optimize the solution accuracy, which is more capable for this task.

Furthermore, we observe that the neural model and the traditional feature-based model are complementary. To take the advantage of both approaches, we add the result of our neural model as a simple feature to the feature-based model (Huang et al., 2017) to create a combined model.

We test our model on three publicly available datasets. The experimental results show that the copy and alignment mechanism is effective. Reinforcement learning leads to better performance than MLE. When combining our neural model with the feature-based model, we achieve the state-of-the-art results on all publicly available datasets.

The contributions of this paper are as follows:

1) We incorporate copy and alignment mechanism that augment the standard seq2seq model to address two types of errors: generating spurious numbers and generating numbers in wrong positions.

2) We adopt the reinforcement learning to optimize the solution accuracy, which is more capable for this task and leads to better performance.

3) We propose a simple but effective way to combine the neural model with a traditional feature-based model. The combined model outperforms the state-of-the-art models.

2 Problem Statement and Datasets

Given a math word problem P, the goal is to predict its answer A_p. In the training phase, we have annotations of both equation system E_p and answer A_p for each problem. In the testing phase, we obtain the final answer by generating equation and executing it with a math solver. We evaluate the task using solution accuracy.

Equation template is a unique form of an equation system. For example, given an equation system $\{2 * x + 4 * y = 34, x + 4 = y\}$, we replace the numbers with four number tokens $\{n_1, n_2, n_3, n_4\}$ and generalize the equations as the following equation template $\{n_1 * x + n_2 * y = n_3, x + n_4 = y\}$.

We can see that an equation system includes one or more equations and it is a solution for a specific

math word problems. In contrast, an equation template can correspond to several math problems. The number of templates in a dataset reflects the diversity of problem types. Specifically, we have a subset setting $T6$, which represents problems for which the associated template appeared equal to or more than six times in the subset. Note that T6 is a soft constraint of previous feature-based models.

We evaluate different models on three publicly available math word problem datasets[1].

- **Algebra 514** (Alg514) is created by Kushman et al. (2014). It contains 514 algebra word problems from Algebra.com. In the dataset, each template corresponds to at least 6 problems (T6 setting). It only contains 28 templates in total.

- **Number Word Problem** (NumWord) is created by Shi et al. (2015). It contains 2,871 number word problems (i.e., verbally expressed number problems) with 1,183 templates. The T6 subset contains 348 problems. One example problem is *"The sum of two numbers is 10. Their difference is 4. What are the two numbers?"*. We use its linear subset, which contains 986 problems. The vocabulary of this dataset is the smallest among the three, but contains more templates than Alg514.

- **Dolphin18K** (Dophin18K) is created by Huang et al. (2016). It contains 18,711 math word problems from Yahoo! Answers with 5,738 templates. It has much more problem types than the previous two datasets. This dataset is the most challenging of the three. We use its subset with equation annotation, which contains 10,644 problems. The T6 subset contains 6,827 problems.

3 Modeling

Math word problem solving can be formulated as a sequence prediction problem. We set x as the sequence of words in a math word problem description and we want to generate y, the sequence of tokens in an equation system. In this section, we describe (1) the baseline seq2seq model, (2) our two number-related mechanisms to address the issues in existing model.

3.1 Basic Sequence-to-Sequence Model

Following Wang et al. (2017), we first map numbers in the problem description to a list of number tokens $\{n_1,...,n_m\}$ and replace the corresponding numbers in the equation system with the number tokens. As shown in Figure 1, the problem description of *Problem 1* will be as follows after number mapping:
Two buses leave Pleasant Grove High School at the same time going in opposite directions. One bus travels n_1 mi/h and the other travels n_2 mi/h. In how many hours will they be n_3 miles apart?
And the equation system is normalized to: *(n_2 + n_1) * x = n_3*.

The baseline model of seq2seq with attention is based on the work by Bahdanau et al. (2015). It can be viewed as an encoder-decoder model. Basically, the encoder (that is implemented as a single-layer bidirectional GRU) reads the source tokens in problem description one-by-one and produces a sequence of hidden states $h_i = [h_i^F, h_i^B]$ with:

$$h_i^F = GRU(\phi^{in}(x_i), h_{i-1}^F) \quad (1)$$

$$h_i^B = GRU(\phi^{in}(x_i), h_{i+1}^B) \quad (2)$$

where ϕ^{in} maps each token x_i to a fixed-dimensional vector.

At each decoding step j, the decoder receives the embedding of the previous generated token, the current decoder hidden state and the context vector to produce the target vocabulary distribution as described in the following equation:

$$P_{vocab}(w_j) = softmax(U[\phi^{out}(y_{j-1}), c_j, s_j] + b) \quad (3)$$

[1] (Wang et al., 2017) create a dataset containing 23,161 Chinese algebra math problems which has not been public yet.

where s_j is the decoder state and $\phi^{out}(y_{j-1})$ is the previous output embedding. c_j is the context vector and we calculate it as follows:

$$e_{ji} = v^T tanh(W_h h_i + W_s s_j + b_{attn}) \tag{4}$$

$$a_{ji} = \frac{\exp(e_{ji})}{\sum_{i'=1}^{m} \exp(e_{ji'})} \tag{5}$$

$$c_j = \sum_{i=1}^{m} a_{ji} h_i \tag{6}$$

Intuitively, a_{ji} defines the probability distribution over the input tokens. They are computed from the unnormalized attention scores e_{ji}. c_j is the weighted sum of the encoder hidden states. Specifically, W_h, W_s, U, b_{attn}, and b are parameters of the model.

Once we obtain the decoding result, a post-processing step recovers all tokens n_i to their corresponding numbers in the problem description.

3.2 Copy Numbers

In the basic model, the output token y_j is chosen via a softmax over all words in the output vocabulary. However, this model has the problem of generating spurious number tokens. For example, *Problem 1* in Figure 1 only contains three numbers, replaced with tokens $\{n_1, n_2, n_3\}$. Since the output vocabulary contains other tokens, the model may generate a token "n_4", which cannot be recovered and results in generating wrong equations.

To address this problem, we incorporate an attention-based copy mechanism into the basic model similar to Jia and Liang (2016). In our case, we only copy numbers from the source problem.

At each decoding step j, the model has to decide whether to *generate a token* from target vocabulary or *copy a number* from the problem description. The generation probability p_{gen} is modeled by:

$$p_{gen} = \sigma(W_c c_j + W'_s s_j + W_y y_{j-1} + b_{gen}) \tag{7}$$

where W_c, W'_s, W_y, and b_{gen} are parameters of the model and σ is the sigmoid function.

Then the output candidates are extended to the concatenation of the target vocabulary and the numbers in the math problem. We can obtain the output probability distribution:

$$P(w_j = w) = p_{gen} * P_{vocab}(w_j) + (1 - p_{gen}) * \frac{\sum_{i:w_i=w} a_{ji}}{\sum_{k:w_n} a_{jk}} \tag{8}$$

w_n is the set of numbers in the problem description. In this way, the model is capable of eliminating the spurious word error.

3.3 Align Numbers

In the decoding phase, the model often generates equations with numbers in wrong positions. *Problem 2* in Figure 1 is an example. The output equation structure is correct by the basic model. However, the numbers are aligned wrongly. When decoding the last token, the model should pay more attention to the source token "1170". Instead, the model wrongly aligned to the source token "30".

One characteristic of math word problems is that they have explicit alignment information between numbers in the problems and numbers in the equations. To improve the alignment in math problems, we use a supervised align mechanism to guide the training of our seq2seq model. Similar to Mi et al. (2016), the basic idea is minimize the cost of distance between the "true" alignment and the model predicted attention. We use the cross entropy loss function in the following:

$$\delta(a^i, \hat{a}^i) = -\sum_m \sum_n \hat{a}^i_{m,n} \times \log a^i_{m,n} \tag{9}$$

Please note that the disagreement only exists in numbers. The actual distribution $\hat{a}^i_{m,n}$ will be 1 if the *m*th token in the source is a number and equals to the *n*th tokens in the target sequence, otherwise it is 0.

4 Reinforcement Learning

As previously mentioned, MLE optimizes the surrogate objective of maximizing equation likelihood, while the evaluation metric of the task is solution accuracy. Besides, MLE assumes ground truth is provided at each timestep to predict the next token during training, which is not the case at test time. To remedy the discrepancy, we adopt the reinforcement learning technique, which directly optimizes the solution accuracy.

4.1 Policy Learning

The goal of the REINFORCE (Williams, 1992) is to find an agent that maximizes the task-level expected reward. We view our seq2seq model as a RL agent, which takes math problem description as input and then at each step, outputs a token y_j either by generating from the vocabulary or by copying numbers from the input problem. The agent follows a policy $\pi(y_j|\cdot)$, which we define as Equ 8.

The loss function and the gradient in the reinforcement learning are:

$$L_{RL} = -\sum_i \mathbb{E}_{p_\theta(\mathbf{y}^i|\mathbf{x}^i)}[R(\mathbf{x}^i, \mathbf{y}^i)] \tag{10}$$

$$\nabla_\theta L_{RL} = -\sum_i \mathbb{E}_{p_\theta(\mathbf{y}^i|\mathbf{x}^i)}[R(\mathbf{x}^i, \mathbf{y}^i)\nabla_\theta \log p_\theta(\mathbf{y}^i|\mathbf{x}^i)] \tag{11}$$

$$\approx -\sum_i \sum_{\mathbf{y}^i} p_\theta(\mathbf{y}^i|\mathbf{x}^i)R(\mathbf{x}^i, \mathbf{y}^i)\nabla_\theta \log p_\theta(\mathbf{y}^i|\mathbf{x}^i) \tag{12}$$

where $R(\mathbf{x}^i, \mathbf{y}^i)$ is the reward function. We define it as +1 if $\mathbf{y}^i$ yields to the correct solution, and -1 if $\mathbf{y}^i$ is not a valid equation or yields to a wrong solution.

Gradient Approximation It is often intractable to compute the gradient (Equ 11) because it involves taking an expectation over all possible equations. Therefore we sample from the model by using the top-k equations in the beam to approximate the gradient (Equ 12). Note that the gradient weights $p_\theta(\mathbf{y}^i|\mathbf{x}^i)$ of our sampling equations are renormalized to be summed up to 1.

In practice, the REINFORCE algorithm is unstable and converges slowly when the search space is large. Thus we pre-train our model based on maximum-likelihood for a few iterations before starting reinforcement learning.

4.2 Mixed Objective Function

To consider the alignment loss in Section 3.3, we define a mixed learning objective function:

$$L = L_{RL} + \lambda * \delta(a^i, \hat{a}^i) \tag{13}$$

where λ is a hyper-parameter that controls the magnitude of number alignment disagreement in the loss. In the pre-training step based on MLE, we replace the loss L_{RL} with the negative log likelihood:

$$L_{MLE} = -\sum_i \log p(\mathbf{y}^i|\mathbf{x}^i; \theta) \tag{14}$$

5 Model Ensemble

In this section, we observe and discuss that the neural model and the traditional feature-based model are complementary. To explore the advantage of both approaches, we combine two models by adding the result of our neural model as a feature to the feature-based model.

5.1 Feature-based Model

We use the state-of-the-art feature-based model (Huang et al., 2017) in our experiments. It contains two stages:

(1) Template retrieval. Candidate templates are derived from the training data. Given a problem p_i, they create a feature vector $f(p_i, t_j)$ for each candidate template t_j, and learn to rank the templates. They retrieve the top N templates.

(2) Equation ranking. Given the top N templates, they generate candidate equations with all possible number alignments. For example, there are two candidate equations given the template $x = n_1 - n_2$ and the numbers $\{3, 5\}$: $x = 3 - 5$ and $x = 5 - 3$. Similar to the previous stage, they create a feature vector $f(p_i, e_k)$ for each candidate equation e_k, and learn to rank the equations.

5.2 Generalization Ability of Neural Model

In Figure 2 we show the statistic of problems solved by our neural model and the feature-based model on Dolphin18K. 10.4% of problems can be solved correctly by both models, 18.0% can only be solved correctly by the feature-based model and 5.5% can only be solved correctly by our neural model.

To explore the generalization ability of our neural model, we further look into the 5.5% of problems that can only be solved correctly by our neural model (blue area in Figure 2). They can be summarized into two categories (examples are shown in Table 1):

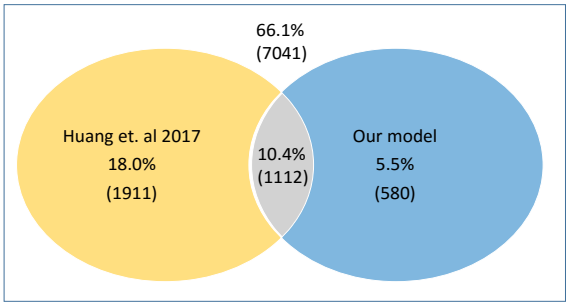

Figure 2: Statistic of problems solved by our neural model and feature-based model.

(1) **Ability to generate new equation templates**. Among the 5.5% of problems, there are 32.3% for which the template does not exist in the training data. Note that the feature-based model can only retrieve candidate templates from the training data. It means that the neural model has the ability to generate new equation templates, similar to the observation in Wang et al. (2017).

(2) **Ability to capture novel features**. For the remaining 67.7% of problems that can only be solved correctly by our neural model, their templates exist at least one time in the training data. The feature-based model should be able to retrieve the correct template and get the correct ranking for the equation, but it fails. This indicates that the neural model can capture novel features that the feature-based model is missing.

(1) **Problem**: Find 2 consecutive even integer such that 5 time the small integer be 10 more than 3 time the large integer. **Equation**: $5 * (2 * x) = 3 * (2 * x + 2) + 10$ (Our model generates the equation of which template does not exist in the training data)
(2) **Problem**: The area of a rectangular garden is 4472 ft$\hat{2}$. If the length of the garden is 86 feet, what is its width? **Equation**: $86 * x = 4472$ (its template exists in the training data)

Table 1: Example problems that are only solved correctly by our neural model.

5.3 Model Ensemble

In previous section, we observe that neural model is complementary to the feature-based approach when the templates are sparse or do not exist in the training data. Hence, it is intuitive to combine the neural model and feature-based approach to obtain better performance. To ensemble both models, We incorporate the neural model output in the two stages of the feature-based approach by (Huang et al., 2017):

(1) In the template retrieval stage, we add a feature of neural template. Given a problem, we derive the template t_{seq} of our neural output equation. For each candidate template t_i, if it is equivalent to t_{seq}, we set the value of the neural template feature to 1, otherwise set to 0.

(2) In the equation ranking stage, we add a feature of neural answer. Given a problem, we calculate the answer of our output equation a_{seq}. For each candidate equation e_j, if its answer a_j is equal to a_{seq}, we set the value of the neural answer feature to 1, otherwise set to 0.

6 Experiments

In this section, we test the performance of our model on three datasets. Furthermore, we conduct experiments to examine the effectiveness of our neural model as a feature in the hybrid model.

6.1 Implementation Details

Experiments are done in 5-fold cross-validation: in each run, 70% is used for training, 10% for validation, and 20% for testing. We report answer accuracy. The dimension of encoder hidden state, decoder hidden state and embeddings are 100 in NumWord and Alg514, 512 in Dolphin18K. All model parameters are initialized randomly with Gaussian distribution. The hyper-parameter λ for supervised attention of alignment is set to 1.0. We use SGD optimizer with decaying learning rate initialized as 0.5. Dropout rate is set to 0.5. The criterion for learning to stop is answer accuracy in validation set. The vocabulary consists of words observed in the training data more than or equal to N times. We set $N = 1$ for NumWord and $N = 5$ for the other two datasets. The beam size is set to 20 in the decoding stage. For reinforcement learning, we utilize a pre-training with maximum likelihood for 50 iterations. We set the beam size for sampling to 10. We tune all the hyper-parameters using a separate dev set.

6.2 Results

We implement the approach in Wang et al. (2017) as the baseline (**Seq2SeqAttn**). Its performance on Alg514 is 19.4%, versus 17.2% they reported.

Models	Alg514	NumWordT6	NumWordT1	Dolphin18KT6	Dolphin18KT1
Seq2SeqAttn (MLE)	19.4%	19.7%	11.0%	13.0%	10.2%
+Copy (MLE)	41.4%	59.9%	23.0%	20.2%	12.9%
+Copy+Align (MLE)	41.8%	60.4%	26.8%	21.0%	13.1%
+Copy+Align (RL)	44.5%	64.0%	29.2%	23.3%	15.9%
Huang et al. (2017)	81.6%	42.0%	20.8%	30.6%	28.4%
+ CASS^{RL} (hybrid)	**82.5%**	**65.8%**	**29.7%**	**33.2%**	**29.0%**

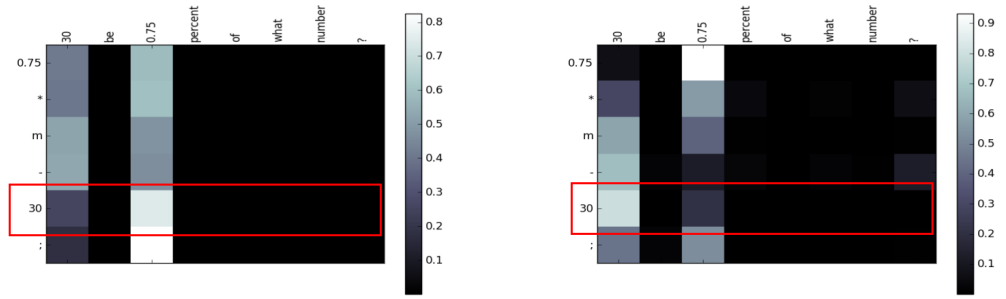
Table 2: Performances on three datasets. "*CASS*" means Seq2SeqAttn + Copy + Align.

From Table 2, we can see that our approach significantly improves the performance over the baseline. Especially on NumWord dataset, our model greatly exceeds the baseline with 44.3% increase on $T6$ and 18.2% increase on $T1$, and is already better than current state-of-the-art model (Huang et al., 2017).

Copy impact The copy mechanism contributes greatly on all three datasets as shown in Table 2. It achieves a 40.2% accuracy on NumWordT6, even outperforms the feature-based models. In the most challenging dataset Dolphin18K among the three, with more diverse problems and larger problem size, our model still gets a 7.2% increase on Dolphin18KT6 and 2.7% increase on Dolphin18KT1.

Align impact From Table 2, we can see our model achieves a consistent improvements over all three datasets using number alignment. In the math problem in Figure 3a, for the target number "30", Seq2SeqAttn + Copy model has a higher attention weight of the source number "0.75" than the source number "30". Thus the model wrongly aligned the target number "30" to the source number "0.75". After incorporating the alignment mechanism, the target number "30" is now aligned correctly as shown in Figure 3b.

Reinforcement learning We can see RL performs substantially better than MLE. As the objective of RL is to optimize the solution accuracy, we further investigate the model's capability of considering multiple admissible equations. We compare the annotated equations with the equations generated by our model on Dolphin18KT1. Using RL training, there are **7.1%** of problems of which the predicted equations are different from the annotated ones but still yield to correct solutions, compared to 4.4% using MLE.



(a) **Seq2SeqAttn+Copy** (b) **Seq2SeqAttn+Copy+Align**

Figure 3: Example alignments of (a) Seq2SeqAttn + Copy, (b) Seq2SeqAttn + Copy + Align.

6.3 Model Ensemble

We further test the performance of the hybrid model that combines our neural model into the feature-based model.

From Table 2, we can see that when our neural model is incorporated into the feature-based model, we achieve the state of the art. This indicates that the two models are complementary and the hybrid model takes advantages of both models.

Furthermore, we show detailed results when our neural model is incorporated in each of the two stages:

(1) Template retrieval. Same as Huang et al. (2017), we report Hit@N accuracy, which means the correct template for a problem is included in the top N list returned by the model. Table 3 shows the Hit@1/Hit@3 accuracy.

We can see that incorporating neural model helps increase template Hit@N accuracy, which means it can retrieve accurate templates for more problems. Except for Alg514, adding the neural feature drops Hit@3 by 1.3%. On Alg514, the feature-based model already outperforms our neural model. In addition, its data size is the smallest among the three datasets, which might be challenging for neural model to learn from. Therefore, adding neural feature on this dataset might bring much noise that leads to performance decrease.

Dataset	Huang et al. (2017)	+Neural
Alg514	62.8/80.9	60.3/79.6
NumWordT6	38.6/70.0	**38.9/72.9**
NumWordT1	20.0/35.1	20.4/35.1
Dolphin18KT6	27.3/39.7	**27.3/41.1**
Dolphin18KT1	17.5/26.3	**18.2/27.1**

Table 3: Accuracy (%) of template retrieval with top 1 / top 3 templates retrieved.

(2) Equation ranking (final accuracy). After retrieving the top N templates from the previous stage, we align numbers with template slots to generate candidate equations for ranking. The final results are shown in the last row of Table 2.

From the table, we can see that the neural feature is effective, achieving the state of the art on all three datasets. Especially, on NumWord dataset, incorporating neural model contributes to 23.8% accuracy increase on T6 and 8.9% increase on T1. Surprisingly, the performance on Alg514 is still improved, though the template retrieval accuracy in previous stage decreased. This indicates that the feature-based model has included some errors that caused by wrong number alignment in the second stage, and our neural feature eliminates this type of errors.

7 Related Work

Our work is related to three research areas: math word problem solving, the seq2seq model, and reinforcement learning for sequence generation.

7.1 Math Word Problem Solving

The approaches to solve math word problems can be divided into three categories: rule-based approach, feature-based approach, and neural-based approach.

Rule-based approaches (Bobrow, 1964a; Bobrow, 1964b; Bakman, 2007; Liguda and Pfeiffer, 2012; Shi et al., 2015) accept only well formed input sentences and map them into predefined structures by rules. These methods require strict constraints on both input text and math problem types.

Feature-based approaches design features and learn rankers to rank equation candidates to the math problems. Hosseini et al. (2014) design features to classify verbs to addition or subtraction. Kushman et al. (2014), Zhou et al. (2015), Upadhyay et al. (2016) use features such as dependency path between two numbers. Koncel-Kedziorski et al. (2015), Roy and Roth (2015) extract quantity information as features. Wang et al. (2018) extract features for quantity pairs and uses a reinforcement framework to construct an equation tree with the constraint of one unknown variable. Roy and Roth (2015), Roy et al. (2016) leverage the tree structure of equations. Mitra and Baral (2016), Roy and Roth (2018) design features for a few math concepts (e.g. Part-Whole, Comparison). Huang et al. (2017), Roy and Roth (2017) focus on the use of fine-grained expression and number units. These approaches requires manual feature design and it is difficult to generalizing the features to other problem types.

Recently, researchers try to build end-to-end neural models to solve math word problems. Ling et al. (2017) focus on multiple-choice problems. It takes a problem description as input and outputs the rationale and the final choice. Wang et al. (2017) apply a standard seq2seq model to generate equations under the constraint of one variable. However, the model is prone to generate numbers that do not exist in the problem or in wrong positions. Our model addresses these issues by incorporating copy and align.

7.2 Sequence-to-Sequence Models

Recent applications of seq2seq model in many areas have shown promising results.

Copy mechanism is proved effective in dealing with rare or unknown words. The main idea is to decide when and what to copy from the source words in the decoding phase. Jia and Liang (2016) use an attention-based copy mechanism to copy arguments from natural language query to logical form for the task of semantic parsing. Gulcehre et al. (2016) design a pointer network to select tokens in the input. Different from previous work, we consider copying only numbers from the problem description.

Some recent work have been proposed to improve the alignment for neural machine translation (Liu et al., 2016; Mi et al., 2016). They introduced a supervised attention mechanism to utilize the word alignment information between sentence pairs in the training data. They first obtain soft word alignments from conventional alignment models. Then they try minimize the distance between the soft word alignments and the word alignments based on model attention in the training procedure. In our math problems, the alignment information is explicit and can be directly obtained.

7.3 Reinforcement Learning for Sequence Generation

The classic REINFORCE algorithm (Williams, 1992) has been applied to solve a wide variety of tasks: machine translation (Norouzi et al., 2016), image captioning (Rennie et al., 2017), semantic parsing (Liang et al., 2017; Guu et al., 2017) and summarization (Paulus et al., 2018). Reinforcement learning is applied usually when the evaluation metric is non-differentiable, or there are multiple candidates that yields to the ground truth despite of token orders in target sequence. It trains an agent with a given environment to directly optimize the task evaluation metric (e.g., BLEU or ROUGE). We apply reinforcement learning in math problem solving for two reasons: (1) we evaluate our task with solution accuracy which is not directly optimized in maximum likelihood estimation; (2) there are multiple equations that yield to the correct solution which maximum likelihood estimation would ignore.

8 Conclusion

In this paper, we follow previous work that applies seq2seq model to solve math word problems. We augment the model with two mechanisms: copy and align. When training the model, we adopt the reinforcement learning to directly optimize the solution accuracy. Our model significantly improves the

performance. To further explore the effectiveness of both neural approach and feature-based approach, we add our model output as a feature into the feature-based model. The combined model leverages advantages of both approaches and achieves the-state-of-the-art result.

In the future work, we will design more methods to combine the two models to better leverage each approach. Furthermore, for math problems, several modules are important, such as mathematical concept and commonsense knowledge, which we plan to incorporate into our model in the future.

Personalizing Lexical Simplification

John Lee, Chak Yan Yeung
Department of Linguistics and Translation
City University of Hong Kong
jsylee@cityu.edu.hk, chak.yeung@my.cityu.edu.hk

Abstract

Given an input text from the user, a lexical simplification (LS) system makes the text easier to understand by substituting difficult words with simpler words. The best substitution may vary from one user to another, given individual differences in vocabulary proficiency level. Most current systems, however, do not consider these variations, and are instead trained to find one optimal substitution or list of substitutions for all users. This paper measures the benefits of using complex word identification (CWI) models to personalize an LS system. Experimental results show that even a simple CWI model, based on graded vocabulary lists, can help reduce the number of unnecessary simplifications and complex words in the output for learners of English at different proficiency levels.

1 Introduction

Lexical simplification (LS) is the task of replacing difficult words with simple words in a text, while preserving its meaning and grammaticality. It aims to produce output text that is easier to understand for readers with special needs, such as language learners, children (Kajiwara et al., 2013), and those with language disabilities (Devlin and Tait, 1998; Carroll et al., 1999). Table 1 shows an example input sentence to an LS system, and the ranked list of possible substitutions for the target word, i.e., the word that should be simplified. Most LS systems first perform complex word identification (CWI) to detect target words (i.e., "avoid" in this case), and then find appropriate substitutions for them (i.e., "prevent", "stop", etc., in order of preference).

CWI is thus an important first step in the LS pipeline. On the one hand, an overly conservative CWI model would fail to detect many complex words, leaving them unsimplified and limiting the utility of the LS system. On the other hand, an overly aggressive CWI model would be prone to misidentify simple words as complex, leading to unnecessary simplifications and increasing the risk of substitution errors. In an error analysis on LS systems, CWI-related error categories turned out to be among the most frequent (Shardlow, 2014). CWI has been receiving increasing attention in recent years, including a recent SemEval shared task (Paetzold and Specia, 2016b). Since the test set was annotated by a single learner, however, CWI performance on language learners at different levels of vocabulary proficiency continues to be under-explored.

Indeed, most LS evaluations assume one best substitution or one fixed ranked list of substitutions (cf. Table 1), and do not take into account variations in vocabulary knowledge among users. This "one-size-fits-all" approach is suboptimal since word complexity is in the eye of the beholder: a word that is complex for a low-proficiency user may be perfectly familiar to a high-proficiency user, or even to a low-proficiency user whose native language has a cognate word. As a case in point, consider the dataset in the SemEval 2016 CWI shared task. The Krippendorff's Alpha agreement was 0.244 among the 20 annotators. Further, suppose one builds an oracle CWI system on the test set in the shared task, and apply it on the Japanese learners of English in the dataset constructed by Ehara et al. (2010). For the

Input sentence	Gold ranked list of substitutions
Typically, a fast shutter speed will require a larger aperture to ensure sufficient light exposure, and a slow shutter speed will require a smaller aperture to *avoid* excessive exposure.	1. prevent 2. stop 3. {dodge, miss, evade, escape} 4. {elude, limit, avert, bypass, deter}

Table 1: An input sentence to a lexical simplification system, and the gold ranked list of substitutions for the target word, "avoid". This example is taken from the BenchLS dataset (Paetzold and Specia, 2016a).

least proficient learner in this dataset, the oracle would fail to identify 35.30% of the complex words; for the most proficient learner, it would cause false alarm for 93.67% of the non-complex words.

To address "the expected heterogeneity among non-native speakers with different language backgrounds and proficiency levels" (Paetzold and Specia, 2016b), this paper argues for the use of personalized CWI models to improve LS performance. We present the first quantitative evaluation of personalized LS on learners at varying levels of English proficiency. Further, we demonstrate that even a simple CWI model, based on graded vocabulary lists, can reduce the number of unnecessary simplifications and complex words in the output text.

The rest of the paper is organized as follows. The next section summarizes previous LS research, focusing on CWI and Substitution Ranking, where we will attempt personalization. Section 3 gives details on our data. Section 4 describes our approach and baselines. Section 5 defines the evaluation metrics. Section 6 presents experimental results and discusses the extent to which LS systems can benefit from personalized CWI. Finally, Section 7 concludes.

2 Previous work

Most lexical simplification (LS) systems adopt a pipeline architecture (Shardlow, 2014; Paetzold and Specia, 2016b). The pipeline typically begins with **Complex Word Identification** (CWI) to find target words to be simplified. A **Substitution Generation** component then generates candidate replacements for these complex words. These substitutions can be learned, for example, from standard Wikipedia and Simple Wikipedia (Horn et al., 2014), or with word embedding models (Glavaš and Štajner, 2015; Paetzold and Specia, 2016c). The **Substitution Selection** step then discards candidates that may distort the meaning of the text or affect its grammaticality, and retains those that best fits the context. Lastly, **Substitution Ranking** determines the best output by ranking the remaining candidates by simplicity.

LS research has mostly adopted the user-independent approach. We now review previous work in two components of the pipeline to which we will attempt to add personalization: CWI (Section 2.1) and Substitution Ranking (Section 2.2).

2.1 Complex word identification

The complex word identification (CWI) task classifies words in a text as either "complex" or "non-complex". Complex words are those that are difficult for a non-native speaker to understand; non-complex words are those that are not (Paetzold and Specia, 2016b; Yimam et al., 2017). In the 2016 SemEval CWI shared task, the best team, which combined various lexicon-based, threshold-based and machine learning voter sub-systems, achieved a precision of 0.147 and recall of 0.769 (Paetzold and Specia, 2016b). Overall, word frequencies were found to give the most reliable prediction for word complexity. The shared task was not designed to test performance on users at different proficiency levels, since the test set was annotated by a single learner.

To date, most CWI research has taken the user-independent approach, with only a few published studies on personalized CWI. Zeng et al. (2005) showed that demographic features can help improve CWI performance for individual users in the medical domain. Laufer and Nation (1999) proposed the "word sampling" method. Using a ten-level proficiency scale, with 1000 words at each level, this method samples a fixed number of words from the learner as the training set, and then labels unseen words based on their proximity to these words. Ehara et al. (2012; 2014) described a two-step algorithm, mainly using

word frequency statistics as features. In the first step, all words are organized as a multiple complete graph. The k most informative nodes, or words, are selected by a graph-based active learning approach. The learner then rates his/her knowledge of these k words on a five-point scale (see Section 3.1). Lee and Yeung (2018) followed the same procedure to create a training set for Chinese CWI. In the second step, a personal CWI classifier is trained for each learner. Using a 50-word training set, Ehara et al. (2014) achieve 76.44% accuracy in English CWI with Local and Global Consistency, a label propagation algorithm. Lee and Yeung (2018) reported 78.0% accuracy for Chinese CWI with an SVM classifier.

An alternative approach is to build only a fixed number of CWI models. After soliciting annotation of vocabulary knowledge on a small number of sample words from the user, the system predicts the most suitable model. These models can correspond to graded vocabulary lists, such as the New General Service Lists (http://www.newgeneralservicelist.org), or they may potentially be trained on graded text corpora, such as the Newsela corpus (Xu et al., 2015). This approach thus offers more coarse-grained personalization, akin to graded readers, and not every user necessarily fits neatly into one of the predetermined levels.

2.2 Substitution ranking

Given a set of candidates from the Substitution Selection step, the Substitution Ranking step chooses the simplest candidate. Most current approaches impose the same notion of simplicity on all users. Recent systems have applied machine learning approaches, such as the SVM (Horn et al., 2014) and neural models (Paetzold and Specia, 2017), on a range of features including word frequencies in large corpora and human rankings in LS datasets. This step can potentially be enhanced with CWI to filter out candidates that are complex words.

3 Data

In this section, we first describe our dataset of language learners (Section 3.1), and then explain how we used it to create personalized versions of an existing, user-independent dataset of lexical simplification (Section 3.2).

3.1 User dataset

Our user dataset was annotated by 15 learners of English as a foreign language who were native speakers of Japanese (Ehara et al., 2010). Each learner rated their knowledge of 12,000 English words on a five-point scale: (1) Never seen the word before; (2) Probably seen the word before; (3) Absolutely seen the word before but do not know its meaning, or tried to learn the word before but forgot its meaning; (4) Probably know, or able to guess, the words meaning; and (5) Absolutely know the words meaning. Following Ehara et al. (2014), we collapsed these five categories into either "complex" (score 1 through 4) or "non-complex" (score 5). Table 2 shows some example annotations.

These 15 learners covered a wide range of proficiency levels. The least proficient learner rated only 17.97% of the words as "non-complex", while the most proficient one rated 94.26% of the words as "non-complex". To help analyze the effect of personalized LS at different proficiency levels, we define two subsets of learners based on vocabulary proficiency:

- **Low Proficiency.** The four least proficient learners, all of whom knew less than 41% of the words, constitute the "Low" proficiency subset.
- **High Proficiency.** The four most proficient learners, all of whom knew more than 75% of the words, constitute the "High" proficiency subset.

3.2 Personalized lexical simplification dataset

The BenchLS dataset contains 929 instances of target words and their gold simple words, annotated by English speakers from the U.S. (Paetzold and Specia, 2016a). For the 15 users (Section 3.1), we created 15 personalized versions of BenchLS with the following steps:

Word	User A	User B	User C	User D
avert				
avoid				√
bypass	√	√	√	√
deter				√
dodge				√
elude				
escape	√	√		√
evade				√
limit	√	√	√	√
miss	√	√		√
prevent		√		√
stop	√	√	√	√

Table 2: Annotations on 12 example words by four users in the user dataset (Section 3.1). Non-complex words are indicated with a checkmark (√); all other words are complex.

User A	User B	User C	User D
1. stop 2. {miss, escape} 3. {limit, bypass}	1. prevent 2. stop 3. {miss, escape} 4. {limit, bypass}	1. stop 2. {limit, bypass}	*null*

Table 3: Personalized gold ranked list of substitutions for the target word "avoid" in Table 1, based on annotations in the user dataset shown in Table 2.

- When the target word is non-complex for the user, we set the gold answer to *null*. Since the user already understands the word, in the interest of meaning preservation, the system should not simplify it. Consider the target word "avoid" in Table 1. Since it is non-complex for User D (Table 2), the gold answer for this target word should be *null* for User D (Table 3).

- When the target word is complex for the user, the system should attempt simplification on it. We retrieve the gold ranked list of substitutions in BenchLS, and remove all complex words from the list, since they would not be helpful for the user. If the list becomes empty, we exclude this instance from our evaluation. Consider again the target word and its gold list of substitutions in Table 1. When editing this list for Users A, B, and C, we keep only those words that are non-complex for them, according to their annotations in Table 2. Notably, the first-ranked substitution is no longer "prevent" for Users A and C, since they do not know this word. The resulting personal gold lists are shown in Table 3.

After filtering, our evaluation dataset contained 883 instances.

4 Approach

We propose a lexical simplification (LS) algorithm that aims to turn complex words in a text into non-complex ones for the user, while keeping intact the non-complex words in the text. This algorithm applies a personalized complex word identification (CWI) model in two steps in the LS pipeline:

- **CWI for detection**: Most current approaches deploy a user-independent CWI model as the first step in their pipeline to detect words that should be simplified (Section 2.1). In contrast, we train a personalized CWI model for this purpose, such that the choice of target words can vary from one user to another. For example, given the input sentence in Table 1, the system is expected to simplify "avoid" for Users A, B, and C, but not for User D (Table 3).

Level	# Words	Content of vocabulary List
1	1,000	First 1,000 words in the New General Service List (NGSL)
2	2,000	First 2,000 words in the NGSL
3	2,800	All words in the NGSL
4	6,777	All words in the NGSL, the TOEIC Service List (TSL), the New Academic Word List (NAWL), and the Business Service List (BSL)

Table 4: Vocabulary lists corresponding to the four CWI models used in the Graded Vocabulary List approach (Section 4).

- **CWI for ranking**: The Substitution Ranking step of the pipeline ranks the substitution candidates according to their simplicity (Section 2.2). In addition, we apply the personalized CWI model to filter out candidates that are complex for the user. For example, given the list of candidate substitutions in Table 1, the system is expected to reject the word "prevent" for Users A and C, since they do not know it. If the model predicts all candidates to be complex, it still returns the first-ranked candidate as the suggested substitution.

Our experiments apply various configurations of the following three models[1] to perform CWI for detection and CWI for ranking, respectively:

- **Baseline** (`nil`): When used as CWI for detection, this baseline always predicts a word to be complex regardless of the user, so the system always attempts simplification. When used as CWI for ranking, it always predicts a word to be non-complex, so the system never removes any word from the user-independent list of substitutions.

- **Oracle** (`gold`): The oracle performs perfect CWI on each user, according to his/her annotation in the user dataset (Section 3.1). When the oracle is used as CWI for detection, the system attempts simplification if and only if the word is complex. When it is used as CWI for ranking, the system returns the highest-ranked substitution that is non-complex for the user.

- **Graded Vocabulary List** (`auto`): This model automatically predicts a word as complex or non-complex, based on graded vocabulary lists. As shown in Table 4, we define four vocabulary proficiency levels, based on 6,777 words covered by a number of vocabulary lists. We then construct four CWI models corresponding to these four levels; each model predicts all words in its vocabulary list to be "non-complex", and all other words to be "complex".

  Next, we select n out of the 6,777 words in the dataset as the training set, with the n words divided evenly among the four levels. For each user, based on his/her annotation in the user dataset (Section 3.1), we calculate the precision and recall of each of the four CWI models. We then assign the user to the model with the highest F-score. In our evaluation, we set $n = 40$, meaning that each user would have to annotate 40 words as "complex" or "non-complex" in order to personalize the LS system.[2]

5 Evaluation metrics

We report two metrics used in previous LS research (Horn et al., 2014; Glavaš and Štajner, 2015):

- *Precision* is the ratio of correct simplifications out of all simplifications made by the system.

- *Accuracy* is the ratio of correct simplifications out of all target words that should be simplified, i.e., in our context, out of all complex target words.

[1] We did not evaluate the model proposed by Ehara et al. (2014) since we were not able to get access to its system output.
[2] Users who do not know any of the 40 words are assigned to the level-1 model.

CWI for detection	CWI for ranking	Precision	Accuracy	Readability
nil	nil	21.39%	89.95%	91.47%
		43.14% (low only)	76.31% (low only)	80.02% (low only)
		4.25% (high only)	100% (high only)	99.01% (high only)
auto	nil	31.97%	76.19%	89.40%
nil	auto	23.36%	**94.19%**	**94.57%**
auto	auto	**34.81%**	80.36%	91.67%
gold	nil	89.95%	89.95%	95.55%
nil	gold	26.31%	100%	100%
gold	gold	100%	100%	100%

Table 5: Performance on the personalized LS dataset (Section 3.2), based on gold substitution lists in BenchLS (Paetzold and Specia, 2016b) and on three methods for CWI for detection and CWI for ranking: nil predicts all target words to be complex, and all candidate substitutions to be non-complex; gold returns the annotation in the user dataset (Section 3.1); auto is the automatic CWI model based on graded vocabulary lists. Low and high refer to proficiency level (Section 3.1).

Correctness of a simplification is based on the personalized LS dataset (Section 3.2) rather than the BenchLS dataset (Paetzold and Specia, 2016a). For instance, in the sentence in Table 1, it is correct to substitute "avoid" with "prevent" for User B, but incorrect to do so for User A and C. Further, it is deemed incorrect to make any substitution for User D (Table 3).

Note that precision penalizes simplifications of non-complex words, even if the substitution is also a non-complex word in the gold list in BenchLS. For some users, this penalty may be reasonable since few substitutions fully preserve the meaning and intent of the original text. For others, unnecessary simplifications may be perfectly acceptable, given the overriding goal of minimizing the number of unknown words in the output text.

To represent the latter perspective, we also report the *readability* metric, which computes the proportion of words in the output text that can be understood by the user and do not distort the original meaning. More precisely, a word in the output text is *readable* if it satisfies two conditions: (1) it is non-complex for the user; and (2) it is either included in the original gold substitution list in BenchLS, or it is unsimplified. Since this metric does not consider whether the original word is complex or non-complex, it allows unnecessary simplification as long as it is appropriate.

6 Experiments

We conducted two experiments to evaluate the effect of adding personalization to a lexical simplification (LS) system. In both experiments, the baseline is a user-independent ranked list of substitutions. We manipulate the list with various combinations of CWI for detection and/or CWI for ranking (see Section 4), and then measure any gain in LS performance. All results are averaged among the 15 users in the dataset (Section 3.1).

6.1 Experiment 1: Personalization with gold substitutions

To better isolate the performance gain as a result of personalization, the first experiment used the gold substitution lists in BenchLS. This design ensures that the performance gain would not be influenced by the extent and nature of the particular substitution errors made by the LS system chosen as baseline.

Table 5 reports performance on the personalized LS dataset (Section 3.2). Because of the use of gold substitutions in BenchLS, the absolute level of performance is overestimated. We will focus on the *difference* between the baseline and the personalized systems, and will verify if the difference holds in realistic conditions in the second experiment.

Precision. The oracle (detect=gold, rank=gold), by definition, achieved the perfect score in all metrics. In contrast, the user-independent approach (detect=nil, rank=nil), even with perfect substi-

CWI for detection	CWI for ranking	Precision	Accuracy	Readability
nil	nil	8.09% (low only) 14.87% (high only) 1.96%	39.17% (low only) 27.06% (high only) 51.25%	37.94% (low only) 27.53% (high only) 45.94%
auto	nil	12.03%	32.59%	61.27%
nil	auto	12.37%	**50.91%**	53.45%
auto	auto	**18.01%**	42.25%	**69.39%**
gold	nil	39.28%	39.17%	83.38%
nil	gold	14.57%	52.52%	56.01%
gold	gold	58.57%	52.52%	87.44%

Table 6: Performance on the personalized LS dataset (Section 3.2), based on output from a user-independent LS system (Paetzold and Specia, 2017), and on three methods for CWI for detection and CWI for ranking: nil predicts all target words to be complex, and all candidate substitutions to be non-complex; gold returns the annotation in the user dataset (Section 3.1); auto is the automatic CWI model based on graded vocabulary lists. Low and high refer to proficiency level (Section 3.1).

tutions, hit a ceiling at 21.39% precision. One source of error for precision was the simplification of non-complex words in the input text, since the system always attempted simplification. Naturally, this was especially problematic for high-proficiency users, as reflected in the lower precision (4.25%), but had less impact on low-proficiency users (43.14% precision). Personalized CWI reduced these unnecessary simplifications, raising precision to as high as 89.95% with oracle CWI for detection (detect=gold, rank=nil). The automatic CWI approach (detect=auto, rank=nil), based on vocabulary lists, also succeeded in reducing them and attained 31.97% precision, a 10% absolute improvement over the baseline.

Accuracy. Another source of error for the user-independent approach was the fact that some gold substitutions were complex; in other words, while these substitutions were considered simpler than the target words, they were still too difficult for the user. This phenomenon resulted in the 89.95% accuracy rate for the user-independent approach (detect=nil, rank=nil). As expected, the phenomenon was magnified among low-proficiency users, as shown by the lower accuracy (76.31%), but it barely affected the high-proficiency users (100% accuracy). Personalized CWI helped steer the system to choose non-complex words as output. Oracle CWI for ranking (detect=nil, rank=gold), by definition, achieved 100% accuracy. The automatic CWI approach (detect=nil, rank=auto) yielded smaller improvement but, at 94.19% accuracy, still outperformed the baseline by over 4% absolute.

Readability. With respect to the readability measure, which accepts unnecessary simplifications, personalized approaches still produced better output than the user-independent baseline. Among configurations that did not involve gold, the highest readability score (94.57%) was achieved by the system that always attempted simplification but used automatic CWI for ranking (detect=nil, rank=auto); this represented a 3% improvement over the baseline. It also achieved the highest accuracy (94.19%). Using automatic CWI for both detection and ranking (detect=auto, rank=auto) produced the best precision (34.81%), an absolute improvement of over 13% over the baseline. However, its accuracy and readability were suboptimal because, by making fewer simplifications, it left more complex words in the input text unsimplified.

6.2 Experiment 2: Personalization with automatically generated substitutions

Results from the first experiment, which assumed perfect substitutions, showed consistent performance gains as a result of personalization. The second experiment investigated whether these gains would hold under more realistic conditions. Instead of gold substitutions from BenchLS, we used the output of a state-of-the-art, user-independent LS system (Paetzold and Specia, 2017). Table 6 shows the performance on the personalized LS dataset (Section 3.2). In this setting, the oracle (detect=gold, rank=gold)

attained only 58.57% precision and 52.52% accuracy. As will be discussed below, the gap between the baseline and the personalized systems persisted.

Precision. The user-independent approach (detect=`nil`, rank=`nil`) achieved only 8.09% precision. A major source of error for precision, as observed in the first experiment, was the simplification of non-complex words in the input text. Oracle CWI for detection (detect=`gold`, rank=`nil`) raised the precision to 39.28%. Automatic CWI for detection (detect=`auto`, rank=`nil`) yielded 12.03% precision, improving the baseline by almost 4% absolute.

Accuracy. The ability of personalization to reduce the other major source of error — selection of complex words as substitutions — was also observed in this experiment. While the accuracy of the user-independent approach (detect=`nil`, rank=`nil`) was only 39.17%, automatic CWI for ranking (detect=`nil`, rank=`auto`) improved it by over 11% to reach 50.91%. This level of performance was very close to the upper bound of 52.52% accuracy suggested by oracle CWI for ranking (detect=`nil`, rank=`gold`).

Readability. In terms of readability, after excluding configurations that involve `gold`, the best readability score (69.39%) was achieved by using automatic CWI for both detection and ranking (detect=`auto`, rank=`auto`). This represented an absolute improvement of over 31% in comparison to the user-independent baseline. Unlike in the first experiment, the system's conservativeness in making simplifications worked in its favor because of the presence of substitution errors. This configuration also yielded the highest precision (18.01%), outperforming the baseline by almost 10%. However, the highest accuracy (50.91%), similar to the first experiment, was obtained by using automatic CWI for ranking only (detect=`nil`, rank=`auto`).

7 Conclusion

Most current approaches to lexical simplification (LS) are user-independent. This paper proposed the use of personalized models of complex word identification (CWI) to tailor LS systems to the vocabulary proficiency of the user. We presented the first study on the effect of personalized CWI in two steps of the LS pipeline: to detect which words require simplification, and to reject substitution candidates that are still too difficult for the user. We measured both the upper bounds of performance gains with an oracle CWI model, as well as the actual gains of a simple automatic CWI model that required only a 40-word training set per user, based on graded vocabulary lists.

Experimental results with oracle CWI demonstrated much room for improving LS systems through personalization. Further, systems that used the automatic CWI model consistently outperformed the user-independent baseline, by reducing both the number of unnecessary simplifications and the number of complex words in the output. The performance gains persisted regardless of whether the substitutions were gold or automatically generated, yielding improvement in precision and accuracy ranging from 4% to 13%. As CWI research produces higher-performing models, future LS systems can expect to derive even greater benefits from personalization.

Abstract

Distributional word representations (often referred to as word embeddings) are omnipresent in modern NLP. Early work has focused on building representations for word types, and recent studies show that lemmatization and part of speech (POS) disambiguation of targets in isolation improve the performance of word embeddings on a range of downstream tasks. However, the reasons behind these improvements, the qualitative effects of these operations and the combined performance of lemmatized and POS disambiguated targets are less studied. This work aims to close this gap and puts previous findings into a general perspective. We examine the effect of lemmatization and POS typing on word embedding performance in a novel resource-based evaluation scenario, as well as on standard similarity benchmarks. We show that these two operations have complementary qualitative and vocabulary-level effects and are best used in combination. We find that the improvement is more pronounced for verbs and show how lemmatization and POS typing implicitly target some of the verb-specific issues. We claim that the observed improvement is a result of better conceptual alignment between word embeddings and lexical resources, stressing the need for conceptually plausible modeling of word embedding targets.

1 Introduction

Word embeddings learned from unlabeled corpora are one of the cornerstones of modern natural language processing. They offer important advantages over their sparse counterparts, allowing efficient computation and capturing a surprising amount of lexical information about words based solely on usage data.

Since precise word-related terminology is important for this paper, we introduce it early on. A **token** is a unique word occurrence within context. Tokens that are represented by the same sequence of characters belong to the same word **type**. A type signifies one or — in case of morphological ambiguity — several **word forms**. Word forms encode the grammatical information carried by the word and are therefore POS-specific. One of the word forms is considered the **base form** - or **lemma** of the word. All possible word forms of a word represent the **lexeme** of this word. From a semantic perspective, a word is assigned to a minimal sense-bearing **lexical unit** (LU). In general, multi-word and sub-word lexical units are possible, but in this paper we focus on single-word units. LUs are the reference point to the semantics of the word and might be used to describe further properties of the words within a specific **lexicon**, e.g. get assigned one or several senses, related to other LUs via lexical relations etc. Figure 1 illustrates these concepts and positions some of the relevant approaches w.r.t. the level they operate on.

In general, the training objective in the unsupervised word embedding setup (e.g. (Mikolov et al., 2013)) is to induce vector representations for **targets** based on their occurrences in an unlabeled reference corpus. For each occurrence of the target, **context** representation is extracted. The goal is to encode targets so that targets appearing in similar contexts are close in the resulting **vector space model** (VSM). We further refer to the set of targets in a given VSM as **target vocabulary** of this VSM.

The applications of word embeddings can be roughly grouped in two categories, **occurrence-based** and **vocabulary-based**: the former aims to classify tokens (e.g. parsing, tagging, coreference resolution), the

Proceedings of the 27th International Conference on Computational Linguistics, pages 233–244
Santa Fe, New Mexico, USA, August 20-26, 2018.

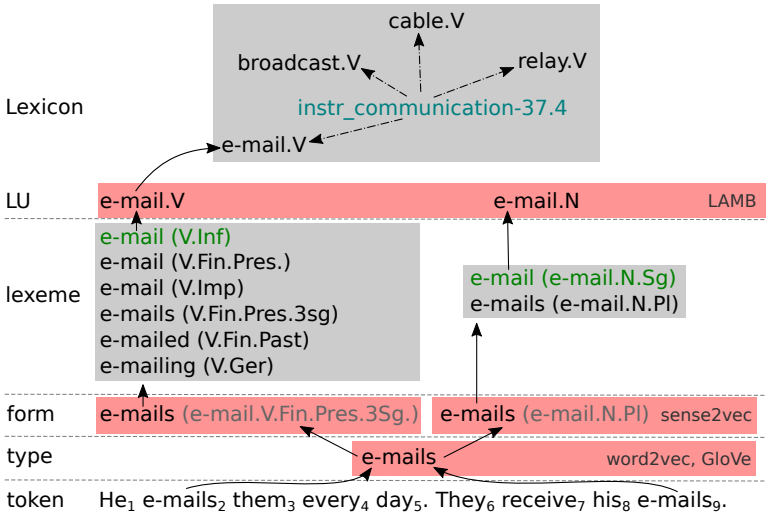

Figure 1: Hierarchy of word-related concepts for *emails*, with VerbNet as lexicon example.

latter aims to classify lexemes (e.g. word clustering, thesaurus construction, lexicon completion). Lexical resources mostly operate on lexeme or lexical unit level. This includes most of the similarity benchmarks (Finkelstein et al., 2001; Bruni et al., 2014; Hill et al., 2015; Gerz et al., 2016) that implicitly provide similarity scores for lexemes and not word types. Traditional word embeddings approaches (Mikolov et al., 2013; Pennington et al., 2014) induce representations on word type level. As our example in Figure 1 shows, this leads to a conceptual gap between the lexicon and the VSM, which has practical consequences. Consider the standard scenario when a type-based VSM is evaluated against a lexeme-based benchmark. One of the types contained in the VSM vocabulary corresponds to the base form (lemma), and the vector for the base word form is used for evaluation. This particular form, however, is selected based on *grammatical* considerations and, as we later demonstrate, is neither the most frequent nor the most representative in terms of contexts, nor the most unambiguous. As a result, (1) the contexts for a given lexical unit are under-represented, ignoring other word forms than the base form; (2) in case of ambiguity the same context-based representation is learned for several different lexemes sharing the same word type.

Recent studies demonstrate that even partially addressing these problems leads to improved performance. Ebert et al. (2016) introduce the lemma-based LAMB embeddings and show that lemmatization of the targets improves the results cross-linguistically on similarity benchmarks and in a WordNet-based evaluation scenario. In our scheme this represents a step up in the conceptual hierarchy but still leaves room for ambiguity on the LU level. Trask et al. (2015) experiment with POS-disambiguated targets, and also report improved performance on a variety of tasks.

While prior work shows that lemmatization and POS-typing of targets in isolation are beneficial for downstream tasks, it does not provide a detailed investigation on why it is the case and does not study the effects of combining the two preprocessing techniques. This paper aims to close this gap. We evaluate the effects of lemmatization and POS disambiguation separately and combined on similarity benchmarks, and further refine our results using a novel resource-based word class suggestion scenario which measures how well a VSM represents VerbNet (Schuler, 2005) and WordNet supersense (Ciaramita and Johnson, 2003) class membership. We find that POS-typing and lemmatization have complementary qualitative and vocabulary-level effects and are best used in combination. We observe that English verb similarity is harder to model and show that using lemmatized and disambiguated embeddings implicitly targets some of the verb-specific issues. In summary, the contributions of this paper are as follows:

- We suggest using lemmatized *and* POS disambiguated targets as a conceptually plausible alternative to type, word form and lemma-based VSMs;
- We introduce the suggestion-based evaluation scenario applicable to a wide range of lexical resources;
- We show that lemmatization and POS disambiguation improve both benchmark and resource-based performance by implicitly targeting some of the grammar-level issues.

2 Related work

The starting point for our study are the results from the lemma-based word embedding approach by Ebert et al. (2016), the POS-disambiguated *sense2vec* embeddings by Trask et al. (2015) and the dependency-based contexts by Levy and Goldberg (2014). Our primary focus is the effect of word embedding targets on vocabulary-based task performance. However, to put our work in context, we provide an extended overview of the issues related to traditional type-based approaches to VSM construction, along with relevant solutions.

Type-based VSMs (Mikolov et al., 2013; Pennington et al., 2014) have several limitations that have been extensively studied. They have **restricted vocabularies** and hence lack the ability to represent out-of-vocabulary words. Several recent approaches treat this issue by learning vector representations for sub-word units, e.g. *fastText* (Bojanowski et al., 2016) and *charagram* (Wieting et al., 2016).

Type-based VSMs do not abstract away from **word inflection**: different forms of the same word are assigned different representations in the VSM. Ebert et al. (2016) introduces lemmatized LAMB embeddings as a way to address this issue and shows that lemmatization is highly beneficial for word similarity and lexical modeling tasks even for morphologically poor English, while using *stems* doesn't lead to significant improvements. Their approach is similar to our `lemma-w2` setup (Section 3). Another recent attempt to address this problem is the study by Vulić et al. (2017b), which uses a small set of morphological rules to specialize the vector space bringing the forms of the same word closer together while setting the derivational antonyms further apart. We relate to this approach in Section 4.

Finally, type-based VSMs neglect the problem of **polysemy**: all senses of a word are encoded as a single entry in the VSM. This issue has been recently approached by multi-modal word embeddings (Athiwaratkun and Wilson, 2017) and Gaussian embeddings (Vilnis and McCallum, 2014). Partially disambiguating the source data via POS tagging has been employed in (Trask et al., 2015). Here, instead of constructing vectors for word forms, POS information is integrated into the vector space as well. This is similar to our `type.POS-w2` setup (Section 3) which, as we show, introduces additional sparsity and ignores morphological inflection.

An alternative line of research aims to learn embeddings for lexical units by using an external WSD tool to preprocess the corpus and applying standard word embedding machinery to induce distributed representations for lexical units, e.g. (Iacobacci et al., 2015; Flekova and Gurevych, 2016). Such approaches require an external WSD tool which introduces additional bias and might not be available for lower-resourced languages. Moreover, to query such VSMs it is necessary to either apply WSD to the input, or to align the inputs with the senses in some other way, which is not always feasible.

From the evaluation perspective, a popular method to assess the performance of a particular vector space model is **similarity benchmarking**. A similarity benchmark consists of word pairs along with human-assessed similarity scores, which are compared to cosine similarities returned by VSMs via rank correlation. Some common examples include WordSim-353 (Finkelstein et al., 2001) and MEN (Bruni et al., 2014). The recent SimLex-999 (Hill et al., 2015) and SimVerb-3500 (Gerz et al., 2016) particularly focus on word similarity as opposed to word relatedness (e.g. *bank* and *money* would be related, but not similar) and have been shown difficult for word embedding models to tackle.

Being attractive from the practical perspective, similarity benchmarks are expensive to create and do not provide detailed insights about the lexical properties encoded by the word embeddings. Motivated by that, **resource-based benchmarking** strategies have been suggested. (Ebert et al., 2016) represents WordNet as a graph and measures the correspondence of similarity ranking to the distances between query words in the graph via mean reciprocal rank. Vulić et al. (2017a) and Sun et al. (2008) apply a clustering algorithm to the input words and measure how well the clusters correspond to the word groupings in VerbNet via purity and collocation. Both methods have certain limitations, which we discuss and attempt to resolve via a novel general suggestion-based approach in Section 5.

3 General setup

Distributional word representations aim to encode word targets based on the context words they co-occur with. One popular general-purpose model for inducing such representations is skip-gram with negative

sampling (SGNS), exemplified by word2vec (Mikolov et al., 2013).

In the original SGNS targets and contexts belong to the same type-based vocabulary, but this is not required by the model. In this study we experiment with the following targets: `type` (*going*), `lemma` (*go*), `type.POS`[1] (*going.V*) and `lemma.POS` (*go.V*). Word embeddings demonstrate qualitative differences depending on context definition (Levy and Goldberg, 2014), and we additionally report the results on 2-word window-based (`w2`) and dependency-based (`dep-W`) contexts. To keep the evaluation setup simple, we only experiment with word type-based contexts.

We train 300-dimensional VSMs on a recent English Wikipedia dump, preprocessed using the Stanford Core NLP pipeline (Manning et al., 2014) with Universal Dependencies 1.0. The text is extracted using the *wikiextractor* module[2] with minor additional cleanup routines. Training the VSM is performed with the skip-gram based *word2vecf* implementation from (Levy and Goldberg, 2014) with default algorithm parameters.

4 Similarity Benchmarks

Following previous work, we first evaluate the effect of lemmatization and POS-typing on similarity benchmarks SimLex-999 (Hill et al., 2015) and SimVerb-3500 (Gerz et al., 2016). Both benchmarks provide POS information, which is required by POS-enriched VSMs. SimLex-999 contains nouns (60%), verbs (30%) and adjectives (10%); SimVerb-3500 is verbs-only. Table 1 summarizes the performance of the VSMs in question on similarity benchmarks.

Context: `w2`

	SimLex				SimVerb
target	N	V	A	all	V
type	.334	**.336**	**.518**	.348	.307
+ POS	.342	.323	.513	.350	.279
lemma	**.362**	.333	.497	**.351**	.400
+ POS	.354	**.336**	.504	.345	**.406**
* type	-	-	-	.339	.277
* type MFit-A	-	-	-	.385	-
* type MFit-AR	-	-	-	.439	.381
Context: `dep-W`					
type	.366	.365	.489	.362	.314
+ POS	.364	.351	.482	.359	.287
lemma	**.391**	.380	**.522**	**.379**	.401
+ POS	.384	**.388**	.480	.366	**.431**
* type	-	-	-	.376	.313
* type MFit-AR	-	-	-	.434	.418

Table 1: Benchmark performance, Spearman's ρ. SGNS results with * taken from (Vulić et al., 2017b). Best results per column (benchmark) annotated for our setup only.

Several observations can be made. Lemmatized targets generally perform better, with the boost being more pronounced on SimVerb. English verbs have richer morphology than other parts of speech and benefit more from lemmatization. Adding POS information benefits the SimVerb and SimLex verb performance, which can be attributed to the **coarse disambiguation** of verb-noun and verb-adjective homonyms. However, the `type.POS` targets show a considerable performance drop on SimVerb and SimLex verbs. This is due to **vocabulary fragmentation**, when the same word type is split into several entries based on the POS, e.g. *acts (110)* $\rightarrow$ *acts.V (80) + acts.N (30)*. As a result, some word types do not exceed the frequency threshold and are not included into the final VSM. Another way to see it

[1] We use coarse POS classes obtained by selecting the first character in the Penn POS tags assigned by the tagger

[2] `https://github.com/attardi/wikiextractor`

is that POS disambiguation increases the sparsity, which lemmatization, in turn, aims to reduce. Using dep-W contexts proves beneficial for both datasets since modeling the context via syntactic dependencies results in more similarity-driven (as opposed to relatedness-driven) word embeddings (Levy and Goldberg, 2014).

We provide the Morph-Fitting scores (Vulić et al., 2017b) as a state-of-the-art reference; a direct comparison is not possible due to the differences in the training data and information available to the models. This approach uses word type-based VSMs specialized via Morph-Fitting (MFit), which can be seen as an alternative to lemmatization. Morph-Fitting consists of two stages: the Attract (A) stage brings word forms of the same word closer in the VSM, while the Repel (R) stage sets the derivational antonyms further apart. Lemma grouping is similar to the Attract stage. However, as the comparison of MFit-A and -AR shows, a major part of the Morph-Fitting performance gain on SimLex comes from the derivational Repel stage[3], which is out of the scope of this paper.

While some properties of lemmatized and POS disambiguated embeddings are visible on the similarity benchmarks, the results are still inconclusive, and we proceed to a more detailed evaluation scenario.

5 Word Class Suggestion

5.1 Background

Similarity benchmarks serve as a standard evaluation tool for word embeddings, but provide little insights into the nature of relationships encoded by the word representations. A more fine-grained context-free evaluation strategy is to assess how well the relationships in a certain **lexical resource** are represented by the given VSM. Two recent approaches to achieve this are rank-based and clustering-based evaluation.

Rank-based evaluation treats the lexical resource as a graph with entries as nodes and lexical relations as edges, and estimates how well the similarities between the VSM targets represent the distances in this graph via mean reciprocal rank (MRR), e.g. Ebert et al. (2016) use WordNet (Miller, 1995). It requires the target lexical resource to have a dense linked structure which might be not present.

Clustering-based evaluation, e.g. Vulić et al. (2017a) utilize the VSM to produce target clusters which are compared to the groupings from the lexical resource via collocation and purity. This approach only requires lexical entries to be grouped into classes. However, it doesn't model word ambiguity: a word can only be assigned to a single cluster. Moreover, it introduces an additional level of complexity (clustering algorithm and its parameters) which might obscure the VSM performance details.

In this paper we propose an alternative, suggestion-based evaluation approach: we use the source VSM directly to generate **word class suggestions** (WCS) for a given input term. Many lexical resources group words into intersecting word classes, providing a compact way to describe word properties on the class level. For example, in VerbNet (Schuler, 2005) verbs can belong to one or more Levin classes (Levin, 1993) based on their syntactic behavior, FrameNet (Baker et al., 1998) groups its entries by the semantic frames they can evoke, and WordNet (Miller, 1995) provides coarse-grained supersense groupings. Suggestion-based evaluation can be seen as flexible alternative to clustering-based evaluation, which intrinsically takes ambiguity into account and does not require an additional clustering layer. The following section describes the suggestion-based evaluation in more detail[4].

5.2 Task formulation

Abstracting away from the resource specifics, a **lexicon** L defines a mapping from a set of **members** $m_1, m_2, ...m_i \in M$ to a set of **word classes** $c_1, c_2...c_j \in C$. We further denote the set of classes available for a member m as $L(m)$ and the set of members for a given class c as $L'(c)$. Given a **query** q, our task is to provide a set of word class suggestions $WCS_L(q) = \{c_a, c_b...\} \in C$. Note that we aim to predict all *potential* classes for a member given its vector representation on vocabulary level, independent of context.

[3] See also (Vulić et al., 2017b), Table 5.

[4] Our implementation is available at https://github.com/UKPLab/coling2018-wcs

5.3 Suggestion strategies

Given an input target w, the source vector space VSM provides its vector representation $VSM(w)$. We use cosine similarity between targets $sim(w_i, w_j)$ to rank the word classes.

A lexical resource might already contain a substantial number of members, and a natural solution for word class suggestion is to find the **prototype** member m_{proto} closest to the query q in the VSM, and use its classes as suggestions. This scenario mimics human interaction with the lexicon. If $q \in M$, this is equivalent to a lexicon lookup. More formally,

$$m_{proto} = argmax_{m \in M} sim(q, m) \qquad score_{proto}(q, c, L) = \begin{cases} 1, & \text{if } c \in L(m_{proto}) \\ 0, & \text{otherwise} \end{cases}$$

The prototype strategy per se is sensitive to the coverage gaps in the lexicon and inconsistencies in the VSM. We generalize it by ranking *each* word class $c \in C$ using the similarity between the query q and its closest member in c:

$$score_{top}(q, c, L) = max_{m \in L'(c)} sim(q, m)$$

This is equivalent to performing the prototype search on each word class, and scoring each class by the closest prototype among its members, given the query. We use this generalized strategy for our WCS experiments throughout this paper. The output of the model $WCS_L(q, VSM)$ is a set of classes ranked using the input VSM, as illustrated by Table 2.

query	top classes / prototypes	query	top classes / prototypes
dog→	animal (*cat*), food (*rabbit*) ...	idea→	cognition (*concept*), artifact (*notion*) ...
crane→	artifact (*derrick*), animal (*skimmer*) ...	bug→	animal (*worm*), state (*flaw*) ...

Table 2: WCS output for WordNet supersenses

5.4 Evaluation procedure

For each member m in the lexicon in turn, we remove it from the lexicon, resulting in a reduced lexicon L_{-m}. We aim to reconstruct its classes using the suggestion algorithm and the remaining mappings.

The performance is measured via precision (P) and recall (R) at rank k with the list of original classes for a given lexical unit serving as *gold* reference. Formally, given m we compute the ranking $WCS_{L_{-m}}(m, VSM)$. Let S_k be the set of classes suggested by the system up to the rank k, and T be the true set of classes for a given member in the original lexicon. Then

$$P_{@k} = \frac{|S_k \cap T|}{|S_k|} \qquad R_{@k} = \frac{|S_k \cap T|}{|T|}$$

To get a single score, we average individual members' $P_{@k}$ and $R_{@k}$ for each value of k, resulting in scores $\overline{P}_{@k}$ and $\overline{R}_{@k}$. F-measure might be then calculated using the standard formula

$$F_{@k} = \frac{2\overline{P}_{@k}\overline{R}_{@k}}{\overline{P}_{@k} + \overline{R}_{@k}}$$

Upper bound Since the number of gold classes is not known in advance, the evaluation is always performed on k ranks, which leads to a resource-specific upper bound on P. For example, if a member only has one class, the ranked list of 10 suggestions will inevitably show lower precision. When the member set is not fully covered by the VSM target vocabulary, additional upper bound on R applies.

6 Experiment

6.1 Resources

We use two lexical resources for suggestion-based evaluation: VerbNet 3.3 (Schuler, 2005) and WordNet 3.1 (Miller, 1995). VerbNet groups verbs into classes[5] so that verbs in the same class share syntactic behavior, predicate semantics, semantic roles and restrictions imposed on these roles. For example, the verb *buy* belongs to the class *get-13.5.1*. The class specifies a set of available roles, e.g. an animate `Agent` (buyer), an `Asset` (price paid) and a `Theme` (thing bought), and lists available syntactic constructions, e.g. the `Asset V Theme` construction (*"$50 won't buy a dress"*). A verb might appear in several classes, indicating different verb senses. For example, the verb *hit* allows several readings: as *hurt* (*John hit his leg*), as *throw* (*John hit Mary the ball*) and as *bump* (*The cart hit against the wall*). VerbNet has been successfully used to support semantic role labeling (Giuglea and Moschitti, 2006), information extraction (Mausam et al., 2012) and semantic parsing (Shi and Mihalcea, 2005).

WordNet, besides providing a dense network of lexical relations, groups its entries into coarse-grained supersense classes, e.g. `noun.animal` (*aardvark*, *koala*), `noun.location` (*park*, *senegal*), `noun.time` (*forties*, *nanosecond*). WordNet supersense tags have been applied to a range of downstream tasks, e.g. metaphor identification and sentiment polarity classification (Flekova and Gurevych, 2016). WordNet differs from VerbNet in terms of granularity, member-class distribution and part of speech coverage, and allows us to estimate VSM performance on nominal as well as verbal supersenses, which we evaluate separately. Table 3 provides the statistics for the resources. We henceforth denote VerbNet as `VN`, WordNet nominal supersense lexicon as `WN-N` and WordNet verbal supersense lexicon as `WN-V`.

	classes	members	ambig	%ambig
VN	329	4 569	1 366	30%
WN-V	15	8 702	3 326	38%
WN-N	26	57 616	9 907	17%

Table 3: Lexicon statistics, single-word members

6.2 Results

We use the suggestion-based evaluation to examine the effect of lemmatization and POS-disambiguation. We first analyze the coverage of the VSMs in question with respect to the lexica at hand, see Table 4. For brevity we only report coverage on `w2` contexts[6].

target	VN	WN-V	WN-N
type	81	66	47
+POS	54	39	43
lemma	88	76	53
+POS	79	63	50
shared	54	39	41

Table 4: Lexicon member coverage (%)

Coverage analysis on lexica confirms our previous observations: lemmatization allows more targets to exceed the SGNS frequency threshold, which results in consistently better coverage. POS-disambiguation, in turn, fragments the vocabulary and consistently reduces the coverage with the effect being less pronounced for lemmatized targets. `WN-N` shows low coverage containing many low-frequency members. Due to significant discrepancies in VSM coverage, we conduct our experiments on **shared vocabulary**, only including members found in all VSMs to analyze the qualitative differences between VSMs.

[5]For simplicity in this study we ignore subclass divisions.

[6]We have observed slight coverage differences for `dep` contexts, and attribute this to the context vocabulary fragmentation caused by dependency typing of the contexts, similar to the POS fragmentation effect described earlier.

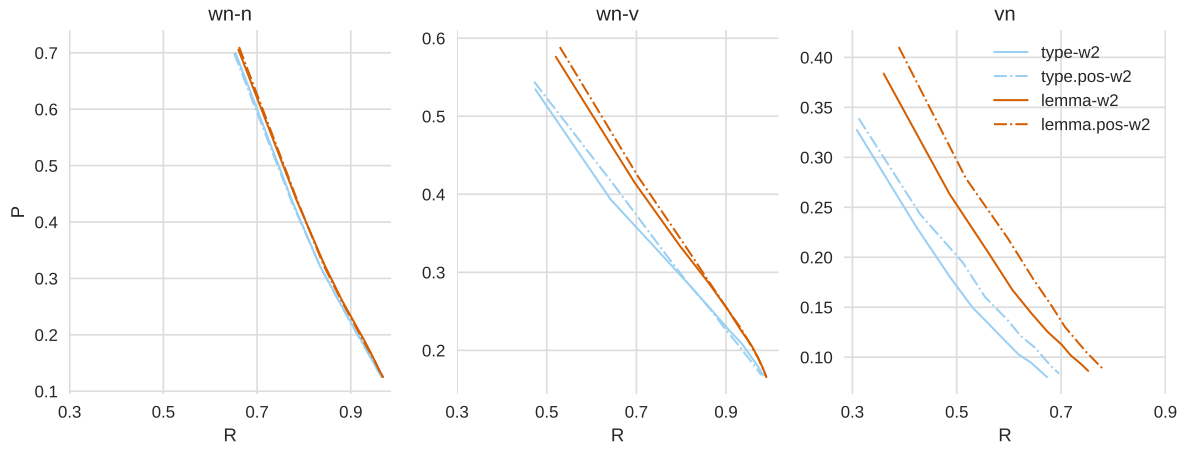

Figure 2: WCS PR-curve, shared vocabulary, w2 contexts.

We treat the cutoff rank k as a parameter that specifies the Precision-Recall trade-off. As Figure 2 demonstrates, lemmatized targets consistently outperform their word form-based counterparts on the WCS task. The magnitude of improvements varies between resources: verb-based WN-V and VN benefit more from lemmatization, and VN gains most from POS-disambiguation. This aligns with the similarity benchmarking results where the verb-based SimVerb benefits more from addition of lemma and POS information.

	WN-N			WN-V			VN		
	P	R	F	P	R	F	P	R	F
Context: w2									
type	.700	.654	.676	.535	.474	.503	.327	.309	.318
+POS	.699	.651	.674	.544	.472	.505	.339	.312	.325
lemma	.706	.660	.682	.576	.520	.547	.384	.360	.371
+POS	**.710**	**.662**	**.685**	**.589**	**.529**	**.557**	**.410**	**.389**	**.399**
Context: dep									
type	.712	.661	.686	.545	.457	.497	.324	.296	.310
+POS	.715	.659	.686	.560	.464	.508	.349	.320	.334
lemma	**.725**	**.668**	**.696**	.591	.512	.548	.408	.371	.388
+POS	.722	.666	.693	**.609**	**.527**	**.565**	**.412**	**.381**	**.396**

Table 5: WCS performance, shared vocabulary, $k = 1$. Best results across VSMs in bold.

Table 5 provides exact scores for reference. Note that the shared vocabulary setup puts the type and type.POS VSMs at advantage since it eliminates the effect of low coverage. Still, lemma-based targets significantly[7] ($p \leq .005$) outperform type-based targets in terms of F-measure in all cases. For window-based w2 contexts POS disambiguation yields significantly better F scores on lemmatized targets for VN ($p \leq .005$) with borderline significance for WN-N and WN-V ($p \approx .05$). When dependency-based dep contexts are used, the effect of POS disambiguation is only statistically significant on type targets for VN ($p \leq .005$) and on lemma-based targets for WN-V ($p \leq .005$). We attribute this to the fact that dependency relations used by dep contexts are highly POS-specific, reducing the effect of explicit disambiguation. Lemma-based targets without POS disambiguation perform best on WN-N when dependency-based contexts are used; however, the difference to lemmatized *and* disambiguated targets is not statistically significant ($p > .1$).

Our results are in line with the previous observations (Gerz et al., 2016) in that the verb similarity is

[7]Wilcoxon signed-rank test over individual lexicon members' F scores

	SimLex			SimVerb	WN-N	WN-V	VN
	N	V	A	V	N	V	V
base	.80	.26	1.0	.24	.86	.21	.22
avg #POS	1.08	1.01	1.39	1.50	1.15	1.37	1.42
single POS	.93	.99	.62	.51	.85	.65	.59

Table 6: Base form ratio and available POS averaged over members; % members with single POS.

hard to capture with standard VSMs. To investigate why verbs benefit most from lemmatization and POS disambiguation, we analyze some relevant statistics based on our Wikipedia data. Table 6 shows the ratio of base form to total occurrences in our corpus[8]. As we can see, the base form (lemma) is by far not the dominating form for verbs. Practically this means that for our resources verbal `type` targets have direct access to only 20-25% of the corpus occurrence data on average. Individual verbs and nouns also differ in terms of preferred word forms, which introduces additional bias into the evaluation. This effect is countered by lemmatization.

The second important difference between the noun- and verb-based lexica is the number of POS available for the lexicon members' lemmas. As Table 6 further demonstrates, nouns are less ambiguous in terms of POS: for example, `VN` member lemmas appear with 1.42 distinct POS categories on average, compared to 1.15 categories for `WN-N`. Individual members might differ in terms of POS frequency distribution, again biasing the evaluation. One regular phenomenon accountable for this is the *verbification* of nouns and adjectives, when a verbal form is constructed without adding any derivational markers. While these derivations might to some extent preserve the similarities between words (e.g. *e-mail.N→e-mail.V* is similar to *fax.N→fax.V*), many cases are less transparent and benefit from POS separation (e.g. the meaning shift in *air.N→air.V* is different from *water.N→water.V*). One exception is the verb subset of SimLex which has a particularly low POS ambiguity.

7 Future work

Lexical unit-based modeling. In this work we have shown that lemmatization and subsequent POS disambiguation benefit both benchmark- and resource-based performance of word embeddings. While verb semantics is notoriously hard to pinpoint per se, we show that modeling verbs via type-based distributed representations also meets grammar-related challenges which can be partially addressed with lemmatization and POS-disambiguation of the inputs. From the conceptual perspective, lemmatized and POS-tagged targets can be seen as another step towards conceptually plausible lexical unit-based modeling of word usage. In this work we focused on single-word entities, and analyzing the effect of including multi-word expressions into the VSM vocabulary is an important direction for future studies.

Word embedding methods. To ensure fair comparison and to keep our evaluation setup compact, we have consciously restricted the scope of the study to a single word embedding model (SGNS), single context size (`w2`) and a single parameter set (*word2vecf* SGNS default). Our results could be further validated by experimenting with alternative context definitions and word embedding models, e.g. GloVe (Pennington et al., 2014) and CBOW (Mikolov et al., 2013). Experiments on character-based models, e.g. *fasttext* (Bojanowski et al., 2016) or *charagram* (Wieting et al., 2016) could be another interesting extension to our work. However, it is not clear how to integrate lemma and POS information with character-based representations in an elegant way.

Cross-linguistic studies. POS tagging and lemmatization are general and well-defined language-independent operations. We have focused on English and have shown that POS-typing and lemmatization implicitly target several grammar-level issues in the context of word embeddings. (Ebert et al., 2016) demonstrate that the improvements from lemmatization hold in a cross-lingual setup. While we believe our results to generally hold cross-linguistically, the relative contribution of POS disambiguation and

[8]We use all lemmas that appear more than 100 times in the corpus; to smooth the effect of tagging errors we only count POS that appear with the target lemma in more than 10% of total lemma occurrences. All statistics averaged over individual lemmas.

lemmatization will inevitably depend on the grammatical properties of the language, constituting another topic for further research.

Suggestion-based evaluation. Our evaluation procedure has clear advantages: it is word class-based, polysemy-aware, does not introduce additional complexity and does not require an annotated corpus. It is resource-agnostic and only requires the target lexical resource to group words into classes. However, several issues must be addressed before it can be used on large scale. Our leave-one-out scenario excludes *singleton classes*, i.e. classes that only have one member. This issue will become less severe with resource coverage increasing over time. The evaluation depends on resource and VSM vocabulary coverage, and for qualitative comparison between VSMs vocabulary intersection should always be taken into account. Alternative suggestion strategies might be explored, e.g. averaging among class members instead of selecting the closest prototype.

Application scenarios. We have introduced word class suggestion as an evaluation benchmark for word embeddings. However, the WCS output might be used in vocabulary-based **application scenarios**, e.g. as annotation study support in cases when the lexicon is available, but the usage corpora are scarce; as a lexicographer tool for finding the gaps in existing lexica; and as a source for context-independent unknown word class candidates in a word sense disambiguation setup.

8 Conclusion

This paper has investigated the effect of lemmatized and POS-disambiguated targets on vector space model performance. We have shown that these preprocessing operations lead to improved performance on the standard benchmarks as well as in a novel word class suggestion scenario. Our results stress the need for more conceptually sound distributional models which align better to lexical resources. This would help to abstract away from the grammar-level issues and allow to further focus on bridging the gap between distributional models and lexical resources on the semantic level.

Lexi: A tool for adaptive, personalized text simplification

Joachim Bingel[1] **Gustavo H. Paetzold**[2] **Anders Søgaard**[1]

Abstract

Most previous research in text simplification has aimed to develop generic solutions, assuming very homogeneous target audiences with consistent intra-group simplification needs. We argue that this assumption does not hold, and that instead we need to develop simplification systems that adapt to the individual needs of specific users. As a first step towards personalized simplification, we propose a framework for adaptive lexical simplification and introduce Lexi, a free open-source and easily extensible tool for adaptive, personalized text simplification. Lexi is easily installed as a browser extension, enabling easy access to the service for its users.

1 Introduction

Many a research paper on text simplification starts out by sketching the problem of text simplification as rewriting a text such that it becomes easier to read, changing or removing as little of its informational content as possible (Zhu et al., 2010; Coster and Kauchak, 2011; De Belder and Moens, 2010; Paetzold and Specia, 2015; Bingel and Søgaard, 2016). Such a statement may describe the essence of simplification as a research task, but it hides the fact that it is not always easy to decide what is easy for a particular user. This paper discusses why we need custom-tailored simplifications for individual users, and argues that previous research on non-adaptive text simplification has been too generic to unfold the full potential of text simplification.

Even when limiting ourselves to lexical substitution, i.e. the task of reducing the complexity of a document by replacing difficult words with easier-to-read synonyms, we see plenty of evidence that, for instance, dyslexics are highly individual in what material is deemed easy and complex (Ziegler et al., 2008). Lexi, which we introduce in this paper, is a free, open-source and easily extensible tool for adaptively learning what items specific users find difficult, using this information to provide better (lexical) simplification. Our system initially serves Danish, but is easily extended to further languages. For surveys of text simplification, including resources across languages, see Siddharthan (2014), Shardlow (2014b) and Collins-Thompson (2014).

1.1 There is no one-size-fits-all solution to text simplification

Text simplification is a diverse task, or perhaps rather a family of tasks, with a number of different target audiences that different papers and research projects have focused on. Among the most prominent target audiences are foreign language learners, for whom various approaches to simplifying text have been pursued, often focusing on lexical (Tweissi, 1998) but also sentence-level simplification (Liu and Matsumoto, 2016). Other notable groups that have been specifically targeted in text simplification research include dyslexics (Rello et al., 2013), and the aphasic (Carroll et al., 1998), for whom particularly long words and sentences, but also certain surface forms such as specific character combinations, may pose difficulties. People on the autism spectrum have also been addressed, with the focus lying on reducing the amount of figurative expressions in a text or reducing syntactic complexity (Evans et al., 2014). Reading beginners (both children and adults) are another group with very particular needs, and text simplification

Proceedings of the 27th International Conference on Computational Linguistics, pages 245–258
Santa Fe, New Mexico, USA, August 20-26, 2018.

research has tried to provide this group with methods to reduce the amount of high-register language and non-frequent words (De Belder and Moens, 2010).

Evidently, each target group has its own simplification needs, and there is considerable variation as to how well the specifics of what makes a text difficult is defined for each group and simplification strategy. While difficult items in a text may be identified more easily and generally for problems such as resolving pronoun reference, questions such as what makes a French word difficult for a native speaker of Japanese, or what dyslexic children consider a difficult character combination or an overly long sentence, are much harder to answer. Nevertheless, there is a vast body of work (Yatskar et al., 2010; Biran et al., 2011; Horn et al., 2014) that ventures to build very general-purpose simplification models from simplification corpora such as the Simple English Wikipedia corpus (Coster and Kauchak, 2011), which has been edited by amateurs without explicit regard to a specific audience, and with rather vague guidelines as to what constitutes difficult or simple language.

Other work in simplification attempts to answer the above questions by inducing models from specifically compiled datasets, which for instance may have been collected by surveying specific target groups and asking them to indicate difficult material in a text. Yet even those approaches often cannot live up to the real challenges in simplification, seeing that we find very heterogeneous simplification needs also within target groups. Foreign language learners with different linguistic backgrounds (pertaining both to their native and second languages) will find very different aspects of the same foreign language difficult. Young readers in different school grades will quickly advance their reading habits and skills, and also within the same class or age reading levels may differ greatly. Likewise, people with autism exhibit very different manifestations of the type and degree of their condition (Alexander et al., 2016), also with respect to reading (Evans et al., 2014), just as there exist many different forms of cognitive impairments affecting literacy, including many different forms of dyslexia (Watson and Goldgar, 1988; Bakker, 1992; Ziegler et al., 2008). In fact, while there is a relatively strong agreement on the existence of some typologies of dyslexia or autism, specific typologies that have been proposed are heavily debated, such that it would not even be straightforward to create simplification tools for specific subtypes of these conditions.

From this it becomes apparent that in order to build simplification systems that truly help specific individuals, those systems have to be personalized or personalizable. Further, due to the frequent lack of insight into what an individual's specific reading problems are (and because any introspection is difficult to verify), such systems need to be able to learn themselves what those individual challenges are, and ultimately adapt to those.

1.2 Obtaining individual data

In order to learn specific reading challenges for an individual person, a simplification system needs individual data for this person, from which a personalized model can then be induced. This brings up the question of how best to obtain such data. A straightforward approach would be to ask each individual to provide ratings for some number of stimuli as they start using a simplification system. However, this would pose a relatively unnatural reading scenario, which might introduce a certain bias in the data and thus distort the induced model. Further, it might create a dissatisfying user experience, and users might not be willing to invest much time into such a calibration phase, especially when they perceive reading as a particularly strenuous activity. Yet perhaps most importantly, the model will not necessarily be well-adapted to the specific domains and genres that a specific user typically consumes text from.

As an alternative, we propose to collect data as the system is used, and to continuously update the system with feedback it collects from the user. In this way, the system can base its model on exactly those text types the user consumes. We discuss how feedback can be incorporated into a system in Section 3 and provide details on how this is implemented in our proposed system in Section 4.

1.3 Contributions

We present Lexi, an open source and easily extensible tool for adaptive, personalized text simplification. Lexi is based on an adaptive framework for lexical simplification that we also describe in this paper. This framework incorporates feedback from users, updating personalized simplification models such as to

meet their individual simplification needs. Lexi is made publicly available under a CC-BY-NC license[1] at https://www.readwithlexi.net.

2 Related Work

Perhaps the earliest contribution that focuses on on-demand lexical simplification is the work of Devlin and Unthank (2006), who present HAPPI, a web platform that allows users to request simplified versions of words, as well as other "memory jogging" pieces of information, such as related images.

Another example is the work of Azab et al. (2015), who present a web platform that allows users to select words they do not comprehend, then presents them with synonyms in order to facilitate comprehension. Notice that their approach does not simplify the selected complex words directly, it simply shows semantically equivalent alternatives that could be within the vocabulary known by the user.

The recent work of Paetzold and Specia (2016a) describes Anita, yet another web platform of this kind. It allows users to select complex words and then request a simplified version, related images, synonyms, definitions and translations. Paetzold and Specia (2016a) claim that their approach outputs customized simplifications depending on the user's profile, and evolves as users provide feedback on the output produced. However, they provide no details of the approach they use to do so, nor do they present any results showcasing its effectiveness.

Therefore not counting Paetzold and Specia (2016a) as work in *personalized* simplification, we are not aware of any previous approaches that address this. We further refer to related work on specific aspects of text simplification as they become relevant in the course of this paper.

3 Adaptive text simplification

As we mapped out in the introduction, we devise a simplification system that continuously learns from user feedback and adapts to the user's simplification needs. This section discusses how such feedback can be incorporated into a *lexical simplification* model via online learning, and where in the lexical simplification pipeline it is sensible to implement adaptivity.

3.1 Adaptivity in the lexical simplification pipeline

Lexical simplification, i.e. replacing single words with simpler synonyms, classically employs a pipeline approach illustrated in Figure 1 (Shardlow, 2014a; Paetzold and Specia, 2015). This pipeline consists of a four-step process, the first step of which is to identify simplification targets, i.e. words that the model believes will pose a difficulty for the user. This step is called *Complex Word Identification* (CWI) and has received a great deal of attention in the community, including two shared tasks (Paetzold and Specia, 2016b; Yimam et al., 2018). In a second step, known as *Substitution Generation*, synonyms are retrieved as candidate replacements for the target These are then filtered to match the context, resolving word sense ambiguities or stylistic mismatches, in *Substitution Selection*. Finally, those filtered candidate are ranked in order of simplicity in what is known as *Substitution Ranking* (SR).

Out of these four steps, we consider CWI and SR as the most natural ones to make adaptive, whereas generation and selecting candidates can be regarded as relatively independent from a specific user. In order to implement adaptivity, we propose to make use of online learning methods as discussed below and, departing from a seed model, train and maintain *user-specific models* as we collect feedback.

3.1.1 Adaptive CWI

Complex Word Identification is usually approached as a binary classification task, where the goal is to decide for some word *in context* whether or not it poses a difficulty to a reader. Existing datasets, for instance the ones used at previous CWI shared tasks (Paetzold and Specia, 2016b; Yimam et al., 2018), therefore provide a sentence and a target word (or multi-word expression) together with a binary label.

A model trained on this data with a learning algorithm based on gradient descent on t examples can now easily integrate newly collected data points into its parameters θ using an update rule such as

$$\theta^{(t+1)} = \theta^{(t)} - \eta \nabla_{\theta^{(t)}} J(\theta^{(t)}; x, y), \quad (1)$$

[1] https://creativecommons.org/licenses/by-nc/4.0/

where x is a representation of a target word in context and y is a binary complexity label we receive from user feedback. As an alternative to gradient descent based algorithms, we can use other online learning models, e.g. the Perceptron algorithm. CWI datasets are typically not very large (between 2,500 and 5,500 positive examples per dataset in the mentioned shared tasks), such that data points sampled from users can quickly have an impact on a generic base model.[2]

3.1.2 Adaptive Substitution Ranking

Substitution Ranking has received relatively little attention in the community compared to CWI. Most lexical simplifiers rank candidates using unsupervised approaches. The earliest example is the approach of Carroll et al. (1998), who rank candidates according to their Kucera-Francis coefficients, which are calculated based on frequencies extracted from the Brown corpus (Rudell, 1993). Other unsupervised approaches, such as those of Ligozat et al. (2012) and Glavaš and Štajner (2015), go a step further and use metrics that incorporate multiple aspects of word complexity, including context-aware features such as n-gram frequencies and language model probabilities. But even though unsupervised rankers perform well in the task, they are incapable of learning from data, which makes them unsuitable for adaptive SR.

Our approach to adaptive SR is similar to our approach to adaptive CWI, namely to train an initial model over manually produced simplicity rankings, then continuously update them with new knowledge as Lexi users provide feedback on the simplifications they receive. The feedback in this scenario is composed of a complex word in context, a simplification produced by Lexi, and a binary rank provided by the user determining which word (complex or simplification) makes the sentence easier to understand. For that purpose, we need a supervised model that (i) supports online learning so that it can be efficiently updated after each session, and (ii) can learn from binary ranks.

Paetzold and Specia (2017) offer some intuition on how this can be done. They exploit the fact that one can decompose a sequence of elements $\{e_1, e_2, ..., e_n\}$ with ranks $\{r_1, r_2, ..., r_n\}$ into a matrix $m \in \mathbb{R}^{n \times n}$, such that $m(i,j) = f(r_i, r_j)$, and function $f(r_i, r_j)$ estimates a value that describes the relationship between the ranks of elements e_i and e_j. For example, f could be described as:

$$f(r_i, r_j) \begin{cases} 1 \text{ if } r_i < r_j \\ -1 \text{ if } r_i > r_j \\ 0 \text{ otherwise} \end{cases} \quad (2)$$

The ranker of Paetzold and Specia (2017) uses a deep multi-layer perceptron that predicts each value of m individually. It takes as input feature representations of e_i and e_j, and produces a function f similar to the one depicted in Equation 2. Their approach would be perfectly capable of learning from the feedback produced by Lexi users, but it would be very difficult to train it through online learning, given that deep multi-layer perceptrons are characterized by a large number of parameters that are costly to optimize in an on-demand basis. We instead propose to employ an online learning model that has fewer parameters, e.g. logistic regression.

4 Implementation

Lexi consists of a client-side frontend and a server-side backend that communicate with each other via a RESTful API (Fielding, 2000), exchanging requests and responses as described further in 4.3. The client-server architecture allows for easy portability of the software to users, minimizing user-side installation efforts, hardware usage and dependencies on other libraries. It also centralizes the simplification engine, such that amendments to and maintenance of the latter need only be implemented on the server side.

Lexi is currently limited to performing lexical simplification. Note, however, that this is merely a limitation of the backend system, which only implements a lexical simplification system for now. From the frontend perspective, however, there are no limitations as to the nature and length of the simplified items in a text, and extending Lexi to support higher-level modes of simplification simply amounts to

[2] An alternative to traditional, one-size-fits-all approaches has recently been proposed by Bingel et al. (2018), who use eye-tracking measures to induce personalized models to predict misreadings in children with reading difficulties.

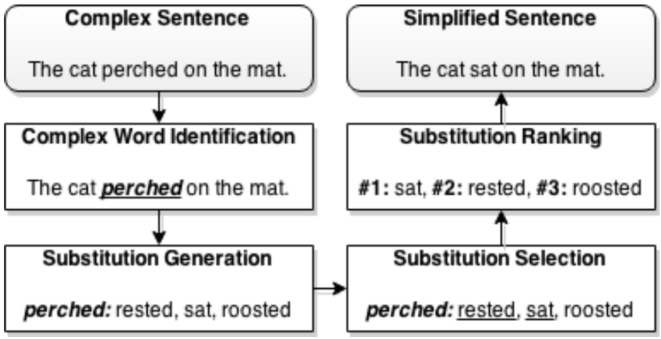

Figure 1: Lexical simplification pipeline as identified by Paetzold and Specia (2015). The simplification workflow consists of identifying simplification targets, i.e. words that pose a challenge to the reader. In the generation step, possible alternatives for each target are retrieved, which are then filtered in the selection step, eliminating words that do not fit the context. In the ranking step, the system finally orders the candidates by simplicity.

implementing a backend system supporting this.[3]

We initially focus on lexical simplification for a number of reasons: (i) We have existing baseline models that we expect to work well in a real-world setting. (ii) Given a relatively small number of parameters in those models, we expect fast adaptation to individual users from relatively little feedback. (iii) Compared to other forms of simplification, lexical simplification needs to make a selection from a relatively limited search space that is still reasonably diverse, such that we expect personalized models to make a difference more easily.

4.1 Frontend

Lexi's frontend is implemented in JavaScript and jQuery under the Mozilla WebExtension framework, supported by most modern browsers.[4] WebExtensions employ *content scripts* to modify a webpage upon certain specified events, for instance a click on some page element. The remainder of this section describes Lexi's basic usage as the user registers an account and asks the system for simplifications, thereby illustrating the user interface and sketching the inner workings of the frontend.

4.1.1 User log-in and registration

Upon installation of the Lexi extension in the browser, the user is prompted to register an account, providing an email address as well as basic demographic information (year of birth and educational level, see Figure 2). This information is sent to the backend using its registration endpoint (see Table 1). If the user has previously created an account and simply reinstalled the extension, they may also just provide their email address to keep using their existing profile. The user's email address is stored locally in the browser, where it is kept until the browser storage is cleared or the extension is uninstalled.

4.1.2 Simplification requests and display

Whenever the user visits a webpage, the extension injects an event listener into the page, which triggers upon the selection of some text and offers the user to simplify the selected content in the form of a small button that is displayed just above the selection. When this button is clicked, the extension retrieves the user's email address from the browser storage (prompting the user to log in if no email address is stored) and verifies that a user with that email address exists in the backend's database, using the login endpoint as given in Table 1. The script then submits a *simplification request* to the backend's simplification endpoint, enclosing a JSON object that contains the user's email address (used by the backend to retrieve

[3]Note that, in general, this paper describes the Lexi frontend and backend versions 1.0. Both parts of Lexi are under ongoing development, with details pertaining to the implementation possibly subject to change.

[4]`https://developer.mozilla.org/en-US/Add-ons/WebExtensions`

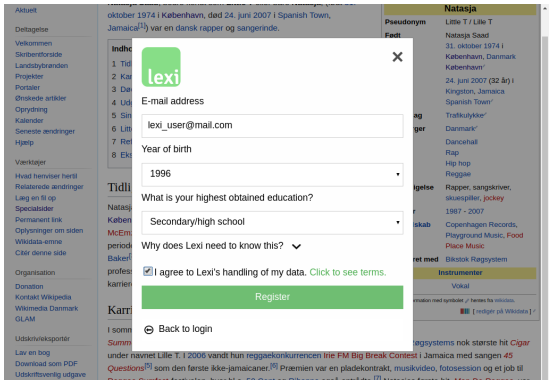

Figure 2: User account registration form

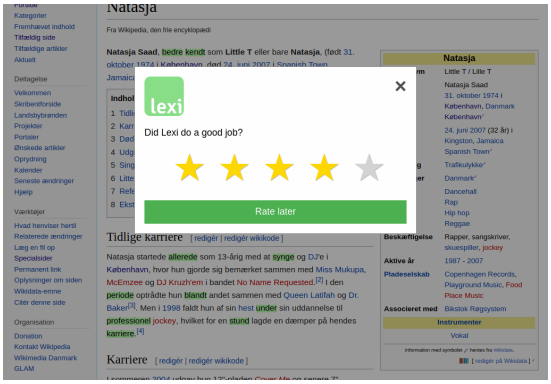

Figure 3: Five-point rating form

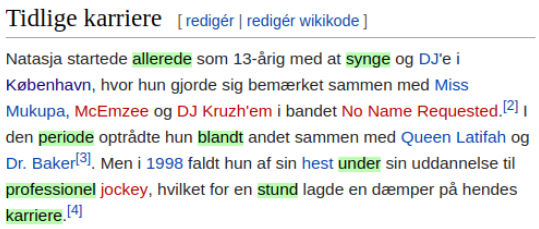

Figure 4: Simplification spans are marked up in light green. As the user clicks on a simplification span, the currently displayed word is replaced with an alternative.

the personal simplification model) and the HTML code of the element containing the text selection. See Appendix A.1 for an example.

The response from the backend then transmits a JSON object with augmented HTML, where elements with unique IDs are wrapped around simplification targets. The response object further contains an array of *simplification objects*, each of which in turn contains a list of synonyms ordered by simplicity ranking (including the target). An example is given in Appendix A.2. The content script replaces the original source with the augmented HTML and displays each simplification span with a light green background color (see Figure 4). The script then shifts through the simplification alternatives for a given target whenever the user clicks on the respective span on the page, advancing one alternative per click and reverting to the first alternative at the end of list. The original item is marked in a slightly but discernibly darker shade than the proposed simplifications.

4.1.3 User feedback

In order to provide personalized simplifications and to adapt to individual users, Lexi needs to be able to decide which alternative a user prefers over the others for every target. In a classical, controlled annotation setting, one would probably present subjects with a set of alternatives and have them rank these or pick a single favorite. However, as Lexi aims to provide as natural and smooth a reading scenario as possible to its users, explicitly asking for such feedback would critically obstruct the reading process.

Lexi therefore interprets whatever final selection a user makes for some simplification span as their preferred alternative in this context.[5] As the user finally navigates away from the webpage that Lexi was invoked on, Lexi solicits feedback from the user on a five-point scale (see Figure 3) and submits this rating along with the simplification objects and their final selections (and click-through counts) to the

[5]In the instructions, users are made aware of this. The frontend further keeps track of how many times the user clicked on a given simplification span, thus providing the backend with information such as how many times the user clicked through the entire list, or whether perhaps no alternatives were solicited for some item.

feedback endpoint of the backend.[6] See Appendix A.3 for an example of the feedback.

4.1.4 Qualitative evaluation of usability

The frontend design was developed in close collaboration with Nota, the Danish Library and Expertise Center for people with reading disabilities.[7] In February 2018, the software was intensively tested by four dyslexic members of Nota, all female students in secondary/higher education and aged between 20 and 30. Each test started with a short preliminary interview in which the subjects were asked about their age, occupation/study field, reading habits, degree of dyslexia and use of browser extensions. The subjects were then given the possibility to watch an introduction video (of 1:30 min length) outlining Lexi's basic functionality and user interface. Two of the four subjects opted for this, while the other two decided to skip the video as they do not usually watch introduction videos when using new software. Next, the subjects were asked to locate Lexi in the Chrome Webshop, install it in the browser and create a user account. Once set up, each subject navigated to a site of her choice and used Lexi to receive simplifications as outlined in 4.1.2. The two subjects who had not watched the video did so now, and both declared they gained further insight into Lexi's functionality through the video, but that it was not crucial in order to understand its basic usage.

In qualitative interviews directly succeeding each test, the test subjects overall reacted very positively to the prospect of a personalized simplification tool in general, and to Lexi and its design in particular.[8] The test subjects suggested a number of improvements, most of which have now been implemented. One suggested improvement, which we have not been able to implement but intend to do so for a future version, is the support for multilingual simplification. Two subjects said they would greatly appreciate this, as much of their study material is only available in English.

4.2 Backend

Lexi's backend consists of a simplification system, implemented in Python 3.5, and a database that stores user information and their simplification histories.

4.2.1 Simplification system

As stated above, Lexi's simplification system currently focuses on lexical simplification, abiding to the *de-facto* standard pipeline depicted in Figure 1. Since Lexi lets users choose which words they wish to have simplified, it does not employ any automatic CWI.[9] Below we sketch Lexi's simplification system as it receives simplification requests from the frontend. As our lexical simplification approach is sensitive to the context of a word, Lexi's first step is to preprocess the HTML source transmitted from the frontend, identifying the boundaries of the sentence that contains the target word, if any.[10]

For Substitution Generation, Lexi implements the embeddings-based approach inspired by the contributions of Glavaš and Štajner (2015) and Paetzold and Specia (2016c). In their work, they extract as candidate substitutions the N words with the highest cosine similarity with a target word. As Danish, the language currently served by Lexi, is not as well-resourced as for example English, Lexi extends the embedding-based Substitution Generation approach by using an ensemble of embeddings models that are trained independently on different text sources, the Danish Wikipedia and a news corpus.[11] The overall similarity score for a target-candidate pair is then defined as the mean score across these embeddings models. Lexi returns the ten most similar candidates whose mean similarity score exceeds some

[6] More correctly, feedback is not solicited when the user actual navigates away from the page, as security restrictions in browsers disallow custom scripts to run upon closing a page. Instead, Lexi asks for feedback via a small notification box in the upper right corner of the page, which pops up as the operating system's *focus* changes to a different window, or when the mouse leaves the browser's viewport (e.g. for the address bar).

[7] `http://www.nota.dk`

[8] An informal evaluation of the software on a 5-point scale (with 1 being worst and 5 best) yielded two ratings of 5, one 4 and one 3.

[9] We do plan, however, to implement CWI as the user solicits simplifications for longer text passages or entire pages.

[10] In order to reduce bandwidth and modify the page more easily, the frontend only transmits the HTML source of the least HTML node fully containing the selection, which typically is a paragraph (`<p>`), but may also be a single word contained in a heading (e.g. `<h1>`), in which case no context is available. Sentence boundaries are identified using NLTK.

[11] `https://ordnet.dk/korpusdk`

configurable threshold. Alternatively, Lexi allows to generate synonyms from a simple dictionary, in the case of Danish using the Danish WordNet (Pedersen et al., 2009), yet this approach suffers from severely reduced coverage compared to word embeddings.

Once generated, the candidates are filtered during Substitution Selection by an unsupervised boundary ranker (Paetzold and Specia, 2016c). In this approach, a supervised ranker is trained with instances gathered in an unsupervised fashion: we generate candidate substitutions for complex words using our generation approach, then assign label 1 to the complex words and 0 to the generated candidates. The boundary between the two classes is then used to rank and filter candidates. Paetzold and Specia (2016c) show that this is a state-of-the-art approach that outperforms all earlier supervised and unsupervised strategies. Given a target word and a set of generated candidate substitutions, the model ranks the candidates based on how far in the positive side of the data they are, then selects 65% of the highest ranking ones.

Finally, the selected candidates are ranked with a supervised Substitution Ranking model following the approach we outlined in Section 3.1.2. It is during this step that Lexi is capable of producing customized output based on the user's needs, and to evolve based on the user's feedback. Lexi employs a pairwise online logistic regression model that learns to quantify the simplicity difference between two candidate substitutions. Given an unseen set of candidate substitutions, the regressor estimates the simplicity difference between each candidate pair, then ranks all candidates based on their average score.

Note that the user's feedback, sent by the frontend, consists of a set S and an index i, where S is the full set of suggested synonyms, including the target, and i is the index of the item in S that the user finally selected. As the regressor, however, learns from pairwise rankings, Lexi passes all pairs $\{\langle S_i, S_j \rangle | j \neq i\}$ to the regressor, i.e. it pairs the selected item with all others and updates the ranker accordingly, postulating that the selected item is easier for this user than each other suggestion.

Using a seed dataset of complex-simple word correspondences in context, we train a default model that produces initial simplifications as a user solicits simplifications for the first time.[12] As Lexi receives feedback for this user for the first time, the seed model is copied and personalized with the first batch of feedback, then this model is saved for later requests by this user.

4.2.2 Database

Lexi stores user information and simplification histories in a PostgreSQL database. More specifically, it employs three different tables, called `users`, `models` and `sessions`. In the first of these, it links a unique, numerical user ID to a user email address, and stores when the user first and last used Lexi. It further contains the demographic information the user provides at registration, i.e. their year of birth and educational status. The `models` table stores a path to the serialized personal model for each user ID. Finally, the `sessions` table stores each simplification request issued to the backend with a unique session ID, the respective user ID, a time stamp for the session start and one for the submission of feedback, the webpage URL, simplification objects serialized as JSON, the provided rating and finally the frontend version number used in this session.

4.3 Communication between backend and frontend

Lexi's backend offers a RESTful API implemented in Python 3.5, using the Flask package.[13] The services available through HTTP POST requests, with their URI paths listed in Table 1. Input and output values are communicated via a JSON-based protocol exemplified in the appendix. Lexi further defines a set of error codes for easier troubleshooting and flexible internationalization of the frontend via the i18n API used by WebExtensions.

[12] Such a seed dataset is not necessarily available for any language. However, in its absence, a seed model could either be trained with simple heuristics, e.g. replacing infrequent words with higher-frequency synonyms. Alternatively, the system could choose to initially rank candidates with such a heuristic and only start learning once the first feedback is available.

[13] `http://flask.pocoo.org/`

URI path	Input	Returns
`/simplify`	User ID; page HTML	Augmented HTML, simplification objects
`/login`	User email address	If successful: User ID, else error code
`/register`	User information	If successful: User ID, else error code
`/feedback`	User ID; simplification objects updated with selections; rating	Status code (successful update or error)

Table 1: RESTful API endpoints defined by Lexi's backend.

4.4 Language support and extensibility

Lexi's design does not impose any restrictions on the support of new (written) languages, including right-to-left or non-alphabetic writing systems. In fact, supporting a new language simply amounts to providing a new language-specific simplification pipeline as illustrated in Figure 1.

Depending on the specific implementation of the simplification system, certain resources are however needed to induce a first seed model for simplification. Most centrally, this pertains to Substitution Generation, where a synonym database or good word embeddings are required in the case of lexical simplification, or a reliable paraphrase module in the case of higher-level simplification. With respect to Substitution Ranking, the availability of resources such as simplification corpora is less critical, as simple heuristics (e.g. simplicity proxies such as length and frequency) might give a reasonable baseline upon which the system can then improve through user feedback.

Lexi currently does not offer multilingual support, but is confined to one language per backend instance. Supporting multilingual simplification could be implemented through a language identification module upstream to the set of simplification pipelines, consisting of one pipeline per language. This raises the interesting question whether knowledge about one user's simplification preferences in one language could be transferred to another language. Support for this hypothesis comes, among others, from the cross-lingual track in the recent CWI shared task by Yimam et al. (2018).

4.5 Ethical and legal considerations

As any software interacting with users and storing information on them, Lexi is naturally subject to ethical and legal concerns, especially those regarding privacy. The EU General Data Protection Regulation (GDPR), for instance, defines a number of regulations such as the clear statement of terms and conditions or that users need to be provided, upon request, with full access to whatever data is stored on them. Lexi does not explicitly store users' names, but in many cases they will be encoded in email addresses. Personally identifiable information may also be stored in the form of simplified text that is logged in the database, for instance if Lexi is used on a user's personal social media profile. The above also highlights the need for encrypted communication between the client and the server, which is safeguarded through TLS encryption over the HTTPS protocol.

Ethical concerns pertaining to text simplification arise when infelicitous simplifications distort the meaning of a text and thus potentially misinform the reader. This is difficult to completely rule out, such that the user should clearly be informed of this possibility. Other concerns revolve around the hypothesis that reducing text complexity will "dumb down" the material and keep users at a low reading level by under-challenging them (Long and Ross, 1993). However, as Rello et al. (2013) point out, "anything which might help [dyslexics] to subjectively perceive reading as being easier, can potentially help them to avoid this vicious circle [of reading less and staying on a low reading level], even if no significant improvement in readability can be demonstrated."

5 Availability and applications

The Lexi software and code, including its backend and frontend, are freely available for non-commercial use under a CC-BY-NC license, obtainable at `https://www.readwithlexi.net`. Researchers can set up their own, customized version of the software and distribute the browser extension to users. It is

straightforward to modify features of the software such as offered languages or the exact resources used to induce the initial models.

Besides its core functionality, which we mapped out in the previous sections, Lexi has a number of alternate use cases, which we discuss in this section.

Preloaded simplifications Lexi's primary use case, as described earlier, is to provide simplifications to users as they select a span of text, which circumvents the need for a CWI module as only such items are simplified that the user explicitly solicits replacements for. Alternatively, users may wish to have the entire page simplified before they start reading. Lexi currently implements this functionality, letting the user solicit simplifications for the entire site via a click on the Lexi icon. As there is no personalized CWI module implemented yet, simplification targets are identified via a confidence threshold during Substitution Generation.

Evaluation of simplification quality Via its rating function (Figure 3), Lexi continuously tracks user satisfaction as a means of evaluating synchronic simplification quality as well as the diachronic development of model adaptation. An adaptive model that is continuously customized is expected to gradually improve the average rating it receives from the user.

Data collection Lexi makes it possible to collect user choices over a longer period in order to create bigger simplification datasets. If sufficiently homogeneous subgroups can be identified across users, this data may give insight into their simplification needs, to build better simplification models for them.

Other plausible approaches may understand different users as different *tasks* and apply multi-task learning methods to transfer knowledge between users, thus both regularizing the models for the individual user and increasing the available amount of data that the individual models can be learned from.

6 Conclusion and Future Work

This paper is a first work in personalized, adaptive text simplification, a direction of research motivated by the observation that generic, user-independent simplification systems cannot fully unfold their potential in making text simpler for specific end users. We propose a framework for adaptive lexical simplification, outlining how user feedback can be used to gradually enhance and personalize text simplification. As a concrete first solution to the problem, we present Lexi, an open-source tool for personalized, adaptive text simplification that has been very positively evaluated in a first usability test. In its current implementation, Lexi focuses on lexical simplification in Danish. An extension to other languages is simple, requiring only a medium-sized monolingual corpus on which a language model and word embeddings can be trained.

In future work, we aim to extend the proposed framework to sentence-level simplifications. We further plan to implement support for multilingual simplification.

Identifying Emergent Research Trends by Key Authors and Phrases

Abstract

Identifying emergent research trends is a key issue for both primary researchers as well as secondary research managers. Such processes can uncover the historical development of an area, and yield insight on developing topics. We propose an embedded trend detection framework for this task which incorporates our bijunctive hypothesis that important phrases are written by important authors within a field and vice versa. By ranking both author and phrase information in a multigraph, our method jointly determines key phrases and authoritative authors. We represent this intermediate output as phrasal embeddings, and feed this to a recurrent neural network (RNN) to compute trend scores that identify research trends. Over two large datasets of scientific articles, we demonstrate that our approach successfully detects past trends from the field, outperforming baselines based solely on text centrality or citation.

1 Introduction

At no time prior to now has the advance of science – as measured by the rate of growth in scientific publications – bloomed more rapidly. Even practitioners of narrowly-defined, specific fields need help to scan the masses of literature to summarize work and to identify developments likely to spur long-term impact due to the potential problem of information excess (Fujita et al., 2012). The identification of such **emergent research trends** — "radically novel and relatively fast growing research topic characterized by a certain degree of coherence, and a considerable scientific impact" (Wang, 2017) — is a task that is growing in importance and urgency with the increasingly large scale of scholarly literature.

Wang (2017)'s survey reveals two important techniques that characterize the state-of-the-art work on this task. First, text mining — specifically in the guise of topic models — have been employed to yield a summative form of large corpora. Both the Dynamic Topic Model (Blei and Lafferty, 2006) and Author–Topic Model (Rosen-Zvi et al., 2004) cater towards different aspects of the special temporal and authoring aspects of topics in scientific documents, specializing the basic Latent Dirichlet allocation (LDA; Blei et al. (2003)) topic model. Second, dense citations among papers has been used to measure the coherence contributing to a well-defined research trend (Price, 1965). Through appropriate metrics, core works can be identified, from which extracted keywords are treated as a trend's central concepts. Analyses often establish a co-citation network, as typified by Shibata et al. (2008).

These works point to the importance of side information external from the content itself, such as publication date or author identity, and its necessary incorporation into a detection methodology. Our observation is that these attributes often correlate with each other, naturally hinting to a framework where such information can reinforce their signal.

We thus take inspiration from other natural language processing and information retrieval scenarios where such mutual recursion has found application. Hyperlink Induced Topic Search (HITS; (Kleinberg, 1999)) showed web pages arranged as nodes of a hyperlinked graph can be mutually related and ranked by an authority and a hub (popularity) score, where the two scores are calculated using mutual recursion.

Proceedings of the 27th International Conference on Computational Linguistics, pages 259–269
Santa Fe, New Mexico, USA, August 20-26, 2018.

Yan et al. (2017) applied a similar logic to the task of ranking sentences and words with mutual recursion, where it is assumed that important sentences and important words are correlated. They achieved better performance for keyphrase extraction compared with TextRank (Mihalcea and Tarau, 2004), a non-recursive formulation.

Furthermore, with the current advent of deep learning and better semantic representations via embeddings, there is opportunity to utilize both advances in trend detection.

Applying these observations to the research trend task, we make the following assumptions when formulating our model detailed in Section 3:

- Important authors often collaborate together, *i.e.*, the co-authorship among key-authors contributes to the research trend emergence.
- Important authors often write important keyphrases. Such phrases are then often trending phrases for a research area.
- High centrality values for nodes are key features to identify the core items within a graph. For identifying emergent trends, these metrics must exhibit values that connote both importance and urgency.
- We neuralize the traditional trend detection pipeline. Specifically, we represent obtained keyphrases as averaged *tf-idf* word embeddings and use a recurrent neural network (RNN) model to perform supervised learning for trend status.

We use a multigraph ranking (MGR) core component to compute trending scores for keyphrases. We take these MGR outputs as input to our neuralized embedded trend detection (EDM) framework: namely, we represent the outputs as word or phrase embeddings, and feed their ranking scores into a recursive neural network to identify trends per time slice in a target dataset. This results in our final embedded trend detection model – ETD (MGR), or "ETD-M" for short.

2 Prior Work

Previous studies have addressed both of our tasks of obtaining keyphrases and identifying research fronts from scientific publications. We review this area first, then review mutually recursive algorithms used in practice.

Research Trend Detection. Wang (2017) classified research trend detection models into two categories, namely, text- and bibliometric-based approaches. In text-based approaches, keywords and terms representing the core topics have been the focus of study. Hall et al. (2008) performed post-hoc analysis by applying the LDA model to the batch of publications in the same year; top keywords generated in different years are compared in an effort to identify the transition of topics. Mörchen et al. (2008) attempts to combine keywords and the time of their appearances: the variation of term frequencies in two different timestamps provides the insights on how significant the term is becoming. Sessions within conferences are another perspective that have been investigated. Furukawa et al. (2014) constructed *tf-idf* vectors (Salton et al., 1983) from publications' abstracts to obtain the relative importance of sessions, and then applied the vectors to assess the evolution of a publication venue.

In bibliometric approaches, citations are used to connect papers. Hopcroft et al. (2004) have proposed the concept of co-citation, where papers are connected if they are both cited by another paper published later; following the co-citation relation, the graph of papers can be used for further studies (Shibata et al., 2008): topological clusters inside the graph was identified, where tightly knit clusters with densely distributed edges represent the general topics. Subsequently, NLP techniques such as *tf-idf* are employed to generate the top terms associated with the topic. Similar to textual approaches, top keywords from clusters in different years can then be used for research fronts analysis. Elkiss et al. (2008) tried to analyze the cohesion of texts based on the citing sentences and co-citation metrics, which provides insights on the

focused perspective of the cited paper. He et al. (2009) proposed an inheritance topic model to identify topic evolution by fully utilizing the impact of citations.

We note that both textual and bibliometric approaches expose shortcomings: they are restricted to historical data, and human interpretations are often required to establish the link between different timestamps; additionally, without a comprehensive keywords extraction method, the final output can be ambiguous and uninformative.

Mutual Recursive Algorithms. Hyperlink Induced Topic Search (HITS) Algorithm (Kleinberg, 1999) is a prototypical example and used for ranking pages on the Internet, where each page is assigned with two values: an "authority" score and a "hub/popularity" score. The rationale states that a good hub page points to many other pages, where a good authority page is pointed to by many hubs. Therefore, the two scores are computed dependently on each other.

In natural language processing, the implication of mutual recursion can apply to keyphrase extraction models: Yan et al. (2017) implemented a ranking model by constructing separate sentence and word graphs. They assume that important sentences and words are correlated, hence by linking the two graphs together and ranking sentences and words recursively, salient keywords can be extracted. Their model outperforms standard TextRank algorithm (Mihalcea and Tarau, 2004). Zhang et al. (2017) also proposed a graph-based keyphrase extraction approach by capturing mutual influences among different types of information on a candidate word, which have been widely used in existing supervised or graph-based approaches.

3 Methodology

Our goal is to mine and assign high fidelity importance scores to keyphrases, and then to use these to predict emerging trends, based on the abstracts for a large target scientific publication dataset. Our embedded trend detection (ETD) model consists of the following three components: 1) extraction of keyphrases, 2) representativeness enhancement with word embeddings, and 3) predictions and rankings of phrase with RNN. In the following, we detail each of the components.

3.1 Multigraph Ranking for Key Phrase and Author Extraction

Our ETD framework admits any means of identifying the keyphrases, so any keyphrase generation algorithm can be employed (*e.g.*, TextRank). However, since our task is slightly different in that we want to generate keyphrases for overall trend detection of an area (as opposed to the more typical characterization of a single publication), we need to introduce several refinements.

As a result, we propose our multigraph ranking (MGR) component for salient keyphrase extraction. Our MGR model starts with the extraction of keyphrases and key-authors based on the assumption that important authors are more likely to write potentially trending phrases. We extract them via iterative score ranking in a pair of jointly-connected graphs.

We construct the graphs as follows: documents are first grouped into year-based clusters. For each of the cluster, we build an "author" graph, which contains individual authors who have published at least one paper in that year; authors are connected by undirected edges whose weights are determined by the number of publications two authors have made together during the year. We also construct a "phrase" graph following the logic of TextRank with modifications. Compare this to the standard TextRank model, where the nodes in the graph are tokenized words from the raw text, and the edges conceptualize the adjacency when tokens occur within a predefined window size.

Our empirical results demonstrate that domain-specific single-word terms dominate the final keyphrase list. Hence in our model, we pre-process the input to extract noun phrases via regular expression over parts-of-speech[1] before TextRank processing.

Consider the sample document in Figure 1: after transforming the raw text to a set of noun phrases, each noun phrase is split further: for {coherency protocols}, two separate nodes will be added to the

[1]Using the Natural Language Toolkit (NLTK) via `<DT>?<JJ|NN|NNS>*<NN|NNS>` (where `DT` stands for determiner; `JJ` for adjectives, and `NN|NNS` for nouns).

Title: Evaluating the performance of four snooping cache coherency protocols.
Authors: S. Eggers and R. Katz.
Publication Year: 1989.
Abstract: ... **coherency protocols** have been criticized for being unable to achieve **good bus performance** across **all cache configurations** ...

Transformed Token List: {coherency protocols, good bus performance, all cache configurations}

Figure 1: Example text from 1989, with noun phrases bolded.

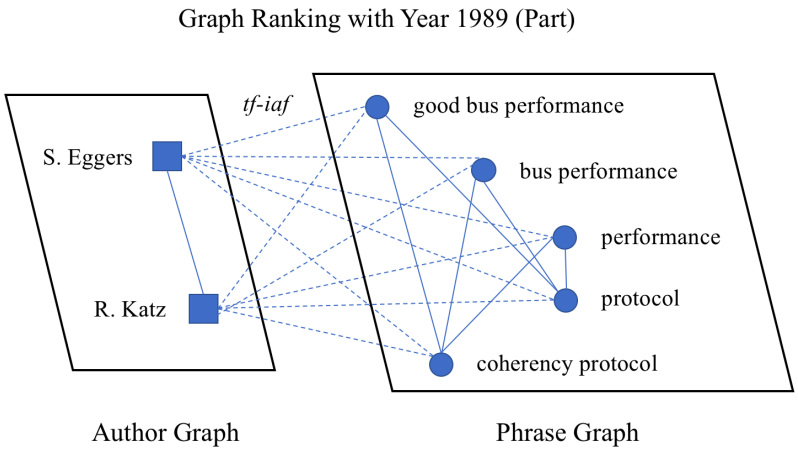

Figure 2: Portion of the multigraph derived from the text in Figure 1. Note that in the complete graph, nodes may connect with other unseen authors and phrases; we only show the part constructed by the sample document.

"phrase" graph: **coherency protocol** and **protocol**; similarly, **good bus performance**, **bus performance**, and **performance** from the next noun phrase. Subsequently, each node from {coherency protocol} will be linked with another node from {good bus performance}. Therefore, single nodes in our "phrase" graph can be entire noun phrases.

The "author" and "phrase" graphs are jointly connected based on the "author-writes-phrase" relationship, in which an author–phrase pair is denoted as { author a_i – phrase p_j}. We then propose *tf-iaf*, which is a variant of *tf-idf* (Salton et al., 1983) to calculate the weight of the edges:

$$\begin{aligned} tf\text{-}iaf_{a_i,p_j} &= tf_{a_i,p_j} \times iaf_{p_j} \\ &= \frac{Occ(a_i,p_j)}{\sum_{z=1}^{n} Occ(a_i,p_z)} \times \log \frac{|A|}{|A(p_j)|}, \end{aligned} \tag{1}$$

where $Occ(a_i, p_j)$, $|A(p_j)|$, and $|A|$ denote the number of occurrences of p_j by a_i, the number of authors who write p_j, and the total number of authors, respectively.

Returning to our running example, for the document group for year 1989, a portion of the graph is demonstrated in Figure 2.

Ranking and extraction of the key-authors and keyphrases can then be implemented through an iterative method, similar to the HITS algorithm. We use three matrices to store the "author", "phrase", and the *tf-iaf* graphs. More specifically,

· $\boldsymbol{N}_{m\times m}$ is a matrix for the set of authors $A = \{a_i | 1 \le i \le m\}$. Each element $n_{i,j}$ denotes how many papers auhtors a_i and a_j co-authored during the year. In the sample document presented above, if the authors "S. Eggers" and "R. Katz" have only collaborated on this paper in 1989, then we have $n_{Eggers,Katz} = 1$ for matrix $\boldsymbol{N}$.

· $\boldsymbol{W}_{n\times n}$ is a matrix for the set of phrases $P = \{p_j | 1 \le j \le n\}$. Each element $w_{i,j}$ denotes that how

often phrase p_i and p_j have co-occurred across all documents since that year. Note that for matrices $\boldsymbol{N}$ and $\boldsymbol{W}$, we have $\boldsymbol{N} = \boldsymbol{N}^T$ and $\boldsymbol{W} = \boldsymbol{W}^T$.

· $\boldsymbol{L}_{m \times n}$ is a matrix for the *tf-iaf* scores defined by Equation (1). Each element $l_{i,j}$ denotes the *tf-iaf* value, in other words, $l_{i,j} = tf\text{-}iaf_{a_i,p_j}$.

Additionally, we use a $m \times 1$ vector $\vec{i}$ and a $n \times 1$ vector $\vec{j}$ to represent the scores of the authors and phrases, respectively. Both vectors are initialized with 1 for each entry; subsequently, the score vectors $\vec{i}$ and $\vec{j}$ are updated using the following rule:

$$\begin{aligned} \vec{i} &= (\alpha \times \boldsymbol{N}\vec{i} + (1-\alpha) \times \boldsymbol{L}\vec{j}).normalized(), \\ \vec{j} &= (\alpha \times \boldsymbol{W}\vec{j} + (1-\alpha) \times \boldsymbol{L}^T\vec{i}).normalized(). \end{aligned}$$

where α is a tuning coefficient to determine the relative importance of authors and phrases during ranking.

Therefore, after the iterative ranking, noun phrases are assigned a score based on both the adjacency with other phrases and the author information for a particular year. Consolidating all scores for all phrases produces a $2D$ array, of which each row stands for the time series scores for a phrase.

3.2 Representativeness with Word Embeddings

A key point here is that the meaning of a phrase and its relation to other phrases evolves over time. For instance, during the development of the topic *Machine Learning*, the phrase "machine learning" was likely to be associated with popular supervised approaches such as "decision tree" and "SVM" around 2000, but after 2010 co-occurs more often with "deep neural networks". These changes indicate that the representativeness of a phrase to a topic also shifts over time. To model such dynamics, we use word embeddings to further refine the phrase scores from the previous step in our ETD pipeline.

Our model assigns a vector per phrase, per unit time step (year). We construct phrase vectors by averaging its individual word embeddings (originating from the 300-dimensional version of Google's Word2Vec model (Mikolov et al., 2013)). The phrase vector is calculated by taking the *tf-idf* weighted average of the vectors of individual words, where the *tf-idf* is calculated on the basis of the yearly-divided corpus. We note that we tried training dynamic word embeddings based on recalibrating the vectors as per many standard NLP application, but that technique did not lead to better performance.

As individual phrases are too fine-grained to be minted as trends, we apply a form of dimensionality reduction to find key phrases that can serve as a label for a trend. We group the vectors into clusters using the k-means algorithm, where each phrase is associated with a representativeness value calculated by taking the cosine similarity between its vector and its respective cluster center. The phrase score obtained from the graph ranking step is multiplied with the representativeness score. In this way, we assign phrases with the list of scores indicating their significance and representativeness over the years.

3.3 Predictions with RNN and Trending Phrase Ranking

For a particular phrase, given its scores over a certain period of time, we expect our model to predict the phrase score in the following time interval. In our model, we implement a basic recurrent neural networks (RNNs) to makethese predictions.

The model employs scores from the first k sequential years to predict $(k+1)^{th}$ score defined as:

$$x_{k+1} = f(x_1, x_2, x_3, ..., x_k).$$

For the array of scores from 1958 to 2015, this is a list of training samples where $\boldsymbol{x}$ is score vector that consists of k sequential years and $\boldsymbol{y}$ is the score in the $(k+1)^{th}$ year. The input of the RNN is $1 \times k$ representing the same feature (score of a certain year) spanned across k years, and the output is a single value representing the score in the $(k+1)^{th}$ year.

With the scores for each phrase predicted from year 1958 to 2015, it is then possible to investigate further into the phrases. As illustrated previously, it is expected that our model could make predictions of trending research fronts. Specifically, trends refer to research areas which are gradually being studied,

hence, there should be a strong foundation for them, meaning that there are certain level of existing work associated with them; yet they should not be the mostly-discussed issue at the same time. Based on these assumptions, we have defined a *trending score* for each phrase, which can be defined as follows:

$$trend = \beta \times (x_{k+1} - \max(x_1, \ldots, x_k)) + (1 - \beta) \times \max(x_1, \ldots, x_k),$$

where β is another tuning weight similar to that used in the graph ranking algorithm. Coupled with the previous steps' score computations, we can then determine the most influential and trending phrases in each year with the predictions from RNN. Our model selects the top ranked phrases based on their actual scores for each year, and produces another list based on predictions from RNN. It is expected that when comparing these two lists, phrases appearing near the top of the actual list also appear at the top of the prediction list.

4 Experiments

Evaluation of research trend detection is largely indicative, since the task is subjective, sources various, and replicability of prior work is difficult at best. Despite these problems, we propose a workflow that allows better future replicability, including the standardization of the datasets and the availability of the algorithms' prediction output[2].

In our experiments, we use the abstract of each paper and the published year as one document entry and the timestamp, respectively. After describing specific parameter settings, we describe our evaluation for the two different datasets in turn.

4.1 Parameter Settings

For the three sub-components of our model, we set the parameters as follows:

In the multi-graph ranking component, when iterating through the texts, phrases appearing within a window size of 3 are identified as adjacent tokens and are hence connected in the graph, when updating the final score vectors with Equation (1). We set α to 0.5.

When incorporating the Word2Vec model into phrase scores, we use the k-means algorithm to cluster the phrase vectors. We compare the performance of the model on various settings of $k = \{10, 15, 20, 25\}$. For the recurrent neural network predictions, we set a (context) block size of 3 for the input shape (*i.e.*, in the $2D$ array of scores, for each phrase, its time series scores incorporate the three prior values: $x_4 \leftarrow < x_1, x_2, x_3 >$).

The generated training samples are then fed into the RNN, which includes 2 hidden layers, where each layer has 4 neurons. We use mean squared error as the loss function (as the result is continuous), which naturally dictates the use of RMSProp as the optimizer. Following typical training regimes, we use a batch size of 10, and 80 epochs before termination. We also empirically tuned β to 0.8, emphasizing the positive and increasing trend in importance in defining trending topics and research fronts.

4.2 ACM Periodical Dataset

We use this dataset to evaluate the performance of multigraph ranking (MGR) component as we hypothesize that its mutual recursion will improve trend detection over the baseline TextRank source. This dataset includes around 9,740 XML files representing publications copyrighted by the Association of Computing Machinery (ACM), in the domain of computer science, published from 1958 to 2015. It is available from the ACM used by explicit permission. We use the abstract and metadata (specifically, publication time, authors, and keywords) for each paper. For space, in this presentation, we restrict the field of study to "software engineering"[3].

We evaluate our model with **Recall@n** and **nDCG@n**, and then compare it with the standard TextRank algorithm (Mihalcea and Tarau, 2004) as a baseline.

[2]Code is available at: `https://github.com/RichardeJiang/racode`.

Table 1: Performance comparison of Recall@n (top) and nDCG@n (bottom), varying the number of clusters $k = \{10, 15, 20, 25\}$ generated by k-means. Best system figures are bolded. "ETD-TR" and "ETD-M" stand for embedded trend detection with TextRank (Mihalcea and Tarau, 2004) (baseline) and our multigraph ranking, respectively.

Recall @ 20, $k = 20$					
Run	1	2	3	4	5
ETD-TR	7.4%	10.3%	8.6%	11.1%	9.2%
ETD-M	15.6%	14.0%	15.6%	13.2%	20.1%

Table 2: Comparison of Recall@20 with $k = 20$ clusters over different runs of our model.

Our embedded trend detection workflow consists of the three stages: keyphrase extraction, embedding representation, and final prediction with RNN. Our evaluation here tests the effectiveness when we change the first component to our proposed MGR. We replace the MGR with the standard TextRank algorithm and use the output as the baseline, and compare the resulting ranking model.

Recall@n measures how many predicted phrases are the actual top terms computed by the system. For each year, the first component (MGR and baseline TextRank) returns a list of the top terms. These are further enhanced through Word2Vec embeddings and fed to the RNN to generate top trending phrases. We first compute average recall based on this final output for all available years, and then compute normalized discounted cumulative gain (nDCG) (Järvelin et al., 2000) to further assess the quality of the element ranking. A system performs better if it returns true positive trending phrases towards the top of its rankings, as opposed to the bottom.

We test different settings of $k \in \{10, 15, 20, 25\}$ for the number of clusters when performing the k-means algorithm in the second Word2Vec stage for incorporation, as shown in Table 1.

From Table 1, we note that when extracting the keyphrases and make value predictions, our model consistently outperforms the baseline TextRank algorithm, in both the number of correctly predicted phrases (Recall) and their ordering (nDCG). Since the only difference between the baseline TextRank and our MGR model is how the phrases are ranked, we conclude that our multi-graph ranking algorithm yields more consistent scores in this dataset. We take this as evidence that in our MGR model, random interference is reduced when compared against the standard TextRank algorithm. This provides the empirical justification for our assumption when formulating the multi-graph ranking step – that important authors are more likely to cooperate with each other; and that words written by them are more likely to be trending in their respective fields. Additionally, the use of graphical techniques which find central components does reveal useful core nodes (concepts).

As the k-means algorithm does not guarantee to produce the same cluster result when we run the algorithm for several times, in order to show the consistency of performance, we have tested the system multiple times with the same set of parameters. Here, we show the example when $k = 20$ (number of clusters), and we compute the **Recall@20**, as illustrated in Table 2. We observe that results will be different when testing the system in different runs, which conform to the nature of k-means algorithm; however, our model (ETD-M) consistently outperforms the baseline ETD-TR with the same parameter settings.

2001	**growth**, **layers**, temperature, temperatures, **substrates**, emission, **layer**, epitaxy, measurements, spectroscopy, **surface**, molecular beam epitaxy, properties, diffraction, **films**, microscopy, beam epitaxy, cm, **photoluminescence**, **structure**

Table 4: Top keyphrases predicted by our ETD-M model. Phrases detected by both ETD-M and Shibata et al.'s (2008) model marked as bolded.

We also tested the sub-systems by eliminating the Word2Vec component from our pipeline of ETD: meaning that after we obtained the phrases together with their time series scores using graph ranking algorithms (either with TextRank or our proposed multigraph ranking, MGR), we feed the data into RNN and evaluate the performance. The resulting Recall@20 for TextRank and MGR are **14.5%** and **17.1%**, respectively. The values illustrate two inferences: firstly, even without the reinforcement of word embeddings, our proposed MGR still produces more consistent ranking scores. Secondly, if comparing the result with average Recall@20 from Table 1 (10.5%, 12.9%, 7.4%, 13.2% for TextRank, 21.9%, 23.5%, 15.6%, 13.6% for MGR), we observe that when the embedding component is added to our system, ETD-M outperforms ETD-TR when the number of k-means clusters is relatively small. By comparison, TextRank considers all available tokens, hence the adjacency relationship includes more information on the representativeness of each word. Therefore, in ETD-TR, we believe that word embeddings introduce noise to the original values. On the other hand, in MGR, the spatial information is diluted and Word2Vec helps to centralize the popularity of each phrase, especially when the number of clusters is small. This indicates that word embeddings are effective in our ETD-M model.

4.3 Science and Social Science Citation Index Datasets

In their paper, Shibata et al. (2008) provided the research fronts detected by their system for the domain of Gallium Nitride (GaN) – a prominent research field in applied physics and material science – for the year 2000 (Table 3). We wish to compare directly with their reported results, contrasting the top terms generated for phrases in the year range of 1999–2001, as shown in Table 4, hypothesizing that our ETD-M system can outperform their inferred keyphrase in terms of subjective keyphrase quality.

They used data gleaned from the Science Citation Index (SCI) and Social Science Citation Index (SSCI) original compiled by the Institute for Scientific Information, which are available from Web of Science databases. To compare with their results as best as possible, we have retrieved the papers using the same database query provided by their research: "GaN OR Gallium Nitride" to compare our results with theirs. We collected papers whose years of publication range from 1970 to 2004, to exactly match the parameters used in Shibata et al.'s work. The total number of the papers is around 15,200.

We note that about half of the keyphrases obtained by Shibata et al.'s work are also predicted suc-

cessfully by the ETD-M model. Examining the two tables carefully, we believe that phrases from our model provide better quality insight: element names such as "ga", "ni", and "al" recognized by Shibata et al.'s work unfortunately provide no detail on the study; furthermore, some terms recognized by them like "american institute" are also irrelevant to the research topic.

Since Shibata et al.'s work filters out non-core papers first, potential keywords can only originate from core papers. According to their results, out of 4,000 publications collected in the year 2000, around 30 are selected based on the roles of each paper within its cluster. Although we cannot replicate their work exactly, we surmise that these central papers may manifest such terms with sufficiently high frequency to be extracted, resulting in the large involvement of element names and non-relevant terms in the output. Due to the mutual recursion element of ETD-M, we can propagate the influence of keyphrases beyond such a core, while assigning an appropriate level of credit. Such results allow ETD-M to convey and rank longer, meaningful phrases such as "molecular beam epitaxy" and "metalorganic chemical vapor deposition" within that domain.

5 Future Work

The three-stage pipeline in our ETD-M model is designed to provide insights on the trending research keywords and has been proven to work better than the standard TextRank and bibliometric approaches. Additionally, the model can be improved from various perspectives.

In our multigraph ranking (MGR) step, the score vectors for authors and phrases are normalized after each iteration of updates to limit the values within the range of $[0, 1]$; the matrices representing author and phrase mutual relations ($\boldsymbol{N}, \boldsymbol{W}, \boldsymbol{L}$) are non-smoothed. We expect by normalizing matrices $\boldsymbol{N}, \boldsymbol{W}, \boldsymbol{L}$ to $\hat{\boldsymbol{N}}, \hat{\boldsymbol{W}}, \hat{\boldsymbol{L}}$ in the first place, and then using the normalized matrices in the ranking, the output score vector will therefore indicate the relative importance and the value will be smoothed. The update rules hence become:

$$\begin{aligned} \vec{i} &= \alpha \times \hat{\boldsymbol{N}}\vec{i} + (1-\alpha) \times \hat{\boldsymbol{L}}\vec{j}, \\ \vec{j} &= \alpha \times \hat{\boldsymbol{W}}\vec{j} + (1-\alpha) \times \hat{\boldsymbol{L}}^T\vec{i}. \end{aligned}$$

Our model uses Google's Word2Vec to enhance the representativeness of each phrase in every year by taking the cosine similarities between the vector representation of a phrase and its respective cluster center. Given a specific collection of documents, the embedding for its vocabulary can be rather different from the fixed, pretrained Word2Vec, so in the future we may consider further training the existing Word2Vec with our yearly-divided data. In addition, the representativeness of phrases can also be extended by incorporating topic models, so as to assign a topic and a value to each phrase would admit the relative importance of the phrase, while providing an intuitive approach in clustering.

The evaluation of our model is largely subjective: whether the output keyphrase list provides insights with better quality depends on human interpretation. To better understand the efficacy of our model, it can be applied to other disciplines such as using the PubMed data, and then we employ domain experts to manually evaluate the keyphrase list.

One common issue with a pipeline model is that error may propagate through different stages and accumulate. Therefore, the overall structure of the model can be redesigned such that the graphs are already time-aware during ranking. Wang et al. (2013) have provided an article ranking model which takes publication time into account. When applying to our model, we could introduce a "time" graph to the existing MGR model, where the heterogeneous graph incorporates publication times.

6 Conclusion

We have presented our ETD-M model for detecting research fronts and trends from scientific publications. Unlike prior work that emphasize evidence from citation links and topological measures, our model mines salient phrases from the abstract of the publications themselves. Our three-stage ETD-M pipeline features a multigraph keyphrase ranking (MGR) algorithm, followed by k-means clustering and keyphrase representation utilizing word embeddings, with a final stage of detecting the topics using an RNN for the final, temporally-sensitive inference of trending topics.

A key contribution from our work lies in the first stage of evidence gathering, in the form of our keyphrase extraction. We structure this task as a mutual recurrence between important authors and their keyphrases. We compare our MGR against the TextRank algorithm within the ETD framework, which clearly showed the advantages of utilizing author information in identifying salient keyphrases. Additionally, we feel that our MGR model's inferred research fronts align well with historical fact.

Our ETD-M model can be extended further for a more comprehensive structure. Applying normalized author and phrase matrices to the update rule makes the scores more reasonable; Mikolov's Word2Vec can be adjusted to fit in our own dataset for each year. Additionally, we can introduce human evaluation by feeding in data from various fields of study, to further evaluate the efficacy of our model while discovering trend insights to these other scientific research areas.

Acknowledgments

This research is supported in part by the National Research Foundation, Prime Ministers Office, Singapore under its International Research Centres in Singapore Funding Initiative. In addition, our experiments are carried out based on the ACM Digital Library dataset (with the metadata state dated 11 September 2015) furnished in collaboration with the Association for Computing Machinery.

Abstract

In this paper, we study how we can improve a deep learning approach to textual entailment by incorporating lexical entailment relations from WordNet. Our idea is to embed the lexical entailment knowledge contained in WordNet in specially-learned word vectors, which we call "entailment vectors." We present a standard neural network model and a novel set-theoretic model to learn these entailment vectors from word pairs with known lexical entailment relations derived from WordNet. We further incorporate these entailment vectors into a decomposable attention model for textual entailment and evaluate the model on the SICK and the SNLI dataset. We find that using these special entailment word vectors, we can significantly improve the performance of textual entailment compared with a baseline that uses only standard word2vec vectors. The final performance of our model is close to or above the state of the art, but our method does not rely on any manually-crafted rules or extensive syntactic features.

1 Introduction

Recognizing textual entailment (RTE) is the task of determining whether a hypothesis sentence can be inferred from a given premise sentence. The task has been well studied since it was first introduced by Dagan et al. (2006). Recently, there has been much interest in applying deep learning models to RTE (Bowman et al., 2015; Rocktaschel et al., 2016; Wang and Jiang, 2016; Parikh et al., 2016; Sha et al., 2016). These models usually do not perform any linguistic analysis or require any feature engineering but have been shown to perform very well on this task.

Intuitively, lexical-level entailment relations should help sentence-level RTE. For example, Table 1 shows a premise and a hypothesis taken from the test data of the SICK dataset (Marelli et al., 2014). We can see that in this example the premise entails the hypothesis, and in order to correctly identify this relation, one has to know that the word *kettle* entails the word *pot*. However, if we train a neural network model on a set of labeled sentence pairs, and if the training dataset does not contain the word pair *kettle* and *pot* anywhere, it would be hard for the learned model to know that *kettle* entails *pot* and subsequently predict the relation between the premise and the hypothesis to be *entailment*. On the other hand, from WordNet we can easily find out that *pot* is a direct hypernym of *kettle* and therefore *kettle* should entail *pot*. If this kind of prior knowledge can be injected into a trained RTE model, then for sentence pairs with words that do not occur in the training data but can be found in WordNet, the RTE predictions could potentially be made easier.

Premise: *Someone is stirring chili in a* ***kettle****.*
Hypothesis: *Someone is stirring chili in a* ***pot****.*

Table 1: An example of a pair of premise and hypothesis from SICK.

Indeed, WordNet (Miller, 1995) knowledge has been used to help RTE in a number of previous studies (Corley and Mihalcea, 2005; Beltagy et al., 2016; Martinez-Gomez et al., 2017). However, these

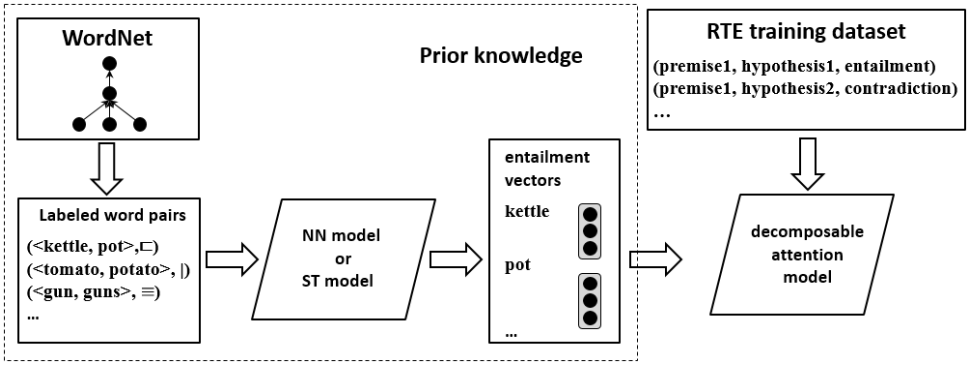

Figure 1: An overview of our approach.

previous studies were not based on neural network models, and thus their base models without using WordNet may not represent the state of the art or may require much human effort. For example, our baseline model based on a neural network model without using any WordNet knowledge can achieve an accuracy of 84.1% on the SICK test data, but the baseline model by Martinez-Gomez et al. (2017), which uses logical semantic representations and a theorem prover, can only achieve an accuracy of 76.7%. Given the advantages of deep learning approaches to RTE, it is therefore desirable to incorporate WordNet knowledge into deep learning based solutions to RTE. However, it is not immediately clear how WordNet knowledge could be easily brought into neural network models. To the best of our knowledge, there has not been any previous work in this direction.

In this paper, we propose to first embed lexical entailment knowledge contained in WordNet into word vectors. We call these special word vectors "entailment vectors." We then incorporate these entailment vectors into a recently proposed decomposable attention model for RTE. To learn these entailment vectors that encode lexical entailment relations, we can use a standard neural network. We also propose a set-theoretic model that has better theoretical justification. Our experiments show that using these entailment vectors learned from WordNet can indeed significantly improve the performance of RTE on the SICK dataset and the SNLI dataset. The performance of our method is also better compared with the state of the art on SICK.

2 Method

In this section, we present our method that learns the entailment vectors that encode prior knowledge of lexical entailment relations. We also present how we incorporate these entailment vectors into a neural network model for RTE. The overall framework of our method is illustrated in Figure 1.

2.1 Learning Entailment Vectors

We assume that our prior knowledge of lexical entailment relations is contained in word pairs and their entailment relations. Specifically, let $\mathcal{R}$ denote a set of lexical entailment relations. For example, $\mathcal{R}$ may contain *entailment* and *reverse-entailment*. Let $\mathcal{L} = \{(w_{i,1}, w_{i,2}, r_i)\}_{i=1}^{N}$ denote a set of N word pairs together with their relation labels, where $w_{i,1}$ and $w_{i,2}$ are two words and $r_i \in \mathcal{R}$. For example, $\mathcal{L}$ may contain the triplet (<*pot*, *kettle*>, *reverse-entailment*). Let $\mathcal{V}$ denote the set of all unique words found in $\mathcal{L}$.

In order to encode the lexical entailment knowledge contained in $\mathcal{L}$, we propose to learn a dense vector for each word $w \in \mathcal{V}$ such that the entailment relation between two words in $\mathcal{V}$ can be easily detected from their word vectors. We refer to these dense word vectors as "entailment vectors." Note that these entailment vectors are different from commonly-used word embeddings such as GloVe and word2vec, because the entailment vectors are not learned from a large corpus and thus do not encode the distributional properties of words. They are learned from labeled word pairs in $\mathcal{L}$. We will show later that they can be used in combination with common word embeddings such as word2vec to help RTE.

In what follows, we first describe what lexical entailment relations we include in $\mathcal{R}$. We then present

Name	Symbol	Set-theoretic definition	Example
(strict) entailment	$x_1 \sqsubset x_2$	$x_1 \subset x_2$	woman, person
(strict) reverse entailment	$x_1 \sqsupset x_2$	$x_1 \supset x_2$	person, woman
equivalence	$x_1 \equiv x_2$	$x_1 = x_2$	couch, sofa
alternation	$x_1 \mid x_2$	$x_1 \cap x_2 = \varnothing \wedge x_1 \cup x_2 \neq \mathcal{D}$	woman, man
negation	$x_1 \wedge x_2$	$x_1 \cap x_2 = \varnothing \wedge x_1 \cup x_2 = \mathcal{D}$	able, unable
cover	$x_1 \smile x_2$	$x_1 \cap x_2 \neq \varnothing \wedge x_1 \cup x_2 = \mathcal{D}$	person, non-woman
independence	$x_1 \# x_2$	(else)	woman, doctor

(a)

	$c_{0,0}$	$c_{0,1}$	$c_{1,0}$	$c_{1,1}$
$x_1 \sqsubset x_2$	–	> 0	$= 0$	–
$x_1 \sqsupset x_2$	–	$= 0$	> 0	–
$x_1 \equiv x_2$	–	$= 0$	$= 0$	–
$x_1 \mid x_2$	> 0	–	–	$= 0$
$x_1 \wedge x_2$	$= 0$	–	–	$= 0$
$x_1 \smile x_2$	$= 0$	–	–	> 0
$x_1 \# x_2$	> 0	–	–	> 0

(b)

Table 2: (a) Seven basic semantic relations defined by MacCartney and Manning (2009). Here $\mathcal{D}$ is the universe that contains all entities. Each x_1 (or x_2) is a language unit that represents a subset of $\mathcal{D}$. (b) Criteria for different basic semantic relations based on the counters $c_{0,0}$, $c_{0,1}$, $c_{1,0}$ and $c_{1,1}$.

two different neural network models used to learn the entailment vectors from $\mathcal{L}$. We defer the description of how we derive labeled word pairs $\mathcal{L}$ from WordNet until Section 2.3.

Lexical Entailment Relations

Recall that eventually the entailment vectors will be used for textual entailment. In standard textual entailment datasets such as SICK and SNLI, there are three sentence-level entailment relations: *entailment*, *contradiction* and *neutral*. However, at word-level the entailment relations are different.

In a previous study, MacCartney and Manning (2009) developed a framework for natural language inference. As the basis of their framework, they defined seven basic semantic relations between language units, which we show in Table 2a. These relations cover all the possible relations between two language units x_1 and x_2. We can see that each relation has an equivalent set-theoretic definition, which dates back to Montague Semantics (Janssen, 2011). Each language unit x_1 or x_2 is modeled as a set, and is supposedly a subset of the universe $\mathcal{D}$. Therefore their relations can be determined by the relation between the two sets. For example, if the language units we consider are nouns, we can regard $\mathcal{D}$, the universe, as the set of all entities in the world. If x_1 is the word "person," we can regard x_1 as a set that contains all people. If x_2 is the word "woman," we can regard x_2 as a set that contains all people who are female. Since x_1 is a superset of x_2, based on the definition, x_1 reversely entails x_2, or $x_1 \sqsupset x_2$. This makes sense because "person" reversely entails "woman," or in other words, "woman" entails "person."

In this work, we only use a subset of these relations, namely, *entailment* ($\sqsubset$), *reverse-entailment* ($\sqsupset$), *alternation* ($|$) and *equivalence* ($\equiv$). In other words, $\mathcal{R} = \{\sqsubset, \sqsupset, |, \equiv\}$. We do not include *negation*, *cover* or *independence* because we find it hard to automatically derive word pairs with these relations from WordNet.

Standard Neural Network Model

To learn entailment vectors from $\mathcal{L}$, we first consider a standard neural network model. Let $\mathbf{w}_1, \mathbf{w}_2 \in \mathbb{R}^d$ denote the entailment vectors of two words, which we are trying to learn, where d is the number of dimensions of the vectors. We can combine the two vectors into a single vector as follows:

$$\mathbf{h} = \tanh(\mathbf{M}\begin{bmatrix}\mathbf{w}_1 \\ \mathbf{w}_2\end{bmatrix} + \mathbf{b}),$$

where $\mathbf{M} \in \mathbb{R}^{l \times 2d}$ is a weight matrix, $\mathbf{b} \in \mathbb{R}^l$ is a weight vector, $\tanh(\cdot)$ is applied element-wise to the vector, $\mathbf{h} \in \mathbb{R}^l$ is a hidden vector and l is the number of dimensions of the hidden vector.

The hidden vector $\mathbf{h}$ can then go through a linear transform followed by a softmax layer to be used to predict the relation label r between the two words:

$$p(r \mid \mathbf{h}) = \text{softmax}(\mathbf{M}'\mathbf{h} + \mathbf{b}'), \quad (1)$$

where $\mathbf{M}' \in \mathbb{R}^{k \times l}$ and $\mathbf{b}' \in \mathbb{R}^k$ denote a weight matrix and a bias vector, and $k = |\mathcal{R}|$.

Given all the labeled word pairs in $\mathcal{L}$, we can use the cross entropy loss as the objective function to learn the entailment vector for each $w \in \mathcal{V}$ as well as the various parameters above.

Set-Theoretic Model

Although the standard neural network model above is straightforward, it is hard to explain how the learned word vectors can encode the lexical entailment relations. Inspired both by the set-theoretic definitions of the basic semantic relations shown in Table 2a and by some recent work on formal distributional semantics (Grefenstette, 2013; Rocktaschel et al., 2014), we hypothesize that a good entailment vector for a word essentially encodes which elements in $\mathcal{D}$ are members of the set representing this word. We now present a novel set-theoretic model to learn the entailment vectors.

To illustrate our idea, we first show that in the extreme case when word vectors we try to learn are binary vectors precisely representing set memberships, the semantic relation between two words can be determined by comparing the two vectors element-wise. Specifically, let D denote the size of the universe $\mathcal{D}$. Since a word x can be regarded as a subset of $\mathcal{D}$, we assume that the entailment vector of x is a D-dimensional binary vector $\mathbf{x}$, where $\mathbf{x}_i$ is 1 if the i^{th} element in $\mathcal{D}$ is inside the set x and 0 otherwise. Given two vectors $\mathbf{x}_1$ and $\mathbf{x}_2$ representing two words, in order to determine the relationship between them, we need to check the relationship between the two sets. To do so, we define the following counters for $p, q \in \{0, 1\}$:

$$c_{p,q} \quad = \quad \sum_{i=1}^{D} \delta(x_{1,i}, p)\delta(x_{2,i}, q),$$

where $\delta(s, t)$ is 1 if s is equal to t and 0 otherwise. Essentially if we compare $\mathbf{x}_1$ and $\mathbf{x}_2$ element-wise, then $c_{0,0}$, $c_{0,1}$, $c_{1,0}$ and $c_{1,1}$ count the number of times we see (0, 0), (0, 1), (1, 0) and (1, 1), respectively. It is not hard to show that the seven basic semantic relations in Table 2a correspond to different values of these $c_{p,q}$. For example, if $c_{0,1}$ is 0 and $c_{1,0}$ is 0, then the two sets (words) are equivalent. If $c_{0,1}$ is positive and $c_{1,0}$ is 0, then $\mathbf{x}_1$ is a subset of $\mathbf{x}_2$, and therefore the first word entails the second word. Table 2b shows the criteria for each basic semantic relation based on the values of these counters $c_{0,0}$, $c_{0,1}$, $c_{1,0}$ and $c_{1,1}$.

We can use a simple example to illustrate the idea above. Suppose the universe contains four elements: $\mathcal{D} = \{dog, cat, tiger, computer\}$. The word *animal* is a set that contains *dog*, *cat* and *tiger*, and thus can be represented by the vector $[1, 1, 1, 0]$. The word *pet* should contain only *dog* and *cat*, so it can be represented by the vector $[1, 1, 0, 0]$. In this case, the values of the four counters are the following: $c_{0,0} = 1$, $c_{0,1} = 0$, $c_{1,0} = 1$, and $c_{1,1} = 2$. According to Table 2b, we can determine that *animal* reversely entails *pet* based on the values of these counters.

Generally speaking, however, the number of elements in the universe is huge and therefore it is not feasible to learn word vectors that precisely represent the memberships of all these elements. In the following model we propose, we do not strictly force the entailment vectors to be binary. We also introduce a hidden layer that is deterministically derived from the entailment vectors. This hidden layer essentially represents $c_{0,0}$, $c_{0,1}$, $c_{1,0}$ and $c_{1,1}$, and it is used for the prediction of the relation between two words.

Specifically, let $\mathbf{w}_1, \mathbf{w}_2 \in \mathbb{R}^d$ represent the entailment vectors corresponding to words w_1 and w_2. Next, we introduce two complementary vectors:

$$\bar{\mathbf{w}}_1 = \mathbf{1} - \mathbf{w}_1, \qquad \bar{\mathbf{w}}_2 = \mathbf{1} - \mathbf{w}_2,$$

where $\mathbf{1}$ is a d-dimensional vector of 1s.

We then define a hidden vector $\mathbf{h}$ to be a 4-dimensional vector as follows:

$$\mathbf{h} = \frac{1}{d}\begin{bmatrix} \mathbf{w}_1^\top \mathbf{w}_2 & \mathbf{w}_1^\top \bar{\mathbf{w}}_2 & \bar{\mathbf{w}}_1^\top \mathbf{w}_2 & \bar{\mathbf{w}}_1^\top \bar{\mathbf{w}}_2 \end{bmatrix}^\top. \tag{2}$$

We can see that this hidden vector $\mathbf{h}$ roughly correspond to the four counters $c_{0,0}$, $c_{0,1}$, $c_{1,0}$ and $c_{1,1}$ defined above if the entailment vectors are binary vectors. But since we do not have the binary constraint, $\mathbf{h}$ actually contains real values rather than integer values. We also perform normalization by dividing the counts by d.

The same as shown in Eqn. (1), we can use $\mathbf{h}$ to predict the relation label between two words through a linear transform and a softmax layer. We can then again use the cross entropy loss as the objective function to learn the entailment vectors and the model parameters.

2.2 Using Entailment Vectors for RTE

Given the entailment vectors learned from $\mathcal{L}$ using either the standard neural network model or our proposed set-theoretic model, we can use them in a neural network model for textual entailment. In this paper we use a slightly modified version of the decomposable attention model proposed by Parikh et al. (2016) because of its relative simplicity and good performance on the SNLI (Bowman et al., 2015) dataset.

The setup of the textual entailment task is as follows. We are given two input sentences: a premise $X = ((\mathbf{x}_1, \mathbf{x}'_1), (\mathbf{x}_2, \mathbf{x}'_2), \ldots, (\mathbf{x}_m, \mathbf{x}'_m))$ and a hypothesis $Z = ((\mathbf{z}_1, \mathbf{z}'_1), (\mathbf{z}_2, \mathbf{z}'_2), \ldots, (\mathbf{z}_n, \mathbf{z}'_n))$, where each $\mathbf{x}_i$ (or $\mathbf{z}_j$) is a standard word embedding such as the word2vec embedding of the i^{th} (or j^{th}) word in the premise (or hypothesis), and $\mathbf{x}'_i$ (or $\mathbf{z}'_j$) is the newly-learned entailment vector of the i^{th} (or j^{th}) word in the premise (or hypothesis), as described in Section 2.1.[1] The goal is to predict a label $y \in \{\textit{entailment}, \textit{contradiction}, \textit{neutral}\}$ from X and Z.

The Modified Decomposable Attention Model

The decomposable attention model consists of the following three steps.

Attend: At this step, we derive attention weights from the word embeddings from X and Z. We first define

$$e_{ij} = F(\mathbf{x}_i)^\top F(\mathbf{z}_j),$$
$$\alpha_{ij} = \frac{\exp(e_{ij})}{\sum_{j'=1}^{n} \exp(e_{ij'})}, \qquad \beta_{ij} = \frac{\exp(e_{ij})}{\sum_{i'=1}^{m} \exp(e_{i'j})},$$

where $F(\cdot)$ is a standard single-layer feed-forward neural network with ReLU activations (Glorot et al., 2011). We then define

$$\tilde{\mathbf{x}}_i = \sum_{j=1}^{n} \alpha_{ij} \cdot \mathbf{z}_j, \qquad \tilde{\mathbf{x}}'_i = \sum_{j=1}^{n} \alpha_{ij} \cdot \mathbf{z}'_j,$$
$$\tilde{\mathbf{z}}_j = \sum_{i=1}^{m} \beta_{ij} \cdot \mathbf{x}_i, \qquad \tilde{\mathbf{z}}'_j = \sum_{i=1}^{m} \beta_{ij} \cdot \mathbf{x}'_i.$$

$\tilde{\mathbf{x}}_i$ is a weighted version of the word embeddings from Z to match $\mathbf{x}_i$, and similarly $\tilde{\mathbf{x}}'_i$ is a weighted version of the entailment vectors from Z to match $\mathbf{x}'_i$. The same idea applies to $\tilde{\mathbf{z}}_j$ and $\tilde{\mathbf{z}}'_j$.

Compare: At this step, another single-layer feed-forward neural network G with ReLU activations is used to compare the aligned words. Normally, without considering the entailment vectors, the comparison is done as follows:

$$\mathbf{v}_{1,i} = G(\mathbf{x}_i \oplus \tilde{\mathbf{x}}_i), \qquad \mathbf{v}_{2,j} = G(\mathbf{z}_j \oplus \tilde{\mathbf{z}}_j),$$

where $\oplus$ is concatenation, and $\mathbf{v}_{1,i}$ and $\mathbf{v}_{2,j}$ represent the comparison results for the i-th word in X and the j-th word in Z, respectively.

When we do consider the entailment vectors $\mathbf{x}'_i$ and $\mathbf{z}'_j$, as well as their counterparts $\tilde{\mathbf{x}}'_i$ and $\tilde{\mathbf{z}}'_j$ from the **Attend** step, we need to perform the comparison slightly differently. Here we use two different ways to perform the comparison, depending on whether the entailment vectors are learned using the standard neural network model or the set-theoretic model. If the standard neural network model is used to learn the entailment vectors, we simply concatenate all the vectors to perform comparison as follows:

$$\mathbf{v}_{1,i} = G(\mathbf{x}_i \oplus \tilde{\mathbf{x}}_i \oplus \mathbf{x}'_i \oplus \tilde{\mathbf{x}}'_i), \qquad \mathbf{v}_{2,j} = G(\mathbf{z}_j \oplus \tilde{\mathbf{z}}_j \oplus \mathbf{z}'_j \oplus \tilde{\mathbf{z}}'_j).$$

[1] For those words which do not appear in $\mathcal{L}$ (the set of unique words in the training data), we randomly generate their entailment vectors in the range $(-0.1, 0.1)$.

However, if the entailment vectors are learned using the set-theoretic model, because of the special properties of the entailment vectors as explained in Section 2.1, we perform comparison as follows:

$$\mathbf{v}_{1,i} = G(\mathbf{x}_i \oplus \tilde{\mathbf{x}}_i \oplus (\mathbf{x}'_i \odot \tilde{\mathbf{x}}'_i) \oplus (\mathbf{x}'_i \odot (1 - \tilde{\mathbf{x}}'_i)) \oplus ((1 - \mathbf{x}'_i) \odot \tilde{\mathbf{x}}'_i) \oplus ((1 - \mathbf{x}'_i) \odot (1 - \tilde{\mathbf{x}}'_i))),$$
$$\mathbf{v}_{2,j} = G(\mathbf{z}_j \oplus \tilde{\mathbf{z}}_j \oplus (\mathbf{z}'_j \odot \tilde{\mathbf{z}}'_j) \oplus (\mathbf{z}'_j \odot (1 - \tilde{\mathbf{z}}'_j)) \oplus ((1 - \mathbf{z}'_j) \odot \tilde{\mathbf{z}}'_j) \oplus ((1 - \mathbf{z}'_j) \odot (1 - \tilde{\mathbf{z}}'_j))),$$

where $\odot$ is element-wise multiplication of two vectors.

Aggregate: Given $\mathbf{v}_{1,i}$ $(1 \le i \le m)$ and $\mathbf{v}_{2,j}$ $(1 \le j \le n)$ as defined above, we first use a standard LSTM model to process the two sequences separately, and then we use MaxPooling to aggregate the derived hidden vectors in order to obtain a single vector for each sequence:

$$\mathbf{h}_{1,i} = \text{LSTM}(\mathbf{v}_{1,i}, \mathbf{h}_{1,i-1}), \qquad \mathbf{h}_{2,j} = \text{LSTM}(\mathbf{v}_{2,j}, \mathbf{h}_{2,j-1}),$$
$$\mathbf{v}_1 = \text{MaxPooling}(\mathbf{h}_{1,1}, \mathbf{h}_{1,2}, \ldots, \mathbf{h}_{1,m}), \qquad \mathbf{v}_2 = \text{MaxPooling}(\mathbf{h}_{2,1}, \mathbf{h}_{2,2}, \ldots, \mathbf{h}_{2,n}).$$

We then use $\mathbf{v}_1$ and $\mathbf{v}_2$ to make the final prediction:

$$p(y|\mathbf{v}_1, \mathbf{v}_2) = \text{softmax}(\mathbf{W}(\mathbf{v}_1 \oplus \mathbf{v}_2) + \mathbf{c}),$$

where $\mathbf{W}$ and $\mathbf{c}$ are parameters to be learned.

2.3 Implementation Details

In this section, we describe how we derive labeled word pairs from WordNet to construct $\mathcal{L}$. Because eventually we will test the learned entailment vectors on the SICK and SNLI textual entailment datasets, we focus on extracting word pairs with at least one word appearing in SICK or SNLI.

Specifically, we follow the following steps to construct $\mathcal{L}$. In all the steps, w_1 and w_2 refer to nouns found in WordNet.

- If the synset of w_1 is a hypernym of the synset of w_2, we add $(w_1, w_2, \sqsupset)$ and $(w_2, w_1, \sqsubset)$ to $\mathcal{L}$.
- If w_1 and w_2 are in the same synset, or w_1 (w_2) is the plural form of w_2 (w_1), we add $(w_1, w_2, \equiv)$ and $(w_2, w_1, \equiv)$ to $\mathcal{L}$.
- If the synsets of w_1 and w_2 share the same parent synset, we add $(w_1, w_2, |)$ and $(w_2, w_1, |)$ to $\mathcal{L}$.
- We remove word pairs from $\mathcal{L}$ where neither word occurs in the SICK or the SNLI dataset.

3 Experiments

3.1 Direct Evaluation of Entailment Vectors

As a first step to evaluate our method, we first test whether our entailment vectors learned from labeled word pairs can indeed encode lexical entailment relations. To do this, we report the prediction accuracy on $\mathcal{L}$. Recall that $\mathcal{L}$ is derived from nouns in WordNet. In total we have 13,029 unique words and 67,935 labeled word pairs in $\mathcal{L}$. The four entailment relations are quite evenly distributed except for alternation, which has roughly twice as many word pairs as the other relations.

We compare the entailment vectors learned from the standard neural network model and from the set-theoretic model. We refer to these two as **NN** and **ST**. In addition, we also consider one baseline method, which train an SVM with RBF kernel on the word2vec embeddings of two words to predict their semantic relation.[2] We refer to this baseline as **word2vec**.

For all the methods, we take two thirds of $\mathcal{L}$ for training/validation and the remaining one third for testing. We repeat this three times and report the average accuracies. We tune the hyperparameters as follows: The dimensionality of the entailment vectors is chosen from $\{25, 50, 100, 200\}$ and the learning rate from $\{0.05, 0.1, 0.15\}$. We applied stochastic gradient descent with a mini-batch size of 5 for optimization.

[2]We have also tried to use a standard neural network model instead of SVM on the word2vec embeddings, and the performance is 68.5%, which is similar to using SVM.

(c)

Table 3: (a) Results of direct evaluation on $\mathcal{L}$. d is the optimal dimensionality of the entailment vectors (for NN and ST) or of the word embeddings (for word2vec) based on validation. SD stands for standard deviation. (b) Numbers of sentence pairs in the SICK and the SNLI datasets. (c) Textual entailment results on the two datasets by different methods. MLN-eclassif (Beltagy et al., 2016) and CAFE (Tay et al., 2018) represent the state of the art on the SICK and the SNLI datasets, respectively. DAM (Beltagy et al., 2016) is the original decomposable attention model. The numbers shown in the table are what was reported in these papers. ** and * indicate statistical significance ($p \leq 0.01$) and ($p \leq 0.05$) compared with w2v by McNemars test, respectively.

We show the results in terms of accuracy and F1 in Table 3a. We can observe the following from the table. (1) The entailment vectors give better accuracies for predicting the entailment relations compared with using word2vec embeddings. (2) Between the standard neural network model and our set-theoretic model, the set-theoretic model achieves better performance.

Levy et al. (2015) previously showed that for some models using word embedding vectors to identify hypernyms, the model is essentially memorizing "prototypical" hypernyms. In order to check whether this happens to our model, we create a special set of labeled word pairs in which we introduce some "confusing" word pairs. We use the following rule to generate these word pairs: If we know ($\langle w_2, w_1 \rangle, \sqsubset$) and ($\langle w_1, w_3 \rangle, |$), then we can infer that ($\langle w_2, w_3 \rangle, |$). We obtain 719 labeled word pairs in this way. For example, ($\langle$*staple gun, musical instrument*$\rangle, |$) is one in this set. We denote this dataset as confusion set (CS). The accuracy and F1 scores are shown in the last two columns of Table 3a, respectively. We can see that the entailment vectors learned using the standard neural network models perform very poorly on this special set, suggesting that the learned entailment vectors may be memorizing the prototypical hypernyms. Using word2vec embeddings performs poorly, too. However, entailment vectors learned from the set-theoretic model perform very well, suggesting that the set-theoretic model we proposed does not simply learn "prototypical" hypernyms.

3.2 Evaluation on Textual Entailment

In this section, we evaluate whether the learned entailment vectors can help RTE. Here the entailment vectors are trained using the entire set of labeled word pairs derived from WordNet as we have described in Section 2.3. We use the SICK dataset and SNLI dataset for this experiment.

Recall that we have earlier hypothesized that when there are many word pairs in the test data that are not found in the training data, external lexical entailment knowledge about these word pairs is especially important. In order to verify this hypothesis, we also construct a different split of the data. We use the following steps to build this split:

- For every sentence pair, find all possible matching word pairs that occur in the WordNet data. E.g., we extract ⟨someone, someone⟩, ⟨stirring, stirring⟩, ⟨chili, chili⟩ and ⟨kettle, pot⟩ from the sentence pair in Table 1.
- For every word pair, randomly assign all sentence pairs containing such word pair into either the

training set or the test set. This is to ensure that the test set contains word pairs that have not appeared in the training data at all.
- Randomly split the training set into the final training set and a development set with a ratio of 9:1.

We denote the original split of the data as the "standard split" (ss) and the new split of the data as the "non-overlap split" (ns). This results in two additional specific-split datasets. Table 3b shows the numbers of sentence pairs of all the four datasets.

We compare the following settings of using entailment vectors in the decomposable attention model for RTE:

- w2v: This is the original decomposable attention model for RTE without using the entailment vectors. The word embeddings used are word2vec.
- w2v+NN: This setting uses the modified decomposable attention model with both word2vec word embeddings and the entailment vectors learned from the standard neural network model.
- w2v+ST: This setting uses the modified decomposable attention model with both word2vec word embeddings and the entailment vectors learned from the set-theoretic model.

The SICK dataset has a vocabulary of 2,331 words, 1,560 of which can be found in the WordNet dataset. For the SNLI dataset, the vocabulary contains 32,497 words, of which only 3,599 appear in the WordNet. During training, we experiment with 2-layer feed-forward neural networks with 200 neurons in all sets. Learning rate is set to be 0.03 and batch size is 30. In order to better compare different models, we use the McNemar test to test the statistical significance of the performance differences between different models.

We show the experiment results in Table 3c. We have the following observations. (1) The result of our baseline w2v on the standard split of the SNLI dataset is almost the same as the one reported by Parikh et al. (2016). This shows that our baseline implement is as strong as the DAM model. (2) For the standard split of the datsets, both w2v+NN and w2v+ST can outperform w2v, and w2v+ST's accuracy is significantly better than w2v. In particular, our model outperforms the state-of-the-art performance on the SICK dataset. Even though the performance on SNLI is not better than the best result reported (Tay et al., 2018), where extensive syntactic features were used, we still can outperform the basic model (Parikh et al., 2016) by injecting WordNet knowledge into the model. (3) For the non-overlap split, especially on the SICK dataset, using only word2vec, the RTE performance on the development set is quite high, but when it comes to the test set, the performance drops drastically. This demonstrates that without observing the necessary word pairs from the training set, it is hard to make the right predictions on the test set. In contrast, using entailment vectors performs better in the non-overlap split setting. For the SNLI dataset, the improvement is not so obvious. This may be because SNLI has a low percentage of words that can be found in WordNet. (4) Comparing w2v+NN and w2v+ST, we can see that w2v+ST performs slightly better than w2v+NN most of the time. This shows the advantage of our set-theoretic model for learning the entailment vectors.

3.3 Further Analyses

We also conduct some further analyses on the results to better understand our method.

Analysis of the Set-Theoretic Model

Recall that for the set-theoretic model, the hidden vectors $\mathbf{h}$ as defined in Eqn. (2) roughly correspond to the four counters $c_{p,q}$, and these counters are essential to how the set-theoretic model works. To see whether the set-theoretic model indeed works as we have expected, we plot the values of $\mathbf{h}$ for some example word pairs. Figure 2a shows the $\mathbf{h}$ vectors for four word pairs from WordNet with different lexical entailment relations. Figure 2b shows the weights applied to $\mathbf{h}$ as defined in Eqn. (1) to make the final predictions of lexical entailment relations. We can see in Figure 2a that for the word pair $(\langle \text{child, juvenile} \rangle, \sqsubset)$, it has a large value for the counter $c_{0,1}$, and this counter has a positive weight for relation $\sqsubset$ in Figure 2b. On the other hand, for $\sqsupset$, the counter $c_{1,0}$ has a positive weight. Also, $|$ needs positive weights for $c_{1,0}$ and $c_{0,1}$ while $\equiv$ needs negative weights for them. All these match our expectations from Table 2b.

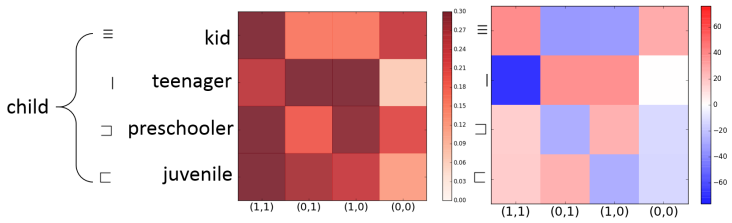

Figure 2: (a) Visualization of the 4-dimensional $\mathbf{h}$ for four types of relations with the corresponding word pairs labeled on the left and the meaning of the 4 dimensions labeled at the bottom. (b) Visualization of the weights applied to $\mathbf{h}$ with the corresponding relations labeled on the left and the meanings of the 4 dimensions labeled at the bottom.

SICK(ns)	81.8%	84.4%	84.0%	85.1%

Table 4: Evaluations of concrete concepts and abstract concepts on SICK(ns) data.

Analysis of Concrete and Abstract concepts

In Section 2.1, we show that our entailment vectors are mainly inspired by the set-theoretic definitions of basic semantic relations. Intuitively they work mostly for nouns presenting concrete concepts such as "animal" and "dog." It would be interesting to see how well they work for abstract nouns such as "idea" and "proposal." In order to check this, we conduct the following analysis.

We make use of an existing dataset[3] that contains concreteness ratings for 40,000 common English lemmas, collected using Amazon Mechanical Turk (Brysbaert et al., 2014). The ratings are from 0 to 5. We select words with scores 4.5 and higher to form our concrete concept list and words with scores 2.5 and lower to form another abstract concept list. This results in 596 concrete words and 250 abstract words. We then re-run the textual entailment experiments on the SICK data with the "non-overlap split" (ns). But instead of incorporating the entailment vectors of all words found in $\mathcal{L}$, we try two new settings, where we incorporate only the entailment vectors of the words found in the concrete word list or the abstract word list. We use entailment vectors learned from the set-theoretic model. We refer to these two new settings as w2v+ST(concrete) and w2v+ST(abstract). We show the performance in terms of accuracy in Table 4. For comparison, we also show w2v, which is our baseline that does not use any entailment vectors, and w2v+ST, which uses entailment vectors of all words. As we can see from the table, incorporating entailment vectors of concrete words works slightly better than of abstract words, but both settings perform better than the baseline w2v. This shows that even for abstract concepts, our model is still able to capture lexical-level entailment knowledge and incorporate such knowledge into the textual entailment model. Overall, incorporating entailment vectors of all words still works the best.

Case Studies

In Table 5 we show some successful as well as erroneous RTE predictions made by our method using the entailment vectors trained by the set-theoretic model. In the first example, since the words *kettle* and *pot* never co-occur in the training set, using only word2vec embeddings makes a wrong prediction. But injecting the entailment vectors trained using the set-theoretic model from the WordNet labeled word pairs, the knowledge that *kettle* entails *pot* is brought into the model, and therefore the w2v+ST method can correctly make a prediction. We can see that the w2v+NN method could not inject such knowledge either. The same thing happens in the next example, where WordNet provides the knowledge $(\langle \textit{inside, outside} \rangle, |)$, which is never learned from the training set.

We also provide two negative examples where w2v+ST makes wrong predictions. In the third example, the knowledge $(\langle \textit{lawn, field} \rangle, \sqsubset)$ provided by WordNet is not applicable, because here *lawn* and *field* are

considered to be different. The last example shows that for paraphrases not at the lexical level, our entailment vectors cannot help.

4 Related Work

Lexical entailment: Our work is related to recognizing lexical entailment. Many existing methods for lexical entailment are based on the distributional inclusion hypothesis and leverage co-occurrence information of words from a large corpus (Weeds et al., 2004; Geffet and Dagan, 2005; Kotlerman et al., 2010; Bernardi et al., 2012). In contrast, our work uses labeled word pairs derived from WordNet to learn entailment vectors to encode the lexical entailment relations. The semantic relations we consider are also designed specifically for natural language inference.

Word embeddings: Recently, neural-network-based approaches have been developed to learn vector representations of words (Mikolov et al., 2013; Pennington et al., 2014). These word embeddings are trained from an unlabeled large corpus and for general usage. In contrast, our entailment word vectors are not meant to be used as general-purpose word embeddings. They are designed specifically for incorporating external knowledge from WordNet into neural network models for RTE. Although there has been some work attempting to inject external lexical knowledge into word embeddings (Faruqui et al., 2015; Chen et al., 2015), they have not investigated the usage of these enhanced word embeddings for RTE.

Textual entailment with lexical knowledge: Many studies have attempted to inject lexical knowledge into the RTE task. Balkir et al. (2015) proposed compositional distributional models to extend representations from words to sentences. By mapping from a premise to a hypothesis by dependency trees or proposition extraction and then comparing lexical entailment between nodes or words, Herrera et al. (2005) and Ofoghi and Yearwood (2009) tried to solve RTE via WordNet. Beltagy et al. (2013), Beltagy et al. (2016) and Martinez-Gomez et al. (2017) first changed sentences to logical forms and then leveraged logic inference engines combined with lexical entailment axioms to make entailment judgments. But we are not aware of any work on how to apply lexical knowledge to textual entailment based on neural networks.

5 Conclusions

In this paper, we propose to learn entailment vectors that encode lexical entailment knowledge from WordNet. We incorporate such entailment vectors into a decomposable attention model for RTE. Our empirical evaluation shows that the entailment vectors can indeed improve the performance of RTE when evaluated on the SICK and the SNLI datasets. In the future, we plan to study how to automatically obtain more training data for learning entailment vectors and how to encode phrase-level entailment relations in such entailment vectors. Our data and code have been made publicly available.[4]

Abstract

Fine-grained entity typing aims at identifying the semantic type of an entity in $\mathcal{KB}$. Type information is very important in knowledge bases, but is unfortunately incomplete even in some large knowledge bases. Limitations of existing methods are either ignoring the structure and type information in $\mathcal{KB}$ or requiring large scale annotated corpus. To address these issues, we propose an attributed and predictive entity embedding method, which can fully utilize various kinds of information comprehensively. Extensive experiments on real DBpedia dataset show that our proposed method significantly outperforms 8 state-of-the-art methods, with 3.4% and 2.9% improvement in Mi-F1 and Ma-F1, respectively.

1 Introduction

Knowledge about entities in Knowledge Base ($\mathcal{KB}$) is essential for language understanding. This knowledge can be attributional (e.g., *canFly*, *hasAge*), relational (e.g., *marriedTo*, *bornIn*) or type-based (e.g., *isFood*, *isLocation*). Type information, which clusters a group of entities with same properties, is valuable in $\mathcal{KB}$, because it is the glue that holds our mental world together (Murphy, 2004). Types in $\mathcal{KB}$ are usually organized as a hierarchical structure, namely *type hierarchy*. **Entity typing** assigns types (e.g., *Person*, *Athlete*, *BasketballPlayer*) to an entity (e.g., *Yao Ming*) in $\mathcal{KB}$, and is a fundamental task in knowledge base construction.

Traditional entity typing focuses on a small set of types, such as *Person*, *Location* and *Organization* (Ratinov and Roth, 2009; Nadeau and Sekine, 2007), while **fine-grained entity typing** assigns more specific types to an entity, which normally forms a *type-path* in the type hierarchy in $\mathcal{KB}$ (Ren et al., 2016a). As shown in Fig. 1, *Yao Ming* is associated with a type-path */Thing/Agent/Person/Athlete/BasketballPlayer*. Fine-grained types (e.g., *Athlete* and *BasketballPlayer*) are more informative than coarse-grained types (e.g., *Person*), because they provide more specific semantic information about the entity (Xu et al., 2016). Characterizing an entity with fine-grained types (type-paths) benefits many real applications, such as *knowledge base completion* (Dong et al., 2014), *entity linking* (Ling et al., 2015; Durrett and Klein, 2014), *relation extraction* (Liu et al., 2014), and *question answering* (Yahya et al., 2014).

Many researches have been carried out on *fine-grained entity typing **in text***, which detects local types for an entity mention in a particular plain text from predefined fine-grained entity types (Ling and Weld, 2012; Yogatama et al., 2015; Ren et al., 2016a; Shimaoka et al., 2017; Xin et al., 2018). However, only a few works aim at *fine-grained entity typing **in knowledge base***, that is, inferring missing types for an entity in $\mathcal{KB}$, which is the focus of this paper. Most $\mathcal{KB}$s are incomplete and lack of type information, in part because the world is always changing. For example, 36.53% entities in DBpedia do not have type information. Therefore, $\mathcal{KB}$s are aways in need of updating and completing. To this end, there are two main methods in the literature as follow: One method exploits various kinds of information to construct the feature representation of an entity, such as entity textual description, property and category (Neelakantan and Chang, 2015; Xu et al., 2016). After that, a predict function $P(t|e)$ is learned to infer

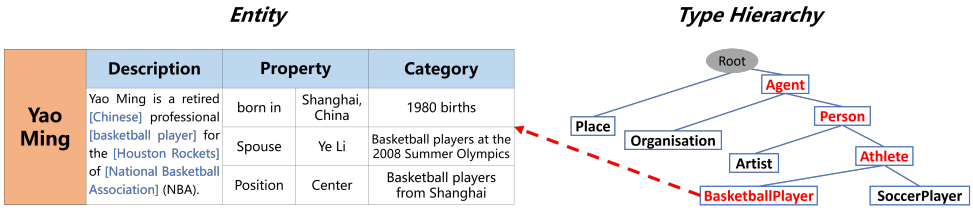

Figure 1: An example of fine-grained entity typing in $\mathcal{KB}$. The left part is an entity with various information. The red ones are assigned types, which forms a type-path.

whether entity e is an instance of type t. This method ignores rich structural information in $\mathcal{KB}$ (i.e., link relation between entities). It is a promising and challenging problem to utilize structural information for type inference. The second method utilizes **annotated corpus** to learn entity low-dimensional representations then makes type inference based on the learned embeddings (Yaghoobzadeh and Schütze, 2015; Yaghoobzadeh and Schütze, 2017). Apparently, it requires large scale corpus in which entity mentions are annotated. But large scale highly-qualified annotated corpus is often difficult to obtain.

To address the above issues, we propose a novel *attributed and predictive entity embedding* method, which can be described as follow: We first construct a partially-labeled attributed entity network, which contains structural, attribute and type information for entities. Here "partially-labeled" means some entities have been labeled with type information, while others not. Then, we employ a deep neural network to integrate the structural and attribute information for entity representation learning. For an unlabeled entity, we jointly utilize its structural and attribute information for neighbor prediction. For a labeled entity, besides neighbors, we also predict its types and type hierarchy via a margin-based loss function. Finally, a multi-label classification model is used for type inference based on the learned entity embeddings.

The main contributions of this paper can be summarized as follows:

- We encode various kinds of information into a partially-labeled entity network and propose a deep neural network model to effectively integrate the structural and attribute information for entity representation learning.
- We utilize type information of labeled entities to equip the learned embeddings with strong predictive power in entity typing task, and further incorporate the structure of type hierarchy via a margin-based loss function to meet the fine-grained demand.
- We construct a dataset from DBpedia. Extensive experiments show that our proposed method significantly outperforms 8 state-of-the-art methods, with 3.4% and 2.9% improvement in Mi-F1 and Ma-F1, respectively.

The rest of this paper is organized as follows. In Section 2, we formally define the problem of fine-grained entity typing in knowledge bases. Section 3 demonstrates the proposed approach in detail. The dataset description and evaluation are presented in Section 4. Section 5 outlines some related works. Section 6 concludes our work.

2 Problem Formulation

In this section, we formally define the problem of *Fine-Grained Entity Typing* in $\mathcal{KB}$.

Definition 1 ***Knowledge Base*** *is defined a tuple of entities $\mathcal{E}$ and a type hierarchy $\mathcal{H}$, formally, $\mathcal{KB} = \langle \mathcal{E}, \mathcal{H} \rangle$, where $\mathcal{H}$ is used to organize entities in $\mathcal{E}$. Each entity $e \in \mathcal{E}$ denotes a specific thing in the real world.*

Definition 2 ***Type Hierarchy*** *$\mathcal{H}$ is defined as a tree or a directed acyclic graph (DAG). It provides a natural way to categorize and organize entities in large $\mathcal{KB}$. It is formalized $(\mathcal{T}, \mathcal{R})$, where $\mathcal{T}$ is the type set and $\mathcal{R} = \{(t_i, t_j) | t_i, t_j \in \mathcal{T} \wedge i \neq j\}$ is the relation set, in which (t_i, t_j) means that t_i is the subtype of t_j.*

We distinguish three kinds of entity knowledge which are beneficial to *fine-grained entity typing* task.

- **Entity Link Relation:** $\mathcal{KB}$ contains a large number of link relations between entities. It is natural to convert entities in $\mathcal{E}$ into a network structure via these link relations. If an entity e_i links to another entity e_j in $\mathcal{KB}$, there will be a directed edge from entity e_i to entity e_j. These link relations reflect the overall structure of $\mathcal{KB}$ and provide important semantic relatedness between entities.

- **Entity Attribute:** Besides the above link structure, each entity $e \in \mathcal{E}$ also has textual description, properties and categories (shown in Fig. 1). We term all such auxiliary information of an entity as attributes. The attributes of an entity provide valuable clues to predict its types.

- **Entity Type:** Part of entities in $\mathcal{E}$ have been assigned with types, we refer them as $\mathcal{E}^l$. The assigned types for an entity form a type-path in type hierarchy $\mathcal{H}$, which starts from the root and ends at one specific type (not necessary to end at the leaf type). Those entities in $\mathcal{E}$ without type information are referred as $\mathcal{E}^u$. The type information observed in $\mathcal{E}^l$ can be a useful signal to infer missing type information in $\mathcal{E}^u$.

From the above definitions, we achieve a **partially-labeled attributed entity network**, including link structure, entity attributes, and type information. We formally define this entity network as follow:

Definition 3 ***Entity Network:*** *Let $\mathcal{G} = (\mathcal{E}, \mathcal{L})$ be an entity network. $\mathcal{E} = \mathcal{E}^l \cup \mathcal{E}^u$ is the entity set, where $|\mathcal{E}| = N$ and $|\mathcal{E}^l| = N^l$. $\mathcal{L} = \{(e_i, e_j) \,|e_i, e_j \in \mathcal{E} \text{ and } i \neq j\}$ is the link relation set.*

For the convenience of formula deduction, we redefine this entity network in matrix form, $\mathbf{G} = (\mathbf{A}, \mathbf{X}, \mathbf{Y})$. Adjacency matrix $\mathbf{A} \in \mathbb{R}^{N \times N}$ is equivalent to link set $\mathcal{L}$, $\mathbf{A}_{ij} = 1$ if there is a link from e_i to e_j, otherwise 0. Each row in $\mathbf{A}$ refers to an entity's link vector $\mathbf{A}_i$. Attribute matrix $\mathbf{X} \in \mathbb{R}^{N \times M}$ collects attributes for all entities, where *M* is the number of attributes. Each row in $\mathbf{X}$ refers to an entity's attribute vector $\mathbf{X}_i$. $\mathbf{X}$ can either be binary or take any real value. Type matrix $\mathbf{Y} \in \mathbb{R}^{N^l \times K}$ collects type information for entities in $\mathcal{E}^l$, where *K* is the number of types. Each row in $\mathbf{Y}$ refers to the type vector $\mathbf{Y}_i$ of a labeled entity in $\mathcal{E}^l$. $\mathbf{Y}_{ij} = 1$ if e_i has been assigned with type t_j, otherwise 0.

Based on the terminologies described above, we formally define the problem of *fine-grained entity typing in $\mathcal{KB}$* as follows:

Definition 4 ***Fine-grained entity typing in KB:*** *Given a partially-labeled attributed entity network $\mathcal{G} = (\mathcal{E}, \mathcal{L})$, we aim at learning a type predictor from $\mathcal{E}^l$, which comprehensively takes link structure, entity attributes and type information into account. Then we utilize the learned type predictor to predict the type of $e \in \mathcal{E}^u$, i.e., infer whether entity $e \in \mathcal{E}^u$ is an instance of type $t \in \mathcal{T}$.*

3 The Proposed Approach

3.1 General Architecture

A general state-of-the-art architecture for fine-grained entity typing consists of two components.

- **Entity Representation:** It learns distributed representation $\vec{v}(e)$ for each entity $e \in \mathcal{E}$.

- **Type Predictor:** It learns a predict function $P(t|e)$ using $\mathcal{E}^l$ as training examples. $P(t|e)$ denotes the probability that entity *e* belongs to type *t*, and it is often used to infer types of those unlabeled entities in $\mathcal{E}^u$.

Type predictor is regarded as a multi-label classification model. $P(t|e)$ is calculated through a two-layer Multi-Layer Perceptron (MLP).

$$[P(t_1|e) \cdots P(t_K|e)] = \sigma\left(\mathbf{W}_{out} f\left(\mathbf{W}_{in} \vec{v}(e)\right)\right) \tag{1}$$

Each entry of output layer indicates the predicted probability of type t_i for a given entity *e*. $\mathbf{W}_{in}$ and $\mathbf{W}_{out}$ are MLP parameter matrices. σ is the sigmoid function. f is the nonlinear activation function, such as *ReLU* and *tanh*.

The loss L for a prediction $\mathbf{y} = [P(t_1|e) \cdots P(t_K|e)]$ when the true labels are encoded in a binary vector $\mathbf{y}^* \in \{0,1\}^{1\times K}$ is the following cross entropy loss function:

$$L(\mathbf{y}, \mathbf{y}^*) = \sum_{i=1}^{K} -\mathbf{y}^{*(i)} \log \mathbf{y}^{(i)} - \left(1 - \mathbf{y}^{*(i)}\right) \log\left(1 - \mathbf{y}^{(i)}\right) \tag{2}$$

The key difficulty in computing $P(t|e)$ is to learn a good representation $\vec{v}(e)$ for entity e. Several models have achieved the state-of-the-art performance. However, these models still face the following non-trivial challenges:

- Entity attributes and link structure are typically regraded as separated features without considering their correlations. Recent research shows the importance of integrating link structure and entity attributes for learning more informative representations (Liao et al., 2017; Li et al., 2017). Could we seamlessly integrate entity attributes and link structure into a unified entity network? Since the link structure and entity attributes offer different sources of information, how shall we capture the complex non-linear relationship between them?

- The type information of the labeled entities in $\mathcal{E}^l$ is only used in the learning phase of the type predictor, but totally ignored in the representation learning phase. Recent research shows incorporating labeled information in representation learning could enhance the predictive power of the learning embeddings for specific tasks (Tang et al., 2015a; Yang et al., 2016). In our task, the entity types and their formed type hierarchy $\mathcal{H}$ are valuable labeled information, could we design a predictive model to make full use of the type information in $\mathcal{E}^l$ and the structure of type hierarchy?

To address the above challenges, we propose a novel attributed and predictive entity embedding method to learn entity representations. It combines the advantages of attributed network embedding method and semi-supervised learning. We integrate entity attributes and link structure via a deep neural network model (Section 3.2). For an entity e_i in $\mathcal{E}^l$, we jointly predict its type and its neighbor entities in the entity network (Section 3.3). In this way, we can fully utilize the type information in $\mathcal{E}^l$.

3.2 Attributed Entity Embedding

We aim at learning low-dimensional vector representations for each entity in the entity network, such that original link structure and entity attribute proximity can be preserved in vectors. The most intuitive idea is to directly concatenate the embeddings learned from different parts. However, this way can not capture the complex non-linear relationship between them, because each part is trained separately without interaction. To address this issue, we present a neural network model to integrate link structure (structural information) and entity attributes (attribute information). For an entity $e_i \in \mathcal{E}$, we jointly utilize its link vector $\mathbf{A}_i$ and attribute vector $\mathbf{X}_i$ to predict the link probability between e_i and other entities (shown in Fig. 2). Our model integrates structure and attribute information on the input layer, so that these two parts closely interact with each other and all parameters can be optimized simultaneously.

In our design, each entity *e* has two vector representations, *self representation* and *context representation*. $\mathbf{e}$ is self representation of *e* when it is treated as an entity in entity network $\mathcal{G}$. While $\tilde{\mathbf{e}}$ is context representation of *e* when it is treated as a specific context. To comprehensively represent an entity *e*, we add $\mathbf{e}$ and $\tilde{\mathbf{e}}$ as the final representation $\vec{v}(e)$.

Input and Embeddings. For an entity $e_i \in \mathcal{E}$, $\mathbf{A}_i$ and $\mathbf{X}_i$ denote its link vector and attribute vector as defined in Section 2. Our model takes both structural information ($\mathbf{A}_i$) and attribute information ($\mathbf{X}_i$) as input, and utilizes two embedding weight matrices to achieve the final input embeddings. $\mathbf{W}_{stru}$ projects the link vector $\mathbf{A}_i$ to a dense vector $\mathbf{u}_{stru}$ which captures structural information. $\mathbf{W}_{attr}$ encodes the attribute vector $\mathbf{X}_i$ and generates a compact vector $\mathbf{u}_{attr}$ which aggregates attribute information. We concatenate $\mathbf{u}_{stru}$ and $\mathbf{u}_{attr}$, then feed this concatenated vector into a Multi-Layer Perceptron.

Information Fusion. We employ a Multi-Layer Perceptron to integrate structural and attribute information. Recent research shows stacked multiple non-linear layers can help learn better representations

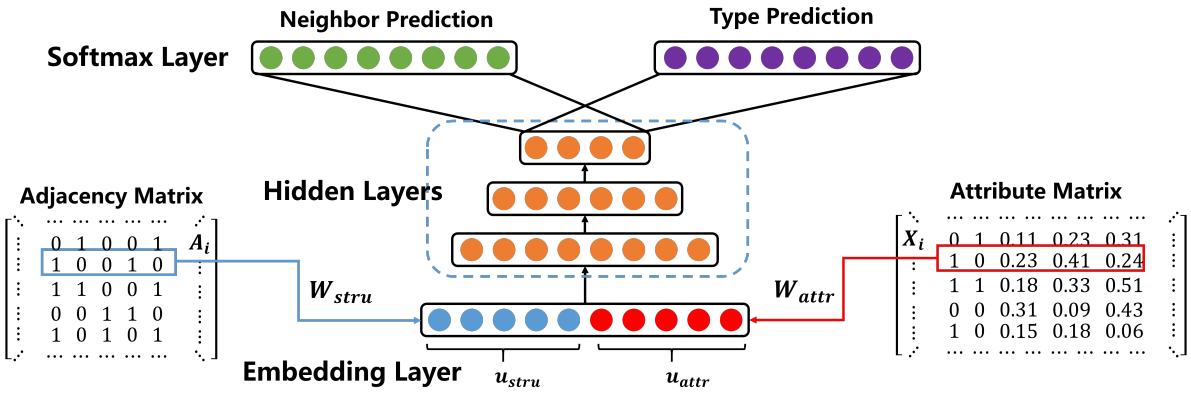

Figure 2: Attributed entity embedding framework

of data (Liao et al., 2017). Each layer is calculated as follows:

$$\mathbf{h}^{(1)} = f\left(\mathbf{W}^{(1)}\left[\mathbf{u}_{stru}, \lambda\mathbf{u}_{attr}\right] + \mathbf{b}^{(1)}\right) \tag{3}$$

$$\mathbf{h}^{(k)} = f\left(\mathbf{W}^{(k)}\mathbf{h}^{(k-1)} + \mathbf{b}^{(k)}\right), k = 1, 2, \cdots, n \tag{4}$$

λ is the trade-off factor for structure and attribute information. f denotes the activation function. n is the number of hidden layers. From the last hidden layer, we obtain an informative representation $\mathbf{h}^{(n)}$, which is regarded as the self representation $\mathbf{e}_i$ of the input entity e_i.

Neighbor Prediction. Finally, we predict neighbors for an input entity e_i (if there is a link from e_i to e_j, e_j is e_i's neighbor). We call it neighbor prediction, which is widely used to model network structure (Tang et al., 2015a; Liao et al., 2017). Specifically, we utilize the self representation $\mathbf{e}_i$ to predict the link probability between entity e_i and other entities. The predictive link probability is defined through a softmax layer as follows:

$$p\left(e_j|e_i\right) = \frac{\exp\left(\tilde{\mathbf{e}}_j \cdot \mathbf{e}_i\right)}{\sum_{j'=1}^{N}\exp\left(\tilde{\mathbf{e}}_{j'} \cdot \mathbf{e}_i\right)} \tag{5}$$

$\tilde{\mathbf{e}}_j$ denotes the context representation of entity e_j. Let $\mathbf{y}_i$ denotes the predicted link probability vector for entity e_i, $\mathbf{y}_i^{(j)}$ is the j-th entry of the vector $\mathbf{y}_i$. $\mathbf{A}_i$ is e_i's link vector (in Section 2), $\mathbf{A}_{ij}$ indicates whether there is a link from e_i to e_j. The loss function L_{attr} is defined as cross entropy over all entities in $\mathcal{E}$

$$L_{attr} = \sum_{i=1}^{N}\sum_{j=1}^{N} -\mathbf{A}_{ij}\log\mathbf{y}_i^{(j)} - \left(1 - \mathbf{A}_{ij}\right)\log\left(1 - \mathbf{y}_i^{(j)}\right) \tag{6}$$

3.3 Predictive Entity Embedding

In this section, we propose predictive entity embedding learning that makes full use of the type information in $\mathcal{E}^l$, which is often ignored by existing methods in representation learning phase. Inspired by (Tang et al., 2015a; Yang et al., 2016), we first introduce a type prediction loss to equip learned embeddings with strong predictive power for entity typing task (Section 3.3.1). Then, to meet the fine-grained demand, we model the tree-structured type hierarchy in a margin-based framework (Section 3.3.2).

3.3.1 Type Prediction

We fully utilize type information in $\mathcal{E}^l$ to make the learned embeddings more predictive. For each entity $e_i \in \mathcal{E}^l$, we not only predict its neighbors in $\mathcal{G}$ (Section 3.2), but also predict its types. We add another softmax layer, the probability of entity e_i being an instance of type t_j is defined as follows:

$$p\left(t_j|e_i\right) = \frac{\exp\left(\mathbf{t}_j \cdot \mathbf{e}_i\right)}{\sum_{j'=1}^{K}\exp\left(\mathbf{t}_{j'} \cdot \mathbf{e}_i\right)} \tag{7}$$

$\mathbf{t}_j$ denotes the representation of type t_j. Let $\mathbf{y}_i$ denotes the predicted type probability vector for entity e_i, $\mathbf{y}_i^{(j)}$ is the *j*-th entry of the vector $\mathbf{y}_i$. $\mathbf{Y}_i$ is e_i's type vector (in Section 2), $\mathbf{Y}_{ij}$ indicates whether e_i is an instance of t_j. The loss function L_{type} is defined as cross entropy over all entities in $\mathcal{E}^l$:

$$L_{type} = \sum_{i=1}^{N^l} \sum_{j=1}^{K} -\mathbf{Y}_{ij} \log \mathbf{y}_i^{(j)} - (1 - \mathbf{Y}_{ij}) \log \left(1 - \mathbf{y}_i^{(j)}\right) \tag{8}$$

3.3.2 Type Hierarchy Modeling

Fine-grained entity typing requires us to pay more attention to specific types (fine-grained types) than to general types (coarse-grained types), because specific types are more informative. For example, *Yao Ming* belongs to *BasketballPlayer* and *Athlete*, and it should get higher score on *BasketballPlayer* than *Athlete*, because the former characterizes *Yao Ming* more accurately. Besides, *Yao Ming* should get higher score on the correct type *BasketballPlayer* than its wrong sibling type *SoccerPlayer* although both types belong to *Athlete*. If different types are treated equally, the structural information between types will be lost. Therefore, we use *type order* to model different relatedness between an entity and its related types, which reflects the structural information of type hierarchy to a certain degree. In particular, we define two kinds of *type order* as follow:

Definition 5 ***Ancestor order:*** *In the type-path of an entity, specific types should get higher score than its ancestor. For example, Yao Ming should get higher score on BasketballPlayer than Athlete.*

Ancestor order reflects the relationship between a type and its ancestor types. For each triple (e, t, t^a), where *t* is one of the type for entity *e*, and t^a is *t*'s ancestor in type hierarchy. We define adaptive margin $\gamma_{tt^a} = \xi \times \frac{l(t^a,t)}{l(root,t)}$, where $l(t^a, t)$ denotes the number of steps going down from type t^a to type t. The hinge loss is defined as:

$$\max\left(0, s\left(e, t^a\right) - s\left(e, t\right) + \gamma_{tt^a}\right) \tag{9}$$

$$L_{ancestor} = \mathbb{E}_{(e,t,t^a)}\left[\max\left(0, s\left(e, t^a\right) - s\left(e, t\right) + \gamma_{tt^a}\right)\right] \tag{10}$$

where $s\left(e, t\right)$ is the score function, defined as the inner product of $\mathbf{e}$ and $\mathbf{t}$.

Definition 6 ***Sibling order:*** *For an entity, the correct type should get higher score than its wrong sibling type in type hierarchy. For example, Yao Ming should get higher score on BasketballPlayer than SoccerPlayer.*

Sibling order reflects the relationship between a type and its sibling types. For each triple (e, t, t^s), where *t* is one of the true type for entity *e*, and t^s is its wrong sibling type of entity *e*. We use the fixed margin ξ. The hinge loss is defined as:

$$\max\left(0, s\left(e, t^s\right) - s\left(e, t\right) + \xi\right) \tag{11}$$

$$L_{sibling} = \mathbb{E}_{(e,t,t^s)}\left[\max\left(0, s\left(e, t^s\right) - s\left(e, t\right) + \xi\right)\right] \tag{12}$$

We achieve the loss function L_{hier} for type hierarchy modeling: $L_{hier} = L_{ancestor} + L_{slibing}$.

Objective and Training. Finally, we sum these three loss function to get the final objective function of entity representation component.

$$Loss = L_{attr} + \lambda_1 \cdot L_{type} + \lambda_2 \cdot L_{hier} \tag{13}$$

λ_1 and λ_2 are weight parameters. We apply negative sampling (Mikolov et al., 2013; Tang et al., 2015b), where only a very small subset of entities are sampled from $\mathcal{E}$. Parameters are optimized through Adaptive Moment Estimation (Adam). In the embedding layer and each hidden layer, we also add dropout component to alleviate over fitting.

4 Experiments and Analysis

In this section, we evaluate the proposed method using real world dataset collected from DBpedia. We will introduce the dataset and experiment settings in Section 4.1, present the comparison results in Section 4.2 and investigate some method details in Section 4.3. Our source code is available[1] for reference.

4.1 Datasets and Experimental Setup

Datasets: To the best of our knowledge, there is no public large-scale dataset available for fine-grained entity typing in $\mathcal{KB}$. We construct a dataset from DBpedia. The type hierarchy in DBpedia is of tree structure. We extract link relation and attribute information from DBpedia[2]. For each entity, we use the single type-path assigned in DBpedia as the ground truth.

For this dataset, we remove those entities which are only labeled as *Thing*. Because they do not provide any semantic information. In representation learning phase, we utilize the whole dataset with only 50% entities are labeled with types. In type predictor phase, we follow a 50/30/20 ratio to split the dataset into training, dev and test sets. Table 1 shows the detailed statistics. Each entity has 3.27 types on average.

Table 1: Statistics of the dataset

Type	Entity	Link	Attribute		
			word	property	category
214	300,000	5,243,230	5,350	200	350

Metrics: To evaluate the performance of our proposed method, we use Accuracy (**Strict-F1**), Micro-averaged F1 (**Mi-F1**) and Macro-averaged F1 (**Ma-F1**), which have been used in many fine-grained typing systems (Yaghoobzadeh and Schütze, 2015; Yaghoobzadeh and Schütze, 2017; Ren et al., 2016a).
Parameter Settings: Our implementation of **APE** is based on TensorFlow[3]. Regarding the choice of activation function of hidden layers, we have tried *ReLU*, *softsign* and *tanh*, finding *softsign* leads to the best performance in general. We randomly initialize model parameters with a Gaussian distribution (with a mean of 0.0 and standard deviation of 0.01), optimizing the model with mini-batch Adam (Kingma and Ba, 2014). We set fixed margin $\xi = 1$ in our experiments. Both λ_1 and λ_2 are chosen among $\{0.2, 0.4, 0.6, 0.8\}$, we found $\lambda_1 = 0.8$ and $\lambda_2 = 0.4$ achieve best performance.
Baseline: We denote our model as **APE**, and compare it with three sets of methods:

- **Entity typing methods**: We compare **APE** with five state-of-the-art entity typing methods. **FIGMENT** uses entity representation learned from annotated corpus for type inference (Yaghoobzadeh and Schütze, 2015). **CUTE** employs a multi-label hierarchical classification method to address entity typing task (Xu et al., 2016). **MuLR** uses multi-level representations of entities (character, word and entity) to make type inference in $\mathcal{KB}$ (Yaghoobzadeh and Schütze, 2017). **Global** utilizes entity text description to infer missing entity type instances (Neelakantan and Chang, 2015). **Corpus** designs global and context model to make type inference jointly (Yaghoobzadeh et al., 2017).

- **Network Embedding methods**: Attributed and predictive network embedding methods can learn informative entity representations, so we compare **APE** with them. **PTE** learns predictive text embeddings from heterogeneous network (Tang et al., 2015a). **Planetoid** is a semi-supervised network embedding method which makes neighbor and label prediction jointly (Yang et al., 2016). **ASNE** integrates structural and attribute information via a deep neural architecture (Liao et al., 2017).

- **APE's variants**: If we ignore the type information, that is, utilize the embeddings learned from section 3.2 to make type inference, the method is denoted as $\textbf{APE}_{no\_type}$. Similarly, if we omit the type hierarchy modeling in Section 3.3.2, the method is denoted as $\textbf{APE}_{no\_hierarchy}$.

4.2 Overall Comparison Results

Table 2 shows the overall performance and we have the following conclusions:

[1] https://github.com/Tsinghua-PhD/APE
[2] http://wiki.dbpedia.org/downloads-2016-10
[3] https://www.tensorflow.org/

Table 2: Typing performance on DBpedia dataset

Type	Algorithm	Acc	Ma-F1	Mi-F1
Entity Typing	**FIGMENT**	0.463	0.619	0.628
	CUTE	0.515	0.673	0.677
	MuLR	0.501	0.654	0.662
	Corpus	0.488	0.662	0.659
	Global	0.457	0.608	0.615
Network Embedding	**Planetoid**	0.434	0.585	0.590
	ASNE	0.417	0.568	0.573
	PTE	0.352	0.512	0.518
Our Variants	$\mathbf{APE}_{no\_type}$	0.492	0.649	0.657
	$\mathbf{APE}_{no\_hierarchy}$	0.531	0.694	0.689
	APE	**0.545**	**0.702**	**0.711**

Comparison with Entity Typing methods. Our model outperforms the state-of-the-art entity typing methods, and achieves 3.4% and 2.9% improvement in Mi-F1 and Ma-F1 respectively, because it employs multiple kinds of information for type inference. Each part can provide complementary information about entities for type inference. Our model leverages label information (type information) in representation learning phase, equip the learned embeddings with strong predictive power in entity typing task.

Comparison with Network Embedding methods. Our model outperforms the state-of-the-art network embedding methods (i.e., **Planetoid**, **ASNE** and **PTE**), and achieves 12.1% and 11.7% improvement in Mi-F1 and Ma-F1 respectively. We model the structure of type hierarchy in a margin-based loss function. Specifically, ancestor order makes entities closer to specific types than general types, and sibling order makes the learned entity embeddings have strong discriminative power between sibling types.

Comparison with Variants. **APE** consistently outperforms $\mathbf{APE}_{no\_type}$ and $\mathbf{APE}_{no\_hierarchy}$, and the simplest version $\mathbf{APE}_{no\_type}$ could achieve comparable results with state-of-the-art methods. The results verify that each of these information sources contributes complementary information for *fine-grained typing of entities*. Structural information (link relation) provides important semantic relatedness between entities. Attribute information (text, property and category) provides additional clues for type inference. Type information (type hierarchy) makes our model more powerful in classification task.

4.3 Result Analysis

4.3.1 Impact of Features

We investigate the effect of information sources used to learn entity embeddings. In Table 3, **Stru**, **T**, **P** and **C** is short for structural information, text description, property and category, respectively. From Table 3, we find different information sources play different roles in this task. *Structural information* is most common in $\mathcal{KB}$, it makes related entities have similar representations. It models the relation between entities, while neglecting entities's self-information. *Attribute information* (i.e., text description, property and category) can be viewed as entity features, which is often informative for type inference. We compare our model **APE**, $\mathbf{APE}_{no\_type}$ and $\mathbf{APE}_{no\_hierarchy}$ with different kinds of information combination. For attribute information, category information is more import than property information and text descriptions.

4.3.2 Effects of Labeled Data

We investigate the effect of labeled data proportion. Intuitively, our model can learn better embeddings and achieve better performance if we have more labeled entities. The results in Fig. 3 show that three metrics strikingly increase with more labeled data added, and gradually become stable when the proportion is over 0.5. It proves that our model can achieve a satisfactory result with not too much labeled data, and this advantage benefits from the entity link relations and network embedding.

Table 3: Performance on different information source combination.

Information Type	APE			APE_{no_type}			$\text{APE}_{no\_hierarchy}$		
	Acc	Ma-F1	Mi-F1	Acc	Ma-F1	Mi-F1	Acc	Ma-F1	Mi-F1
Stru+T	0.467	0.623	0.631	0.463	0.625	0.634	0.472	0.632	0.633

APE	**0.461**	**0.792**	**0.681**

4.3.3 Results of Frequent/Infrequent Types

We use type macro average F1 proposed by (Yosef et al., 2012) to evaluate the performance on *frequent types* and *infrequent types*. Note that it is different from Ma-F1 reported in Table 2. The results for infrequent types (occur less than 2,000 times) and frequent types (occur more than 10,000 times) are shown in Table 4. Generally, the performance on infrequent types is worse than frequent ones. Our model consistently outperforms the other methods on infrequent types, which demonstrates its ability on dealing with rare types.

5 Related Work

Fine-grained entity typing in $\mathcal{KB}$ is an important sub-task of knowledge base completion. One way to address this problem is making type inference based on entity's attribute information in $\mathcal{KB}$, such as textual description, property, category and so on. (Neelakantan and Chang, 2015) infer missing types for entities in $\mathcal{KB}$ based on text descriptions. (Xu et al., 2016) employ a multi-label hierarchical classification method to assign Chinese entities with DBpedia types based on property and category information. The other way relies on large-scale annotated corpus, then extracts type information from the annotated corpus for entities in $\mathcal{KB}$. (Yaghoobzadeh and Schütze, 2015) first propose FIGMENT to address this problem. They only used contextual information to assign types for entities in $\mathcal{KB}$. After that, they present FIGMENT-Multi to learn multi-level representations of entities on three complementary levels (character, word and entity). FIGMENT-Multi predicts whether an entity is a member of a type based on the learned embeddings (Yaghoobzadeh and Schütze, 2017). Finally, they propose an embedding based method which combines a global model with a context model. A global model that scores based on aggregated context information and a context model that aggregates the scores of individual contexts (Yaghoobzadeh et al., 2017).

Fine-grained entity typing in text is related to our task. Different from the works mentioned above, it

seeks to detect local types of an entity mention inside an individual sentence, and the same entity could have different types in different sentences (Ling and Weld, 2012; Yosef et al., 2012; Gillick et al., 2014; Dong et al., 2015; Del Corro et al., 2015; Yogatama et al., 2015; Ren et al., 2016b; Ren et al., 2016a; Shimaoka et al., 2017; Rabinovich and Dan, 2017).

6 Conclusion

In this paper, we propose an attributed and predictive entity embedding method to address the task of fine-grained entity typing in $\mathcal{KB}$. It combines the advantages of attributed network embedding method and semi-supervised learning. Specifically, it employs a deep neural network architecture to integrate structure and attribute information of an entity. We jointly predict a labeled entity's neighbors and types, and model the structure of type hierarchy in a margin-based way. Experiments on real world datasets demonstrate the effectiveness of the proposed model.

Joint Learning from Labeled and Unlabeled Data for Information Retrieval

Abstract

Recently, a significant number of studies have focused on neural information retrieval (IR) models. One category of works use unlabeled data to train general word embeddings based on term proximity. The general embeddings can be integrated into traditional IR models. The other category employs labeled data (e.g. click-through data) to train *end-to-end* neural IR models consisting of layers for target-specific representation learning. The latter idea accounts better for the IR task and is favored by recent research works, which is the one we will follow in this paper. We hypothesize that general semantics learned from unlabeled data can complement task-specific representation learned from labeled data of limited quality, and that a combination of the two is favorable. To this end, we propose a learning framework which can benefit from both labeled and more abundant unlabeled data for representation learning in the context of IR. Through a joint learning fashion in a single neural framework, the learned representation is optimized to minimize both the supervised loss on query-document matching and the unsupervised loss on text reconstruction. Standard retrieval experiments on TREC collections indicate that the joint learning methodology leads to significant better performance of retrieval over several strong baselines for IR.

1 Introduction

In recent years, the research community has noticed the great success of neural networks in computer vision (Krizhevsky et al., 2012), speech recognition (Hinton et al., 2012) and natural language processing (Mikolov et al., 2013) tasks. However, the potential of neural networks has not been fully investigated in the IR field. Although a significant number of studies (e.g. (Huang et al., 2013; Ganguly et al., 2015; Zheng and Callan, 2015; Guo et al., 2016; Zamani and Croft, 2016; Dehghani et al., 2017; Mitra et al., 2017)) try to apply neural networks in IR, there have been few studies reporting the performance that is comparable to state-of-the-art IR models. These approaches rely on the general idea that neural network can provide a low-dimensional and semantics-rich representation for both queries and documents. Such a representation can bridge lexical and semantic gaps in traditional IR models. Depending on if the embeddings are trained with discriminative information for IR tasks, existing works can be broadly divided into two categories (Zhang et al., 2016; Mitra and Craswell, 2017).

The first category of approaches extend traditional IR models to incorporate word embeddings that are trained on huge and unlabeled corpora with existing models such as *Word2vec* (Mikolov et al., 2013) and *GloVe* (Pennington et al., 2014) in an unsupervised manner. These approaches (e.g. (Zheng and Callan, 2015; Nalisnick et al., 2016)) leverage semantic information captured by word embeddings in order to enhance traditional IR models. We note that such models trained without references to the retrieval task model term proximity and do not contain discriminative information adapted for IR (Zamani and Croft, 2017). The second category (e.g. (Huang et al., 2013; Guo et al., 2016)) tries to incorporate word embedding learning within neural models for IR, which reflects a more significant shift toward an *end-to-end* framework. These approaches treat word embeddings as layers in neural IR models, to be learned

Proceedings of the 27th International Conference on Computational Linguistics, pages 293–302
Santa Fe, New Mexico, USA, August 20-26, 2018.

along with all model parameters in a supervised manner. Most studies in the second category rely on click-through data for relevance judgment between queries and documents. Text representation learned with relevance information captures relevance rather than term proximity, which clearly accounts better for IR requirements (Zamani and Croft, 2017). However, supervised signals such as click-through data are often limited outside of large industrial research labs, probably due to user privacy concerns. It is thus not surprising to see that many authors following this methodology have industrial background (e.g. (Huang et al., 2013; Shen et al., 2014b; Nalisnick et al., 2016; Mitra et al., 2017)). In addition, Ye et al. (2015) point out that previous studies using click-through data make implicit but strong assumptions about clicked query-document pairs which are not necessarily met in practice.

Neural networks are hungry for data, a fact which also holds for neural IR tasks. One can find from above discussions that the second category of approaches suffer from the data spareness problem, although there have been recent attempts (Gupta et al., 2017; Dehghani et al., 2017) trying to pseudo label query-document pairs automatically with unsupervised retrieval models such as BM25. Using pseudo labels as relevance signals relieves data spareness in terms of quantity but not quality. The idea of using unsupervised learning to complement supervision has been practiced successfully in computer vision (Yang et al., 2013) and natural language processing (Rasmus et al., 2015) tasks. In such a background, we hypothesize that semantics learned from unlabeled data can complement task-specific representation learned from pseudo-labeled data of limited quality, and a combination of the two is favorable in IR. To the best of our knowledge, such a combination has never been investigated in neural IR models.

In this paper, we propose a learning framework which can benefit from both labeled and more abundant unlabeled data for representation learning in IR. Through joint learning in a single neural network, the learned representation can account for task-specific characteristics via supervised loss optimization on query-document matching, as well as preserving general semantics via unsupervised loss optimization on text reconstruction. We demonstrate by experiments that the joint learning model leads to significantly better performance over state-of-the-art IR models.

2 Related work

Representation learning approaches based on neural networks have gained in prominence in recent years due to their extreme efficiency. They motivate the emerging research field of Neural IR. Neural approaches have attracted increasing interests of the IR community in very recent years. Apart from learning to rank approaches that train their models over a set of hand-crafted features (Liu, 2009), neural IR models typically accept the raw text of queries and documents as input. The dense representations of words or texts can then be learned with or without reference to retrieval tasks, respectively corresponding to the two categories of methods summarized in section 1.

Unsupervised approaches learn general text representation without query and document interaction information. Embeddings pre-trained on unlabeled text with tools such as *Word2vec* (Mikolov et al., 2013) and *Glove* (Pennington et al., 2014) have been used to extend traditional IR models. Ganguly et al. (2015) develop a generalized language model with query-likelihood language modeling for integrating word embeddings as additional smoothing. Zheng and Callan (2015) represent term and query as vectors in the same latent space based on word embeddings so as to learn a model to reweight terms. Nalisnick et al. (2016) retain both input and output embeddings of *Word2vec* and map query words into the input space and document words into the output space. Zamani and Croft (2016) propose to use word embeddings to incorporate and weight terms not present in the query, acting as smoothing and query expansion. There are also studies developing their own embedding learning algorithms instead of using standard tools for embedding learning. For instance, Salakhutdinov and Hinton (2009) propose a deep auto-encoder model to generate a condensed binary vector representation of documents. Clinchant and Perronnin (2013) use latent semantic indexing to induce word embeddings for IR. Vulić and Moens (2015) propose to learn from document-aligned comparable corpora the embeddings that can be used for both monolingual IR and cross-lingual IR.

Supervised approaches use query-document relevance information to learn the representation that is optimized *end-to-end* for the task at hand. With click-through data, Huang et al. (2013) develop DSSM, a

feed forward neural network with a word hashing phrase as the first layer to predict the click probability given a query string and a document title. DSSM is extended in (Shen et al., 2014a; Shen et al., 2014b) by incorporating convolutional neural network and max-pooling layers to extract the most salient local features. Since the DSSM related methods make implicit but strong assumptions about clicked data, Ye et al. (2015) try to relax the assumptions in their model. Guo et al. (2016) develop the DRMM model that takes the histogram-based features representing interactions between queries and documents as input into neural networks. DRMM is one of the first neural IR models to show improvement over traditional IR models. Mitra et al. (2017) aim to simultaneously learn local and distributional representation to capture both lexical matching and semantic matching in IR. Following the discussion in section 1, we note that click-through data are not always available in massive amount outside of industrial labs. More recent works propose to use unsupervised IR models to pseudo label query-document pairs that provide weak supervision for representation learning. Dehghani et al. (2017) use BM25 to obtain relevant documents for a large set of AOL queries (Pass et al., 2006) which are then used as weakly supervised signals for joint embedding and ranking model training. Zamani and Croft (2017) employ similar supervision signals as (Dehghani et al., 2017) to train an embedding network similar to *Word2vec* and use the obtained embeddings for query expansion and query classification. Gupta et al. (2017) develop a cross-lingual IR model based on weak supervision. Luo et al. (2017) propose to train deep ranking models with weak relevance labels generated by click model based on click behavior of real users.

We can conclude from above discussions that supervised approaches account better for task-specific features and are superior in IR. They rely on relevance information between query-document pairs of which the quality is relatively low in practice. In this paper, we follow successful practice in CV and NLP tasks and hypothesize that general and rich semantics learned from unlabeled data can complement task-specific representation learned from labeled data of limited quality. We will propose in section 3 a learning framework which can simultaneously learn from labeled and more abundant unlabeled data in the context of IR. By the way, we note that the joint learning framework resembles those studies (e.g. (Liu et al., 2015)) which couple IR with another supervised learning task. Our framework differs from those studies in that we do not require additional data that are labeled for another supervised learning task.

3 Joint learning framework for IR

In this section, we will develop a joint framework to learn low-dimensional representation of queries and documents from both labeled and unlabeled data.

3.1 Learning framework

The joint learning framework is illustrated in figure 1. It consists of three crucial components:

- **An encoding network.** It embeds the raw input into low-dimensional representations that are designed to capture target-specific characteristics of IR.
- **A decoding network.** It tries to reconstruct the input so as to benefit from unlabeled data.
- **A pairwise ranking model.** It makes use of supervision signals from labeled query-document pairs to perform document ranking.

On top of the network structure, we perform joint optimization of both supervised loss and unsupervised loss. The unsupervised learning process uses all the text collection (e.g. queries and documents) for learning rich and general semantics. The supervised learning process learns, from labeled query-document pairs, discriminative representations adapted for IR. The joint training fashion makes two learning processes complement each other via co-tuning the shared hidden layers in the encoding networks to help the representation generalize better in the IR task.

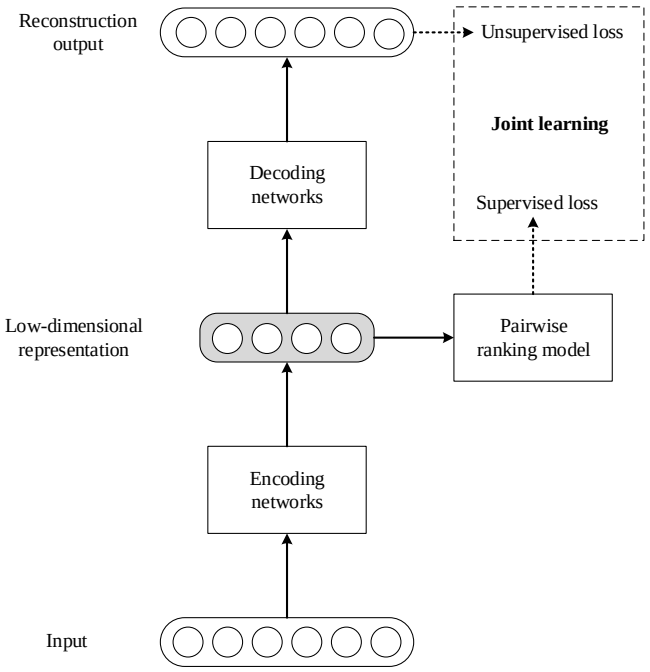

Figure 1: The joint learning framework with labeled and unlabeled data. It consists of an encoding network, a decoding network and a pairwise ranking model. We impose an unsupervised loss and a supervised loss respectively on the reconstruction output and the pairwise ranking output, which is learned in a joint fashion in this paper. The low-dimensional representation is the one our model aims to learn.

3.2 Unsupervised learning

The unsupervised part learns the low-dimensional representation of text via an autoencoder style, which uses all the available text data. Following previous studies on text autoencoder (Chen and Zaki, 2017), we opt for the simple feed-forward neural network architecture for both the encoding and decoding parts in figure 1. For each layer of the encoding/decoding networks, we use Rectified Linear Unit (ReLU) as the activation function, a function recommended by many works in deep learning (LeCun et al., 2015). In the feed-forward step, each layer $l(l \geq 1)$ is a fully-connected layer and its activation potential $\boldsymbol{z}_l$ is given by:

$$\boldsymbol{z}_l = \max(0, \boldsymbol{W}_l \boldsymbol{z}_{l-1} + \boldsymbol{b}_l)$$

where $\boldsymbol{W}_l$ is the weight matrix at layer l and $\boldsymbol{b}_l$ is the corresponding bias.

The input layer (corresponding to $l = 0$) maps the input text into fixed-length vector. There have been two methodologies we can employ to represent the input text: one is the one-hot representation (Gupta et al., 2017) and its variants (Zhai and Zhang, 2016); the other one is the dense and semantically rich representations (He et al., 2017). Empirical results do not indicate that one is always better than the other and we will make use of the former one in this paper. Given the set of text T, we follow previous studies such as (Zhai and Zhang, 2016; Chen and Zaki, 2017) and represent each input text t in T as log-normalized word count vector $\boldsymbol{x} \in R^{|V|}$ where $|V|$ is the size of the vocabulary V. Each dimension of the input vector $\boldsymbol{x}$ is represented by:

$$\boldsymbol{x}_i = \frac{\log[1 + tf(i)]}{\max_{i \in V} \log[1 + tf(i)]}, \text{ for } i \in V$$

where $tf(i)$ is the term frequency of the i-th word in the vocabulary. Since the unsupervised learning part of the framework is modeled as an autoencoder, we want the unsupervised output $\boldsymbol{x}'$ to resemble the

input $\boldsymbol{x}$, leading to the binary cross-entropy loss function l_u on t that can be defined as:

$$l_u(t) = -\sum_{i \in V} [\boldsymbol{x}_i \log(\boldsymbol{x}'_i) + (1 - \boldsymbol{x}_i) \log(1 - \boldsymbol{x}'_i)] \tag{1}$$

3.3 Supervised learning

The document ranking problem can not be modeled with the standard classification or regression framework. Following the methodology in learning to rank (Liu, 2009), we model document ranking in the *pairwise* style where the relevance information is in the form of preferences between pairs of documents with respect to individual queries. In addition, we follow previous studies (Gupta et al., 2017) and make use of well-performing unsupervised retrieval models (e.g. BM25) to pseudo-label query and document pairs so as to obtain the relevance information. More details will be given in section 4.1.

From figure 1 one can note that the hidden layers in the encoding networks are shared by unsupervised and supervised learning, and one can refer to the unsupervised learning part for details of the layers in the encoding networks. The supervised model, on top of the top-level representation layer (i.e. low-dimensional representation), tries to learn a model that, given the query q, assigns a larger score to document d_1 than document d_2 if the ground truth is that d_1 matches to q better. The supervised model is implemented as a pairwise ranking model in figure 1, which is again a feed forward neural networks. Inspired by such studies as (Yih et al., 2011), we can derive the probability $P'(d_1 \succ_q d_2)$ that d_1 is ranked higher than d_2 with respect to the query q via a logistic function:

$$P'(d_1 \succ_q d_2) = \frac{1}{1 + e^{-\sigma[\text{score}(q,d_1) - \text{score}(q,d_2)]}}$$

where the *score* function is computed with the pairwise ranking model, and the parameter σ is used to determine the shape of the sigmoid. The supervised training objective l_s on a triplet of query-document pair (q, d_1, d_2) can then be defined as the cross entropy loss, which is:

$$\begin{aligned} l_s(q, d_1, d_2) = &- P(d_1 \succ_q d_2) \log P'(d_1 \succ_q d_2) \\ &- [1 - P(d_1 \succ_q d_2)] \log[1 - P'(d_1 \succ_q d_2)] \end{aligned} \tag{2}$$

where $P(d_1 \succ_q d_2)$ is the actual probability that d_1 is ranked higher than d_2 according to annotations (i.e. pseudo-labels of query-document pairs). The actual probability in this paper is estimated in a similar way as in (Dehghani et al., 2017), which is:

$$P(d_1 \succ_q d_2) = \frac{1}{1 + e^{-\sigma[\text{S}(q,d_1) - \text{S}(q,d_2)]}}$$

where s denotes the relevance scores obtained from training instances. In the training process, the positive sample d_1 for the query q can be chosen as the most relevant documents according to annotated relevance scores. The negative sample d_2 is selected randomly from the document collection.

3.4 Joint learning with regularization

Combining the unsupervised loss l_u in equation 1 on all text data, the supervised loss l_s in equation 2 on all labeled query-document pairs, and the $L2$ norm regularization for weight matrices, one finally arrives at the objective function for the joint learning model, which is:

$$\begin{aligned} L(T, DS) = &\frac{\alpha}{|T|} \sum_{t \in T} l_u(t) + \frac{\beta}{|QD|} \sum_{(q,d_1,d_2) \in QD} l_s(q, d_1, d_2) \\ &+ \sum_{l \in LY} \|W_l\|_F^2 \end{aligned} \tag{3}$$

where T and $|T|$ denote the set of text data and its size, QD and $|QD|$ denote the set of labeled query-document pairs and its size, LY stands for all the hidden and output layers of the framework in figure 1, and W_l is the weight matrix of the layer l in the network. The hyper-parameters α, β control the importance of the unsupervised loss and the supervised loss. The joint loss function $L(T, DS)$ can be optimized in the gradient-based way, and we use the Adam algorithm (Kingma and Ba, 2015) to compute the gradients.

4 Experiments and results

In this section, we conduct IR experiments to demonstrate the effectiveness of our proposed model.

4.1 Data sets

The IR experiments are carried out against standard TREC collections consisting of one Robust track and one Web track, which represent different sizes and genres of heterogeneous text collections. These collections have been broadly used in recent studies (Zheng and Callan, 2015; Guo et al., 2016; Dehghani et al., 2017). The details of these collections and corresponding queries are given in table 1. The Robust dataset is used in the standard form without change. The ClueWeb-09-Cat-B collection (or *ClueWeb* for short) is filtered to the set of documents with spam scores in the 60-th percentile with Waterloo Fusion spam scores[1]. For all TREC queries, we only make use of the title fields for retrieval.

Table 1: IR collection statistics (M = million, B=Billion).

Collections	Doc count	Word count	TREC topics
Robust04	0.5M	252M	301-450, 601-700
ClueWeb	34.0M	26.1B	1-200

In order to build the labeled query-document pairs for supervised learning, we choose to use the more general methodology in (Gupta et al., 2017) instead of the one in (Dehghani et al., 2017) to relieve from data (i.e. AOL queries) only available from industrial labs. We fetch a set of news titles from the China Daily website[2] and use these titles as training queries to produce annotated query-document pairs. We use these training queries to retrieve the document collection with BM25. We make sure that no training queries appear in the evaluation query set in table 1. For each training query, we take the top 500 retrieved documents as positive samples. The negative samples are picked randomly from the document collection. There are other strategies for choosing negative samples (Wieting et al., 2015), which is out of the scope of this paper. For unsupervised learning, we make use of training queries and evaluation document sets listed in table 1, as well as the Wikipedia articles[3] as the external resource.

4.2 Experimental setup

We set the hyper-parameters of our model by following similar tasks such as (Dehghani et al., 2017). The size and number of hidden layers are respectively selected from $\{64, 128, 256, 512, 1024\}$ and $\{1, 2, 3, 4\}$. The values of α, β in equation 3 are chosen from $\{0.001, 0.01, 0.1, 1, 10, 100, 1000\}$. We select the initial learning rate from $\{10^{-3}, 10^{-4}, 5 * 10^{-4}, 10^{-5}, 5 * 10^{-5}\}$. The batch size for learning is selected from $\{64, 128, 256, 512\}$. These model hyper-parameters are tuned on the validation set (20% of the training queries used for validation).

For IR evaluation, we make use of mean average precision (MAP) of top-ranked 1000 documents , precision at rank 20 (P20), and normalized discounted cumulative gain at rank 20 (nDCG20). Statistically significant differences between various models are determined using the two-tailed paired t-test with $p < 0.05$.

We compare the retrieval performance of our joint learning retrieval model with two categories of IR models: classic IR models showing state-of-the-art performance, and the recent neural ranking models for IR. Since our model is representation-focused rather than interaction-focused, we do not plan to compare our model with those based on relevance matching (Guo et al., 2016) in this paper. More importantly, since our model learns from weakly supervised signals by BM25, we are more interested in the comparisons to BM25 and similar models using weakly supervised signals, an experimental strategy also employed in (Dehghani et al., 2017). Under such considerations, we perform experiments with the following baselines:

[2] http://www.chinadaily.com.cn

[3] The wikipedia dump on September 1, 2017 can be obtained from https://dumps.wikimedia.org

Table 2: Retrieval performance of all models on TREC collections. Significant improvement or degradation at the level 0.05 with respect to *BM25* is indicated as (+/-). The other significance comparisons are given in the text.

	Robust04			**ClueWeb**		
	MAP	P20	nDCG20	MAP	P20	nDCG20
BM25	0.248	0.351	0.406	0.091	0.237	0.190
QL	0.245	0.352	0.404	0.092	0.239	0.193
DSSM	0.088^{-}	0.163^{-}	0.184^{-}	0.037^{-}	0.126^{-}	0.104^{-}
NRMS	0.275^{+}	0.378^{+}	0.441^{+}	0.127^{+}	0.302^{+}	0.236^{+}
Our Model	$\mathbf{0.287}^{+}$	$\mathbf{0.391}^{+}$	$\mathbf{0.450}^{+}$	$\mathbf{0.136}^{+}$	$\mathbf{0.317}^{+}$	$\mathbf{0.251}^{+}$

- *Classic models:* The probabilistic *BM25* model and query likelihood (*QL*) model based on Dirichlet smoothing are highly efficient IR models.
- *DSSM:* It is a representative deep matching model proposed in (Huang et al., 2013), which is a representation-focused model. The model is framed as a feed forward neural network with a word hashing layer.
- *NRMS:* It is a weakly-supervised neural IR model learned with automatically annotated query-document pairs (Dehghani et al., 2017). NRMS shows significant improvement over traditional IR models.

4.3 Results and analysis

Comparisons to classic models. We use here the recommended settings of the baseline models according to their original papers. Table 2 reports the experimental results on TREC datasets for our model and all the baseline models. One can find from the results that classic IR models BM25 and QL perform similarly on the two collections, a conclusion that is coincident with previous findings. Since BM25 is the model we employ to produce pseudo labels for supervised learning, we will not compare neural models with QL in the following discussions. The neural IR model DSSM performs significantly worse than the traditional BM25 model, due to its unsuitability for relevance matching and for handling the diverse matching requirements in long documents (Guo et al., 2016). NRMS is a neural ranking model learned from automatically labeled data, which resembles our model. NRMS shows all the significant improvements over BM25. Our model proposed in this paper, by jointly learning from the labeled and unlabeled data, achieves the best overall performance. Our model always significantly outperforms BM25 by a large margin.

Comparisons to neural models. We further compare our model with the neural IR models DSSM and NRMS. We find that our model performs better than DSSM and NRMS on all collections. Our model significantly outperforms DSSM in all the cases considered above. Our model significantly outperforms NRMS with only one exception that is not significant on Robust04 with nDCG20. By the way, we find that NRMS is also always significantly better than DSSM on all collections. The experimental conclusion is that our model is always significantly better than traditional IR models and mostly outperforms neural IR models considered above. Furthermore, we find that using unlabeled data for training in neural IR models is useful, since it leads to significant improvement over the neural models only using labeled data.

Impact of unsupervised learning. It has been confirmed above that our model shows the best performance overall. However, it is not clear how much unsupervised learning contributes to the retrieval performance. We thus compare representations learned in a different setting without the help of unsupervised loss, which amounts to removing the unsupervised loss l_u from equation 3. We perform IR experiments with the new model over data sets in table 1 and list results in table 3. From the results one can find that the performance of the model without unsupervised loss decreases from the joint model with significance in all the cases considered. It indicates that it is beneficial to combine unsupervised

Table 3: Retrieval performance of the model without unsupervised loss. Significant degradation at the level 0.05 with respect to our original model is indicated as -.

	Robust04			**ClueWeb**		
	MAP	P20	nDCG20	MAP	P20	nDCG20
Original Model	0.287	0.391	0.450	0.136	0.317	0.251
Without unsupervised loss	0.262^{-}	0.356^{-}	0.413^{-}	0.114^{-}	0.298^{-}	0.231^{-}

learning with supervised learning in neural IR. Empirical results in this part support our claim in this paper that learning from unlabeled data complements knowledge learned from labeled data in neural IR.

5 Conclusions

In this paper, we propose a neural IR model which jointly learns from labeled and unlabeled data to benefit from both the rich and general semantics in unlabeled data and target-specific features in labeled data. As far as we can tell, it is the first time such a combination is investigated in neural IR. Experiments on TREC collections show that our model, without any human annotation, is significantly better than traditional IR models and recently proposed models based on neural networks. Experiments also show that using unsupervised learning to complement supervised learning with weak supervision is important in IR. A future direction to follow would be to use more expressive architectures such as LSTM to replace feed-forward networks used in this paper.

Modeling the Readability of German Targeting Adults and Children: An empirically broad analysis and its cross-corpus validation

Abstract

We analyze two novel data sets of German educational media texts targeting adults and children. The analysis is based on 400 automatically extracted measures of linguistic complexity from a wide range of linguistic domains. We show that both data sets exhibit broad linguistic adaptation to the target audience, which generalizes across both data sets. Our most successful binary classification model for German readability robustly shows high accuracy between 89.4%–98.9% for both data sets. To our knowledge, this comprehensive German readability model is the first for which robust cross-corpus performance has been shown. The research also contributes resources for German readability assessment that are externally validated as successful for different target audiences: we compiled a new corpus of German news broadcast subtitles, the *Tagesschau/Logo* corpus, and crawled a *GEO/GEOlino* corpus substantially enlarging the data compiled by Hancke et al. (2012).

Zusammenfassung

Wir untersuchen zwei neue Datensätze deutscher Bildungs- und Mediensprache für Kinder und Erwachsene. Die Analyse basiert auf 400 automatisch extrahierten Maßen sprachlicher Komplexität, die verschiedene linguistische Domänen abdecken. Unsere Ergebnisse zeigen, dass in beiden Datensätzen die sprachliche Gestaltung der Texte in ähnlicher Weise breitflächig an ihr jeweiliges Zielpublikum angepasst wird. Unser erfolgreichstes binäres Klassifikationsmodell erzielt Genauigkeitswerte von 89,4% und 98,9% über beide Datensätze hinweg. Unseres Wissens handelt es sich bei diesem umfassend durch verschiedene linguistische Bereiche informtiertem Modell deutscher Text-Lesbarkeit um das erste, für das robuste Ergebnisse in einer korpusübergreifenden Evaluation dokumentiert sind. Darüber hinaus tragen wir mit unserer Arbeit zwei neue Datensätze zur Erforschung deutscher Text-Lesbarkeit bei, die auf Texten basieren, deren Eignung für ihre respektiven Zielgruppen extern durch wiederholte Rezeption validiert wurde: Wir haben aus Untertiteln deutscher Nachrichtenbeiträge das *Tagesschau/Logo* Korpus erstellt. Weiterhin haben wir das *GEO/GEOlino* Korpus beträchtlich erweitert, das ursprünglich von Hancke et al. (2012) erstellt wurde.

1 Introduction

Readability assessment refers to the task of (automatically) linking a text to the appropriate target audience based on its complexity. A diverse spectrum of potential application domains has been identified for this task in the literature, ranging from the design and evaluation of education materials, to information retrieval, and text simplification. Given the increasing need for learning material adapted to different audiences and the barrier-free access to information required for political and social participation, automatic readability assessment is of immediate social relevance. Accordingly, it has attracted considerable

Proceedings of the 27th International Conference on Computational Linguistics, pages 303–317
Santa Fe, New Mexico, USA, August 20-26, 2018.

research interest over the last decades, particularly for the assessment of English (Crossley et al., 2011; Chen and Meurers, 2017; Feng et al., 2010).

For German readability assessment, however, little progress has been made in recent years, despite a series of promising results published around the turn of the decade (Vor der Brück et al., 2008; Hancke et al., 2012). In particular, German readability research has suffered from the lack of a shared reference corpus and sufficiently comparable corpora for cross-corpus testing of readability models: While for English research, the *Common Core* corpus consisting of examples from the English Language Arts Standards of the Common Core State Standards, and the *WeeklyReader* corpus of online news articles have been widely used in studies on English readability and text simplification (Vajjala and Meurers, 2014; Petersen and Ostendorf, 2009; Feng et al., 2010), there are no comparable resources for German. This is particularly problematic, as over-fitting is a potential issue for classification algorithms, especially given the limited size of the typical data sets.

To address these issues, we first present two new data sets for German readability assessment in Section 3: a set of German news broadcast subtitles based on the primary German TV news outlet *Tagesschau* and the children's counterpart *Logo!*, and a GEO/GEOlino corpus crawled from the educational GEO magazine's web site, a source first identified by Hancke et al. (2012), but double in size.[1] The longstanding success of these outlets with their target audiences provides some external validity to the nature of the implicit linguistic adaptation of the language used. As Bryant et al. (2017) showed for German secondary school textbooks, this is not necessarily the case across all linguistic dimensions and adjustments may even be limited to only the surface level of text, sentence, and word length. We conducted a series of analyses on these two data sets to accomplish the following objectives:

1. Investigate how instances of German educational news language differ in terms of language complexity across adult and child target audiences.

2. Build a binary readability model for German educational language targeting adults and children that shows high, robust classification performance across corpora.

For the purposes of our studies, we operationalize child target audience of German educational news language as children aged between 8 and 14. This is the typical audience age range of the child-targeting news media we analyzed.[2] Adult target audience then is defined as over 14 years of age.

To address our first research question, after introducing a broad set of complexity measures in Section 4, we compare their informativeness for distinguishing adult and child level in the two data sets in Section 5. In Section 6, we define a series of readability models for German, including one showing high classification accuracy between 89.4% and 98.9% on both data sets. The paper closes with a discussion of the implications of our results for the current research discussion and an outlook on future work.

2 Related Work

For over a century, text readability has been assessed using surface measure-based readability formula such as the Flesch-Kincaid formula (Kincaid et al., 1975) or the Dale-Chall readability formula (Chall and Dale, 1995), see for an overview DuBay (2004). While these formula are still used in some non-linguistic studies (Woodmansey, 2010; Grootens-Wiegers et al., 2015; Esfahani et al., 2016), a decade ago research shifted towards using more elaborate statistical modeling approaches based on larger sets of linguistically more informed features. Automatic readability assessment has benefited from the use of Natural Language Processing tools for the assessment of syntactic, lexical, and discourse measures and from adapting complexity measures employed in Second Language Acquisition research (Vajjala and Meurers, 2012; Feng et al., 2010). There has also been extensive research on the relevance of cohesion

[1] We are currently negotiating with the broadcasters of *Tagesschau* and *Logo!* and the publishers of *GEO*/*GEOlino* to make the data freely available to other researchers and will make it available from `http://www.icall-research.de` in that case.

[2] The *GEOlino* magazine is advertised as targeting children between 8 and 14 years (cf. `http://www.geo.de/magazine/geolino-magazin`, accessed 11.06.18, 15:49). *Logo!* does not specify the age of its target audience, but has been reported to be particularly popular with children from age 8 to 12 (vom Orde, 2015).

and discourse measures for readability assessment that have successfully been employed for proficiency assessment in the *CohMetrix* project (Crossley et al., 2008; Crossley et al., 2011). Another example is the work by Feng et al. (2010), who evaluate which of the typically proposed measures of text readability are most promising by studying their relevance on primary school students reading material. They find language model features and cohesion in terms of entity density to be particularly useful, as well as measures of nouns. Interestingly, they also observe overall sentence length to be more informative than more elaborate syntactic features. While Feng et al. (2010) do not elaborate further on other lexical measures than POS features, Chen and Meurers (2017) conduct an elaborate cross-corpus study on the use of word frequency features for readability assessment. They show, that the typical aggregation of word frequencies across documents are less informative than richer representations including frequency standard deviations.

In contrast to English, research on readability assessment for other languages, such as German, is more limited. There was a series of articles on this issue from the late 2000s to the early 2010s that demonstrated the benefits of broad linguistic modeling, in particular the use of morphological complexity measures for languages with rich morphological systems like German (Vor der Brück et al., 2008; Hancke et al., 2012), but also Russian (Reynolds, 2016) or French (François and Fairon, 2012). The readability checker *DeLite* of Vor der Brück et al. (2008) is one of the first more sophisticated approaches that went beyond using simple readability formulas for German. The tool employs morphological, lexical, syntactical, semantic, and discourse measures, which they trained on municipal administration texts rated for their readability by humans in an online readability study involving 500 texts and 300 participant, resulting in overall 3,000 ratings. However, due to the specific nature of the data, the robustness of the approach across genres is unclear. Municipal administration language is so particular that results are unlikely to generalize to educational or literary materials, which are more attractive in first and second language acquisition contexts.

Later work by Hancke et al. (2012) also combines traditional readability formula measures, such as text or word length, with more sophisticated lexical, syntactic, and language model, and morphological features to assess German readability, but they employ an overall broader and more diverse feature set than *DeLite*. They investigate readability of educational magazines on the GEO/GEOlino data set, which they compiled from online articles freely available at the GEO magazine's web page. Their work illustrates the relevance of rich linguistic modeling for readability assessment and in particular the value of morphological complexity features for German.

The latest large scale research endeavor for the assessment of German text readability has focused more on identifying linguistic differences between texts targeting different audiences than on building readability models: In the *Reading Demands* project, complexity differences in German secondary school book texts across grade levels and school types were investigated. Berendes et al. (2017) and Bryant et al. (2017) analyze to which extent publishers successfully adapt their reading material to their target audiences. They find a lack of consistent adaptation for passive constructions, concessive and adversative connectives, and relative clauses, and only some limited adaptation in terms of lexical variation, noun complexity, and dependency length measures.

3 Data Sets

3.1 GEO/GEOlino

The GEO/GEOlino data set consists of online articles from one of the leading German monthly educational magazines, *GEO*, and the counterpart for children, *GEOlino*.[3] They are comparable to the *National Geographic* magazine and cover a variety of topics ranging from culture and history to technology and nature. Hancke et al. (2012) first compiled and analyzed a data set from this web resource. We followed their lead and crawled 8,263 articles from the GEO/GEOlino online archive, almost doubling the size of the original corpus. We removed all material flagged as non-article contents by GEO as well as all articles that contained less than 15 words. We further cleaned our data from crawling artifacts and performed near-duplicate detection with the Simhash algorithm. We then grouped all texts into topic categories

[3] `http://www.geo.de` and `http://www.geo.de/geolino`

based on the subdomains they were published under, following the web page topic structure.[4] Table 1 shows the composition of the corpus in terms of the topic groups. Since the number of documents in the different topic groups differ between GEO and the smaller GEOlino set, we created a more balanced subset (GEO/GEOlino$_S$). For this, we included only topic categories existing in both GEO and GEOlino, included all GEOlino texts in those categories and sampled from the GEO texts in those categories until we reached the same overall size of 2480 texts each.

Topic	GEO	GEOlino	$\sum$	GEO$_S$	GEOlino$_S$	$\sum_S$
Do It Yourself	0	663	663	0	0	0
Humanity	1,476	1,168	2,644	1,047	1,168	2,215
Nature	1,704	576	2,280	1,218	576	1,794
Reviews	300	736	1,036	215	736	951
Technology	0	121	121	0	0	0
Travel	1,519	0	1,519	0	0	0
$\sum$	4,999	3,264	8,263	2,480	2,480	4,960

Table 1: Distribution of topics in the full and sampled GEO/GEOlino data set.

3.2 Tagesschau/Logo

The Tagesschau/Logo data set is compiled from subtitles of German daily news broadcasts of *Tagesschau* and its children's counterpart *Logo!*. *Tagesschau* is the dominant national television news service of Germany, produced by the German public-service television network ARD. It broadcasts multiple updated editions of daily news throughout the day. *Logo!* is a television news service for children produced by the German public-service television broadcaster ZDF airing once a day. The data set consists of subtitles for all editions of both news outlets that have been broadcasted from December 2015 to January 2017. For this paper, we limited the *Tagesschau* data to the main edition broadcasted at 8pm. This amounts to overall 421 editions for *Tagesschau* and 415 editions for *Logo!*, with the small difference arising from a lack of Logo! broadcasts on some public holidays or due to special broadcasts. We cleaned the subtitles by removing non-spoken comments (e.g., * *music playing* * or * *cheering* *).

3.3 Characteristics of the two data sets

Table 2 compares the profiles of the GEO/GEOlino$_S$ and the Tagesschau/Logo data sets that we used.

	GEO$_S$	GEOlino$_S$	Tagesschau	Logo
Num. Documents (total)	2,480	2,480	421	415
Num. Words (median)	383	350	1631	1322
Num. Sentences (median)	23	25	167	125

Table 2: Corpus profile for sampled GEO/GEOlino data set and the Tagesschau/Logo data set.

While GEO/GEOlino contains more documents than Tagesschau/Logo, they are considerably shorter in terms of the number of words and sentences they contain. Another difference arises in terms of the medium: GEO/GEOlino articles are self-contained reading material and Tagesschau/Logo subtitles

[4]Subdomains were mapped to topic groups in the following way based on the URL components following `http://www.geo.de` and `http://www.geo.de/geolino`: building ("basteln"), learning ("lernen"), children's recipes ("kinderrezepte"), and competitions ("wettbewerbe") were categorized as DO IT YOURSELF. Jobs ("berufe"), extras ("extras"), photography ("fotografie"), creativity ("kreativ"), info ("info"), love ("liebe"), magazines ("magazine"), human ("mensch"), idioms ("redewendungen"), and knowledge ("wissen") were categorized as HUMANITY. Nature ("natur"), nature and environment ("natur-und-umwelt"), and animal encyclopedia ("tierlexikon") were labeled as NATURE. Book reviews ("buechertipps"), movie reviews ("filmtipps"), game reviews ("spieletest"), and GEO television ("geo-tv") were labeled as REVIEWS. Research and technology ("forschung-und-technik") was labeled as TECHNOLOGY. Travel ("reisen") was labeled as TRAVEL.

complement video material. At the same time, they consist of German educational media language and share the functional goal of conveying information to the reader, so that we consider them to be sufficiently similar to support a cross-corpus analysis.

4 Complexity Analysis

For the assessment of German language complexity, we extract 400 complexity measures using state of the art NLP techniques. All features are theoretically grounded in the contemporary research in linguistic subdisciplines, in particular Second Language Acquisition research, where Complexity is one of three dimensions of language proficiency, together with Accuracy and Fluency (Housen et al., 2012). SLA research has a rich tradition of analyzing the complexity development of learner language, see Lu (2010; 2012) for an overview. Vajjala and Meurers (2012) show that these measures can be successfully applied to readability research. Building on these findings, we follow the SLA definition of complexity as the elaborateness and variability of language (Ellis and Barkhuizen, 2005). Our measures can be grouped into seven categories: i) lexical complexity, ii) clausal complexity, iii) phrasal complexity, iv) morphological complexity, v) discourse complexity, vi) cognitive complexity, and vii) language use. While the former five groups are rooted in the linguistic system, the latter two categories were derived from psycholinguistic research. The resulting complexity assessment covers a broad variety of measures. To the best of our knowledge, this is currently the most extensive feature collection for German complexity assessment.[5] Table 3 gives an overview of the feature categories and how much they contribute to our assessment.[6]

Category	#	Description
Descriptive	2	Total number of sentences and words.
Lexical	73	Lexical diversity measures such as general and POS-specific type-token ratios as well as semantic relatedness measures.
Sentential	119	Ratios measuring sentential elaboration and variation, such as clauses per sentence.
Phrasal	41	Ratios measuring phrasal elaboration and variation, such as modifiers per noun phrase.
Morphological	39	Ratios of inflection, derivation, and composition measures.
Cohesion	48	Subsequent (local) or across text (global) use of implicit or explicit cohesion markers such as connectives, pronouns, or grammatical transitions.
Cognitive	23	Dependency lengths, verb-argument distances, and ratios of cognitive integration costs assessing cognitive processing load based on Gibson's (2000) Dependency Locality Theory.
Language Use	54	Word frequency ratios based on Subtlex-DE (Brysbaert et al., 2011), dlexDB (Heister et al., 2011), Karlsruhe Children's Texts (Lavalley et al., 2015) Approximation of age of active use based on Karlsruhe Children's Texts.

Table 3: Overview over complexity measures grouped by feature categories.

In order to extract these measures, we employ an elaborate analysis pipeline which relies on a number of NLP tools and external linguistic resources. We use OpenNLP 1.6.0 for tokenization and sentence segmentation.[7] This serves as input for the Mate tools 3.6.0 (Bohnet and Nivre, 2012), which perform a morphological analysis, lemmatization, POS tagging, and dependency parsing. We then use the JWord-

[5] Our feature collection draws from varying perspectives on language complexity including SLA and human language processing research. While the confirmation or refutation of specific theories underlying these measures is an interesting research endeavor, our empirical questions focus on which of these features support the distinction of texts targeting different audiences.

[6] We are working on integrating our German complexity analysis pipeline into CTAP (Chen and Meurers, 2016) to make it generally available and will include an online documentation for each feature.

[7] `http://opennlp.apache.org`

Splitter 3.4.0 for compound analysis.[8] The Mate POS tags are further used to inform the Stanford PCFG parser 3.6.0 (Rafferty and Manning, 2008) and the Berkeley parser 1.7.0 (Petrov and Klein, 2007), which we use for constituency and topological field parsing. For all tools, we use the German default models that were provided with them, except for the Berkeley parser, for which we use the topological field model by Ziai and Meurers (2018). With these annotations, we extract all instances of the linguistic constructs that we need to calculate the final 400 complexity ratios.[9]

5 Study 1: Which complexity measures are informative?

5.1 Set-Up

We first want to determine the informativeness of each measure for distinguishing between adult and child target audience. For this, we calculate the information gain of each measure on both data sets using 10-folds cross-validation for training and testing. We then compare across both data sets i) the number of features that are informative, and ii) the 20 most informative measures that show a Pearson correlation smaller than ± 0.8 with each other.[10] This allows us to gain insights into the range of linguistic properties of the documents targeting adults and children. We used WEKA (Hall et al., 2009) to calculate information gain and R for the correlation analysis.

5.2 Results and Discussion

Table 4 shows the percentage of measures that exhibited an average information gain above zero.

Data Set	Percentage	Informative to Total
GEO/GEOlino	79.00%	316/400
Tagesschau/Logo	88.25%	353/400

Table 4: Percentage of informative measures based on 10-folds cross-validated information gain.

Overall, 79.00% of the measures are informative for the GEO/GEOlino data and 88.25% for the Tagesschau/Logo data. This shows, that the documents are adjusted to their different target audiences in terms of a broad range of dimensions of linguistic complexity.

Table 5 provides a deeper look into the linguistic design of the documents by showing the 20 most informative measures distinguishing adult from child targeted documents, including only measures with a correlation less than ± 0.8. The table shows the original rank of each measure before removal of correlated measures, the average merit of each measure for the distinction of the target audience, the type of complexity measures it belongs to, and the feature name.

The results for both data sets show a diverse collection of features, some of which are similar for both data sets, but also some interesting differences. In total the measures seem to be more informative for Tagesschau/Logo, as indicated by the higher average merit, and more correlated, as can be seen from the wider range of original ranks. Language use as captured by frequency measures is particularly relevant for both data sets. The table includes seven measures of word frequency for GEO/GEOlino and five for Tagesschau/Logo. For both data sets, the most informative measure is one of language use: For GEO/GEOlino it is the average minimal age of active use of lexical types found in the Karlsruhe Children's Corpus (KCT) of Lavalley et al. (2015). For Tagesschau/Logo it is the average log lexical type frequency based on Google Books 2000. The other language-use measures are very similar across data sets: Lexical types unknown to the Subtlex-DE data base (Brysbaert et al., 2011), for example, rank 4th and 2nd on both data sets and while on Tagesschau/Logo the lemma frequency per lexical type found in KCT is the 12th most informative measure, its log counterpart ranks 8th on GEO/GEOlino.

[8] `http://www.danielnaber.de/jwordsplitter`

[9] To support transparent comparison with other complexity studies, we include a description of the operationalization of all linguistic units that allow for varying definitions in Appendix A, as has been suggested by Bulté and Housen (2014).

[10] We set the Pearson correlation threshold relatively high since we primarily are interested in qualitatively inspecting the types of measures that are informative, not in removing all correlations.

Table 5: Top 20 most informative measures on balanced GEO/GEOlino and Tagesschau/Logo data based on information gain with $r \leq 0.8$.

Cohesion measures are highly informative, too, although more so for Tagesschau/Logo. In particular the use of certain personal or possessive pronouns is highly informative for GEO/GEOlino. The use of second person pronouns ranks highly for both data sets, which may easily be explained by it being used for the informal German address appropriate when speaking to children. This is further corroborated by the ratio of second person verb inflections being ranked as the 13th most important measure. For Tagesschau/Logo, other implicit measures of textual cohesion based on content overlap are also informative as well as the use of causal connectives. Overall 55% of the most informative 20 measures for both data set are captured by these two categories.

The other feature groups are less frequently represented, but provide some interpretable insights into the data. First, both data sets show indications of differences in the degree of nominalization used in language targeting adults and children: For GEO/GEOlino, complex noun phrases per t-unit and finite clause are highly informative as well as the use of the nominalization suffix *-ion*. On Tagesschau/Logo, genitive case, determiners per noun phrase, and the percentage of compound nouns indicate a similar relevance of differences regarding the organisation of the nominal domain. Lexical and sentential complexity seems to be less homogeneous for the distinction of adult and child targeted language across data sets: There are two measures of lexical complexity assessing word length in syllables and the semantic inter-relatedness of words ranked high for GEO/GEOlino, while on Tagesschau/Logo, lexical diversity and verb variation are particularly informative. For sentential complexity, constituency tree complexity, the average length of the middle field, and the use of prepositional phrases per t-unit are particularly informative on GEO/GEOlino. On Tagesschau/Logo, parse tree height and the use of conjunctional clauses are relevant. Cognitive measures do not seem to play an important role on either data set, except for the sum of longest dependencies per clause on Tagesschau/Logo.

Overall, these results clearly show that for both data sets the distinction between target audiences is not just made based on surface modifications such as sentence or word length. In fact, these measures do not occur among the most informative measures at all. Rather, measures of language use and cohesion are predominantly informative for the distinction of adult and child targeting texts, but also measures of phrasal, sentential, lexical, and morphological complexity. The adjustment of the data to their audience observed here thus seems to be more linguistically refined than that found in the *ReadingDemands* textbook data, where Berendes et al. (2017) found only few adjustment across dimensions.

6 Study 2: Can we successfully model readability for German, also across data sets?

6.1 Set-Up

Our second objective is the design of a robust model of educational media language that distinguishes robustly between language targeting adults and children across corpora and genres. For this, we train two binary Sequential Minimal Optimization (SMO) support vector classifier (Platt, 1998) with linear kernels using the WEKA machine learning toolkit (Hall et al., 2009). Each model is tested i) on the same corpus it is trained on, using 10-folds cross-validation, and afterwards ii) on the other data set for cross-corpus testing after training on the full data set. For model performance evaluation, we report classification accuracy and the classification confusion matrices, and random baselines as reference point.

6.2 Results and Discussion

Table 6 shows the accuracy of our SMO models on both data sets and compares them with a random baseline. Both models clearly outperform the baseline of 50.0%. On GEO/GEOlino$_S$, the performance is comparable to the performance observed by Hancke et al. (2012) on the original GEO/GEOlino data.[11]

As Table 7a shows, erroneous classifications are roughly balanced across both classes, showing that the model does not prefer one class over the other. When training a model using only the 20 most informative measures identified in Study 1, we reach an accuracy of 85.1%, i.e., the additional measures only account only for 3.3%.[12] When testing the models on the Tagesschau/Logo corpus, accuracy increases to 98.8% for both models. The confusion matrix for the model using 400 measures in Table 7b seems to indicate

[11] After observing these results, we obtained the original GEO/GEOlino data set from Hancke et al. (2012) and trained and tested a model with 10-folds cross-validation on it. When using the same data, our model outperforms their best performing

Model	Training	Testing	Features	Accuracy	SD
Baseline		GEO/GEOlino$_S$		50.0

a minor tendency towards classifying *Logo!* texts as Tagesschau texts, but due to the low number of incorrect classifications this is not conclusive.

Overall, performance of both models trained on GEO/GEOlino$_S$ on the Tagesschau/Logo data is comparable to the performance of both models trained and tested on Tagesschau/Logo with 10-folds cross-validation, although the confusion matrix for the cross-validated Tagesschau/Logo model using 400 measures does not exhibit any tendency towards predicting one class preferred over the other, as may be seen in Table 8a.

$\downarrow$Obs./Prd.$\rightarrow$	Child$_{Logo!}$	Adult$_{TS}$
Child$_{Logo!}$	415	0
Adult$_{TS}$	1	420

Child$_{GEOlino}$	2,472	8
Adult$_{GEO}$	2,362	118

(b) Cross-corpus testing on GEO/GEOlino$_S$

Table 8: Confusion matrices for testing models with 400 features trained on Tagesschau/Logo

The model trained and tested on Tagesschau/Logo reaches an unexpectedly high accuracy of 99.9% for using 400 measures and 99.8% when using only the 20 most informative measures reported in Study 1. Since the performance remains high when using only 20 measures and the standard deviation across folds is very low, the results seem not to be due to over-fitting. The model learns linguistic properties of the data set that generalize across. It is important to stress here than none of our measures include n-gram language models or any other lexical content features but only complexity measures aggregated over each document.[13]

model with 91.1%, confirming that our approach is in fact competitive with the state of the art.

[12]We do not show the confusion matrices for the models with 20 features, because they are equivalent to the matrices in Table 7. The same holds for the models tested on Tagesschau/Logo and their matrices in Table 8.

[13]Content features are problematic since they can pick up recurring phrases that are characteristic of particular media outlets rather than generalizable linguistic complexity characteristics. E.g., the *Tagesschau* always starts with the greeting "Hier ist das Erste Deutsche Fernsehen mit der Tagesschau." (*Here is the first public German TV channel with the daily news.*).

When testing the models trained on the Tagesschau/Logo data set on the GEO/GEOlino$_S$ data, it becomes apparent that the characteristics learned from the Tagesschau/Logo data set do not generalize, with the model based on 400 measures performing only marginally above chance, and the model using the 20 measures performing slightly better with 56.2%. When considering the confusion matrix for this model in Table 8b, we see that most texts are classified as GEOlino texts, irrespective of whether they belong to GEO or GEOlino. The Tagesschau/Logo trained models do not generalize well to the other adult/child corpus. Since the model trained on GEO/GEOlino$_S$ is highly successful when tested on Tagesschau/Logo, this cannot be due to an actual lack of generalizable differences in the linguistic characteristics of the adult and child targeting texts contained in both data sets. One possible reason for these results may be that, as Study 1 showed, the measures are considerably more informative on Tagesschau/Logo than on GEO/GEOlino$_S$. It could be, that the differences between the news subtitles designed for different target audiences are more extreme than those observable for the GEO magazines. This would explain the surprisingly good performance of the GEO/GEOlino$_S$ model on the Tagesschau/Logo data, which would then be easier to distinguish, while also accounting for the poor performance in the opposite case.

7 Summary and Outlook

We presented a study of the difference between German targeting adults and children, as far as we know the most broadly based linguistic complexity analysis to date. We created and analyzed a novel data set compiled from German news subtitles that consists of news broadcasts for adults and children from the same days, ensuring a relatively parallel selection of topics. We compared this with a newly compiled GEO/GEOlino corpus consisting of online articles of two magazines for adults and children by the same publisher discussing the similar topics. Based on these two data sets, we presented within-corpus (10-fold CV) and cross-corpus experiments and built binary classification models of German educational media text readability that perform with very high accuracy across both data sets. The model is based on a broad range of features that are highly informative for both data sets. This model is a valuable contribution since i) it is based on a considerably broader data basis than previous approaches to German readability, and ii) it successfully generalizes across the data sets, illustrating surprising robustness across rather different text types. The approach presented thus extends the state-of-the-art in Hancke et al. (2012) in terms of the breadth of features integrated and the accuracy and generalizability of the model – and provides two new data sources for this line of research.

The paper also contributes some new insights into the linguistic characteristics of German media language targeting adults and children. Since all the language is produced by adults, it is not necessarily clear how well it is in fact adjusted to the target audience. As demonstrated by Berendes et al. (2017), German textbook publishers indeed do not seem to be adjusting the complexity of the language used according to school type and grade level in any systematic way. Our results for educational media language indicate, that i) both data sets are successfully and broadly adapted towards their target audiences; and ii) that they form two distinct, cross-corpus generalizable constructs of German educational media language for children and adults. In a next step, we plan to test to which extent this linguistically diverse and generalized construct matches the language competence of the intended children target group by comparing it with the Karlsruhe Children's Text corpus (Lavalley et al., 2015). We also plan to further investigate the linguistic properties of our two data sets. In particular, the Tagesschau/Logo data set requires further statistical and qualitative analyses to investigate why its linguistic characteristics generalize well across all folds of the data set itself but not across GEO/GEOlino. We also plan to conduct more analyses of the informativeness of the different complexity feature groups for the target audience distinction.

Acknowledgements

We would like to thank Peter Lindner of the NDR and the editorial office of *ARD Aktuell* for providing us with the news subtitles of the *Tagesschau* broadcasts and Christiane Müller of the ZDF for giving us access to the subtitles from *Logo!*.

Appendix A. Definitions of Linguistic Units

Clauses are all maximal projections of finite verbs and elliptical constructions with sentential status (i.e. all sub-trees tagged with *S*), as well as *to* infinitives that have a sentential status (*satzwertige zu Infinitive*).

Complex t-units are t-units that include subordinate clauses.

Conjunctional clauses are all dependent clauses that are introduced by a subordinating conjunction such as *dass*, *weil*, or *wenn*.

Dependent clauses with conjunction are all conjunctional clauses, but also interrogative and relative clauses. Dependent clauses without conjunction are mostly dependent main clauses, such as *Ich weiß, es ist spät*.

(Graphematic) sentences are strings of at least one token that are ended by sentence ending punctuation marks: *!*, ., *?*. There is a broad discussion on alternative sentence definitions, see for example Schmidt (2016) for a more elaborate theoretical account. However, since sentences are identified by sentence segmentation tools, which are primarily based on punctuation, sentences are always defined as graphematic sentences.

Half modals are *haben*, *sein*, *scheinen*, *drohen*, *versprechen*, if they govern an infinitive with *zu* (Duden, 2009, §101), e.g. *ist zu machen*, *droht zu schneien*.

Lexical words are all nouns, adjectives, adverbs, foreign words, numbers, main verbs, and modal verbs. Note that there is an ongoing discussion on whether modals actually qualify as lexical words (Reis, 2001), hence there is also a subset of lexical words excluding modals employed throughout the system.

Parts-of-Speech are operationalized following the Tiger POS tags (Albert et al., 2003, 121).

Quasi passives are *bekommen*, *erhalten* or *kriegen* if they govern a past participle (Duden, 2009, §179), e.g. *bekommt gemacht*, *kriegt eröffnet*.

T-units are "one main clause plus any subordinate clause or non clausal structure that is attached to or embedded in it" (Hunt, 1970, 4).

Appendix B. Example Extracts from *Tagesschau* and *Logo!* subtitles

Report on New Years shooting in Istanbul by *Tagesschau*, extracted from the subtitles for the broadcast on 01.01.2017, 20:00.

> In der Türkei ist der Jahreswechsel von einem Anschlag in Istanbul überschattet: Mind. ein bewaffneter Angreifer drang in einen Nachtclub ein und schoss um sich. 39 Menschen wurden getötet und mehr als 60 verletzt. Unter den Todesopfern sind zahlreiche Ausländer. Ob Deutsche betroffen sind, ist unklar. Die Suche nach dem Täter dauert an, bekannt hat sich niemand. Das Attentat ereignete sich im europäischen Teil Istanbuls. Dort liegt direkt am Bosporus der Club "Reina", der bei Prominenten beliebt ist. Nur eine Stunde währte in der Türkei die Hoffnung, 2017 könnte ruhiger werden als 2016, das von Bombenanschlägen geprägt war. Doch um 1.15 Uhr Ortszeit macht im Istanbuler Nachtclub "Reina" ein Attentäter mit einem Gewehr Jagd auf Gäste einer Silvesterparty. Zuvor wurde vorm Club ein Polizist erschossen. Der Täter konnte fliehen, eine Großfahndung läuft. Bis zu 800 Personen sollen sich in der Diskothek aufgehalten haben. Gäste berichten, Panik sei ausgebrochen. Einige Besucher sollen in den Bosporus gesprungen sein. Unter den Toten und Verletzten sind Ausländer. Bekannt hat sich niemand zu der Tat. Türkische Medien vermuten den IS hinter dem Terrorakt. Die Regierung verhängte eine Nachrichtensperre. Wir lassen uns vom Terror nicht beirren. Was hier passierte, kann morgen an einem anderem Ort geschehen. Es gibt keine Garantien. Der Nachtclub "Reina" liegt am Bosporus, im Stadtteil Ortaköy. Er ist der berühmteste der Türkei, teuer und bei Touristen beliebt. Die Sicherheitsvorkehrungen waren landesweit erhöht worden. In Istanbul waren 17.000 Polizisten im Einsatz. Trotz Großaufgebot der Polizei, hochaktiver Geheimdienste, Ausnahmezustand und markiger Politikerworte: Die Sicherheitslage in der Türkei spitzt sich zu. Beängstigende Aussichten für Wirtschaft und Menschen.

Report on New Years shooting in Istanbul by *Logo!*, extracted from the subtitles for the broadcast on 02.01.2017, 19:50 (no broadcast on 01.01.2017).

> In der türkischen Großstadt Istanbul hat es an Silvester einen Anschlag in einer Disco gegeben. Ein Mann stürmte mit einem Gewehr in den Club und hat 39 Menschen getötet, darunter auch zwei Männer, die in Deutschland gelebt haben. Die türkische Polizei sucht jetzt nach dem Täter. Er ist seit dem Anschlag auf der Flucht. Auch am zweiten Tag nach dem Anschlag kamen viele Menschen an die Polizeiabsperrung, um Blumen für die Opfer niederzulegen. Der Terrorist stürmte dort in der Silvesternacht mit einem Gewehr in die Disco. Ich war völlig geschockt, konnte mich nicht bewegen. Der Täter schoss erst auf einen Polizisten und dann auf die Gäste. Wir hörten plötzlich Schüsse, da sind wir raus aus dem Ballsaal auf die Terrasse und haben uns dort versteckt. Im Internet behauptet die Terrorgruppe IS, Islamischer Staat, dass sie hinter dem Anschlag stecke. Die Kämpfer dieser Terrorgruppe wollen, dass alle Menschen nach ihren strengen religiösen Regeln leben. Wer sich nicht daran hält, wird sogar umgebracht. Besonders aktiv ist der IS in Teilen von Syrien und dem Irak. Beide Länder grenzen an die Türkei. Dort haben die Kämpfer in letzter Zeit schon öfter Anschläge verübt. In der ganzen Türkei sucht die Polizei jetzt nach dem Attentäter. Acht Verdächtige wurden schon festgenommen. Auf logo.de könnt ihr mehr zur Terrorgruppe Islamischer Staat lesen und da gibt es auch viele Infos zu unserem nächsten Thema.

Appendix C. Example Articles from GEO and GEOlino

GEO article titled "Was ist ein Planet?" (What is a Planet?).[14] It discusses criteria celestial bodies need to fulfill to be considered a planet.

> Lange bezeichneten Menschen alle Lichtpunkte, die über den Nachthimmel wanderten, als Planeten (griech. planáomai = umherirren) – gleich, ob es sich um Venus, Mars, Mond oder Asteroiden handelte. In der Neuzeit durften den Titel nur noch die großen Himmelskörper tragen, die um die Sonne kreisten, aber keine Monde waren – also nicht ihrerseits einen anderen Planeten umrundeten. Als Astronomen von 1992 an in den Randbezirken des Sonnensystems immer neue Objekte entdeckten, manche ähnlich groß wie Pluto (bis dahin der neunte Planet), sah sich die Internationale Astronomische Union genötigt, erstmals zu definieren, was ein Planet genau ist. Nach heftigen Diskussionen beschlossen die Astronomen 2006 die Resolution B5. Demnach muss ein Planet drei Kriterien erfüllen: Er muss um die Sonne kreisen. Er muss ausreichend Masse aufweisen, sodass er unter seiner eigenen Schwerkraft eine nahezu runde Form angenommen hat. Und er muss die Umgebung seiner Umlaufbahn freigeräumt haben. Objekte, die ihm auf seiner Bahn nahekommen, "schluckt" er in einer Kollision oder schleudert sie in einen anderen Orbit. Pluto, Eris und andere große Himmelskörper zählen nun zu den Zwergplaneten, da sie es nicht schaffen, ihre Bahn zu bereinigen, sondern sie sich mit anderen Objekten teilen. Damit kreisen nach derzeitigem Stand acht Planeten um die Sonne. Die Astronomen unterteilen sie in die vier terrestrischen Planeten Merkur, Venus, Erde, Mars (sie werden wegen ihrer festen Oberfläche häufig steinige Planeten genannt) und in die vier jovianischen – jupiterähnlichen – Planeten Jupiter, Saturn, Uranus, Neptun (aufgrund ihrer Zusammensetzung oft als Gasplaneten oder Gasriesen bezeichnet). Wobei Uranus und Neptun manchmal auch als "Eisriesen" beschrieben werden, da sie weniger Wasserstoff als Jupiter und Saturn enthalten, dafür mehr gefrorenes Methan, Wasser und Ammoniak.

GEOlino article titled "Sieben erdähnliche Planeten entdeckt" (Seven Earth-Like Planets Discovered).[15] It reports on the discovery of seven new planets that orbit Trappist-1.

> Dass neue Planeten entdeckt werden, ist erstmal nichts ungewöhnliches. Doch der Fund dieser sieben sogenannten Exoplaneten (Planeten wie Kepler-452b , die sich um einen Stern - außerhalb des Einflusses unserer Sonne - bewegen) ist etwas ganz Besonderes: Denn sechs der neu entdeckten Planeten liegen in einer Temperaturzone, in der Leben möglich ist. Auf den meisten Planeten ist es entweder kochend heiß oder eiskalt - schwierige Bedingungen für die Entwicklung von Leben. Die Sonne der Exoplaneten, der Zwergstern Trappist-1 , ist viel kleiner als die Sonne unseres Sonnensystems : Trappist-1 besitzt nur acht Prozent der Masse unserer Sonne und zwölf Prozent ihres Durchmessers. Auf drei der entdeckten Exoplaneten könnte sogar Wasser existieren, denn ihr Abstand zur Zwergsonne liegt in einem Temperaturbereich, in dem Wasser weder gefrieren noch verdampfen würde. Hier wäre also eine Art von Leben möglich, wie wir es auf unserer Erde kennen.
>
> Die sieben Planeten haben in etwa die Größe unserer Erde und sind wahrscheinlich Gesteinsplaneten. Sie alle umkreisen ihre Sonne, den Stern Trappist-1, der knappe 40 Lichtjahre (ein Lichtjahr ist die Strecke, die Licht in einem Jahr zurücklegt) von uns entfernt im Sternenbild Wassermann liegt. Weil die Sonne des Trappist-1-Systems so klein ist, können die Planeten diese wesentlich schneller umkreisen als wie es in unserem Sonnensystem möglich ist. Die sechs Planeten, die dem Zwergstern am nächsten sind, umrunden ihn in eineinhalb bis zwölf Tagen. Sie haben damit einen engeren Orbit als der Merkur um die Sonne .

Automatic Assessment of Conceptual Text Complexity Using Knowledge Graphs

Sanja Štajner and **Ioana Hulpuş**
Data and Web Science Group
University of Mannheim, Germany
{sanja,ioana}@informatik.uni-mannheim.de

Abstract

Complexity of texts is usually assessed only at the lexical and syntactic levels. Although it is known that conceptual complexity plays a significant role in text understanding, no attempts have been made at assessing it automatically. We propose to automatically estimate the conceptual complexity of texts by exploiting a number of graph-based measures on a large knowledge base. By using a high-quality language learners corpus for English, we show that graph-based measures of individual text concepts, as well as the way they relate to each other in the knowledge graph, have a high discriminative power when distinguishing between two versions of the same text. Furthermore, when used as features in a binary classification task aiming to choose the simpler of two versions of the same text, our measures achieve high performance even in a default setup.

1 Introduction

A text can be complex on various levels. It can contain many infrequent words that are unknown to the reader (lexical complexity). It can contain long sentences with difficult syntactic structures or syntactic structures unknown to the reader (syntactic complexity), especially in the case of children or non-native language learners. A much less studied level of text complexity is the conceptual or semantic level, which accounts for the amount of background knowledge required to understand the meaning of the text. While many methods have been proposed so far for automatic assessment of lexical and syntactic text complexity (Vajjala and Meurers, 2014; Vajjala and Meurers, 2015; Ambati et al., 2016), automatic assessment of conceptual text complexity has never been attempted so far. Similarly, in the task of automatic text simplification, only two systems attempted at simplifying the overall text structure by eliminating irrelevant pieces of information (Narayan and Gardent, 2014; Štajner and Glavaš, 2017).

Texts that are conceptually complex tend to contain difficult and abstract concepts which are not easy to relate to each other, or they mention numerous entities which are not closely related, requiring substantial background knowledge. Kintsch and van Dijk (1978) distinguish between the micro- and macrostructure of text semantics. The former takes into account the individual concepts and their local relations, while the latter considers their organization at a global level. Conceptual complexity is reflected in both those components and thus conceptual simplification must also be performed on both levels.

Conceptual complexity is especially important for low-knowledge readers, who might have problems accessing their prior knowledge (Denton et al., 2015; McNamara et al., 2012). They benefit particularly from texts that require less inferences, and not so much from simplifications at the linguistic level (Arfé et al., 2017). The amount of inferences that readers need to make in order to fill in the gaps in text coherence, and the effort needed to understand the text is a measure of cognitive or conceptual text complexity (Arfé et al., 2017).

Our work sets up a new task of automatic assessment of conceptual complexity. We define conceptual complexity as the level of background knowledge necessary to understand the text. We pose a number of hypotheses on how structured encyclopedic knowledge bases can be used for this task, and propose a number of graph-based features (Section 4) which capture both micro- and macrostructure of conceptual

Proceedings of the 27th International Conference on Computational Linguistics, pages 318–330
Santa Fe, New Mexico, USA, August 20-26, 2018.

text complexity. Our experiments, carried out over documents from a high-quality language learners corpus for English, show that the graph structure of encyclopedic knowledge can be leveraged in order to accurately assess conceptual complexity of informational text (i.e. news stories). This is particularly important as simplification of such texts improves social inclusion of many target audiences (Carroll et al., 1998; Aluísio and Gasperin, 2010; Saggion et al., 2011; Štajner et al., 2014).

2 Knowledge Graphs for Measuring Conceptual Complexity

Language as a networked system has been vastly researched over the last decades, especially with the purpose of capturing word semantics (Borge-Holthoefer and Arenas, 2010). One of the core concepts that have been proposed is that of *semantic networks*. Various types of semantic networks have been studied, with the aim of explaining the organization of human semantic knowledge: hierarchical networks (Collins and Quillian, 1969), associative networks (Nelson et al., 2004), thesauri such as Roget's thesaurus (Jarmasz and Szpakowicz, 2012), terminological ontologies such as WordNet (Miller, 1995), as well as word networks resulted from corpus analysis, e.g. co-occurrence networks (Stubbs, 1996).

Most of these networks were shown to have very similar large-scale structures, and furthermore, also similar to the structure of the World-Wide-Web (Steyvers and Tenenbaum, 2005). Especially in the case of associative networks which are built based on human memory tasks, and corpus based networks that are based on language use, their similarity to the structure of online information networks is very promising as it enables the analysis of information networks as a proxy for human memory.

In this direction, Griffiths *et al*. (2007) hypothesize that if the knowledge in human memory is organized similarly to the knowledge on the World-Wide-Web, then the retrieval processes solve the same problem: identifying items that are relevant to a query from a large network of interconnected pieces of information. They show that PageRank (Brin and Page, 1998), the web page ranking measure, when applied to words in semantic networks, is correlated with prominence of concepts in human memory (Griffiths et al., 2007). This provides us with the intuition that texts that refer to concepts that have high PageRank in semantic networks are easier to understand on a conceptual level.

Grounding our work on those previous findings, we go even further and hypothesize that the background knowledge required during text reading, and which impacts the conceptual complexity of the text, can be estimated by analyzing such networked knowledge resources. However, news articles are well known for their abundance in named entities, therefore semantic networks based on lexical resources cannot cover much of the required background knowledge for news understanding. We address this by focusing on a particular type of semantic networks, specifically *knowledge graphs*. Like all semantic networks, knowledge graphs represent human knowledge by means of a network. But while traditional semantic networks represent knowledge starting from use of language, having nodes as words and relations as untyped word associations, knowledge graphs capture real world concepts and entities, related by facts. We therefore propose a series of measures that leverage the background knowledge graph in order to assess conceptual text complexity.

We focus on a particular knowledge graph that is freely available, DBpedia[1], a network representation of Wikipedia. Its purpose is to provide Wikipedia knowledge in a structured, automatically queryable format. At its core lies the DBpedia Ontology (Bizer et al., 2009), which contains more than 4 million entities, structured based on a hierarchy of 685 classes and 2795 properties. The DBpedia entities correspond to Wikipedia articles. The entities are connected by relations extracted from the Wikipedia article Infobox sections, resulting in a networked structure.

An important characteristic of DBpedia that renders it particularly suitable for conceptual text complexity of informational text such as news, is the fact that, having been created out of Wikipedia's human created Infoboxes, it covers a very broad range of topics. Moreover, being backed by a very active community of Wikipedia editors, Wikipedia's set of article entries is very up-to-date, which is another advantage it has over alternative knowledge bases when dealing with news articles. This makes DBpedia very promising for the task of assessing the amount of required background knowledge for informational text understanding.

[1] www.dbpedia.org

Knowledge graphs such as DBpedia have been widely and successfully used in a series of language understanding tasks such as computing semantic relatedness / similarity between words (Milne and Witten, 2008; Zhu and Iglesias, 2017), word-sense disambiguation and entity linking (Usbeck et al., 2014; Hulpuş et al., 2015), topic/cluster labeling (Hulpuş et al., 2013), document similarity (Schuhmacher and Ponzetto, 2014), etc.

In this paper, we propose to use knowledge graphs for automatically assessing conceptual complexity of text. We argue that the amount of required background knowledge can be estimated by analyzing the parts of knowledge graph that are activated by the text.

3 Easy-to-read Texts

Many initiatives have proposed guidelines for producing plain, easy to read text, which would be more accessible to wider audiences. The "Federal Plain Language Guidelines"[2] instruct how to write governmental documents for the general public. "Make it Simple" guidelines (Freyhoff et al., 1998) assist writers in producing texts for people with intellectual disabilities and other people who cannot read complex texts. These guidelines were proven to improve efficiency (search and reading time) and effectiveness (comprehension scores) in both intellectually disabled people, and the control group (Karreman et al., 2007). Some of the main advises, that appear in all guidelines are: (1) omit unnecessary words; (2) cover only one main idea per sentence; (3) avoid abstract concepts; (4) and avoid definitions as much as possible by removing or replacing a complicated concept, unless the concept is crucial for document understanding.

Ideas from such guidelines are also incorporated in instructions for manual simplification of already existing texts for autistic readers (Orasan et al., 2013), people with Down syndrome (Saggion et al., 2011), or language learners (Newsela, 2016). Several examples of such simplifications found in Newsela's articles are presented in Table 1.

We notice that the above mentioned text requirements resonate with structural properties of knowledge graphs-based representations of text. This motivates the graph-based measures proposed in the next section for assessing text conceptual complexity.

4 Graph-Based Features for Capturing Conceptual Complexity

In our aim for devising features for measuring conceptual complexity, an important objective is to make them independent of syntactical and lexical complexity measures. For instance, one indicator of syntactical complexity is the length of sentences. The length of a sentence influences the number of concepts in the sentence. Therefore, we suggest only measures that are not influenced by the number of concepts in the sentence.

With respect to lexical complexity, the use of an entity linker (see Section 5.2), ensures that purely lexical transformations, that for instance replace a less common word with a more common synonym (e.g. *murder* $\rightarrow$ *killing*, in example #4 in Table 1) are not captured by our measures (as they link to the same entity[3]). In contrast, the conceptual simplification in which a concept is replaced with a more common and more general concept (e.g. *domestic abuse* $\rightarrow$ *beating*, in example #4 in Table 1) is captured by our features, as those two words link to different concepts in DBpedia.[4]

We explore three types of graph-based measures, each focusing on capturing different particularities of conceptual complexity.

4.1 Single Node Measures

The first type of graph measures that we analyze refers to single concepts.[5] These measures target three types of transformations that occur during simplification: (i) removal of non-essential concepts that demand more background knowledge (example #1 in Table 1), (ii) replacement of non-essential

Table 1: Examples of original and simplified text snippets (Newsela, 2016)

demanding concepts with more commonly known ones (examples $\#2$, $\#3$ and $\#4$ in Table 1), and (iii) avoidance of abstract concepts (example $\#8$).

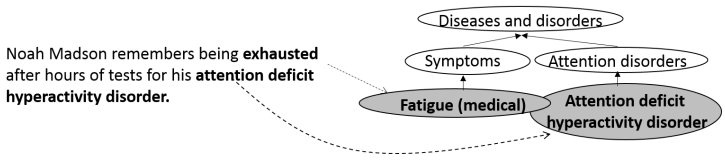
We claim that these edits lead to nodes with different graph properties being favored in simplified texts. There are multiple node properties that come to mind, but we chose to focus on a few most commonly used ones in the network analysis literature.

Node degree is one of the most straightforward measures that describe the popularity of a concept in a network. In knowledge graphs, this translates to the number of concepts that have a direct relation to the concept in question. When referring to the node degree, we consider both incoming and outgoing edges. Under the assumption that the concepts with high degree are more commonly known, our hypothesis is that *when texts are simplified, the high degree nodes are kept, while the lower degree nodes might be omitted, resulting in a higher average node degree in simplified texts (H1).*

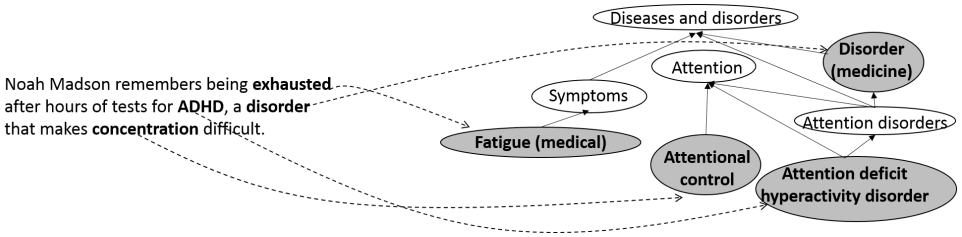
Node clustering coefficient computes how many of the node's neighbors are directly connected among themselves. Therefore, if D is the number of neighbors of a node (equal to its degree), then the clustering coefficient is computed as $\frac{2\times\#related\_neighbors}{D(D-1)}$ The nodes with a low clustering coefficient can be assumed to be more general, since their neighbors tend to be unrelated. Our hypothesis is that *simpler texts tend to favor nodes with low clustering coefficient (H2).*

Node PageRank makes use of a couple of key ideas: (i) a recursive definition of importance such that nodes are important if they are connected to the important nodes; (ii) the importance that a node transmits to a neighbor is diluted by the total number of neighbors that the node has; (iii) a probability governs the decision of transmitting information to a neighbor or randomly to any node in the network. Since PageRank is a measure of node importance in a network, our hypothesis is that concepts with high PageRank in the knowledge graph are prominent in human collective knowledge. We therefore hypothesize that *the conceptually more complex texts will contain more concepts with lower PageRank as compared to the conceptually simpler texts which would, in turn, favor high PageRank concepts (H3).*

We extract the above described measures for all the entities in the text, and use their arithmetic means as conceptual complexity features of the documents. As such, these features should contribute to capturing the semantic *macrostructure* of the text, as defined by Kintsch and van Dijk (1978).



(a) Example sentence before simplification



(b) Example sentence after simplification

Figure 1: Example of simplification through explicitly defining complex but crucial concepts. The simplification leads to a reduced average pairwise shortest path length between the text concepts. The graphs shown in this illustration are drastically reduced, as the complete graphs would be much too complex for visual analysis.

4.2 Pairwise Measures

Besides the properties of the individual entities found in texts, we find it of interest to understand how the entities found within the same sentence or paragraph relate to each other, therefore capturing the *microstructure* of conceptual complexity. We expect that in simpler texts, as a result of the simplification process, the concepts that occur in the same sentence/paragraph are more semantically related.

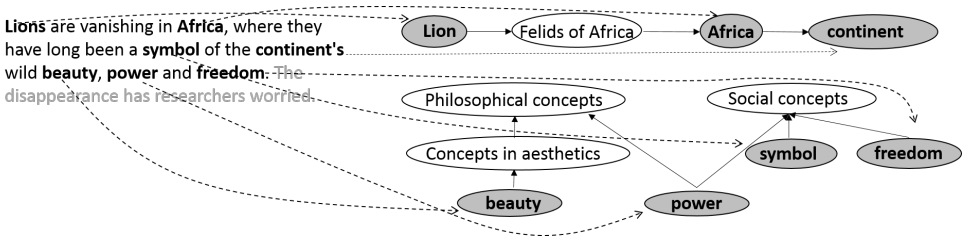
One transformation that is targeted by these measures is that of adding definitions to difficult but essential concepts (examples $\#5$ and $\#6$ in Table 1). The intuition is that when definitions are provided, these explanations usually contain terms that are strongly related to the term they define, increasing the overall relatedness of the simplified text segment.

Another transformation targeted by the pairwise similarity measures is the sentence splitting, that follows the "one main idea per sentence" principle (see Section 3). Each newly formed sentence has a reduced scope, referring to closely related concepts. This is illustrated in the example $\#7$ in Table 1. The original sentence was split so that the smoke topic is mentioned in its own sentence. As a result, the newly formed sentence maintains the particularly high relatedness between its concepts *smoke* and *exhaust*, while separating these concepts from the ones they are not related to such as *driver, cook, hair net, gloves, burger*.

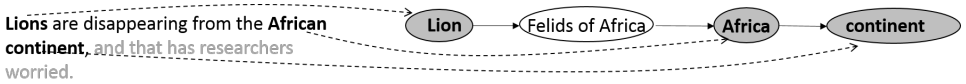
To study those phenomena, we extract the following two measures.

Length of the shortest path is a straightforward measure that we expect to be negatively correlated to two entities' semantic relatedness. When we refer to the paths in the knowledge graph, we consider them undirected. Given a text segment, we compute the length of the shortest path in the knowledge graph between all pairs of entities found in it, and hypothesize that *in a simpler text, the average shortest path lengths between concepts occurring in the same sentence or paragraph tend to be shorter than in conceptually more complex texts (H4).* Figures 1a and 1b visualize the paths between the main concepts extracted from example $\#6$. As shown, by adding a short definition, the average length of shortest path between seed nodes (concepts referred to by the text) becomes shorter: from 4.00 in Figure 1a, to 3.16 in Figure 1b.

Exclusivity-based semantic relatedness is a state-of-the-art relatedness measure (Hulpuş et al., 2015; Zhu and Iglesias, 2017), that considers more paths that connect two concepts rather than just the shortest one. It is based on two key ideas: (i) the direct relations between two nodes are not equally important; their importance is instead governed by an *exclusivity* measure that gives a higher weight to relations whose relation type is less common among the relations of the two target nodes; (ii) the semantic relat-



(a) An original sentence (Newsela, 2016) producing a graph with two disconnected components.



(b) A simplified sentence (Newsela, 2016) with an entire graph connected component removed.

Figure 2: Example of simplification that leads to removal of a connected component from the text segment graph. The graphs shown in this illustration are drastically reduced, as the complete graphs would be much too complex for visual analysis.

edness between two nodes is revealed by more paths between them, not just the shortest path, but the weights of paths are governed by a *length decay* parameter. Using this semantic relatedness measure, our hypothesis is that *the pairwise semantic relatedness between concepts that occur in the same sentence or paragraph tends to be higher in simpler texts (H5).*

4.3 Global Properties of the Graph

The last type of properties of the text segments that we compute over the knowledge graph, refers to the global properties of the graph which is formed by extracting all the paths, up to a certain length, that connect all the entities of the text segment. The resulting graph is called *text segment graph*. The intuition is that the way all the entities of the text segment are connected, including the connecting entities and relation paths, can provide insights into how complex the text is. These features aim to capture the *microstructure* of the conceptual complexity of text, as they analyze the graph produced by concepts that occur in the same sentence/paragraph.

They target similar transformations as the pairwise measures, as well as the removal of abstract concepts and text segments that are not essential for following the main story thread (examples #8, #9, and #10). The graphs that the removed concepts produce are usually disconnected from, or very weakly connected to, the concepts of the main story. Their removal thus results in a more tightly connected graph corresponding to the simplified text. This phenomenon is illustrated in Figures 2a and 2b, using the example #8 in Table 1. We assess the connectivity of the graph by extracting three features.

Number of connected components is the number of groups of interconnected nodes, such that paths exist between all pairs of nodes within the groups, but no paths exists between the nodes in different groups. Multiple connected components usually appear when the text segment deals with very distinct topics resulting in a higher cognitive load on the readers, since they must keep in memory all these disconnected topics simultaneously. For example, the original text in Figure 2a contains two components, and the simplification completely removes one component as seen in Figure 2b. This leads to our hypothesis that *texts whose sentences or paragraphs produce graphs that contain more connected components, are conceptually more complex (H6).*

Average local clustering coefficient computes the mean clustering coefficient of all the nodes in a graph. We compute this measure on the text segment graph. The intuition is similar to that behind the node's clustering coefficient. If the nodes of the text segment graph have high clustering coefficients, they might be quite specific, and hence uncommon. We hypothesize thus that *text segment graphs with low average clustering coefficient tend to be the result of conceptually simpler texts (H7).*

Density of a graph measures how many edges exist between the nodes, out of the total number of possible edges given the number of nodes. Since in knowledge graphs multiple relations can exist be-

tween the same two concepts, when we compute this measure, we do not count the number of effective relations, but the number of related pairs of concepts. The intuition behind using this measure is quite straightforward, since a denser text segment graph can be interpreted as a text in which all concepts are highly related, and accessible from multiple directions. Our hypothesis is therefore that *the denser the graph of a text segment, the simpler the text (H8).*

5 Experimental Setup

5.1 Data

For our experiments, we use the freely available English portion of Newsela language learners corpus (Newsela, 2016). Unlike the original Wikipedia and Simple English Wikipedia corpus (Coster and Kauchak, 2011), where the simplified version is not the result of a direct simplification of the original article, the simplified Newsela articles are direct simplifications of the original articles, manually simplified by trained human editors following strict simplification guidelines (Xu et al., 2016). This ensured the quality of simplifications in the Newsela dataset. More importantly, as the target readers are children and second language learners, and each text is provided in five different difficulty levels, conceptual simplification is expected to be an important component in the Newsela dataset. Additionally, the Newsela dataset allows us to control for the topic in our experiments, which is particularly important in order to isolate the effect of simplification from the influence of the story topics. Different topics naturally lead to different parts of the knowledge graph being activated, thus affecting graph properties and diluting the actual effect of conceptual simplification that we are trying to capture.

5.2 Implementation Details

Entity Linking. The first prerequisite for analyzing the knowledge graph behind text concepts is that the words in the text are linked to the concepts in the knowledge graph. Multiple systems capable of linking words to knowledge graphs, particularly DBpedia, have been researched and are freely available. In this work, we have chosen to use Kan-Dis (Hulpuş et al., 2015) because it links both common nouns and named entities. However, the ideas and measures that make the contribution of this paper do not depend on the linking process, so any linker can be used instead.

Outlier removal. Entity linking must often disambiguate the words, a process that can lead to errors in linking. Mistakes from the entity linking system are capable of affecting our measures, since properties of wrong concepts are then analyzed. To minimize the effects of linking mistakes, we remove from the linked entities those concepts that have a very weak relatedness to the other concepts, under the assumption that this will target particularly wrongly linked concepts. The threshold value chosen for deciding outliers was set empirically to 10^{-6}, computed with exclusivity based relatedness. This outlier removal strategy also makes the analysis less influenced by extreme cases, even if they are correct.

Text Segment Graph Extraction. For the extraction of the text segment graph, we focus on the paths that connect the linked concepts. For all pairs of linked concepts (by the entity linker), we extract all the paths that connect them in the knowledge graph, of length at most four. Most previous work that employs knowledge graphs have converged to the conclusion that a path length of at most four between concepts is sufficient for extracting valuable information about the concepts (Zhu and Iglesias, 2017). Additionally, for all the extracted nodes, we also include in the graph all the direct relations that exist between them.

6 Results

To test our hypotheses (H1–H8), we extract all proposed features on 200 original English Newsela articles and their four manually simplified versions, and examine:

- Whether the values of our 13 graph-based features differ significantly between each two versions of the same text, each corresponding to a different Newsela complexity level (Section 6.1);

- Whether our features can be used for automatically choosing the conceptually simpler of the two given versions of the same text (Section 6.2).

(m) Graph Density of Paragraphs

Table 2: The average change in the feature value (represented as a percentage of the initial value) for each pair of Newsela complexity levels (the original stories belong to the level 0, while the simplest versions belong to the level 4). The cases in which the mean value of the feature was significantly (at a 0.01 level of significance) different (Wilcoxon's signed rank test for paired samples in SPSS) in the two corresponding levels are presented in bold.

6.1 Pairwise Comparison of Texts on Different Complexity Levels

The goal of this analysis is to explore the discriminative power of our features to distinguish across different versions of the same text. For each two versions of the same story, we compute the average change in feature value (as a percentage of the feature value in initial/more complex text). The results are presented in Table 2, where each cell (m, n) corresponds to the change in feature value when simplifying from the complexity level m to the complexity level n. Those cases in which the mean value of the feature is significantly different (at a 0.01 level of significance, measured by Wilcoxon's test for repeated measures) in the corresponding two levels are presented in bold.

Overall results. We note that overall, the pairwise graph-based measures ((d), (e), (g), and (h)) are the most sensitive ones to the complexity level difference, while the single node measures ((a), (b), and (c)) have the lowest discriminative power across all level pairs. This indicates that the conceptual complexity

of the Newsela texts, when computed over DBpedia graph, resides especially in the way the concepts relate to one another (microstructure), rather than in the particular properties of the concepts taken one by one (macrostructure). As expected, the differences are significant especially between the far away levels such as 0-3, 0-4, 1-3 and 1-4, while many measures have a problem to discriminate between the nearby levels, particularly the levels 3-4.[6]

Single node measures. Among the single node measures, the hypothesis H1 and H3 have been proven correct for the distant level pairs, showing the biggest discriminative power for the seed degree (H1) followed by the PageRank (H3). Nevertheless, none of the measures can capture the subtle differences between the nearby levels. This is to be expected since during the simplification of texts the omission or replacement of concepts are measures to be taken very cautiously as the original meaning of the texts should not be noticeably altered. A too abrupt change in this set of measures would rather be indicative of flawed simplification. Regarding the clustering coefficient of the seeds (H2), no trend can be established.

Pairwise graph-based measures. The pairwise graph-based measures perform similarly on both sentences and paragraphs, and are good at distinguishing between any two text complexity levels. Both hypotheses H4 and H5 have been proven to hold.

Global graph-based measures. Regarding the global graph-based measures, we notice that in general, all three measures perform better when computed over sentences than over paragraphs. Computed over sentences, these measures are able to discriminate between the nearby levels, while computed over paragraphs, this does not always hold. This might be due to the fact that, in general, the grouping of the concepts over sentences changes during simplification, but their grouping over paragraphs does not. The global graph-based measure that shows the best discriminative power between each two text complexity levels is the number of connected components of the sentence graph, followed closely by the average local clustering coefficient of the sentence graph. Our hypotheses related to global-graph based measures (H6, H7, and H8) have been proven to hold, except H7 (concerned with the average clustering coefficient) over paragraphs, which only holds for the faraway complexity levels.

This analysis has allowed us to draw conclusions as to how sensitive the proposed measures are to the complexity level of texts. Given the very promising results, in the next section we analyze how these measures perform in a pairwise text classification task.

6.2 Classification Experiments

We perform the pairwise comparison of each two documents corresponding to the same story to assign the label "simpler" if the first document is simpler than the second, and "more complex" if otherwise.

Features. For this binary classification task, each instance has 26 features, obtained by concatenating 13 features of the second text to the 13 features of the first text. Additionally, for each document, we compute a baseline feature as the ratio of unique entities over mentions. On purpose, we avoid using any features which are influenced by the length of the text segment (sentence, paragraph, or entire text). We do so as we are only interested in discriminating texts according to their conceptual complexity, and features that reflect syntactic complexity (i.e. any features that include text segment length) could blur the results.

Dataset. We construct the dataset by pairing texts with the same title and different Newsela complexity level. As we have 200 titles in our collection, that results in a total of 2000 instances (ten for each title, i.e. levels 0-1, 0-2, 0-3, 0-4, 1-2, 1-3, 1-4, 2-3, 2-4, 3-4). To have balanced classes, we randomize the order of the two texts in each pair. This resulted in having 1025 instances in which the first text is simpler than the second, and 975 instances in which the first text is more complex than the second (according to their Newsela complexity levels).

[6]The original stories belong to the level 0, while the simplest versions belong to the level 4.

Algorithm	Feature type (our graph-based features)								Baseline feature (#Entities/#Mentions)	
	All		Single		Pairwise		Global			
	F	Acc.	F	Acc.	F	Acc.	F	Acc.	F	Acc.
NaïveBayes	0.80	80.42	0.57	58.38	0.75	75.67	0.72	72.14	0.61	62.11
Logistic	0.84	84.13	0.56	56.49	0.77	77.43	0.77	77.15	0.60	60.00
SVM-n	0.84	83.73	0.46	53.74	0.77	76.82	0.77	77.40	0.61	61.43
SVM-s	0.84	84.27	0.52	55.19	0.77	77.25	0.77	77.23	0.60	60.53
JRip	0.77	77.44	0.57	57.70	0.76	75.60	0.72	72.09	0.58	58.50
J48 (C4.5)	0.77	77.20	0.51	55.90	0.75	75.52	0.73	73.47	0.57	60.45
RandomForest	**0.85**	**85.00**	**0.70**	**69.85**	**0.81**	**81.11**	**0.79**	**78.95**	**0.64**	**64.36**
Majority class	0.34	50.96	0.34	50.96	0.34	50.96	0.34	50.96	0.34	50.96

Table 3: The weighted F-measure (F) and accuracy (Acc.) for the binary classification task (10-fold cross-validation with 10 repetitions). The best results for each set of features are presented in bold. All classifiers significantly (paired t-test) outperform the majority class baseline.

Algorithms. Our goal is to demonstrate that our feature set has good predictive power in such tasks, and not to build the highest performing classification system. Therefore, we experiment with a range of classification algorithms, and use them in their default parameter setup (without any tuning). We use a ten-fold cross-validation setup with ten repetitions in Weka Experimenter (Hall et al., 2009) to train and test seven classification algorithms: Naïve Bayes (John and Langley, 1995), Logistic (le Cessie and van Houwelingen, 1992), Support Vector Machines (Keerthi et al., 2001) with normalisation (SVM-n) or standardisation (SVM-s), JRip rule learner (Cohen, 1995), J48 - a Weka implementation of the C4.5 decision tree (Quinlan, 1993), and Random Forest (Breiman, 2001).

Results. The results of this set of experiments are presented in Table 3. As can be seen, even without any parameter tuning or feature selection, our set of 13 graph-based conceptual complexity features lead to high performances, both in terms of the weighted F-measure and the accuracy, always significantly (paired t-test at a 0.01 level of significance) outperforming the baseline feature. We also observe that the single node features (Single) perform significantly (paired t-test at 0.01 level of significance) worse than the full set of features, or even any of the other two subsets of features (Pairwise and Global).

7 Conclusion

Text complexity plays an important role in text accessibility. Apart from the usually addressed lexical and syntactic complexity, recent studies emphasize the importance of conceptual complexity, both on micro- and macrostructural levels. Building up on those findings, we set up a new task of automatic assessment of conceptual complexity.

We proposed to measure conceptual complexity by leveraging the structure of knowledge graphs such as DBpedia. We found that properties of individual concepts, as well as the way concepts relate to each other in the graph, successfully capture the conceptual complexity of text. Furthermore, our experiments show that our graph-based measures perform well when used as features in a binary classification task for automatically choosing the simpler of two versions of the same text.

Our research sets a new field and benchmarks the task of automatic assessment of conceptual text complexity. It also shows that knowledge graphs can successfully be used for this task, thus combining recent advances across multiple research areas.

In our future work, we plan to analyze the impact of the entity linking step over the proposed measures, as well as to extend our analysis to other knowledge graphs such as ConceptNet[7] and WikiData[8]. We also plan to explore additional measures for computing conceptual complexity, as well as measures for scoring the relevance of background knowledge facts with respect to making a given text more or less complex. This would naturally lead to methods for extraction of knowledge base facts that would help users understand complex texts.

Par4Sim – Adaptive Paraphrasing for Text Simplification

Seid Muhie Yimam **Chris Biemann**
Language Technology Group
Department of Informatics, MIN Faculty
Universität Hamburg, Germany
{yimam,biemann}@informatik.uni-hamburg.de

Abstract

Learning from a real-world data stream and continuously updating the model without explicit supervision is a new challenge for NLP applications with machine learning components. In this work, we have developed an adaptive learning system for text simplification, which improves the underlying learning-to-rank model from usage data, i.e. how users have employed the system for the task of simplification. Our experimental result shows that, over a period of time, the performance of the embedded paraphrase ranking model increases steadily improving from a score of 62.88% up to 75.70% based on the NDCG@10 evaluation metrics. To our knowledge, this is the first study where an NLP component is adaptively improved through usage.

Title and Abstract in Amharic

1 Introduction

Traditionally, training data for machine learning-based applications are collected amass, using a specific annotation tool. There are a number of issues regarding this approach of data collection. Most importantly, if the behavior of the target application changes over time, this makes the training data outdated and obsolete, an issue known as *concept drift* (Žliobaitė et al., 2016).

In this regard, we opt to design an approach where data can be collected interactively, iteratively and continuously using an adaptive learning model in a live and a real-world application. By adaptive, we mean that the learning model gets signal from the usage data over a period of time and it automatically

Proceedings of the 27th International Conference on Computational Linguistics, pages 331–342
Santa Fe, New Mexico, USA, August 20-26, 2018.

adapts to the need of the application. An adaptive learning model has a spectrum of advantages. First of all, the model gets updated continuously. The model also provides suggestions through usage and the user can correct the suggestions, which in turn improves the model's performance. On top of this, there is no need to collect a large set of training examples a priori, which might be difficult and expensive. We also believe that instead of collecting training data in advance, it is a more natural way to get the training examples from usage data by embedding the adaptive model in the application.

In this premise, we choose the advanced NLP task of text simplification in order to experiment with an adaptive learning approach. Text simplification aims at reducing the complexity (syntactic and lexical) of a text for a given target reader. According to the survey by Shardlow (2014), different approaches such as lexical simplification, explanation generation, and machine translation are used for text simplification. As far as our knowledge is concerned, there is no work regarding the use of an adaptive model, more specifically *adaptive paraphrasing based on usage data* for the task of text simplification.

The main technical challenge is the integration of an adaptive paraphrasing model into a text simplification writing aid tool in order to be able to attain whether it is possible to gain NLP component quality through adaptive learning on usage data. The writing aid tool for text simplification using an adaptive paraphrasing model (Par4Sim) consists of several components. The first component in the pipeline determines the complex or difficult words or phrases (CPs), which is based on the work of Yimam et al. (2017). Once the CPs are identified, the second component produces candidate suggestions from different paraphrase resources. Candidates that do not fit the context in the sentence are filtered or excluded based on a language model score. Finally, an adaptive ranking model reorders candidates based on their simplicity and provides the ranked candidates to the user within an interactive writing aid tool.

This work is aiming to answer the following three research questions:
RQ1: How can an adaptive paraphrase ranking model be integrated into a text simplification writing aid tool?
RQ2: How can an adaptive paraphrase ranking model be evaluated?
RQ3: Can we demonstrate the adaptivity of the approach?

This paper is organized as follows. In Section 2 we briefly review state-of-the-art works in adaptive learning and text simplification. Section 3 outlines the design procedures we have followed in the development of the Par4Sim tool for the integration of adaptive paraphrasing in a text simplification application in detail. In Section 4, a brief description of the data collection and statistics of the collected data is presented. Section 5 describes the learning-to-rank machine learning algorithm employed to build an adaptive ranking model, including the definition of employed feature representation and the evaluation metrics. The experimental results obtained and the contributions of our research work are presented in Section 6 and Section 7. Finally, Section 8 presents the conclusions of our work and indicates future directions on the integration of adaptive approaches for NLP applications.

2 Related Work

Supervised machine learning approaches commonly rely on the existence of a fixed training set, which is collected in advance.

The survey by Parisi et al. (2018) indicates that *continual lifelong learning*, the ability to learn continuously by acquiring new knowledge is one of the challenges of modern computational models. The survey further explains that one of the main problems of continual learning is that training model with new information interferes with previously learned knowledge. The work of To et al. (2009) indicates that the integration of user feedback in an adaptive machine learning approach helps to improve the system's performance. It further shows that the approach helps to reduce the manual annotation efforts. Žliobaitė et al. (2016) revealed that supervised machine learning approaches stationed with static datasets face problems during deployment in a real-world application due to concept drift (Tsymbal, 2004) as applications start generating data streams continually. Applications with such properties include spam filtering and intrusion detection.

Stream-based learning and online learning (Bottou, 1998) are alternative setups to a batch-mode adap-

tive learning system. For example, the work by Levenberg et al. (2010) shows that the deployment of stream-based learning for statistical machine translation improves the performance of their system when new sentence pairs are incorporated from a stream. The work by Wang et al. (2015) presents SOLAR, a framework of scalable online learning algorithms for ranking, to tackle the poor scalability problem of batch and offline learning models. The work by Yimam et al. (2016a) uses MIRA (Margin Infused Relaxed Algorithm) (Crammer and Singer, 2003), a perceptron-based online learning algorithm to generate suggestions in an iterative and interactive annotation setup for a biomedical entity annotation task.

Most text simplification approaches employ basic machine translation models from parallel corpora (Xu et al., 2016; Štajner et al., 2017) and using simple Wikipedia for English (Coster and Kauchak, 2011). Simple PPDB (Pavlick and Callison-Burch, 2016) is such a resource that is built automatically, using machine translation techniques on a large number of parallel corpora.

The work by Lasecki et al. (2015) shows that using crowdsourcing for text simplification is a valid approach. We also conducted our adaptive text simplification experiment on the Amazon Mechanical Turk crowdsourcing platform using a specialized text simplification tool.

3 Design of the Par4Sim System

Par4Sim is a text simplification tool based on an adaptive paraphrasing paradigm. Unlike the traditional text simplification approaches, Par4Sim mimics a normal text editor (writing aid tool). The tool embeds basic text simplification functionalities such as providing suggestions for complex phrases, allowing editing of the texts in place and so on. Our setup is that authors wishing to simplify text can use the tool, without a priori machine learning model, but the system learns from the user interactions in an iterative and interactive manner. In order to run a distributed and web-scale simplification experiment, we have integrated the tool into an existing crowdsourcing platform.

Hence, our targeted users for the Par4Sim experiments are workers from the Amazon Mechanical Turk (MTurk) crowdsourcing platform. As a large number of workers are available in the MTurk platform, we paid special attention in the development of the tool regarding response time, accessibility, and reliability. The tool comprises a front-end component to edit texts and a back-end component, which exposes most of the requests using REST API services. Figure 1 shows the main components of the tool. The detailed instructions for the MTurk task are displayed in Figure 2.

While it is impossible to host complex systems inside the MTurk infrastructure, MTurk supports external human intelligence tasks (HITs) where workers can easily access our system through the MTurk interface. Par4Sim's user interface is embedded into the MTurk web page, but every activity is handled by our own server. This design gives us full control on the collection of the dataset, for training new ranker models, and for updating the model iteratively and seamlessly while we still use the MTurk infrastructure to recruit workers and pay rewards for a web-scale experiment.

As it can be seen in Figure 1, complex words or phrases (CPs) are automatically highlighted (yellow background color and underlined in cyan color). The highlighting of the CPs is based on the work of Yimam et al. (2017). Furthermore, the users can highlight their own CPs and our system will provide ranked candidates. Details about the generation of candidates and the ranking model are provided in Section 4. Besides the highlighting of CPs and providing ranked candidates, the system further provides the following functionalities.

- **Reload text**: If the worker wants to get the original text with the CPs re-highlighted, she can reload the content using the *Reload* button, subject to confirmation.
- **Undo and redo**: At any particular time, workers can undo or redo the changes they have made using the *Undo* and *Redo* buttons.
- **Highlight difficult words**: It is also possible to request our system to automatically highlight difficult words. This functionality is particularly important if the worker has changed the original text but she is not sure if the amended text is in fact simpler. Once the system highlights some words or phrases, she can still check if the suggestions provided by the system could still simplify the text further.

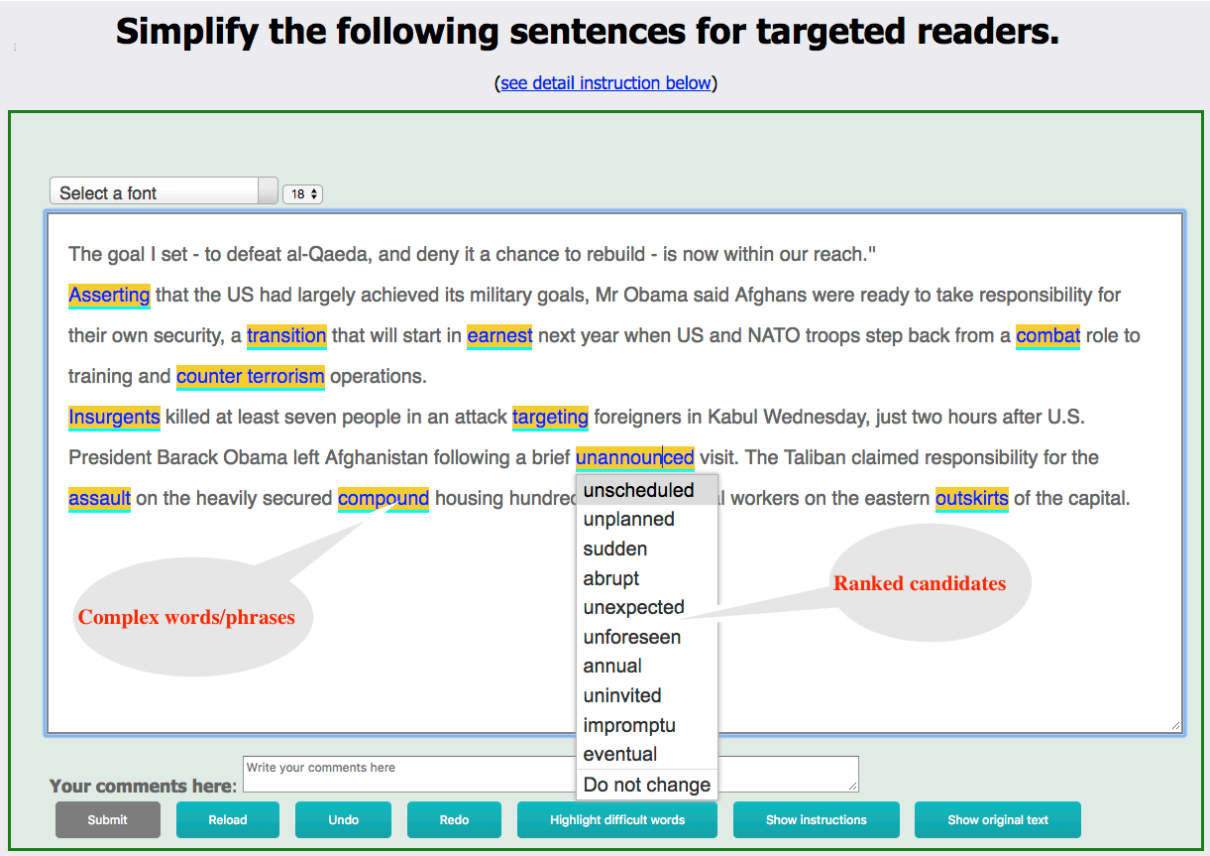

Figure 1: The Par4Sim UI as it is displayed inside the MTurk webpage with the instruction *"Simplify the following sentences for targeted readers"*. The *targeted readers* are explained in the detailed instruction as *children*, *language learner*, and *people with reading impairments*.

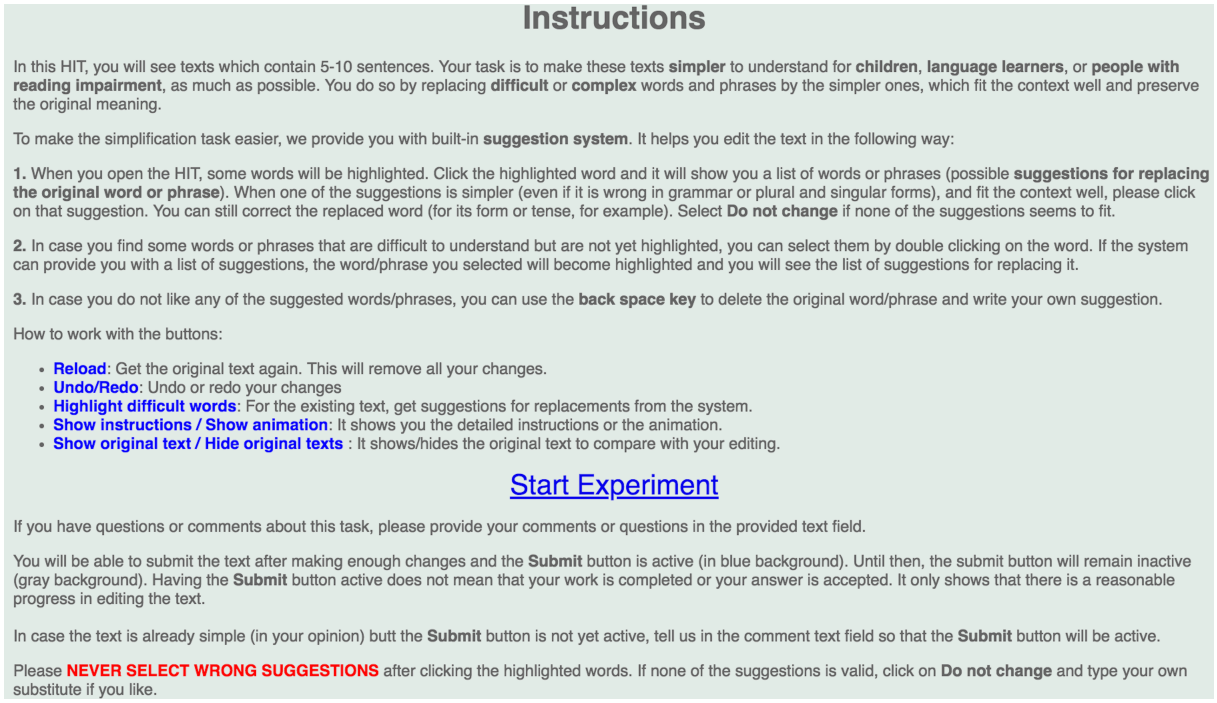
- **Show instruction / Original texts**: The instructions (see Figure 2) are visible at the beginning of each task. Once workers have accepted the task, the instructions will be hidden automatically so that the workers can focus on the simplification task in a clean window. During simplifying the text, the worker can display the instructions below the text editor if she wants to refer to the instructions. Workers can also compare the simplified version of the text with the original text.

- **Show animation**: Crowdworkers prefer a very short task description or the task should be easy enough to be understood by most workers. Since the simplification task is difficult, we decided to include an animated video showing important steps in the text simplification process. The video animation starts as soon as the task description is displayed and is hidden once the task is started. The worker can refer to the animation while completing the task.

With these functionalities, we provided a text simplification aid that comes very close to how a simplification application would look like. The goal was to provide a realistic environment in order to test the adaptive approach within a user-centric scenario. While we embedded the application into MTurk in order to attract paid users, it is straightforward to provide this web-based application online or locally.

4 Task Description and Dataset

In this paper, we address text simplification, which is the task to simplify a given text that is assumed to be difficult to understand for particular readers such as language learners, children or people with reading impairments. A text simplification pipeline usually starts with the complex word or phrase identification.



Instructions

In this HIT, you will see texts which contain 5-10 sentences. Your task is to make these texts **simpler** to understand for **children**, **language learners**, or **people with reading impairment**, as much as possible. You do so by replacing **difficult** or **complex** words and phrases by the simpler ones, which fit the context well and preserve the original meaning.

To make the simplification task easier, we provide you with built-in **suggestion system**. It helps you edit the text in the following way:

1. When you open the HIT, some words will be highlighted. Click the highlighted word and it will show you a list of words or phrases (possible **suggestions for replacing the original word or phrase**). When one of the suggestions is simpler (even if it is wrong in grammar or plural and singular forms), and fit the context well, please click on that suggestion. You can still correct the replaced word (for its form or tense, for example). Select **Do not change** if none of the suggestions seems to fit.

2. In case you find some words or phrases that are difficult to understand but are not yet highlighted, you can select them by double clicking on the word. If the system can provide you with a list of suggestions, the word/phrase you selected will become highlighted and you will see the list of suggestions for replacing it.

3. In case you do not like any of the suggested words/phrases, you can use the **back space key** to delete the original word/phrase and write your own suggestion.

How to work with the buttons:

- **Reload**: Get the original text again. This will remove all your changes.
- **Undo/Redo**: Undo or redo your changes
- **Highlight difficult words**: For the existing text, get suggestions for replacements from the system.
- **Show instructions / Show animation**: It shows you the detailed instructions or the animation.
- **Show original text / Hide original texts** : It shows/hides the original text to compare with your editing.

Start Experiment

If you have questions or comments about this task, please provide your comments or questions in the provided text field.

You will be able to submit the text after making enough changes and the **Submit** button is active (in blue background). Until then, the submit button will remain inactive (gray background). Having the **Submit** button active does not mean that your work is completed or your answer is accepted. It only shows that there is a reasonable progress in editing the text.

In case the text is already simple (in your opinion) butt the **Submit** button is not yet active, tell us in the comment text field so that the **Submit** button will be active.

Please **NEVER SELECT WRONG SUGGESTIONS** after clicking the highlighted words. If none of the suggestions is valid, click on **Do not change** and type your own substitute if you like.

Figure 2: The detailed instructions of Par4Sim, which are displayed at the beginning of the task and hidden afterwards. The worker can display the instruction when required.

For this experiment, we have used parts of the dataset from Yimam et al. (2017), which already contains manually identified complex phrases (CP). In this dataset, the complex phrases are manually identified by 10 native and 10 non-native English speakers. The dataset has been already used for the complex word identification (CWI) shared task 2018[1]. Please refer Yimam et al. (2017) for the details of the dataset. We purposely used the manually identified and verified CPs because 1) we do not want to mix the identification and the simplification tasks, and 2) we want to test the adaptive learning approach in a controlled setting.

We have generated candidate suggestions from different paraphrase resources. The following resources are used to generate candidate suggestions:

- **Lexical and Distributional resources**: We use WordNet (Miller, 1995) and distributional thesaurus (Biemann et al., 2013) to produce candidate results for CPs. We apply lemmatization to reduce the CPs into their base forms and retrieve the top 10 synonyms respectively the top 10 similar words from the lexical resources.

- **PPDB 2.0 and Simple PPDB**: PPDB (Pavlick et al., 2015) is the largest paraphrase resource to date. The recently released simple PPDB (Pavlick and Callison-Burch, 2016) is a particularly relevant resource for the task of text simplification. For each CPs (source entry in PPDB), we retrieve the top 10 candidates (target entry in PPDB).

- **Phrase2Vec**: We have trained a Phrase2Vec model (Mikolov et al., 2013) using English Wikipedia and the AQUAINT corpus of English news text (Graff, 2002). Mikolov et al. (2013) pointed out that it is possible to extend the word-based model to a phrase-based model using a data-driven approach where each phrase or multi-word expressions are considered as individual tokens during the training process. We have used a total of 79,349 multiword expression and phrase resources, which are obtained from the work of Yimam et al. (2016b). We trained the Phrase2Vec embeddings with 200

[1] https://sites.google.com/view/cwisharedtask2018/ (Yimam et al., 2018)

dimensions using skip-gram training and a window size of 5. We retrieve the top 10 similar words to the CPs as candidates.

Obviously, the number of candidate suggestions obtained from these different resources is enormous and we should limit the size before providing to the ranker model. The candidates are ordered by a language model score. We trained a tri-gram language-model (Pauls and Klein, 2011) using the Wikipedia articles. The number of candidates is limited to 10; these are re-ranked using the learning-to-rank model.

For each HIT, we provide between 5 and 10 sentences for simplification. A HIT is then assigned to 10 workers as we need a graded relevance to train the learning-to-rank model (see Section 5). In the experiment, we make sure that a HIT is submitted only in one iteration and most importantly, during the evaluation of the ranking model performance, we make sure that the training data from previous iterations should not contain HITs from the current iteration.

In this experiment, a total of 18,036 training instances have been collected. Figure 3 shows how the training instances collected from the usage data looks like. The number at the end of the simplified sentence shows the number of workers provided the same simplified sentence.

Complex Sentence: *Hajar said his cousin was not* ***affiliated*** *with any terrorist group.*
Simplified Sentence 1: *Hajar said his cousin was not* ***associated*** *with any terrorist group.* → *6*
Simplified Sentence 2: *Hajar said his cousin was not* ***merged*** *with any terrorist group.* → *2*
Simplified Sentence 3: *Hajar said his cousin was not* ***aligned*** *with any terrorist group.* → *1*
Simplified Sentence 4: *Hajar said his cousin was not* ***partnered*** *with any terrorist group.* → *1*

Figure 3: Examples of usage data as training instances. Here affiliated is a CP and associated, merged, aligned, and partnered are the simpler options provided by 6, 2, 1, and 1 workers respectively.

More detailed statistics are shown in Table 1. From Table 1, we see that around 70% of the workers (mainly from India and the US) have successfully completed the task.

	#workers	#visitors
instances	18036	10758
workers	164	71
countries	11	3

Table 1: Statistics of workers and simplification instances collected during all 9 iterations in the experiment. The column #workers shows the number of workers who have accepted and submitted the result while the column #visitors shows the number of workers who did not submit their results.

5 Learning-to-Rank

Learning-to-rank refers to a machine learning technique for training a model based on existing labels or user feedback for ranking task in areas like information retrieval, natural language processing, and data mining (Li, 2014). Learning-to-rank consists of a learning and ranking system. The system is trained by providing pairs of requests/queries and a target/ideal ranking for retrieved items. The learning model then constructs a ranking model on the basis of the training data ranking lists.

Ranklib[2], a well-known learning-to-rank library in Java from the Lemur Project is used to build the ranking models. Specifically, we have used the LambdaMART algorithm to train our learning and ranking models. LambdaMART combines LambdaRank and MART (Multiple Additive Regression Trees) (Burges, 2010; Donmez et al., 2009). While MART uses gradient boosted decision trees for prediction tasks, LambdaMART uses gradient boosted decision trees using a cost function based on NDCG for solving a ranking task.

[2] https://sourceforge.net/p/lemur/wiki/RankLib/

Normalized Discounted Cumulative Gain (NDCG) (Järvelin and Kekäläinen, 2002; Wang et al., 2013) is a family of ranking measures such as mean average precision (MAP) and Precision at K. NDCG is well-suited for our experiment for its capability of incorporating graded judgments. The graded judgments are obtained from the number of workers suggesting the candidate for the given CP target.

5.1 Features

To train the learning-to-rank model, we have designed a set of features that are important for text simplification. Based on the works of (Yimam et al., 2017; Horn et al., 2014), we have implemented the following list of features for the ranking model, which are partially derived from the candidate generating resources.

- **Frequency and length**: Due to the common use of these features in selecting the most simple lexical substitution candidate (Bott et al., 2012), we use three length features specifically the number of vowels, syllables, and characters and three frequency features: the frequency of the word in Simple Wikipedia, the frequency of the word in the document, and the frequency of the word in the Google Web 1T 5-Grams.

- **Lexical and distributional thesaurus resources**: We also use the number of similar words to the CPs and candidate suggestion based on lexical resources such as WordNet and distributional thesaurus as possible features. The features are normalized and scaled using the *featran's*[3] min-max scaler tool.

- **PPDB 2.0 and simple PPDB**: From the PPDB 2.0 and simple PPDB resources (cf. Sect. 4), we use associated scores as given by the resource, i.e.: *ppdb2score*, *ppdb1score*, *paraphraseScore*, and *simplificationScore*.

- **Word embeddings feature**: We use the Phrase2Vec embeddings as described in Section 4 to obtain vector representations for targets (CPs) and candidates. The cosine similarity of the candidates with the whole sentences as well as the cosine similarity of the candidates with the tri-gram words (one word to the left and one word to the right of the target CP) are used as features. The vector representations of the sentences and the tri-grams are the average of the individual vector representations of words in the sentences and the tri-grams.

6 Experiments

6.1 Baseline system

Our baseline system is built using a general purpose paraphrasing dataset from Yimam et al. (2016b). The dataset is based on essay sentences from the ANC[4] and BAWE corpora (Alsop and Nesi, 2009). We use the same feature extraction approach (see Section 5) for the development of the baseline model.

As it can be seen in Table 2, the results from each iteration are compared with the baseline system. We noted that the generic paraphrase datasets do not quite fit the task of text simplification as the need of the task is different. The lower performance on the baseline system can be attributed to the fact that the texts for the baseline system are collected from a different genre (essay sentences). We have to make clear that the first and all the subsequent iterations in the adaptive process do not use the baseline system.

6.2 Adaptive systems

We start with an empty ranking model (iteration 1), where candidates obtained from the resources are provided to the workers without an implied ranking. After collecting enough usage data from iteration 1, we trained a ranking model, which is used to re-rank candidates for the texts in the next iteration (iteration 2). Texts in iteration 2, which are exclusively different from those in iteration 1 are provided to the workers. Once workers completed the simplification task at iteration 2, we re-evaluate the ranking of candidates in iteration 2 based on the usage data (using NDCG@10 metric). An NDCG@10 score of

Testing	NDCG@10									
	Training instances on previous iterations									
	#sentences	baseline	1	≤ 2	≤3	≤4	≤5	≤6	≤7	≤8
1	115	-	-	-	-	-	-	-	-	-
2	214	60.66	62.88	-	-	-	-	-	-	-
3	207	61.05	63.39	65.52	-	-	-	-	-	-
4	210	58.21	60.73	65.93	67.46	-	-	-	-	-
5	233	56.10	62.53	65.66	66.00	70.72	-	-	-	-
6	215	62.18	61.05	66.51	67.86	69.88	72.36	-	-	-
7	213	57.00	62.07	64.02	64.88	67.28	69.27	74.14	-	-
8	195	56.56	59.53	62.11	63.03	64.54	67.40	71.05	75.83	-
9	224	56.14	63.48	65.58	65.87	69.18	69.51	71.31	71.40	75.70

Table 2: NDCG@10 results for each iteration of the testing instances using training instances from the previous iteration. For example, for testing at iteration 2, the NDCG@10 result using training data from the previous iteration, i.e. iteration 1, is 62.88. The baseline column shows the performance in each iteration using the generic paraphrasing dataset used to train the baseline ranking model.

	Iteration 2			Iteration 3			Iteration 4		
Workers	Instances (#)	positive (%)	NDCG score	Instances (#)	positive (%)	NDCG score	Instances (#)	positive (%)	NDCG score
AXXXL5	950	10.21	51.35	2661	10.11	55.87	2771	9.78	56.57

AXXX3E	615	10.73	59.44	1038	10.69	59.51	3451	10.66	62.59
AXXXGI	100	24.00	45.05	1979	11.22	56.72	3160	10.79	57.35

Table 3: The NDCG result for 10 different workers. *Instances* shows the total number of training instances used form the previous iteration while *positive* shows the total number of positive feedback provided by the user. The workers ID are obscured to protect their privacy.

62.88 is obtained (see Table 2), which is already better than using the baseline system (60.66). Figure 4 shows the learning curve over the different iterations conducted in the experiment.

Similarly, training instances collected from iteration 1 and iteration 2 are used to train a ranking model, which is used to re-rank candidates for texts in the next iteration (iteration 3). We continued the experiment for nine iterations and we record the performance at each iteration.

We have observed that the ranking model substantially improves on every iteration based on the NDCG@10 ranking evaluation measure. Table 2 also shows that if we test the performance on each of the models from the earlier iterations, the performance of the system declines, thus the system can make good use of more usage data if available. For example, on iteration 6, testing on a ranking model that is trained based on training instances from iteration 1 up to iteration 5 (≤**5**) produces an NDCG@10 score of 72.36 while testing on the ranking model trained based on training instances from iteration 1 up to iteration 4 (≤**4**) produces an NDCG@10 score of 69.88.

Furthermore, we have explored the effect of the adaptive system for individual workers. In this case, we have built simulated unique models for the 10 top workers, who have participated in at least 4 different batches (iterations) of the task. We use the first iteration the worker has participated as an initial model, and start using the model for the subsequent iterations. As we can see from Table 3 and Figure 5, the NDCG scores improve consistently over the iterations. The results also revealed that text simplification can be modeled differently based on the user needs (personalization).

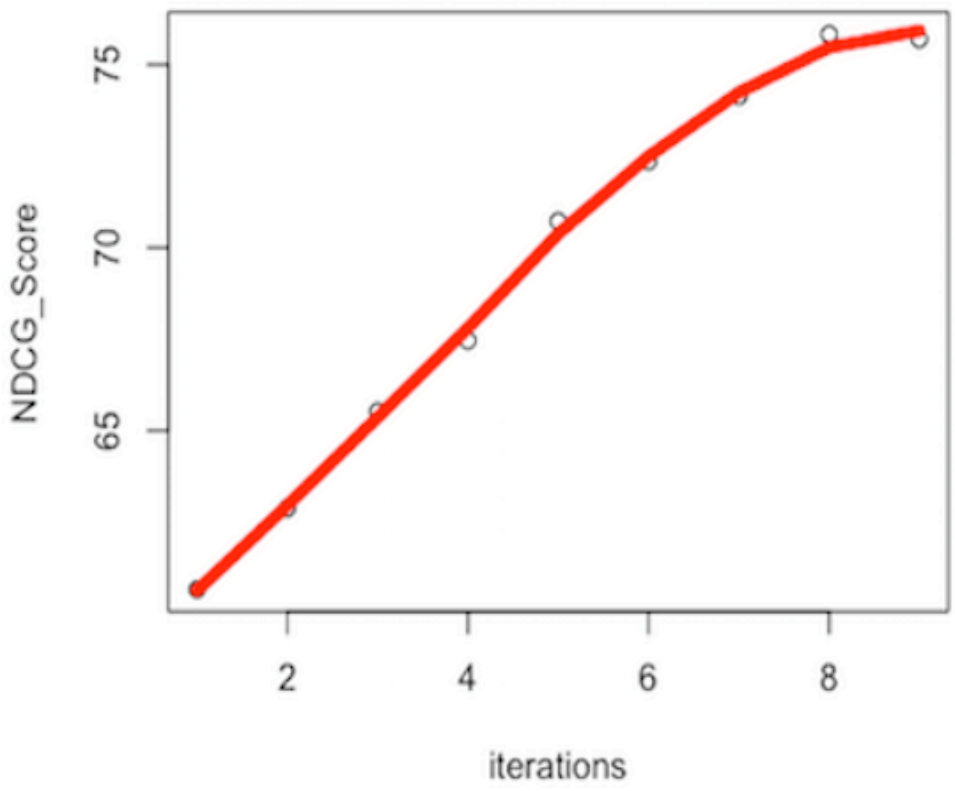

Figure 4: Learning curve showing the increase of NDCG@10 score over 9 iterations.

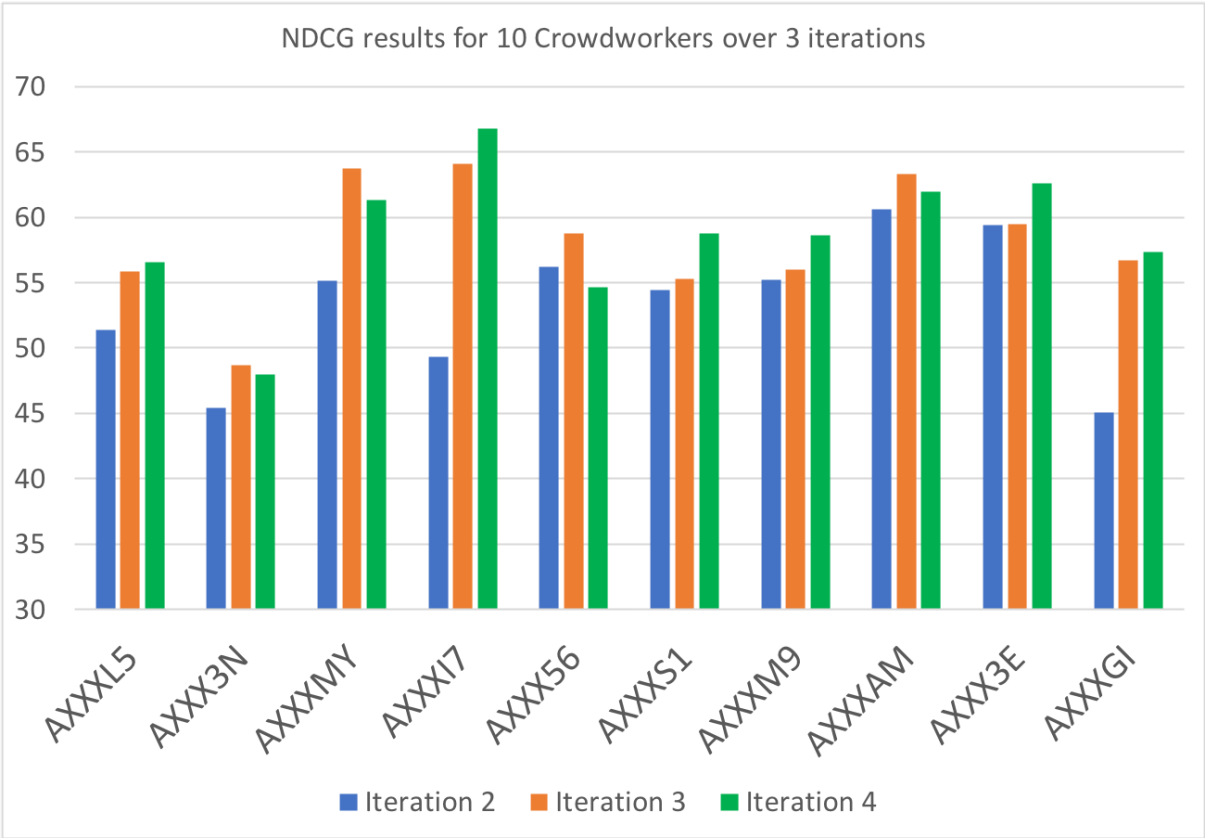

Figure 5: The increase of NDCG@10 score over 3 iterations for the top 10 workers ordered by their productiveness (who have have completed most HITs over several iterations).

7 Discussion

Most text simplification systems, and for that matter, most NLP models, are based on a traditional *collect and train* approach where first all the required training data are annotated , then training and evaluation is carried out after the data collection. To our knowledge, this experiment is the first scientific work to conduct an adaptive approach for text simplification where signals from usage data are collected in an interactive and iterative approach to improve the model of an NLP component.

We have demonstrated that our approach is noble in many aspects: 1) the adaptive learning model is integrated in the real-world NLP application (*live-usage – RQ1*), 2) the performance of the integrated adaptive model improves through usage data of the NLP application (*adaptability – RQ3*), 3) the integrated learning model potentially adapts to the needs of the user or user groups through usage data (*personalized NLP –RQ3*), and 4) we also have shown that adaptive systems can be evaluated incrementally, by comparing the system's suggestions by the ranking model to the actual ranking provided by the users (*incremental evaluation – RQ2*) .

In this research, we also have showcased how to perform web-scaled and real-time adaptive data collection using the Amazon MTurk crowdsourcing platform. The MTurk crowdsourcing platform has been mainly used to collect datasets for tasks that are not complex and difficult to complete such as identifying named entities or biomedical entities in a text, categorizing texts for spam, labeling an image with appropriate captions and so on. Using MTurk's external HIT, we are able to show that the MTurk crowdsourcing platform can be successfully used for complex NLP applications such as text simplification with a writing aid tool, which normally is limited to a lab-based experiment.

8 Conclusion and Future Directions

In this work, we have shown that the integration of an adaptive paraphrase ranking model effectively improves the performance of text simplification task. We have designed a full-fledged, web-scale based text simplification system where we have integrated an adaptive paraphrase ranking model into the tool.

Our tool is integrated with the Amazon Mechanical Turk crowdsourcing platform to collect usage data for text simplification.

To evaluate the performance of the adaptive system on the collected usage data, we have evaluated ranking model performance in an iterative way. In every iteration, we use the usage data exclusively from the previous iterations (except the first iteration that is used solely as a training data and we do not evaluate it) to training the learning-to-rank model. The result shows that, in every iteration, there is a large increase in performance based on the NDCG@10 evaluation metric.

We believe that this experiment is a showcase on how to develop a personalized NLP application. Using a similar approach, one can effectively deploy Par4Sim for a different purpose such as to write technical documents. The research also sheds light on a domain or task adaptions. One can use datasets collected for general purpose domains and it is possible to adapt the model based on the usage data over a period of time. This is a much cheaper alternative than collecting labeled datasets anew.

In the future, we would like to run a long-turn study with arbitrary users and arbitrary texts using a freely available online tool. Specifically for text simplification, the approach can be employed to provided graded complexity level of texts, as it is done for instance in the *Newsela* instructional content platform[5]. We also envision further possible tasks where adaptive learning helps, such as collaborative text composing and recommender systems.

The software is openly available under ASL 2.0 license and the resources and datasets used in this paper are released under CC-BY[6]. The demo of the tool as it was used inside the MTurk browser can be accessed online.[7]

Topic or Style? Exploring the Most Useful Features for Authorship Attribution

Yunita Sari, Mark Stevenson and **Andreas Vlachos**

Abstract

Approaches to authorship attribution, the task of identifying the author of a document, are based on analysis of individuals' writing style and/or preferred topics. Although the problem has been widely explored, no previous studies have analysed the relationship between dataset characteristics and effectiveness of different types of features. This study carries out an analysis of four widely used datasets to explore how different types of features affect authorship attribution accuracy under varying conditions. The results of the analysis are applied to authorship attribution models based on both discrete and continuous representations. We apply the conclusions from our analysis to an extension of an existing approach to authorship attribution and outperform the prior state-of-the-art on two out of the four datasets used.

1 Introduction

Authorship attribution plays an important role in many applications, including plagiarism detection and forensic investigation. Approaches to this problem attempt to identify a document's author through analysis of individual's writing style and/or topics they tend to write about. The problem has been extensively studied and a wide range of features has been explored (Stamatatos, 2013; Schwartz et al., 2013; Seroussi et al., 2013; Hürlimann et al., 2015). However, there has been a lack of analysis of the behavior of features across multiple datasets or using a range of classifiers. Consequently, it is difficult to determine which types of features will be most useful for a particular authorship attribution dataset.

Authorship attribution is a unique task which is closely related to both the representation of individuals' writing style and text categorization. In some cases, where there is a clear topical distinction between the documents written by different authors, content-related features such as those used in text categorization may be effective. However, style-based features are more likely to be effective for datasets containing a more homogeneous set of topics. Previous work on feature exploration for authorship attribution, focused on the overall effectiveness of features without considering the characteristics of the datasets to which they were applied, e.g. (Grieve, 2007; Guthrie, 2008; Stamatatos, 2009; Brennan et al., 2012; Sapkota et al., 2015). A wide range of features have been applied to the authorship attribution problem and many previous studies concluded that using character n-grams is often effective, e.g. (Peng et al., 2003; Koppel et al., 2011; Schwartz et al., 2013; Sapkota et al., 2015; Sari et al., 2017; Shrestha et al., 2017). Thus, character n-grams have become the *go-to* features for this task to capture both an author's topical preferences and writing style.

This study explores how the characteristics of a dataset affect the usefulness of different types of features for the authorship attribution task. Experiments are carried out using four datasets that have previously been widely used for this task. Three types of features are considered: *style*, *content* and *hybrid* (a mixture of the previous two types). In contrast to previous work, this study finds that character n-grams do not perform equally well in all datasets. The analysis holds for authorship attribution models using discrete and continuous representations. Using topic modeling and feature analysis, the most effective features can be successfully predicted for three of the four datasets. The results of this analysis

Proceedings of the 27th International Conference on Computational Linguistics, pages 343–353
Santa Fe, New Mexico, USA, August 20-26, 2018.

are applied via a novel extension of a recently proposed neural approach (Sari et al., 2017) and improved state-of-the-art performance are obtained for two of the four datasets.

2 Related Work

Authorship attribution features are often referred to *stylometric features* since the main goal of the task is often thought to be modeling the authors' writing style. Grieve (2007) conducted experiments which involved thirty-nine different types of textual measurements commonly used in attribution studies. His experiments, which were performed using the Chi-squared test on The Telegraph Columnist corpus, concluded that the combination of word and punctuation mark profiles are effective features for representing authors. Similar to Grieve, Guthrie (2008) carried out an exploration of 166 features used for authorship attribution including commonly used stylistic features and several others intended to capture emotional tone. He reported that fifteen features, including punctuation marks, pronouns, fog index and average sentence length to be the most useful. Stamatatos (2009) divided authorship attribution features into five groups: lexical, character, syntactic, semantic and application-specific features. Compared to others, lexical and character features are commonly used in authorship attribution work as they provide rich information about the author's topical preferences and writing style. In addition, both types of features can be extracted in many languages and datasets with little effort.

Simple lexical features (e.g. word frequencies, word n-grams, function words, hapax legomena, word/sentence length) have been widely used since early attribution work (Mendenhall, 1887). Function words have been proved to be effective features and several studies have reported their usefulness, e.g. (Mosteller and Wallace, 1964; Argamon and Levitan, 2005; Koppel et al., 2005; Juola and Baayen, 2005; Zhao and Zobel, 2005). Bag-of-words approaches have also been reported as being useful for authorship attribution (Koppel et al., 2011). These approaches are also commonly applied for sentiment analysis and topic classification tasks (Zhang et al., 2015; Heap et al., 2017).

The usefulness of character n-grams has been highlighted in several studies including (Peng et al., 2003; Stamatatos, 2013; Schwartz et al., 2013; Sapkota et al., 2015). Koppel et al. (2011) argued that this effectiveness comes from their ability to capture both content and stylistic information. Similar conclusions were reported by Sapkota et al. (2015). They analysed subgroups of character n-grams in both single and cross-domain settings. They concluded that affixes and punctuation n-grams make a significant contribution towards the effectiveness of character n-grams.

Our study differs from previous work in that we perform dataset analysis using topic modeling followed by feature ablation experiments. Thus, we are able to determine the level that each type of feature affects authorship attribution accuracy.

3 Datasets

Experiments[1] are performed using four authorship attribution datasets: Judgment (Seroussi et al., 2011), CCAT10, CCAT50 (Stamatatos, 2008), and IMDb62 (Seroussi et al., 2010). These datasets were chosen because they are all commonly used in previous literature and represent a range of characteristics in terms of the number of authors, topic/genre and document length (see Table 1).

	Judgment	CCAT10	CCAT50	IMDb62
genre	legal judgments	newswire		movie reviews
# authors	3	10	50	62
# total documents	1,342	1,000	5,000	79,550
avg characters per document	11,957	3,089	3,058	1,401
avg words per document	2367	580	584	288

Table 1: Dataset statistics.

[1]Code to reproduce the experiments is available from `https://github.com/yunitata/coling2018`

Judgment consists of legal judgments from three Australian High Court judges while both CCAT datasets are subsets of Reuters Corpus Volume 1 (RCV1) (Rose et al., 2002). The IMDb62 dataset was collected from movie reviews and message board posts of the Internet Movie database. Train/test partitions are provided for both CCAT datasets by the respective authors. For Judgment and IMDb62 we follow previous work (Seroussi et al., 2013) by using 10-fold cross validation in our experiments. We do not make use of datasets from recent authorship attribution shared task events, e.g. PAN (Juola, 2012), due to their relatively small size and fact that they provide a very small number of documents per author.

4 Dataset Analysis

The aim of this analysis is to quantify the topical similarity between authors in each of the datasets considered. The motivation for this is that certain datasets may have clear topical preferences between authors which cause authorship attribution to be biased towards topic classification. Therefore, topic modeling can help assess the topical (dis-)similarity among authors. We use Latent Dirichlet Allocation (LDA) (Blei et al., 2003), a generative probabilistic model for text collections. Documents are represented as mixtures over latent topics, where each topic is characterized by a distribution over words. Assuming a trained topic model over an authorship attribution dataset D, if C_α is the set of documents written by author α and Φ_i is the topic distribution for the i-th document in C_α, then we estimate the topic distribution for a particular author, θ_α, as follows:

$$\theta_\alpha = \frac{\sum_{i=1}^{|C_\alpha|} \Phi_i}{|C_\alpha|} \tag{1}$$

Following this, the difference between two author's topic probability distributions θ_α and θ_β is calculated using the Jensen-Shannon Divergence (JSD) (Cover and Thomas, 2006):

$$JSD(\theta_\alpha, \theta_\beta) = \frac{1}{2} D_{KL}(\theta_\alpha || M) + \frac{1}{2} D_{KL}(\theta_\beta || M) \tag{2}$$

where $M = \frac{1}{2}(\theta_\alpha + \theta_\beta)$ and D_{KL} is Kullback-Leibler divergence.

Table 2 shows the average of JSD for all author pairs in each of the datasets having trained a topic model with varying numbers of topics. High JSD scores indicate more topical dis-similarity between authors in the dataset.[2] The CCAT datasets, which contain on-line news, have higher scores compared to Judgment and IMDb62. The scores for CCAT50 and CCAT10 are similar, despite the fact that the first dataset contains five times the number of authors of the second. The consistency of this comparison across different numbers of topics indicates that this method of assessing content similarity between authors is robust with respect to tuning this parameter. Judgment has the lowest score across the four datasets indicating that the authors discuss the most similar topics. Finally, scores for the IMDb62 dataset obtained were higher than those for Judgment but lower than both CCAT's scores. Differences in scores for IMDb62 are due to the authors' preferences, as some comment on the story while others comment on the characters of the movie. Overall, we observe that the genre of the datasets influences the topical dis-similarity between authors.

Confusion matrices were created to further analyse the differences between authors. These matrices were generated after running LDA with 20 topics for 1000 iterations. Similar patterns were observed using different numbers of topics. Darker color indicates higher JSD score between two authors. In the CCAT50 dataset (Figure 1a), one author (number 11, indicated by an arrow) has very different topic preferences compared to the others. Articles written by author 11 mainly discuss topics related to *gold, exploration, Canada, Indonesia* which are rarely picked by the other authors. A similar pattern is found in IMDb62 (see Figure 1b), where reviews by author 16 (also indicated by an arrow) are dominated by positive comments about movies unlike other authors who tended to write negative reviews or discuss the story and/or the characters. However, unlike the aforementioned datasets, authors in Judgment wrote about relatively similar topics.

[2] We do not assume linear scaling.

#topic	Judgment	CCAT10	CCAT50	IMDb62
3	0.0056	0.2053	0.1785	0.1000
10	0.0148	0.3010	0.2867	0.1471
20	0.0180	0.3193	0.3279	0.1617
30	0.0256	0.3414	0.3269	0.1627
40	0.0272	0.3417	0.3291	0.1681
50	0.0281	0.3403	0.3326	0.1634

5 Feature Analysis

An ablation study was carried out to determine the contribution of different features for each dataset. Following previous studies (Abbasi and Chen, 2008; Stamatatos, 2009), feature groups are divided into three types (see Table 3):

- **Style:** Style-based features, such as usage of function words, digits and punctuation, capture an author's writing style. We used pre-defined sets of 174 function words and 12 punctuation marks.
- **Content:** Content-based features, e.g. bags of n-grams, represent the author's topical preferences. All function words are removed when extracting these features.
- **Hybrid:** The final feature type, hybrid, are character n-grams which are intended to capture both writing style and topical preferences (Koppel et al., 2011; Sapkota et al., 2015).

Both character and word *n*-grams are limited to bi- and tri-grams. As the purpose of these ablation experiments is not to outperform previous work, only the 100 most common n-grams are used for each feature type.

Authorship attribution experiments were carried out using two classifiers: a single hidden layer Feed-forward Neural Network model (FNN) and Logistic Regression (LR). The FNN hyper-parameters including the number of neurons and dropout rates were tuned on the development set for each of the datasets. For Judgment, CCAT10 and CCAT50, we set the number of epochs to 250 and 100 for IMDb62. For all datasets, early stopping was used on the development sets and the models were optimized with the Adam update rule (Kingma and Ba, 2015). Since none of the datasets have a standard development set, we randomly selected 10% of the training data for this purpose. For LR, we found that using the default parameters from Scikit-Learn (Pedregosa et al., 2011) resulted in comparable performances to the FNN. Accuracy was used as the evaluation metric to measure authorship attribution performance.

Type	Group	Category	#	Description
Style	Lexical	Word-level	2	Average word length, number of short words
		Char-level	2	Percentage of digits, percentage of uppercase letters
		Letters	26	Letter frequency
		Digits	10	Digit frequency
		Vocabulary richness	2	Richness (hapax-legomena and dislegomena)
	Syntactic	Function words	174	Frequency of function words
		Punctuation	12	Occurrence of punctuation
Content	Word *n*-gram	Words unigrams	100	Frequency of 100 most common word unigrams
		Words bigrams	100	Frequency of 100 most common word bigrams
		Word trigrams	100	Frequency of 100 most common word trigrams
Hybrid	Char *n*-gram	Char bigrams	100	Frequency of 100 most common character bigrams
		Char trigrams	100	Frequency of 100 most common character trigrams

Table 3: Authorship attribution feature sets.

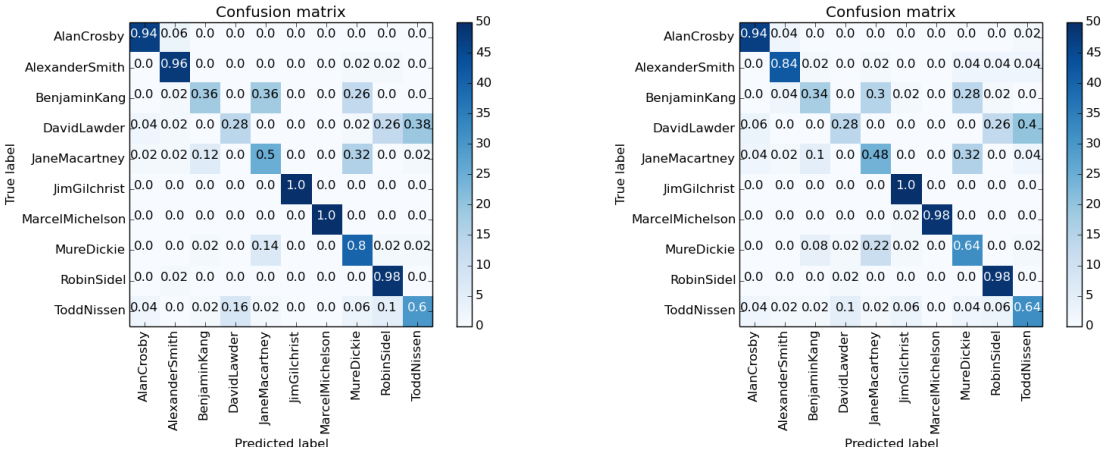
5.1 Feature Ablation Results

Results are presented in Table 4. The $(-)$ symbol indicates that the respective feature type is excluded. The results confirm our topic model-based analysis (see Section 4). Style-based features are more effective for datasets in which authors discuss similar topics, e.g. Judgment and IMDb62. As expected, content-based features are generally more effective when there is more dis-similarity between the topics discussed by the authors in the dataset, e.g. CCAT10 and CCAT50, but are of limited usefulness when the topics are similar (particularly for the Judgment dataset). The hybrid features appear to behave similarly to the content-based features since they are most useful when the topic dis-similarity between authors is high.

Features	Judgment		CCAT10		CCAT50		IMDb62	
	FNN	LR	FNN	LR	FNN	LR	FNN	LR
all features	89.43	90.02	75.40	74.20	60.20	60.56	85.25	85.00
(–) Style	**-3.87**	**-4.32**	-3.00	+0.40	-3.40	-2.60	**-6.91**	**-8.39**
(–) Content	-1.43	+0.30	**-3.60**	**-3.00**	**-4.52**	-4.08	-2.77	-2.68
(–) Hybrid	-0.83	-0.29	-3.40	-1.00	-1.28	**-4.68**	-2.02	-5.32

Table 4: Feature ablation results.

To examine the results further, we generated confusion matrices for the Logistic Regression (LR) classifier applied on CCAT10 dataset (Figure 2). The effect of removing content-based features is shown in Figure 2b where the prediction accuracy for authors *Alexander Smith* and *Mure Dickie* drops from 96% and 80% (see Figure 2a) to 84% and 64% respectively. Content-based features are essential in this particular genre (newswire) dataset, since each author usually has different topical interests. For example, among the ten authors in the dataset, *Alexander Smith* mostly discussed topic related to *investment and*



(a) All features (b) (−) Content

Figure 2: Confusion Matrices of LR classifier with different features types on CCAT10.

finance, while *China* was dominantly written about by *Mure Dickie, Benjamin Kang* and *Jane Macartney*. In addition, writing style between authors in this genre can be very similar. Thus, applying style-based or hybrid features alone may not be effective.

Additional feature exploration was carried out to analyse what types of features are more important to the classifier overall. We performed an analysis using LIME (Ribeiro et al., 2016), a model agnostic framework for intepretability. LIME provides explanations about how a classifier made a prediction by identifying important input features. We selected a document from each of the datasets and analysed what kind of features were used in its prediction. Figures 3, 4, 5 and 6 present the predictions of LR trained on 1000 word unigrams in Judgment, CCAT10, CCAT50, and IMDb62 respectively. In these experiment function words are not removed. For each of the documents presented, LR made correct author predictions with probability close to 100%. The darker shade indicates more important words in the attribution prediction. In the two CCAT datasets the classifier put more weight on content-based words such as *Thomson, Canada* and *Toronto*. In contrast, function words e.g. *at, had, and, was* appear to be more salient in Judgment and IMDb62.

.) . but in bracton 's account of the great convention at merton we read only of those qui nati and not those qui geniti , fuerunt ante sponsalia vel matrimonium , (fol . :) and we learn elsewhere from him (fol .) that it mattered not for legitimacy whether the child was begotten and born after the marriage or begotten before but born into the marriage or begotten in the marriage and born after the marriage had been dissolved and whether dissolved by death or by divorce and that it did not matter whether the union was by matrimonium or (subject to certain exceptions) by sponsalia . but we find that he recognizes adulterine bastardy . the child is to be presumed a bastard , it appears , if feebleness , frigidity or impotence of the husband is proved per multum tempus or absence for two years from the kingdom or from the county or shire is shown . if he returns and finds his wife pregnant or that she has a child of a year or less , whether he avows it and nurtures it or not , the child may rightly be excluded from succession because it could not be heir . but , if it was possible to presume that he could have engendered the child , it seems that decisive importance was given to avowal and nurture by

Figure 3: Important word unigrams features in Judgment.

Alcatel Alsthom said on Monday it was in talks with Aerospatiale and Dassault about a joint offer for the government's 58-percent stake in defence electronics group Thomson-CSF.
Prime Minister Alain Juppe said a decision about the procedure for the privatisation of Thomson-CSF would be made before the end of February.
"There are discussions with the companies mentioned in the press," an Alcatel spokesman said when asked to react to newspaper reports about a joint bid.
Industry sources said that Alcatel chairman Serge Tchuruk had kept the government informed about his plans to form an alliance with Aerospatiale and Dassault in order to win the Thomson-CSF stake.
Alcatel in October lost out to Lagardere Groupe in bidding for state-controlled Thomson SA, which has the stake in Thomson-CSF as well as 100 percent of consumer electronics group Thomson Multimedia (TMM).
But the government had to suspend the sale on December 4 after the independent Privatisation Commission balked against the terms of the sale by Lagardere of TMM to Daewoo Electronics of South Korea.

Figure 4: Important word unigrams features in CCAT10.

We also observed a document in the IMDb62 dataset where the classifier assigns similar prediction

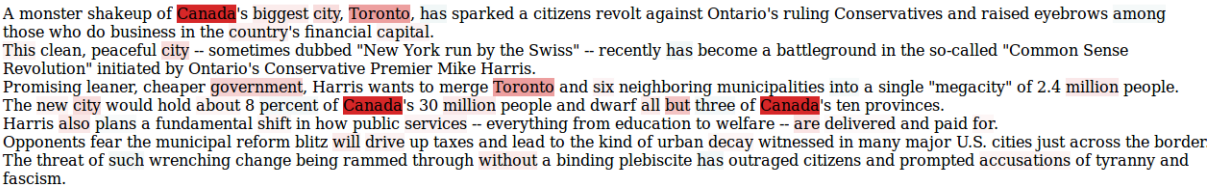


Figure 5: Important word unigrams features in CCAT50.

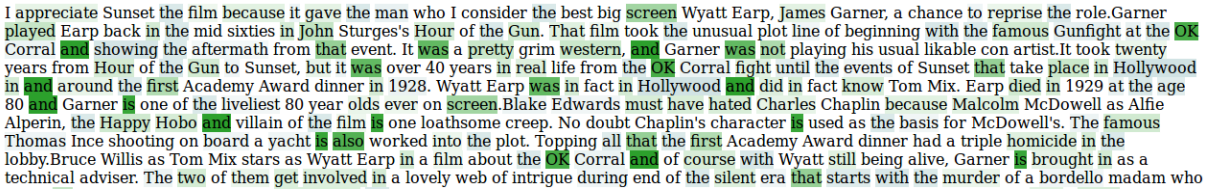

Figure 6: Important word unigrams features in IMDb62.

probabilities to two authors as presented in Figure 7. The classifier put the same weight to function words *and* and *to* which represent two different classes of authors, 26 and not 26 (the LR classifier uses a one-versus-all scheme). The correct decision of the classifier is more likely helped by the presence of some less significant features such as *is, becomes, There, usual* and *could*.

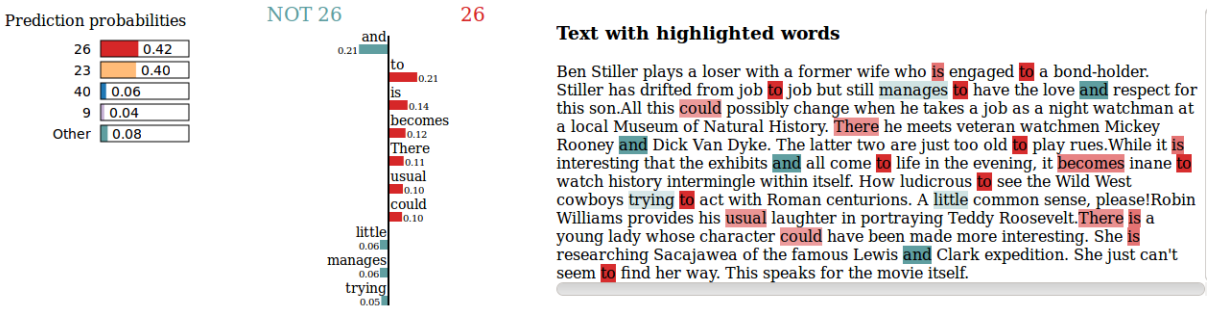

Figure 7: Explanation of individual predictions of Logistic Regression classifier on an IMDb62 document using LIME. The bar chart represent the weight given to the most relevant words which are also highlighted in the text.

6 Extending a Neural Model

These findings are further validated by applying them to a continuous n-grams-based authorship attribution model recently proposed by Sari et al. (2017). They represented a document as a bag of n-grams features and learned the continuous representation of each feature jointly with the classifier in a shallow feed-forward neural network (Joulin et al., 2017). Sari et al. conducted experiments with three different feature choices: characters, words and their combination. The character-based model outperformed the state-of-the-art on the CCAT50 and IMDb62 datasets, while producing comparable results on the remaining two.

We extend their character-based model by incorporating each feature type (*style, content* and *hybrid*) as an auxiliary feature represented in discrete form. Auxiliary features provide additional information related to the dataset characteristics. Given x_{aux} as a normalized auxiliary features frequency vector, V is the weight applied to the features and f is the activation function (ReLu), the hidden layer h performs the following computation:

$$h = f(Vx_{aux}) \tag{3}$$

The probability distribution over the label for a document then can be described as:

$$p(y|x) = softmax(W_{out}[Ax, h]) \tag{4}$$

where x is the frequency vector of features for the document, A is the embedding matrix, W_{out} is the weight matrix of the output layer and $[Ax, h]$ is the concatenation of Ax and h.

All the character n-gram embeddings and hidden layer in the model were initialized using Glorot uniform initialization (Glorot and Bengio, 2010). We used the best hyper-parameters values for each of the datasets which have been tuned in the development set via a small grid search over all combinations of embedding size and dropout rate (specifically dropout in the concatenation layer). The hidden size of hidden auxiliary layer was set to 2. For the rest of the hyper-parameters, we used the values from the baseline model (Sari et al., 2017). For Judgment, CCAT10 and CCAT50, we set the number of epochs to 250 and 100 for IMDb62. For all datasets, early stopping was used on the development sets and the models were optimized with the Adam update rule (Kingma and Ba, 2015).

6.1 Results

Table 5 presents the results of the experiment and compares them against previously reported ones on the same data sets. In the bottom portion of the table it can be seen that for each of the four data sets there is at least one feature type which leads to improved results when it is incorporated into the model. Our results demonstrate that better performance can be achieved by taking the data characteristic into account on choosing authorship attribution features. Moreover, the results provide evidence that character n-grams which have been known as typical *go-to* features do not perform equally well in all types of datasets. For three datasets (CCAT10, CCAT50 and IMDb62) the best result is obtained using the feature type identified as being most useful in Section 5. However, we find that using the style features does not improve results on the Judgment dataset as we had expected. The relatively poor performance of the style features may be due to the baseline model (the continuous character n-grams) which effectively captured all the author's writing style. Thus the addition of auxiliary style features did not lead to any improvement.

The results reported here for the CCAT50 and IMDb62 datasets outperform the previously best reported results (Sari et al., 2017) and the model reported here therefore represents a new state-of-the-art performance. The improvements for IMDb62 are statistically significant ($p < 0.05$, paired t-test).

7 Conclusions

This paper describes experiments on the relationship between the effectiveness of different types of features for authorship attribution and characteristics of datasets. We find that the most effective features for datasets can be predicted by applying topic modeling and feature analysis. Content-based features tend to be suitable for datasets with high topical diversity such as the one constructed from on-line news. Datasets with less topical variance, e.g. legal judgments and movie reviews, benefit more from style-based features. The effectiveness of our proposed analysis is further validated by the performance of our proposed neural model which achieved the state-of-the-art results on two datasets.

Abstract

LSTM-based language models have been shown effective in Word Sense Disambiguation (WSD). In particular, the technique proposed by Yuan et al. (2016) returned state-of-the-art performance in several benchmarks, but neither the training data nor the source code was released. This paper presents the results of a reproduction study and analysis of this technique using only openly available datasets (GigaWord, SemCor, OMSTI) and software (TensorFlow). Our study showed that similar results can be obtained with much less data than hinted at by Yuan et al. (2016). Detailed analyses shed light on the strengths and weaknesses of this method. First, adding more unannotated training data is useful, but is subject to diminishing returns. Second, the model can correctly identify both popular and unpopular meanings. Finally, the limited sense coverage in the annotated datasets is a major limitation. All code and trained models are made freely available.

1 Introduction

Word Sense Disambiguation (WSD) is a long-established task in the NLP community (see Navigli (2009) for a survey) which goal is to annotate lemmas in text with the most appropriate meaning from a lexical database like WordNet (Fellbaum, 1998). Many approaches have been proposed – the more popular ones include the usage of Support Vector Machine (SVM) (Zhong and Ng, 2010), SVM combined with unsupervised trained embeddings (Iacobacci et al., 2016; Rothe and Schütze, 2017), and graph-based approaches (Agirre et al., 2014; Weissenborn et al., 2015).

In recent years, there has been a surge in interest in using Long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) to perform WSD (Raganato et al., 2017b; Melamud et al., 2016). These approaches are characterized by their high performance, simplicity and their ability to extract a lot of information from raw text. Among the best-performing ones is the approach by Yuan et al. (2016), in which an LSTM language model trained on a corpus with 100 billion tokens was coupled with small sense-annotated datasets to achieve state-of-the-art performance in all-words WSD.

Even though the results obtained by Yuan et al. (2016) outperform the previous state-of-the-art, neither the used datasets nor the constructed models are available to the community. This is unfortunate because this makes the re-application of this technique a non-trivial process, and it hinders further studies for understanding which limitations prevent even higher accuracies. These could be, for instance, of algorithmic nature or relate to the input (either size or quality), and a deeper understanding is crucial for enabling further improvements. In addition, some details are not reported, and this could prevent other attempts from replicating the results.

To address these issues, we reimplemented Yuan et al. (2016)'s method with the goal of: 1) reproducing and making available the code, trained models, and results and 2) understanding which are the main factors that constitute the strengths and weaknesses of this method. While a full replication is not possible due to the unavailability of the original data, we nevertheless managed to reproduce their approach with other public text corpora, and this allowed us to perform a deeper investigation on the

Proceedings of the 27th International Conference on Computational Linguistics, pages 354–365
Santa Fe, New Mexico, USA, August 20-26, 2018.

performance of this technique. This investigation aimed at understanding how sensitive the WSD approach is w.r.t. the amount of unannotated data (i.e., raw text) used for training, model complexity, how biased the method is towards the choice of the most frequent senses (MFS), and identifying limitations that cannot be overcome with bigger unannotated datasets.

The contribution of this paper is thus two-fold: On the one hand, we present a reproduction study whose results are publicly available and hence can be freely used by the community. Notice that the lack of available models has been explicitly mentioned, in a recent work, as the cause for the missing comparison of this technique with other competitors (Raganato et al., 2017b, footnote 10). On the other hand, we present other experiments to shed more light on the value of this and similar methods.

We anticipate some conclusions. First, a positive result is that we were able to reproduce the method from Yuan et al. (2016) and obtain similar results to the ones originally published. However, to our surprise, these results were obtained using a much smaller corpus of 1.8 billion tokens (Gigaword), which is less than 2% of the data used in the original study. In addition, we observe that the amount of unannotated data is important, but that the relationship between its size and the improvement is not linear, meaning that exponentially more unannotated data is needed in order to improve the performance. Moreover, we show that the percentage of correct sense assignments is more balanced w.r.t sense popularity, meaning that the system has a less-strong bias towards the most-frequent sense (MFS) and is better at recognizing both popular and unpopular meanings. Finally, we show that the limited sense coverage in the annotated datasets is a major limitation, as shown by the fact that resulting model does not have a representation for more than 30% of the meanings which should have been considered for disambiguating the test sets.

2 Background

Current WSD systems can be categorized according to two dimensions: whether they use raw text without any preassigned meaning (unannotated data henceforth), and whether they exploit the relations between synsets in WordNet (synset relations henceforth). One prominent state-of-the-art system that does not rely on unannotated data nor exploits synset relations is It Makes Sense (IMS) (Zhong and Ng, 2010; Taghipour and Ng, 2015). This system uses an SVM to train classifiers for each lemma using only annotated data as training evidence.

In contrast, graph-based WSD systems do not use (un)annotated data but rely on the synset relations. The system UKB (Agirre et al., 2014) represents WordNet as a graph where the synsets are the nodes and the relations are the edges. After the node weights have been initialized using the Personalized Page Rank algorithm, they are updated depending on context information. Then, the synset with the highest weight is chosen. Babelfy (Moro et al., 2014) and the system by Weissenborn et al. (2015) both represent the whole input document as a graph with synset relations as edges and jointly disambiguate nouns and verbs. In the case of Babelfy, a densest-subgraph heuristic is used to compute the high-coherence semantic interpretations of the text. Instead, in Weissenborn et al. (2015) a set of complementary objectives, which include sense probabilities and type classification, are combined together to perform WSD.

A number of systems make use of both unannotated data and synset relations. Both Tripodi and Pelillo (2017) and Camacho-Collados et al. (2016) make use of statistical information from unannotated data to weigh the relevance of nodes in a graph, which is then used to perform WSD. Rothe and Schütze (2017) use word embeddings as a starting point and then rely on the formal constraints in a lexical resource to create synset embeddings.

Recently, there has been a surge in WSD approaches that use unannotated data but do not consider synset relations. One example is provided by Iacobacci et al. (2016), who investigated the role of word embeddings as features in a WSD system. Four methods (concatenation, average, fractional decay, and exponential decay) are used to extract features from the sentential context using word embeddings. The features are then added to the default feature set of IMS (Zhong and Ng, 2010). Moreover, Raganato et al. (2017b) present a number of end-to-end neural WSD architectures. The best performing one is based on a bidirectional Long Short-Term Memory (BLSTM) with attention and two auxiliary loss functions (part-of-speech and the WordNet coarse-grained semantic labels). Melamud et al. (2016) also make use of unannotated data to train a BLSTM. The work by Yuan et al. (2016), which we consider in this paper,

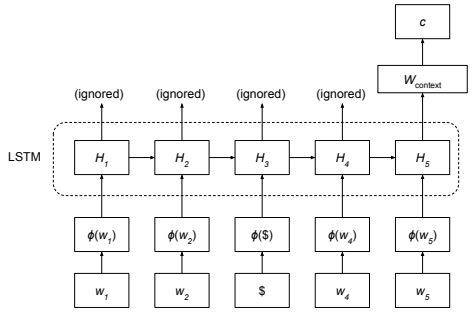

Figure 1: The LSTM model used to perform language modeling and compute context embeddings. At training time, a softmax layer is added, allowing it to predict the omitted word; at test time, the context embeddings are used for WSD in a nearest-neighbor or label-propagation procedure.

belongs to this last category. Different from Melamud et al. (2016), it uses significantly more unannotated data, the model contains more hidden units (2048 vs. 600), and the sense assignment is more elaborated. We describe this approach in more detail in the following section.

3 WSD with Language Models

The method proposed by Yuan et al. (2016) performs WSD by annotating each lemma in a text with one WordNet synset that is associated with its meaning. Broadly speaking, the disambiguation is done by: 1) constructing a language model from a large unannotated dataset; 2) extracting sense embeddings from this model using a much smaller annotated dataset; 3) relying on the sense embeddings to make predictions on the lemmas in unseen sentences. Each operation is described below.

Constructing Language Models. Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) is a celebrated recurrent neural network architecture that has proven to be effective in many natural language processing tasks (Sutskever et al., 2014; Dyer et al., 2015; He et al., 2017, among others). Different from previous architectures, LSTM is equipped with trainable gates that control the flow of information, allowing the neural networks to learn both short- and long-range dependencies.

In Yuan et al. (2016), the first operation consists of constructing an LSTM language model to capture the meaning of words in context. They use an LSTM network with a single hidden layer of h nodes. Given a sentence $s = (w_1, w_2, \ldots, w_n)$, they replace word $w_k\,(1 \leq k \leq n)$ by a special token \$. The model takes this new sentence as input and produces a context vector $\mathbf{c}$ of dimensionality p (see Figure 1).[1]

Each word w in the vocabulary $\mathcal{V}$ is associated with an embedding $\phi_{\text{o}}(w)$ of the same dimensionality. The model is trained to predict the omitted word, minimizing the softmax loss over a big collection $\mathcal{D}$ of sentences.

$$\ell = -\sum_{s \in \mathcal{D}} \sum_{k=1}^{|s|} \log \frac{\exp(\mathbf{c} \cdot \phi_{\text{o}}(w_k))}{\sum_{w' \in \mathcal{V}} \exp(\mathbf{c} \cdot \phi_{\text{o}}(w'))}$$

After the model is trained, we can use it to extract *context* embeddings, i.e., latent numerical representations of the sentence surrounding a given word.

Calculating Sense Embeddings. The model produced by the LSTM network is meant to capture the "meaning" of words in the context they are mentioned. In order to perform the sense disambiguation, we need to extract from it a suitable representation for word senses. To this purpose, the method relies on another corpus where each word is annotated with the corresponding sense.

The main intuition is that words used with the same sense are mentioned in contexts which are very similar to each other as well. This suggests a simple way to calculate sense embeddings. First, the LSTM model is invoked to compute the context vector for each occurrence of one sense in the annotated dataset. Once all context vectors are computed, the sense embedding is defined as the average of all vectors. Let

[1] As usual, vectors are indicated with boldface to distinguish them to scalar and other symbols.

us assume, for instance, that the sense $horse_n^2$ (that is, the second sense of horse as a noun) appears in the two sentences:

(1) The move of the $horse_n^2$ to the corner forced the checkmate.

(2) Karjakin makes up for his lost bishop a few moves later, trading rooks and winning black's $horse_n^2$.

In this case, the method will replace the sense by \$ in the sentences and feed them to the trained LSTM model to calculate two context vectors $\mathbf{c_1}$ and $\mathbf{c_2}$. The sense embedding $\mathbf{s_{horse_n^2}}$ is then computed as:

$$\mathbf{s_{horse_n^2}} = \frac{\mathbf{c_1} + \mathbf{c_2}}{2}$$

This procedure is computed for every sense that appears in the annotated corpus.

Averaging technique to predict senses. After all sense embeddings are computed, the method is ready to disambiguate target words. This procedure proceeds as follows:

1. Given an input sentence and a target word, it replaces the occurrence of the target word by \$ and uses the LSTM model to predict a context vector $\mathbf{c_t}$.
2. The lemma of the target word is used to retrieve from WordNet the candidate synsets $s_1, \ldots, s_n$ where n is the number of synsets. Then, the procedure looks up the corresponding sense embeddings $\mathbf{s_1}, \ldots, \mathbf{s_n}$ computed in the previous step.
3. The procedure invokes a subroutine to choose one of the n senses for the context vector $\mathbf{c_t}$. It selects the sense whose vector is closest to $\mathbf{c_t}$ using cosine as the similarity function.

Label Propagation. Yuan et al. (2016) argue that the averaging procedure is suboptimal because of two reasons. First, the distribution of occurrences of senses is unknown whereas averaging is only suitable for spherical clusters. Second, averaging reduces the representation of occurrences of each sense to a single vector and therefore ignores sense prior. For this reason, they propose to use label propagation for inference as an alternative to averaging. Label propagation (Zhu and Ghahramani, 2002) is a classic semi-supervised algorithm that has been employed in WSD (Niu et al., 2005) and other NLP tasks (Chen et al., 2006; Zhou, 2011). The procedure involves predicting senses for not only the target cases but also for unannotated words queried from a corpus. It represents both the target cases and unannotated words as points in a vector space and iteratively propagates classification labels from the target classes to the words. In this way, it can be used to construct non-spherical clusters and to give more influence to frequent senses.

Overall algorithm. The overall disambiguation procedure that we implemented proceeds as follows:

1. *Monosemous:* First, the WSD algorithm checks whether the target lemma is monosemous (i.e., there is only one synset). In this case, the disambiguation is trivial.
2. *Label propagation:* If the label propagation is enabled, then it checks whether the target lemma occurs at least once in the annotated dataset and at least once in the auxiliary unannotated dataset. In this case, the procedure applies the *label propagation* technique for selecting the candidate synset.
3. *Averaging:* If the previous strategies are not applicable and there is at least one occurrence of the target lemma in the annotated dataset, then we apply the *averaging* technique for selecting the candidate synset.
4. *MFS fallback:* If the target lemma does not appear in the annotated dataset, then the system picks the most-frequent synset.[2]

[2]Notice that Yuan et al. (2016) did not report if they use an MFS-fallback strategy or simply returned no answer.

4 Reproduction Study: Methodology

Before we report the results of our experiments, we describe the datasets used and give some details regarding our implementation.

Training data. The 100-billion-token corpus used in the original publication is not publicly available. Therefore, for the training of the LSTM models, we used the English Gigaword Fifth Edition (Linguistic Data Consortium (LDC) catalog number LDC2011T07). The corpus consists of 1.8 billion tokens in 4.1 million documents, originated from four major news agencies. We leave the study of bigger corpora for future work.

For the training of the sense embeddings, we use the same two corpora used by Yuan et al. (2016):

1. *SemCor* (Miller et al., 1993) is a corpus containing approximately 240,000 sense annotated words. The tagged documents originate from the Brown corpus (Francis and Kucera, 1979) and cover various genres.
2. *OMSTI* (Taghipour and Ng, 2015) contains one million sense annotations automatically tagged by exploiting the English-Chinese part of the parallel MultiUN corpus (Eisele and Chen, 2010). A list of English translations were manually created for each WordNet sense. If the Chinese translation of an English word matches one of the manually curated translations for a WordNet sense, that sense is selected.

Implementation. We used the BeautifulSoup HTML parser to extract plain text from the Gigaword corpus. Then, we used the English models[3] of Spacy 1.8.2 for sentence boundary detection and tokenization. The LSTM model is implemented using TensorFlow 1.2.1 (Abadi et al., 2015). We chose TensorFlow because of its industrial-grade quality and because it can train large-scale models.

The main computational bottleneck of the entire process is the training of the LSTM model. Although we do not use a 100-billion-token corpus, training the model on Gigaword can already take years if not optimized properly. To reduce training time, we assumed that all (padded) sentences in the batch have the same length. This optimization increases the speed by 17% as measured on a smaller model ($h = 100, p = 10$). Second, following Yuan et al., we use the sampled softmax loss function (Jean et al., 2015). Third, we grouped sentences of similar length together while varying the number of sentences in a batch to fully utilize GPU RAM. Together, these heuristics increased training speed by 42 times.

Although Yuan et al. proposed to use a distributed implementation of label propagation (Ravi and Diao, 2015), we found that scikit-learn (Pedregosa et al., 2011) was fast enough for our experiments. For hyperparameter tuning, we use the annotations in OMSTI (which are not used at test time). After measuring the performance of some variations of label propagation (scikit-learn implementation: *LabelPropagation* or *LabelSpreading*; similarity measure: *inner product* or radial basis function with different values of γ), we found that the combination of *LabelSpreading* and *inner product* similarity leads to the best result which is also better than averaging on the development set.

Evaluation framework. For evaluating the WSD predictions, we selected two test sets: one from the Senseval2 (Palmer et al., 2001) competition, which tests the disambiguation of nouns, verbs, adjectives and adverbs, and one from the 2013 edition (Navigli et al., 2013), which focuses only on nouns.

The test set from Senseval-2 is the English All-Words Task; *senseval2* henceforth. This dataset contains 2,282 annotations from three articles from the Wall Street Journal. Most of the annotations are nominal, but the competition also contains annotations for verbs, adjectives, and adverbs. In this test set, 66.8% of all target words are annotated with the most-frequent sense (MFS) of the lemma. This means that the simple strategy of always selecting the MFS would score 66.8% F_1 on this dataset.

The test set from SemEval-2013 is the one taken from task 12: Multilingual Word Sense Disambiguation; *semeval2013* henceforth. This task consists of two disambiguation tasks: Entity Linking and Word Sense Disambiguation for English, German, French, Italian, and Spanish. This test set contains 13 articles from previous editions of the workshop on Statistical Machine Translation.[4] The articles contain

Table 1: Performance of our implementation compared to already published results. We report the model/method used to perform WSD, the used annotated dataset and scorer, and F_1 for each test set. In the naming of our models, *LSTM* indicates that the *averaging* technique was used for the sense assignment, while *LSTMLP* refers to the results obtained using *label propagation* (see Section 3). The datasets following *T:* indicate the annotated corpus used to represent the senses while *U:OMSTI* stands for using OMSTI as unlabeled sentences in case label propagation is used. *P: SemCor* indicates that sense distributions from SemCor are used in the system architecture. Three scorers are used: *"framework"* refers to the WSD evaluation framework from Raganato et al. (2017a); *"mapping to WN3.0"* refers to the evaluation used by Yuan et al. (2016) while *"competition"* refers to the scorer provided by the competition itself (e.g., semeval2013).

1,644 test instances in total, which are all nouns. The application of the MFS baseline on this dataset yields an F_1 score of 63.0%.

5 Results

In this section, we report our reproduction of the results of Yuan et al. (2016) and additional experiments to gain a deeper insight into the strengths and weaknesses of the approach. These experiments focus on the performance on the most- and less-frequent senses, coverage of the annotated dataset and the consequent impact on the overall predictions, the granularity of the sense representation, and the impact of the unannotated data and model complexity on the accuracy of WSD.

Reproduction results. We trained the LSTM model with the best reported settings in Yuan et al. (2016) (hidden layer size $h = 2048$, embedding dimensionality $p = 512$) using a machine equipped with an Intel Xeon E5-2650, 256GB of RAM, 8TB of disk space, and two nVIDIA GeForce GTX 1080 Ti GPUs. During our training, one epoch took about one day to finish with TensorFlow fully utilizing one GPU. The whole training process took four months. We tested the performance of the downstream WSD task three times during the training and observed that the best performance is obtained at the 65$^{\text{th}}$ epoch, despite a later model producing a lower negative log-likelihood. Thus, we used the model produced at the 65$^{\text{th}}$ epoch for our experiments below.

Table 1 presents the results using the test sets *senseval2* and *semeval2013*, respectively. The top part of the table presents our reproduction results, the middle part reports the results from Yuan et al. (2016), while the bottom part reports a representative sample of the other state-of-the-art approaches.

It should be noted that with the test set *semeval2013*, all scorers use WordNet 3.0, therefore the performance of the various methods can be directly compared. However, not all answers in *senseval2* can be mapped to WN3.0 and we do not know how Yuan et al. (2016) handled these cases. In the WSD evaluation framework (Moro et al., 2014) that we selected for evaluation, these cases were either re-annotated or removed. Thus, our F_1 on *senseval2* cannot be directly compared with the F_1 in the original paper.

From a first glance at Table 1, we observe that if we use SemCor to train the synset embeddings, then our results come close to the state-of-the-art on *senseval2* (0.720 vs. 0.733). On *semeval2013*, we achieve results comparable to other embeddings-based approaches (Raganato et al., 2017b; Iacobacci et

Model	senseval2			semeval2013		
	F_1	R_mfs (n=1524)	R_lfs (n=758)	F_1	R_mfs (n=1035)	R_lfs (n=609)
Our LSTM (T: SemCor)	**0.72**	0.88	**0.41**	0.65	0.84	0.33
Our LSTM (T: OMSTI)	0.67	0.87	0.27	0.65	**0.86**	0.29
Our LSTM (T: SemCor+OMSTI)	0.70	0.85	0.40	**0.66**	0.82	**0.38**
Our LSTMLP (T: SemCor+OMSTI)	0.71	**0.91**	0.32	0.64	0.85	0.29

Table 2: Performance of our implementation with respect to MFS and LFS recall. *R_mfs* and *R_lfs* are the recall on the most-frequent-sense and least-frequent-sense instances respectively. n represents the number of considered instances.

al., 2016; Melamud et al., 2016). However, the gap with the graph-based approach of Weissenborn et al. (2015) is still significant. When we use both SemCor and OMSTI for the annotated data, our results drop 0.02 point for *senseval2*, whereas they increase by almost 0.01 for *semeval2013*. Different from Yuan et al. (2016), we did not observe improvement by using label propagation (comparing *T: SemCor, U: OMSTI* against *T:SemCor* without propagation). However, the performance of the label propagation strategy is still competitive on both test sets.

Most- vs. less-frequent-sense instances. The original paper only analyses the performance on the whole test sets. We extend this analysis by looking at the performance for disambiguating the most frequent-sense (MFS) and less-frequent-sense (LFS) instances. The first type of instances are the ones for which the correct link is the most-frequent sense, whereas the second subset consists of the remaining ones. This analysis is important because it is well-known that the simple strategy of always choosing the MFS is a strong baseline in WSD, thus there is a tendency for WSD systems to overfit towards the MFS (Postma et al., 2016).

Table 2 shows that the method by Yuan et al. (2016) does not overfit towards the MFS to the same extent as other supervised systems since the recall on LFS instances is still quite high 0.41 (a lower recall on LFS instances than on MFS ones is expected due to the reduced training data for them).

On semeval13, the recall on LFS is already relatively high using only SemCor (0.33), and reaches 0.38 when using both SemCor and OMSTI. For comparison, the default system IMS (Zhong and Ng, 2010) trained on SemCor only obtains an *R_lfs* of 0.15 on semeval13 (Postma et al., 2016) and only reaches 0.33 with a large amount of annotated data.

Finally, our implementation of the label propagation does seem to slightly overfit towards the MFS. When we compare the results of the *averaging technique* using SemCor and OMSTI versus when we use *label propagation*, we notice an increase in the MFS recall (from 0.85 to 0.91), whereas the LFS recall drops from 0.40 to 0.32.

Meaning coverage in annotated datasets. The WSD procedure depends on an annotated corpus to compose its sense representations, making missing annotations an insurmountable obstacle. In fact, annotated datasets only contain annotations for a proper subset of the possible candidate synsets listed in WordNet. We analyze this phenomenon using four statistics:

1. *Candidate Coverage:* For each test set, we performed a lookup in WordNet to determine the unique candidate synsets of all target lemmas. We then determined what percentage of these candidate synsets that have *at least one* annotation in the annotated dataset.
2. *Lemma Coverage:* Given a target lemma in a test set, we performed a lookup in WordNet to determine the unique candidate synsets. If *all* candidate synsets of that target lemma have at least one annotation in the annotated dataset, we claim that the lemma is covered. The lemma coverage is then the percentage of all covered target lemmas. A high lemma coverage indicates that annotated dataset covers most of the meanings in the test set.
3. *Gold Coverage:* We calculate the percentage of the *correct* answers in the test set that has at least one annotation in the annotated dataset.

The column "Candidate Coverage" of Table 3 shows that SemCor only contains less than 70% of all candidate synsets for *senseval2* and *semeval2013*, meaning that a model will never have a representation

Datasets	senseval2 Candidate Coverage	senseval2 Lemma Coverage	senseval2 Gold Coverage	semeval2013 Candidate Coverage	semeval2013 Lemma Coverage	semeval2013 Gold Coverage
SemCor	63.51%	29.72%	80.92%	66.64%	28.42%	83.08%
OMSTI	29.98%	5.9%	43.82%	31.22%	5.94%	45.23%
SemCor+OMSTI	**66.26%**	**32.25%**	**81.98%**	**69.89%**	**31.83%**	**84.76%**

Table 3: Statistics about the coverage of annotated datasets in WordNet.

Competition	Model	MFS fallback	Averaging	Label propagation
senseval2	Our LSTM (T: SemCor)	0.64 (n=135)	0.66 (n=1712)	-
	Our LSTM (T: OMSTI)	0.66 (n=775)	0.56 (n=1072)	-
	Our LSTM (T: SemCor+OMSTI)	0.64 (n=135)	0.63 (n=1712)	-
	Our LSTMLP (T:SemCor, U:OMSTI)	0.64 (n=135)	0.71 (n=644)	0.61 (n=1068)
semeval2013	Our LSTM (T: SemCor)	0.39 (n=41)	0.56 (n=1262)	-
	Our LSTM (T: OMSTI)	0.58 (n=427)	0.55 (n=876)	-
	Our LSTM (T: SemCor+OMSTI)	0.40 (n=40)	0.57 (n=1263)	-
	Our LSTMLP (T:SemCor, U:OMSTI)	0.40 (n=40)	0.57 (n=397)	0.55 (n=866)

Table 4: The recall is shown for three WSD strategies and n indicates the number of instances it was actually used. The recall on all monosemous instances was 1.0 for both competitions and is hence not shown in the table. There are 435 monosemous instances in *senseval2* and 341 in *semeval2013*.

for more than 30% of the candidate synsets. Even with the addition of OMSTI, the coverage does not exceed 70%, meaning that we lack evidence for a significant number of potential annotations. Moreover, the column "Lemma Coverage" illustrates that we have evidence for all potential solutions for only 30% of the lemmas in both WSD competitions, meaning that in the large majority of the cases some solutions are never seen. The column "Gold coverage" measures whether the right answers are at least seen in the annotated dataset. The numbers illustrate that 20% of the solutions in the test sets do not have any annotations. With our approach, these answers can only be returned if the lemma is monosemous or by random guess otherwise.

To further investigate these issues, Table 4 reports the recall of the various disambiguation strategies which could be invoked depending on the coverage of the lemma (these can be: *monosemous*, *averaging*, *label propagation*, *MFS* – see the overall procedure reported in Section 3).

We observe that the MFS fallback plays a significant role in obtaining the overall high accuracy since it is invoked many times, especially with OMSTI due to the low coverage of the dataset (in this case it is invoked in 775 cases vs. 1072 of averaging). For example, if we had not applied the MFS fallback strategy for *senseval2* using SemCor as the annotated corpus, our performance would have dropped from 0.72 to 0.66, below the MFS baseline of 0.67 for this task.[5] Label propagation was indeed applied on half of the cases, but leads to lower results. From these results, we learn that the effectiveness of this method strongly depends on the coverage of the annotated datasets: If it is not high, as it is with OMSTI, then the performance of this method reduces to the one of choosing the MFS.

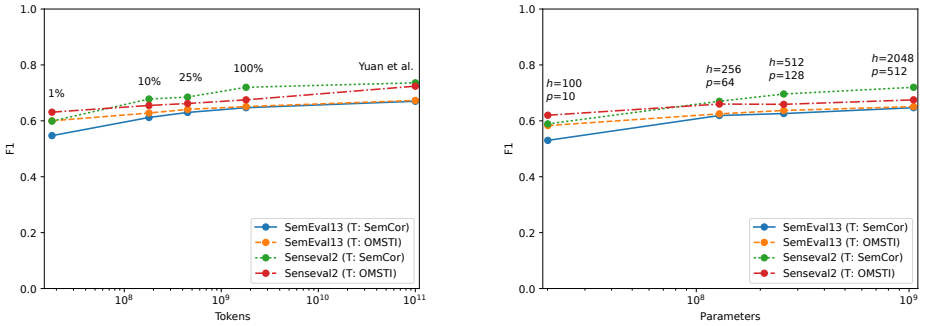
Granularity of sense representation. Rothe and Schütze (2017) provided evidence for the claim that the granularity of the sense representations has an influence on WSD performance. More in particular, their WSD system performed better when trained on sensekeys (called *lexemes* in their paper) than on synsets. Although a sensekey-based disambiguation results in less annotated data per target lemma, the sensekey representation is more precise (since it is a lemma associated with a particular meaning) than at the synset level.

The reimplementation discussed in this paper allows us to answer the question: "How will LSTM models work if we lower the disambiguation level from synset to sensekey?" Table 5 presents the results of this experiment. As we can see from the table, our method also returns better performance on both test sets. This behavior is interesting and one possible explanation is that sensekeys are more discriminative than synsets and this favors the disambiguation.

[5] *senseval2* contains 2,282 instances, of which the system would answer incorrectly 135 instances if the MFS fallback strategy is not used, hence dropping 0.06 in performance.

Model	senseval2		semeval2013	
	sensekey F_1	synset F_1	sensekey F_1	synset F_1
Our LSTM (T: SemCor)	**0.726**	**0.720**	0.661	0.647
Our LSTM (T: OMSTI)	0.688	0.675	0.655	0.651
Our LSTM (T: SemCor+OMSTI)	0.703	0.699	**0.667**	**0.656**

Table 5: Comparison of F_1 scores of our implementation using either synset or sensekey level to represent meanings.



(a) Performance vs. unannotated corpus size

(b) Performance vs. number of parameters

Figure 2: The effect of (a) the size of unannotated corpus and (b) the number of parameters on WSD performance. Number of parameters includes the weights of the hidden layer, the weights of the projection layer, and the input and output embeddings. Notice that the horizontal axis is in log scale.

Impact of unannotated data and model size. Since unannotated data is abundant, it is tempting to use more and more data to train language models, hoping that better word embeddings would translate into improved WSD performance. The fact that Yuan et al. (2016) used a 100-billion-token corpus only reinforces this intuition. We empirically evaluate the effectiveness of unlabeled data by varying the size of the corpus used to train LSTM models and measure the corresponding WSD performance. More in particular, the size of the training data was set at 1%, 10%, 25%, and 100% of the GigaWord corpus (which contains 1.8×10^7, 1.8×10^8, 4.5×10^8 and 1.8×10^9 words, respectively).

Figure 2a shows the effect of unannotated data volume on WSD performance. The data points at 100 billion (10^{11}) tokens correspond to Yuan et al. (2016)'s reported results. As might be expected, a bigger corpus leads to more meaningful context vectors and therefore higher performance on WSD. However, the amount of data needed for 1% of improvement in F_1 grows exponentially fast (notice that the horizontal axis is in log scale). Extrapolating from this graph, to get a performance of 0.8 F_1 by adding more unannotated data, one would need a corpus of 10^{12} tokens. This observation also applies to the balance of the sense assignment. Using only 25% of the unannotated data already yields a recall of 35% on the less-frequent senses.

In addition, one might expect to push the performance further by increasing the capacity of the LSTM models. To evaluate this possibility, we performed an experiment in which we varied the sizes of LSTM models trained on 100% of the GigaWord corpus and evaluated against *senseval2* and *semeval2013*, respectively. Figure 2b suggests that it is possible but one would need exponentially bigger models.

Finally, Reimers and Gurevych (2017) have showed that it is crucial to report the distribution of test scores instead of only one score as this practice might lead to wrong conclusions. As pointed out at the beginning of Section 5, our biggest models take months to train, making training multiple versions of them impractical. However, we trained our smallest model ($h = 100, p = 10$) ten times and our second smallest model ($h = 256, p = 64$) five times and observed that as the number of parameters increased, the standard deviation of F_1 decreased from 0.008 to 0.003. We, therefore, believe random fluctuation does not affect the interpretation of the results.

6 Conclusions

This paper reports the results of a reproduction study of the model proposed by Yuan et al. (2016) and an additional analysis to gain a deeper understanding of the impact of various factors on its performance.

A number of interesting conclusions can be drawn from our results. First, we observed that we do not need a very large unannotated dataset to achieve state-of-the-art all-words WSD performance since we used the Gigaword corpus, which is two orders of magnitude smaller than Yuan et al. (2016)'s proprietary corpus, and got similar performance on *senseval2* and *semeval2013*. A more detailed analysis hints that adding more unannotated data and increasing model capacity are subject to diminishing returns. Moreover, we observed that this approach has a more balanced sense assignment than other techniques, as shown by the relatively good performance on less-frequent-sense instances. In addition, we identified that the limited sense coverage in annotated dataset places a potentially upper bound for the overall performance.

The code with detailed replication instructions is available at: `https://github.com/cltl/wsd-dynamic-sense-vector` and the trained models at: `https://figshare.com/articles/A_Deep_Dive_into_Word_Sense_Disambiguation_with_LSTM/6352964`.

Acknowledgements

The research for this paper was supported by the Netherlands Organisation for Scientific Research (NWO) via the Spinoza-prize Vossen projects (SPI 30-673, 2014-2019). We thank the support of the NWO project scilens (`https://projects.cwi.nl/scilens`) for providing the hardware to run some of the experiments. Experiments were also carried out on the Dutch national e-infrastructure with the support of SURF Cooperative. We would like to thank our friends and colleagues Antske Fokkens, Emiel van Miltenburg, Chantal van Son, Pia Sommerauer, and Roxane Segers for many useful comments and discussions.

Abstract

In this paper, we present a method which learns the word embedding for readability assessment. For the existing word embedding models, they typically focus on the syntactic or semantic relations of words, while ignoring the reading difficulty, thus they may not be suitable for readability assessment. Hence, we provide the knowledge-enriched word embedding (KEWE), which encodes the knowledge on reading difficulty into the representation of words. Specifically, we extract the knowledge on word-level difficulty from three perspectives to construct a knowledge graph, and develop two word embedding models to incorporate the difficulty context derived from the knowledge graph to define the loss functions. Experiments are designed to apply KEWE for readability assessment on both English and Chinese datasets, and the results demonstrate both effectiveness and potential of KEWE.

1 Introduction

Readability assessment is a classic problem in natural language processing, which attracts many researchers' attention in recent years (Todirascu et al., 2016; Schumacher et al., 2016; Cha et al., 2017). The objective is to evaluate the readability of texts by levels or scores. The majority of recent readability assessment methods are based on the framework of supervised learning (Schwarm and Ostendorf, 2005) and build classifiers from hand-crafted features extracted from the texts. The performance of these methods depends on designing effective features to build high-quality classifiers.

Designing hand-crafted features are essential but labor-intensive. It is desirable to learn representative features from the texts automatically. For document-level readability assessment, an effective feature learning method is to construct the representation of documents by combining the representation of the words contained (Kim, 2014). For the representation of word, a useful technique is to learn the word representation as a dense and low-dimensional vector, which is called word embedding. Existing word embedding models (Collobert et al., 2011; Mikolov et al., 2013; Pennington et al., 2014) can be used for readability assessment, but the effectiveness is compromised by the fact that these models typically focus on the syntactic or semantic relations of words, while ignoring the reading difficulty. As a result, words with similar functions or topics, such as "man" and "gentleman", are mapped into close vectors although their reading difficulties are different. It calls for incorporating the knowledge on reading difficulty when training the word embedding.

In this paper, we provide the knowledge-enriched word embedding (KEWE) for readability assessment, which encodes the knowledge on reading difficulty into the representation of words. Specifically, we define the word-level difficulty from three perspectives, and use the extracted knowledge to construct a knowledge graph. After that, we derive the difficulty context of words from the knowledge graph, and develop two word embedding models to incorporate the difficulty context to define the loss functions.

We apply KEWE for document-level readability assessment under the supervised framework. The experiments are conducted on four datasets of either English or Chinese. The results demonstrate that

our method can outperform other well-known readability assessment methods, and the classic text-based word embedding models on all the datasets. By concatenating our knowledge-enriched word embedding with the hand-crafted features, the performance can be further improved.

The rest of the paper is organized as follows. Section 2 provides the related work for readability assessment. Section 3 describes the details of KEWE. Section 4 presents the experiments and results. Finally Section 5 concludes the paper with future work.

2 Related Work

In this section, we briefly introduce three research topics relevant to our work: readability assessment, word embedding, and graph embedding.

Readability Assessment. The researches on readability assessment have a relatively long history from the beginning of last century (Collinsthompson, 2014). Early studies mainly focused on designing readability formulas to evaluate the reading scores of texts. Some of the well-known readability formulas include the SMOG formula (McLaughlin, 1969), the FK formula (Kincaid et al., 1975), and the Dale-Chall formula (Chall, 1995). At the beginning of the 21th century, supervised approaches have been introduced and then explored for readability assessment (Si and Callan, 2001; Collins-Thompson and Callan, 2004; Schwarm and Ostendorf, 2005). Researchers have focused on improving the performance by designing highly effective features (Pitler and Nenkova, 2008; Heilman et al., 2008; Feng et al., 2010; Vajjala and Meurers, 2012) and employing effective classification models (Heilman et al., 2007; Kate et al., 2010; Ma et al., 2012; Jiang et al., 2015; Cha et al., 2017). While most studies are conducted for English, there are studies for other languages, such as French (François and Fairon, 2012), German (Hancke et al., 2012), Bangla (Sinha et al., 2014), Basque (Gonzalez-Dios et al., 2014), Chinese (Jiang et al., 2014), and Japanese (Wang and Andersen, 2016).

Word Embedding. Researchers have proposed various methods on word embedding, which mainly include two broad categories: neural network based methods (Bengio et al., 2003; Collobert et al., 2011; Mikolov et al., 2013) and co-occurrence matrix based methods (Turney and Pantel, 2010; Levy and Goldberg, 2014b; Pennington et al., 2014). Neural network based methods learn word embedding through training neural network models, which include NNLM (Bengio et al., 2003), C&W (Collobert and Weston, 2008), and word2vec (Mikolov et al., 2013). Co-occurrence matrix based methods learn word embedding based on the co-occurrence matrices, which include LSA (Deerwester, 1990), Implicit Matrix Factorization (Levy and Goldberg, 2014b), and GloVe (Pennington et al., 2014). Besides the general word embedding learning methods, researchers have also proposed methods to learn word embedding to include certain properties (Liu et al., 2015; Shen and Liu, 2016) or for certain domains (Tang et al., 2014; Ren et al., 2016; Alikaniotis et al., 2016; Wu et al., 2017).

Graph embedding. Graph embedding aims to learn continuous representations of the nodes or edges based on the structure of a graph. The graph embedding methods can be classified into three categories (Goyal and Ferrara, 2017): factorization based (Roweis and Saul, 2000; Belkin and Niyogi, 2001), random walk based (Perozzi et al., 2014; Grover and Leskovec, 2016), and deep learning based (Wang et al., 2016). Among them, the random walk based methods are easy to comprehend and can effectively reserve the centrality and similarity of the nodes. Deepwalks (Perozzi et al., 2014) and node2vec (Grover and Leskovec, 2016) are two representatives of the random walk based methods. The basic idea of Deepwalk is viewing random walk paths as sentences, and feeding them to a general word embedding model. node2vec is similar to Deepwalk, although it simulates a biased random walk over graphs, and often provides efficient random walk paths.

3 Learning Knowledge-Enriched Word Embedding for Readability Assessment

In this section, we present the details of Knowledge-Enriched Word Embedding (KEWE) for readability assessment. By incorporating the word-level readability knowledge, we extend the existing word embedding model and design two models with different learning structures. As shown in Figure 1, the above one is the knowledge-only word embedding model (KEWE_k) which only takes in the domain knowledge,

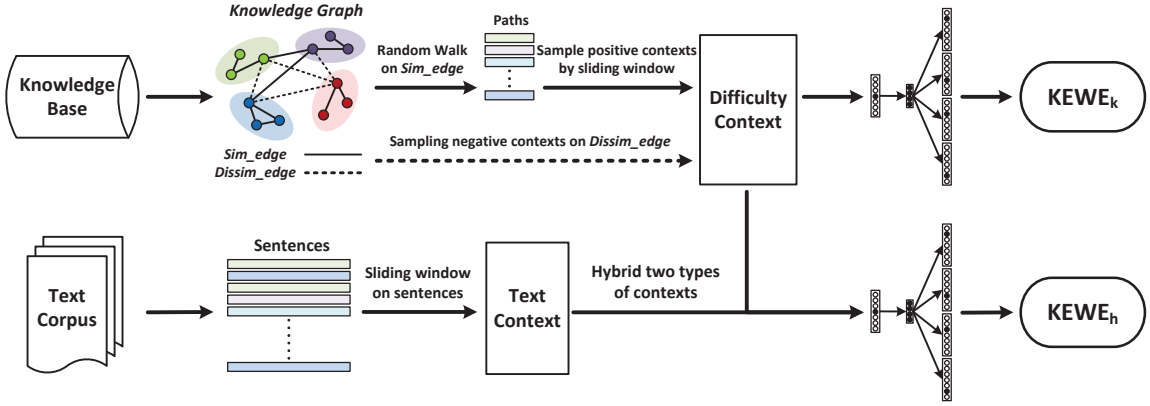

Figure 1: Illustration of the knowledge-enriched word embedding models. KEWE$_k$ is based on the difficulty context, while KEWE$_h$ is based on both the difficulty and text contexts.

the other is the hybrid word embedding model (KEWE$_h$) which compensates the domain knowledge with text corpus.

3.1 The Knowledge-only Word Embedding Model (KEWE$_k$)

In the classic word embedding models, such as C&W, CBOW, and Skip-Gram, the context of a word is represented by its surrounding words in the text corpus. Levy and Goldberg (2014a) have incorporated the syntactic context from the dependency parse-trees and found that the trained word embedding could capture more functional and less topical similarity. For readability assessment, reading difficulty other than function or topic becomes more important. Hence, we introduce a kind of difficulty context, and try to learn a difficulty-focusing word embedding, which leads to KEWE$_k$. In the following, we describe this model in three steps: domain knowledge extraction, knowledge graph construction, and graph-based word embedding learning. The former two steps focus on modeling the relationship among words on reading difficulty, and the final step on deriving the difficulty context and learning the word embedding.

3.1.1 Domain Knowledge Extraction

To model the relationship among words on reading difficulty, we first introduce how to extract the knowledge on word-level difficulty from different perspectives. Specifically, we consider three types of word-level difficulty: acquisition difficulty, usage difficulty, and structure difficulty.

Acquisition difficulty. Word acquisition refers to the temporal stage at which children learn the meaning of new words. Researchers have shown that the information on word acquisition is useful for readability assessment (Kidwell et al., 2009; Schumacher et al., 2016). Generally, the words acquired at primary school are easier than those acquired at high school. We call the reading difficulty reflected by word acquisition as the acquisition difficulty. Formally, given a word w, its acquisition difficulty is described by a distribution K_w^A over the age-of-acquisition (AoA) (Kidwell et al., 2009).

Since the rating on AoA is an unsolved problem in cognitive science (Brysbaert and Biemiller, 2016) and not available for many languages, we explore extra materials to describe the acquisition difficulty. In particular, we collect three kinds of knowledge teaching materials, i.e., in-class teaching material, extra-curricular teaching material, and proficiency test material. These materials are arranged as lists of words, each of which contains words learned in the same time period and hence corresponds to a certain level of acquisition difficulty. For example, given a lists of words, we can define $K_w^A \in \mathbb{R}^a$, where $K_{w,i}^A = 1$ if a word w belongs to the list i, and $K_{w,i}^A = 0$ otherwise.

Usage difficulty. Researchers used to count the usage frequency to measure the difficulty of words (Dale and Chall, 1948), which can separate the words which are frequently used from those rarely used. We call the difficulty reflected by usage preference as the usage difficulty. Formally, given a word w, its usage difficulty is described by a distribution K_w^U over the usage preferences.

We provide two ways to measure the usage difficulty. One way is estimating the level of words'

usage frequency by counting the word frequency lists from the text corpus. The other way is estimating the probability distribution of words over the sentence-level difficulties, which is motivated by Jiang et al. (2015). Usage difficulty is defined on both. By discretizing the range of word frequency into b intervals of equal size, the usage frequency level of a word w is i, if its frequency resides in the ith intervals. By estimating the probability distribution vector P_w from sentence-level difficulties, we can define $K_w^U \in \mathbb{R}^{1+|P_w|}$, and $K_{w,i}^U = [i, P_w]$.

Structure difficulty. When building readability formulas, researchers have found that the structure of words could imply its difficulty (Flesch, 1948; Gunning, 1952; McLaughlin, 1969). For example, words with more syllables are usually more difficult than words with less syllables. We call the difficulty reflected by structure of words as the structure difficulty. Formally, given a word w, its structure difficulty can be described by a distribution K_w^S over the word structures.

Words in different languages may have their own special structural characteristics. For example, in English, the structural characteristics of words relate to syllables, characters, affixes, and subwords. Whereas in Chinese, the structural characteristics of words relate to strokes and radicals of Chinese characters. Here we use the number of syllables (strokes for Chinese) and characters in a word w to describe its structure difficulty. By discretizing the range of each number into intervals, K_w^S is obtained by counting the interval in which w resides, respectively.

3.1.2 Knowledge Graph Construction

After extracting the domain knowledge on word-level difficulty, we then quantitatively represent the knowledge by a graph. We define the knowledge graph as an undirected graph $G = (V, E)$, where V is the set of vertices, each of which represents a word, and E is the set of edges, each of which represents the relation (i.e., similarity) between two words on difficulty. Each edge $e \in E$ is a vertex pair (w_i, w_j) and is associated with a weight z_{ij}, which indicates the strength of the relation. If no edge exists between w_i and w_j, the weight $z_{ij} = 0$. We define two edge types in the graph: *Sim_edge* and *Dissim_edge*. The former indicates that its end words have similar difficulty and is associated with a positive weight. The latter indicates that its end words have significant different difficulty and is associated with a negative weight. We derived the edges from the similarities computed between pairs of the words' knowledge vectors. Formally, given the extracted knowledge vector $K_w = [K_w^A, K_w^U, K_w^S]$ of a word w, E can be constructed using the similarity between pairs of words (w_i, w_j) as follows:

$$z_{ij} = \begin{cases} sim(K_{w_i}, K_{w_j}) & w_j \in \mathcal{N}_p(w_i) \\ -sim(K_{w_i}, K_{w_j}) & w_j \in \mathcal{N}_n(w_i) \\ 0 & otherwise \end{cases} \quad (1)$$

where $sim()$ is a similarity function (e.g., cosine similarity), $\mathcal{N}_p(w_i)$ refers to the set of k most similar (i.e., greatest similarity) neighbors of w_i, and $\mathcal{N}_n(w_i)$ refers to the set of k most dissimilar (i.e., least similarity) neighbors of w_i.

3.1.3 Knowledge Graph-based Word Embedding

After constructing the knowledge graph, which models the relationship among words on difficulty, we can derive the difficulty context from the graph and train the word embedding focused on reading difficulty. For the graph-based difficulty context, given a word w, we define its difficulty context as the set of other words that have relevance to w on difficulty. Specifically, we define two types of difficulty context, positive context and negative context, corresponding to the two types of edges in the knowledge graph (i.e., *Sim_edge* and *Dissim_edge*).

Unlike the context defined on texts, which can be sampled by sliding windows over consecutive words, the context defined on a graph requires special sampling strategies. Different sampling strategies may define the context differently. For difficulty context, we design two relatively intuitive strategies, the random walk strategy and the immediate neighbors strategy, for the sampling of either positive or negative context.

From the type *Sim_edge*, we sample the positive target-context pairs where the target word and the context words are similar on difficulty. Since the similarity is generally transitive, we adopt the random

walk strategy to sample the positive context. Following the idea of node2vec (Grover and Leskovec, 2016), we sample the positive contexts of words by simulating a 2^{nd} order random walk on the knowledge graph with only *Sim_edge*. After that, by applying a sliding window of fixed length s over the sampled random walk paths, we can get the positive target-context pairs $\{(w_t, w_c)\}$.

From the type *Dissim_edge*, we sample the negative target-context pairs where the target word and the context words are dissimilar on difficulty. Since dissimilarity is generally not transitive, we adopt the immediate neighbor strategy to sample the negative context. Specifically, on the knowledge graph with only *Dissim_edge*, we collect the negative context from the immediate neighbors of the target node w_t and get the negative context list $C_n(w_t)$.

By replacing the text-based linear context with our graph-based difficulty context, we can train the word embedding using the classic word embedding models, such as C&W, CBOW, and Skip-Gram. Here we use the Skip-Gram model with Negative Sampling (SGNS) proposed by Mikolov et al. (2013). Specifically, given N positive target-context pairs (w_t, w_c) and the negative context list of the target word $C_n(w_t)$, the objective of KEWE$_k$ is to minimize the loss function $\mathcal{L}_k$, which is defined as follows:

$$\mathcal{L}_k = -\frac{1}{N} \sum_{(w_t, w_c)} \Big[\log \sigma(\mathbf{u}_{w_c}^\top \mathbf{v}_{w_t}) + \mathbb{E}_{w_i \in C_n(w_t)} \log \sigma(-\mathbf{u}_{w_i}^\top \mathbf{v}_{w_t}) \Big] \tag{2}$$

where $\mathbf{v}_w$ and $\mathbf{u}_w$ are the "input" and "output" vector representation of w, and σ is the sigmoid function defined as $\sigma(x) = \frac{1}{(1+e^{-x})}$. This loss function enables the positive context (e.g., w_c) to be distinguished from the negative context (e.g., w_i).

3.2 The Hybrid Word Embedding Model (KEWE$_h$)

The classic text-based word embedding models yield word embedding focusing on syntactic and semantic contexts, while ignoring the word difficulty. By contrast, KEWE$_k$ trains the word embedding focusing on the word difficulty, while leaving out the syntactic and semantic information. Since readability may also relate to both syntax and semantics, we develop a hybrid word embedding model (KEWE$_h$), to incorporate both domain knowledge and text corpus. The loss function of the hybrid model $\mathcal{L}_h$ can be expressed as follows:

$$\mathcal{L}_h = \lambda \mathcal{L}_k + (1 - \lambda) \mathcal{L}_t \tag{3}$$

where $\mathcal{L}_k$ is the loss of predicting the knowledge graph-based difficulty contexts, $\mathcal{L}_t$ is the loss of predicting the text-based syntactic and semantic contexts, and $\lambda \in [0, 1]$ is a weighting factor. Clearly, the case of $\lambda = 1$ reduces the hybrid model to the knowledge-only model.

As there are many text-based word embedding models, the text-based loss $\mathcal{L}_t$ can be defined in various ways. To be consistent with KEWE$_k$, we formalize $\mathcal{L}_t$ based on the Skip-Gram model. Given a text corpus, the Skip-Gram model aims to find word representations that are good at predicting the context words. Specifically, given a sequence of training words, denoted as $w_1, w_2, \cdots, w_T$, the objective of Skip-Gram model is to minimize the log loss of predicting the context using target word embedding, which can be expressed as follows:

$$\mathcal{L}_t = -\frac{1}{T} \sum_{t=1}^{T} \sum_{-s \le j \le s, j \neq 0} \log p(w_{t+j} | w_t) \tag{4}$$

where s is the window size of the context sampling. Since the full softmax function used to define $p(w_{t+j}|w_t)$ is computationally expensive, we employ the negative sampling strategy (Mikolov et al., 2013) and replace every $\log p(w_c|w_t)$ in $\mathcal{L}_t$ by the following formula:

$$\log p(w_c | w_t) = \log \sigma(\mathbf{u}_{w_c}^\top \mathbf{v}_{w_t}) + \sum_{i=1}^{k} \mathbb{E}_{w_i \sim P_n(w)} \log \sigma(-\mathbf{u}_{w_i}^\top \mathbf{v}_{w_t}) \tag{5}$$

where $\mathbf{v}_w$, $\mathbf{u}_w$, and σ are of the same meanings as in Eq. 2, k is the number of negative samples, and $P_n(w)$ is the noise distribution. This strategy enables the actual context w_c to be distinguished from the noise context w_i drawn from the noise distribution $P_n(w)$.

3.3 Model Training

We adopt the stochastic gradient descent to train our models. Specifically, for the hybrid model (KEWE$_h$), we adopt the mini-batch mode used in (Yang et al., 2016). Firstly, we sample a batch of random walk paths of size N_1 and take a gradient step to optimize the loss function $\mathcal{L}_k$. Secondly, we sample a batch of text sentences of size N_2 and take a gradient step to optimize the loss function $\mathcal{L}_t$. We repeat the above procedures until the model converged or the predefined number of iterations is reached. The ratio $\frac{N_1}{N_1+N_2}$ is used to approximate the weighting factor λ in Eq. 3. For training the knowledge-only model, the process is the same without $\mathcal{L}_t$ and λ.

3.4 Readability Assessment

We apply KEWE for document-level readability assessment under a supervised learning framework proposed by Schwarm and Ostendorf (2005). The classifier for readability assessment is built on documents with annotated reading levels. Instead of using the hand-crafted features, we use the word embedding to produce the features of documents.

To extract high level features from documents using word embedding, we design the max layer similar to the one used in the convolutional sentence approach proposed by Collobert et al. (Collobert et al., 2011). The max layer is used to generate a fix-size feature vector from variant length sequences. Specifically, given a document represented by a matrix $M \in \mathbb{R}^{m \times n}$, where the kth column is the word embedding of the kth word in the document, the max layer output a vector $f_{max}(M)$:

$$[f_{max}(M)]_i = \max_t [M]_{i,t} \qquad 1 \leq i \leq m \tag{6}$$

where $t = \{1, 2, \ldots, n\}$ represents "time" of a sequence, and m is the dimension of embedding vectors. Besides the max layer, the min and $average$ layers are also used to extract features. By concatenating all three feature vectors, we get the final feature vector $f(M)$ of the document M as follows, which can be fed to the classifier for readability assessment.

$$f(M) = [f_{max}(M), f_{min}(M), f_{avg}(M)] \tag{7}$$

4 Experiments

In this section, we conduct experiments based on four datasets of two languages, to investigate the following two research questions:

RQ1: Whether KEWE is effective for readability assessment, compared with other well-known readability assessment methods, and other word embedding models?

RQ2: What are the effects of the quality of input (i.e., the quality of the knowledge base and text corpus) and the hybrid ratio (i.e., the weighting factor λ) on the prediction performance of KEWE?

4.1 The Datasets and Knowledge Base

The experiments are conducted on four datasets, including two English datasets: ENCT and EHCT, two Chinese datasets: CPT and CPC. ENCT, CPT (Jiang et al., 2015), and EHCT are extracted from textbooks [1], where the documents have already been leveled into grades; CPC is extracted from the students' compositions [2] written by Chinese primary school students, where the documents are leveled by the six grades of authors. EHCT is collected from the English textbooks of Chinese high schools and colleges, which contains 4 levels corresponding to the 3 grades of high school plus undergraduates. The details of the four datasets are shown in Table 1.

Since the experiments are conducted on two languages, we collect the knowledge bases for both English and Chinese, which are used for extracting domain knowledge and constructing the knowledge graphs, as described in Section 3.1. The details are shown in Table 2.

4.2 Experiment Settings

For readability assessment, we design experiments on the four datasets using the hold-out validation, which randomly divides a dataset into training and test sets by stratified sampling. The test ratio is set as 0.3. To reduce randomness, under each case, 100 rounds of hold-out validations are performed, and the average results are reported. To tune the hyper-parameters, we randomly choose three-tenths of the training set as development set. We choose three widely used metrics (Jiang et al., 2014): Accuracy (Acc), Adjacent Accuracy ($\pm$Acc) and Pearson's Correlation Coefficient (PCC), to measure the performance on readability assessment.

For the training of word embedding, we use all the sentences in the target dataset as the training corpus (denote as the internal corpus), to ensure sufficient word coverage. To avoid mixing the level information into the internal corpus, we shuffle the sentences in it before feeding to the model. For the hyper-parameters of text-based word embedding, we set the dimension as 300, the window size as 5, the number of negative samples as 5, and the iteration number as 5. For KEWE, the default length of random walk path is set as 80 (Grover and Leskovec, 2016). k and λ are tuned using the development set.

4.3 Comparison with Other Methods

To address RQ1, we firstly compare KEWE with the following readability assessment methods:

- SMOG (McLaughlin, 1969) and FK (Kincaid et al., 1975) are two widely-used readability formulas.
- SUM (Collins-Thompson and Callan, 2004) is a smoothed unigram model.
- HCF is the hand-crafted feature based method. For English and Chinese, we employ the state-of-the-art feature set proposed by Vajjala and Meurers (2012) and Jiang et al. (2014) respectively.
- BOW refers to the bag-of-words model.

For the feature-based methods (i.e., HCF, BOW, and KEWE), we use both Logistic Regression (LR) and Random Forest (RF) as the classifiers for readability assessment . Table 3 lists the performance measures of all these methods on four datasets. The value marked in bold in each column refers to the maximum (best) measures acquired by the methods on each dataset by certain metric.

From Table 3, we can see that the performances of readability formulas (SMOG and FK) are not good on all the datasets, except the adjacent accuracies on ENCT. The smoothed unigram model (SUM) outperforms SOMG and FK on all the datasets, and on EHCT, its accuracy is only slightly inferior to KEWE$_h$. HCF performs the best among methods other than KEWE. Even compared with KEWE, it achieves the best performance on CPC and the best adjacent accuracy on ENCT. KEWE is only slightly inferior to HCF in four columns, but outperforms all the other methods in the other eight columns.

Table 4: Performance comparison between KEWE and other word embedding models

Overall, KEWE is competitive for readability assessment. In addition, by combining KEWE with the hand-crafted feature set of HCF, the performance can be further improved in many columns.

Secondly, we compare KEWE with other text-based word embedding models for readability assessment. These models include NNLM (Bengio et al., 2003), C&W (Collobert and Weston, 2008), GloVe (Pennington et al., 2014), CBOW and Skip-Gram (SG) (Mikolov et al., 2013). Random embedding (Random) and knowledge vectors from the three perspectives (KV) are also used as baselines. All the text-based models mentioned are trained on the four datasets respectively. Table 4 lists the results of applying word embedding for readability assessment using Random Forest as the classifier. From Table 4, the model KEWE$_h$ gets the best performance among all the embedding baselines, including SG+KV, which also takes in both knowledge and text corpus. The results demonstrate the superiority of hybridizing the knowledge graph and text corpus to learn the representation of words.

4.4 Model Analysis

To address RQ2, we analyze the effects of the knowledge graph, the text corpus, and the hybrid ratio on the performance of KEWE. Firstly, we study the impacts of the knowledge graph on the performance of KEWE$_k$. Specifically, we study the following three parameters of the knowledge graph: the knowledge vectors generated from the three word-level difficulties (i.e., acquisition difficulty, usage difficulty, and structure difficulty), the similarity function (i.e., $sim()$), and the number of neighbors of each node in the knowledge graph (i.e., k). Figure 2 shows the performance measures of using each of the three

knowledge vectors respectively in bar chart. It can be found that the acquisition difficulty outperforms the other two on all four datasets. By combining the three knowledge vectors, the performance can be further improved. Figure 3 shows the performance measures of using different similarity functions and different values of k in line charts. It can be found that the knowledge graphs achieve a relatively good performance, when the cosine similarity is used and k is close to 50 or 100.

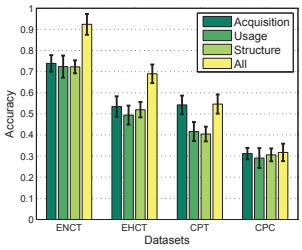

Figure 2: The performance of KEWE$_k$ using different types of knowledge vectors

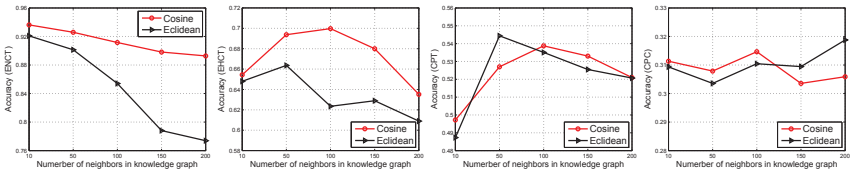

Figure 3: The performance of KEWE$_k$ using knowledge graphs with different similarity functions and neighbor numbers

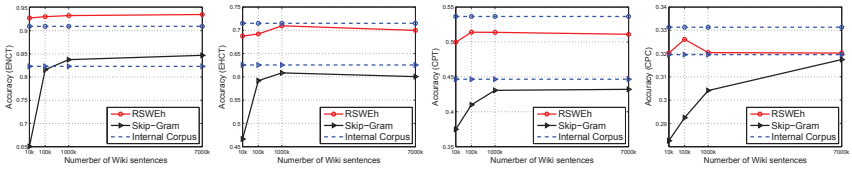

Figure 4: The performance of KEWE$_h$ using different volumes of external corpus

Secondly, we study the impacts of using external corpus on the performance of KEWE$_h$. To learn text-based word embedding for both languages, we collect the external corpus from both English Wikipedia (Ewiki) and Chinese Wikipedia (Cwiki). After preprocessing, Ewiki contains $7M$ sentences and $172M$ words, and Cwiki contains $7.4M$ sentences and $160M$ words. We sample different number of sentences from the corpus for training word embedding, and then measure the performance of KEWE$_h$ on readability assessment. Figure 4 shows the performance measures by using different volumes of external corpus in line charts, with Skip-Gram trained for comparison. Both models are also trained using the internal corpus, and the performance measures (dotted lines) are depicted as baselines. From Figure 4, it can be found that the performance of both Skip-Gram and KEWE$_h$ increases as the volume of external corpus increases, and keeps stable when the corpus is large enough. Besides, on English datasets, word embedding trained using external corpus achieves comparable performance with that using internal corpus. The above suggests that external corpus is a good substitution for the internal corpus, especially on English datasets, and a relative large volume of corpus is required to achieve stable performance.

Finally, we study the impacts of the weighting factor λ on the performance of KEWE$_h$. Since λ is approximated by $N_1/(N_1+N_2)$ in our model, we vary λ from 0 to 1 by setting $N_1+N_2=100$ and then varying N_1 from 0 to 100 stepping by 10. Figure 5 shows the performance of KEWE$_h$ with varied λ in line charts with error bars, where $\lambda=0$ and 1 correspond to Skip-Gram and KEWE$_k$ respectively. From Figure 5, it can be found that KEWE$_h$ can outperform its base models (i.e., KEWE$_k$ and Skip-Gram), by setting λ with a suitable value near the base model which performs better. However, it requires further study to find a suitable λ for training KEWE$_h$.

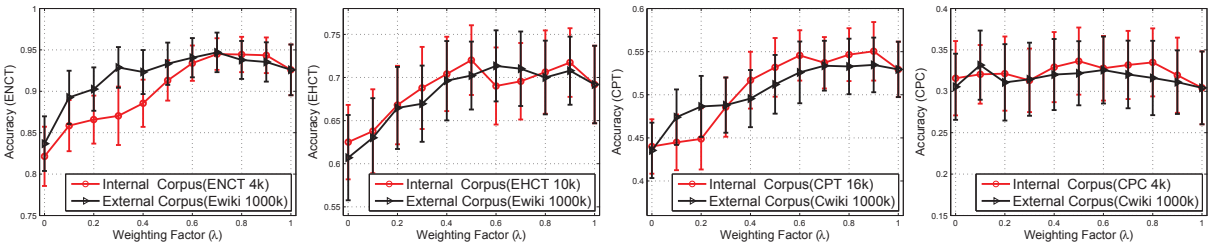

Figure 5: The performance of KEWE$_h$ with varied weighting factor λ

4.5 Error Analysis

To better understand our method, we perform error analysis on the classification results. We mainly describe two sources of errors: word representation failure and word order capturing failure. From the perspective of word representation, the classification error is caused by the fact that the difficulty information may not be properly encoded into the word embedding. Table 4 shows that KEWE performs better than the classical text-based word embeddings in encoding difficulty information into representation, but in the final results there still exists the failure of word representation in KEWE. From the perspective of word order capturing, the classification error is caused by the fact that the order among words may be neglected, so that the syntactic difficulty, pragmatic difficulty, and discourse difficulty of documents are ignored during the process of readability assessment. Table 3 shows that KEWE$_h$ can be further improved by combining with the features related to the word order (i.e., HCF+KEWE$_h$), which means that there exists the failure of word order capturing in KEWE. These two kinds of error sources reveal the limitation of our method. In future work, the neural network accompanied with word embedding is a good alternative, which can produce better representation of documents.

5 Conclusion

In this paper, we propose the knowledge-enriched word embedding (KEWE) for readability assessment. We extract the domain knowledge on word-level difficulty from three different perspectives and construct a knowledge graph. Based on the difficulty context derived from the knowledge graph, we develop two word embedding models (i.e., KEWE$_k$ and KEWE$_h$). The experimental results on English and Chinese datasets demonstrate that KEWE can outperform other well-known readability assessment methods, and the classic text-based word embedding models. Future work is planned to involve extra datasets and additional word embedding strategies so that the soundness of KEWE can be further approved.

Abstract

The exponential increase in the usage of Wikipedia as a key source of scientific knowledge among the researchers is making it absolutely necessary to metamorphose this knowledge repository into an integral and self-contained source of information for direct utilization. Unfortunately, the references which support the content of each Wikipedia entity page, are far from complete. Why are the reference section ill-formed for most Wikipedia pages? Is this section edited as frequently as the other sections of a page? Can there be appropriate surrogates that can automatically enhance the reference section? In this paper, we propose a novel two step approach – **WikiRef** – that (i) leverages the wikilinks present in a scientific Wikipedia target page and, thereby, (ii) recommends highly relevant references to be included in that target page appropriately and automatically borrowed from the reference section of the wikilinks. In the first step, we build a classifier to ascertain whether a wikilink is a potential source of reference or not. In the following step, we recommend references to the target page from the reference section of the wikilinks that are classified as potential sources of references in the first step. We perform an extensive evaluation of our approach on datasets from two different domains – Computer Science and Physics. For Computer Science we achieve a notably good performance with a *precision@1* of 0.44 for reference recommendation as opposed to 0.38 obtained from the most competitive baseline. For the Physics dataset, we obtain a similar performance boost of 10% with respect to the most competitive baseline.

1 Introduction

Wikipedia, the largest online encyclopedia, is a collaborative work of 33,778,487 users and 1,210 admins, with 5,662,889 English articles and a total of 45,132,517 articles in more than 250 languages as of June 7, 2018[1]. Introduced in 2001, it has become one of the most visited websites having global Alexa Rank – 5[2]. Each Wikipedia article contains a rich collection of concepts along with a set of hyperlinks associating crucial terms to other wiki pages (termed as wikilinks), which makes the article more comprehensive. In addition, the ability to edit the entity pages easily with proper source citations and to view the edits reflected in the pages timely are some of the key reasons behind Wikipedia's growth and popularity. As a consequence, Wikipedia has become a destination of all kinds of information about

[1] https://en.wikipedia.org/wiki/Wikipedia:Size_of_Wikipedia
[2] http://www.alexa.com/siteinfo/www.wikipedia.org

Proceedings of the 27th International Conference on Computational Linguistics, pages 379–389
Santa Fe, New Mexico, USA, August 20-26, 2018.

entities and events. Further, Wikipedia is being widely utilized by many applications focused on entity linking and disambiguation (Moro et al., 2014; Hachey et al., 2013; Cucerzan, 2007; Hoffart et al., 2011), named entity disambiguation (Cucerzan, 2007; Barrena et al., 2015), semantic similarity (Gabrilovich and Markovitch, 2007; Wu and Giles, 2015), information extraction (Wu and Weld, 2010) etc.

What is lacking? Nevertheless, there are different competing opinions among the researchers regarding the reliability, integrity and usage of Wikipedia as an authentic source of scientific information. While many researchers consider Wikipedia as a valuable resource, others question the accuracy, comprehensiveness and completeness of the articles. For instance, according to Gorman (2007), Wikipedia is an "unethical resource unworthy of our respect" whereas Orlowski (2005) questions that the technology which makes Wikipedia possible is not a substitute for expert editors, and poor writing will remain unavoidable without any expertise. Chesney (2006) conducted an experiment to evaluate the credibility of Wikipedia and found that the studies focusing only on history articles provide mixed evidence concerning its accuracy. The general solution is to post-process the edits done by the users. In order to ensure the accuracy and quality of writing of articles, Wikipedia has imposed a new policy of requiring senior editors to approve changes to articles.

Even then, the completeness of the article is not fully ensured. Not all Wikipedia pages referring to entities (entity pages) are comprehensive: relevant information can either be missing or added with a delay. In addition, the frequency of editing of different sections in a given Wikipedia article varies extensively. For instance, frequency of editing text is higher than frequency of editing wikilinks or references; also add/edit references is considered as the hardest task[3]. This opens up the requirement for an automated system which increases the number of relevant references by either processing the content of the target article itself or by appropriately collating references from alternative sources so as to make the overall information content of the article more complete.

State-of-the-art: Efforts have been made by the researchers to populate Wikipedia pages automatically. Sauper and Barzilay (2009) propose an approach for populating Wikipedia pages with content coming from external sources by automatically generating whole entity pages for specific entity classes. Taneva and Weikum (2013) propose an approach to generate novel summaries from the external information which could be added to Wikipedia entity pages. Balog and Ramampiaro (2013) and Balog et al. (2013) try to recommend news citations for an entity in Wikipedia. West et al. (2014) focuses on the problem of knowledge base completion, through question answering and tries to complete missing facts in Freebase based on templates. All these works significantly rely on high quality input sources which are utilized to extract textual facts for Wikipedia page population. In one of the recent works, Fetahu et al. (2015) propose a two-stage supervised approach for suggesting news articles corresponding to entity pages. Attempt has also been made to introduce appropriate wikilinks automatically (İkıkat et al., 2015). In a similar line, Raganato et al. (2016) present the automatic construction and evaluation of a Semantically Enriched Wikipedia (SEW) in which the overall number of wikilinks has been more than tripled. Efforts have also been made to generate Wikipedia articles of named entities in a semi-supervised framework (Pochampally et al., 2016).

Motivation: Recently, with the increasing number of scientific articles and with the need for getting an overall view of a particular scientific topic within a very less amount of time, researcher's tendency of referring to the Wikipedia pages instead of going through a set of very specific scientific articles is massively increasing. Given that, such a huge community of researchers rely on Wikipedia for scientific information, it becomes absolutely necessary to deeply focus on the completeness of the Wikipedia articles which talk about some scientific topics.

In the following we enlist some initial observations to show that there is a huge scope of improvement of the scientific Wikipedia articles through the inclusion of a proper set of references. Figure 1 illustrates the snapshot of the reference section of the 'Bigram' page[4] in the year 2018. There are only five references present in the page; very relevant scientific articles like, "Statistical Identification of Language" (Dunning, 1994), "Foundations of Statistical Natural Language Processing" (Manning and

[3] https://www.mediawiki.org/wiki/Editing_Tasks_Survey

[4] https://en.wikipedia.org/wiki/Bigram

Schütze, 1999), etc. are missing, without which the article seems to be incomplete. Also from the survey conducted by wikimedia [5] it has been observed that adding or editing the reference section is harder compared to adding or editing simple text or a wikilink which therefore leads to much less frequent changes of the reference section. In order to further confirm this trend, we conduct an analysis on the edit history of 1120 Wikipedia articles from the Computer Science category and observe that till Jan, 2017 on average around 65% edits are in the text content, 32% are wikilink edits and strikingly only 1% are reference edits. Rest correspond to table, template and category edits etc. We present some example Wikipedia articles along with the statistic of their edit history in Table 1. Clearly, all these observations point to the requirement of an automated reference recommendation system to keep the reference section of a scientific Wikipedia article up-to-date.

What we envisage? Motivated by the fact that wikilink edits are less hard and more frequent compared to reference edits, a natural question that arises is that whether it is possible to develop an automatic procedure to add a set of references whenever there is a wikilink edit on a target page. In this paper, we investigate the possibility of enriching the reference section of a scientific Wikipedia article using the wikilinks present in the article as a surrogate. In particular, *we introduce the novel idea of reference inheritance from the source pages pointed to by the wikilinks present on the target page to populate the reference section of the target page with relevant references*.

For this study, we consider 3842 target Wikipedia pages (till June, 2017) from the Computer Science domain. In order to show that our method is quite generic, we also consider an additional dataset comprising 2871 target Wikipedia pages (till February, 2018) from the Physics domain.

We propose a novel two step approach as follows. In the first step, *we determine the potential wikilinks from which references could be inherited*. In the second step, *we recommend the most relevant references from the potential wikilinks obtained in the first step*.

Key contributions: In summary, we make the following contributions:

a) *Novel problem formulation*: We formulate and address the problem of automatically populating the reference section by inheriting the references from the wikilinks present in a target scientific Wikipedia article.

b) *The two step approach*: We propose a two-step reference recommendation system and show its advantage over simple baselines that do not implement the first step of potential wikilink selection from which

[5] https://commons.wikimedia.org/wiki/File:WMF_editing_tasks_survey_July_2015.pdf

references could be inherited.
c) *Evaluation*: We perform extensive experiments to evaluate our system. We evaluate in two different ways - first, by comparing our recommendations with the references already present on the target page (acting as a ground-truth) and second, through human judgement where experts are tasked to judge the appropriateness of the recommended references. For the automatic evaluation we obtain a *precision@1* of 0.44 for the Computer Science dataset compared to 0.38 obtained for the most competitive baseline. For the Physics dataset we obtain a similar performance boost of 10% over the best baseline. Human judgement experiments show that the average Spearman's rank correlation coefficient (ρ) between the ranked list returned by WikiRef and the one produced by averaging the responses of the annotators is **0.203** compared to 0.168 obtained for the most competitive baseline[6].

2 Problem formulation

Let us assume that we have a scientific Wikipedia article A (i.e., target) whose reference section we wish to populate using a set of relevant references. As an input we use only the text content and wikilinks present in A. Suppose, A has a set of n wikilinks $B_1, B_2, \ldots, B_n$ which in this case simply correspond to the n Wikipedia source articles from which A could possibly inherit the references. We assume that while the reference sections of the individual source pages themselves may not be "well populated", together the reference sections of all the source articles may provide a potential set of references, relevant to A. We divide this task in two major steps. First, we obtain the wikilinks (i.e., a set of Bs) that are appropriate for inheriting references from. We pose this as a binary classification problem thus dividing the set of Bs in those that are relevant (appropriate for inheriting references) vs those that are not. Second, we prepare a ranked list of k references taken from each of the correctly classified (i.e., relevant) wikilinks which could be added to the reference section of A. We pose this second step as a "learning-to-rank" problem and use various features to prepare the final list of recommendations.

3 Dataset

We use datasets from two different domains – Computer Science (CS) and Physics (PH) – to evaluate our system. Note that while CS is our primary focus (owing to the background of the authors) we use the PH dataset to show that our method is quite generic.
CS dataset: In order to prepare the CS dataset we crawl a set of 3842 target Wikipedia pages till June, 2017. The topics we span in this crawl are information retrieval, machine learning, automata theory, graph theory etc. In addition, we also crawl all the source pages corresponding to all the wikilinks present in the 3,842 target articles. The total number of wikipages thus crawled is 121,154.
PH dataset: For the PH dataset we crawl a total of 2,871 target articles spanning topics like gravitation, mechanics, motion etc. The source pages pointed to by the wikilinks present on these target articles together make the total crawl size of 107,332 pages.

4 Building WikiRef

Recall, that our approach works in two steps. We present the details of each of these steps below which together refers to our system – WikiRef.

4.1 Classification of wikilinks (Step - I)

As discussed in Section 2, we have a target Wikipedia article A with n wiklinks ($B_1, B_2, \ldots, B_n$) present in it. Our goal in this step is to ascertain how appropriate a source page pointed to by a wikilink B_i is for inheriting references. To estimate this, we measure the extent of similarity between A and the page pointed to by B_i. The hypothesis is that the higher this similarity, the more relevant is the source page to A and thus higher is the propensity of reference inheritance. We define various notions of similarity that act as features to a binary classifier which classifies if the source is relevant or not.

[6]We perform the human judgement experiment only for the CS domain because of the background of the contributing authors of this paper.

- **Tf-idf similarity of article summaries (TIS):** We represent the summaries (first paragraphs) of A and the source page pointed to by B_i as tf-idf vectors and compute the cosine similarity between them. Note that, inverse document frequency (idf) is calculated only from the dataset we have prepared.
- **Outlinks similarity (OS)**: Outlinks of a Wikipedia article (say A) is the set of Wikipedia articles that A hyperlinks to. We compute outlinks similarity as the Jaccard overlap between the outlinks of A and the source page pointed to by B_i.
- **Inlinks similarity (IS)**: Inlinks of a Wikipedia article (say A) is the set of Wikipedia articles that hyperlink to the page A. We compute inlinks similarity as the Jaccard overlap between the inlinks of A and the source page pointed to by B_i. Note that, for computing inlinks we consider the articles present only in our dataset.
- **Out sentence similarity (OSS)**: Here we consider the common outlinks of A and the source page pointed to by B_i. We collate all the sentences in A where these common outlinks occur, to prepare a document OS_A. Similarly, we collate all sentences in the page pointed to by B_i where these common outlinks occur to form a document OS_{B_i}. Now we represent OS_A and OS_{B_i} as tf-idf vectors and compute cosine similarity between them.
- **In sentence similarity (ISS)**: This is same as OSS with the exception that here we construct the documents based on the sentences where the common inlinks of A and the page pointed to by B_i occur.

Additional deep neural representations: Apart from these five similarity measures we use additional variants of TIS, OSS and ISS where instead of representing a text document as a tf-idf vector we represent it as a document vector obtained using an encoder based on a bi-directional LSTM architecture with max pooling, trained on the Stanford Natural Language Inference (SNLI) dataset (Bowman et al., 2015) as proposed by Conneau et al. (2017). Note that, for applying this architecture we use the GloVe vectors trained on Common Crawl data (840B tokens)[7]as seeds for representing words in a document. We name these variants of TIS, OSS and ISS respectively as vector similarity of article summaries (VS), out-sentence vector similarity (OSVS) and in-sentence vector similarity (ISVS) respectively.

We plug in all these features in classifiers like SVM, Random Forest, Logistic Regression etc. We observe that Random Forest performs the best among these and therefore report the results for this classifier only. This step automatically identifies the wikilinks that are potential candidates for reference inheritance.

4.2 Recommending the exact list of references (Step - II)

As an outcome of the previous step, we have a target Wikipedia article A and a wikilink B_i which is classified as either relevant for reference inheritance or not. Let us assume that for a B_i that is classified as relevant in the first step, the source page pointed to by B_i has m references $R_1, R_2, ..., R_m$. However, all of these m references might not be appropriate to inherit. Therefore, the task here is to produce a ranked list of k references which A can inherit depending on the relevance of the reference with respect to the content of A. In order to estimate the relevance of a reference (say R_j) we propose the following features.

- **Similarity between the citation context of the reference R_j in the source page pointed to by B_i and the citation context of B_i in A**: Citation context represents the sentence in which a reference or wikilink gets cited. We represent the citation contexts as simple tf-idf vectors and compute the cosine similarity between the tf-idf vectors of the citation context of R_j in the source page pointed to by B_i and the citation context of B_i in A. We term this feature as **F1-TI**. We also represent citation contexts as sentence vectors using the bi-LSTM architecture proposed by Conneau et al. (2017) (already discussed earlier) and compute the cosine similarity of these vector representations of the citation contexts of R_j in the source page pointed to by B_i and the citation context of B_i in A. We call this feature **F1-Vec**.
- **Similarity between the title of the reference R_j in the source page pointed to by B_i and the citation context of B_i in A**: As the title of any reference contains the most important clue about the

[7] https://nlp.stanford.edu/projects/glove/

reference itself, we represent the title of the reference R_j in the source page pointed to by B_i and citation context of B_i in A as tf-idf vectors and compute the cosine similarity between them. We call this feature **F2-TI**[8].

We use – SVMRank (Joachims, 2006) – a standard learning-to-rank framework and plug in the above three features to obtain a ranked list of k references to recommend. We report the performance our approach for different values of k in Section 5.

5 Evaluation

We first individually evaluate Step - I and Step - II and subsequently report the performance of WikiRef as a whole. We evaluate the performance using the standard precision-recall metrics and compare it with various baseline approaches that we ourselves propose since there is no known work in the literature that could serve as a suitable baseline for this task.

5.1 Gold standard dataset

As discussed in section 3 we have a total of 3,842 target Wikipedia pages from the Computer Science (CS) domain and 2,871 target Wikipedia pages from the Physics (PH) domain for which we aim to come up with a list of references. We consider the existing references in the target pages (i.e., the A pages) at the time-point of crawling as the gold standard references to be evaluated against.

5.2 Baselines

There have been several reference recommendation systems (Huang et al., 2015; Caragea et al., 2013; Huang et al., 2014; Tang et al., 2014; Ren et al., 2014; Meng et al., 2013; Huang et al., 2012) for scientific articles but all of them either use the the text of the cited paper or the underlying citation network which makes these systems inappropriate to be used as baselines to compare with WikiRef. Therefore, we propose some standard baselines to ascertain the importance of each step in our approach.

Baseline I: Here, Step - I of our approach is skipped and we assume that all the wikilinks present in the target Wikipedia article are relevant for reference inheritance. In Step - II we rank the references of each wikilink only on the basis of tf-idf similarity between references' citation context in the page pointed to by the wikilink and the wikilink's citation context in target Wikipedia article.

Baseline II: Here again, Step - I of our approach is skipped and we assume that all the wikilinks present in the target Wikipedia article are relevant for reference inheritance. In Step - II we rank the references of each wikilink only on the basis of tf-idf similarity between the references' title and the wikilink's citation context in the target Wikipedia article.

Baseline III: Step - I is fully retained. In Step - II we rank the references of each wikilink only on the basis of tf-idf similarity between references' citation context in wikilink's content and wikilink's citation context in target Wikipedia article (F1-TI).

Baseline IV: Step - I is fully retained. In Step - II we rank the references of each wikilink only on the basis of tf-idf similarity between references' title and wikilink's citation context in the target Wikipedia article (F2-TI).

Baseline V: Step - I is fully retained. In Step - II we rank the references of each wikilink only on the basis of cosine similarity between sentence vector representation of references' citation context in the page pointed to by the wikilink and the wikilink's citation context in the target Wikipedia article (F1-Vec).

We compare the performance of these baselines with WikiRef in section 5.5.

5.3 Performance analysis of Step - I

We use 70% of the Wikipedia pages for training and rest 30% of them for testing using the gold standard dataset. However, we observe from the gold standard dataset that on average only 10% wikilinks are suitable for reference inheritance while the rest 90% are irrelevant. To tackle this imbalance in the

[8]We do not use the corresponding deep vectors since the reference title are in many cases very small and do not produce appropriate vectors thus negatively affecting the overall performance of our system.

dataset, we follow the under-sampling technique based on the repeated edited nearest neighbour method proposed by Lemaître et al. (2017).

First, in order to understand the importance of the proposed features we perform a χ-square test for the classification. We report the ranking of the features in Table 2. Subsequently, we plug the features according to this rank from top to bottom one by one into the classifier; the performance obtained thereby are presented in Table 3. We observe that appending the features one by one according to the χ-square test ranking helps to improve the overall performance of the classifier except the last feature which causes no improvements.

Rank	1	2	3	4	5	6	7	8
Feature	TIS	OSS	ISS	OS	OSVS	VS	ISVS	IS

Table 2: χ-square test ranking of features for Step - I (wikilink classification).

Features Used	**Precision**	**Recall**	**F-Measure**
TIS	0.11	0.90	0.20
TIS, OSS	0.16	0.36	0.20
TIS, OSS, ISS	0.39	0.37	0.33
TIS, OSS, ISS, OS	0.47	0.44	0.40
TIS, OSS, ISS, OS, OSVS	0.48	0.42	0.40
TIS, OSS, ISS, OS, OSVS, VS	0.49	0.42	0.40
TIS, OSS, ISS, OS, OSVS, VS, ISVS	**0.50**	**0.45**	**0.42**
TIS, OSS, ISS, OS, OSVS, VS, ISVS, IS	**0.50**	**0.45**	**0.42**

Table 3: Step - I (wikilink classification) evaluation with incremental feature set.

Some of the representative Wikipedia articles from the CS dataset along with the relevant/irrelevant wikilinks for reference inheritance as correctly predicted by our classifier are noted in Table 4. We observe that the relevant wikilinks are semantically more close to the target Wikipedia articles compared to the irrelevant ones, thus making the former ones as more probable candidates for reference inheritance.

Target Wikipedia article	**Relevant wikilinks**	**Irrelevant wikilinks**
Feature (machine learning)	Machine learning, Perceptron	Computer vision, Speech recognition
Vanishing gradient problem	Recurrent neural network, Back-propagation	OPTICS algorithm, Cluster analysis
Sensitivity and specificity	True positive rate, Precision and recall	Clinical research, Airport security

Table 4: Representative results of wikilink classification for the CS dataset.

5.4 Performance analysis of Step - II

Table 5 reports the performance of our approach for various values of k. Considering the difficulty of the task we observe that our system achieves very good performance in terms of precision even for higher values of k. Some of the representative recommended references along with the target Wikipedia articles are shown in Table 6. The correct references in the table signify the references which are actually present in the target Wikipedia article's reference section (i.e., in the gold standard dataset). We also observe that the incorrect references which are actually not present in the target Wikipedia article's reference section are not adjudged as relevant by our system. As we cannot compare these references with the gold standard, we perform manual evaluation for only these references in order to analyze how suitable these references are for the target Wikipedia article (see Section 5.6).

k	**Precision**	**Recall**	**F-Measure**
1	0.44	0.21	0.28
2	0.41	0.23	0.30
3	0.40	0.26	0.30
4	0.37	0.27	0.31
5	0.34	0.30	0.31
10	0.25	0.35	0.30

Table 5: Evaluation of Step - II for different values of k.

Target Wikipedia article	Relevant wikilink	Correct reference	Incorrect reference
Heap (data structure)	Binary heap	Introduction to Algorithms	Min-max heaps and generalized priority queues
Sensitivity and specificity	Precision and recall	An Introduction to ROC Analysis	Advanced Data Mining Techniques

Table 6: Representative results of Step - II for the CS dataset.

5.5 WikiRef vs the baselines

The comparisons of the performances of different baselines with WikiRef are noted in Table 7. The table shows that for all the values of k the performance of BL-III and BL-IV is significantly better than BL-I and BL-II respectively leading to the fact that the role of Step - I is very crucial in this context and, in particular, helps boost the performance of the full system. In addition, we observe that the performance we get only using unsupervised ranking in step - II based on any one of the three features (used in BL-III, BL-IV and BL-V respectively) described in section 4.2 cannot beat the performance of our approach where we use a supervised approach like SVMRank that draws advantage of all the three features.

k	Metric	BL-I	BL-II	BL-III	BL-IV	BL-V	WikiRef
1	Precision	0.22	0.15	0.38	0.31	0.36	**0.44**
	Recall	0.04	0.05	0.18	0.09	0.10	**0.21**
	F-Measure	0.068	0.075	0.20	0.11	0.14	**0.28**
3	Precision	0.12	0.09	0.34	0.26	0.27	**0.40**
	Recall	0.08	0.1	0.22	0.17	0.16	**0.26**
	F-Measure	0.096	0.075	0.28	0.17	0.20	**0.30**
5	Precision	0.1	0.07	0.31	0.23	0.25	**0.34**
	Recall	0.1	0.12	0.26	0.21	0.22	**0.30**
	F-Measure	0.1	0.08	0.27	0.18	0.21	**0.31**
10	Precision	0.06	0.06	**0.25**	0.22	0.23	**0.25**
	Recall	0.19	0.19	0.30	0.25	0.26	**0.35**
	F-Measure	0.09	0.09	0.26	0.20	0.24	**0.30**

Table 7: Comparison of the performance of proposed baselines along with WikiRef. Best results are in green cells and the most competing baseline results are in blue cells.

5.6 Manual evaluation

The aim of this manual evaluation is to understand the quality of the recommendations returned by WikiRef for the cases which are not present in the gold standard dataset. In the survey, we provide a total of 25 Wikipedia pages from the Computer Science (CS) dataset along with five recommended references which are not already present in the gold standard and ask the annotators to choose the appropriate references which should be there in the reference section of the given Wikipedia article to make it more resourceful. A sample evaluation page can be seen in this link[9]. The list of scientific Wikipedia articles that we use for manual evaluation are noted in Table 8. 10 participants with Computer Science background have taken part in this survey. First, we compute absolute performance of our system which shows on an average, the fraction of references actually found to be relevant by the annotators. We compute the performance score per Wikipage as the fraction of the proposed references found to be relevant by the annotators (averaged over all the annotators). We then compute the average over the full list of 25 Wikipages, obtaining a very good performance score of 0.63 leading to the fact that out of 5 recommended references, close to 3 references are found to be relevant by the annotators.

Next, we also attempt to correlate the ranking of the competing systems with the implicit ranking imposed by the annotators. For each Wikipedia article, we rank the five references depending on the number of participants voting for a particular reference, using standard fractional ranking method. Then we compute the Spearman's rank correlation coefficient (ρ) between these ranks and the ranked list returned by WikiRef as well as other baselines. Table 9 shows that WikiRef beats the most competitive baseline by a significant margin.

5.7 Performance analysis for the Physics (PH) dataset

So far, we have reported all the performance figures for the Computer science (CS) dataset. In order to investigate the applicability of our system in other domains, we repeat the experiments on the Physics (PH) dataset as well. The results for both step - I and step - II are noted in Table 10. We use the same eight features (TIS, OSS, ISS, OS, OSVS, VS, ISVS, IS) with Random Forest classifier for step - I and for step - II we again choose the same SVMRank framework fed in with the three features (F1-TI, F1-Vec and F2-TI) as discussed earlier. From Table 11 we observe that for almost all the cases WikiRef performs better than the baselines.

Step		Precision	Recall	F-Measure
Step-I		0.41	0.44	0.37
Step-II	k=1	0.45	0.1	0.16
	k=2	0.41	0.13	0.19
	k=3	0.38	0.16	0.18
	k=4	0.35	0.20	0.25
	k=5	0.32	0.22	0.23
	k=10	0.30	0.25	0.26

Table 10: Performance of WikiRef on the Physics (PH) dataset

k	Metric	BL-I	BL-II	BL-III	BL-IV	BL-V	WikiRef
1	Precision	0.20	0.24	0.36	0.36	0.41	**0.45**
	Recall	**0.11**	0.07	0.09	0.09	0.09	0.1
	F-Measure	0.14	0.09	0.12	0.12	0.13	**0.16**
3	Precision	0.18	0.18	0.28	0.26	0.29	**0.38**
	Recall	**0.18**	0.13	0.15	0.15	0.15	0.16
	F-Measure	0.16	0.11	0.15	0.15	0.16	**0.18**
5	Precision	0.15	0.15	0.24	0.24	0.25	**0.32**
	Recall	**0.22**	0.18	0.19	0.19	0.18	**0.22**
	F-Measure	0.16	0.12	0.16	0.16	0.16	**0.23**
10	Precision	0.17	0.12	0.22	0.22	0.22	**0.30**
	Recall	**0.29**	0.27	0.23	0.23	0.22	0.25
	F-Measure	0.15	0.13	0.17	0.18	0.17	**0.26**

Table 11: Comparison of the performance of proposed baselines along with WikiRef for Physics (PH) dataset. Best results are in green cells and the most competing baseline results are in blue cells.

6 Conclusion

This paper presented a novel two-step recommendation system for enhancing the reference section of the Wikipedia entity pages, dealing with scientific concepts by inheriting the references from the wikilinks present in the page itself. In the first stage we obtain relevant wikilinks for an entity page via a supervised

classification approach. In the second stage we recommend a ranked list of references from the relevant wikilinks obtained from the first stage. WikiRef achieves an overall *precision@1* of 0.44 for the CS dataset and 0.45 for the PH dataset. These are very significant improvements over the most competing baselines in both cases. In addition, manual evaluations over 25 wikipages show that WikiRef also recommends the most relevant references that are absent in the gold standard dataset. We have made our code and data publicly available[10].

Immediate future work would be to focus on further evaluations on various datasets including biology and medicine. Also, the proposed approach can be adapted to filter any type of entity pages' reference section. We further plan to prepare an online tool that triggers WikiRef to recommend references as soon as relvant wikilinks are added to a target Wikipedia article.

Authorship Identification for Literary Book Recommendations

Haifa Alharthi, Diana Inkpen, Stan Szpakowicz
University of Ottawa, Ottawa, Ontario, Canada
{halha060,Diana.Inkpen,szpak@eecs}.uottawa.ca

Abstract

Book recommender systems can help promote the practice of reading for pleasure, which has been declining in recent years. One factor that influences reading preferences is writing style. We propose a system that recommends books after learning their authors' style. To our knowledge, this is the first work that applies the information learned by an author-identification model to book recommendations. We evaluated the system according to a top-k recommendation scenario. Our system gives better accuracy when compared with many state-of-the-art methods. We also conducted a qualitative analysis by checking if similar books/authors were annotated similarly by experts.

1 Introduction

Recommender systems (RSs) are useful for internet users who may find it hard to choose from the multitude of available products and services. RSs predict how likely the target user is to be interested in an item which might have been unknown to her. In this work, we consider book recommender systems, which could be useful in libraries, schools, and on e-learning portals. Nowadays, with the introduction of e-books, readers can access inexpensive resources with little effort. It was expected that the act of reading for pleasure would become widespread, but statistics demonstrate the opposite; it is declining, particularly among young people.[1]

A number of studies have shown the benefits of reading. In a comparison between the well-being of 7,500 Canadian adult readers and non-readers, the former have been found statistically significantly more likely to report better health or mental health, to volunteer, and to feel strongly satisfied with life (Hill, 2013). Fiction has been shown to stimulate profound social communication (Mar and Oatley, 2008). Exposure to fiction correlates with a greater ability for empathy and social support (Mar et al., 2009). It also has a lingering biological effect, notably in the connectivity of the brain (Berns et al., 2013). It is therefore a worthwhile endeavor to deploy artificial intelligence techniques to spark people's interest in books by recommending the right type of books.

There are two main types of traditional recommender systems: collaborative filtering (CF) and content-based recommendation (CB). When a CF system predicts if a user likes a book, it relies on the ratings of all active users in the system. CF depends on a rating matrix which could be large and sparse, and that might lead to inferior recommendations. Sparsity occurs when items/users do not have enough ratings. It can be noticed in library records that many books are never checked out (as is, *e.g.*, the case of 75% of the books in the library of Changsha University of Science and Technology (Yang et al., 2009)). A few other problems face CF systems: *new items* which are difficult to recommend until enough ratings have been received, *the long tail* when most items are overlooked because of few very popular ones, *shilling attack* when items are rated as a way of promotion, and the *gray sheep problem* of users who have tastes entirely different from other users (Alharthi et al., 2017).

Content-based recommendation, on the other hand, relies on the content of items (*e.g.*, a book's genre and author). It is a classifier that finds patterns in the target user's past reading preferences, and predicts

Proceedings of the 27th International Conference on Computational Linguistics, pages 390–400
Santa Fe, New Mexico, USA, August 20-26, 2018.

future interests. CB does not require a rating matrix; that eliminates all the aforementioned issues with CF. A newly added book is recommended if it is similar to the target user's preferences. CB also makes recommendations that are interpretable (*e.g.*, a book is recommended because the user tends to like a specific genre). However, it is difficult for CB to recommend items that have inadequate content. Another weakness, *overspecialization*, occurs when the system makes non-diverse recommendations (Alharthi et al., 2017). Hybrid RSs can combine CF and CB to tackle such issues and enhance the recommendation accuracy.

A content-based RS is proposed that analyzes the texts of books to learn users' reading interests. A survey on book recommender systems (Alharthi et al., 2017) describes only a few RSs that take the actual text of books into account. There is a lot of work that explores literary works, including automatic genre identification (Ardanuy and Sporleder, 2016) and learning the narrative structure (Elson et al., 2010). It is quite surprising, then, that the analysis of the textual content of books to improve their recommendations is still quite limited. A user's reading preferences might be influenced by many elements specific to books. For example, recommendations given by the readers' advisory (a library service that suggests books to patrons) rely on multiple appeal factors. The factors are *characterization, frame, language and writing style, pacing, special topics, storyline,* and *tone*. To obtain information about books' appeal factors, librarians can subscribe (at a fee) to reader-advisory databases such as NoveList, established by professionals (Pera and Ng, 2014a).

Commercial applications that perform natural language processing (NLP) on the text of books have begun to appear; one example is BookLamp which was acquired by Apple in 2014.[2] Also, the well-known Google Books provide a retrieval system that searches inside the full text of books for terms that appear in a given query. Moreover, e-book recommendations are already provided via WIFI-connected Kindle, Kobo and other e-readers. Our proposed system could therefore be deployed by e-book providers, and could help current online stores to boost their deployed collaborative filtering systems.

The basic approach in book retrieval systems is to adopt the bag-of-words method, which creates book representations based on term frequencies. In this case, cosine similarity is often used to retrieve the most similar book representations. More advanced document retrieval methods such as latent Dirichlet allocation (LDA) (Blei et al., 2003) and latent semantic indexing (LSI) (Deerwester et al., 1990) also take advantage of term frequencies. Recently, doc2vec models (Le and Mikolov, 2014) have achieved state-of-the-art results in document classification and recommendations (Gupta and Varma, 2017; Wang et al., 2016).

In this paper, we focus on learning authors' writing styles in aid of book recommendation. Our book RS transfers information learned by an authorship identification (AuthId) classifier to a book recommendation module. It is common in neural network literature, especially in image processing, to train a model (source model) on a dataset for a specific task and then transfer the learned features to another model (target model) working with a different dataset and task. The features are considered *general* if they are learned from first layers in neural networks. *General* features tend to hold basic information (*e.g.*, color blobs in image processing), and are suitable to work on a different dataset/task. *Specific* features, on the other hand, generated by the last layers, are very dependent on the dataset/task (Yosinski et al., 2014). Transferability in NLP applications is explored in (Mou et al., 2016) which concludes its usefulness only for tasks that are mutually semantically similar.

The system has two components: authorship identification and book recommendation. For the former, we adopt two approaches similar to (Solorio et al., 2017); they use convolutional neural networks (CNN) over a sequence of words and sequence of character bigrams. Given the text of a book as input, the AuthId classifier predicts its author, and once it has achieved good accuracy, we extract features from the last hidden layer (before the output layer) and use them for another task (book recommendation). These book features, then, are *specific*. In fact, the first task, author identification, is just a way of representing books as vectors that encode information about their authors' writing styles. The recommendation module, on the other hand, is a content-based RS which makes recommendations after finding patterns in the representations of books read by the target user. To achieve this, a regressor is trained over book AuthId

[2]http://www.businessinsider.com/apple-buys-booklamp-2014-7

features associated with the target user ratings to generate a list of ranked books.

This paper makes several contributions. To our knowledge, this is the first work to transfer the information learned from an author identification model to book recommendations. We evaluated the system according to a top-k recommendation scenario. Our system gives better accuracy when compared against many state-of-the-art methods, namely the vector space model (VSM) (Salton and McGill, 1986), latent Dirichlet allocation (LDA) (Blei et al., 2003), latent semantic indexing (LSI) (Deerwester et al., 1990) and paragraph2vec (Le and Mikolov, 2014). Moreover, qualitative analysis was conducted on the vectors generated by the author identification model. The books with similar vectors have been found to have similar description in NoveList.

The remainder of this paper is organized as follows. Section 2 surveys related work in recommender systems and author identification. Section 3 explains the proposed system in detail. Section 4 describes the evaluation process. Section 5 illustrates the results and analyzes them. Section 6 concludes, and highlights future work.

2 Related work

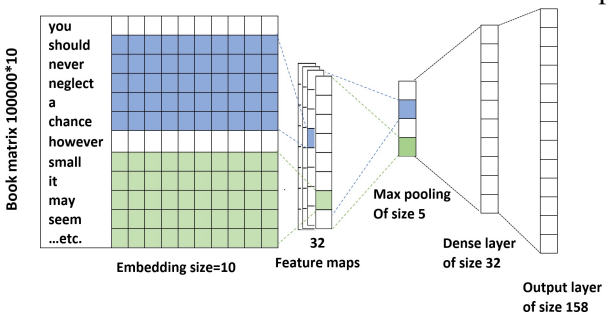
Only a few of more than thirty book RSs surveyed in (Alharthi et al., 2017) take the actual text of books into account. In addition to library circulation analysis, many researchers took advantage of the textual reviews shared by individuals and communities. Another category of book RSs considers stylometry features; they are learned from an author's writing, and can help in authorship identification. Stamatatos (2009) categorizes stylometry features into five classes: lexical, syntactic, semantic, application-specific and character-based. In the stylometric content-based (CB) book RS proposed by (Vaz et al., 2012a), a few features are taken into account. Books were represented in two ways: (1) as vectors of LDA topics, (2) as vectors of stylometric features (document length, vocabulary richness, part-of-speech bigrams and most frequent words). Experiments conducted using the Rocchio algorithm (Manning et al., 2008) on LitRec dataset (Vaz et al., 2012c) showed that the combination of stylometric CB with collaborative filtering (CF) provides better accuracy than an individual CF or CB system. Compared to other representations, the LDA-based vectors showed the best results. Unlike the method we propose, (Vaz et al., 2012a) does not associate stylometric features found in books with authors.

The author's writing style was also considered in (Pera and Ng, 2014a; Pera and Ng, 2014b; Pera and Ng, 2015), yet it is learned from the online reviewers' point of view and not automatically from the textual content of books. Appealing terms (from a fixed number of terms found in (Pera and Ng, 2014a)) are extracted from readers' reviews automatically collected from websites such as Amazon.com. The resemblance between vectors of appealing terms of the preferred and candidate books is calculated, and a recommendation is made accordingly.

Upon receiving the name of the user's favourite author, (Zhang and Chow, 2015) exploit the whole text of an e-book to suggest authors and e-books. To overcome the spatial distribution issue—when words are treated without taking into consideration their order—every author is represented in a hierarchical structure which consists of four layers. The first layer is reserved for the author's related information (*e.g.*, education and political views), while the following three levels are dedicated to the author's books, pages of every book, and paragraphs on each page. The author representations are developed using a multilayer self-organizing map (MLSOM) (Rahman et al., 2007). To recommend books, the system considers the last three layers. On the other hand, to suggest authors, the RS exploits all the layers. The evaluation is conducted by computing the relevance of two books. If a queried book has the same genres as the recommended book, this is considered a relevant recommendation. The results show higher performance when compared with other CB systems, including those using VSM and LSI.

The baseline systems are commonly used in recommender systems. The vector space model, which is the standard approach in information retrieval, was applied to descriptions of books in (Tsuji et al., 2014; Pera and Ng, 2014b), but not to the whole text of books. Both latent semantic indexing and latent Dirichlet allocation are topic-modelling techniques widely used in information retrieval and recommender systems. To name a few, they were used to recommend movies (Bergamaschi and Po, 2015) and articles (Lin, 2017; Nagori and Aghila, 2011). Recently, paragraph2vec—or, as it is frequently

Figure 1: The use of a convolutional neural network for authorship identification



named, Doc2vec—was proposed in (Le and Mikolov, 2014) to offer a fixed-size representation for texts (paragraphs or documents). An unsupervised algorithm predicts the words in a document and generates a vector for every document. Doc2vec was applied in RSs to suggest scientific articles in (Gupta and Varma, 2017) and answers in question-answering systems in (Wang et al., 2016).

A simple system using CNN is proposed in (Solorio et al., 2017). It takes a sequence of characters of a tweet as input and predicts its author, a Twitter user. The system performance with different inputs (including character bigrams, character unigrams and words) is evaluated. The character bigram input gave the best accuracy. Although it has been proposed for short texts, we noticed that it gives acceptable accuracy when predicting authors of books; that is why we have adopted it. As explained in section 3.1, we modified the network in (Solorio et al., 2017) by adding a dense layer which helps extract book AuthId features.

Recent research also shows how the use of recurrent neural networks (RNN) has led to accurate author identification. The work in (Qian et al., 2017) achieved 89% accuracy using Gated Recurrent Unit (GRU), an RNN algorithm, on a dataset from the Gutenberg Project (Lahiri, 2014). Their model represents a sequence of words (initialized as GloVe pretrained embeddings) in a sequence followed by average pooling, and then another GRU that represents the sequence of sentences in an article. A simple recursive neural network adopted in (Macke and Hirshman, 2015) showed high accuracy only when the number of classes was small: 10 authors. Our preliminary experiments show that RNN-based author identification models have poor accuracy, so we do not use such models in this work.

3 Methodology

This section describes the two components of the system. It first illustrates and explains the author identification system, which was proposed by (Solorio et al., 2017), and our modifications to the system. Next, the recommendation procedure is described.

3.1 Author Identification

As shown in Figure 1, drawn similarly to (Kim, 2014), the neural network has the following layers.
Embedding layer (also called *lookup table*). It takes a sequence of words or character bigrams as input, and maps each word or bigram to an embedding of size *k*. The embedding of the *i*th word/character is a dense *k*-dimensional vector $x_i \in R^k$. Each book is represented as a matrix, with one word/character embedding per row. A book has sequence length *n* (*n* is the number of words/characters) where a sequence $x_{1:n} = x_1 \oplus x_2 ... \oplus x_n$ is a concatenation of all words from x_1 to x_n.
Convolution layer. This layer consists of one or more filters (also called kernels) that are applied to windows of words to generate feature maps. Let a filter $w \in R^{hk}$ slide over a window of *h* words $x_{i:i+h-1}$ to generate feature $c_i = f(w \cdot x_{i:i+h-1} + b)$. f is the activation function (non-linear), and b is a bias. A feature map $\mathbf{c} = [c_1, c_2, ...c_{n-h+1}]$ is created by a filter *w* that slides over all the possible windows of words in a book.
Pooling layer. This layer decreases the dimensionality of the feature map. One approach is max-over-time pooling. Given a feature map **c**, it returns $max\{\boldsymbol{c}\}$; as a result, only the features with the highest importance (maximum value) are kept (Kim, 2014).

Fully-connected layer (also called *dense layer*). Each neuron in this layer is connected to each neuron in the previous layer. This layer is essential in our framework, because it generates the book representation. The pooling layer's output is flattened first, then fed to the dense layer which produces a fixed-size vector with dimensions equal to the number of neurons in the layer.
Output layer. It is a fully-connected softmax layer which outputs vector with dimensions equal to the number of authors (labels). Each dimension represents the probability that the input book belongs to a specific author. The values of all elements of one vector sum to 1.

After the model has been trained and achieved accurate predictions, it is used to extract the features of an intermediate layer. Given the text of a book as an input, the fixed-size vector generated by the fourth layer is extracted. This vector is considered as the AuthId book representation which is used in the next step to make recommendations.

3.2 Book Recommendations

Given a user's reading history associated with AuthId book representations, a regressor predicts her future ratings. Book recommendations are ranked according to the predicted rating values. We applied Support Vector Regression (SVR) which is an extension of Support Vector Machine (SVM) (Vapnik et al., 1996). In a non-linear SVR, the training samples X are mapped to a high-dimensional feature space which allows it to learn a linear model in that space. The mapping is achieved by a kernel function such as Radial Basis Function (RBF)—see Equation 1. For every AuthId book representation x_i that has the rating y_i, the SVR algorithm aims to learn a function f(x) as in Equation 2 with α_i^*, where α_i are Lagrange multipliers and N is the number of data points (Gunn, 1997; Basak et al., 2007).

$$k(x_i, x_j) = exp\left(-\frac{\|x_i - x_j\|^2}{2\sigma^2}\right) \tag{1}$$

$$f(x) = \sum_{i=1}^{N}(\alpha_i - \alpha_i^*)k(x_i, x) + b \tag{2}$$

4 Evaluation

4.1 Dataset and Preprocessing

We use the Litrec dataset (Vaz et al., 2012c) which contains data on 1,927 users who rated 3,710 literary works. The dataset incorporates data from Goodreads and from Project Gutenberg. It also has the complete texts of books, labelled with part-of-speech tags (Vaz et al., 2012b). In Goodreads, books are rated on a scale of 1-5 where 1-2 indicate a dislike and 3-5 a like. A book can have a rating of 0 to indicate that the user has read the book but not rated it. We filtered out all zero-rated books (17,976 ratings). Also, in order to train the author identification network, we need multiple books per author. Thus, we only kept authors with a minimum of three books. Data for users with fewer than 10 ratings are also deleted. The lowest number of ratings needed to develop CB with quality recommendations is 10, a threshold adopted by many researchers, including (Wang et al., 2009). The remaining 351 users rated 1010 unique items authored by 157 distinct authors.

The Gutenberg texts have copyright information at the beginning and the end, which we removed using heuristics or manually. The part-of-speech tags are also removed. Some books are very long; the maximum is 565,570 words, while the average is 99,601 words per book. Because of high memory requirement, the processing of large books resulted in a system crash. That is why we considered only the first 100,000 words of each book—slightly higher than the average length.

4.2 The Experimental Setting

A recent survey (Zhang et al., 2017) states that the percentage of RS publications that report ranking metrics is 66%, rating prediction metrics is 28%, and usage metrics 6%. We adopt ranking metrics to evaluate our system using a top-k recommendation scenario where systems provide a user with a ranked list of books. Books rated by a target user are divided into training and test set. The system learns from

the books in the training set and ranks the remaining books in the dataset (we call it the ranked list). The books in the test set are considered more relevant than the unread books on the ranked list; so, an ideal system would rank items from the test set in the top-k list of books. Similar to many related projects, we set k to 10. Three-fold cross-validation is adopted per user, and the results are averaged. We measure the statistical difference in results, using the t-test at a p-value of 0.05 or 0.01.

Metrics. We compute the recommendation accuracy by precision at k (P@k) and recall at k (R@k)—Equations 3-4—where a *relevant* book means to a preferred book, and *recommended* means ranked in the top k list.

$$P@k = \frac{\#\ relevant\ books\ in\ top\ k\ recommended}{k} \tag{3}$$

$$R@k = \frac{\#\ relevant\ books\ in\ top\ k\ recommended}{\#\ of\ relevant\ books} \tag{4}$$

Baselines. To implement LDA, LSI, VSM and Doc2vec, we used gensim,[3] a Python library. The texts of books were tokenized and down-cased, and NLTK stopwords and least frequent words were filtered out. In the first three systems, relevant books in the user training set are compiled and considered as one query. Using cosine similarity, the top-k books most similar to the query are recommended.

For LDA and LSI, we experimented with 10, 50, 100 and 200 topics; the best accuracy is reported. The Doc2vec model was trained on book texts; a book id is considered as the label. For training the model, we tried dimensions of 100 versus 300 and window size of 10 versus 5, and we report the best results. The average of document vectors of relevant books in the user training set is considered as a query. The books with highest cosine similarity to this vector are recommended. We also compare with a plain author-based RS which uses SVR similarly to our proposed system, with one difference: instead of book AuthId representations, author ids are used.

Parameter Settings. One question usually raised with transfer learning is this: when does one stop training the source model? We stop training the author identification model at the point when the validation accuracy stops increasing for five epochs, or if validation accuracy keeps increasing while the training accuracy becomes close to 100%. The network is trained using the RMSprop optimizer over 32 batches. For the non-linearity, rectified linear units are adopted. The number of neurons in the first fully connected layer is decided empirically to be 32. We also experimented with various combinations of parameters: embedding size = 1, 5, 10, number of filters = 16, 32, kernel size = 2, 5, and maximal pooling size = 2, 5.

In the char-bigram CNN, the combination that provides the best validation accuracy (64%) is reached at the 7^{th} epoch with embedding size of 10, 16 filters and kernel size and max-pooling sizes of 2. The sequence character bigrams can be very lengthy (this causes the system to crash); therefore, a maximum of 150,000 tokens is imposed. For the word CNN, a validation accuracy (65%) was achieved at the 17^{th} epoch when using embedding size of 10 with 32 filters and 5 for kernel size and max-pooling size. These experiments were implemented using keras,[4] a Python library, on a NVIDIA GeForce Titan X Pascal GPU with memory of 12,184 MiB.

The SVR was developed using scikit-learn.[5] The Radial Basis Function (RBF) is used with gamma=0.001. For some users who do not have negative ratings, the regressor ended up not distinguishing between relevant and irrelevant items. To solve this issue, we include in the training stage some randomly selected books not read by the target user to work as irrelevant books (excluded from baselines as well). The final number of irrelevant books in the training set is the same as relevant ones.[6]

5 Results and Analysis

Figure 2 illustrates how the proposed system, whether based on words (AuthId_words) or character bigrams (AuthId_char), retrieves relevant books more than the baselines, with the former achieving statis-

Figure 2: Precision@10 and recall@10 generated by our system (AuthId_words and AuthId_char), and the baselines.

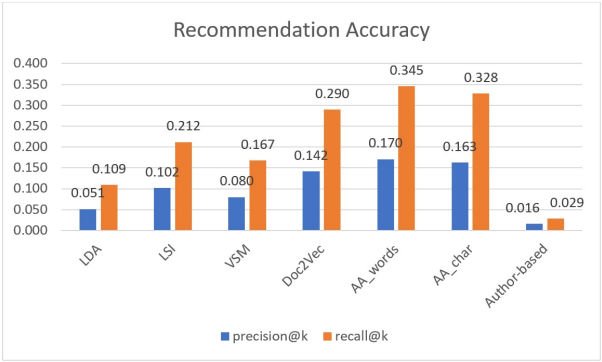

Figure 3: Users' relevant recommended books versus unread books by the same authors

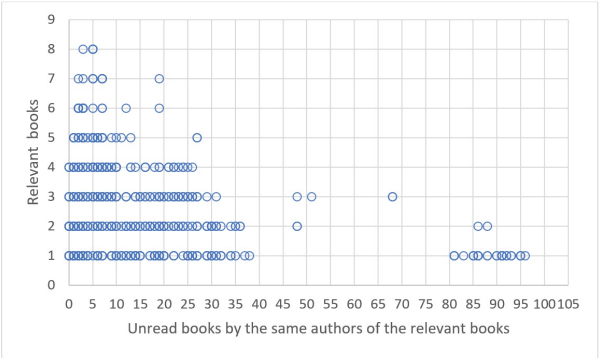


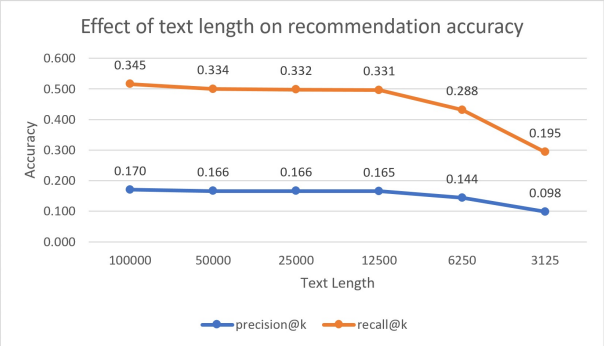
tically higher accuracy at a p-value of 0.01. In fact, AuthId_words score better precision and recall at a p-value of 0.05 when compared with AuthId_char. One possible reason is that in the latter we capped sequence length at 150,000. We also believe that the use of words could capture topical similarity, as highlighted by the qualitative analysis (Table 1).

Many users have fewer than 10 books in their test set. This means that P@10 would never become 1, and also explains why R@10 is greater than P@10. On the other hand, some users have more than 10 books in their test set, making the R@10 very low even for an ideal system. The best baseline is doc2vec, followed by LSI. LDA's low accuracy is surprising, yet it is possible that more preprocessing is required for LDA to work properly. We expected the author-based system to have high recall@k by just assigning high predictions to the target user's favorite authors, but the performance is the poorest. A closer look shows that a preferred author might have many books not read by the user, and when the author-based system recommends a random sample of these books, many of them are considered irrelevant (not read by the user).

This observation has led us to ask how many unread books there are for the authors of books retrieved by our system. To investigate, for each user we obtain the authors of her relevant recommended books, and count the unread books they wrote on the list of books to rank. This analysis is shown in Figure 3 where one circle refers to one test case (one fold for one user). The y-axis represents the number of relevant books in the top 10 recommended list. The x-axis refers to the number of unread books by the same authors who wrote the relevant books. For example, the mark at (3, 68) means that the AuthId_words system could recommend three books relevant to a target user from a list of items containing 68 books written by the same authors as the three retrieved books. In 302 cases, the system could retrieve one or more relevant books from a list with more than ten irrelevant books by the same authors. In 12 cases, the number of unread books exceeded 80. The system recommended at most eight relevant books; that was achieved when three and five irrelevant books were on the list of books to rank.

To assess the effect of text length on the accuracy of recommendations, we developed book AuthId

Figure 4: Effect of text length on recommendation accuracy



representations using fewer texts. We iteratively divided the length by half and fed it to the author identification model. The model was chosen after searching for the most accurate combination of embedding size, number of filters, kernel size and pooling size as in section 4.2. In the author identification model, the validation accuracy of the 100,000 words is similar to 3125 words. However, figure 4 shows that *the shorter the text length, the less accurate the recommendations*. Yet, a statistical difference only occurs when a great deal of the text is removed (*i.e.*, 6250 and 3125 words).

We went further to analyze the quality of AuthId book representations by measuring if similar representations have overlapping descriptions in NoveList. Using cosine similarity, we studied the 10 books most similar to "The Snow-Image: A Childish Miracle" by Nathaniel Hawthorne. We selected this book because NoveList has information on all its related authors. In Tables 1-2, which represent book AuthId using CNN_words and CNN_char_bigrams respectively, one can see Gutenberg book IDs in descending order according to their similarity values, as well as author information.

In both tables, Hawthorne himself authored the first four books. The following list of books by the two methods, however, are entirely different from each other. Table 1 has books by only three authors with many common points with the description of Hawthorne's profile (in Bold). The authors of the first four books and the last five books write mostly about related topics (subject headings). On the other hand, Table 2 contains information on seven unique authors, one sharing the same genre and two having the opposite storyline and pace. Yet, most of them write about different topics than Hawthorne. It is noticeable that the use of words rather than characters captures similarity at the topic level. Solorio et al. (2017) further assess the AuthId model.

6 Conclusion

In the work discussed in this paper, we represent books as vectors learned in relation to authors. Such representations are not only useful in content-based RSs as the results have shown, but can be used to enrich current collaborative filtering systems. The experiments show that AuthId book representation gives better precision and recall compared to LSI, LDA, VSM and Doc2vec. Author writing style may change with time or when writing in different genres. Here, we trained the model to predict the authors regardless of the genre, topics or time of their writing. Taking into consideration these factors may help develop a more accurate author identification model, which is expected to result in better book representations. Other ways for authorship identification should be investigated in the context of book recommendations. More advanced ranking methodologies could be adopted, such as pairwise or list-wise approaches. One possible approach is to adopt multi-task learning where a neural network has two outputs, namely author name and user preferences. We have tried to use NN models to predict user reading preferences from the text of books, but we could not achieve high accuracy in the top-k scenario. We think that performance would improve if the system could work on a larger dataset with more user-item interactions.

Abstract

Effective textual communication depends on readers being proficient enough to comprehend texts, and texts being clear enough to be understood by the intended audience, in a reading task. When the meaning of textual information and instructions is not well conveyed, many losses and damages may occur. Among the solutions to alleviate this problem is the automatic evaluation of sentence readability, task which has been receiving a lot of attention due to its large applicability. However, a shortage of resources, such as corpora for training and evaluation, hinders the full development of this task. In this paper, we generate a nontrivial sentence corpus in Portuguese. We evaluate three scenarios for building it, taking advantage of a parallel corpus of simplification, in which each sentence triplet is aligned and has simplification operations annotated, being ideal for justifying possible mistakes of future methods. The best scenario of our corpus PorSimplesSent is composed of 4,888 pairs, which is bigger than a similar corpus for English; all the three versions of it are publicly available. We created four baselines for PorSimplesSent and made available a pairwise ranking method, using 17 linguistic and psycholinguistic features, which correctly identifies the ranking of sentence pairs with an accuracy of 74.2%.

Title and Abstract in Portuguese

Um Corpus Não Trivial de Sentenças para a Tarefa de Avaliação de Complexidade Sentencial em Português

Uma comunicação textual eficaz depende de os leitores serem proficientes o suficiente para compreenderem o texto e de o texto ser claro o suficiente para ser compreendido pelo público-alvo, em uma tarefa de leitura. Quando o significado das informações e instruções textuais não é bem transmitido, muitas perdas e danos podem ocorrer. Entre as soluções para aliviar este problema está a avaliação automática da complexidade sentencial, tarefa que vem recebendo muita atenção devido a sua grande aplicabilidade. No entanto, a escassez de recursos, como corpora para treinamento e avaliação, dificulta o pleno desenvolvimento dessa tarefa. Neste artigo, geramos um corpus de sentenças não triviais em Português. Avaliamos três cenários para construí-lo, aproveitando um corpus paralelo de simplificação textual, no qual cada trio de sentenças está alinhado e possui operações de simplificação anotadas, sendo ideal para justificar possíveis erros de métodos futuros. O nosso melhor cenário do corpus PorSimplesSent é composto por 4.888 pares, que é maior que um corpus similar para o inglês; todas as três versões do corpus PorSimplesSent estão disponibilizadas publicamente. Criamos quatro métricas *baselines* para o PorSimplesSent e um método de ranqueamento por pares, utilizando 17 métricas linguísticas e psicolinguísticas, que identificam corretamente o ranqueamento dos pares de sentenças com uma acurácia de 74.2%.

1 Introduction

Readability is an issue of great social and economic impact. Effective textual communication depends on readers being proficient enough to comprehend texts, and texts being clear enough to be understood by the intended audience. When the meaning of textual information and instructions is not well conveyed, many losses and damages may occur (Dubay, 2007). In Brazil, for example, only 8% of adult population has reading proficiency (IPM, 2016). The situation is worse in the agriculture and livestock sectors, where only 1% of the surveyed are proficient readers. For this reason, most of rural producers do not have access to new technologies, undermining the development of agribusiness, which accounts for 22% of gross internal product and 30% of Brazilian jobs[1]. Research investments in these sectors, therefore, do not cause as much impact as they potentially might. Identifying which sentences of a text are more complex may help writers of newsletters, manuals and instructions, for example, to adequate their texts to their audiences.

Among the solutions to alleviate this problem is the simplification or adaptation of complex texts, a task that has been partially or fully automatized by Natural Language Processing (NLP) applications. For Brazilian Portuguese, various applications, methods and resources aiming to support simplification in several levels of readability were developed in the Project PorSimples (Aluísio and Gasperin, 2010). Among these resources there is a parallel and aligned corpus with two levels of simplification and annotated simplification operations (Caseli et al., 2009). PorSimples corpus has been used to train readability classifiers for texts (Scarton et al., 2010). Table 1 shows examples of an original sentence of PorSimples corpus (O), its natural simplification (N) and its strong simplification (S). The natural simplification had a substitution of "Uma parcela" by "Alguns" and the strong simplification, shorter than the natural, had a clause removed.

(O) Uma parcela critica o uniforme, porque acredita que ele ameaçaria a individualidade de cada um. (One parcel criticizes the uniform, because it believes that it would threaten the individuality of each one.)
(N) Alguns criticam o uniforme, porque acreditam que ele ameaça a individualidade de cada um. (Some criticize the uniform because they believe that it threatens the individuality of each one.)
(S) Alguns acreditam que o uniforme ameaça a individualidade de cada um. (Some believe that the uniform threatens the individuality of each one.)

Table 1: Examples of simplification in PorSimples.

However, we know that even complex texts have simple sentences, what makes it difficult to identify precisely where complexity lies. In an automatic simplification task, as well, it is difficult to decide which sentence is complex and requires simplification. To address these difficulties, a new task has received attention recently: the prediction of sentences readability, also known by sentence-based readability or sentential complexity task. The first studies on this subject emerged in the beginning of the last decade (Dell'Orletta et al., 2011; Sjöholm, 2012; Del'Orletta et al., 2014).

This task may support simplification systems at least in three applications: (i) to evaluate whether the simplification of a sentence (manual or automatic) is truly simpler than the original sentence or not; (ii) to inform the level of complexity of an original sentence; (iii) to rank the results of several simplification methods, according to their level of complexity. Besides supporting text simplification applications, computer-aided language learning (CALL) systems can benefit from sentence-level readability methods to predict which sentences of a text the students will struggle to read. Furthermore, Open Educational Resources repositories Wiley et

[1] http://www.ibge.gov.br/home/estatistica/economia/agropecuaria/censoagro/

al. (2014) may also take profit of such methods in order to return not merely relevant educational resources, but documents appropriate to the reading level of the user.

Due to its several applications, sentential complexity has been a focus of interest in the NLP studies in recent years, such as Vajjala and Meurers (2014), Vajjala and Meurers (2016), Ambati et al. (2016), Singh et al. (2016), Howcroft and Demberg (2017), Gonzalez-Garduño and Søgaard (2017).

The lack of a sentence-based corpus annotated with regards to readability is a major obstacle to research in this area for Portuguese. Even the English language suffers some drawbacks in what concerns the evaluation of sentential complexity. One of them is the use of benchmarks built from adapted corpora which are automatically aligned, such as Wikipedia and Simple Wikipedia (Zhu et al., 2010). This corpus has some problems to be used as benchmark for text simplification which also prevents its use for the sentential complexity task, for example, automatic sentence alignment errors, inadequate simplifications generating sentences which are not simple, and poor generalization for other genre than encyclopedia (Xu et al., 2015). Other benchmarks for sentential complexity, such as OneStopEnglish corpus (Vajjala and Meurers, 2016), have several positive points — the use of news articles which generalize better for other genres, not having sentence length as high predictive feature, as well as being available by requisition — but also can suffer from errors generated by automatic alignment. Newsela parallel corpus (cf. (Xu et al., 2015)), composed of news articles rewritten by professional editors to be read for children at multiple grade levels, is very beneficial for studying text simplification and could serve as benchmark for sentential complexity if the resulting sentence corpus could be publicly available. Moreover, Scarton et al. (2018) made available the SimPA, an English sentence level corpus for the Public Administration domain with 1,100 original sentences simplified in the lexical (3,300 pairs) and syntactic levels (another 1,100 pairs), annotated by 176 volunteers.

In this paper, we aim at obtaining nontrivial sentence pairs in Portuguese in order to create a gold standard corpus, publicly available. By nontrivial we mean that the pairs are not significantly different in length to avoid the easy judgment that the shorter sentences are the simpler ones. Although it is natural to expect that the simplified sentences are smaller, we found that it is not always true. An example of this is when, in order to simplify a content, one inserts an explanation, examples, or a list of synonyms.

We evaluated three scenarios for building our gold standard corpus from PorSimples corpus, with special care for the split operation, because splitting can generate several short sentences from an original one. The first scenario is a corpus formed of pairs of original and simplified sentences in which, if the split operation is used, we repeat the original sentence to form pairs with each of the simplified sentences. In the second scenario we include pairs with all but the simplified sentences from the split operation. The last scenario is a corpus in which all simplification operations are allowed, but for splitting we only bring the longest simplified sentences to compose the pair original-simplified.

The remainder of this paper is organized as follows. Section 2 reviews the literature on sentence-based readability assessment and its evaluation corpora. Section 3 presents the parallel and aligned corpus of the PorSimples project and explains how we built three evaluation scenarios to create the PorSimplesSent, our corpus for sentence-based readability assessment in Portuguese. In Section 4 we discuss our baselines, our method and features extracted to evaluate the three evaluation scenarios. Conclusions and future work are presented in Section 5.

2 Sentence-based Readability Assessment and its Evaluation Corpora

Initially, sentence-based readability task was considered in isolation by several authors, each one studying a set of features and evaluating in specific corpora. Dell'Orletta et al. (2011) were the first to consider the task of complexity for the sentential level, comparing its difficulty in relation to the textual level, for Italian. They used the SVM method of the LIBSVM library to train a model with 7,000 sentences, half selected in the newspaper *La Repubblica* and half of

the newspaper *Due Parole*, the latter considered simple reading. Interestingly, features at the syntactic level had little influence on the classification of documents, but were very important for the sentential level. Training with 6,000 and testing against 1,000 sentences, they reached 78.2% accuracy at the sentential level. Sjöholm (2012) addressed the task for the Swedish, also using two sets of sentences. For evaluation, 3,500 sentences were taken from the Swedish corpus LäSBarT, considered simple, and 3,500 from the GP2006 (Göteborgsposten journal), considered complex, divided into seven parts, each part used for testing with the model trained in the other six. The best method was Sequential Minimal Optimization (SMO), which reached 83% accuracy. It is important to mention that using the same set of features to evaluate documents (simple and complex) instead of sentences, in the same corpus, they obtained 97% accuracy. Dell'Orletta et al. (2014) returned to the task, addressing the issue of textual genres. They used the same sets of features from the previous article (Dell'Orletta et al., 2011), but now adding three new corpora of different genres to the original journalistic genre: literary, didactic and scientific.

Vajjala and Meurers (2014) made the first evaluation using Wikipedia-Simple Wikipedia corpus, automatically aligned by Zhu et al. (2010). This corpus became the most-used resource for sentential complexity evaluation in the English language. It was created with the matching of the sentences of 65,133 articles of Simple Wikipedia and Wikipedia, using the measure TF-IDF with cosine similarity. For the choice of the alignment measure, they evaluated the performance of three similarity measures: TF-IDF, word overlap and Minimum Edit Distance (MED), against 120 pairs of manually annotated sentences. The accuracy of TF-IDF was above 90%. As a final result, they created 108,016 aligned sentences, annotated in two classes: complex or simple, and a complex sentence may be mapped to one or more simple sentences to handle sentence splitting. This corpus was updated by Hwang et al. (2015), reaching 150,000 pairs of aligned sentences.

Table 2 shows the state-of-the-art (SotA) results we were able to compile, which use Wikipedia-Simple Wikipedia corpus. In the table, the name of each study is listed with the method/baseline used and the accuracy results.

Study	**Method**	**Accuracy (%)**
Flesch-Kincaid	Baseline	72.30
Vajjala and Meurers (2014)	SMOReg	66.00
Vajjala and Meurers (2016)	RankSVM	74.58
Ambati et al. (2016)	SMO	78.87
Singh et al. (2016)	Logistic Regression	75.21
Howcroft and Demberg (2017)	Rank as Classification (RasC)	73.22
Gonzalez-Garduño and Søgaard (2017)	MultiTask MLP	**86.45**

Table 2: SotA results using Wikipedia-SimpleWikipedia corpus.

Vajjala and Meurers (2014) trained a SMO regression model for document complexity, which reached about 90% accuracy. They then applied the model at the sentence level, and even testing in datasets of several sizes, they only achieved 66% accuracy, creating a new *baseline* for the task. They concluded the reason for this low accuracy lies in the incorrect assumption that all Wikipedia sentences are more complex than Simple Wikipedia. Even so, this dataset has been used by several studies of sentence readability. As far as we could see, Gonzalez-Garduño and Søgaard (2017) presents the state-of-the-art for the task, using eye-tracking features together with linguistic and psycholinguistic ones.

Vajjala and Meurers (2016) returned to the task, proposing a new method for evaluating paired sentences based on *ranking*. They contributed with a new corpus of English sentences aligned in three levels, called OneStopEnglish (OSE), used for training and testing. The OSE corpus is a corpus of aligned sentences created from articles rewritten by teaching experts for English language learners at three reading levels (elementary, intermediate, advanced). They used 76 triplets of articles published between 2012 and 2014, resulting in a total of 837 written

sentences with three levels (OSE3). For the alignment, TF-IDF and cosine similarity were used, with values above of 0.7. In addition to OSE3, a second corpus (OSE2) was compiled, which resulted in 3,113 sentence pairs: elementary-intermediate, intermediate-advanced, and elementary-advanced. This corpus was divided in two parts: 65% of pairs for training and the rest for testing.

In addition to significantly improving the accuracy of the task (over 80%), they assessed the impact of linguistic (lexical, syntactic, morphosyntactic) and psycholinguistic features, confirming the importance of eight features in OSE2: AoA (Age of acquisition), CTTR (corrected Type-token ratio), number of subtrees, average length of clause, average word imagery rating, average word familiarity rating, average Colorado meaningfulness rating of words, average concreteness rating. It is important to note that sentence length was not predictive in OSE2 corpus, as in this dataset rewriting and paraphrasing were the most used simplification operations.

As may be seen in Section 3, for our corpus, traditional psycholinguistic features such as AoA, imagery, concreteness, familiarity, have not been used to rank the three types of sentence pairs of PorSimplesSent. We have, indeed, analyzed their contribution to distinguish the three sentence levels, using the resource created by Santos et al. (2017). However, the results were not discriminative. We hypothesize two reasons for this. One of them is related to characteristics of the resource, which has been created automatically based on existing psycholinguistic norms and may contain some bias. The other reason is related to characteristics of the corpus. The corpus PorSimples contain a lot of explanation relating to difficult words (this is a simplification strategy to deal with lexical complexity). However, once explained, the difficult words are repeated along the text. In PorSimplesSent, when there is a split operation, the explanations remain isolated, benefiting only the sentence they appear, whereas the other sentences containing the repetitions of difficult words remain lexically complex. In fact, the psycholinguistic features did not perform well in our corpus and, therefore, they were not chosen as best features for our method.

Table 3 shows SotA results we were able to compile, which use OSE2 corpus, automatically aligned by Vajjala and Meurers (2016). In the table, the name of each study is listed with the method used and the accuracy results, separated by OSE2 subcorpus. OSE(A-E) stands for pairs at the levels Advanced and Elementary; OSE(A-I) for pairs at Advanced and Intermediate levels; OSE(I-E) for Intermediate and Elementary, and OSE(All) for all three pairs. Howcroft and Demberg (2017) joined the subcorpus OSE(A-I) and OSE(I-E), calling it OSE_{near}.

Study	**Method**	OSE(A-E)	OSE(A-I)	OSE(I-E)	OSE(All)
			OSE_{near}		
Flesch-Kincaid	Baseline				69.6
Vajjala and Meurers (2016)	RankSVM				**81.5**
Howcroft and Demberg (2017)	RasC	**85.3**	74.6		77.9
Gonzalez-Garduño and Søgaard (2017)	Multitask MLP	68.5	61.9		

Table 3: SotA accuracy results using OSE2 corpus.

Vajjala and Meurers (2016) explored whether the types of simplification operations are different between Advanced sentences simplified to Intermediate, and Intermediate sentences simplified to Elementary, using OSE3 corpus. That is why we don't have explicit evaluation between these pairs nor between Advanced and Elementary sentence pairs in Table 3.

3 PorSimplesSent Corpus

3.1 PorSimples Corpus

In order to create the PorSimplesSent, our corpus for sentence-based readability assessment in Portuguese, and to train and evaluate methods to predict sentential complexity for this language, we took advantage of PorSimples corpus (Caseli et al., 2009; Aluísio and Gasperin, 2010).

PorSimples corpus consists of 2,915 original sentences simplified into two levels of complexity:

Natural and Strong. All the sentences are from informational texts, being 30% of scientific issues from newspaper Folha de São Paulo[2] and 70% of other issues from newspaper Zero Hora[3].

PorSimples corpus contains complete annotation of each operation made during the simplification process. This was facilitated by the Simplification Annotation Editor, developed in PorSimples project (Caseli et al., 2009). The editor allows the human simplifier to register decisions of lexical and syntactic simplifications, which include substituting words, merging and splitting sentences, deleting part of the sentence, rewriting sentences with other words, and changing constituents order. The editor has a list of operations that may be chosen by the human simplifier. Simplification process in PorSimples was instructed by simplification guidelines, advising how to turn sentences simpler (Specia et al., 2008). Examples show how to tackle with complex structures, like apposition, subordinate clauses, clauses initiated by non-finite verbs, passive voice, inversion of constituents order and embedded clauses.

In a totally annotated process, the alignment between the simplified sentences and their respective simplifications is systematically ensured. This ensured alignment, added to the fact that the corpus contains a large variety of simplification strategies, makes PorSimples a unique corpus, entirely appropriate to evaluate readability predictors.

3.2 Methodology

We created 4,968 pairs and 1,141 triplets of sentences, combining the three levels of PorSimples corpus: Original, Natural and Strong. Pairs and triplets have two or three different sentences aligned, being the Original the more complex in Original-Natural and Original-Strong pairs, and Natural the more complex in Natural-Strong pairs.

In theory, there should be 8,745 pairs (an original-natural, an original-strong and a natural-strong pairing for each of the 2,915 sentences) and 2,915 triplets (original-natural-strong). However, it occurred 3,777 pairs and 1,774 triplets containing at least two identical sentences, because some of the sentences were simplified only in one level or were not simplified at all (they were considered originally simple). Such pairs and triplets were removed from the corpus, which remained with 4,968 pairs and 1,141 triplets.

Table 4 shows what happened with the original sentences of the texts during the simplification process that gave origin to PorSimples corpus. Part of the sentences has not been simplified, possibly because the sentences were considered already simple. The other part is composed of the simplified sentences, which followed one of three possible paths: simplification in both levels (Natural and Strong) or in only one of them (Natural or Strong).

Application of Simplification Operations in PorSimples Sentences	Number of Sentences
NOT simplified in any level	372
Simplified in two levels	1,105
Simplified only in Natural Level	1,268
Simplified only in Strong Level	170
TOTAL	2,915

Table 4: Distribution of original sentences according to the level of simplification.

Additionally, in the PorSimples corpus, 3,873 sentences were simplified into two or more sentences, generating 5,938 sentences, distributed as shown in Table 5. The split leads to an increase of 53% in the overall quantity of simplified sentences.

Each of the resulting sentences is obviously simpler than the split sentence, however, differently from the other pairs, the sentences deriving from split are part and not an integral simplified version of the respective simplified sentence. To evaluate the effect of splitting on the accuracy of

[2]https://www.folha.uol.com.br
[3]https://gauchazh.clicrbs.com.br

Input/Output Levels	Input (A+B)	Non-split sentences (A)	Split sentences (B)	Sentences resulting from split (C)	Output (A+C)	Percentage Increase
Original/ Natural	2,372	1,543	829	1,992	3,535	49%
Natural/ Strong	1,501	782	719	1,621	2,403	60%
TOTAL	3,873	2,325	1,548	3,613	5,938	53%

Table 5: Distribution of sentences increase due to split.

the complexity assessment task, we created three versions of PorSimplesSent. The three versions are very similar, as they pair all the sentences with their respective simplified sentences. They differ in what concerns split sentences.

As we can see in Table 6, the first version, PorSimplesSent1, has 10,616 pairs, including a pair for each sentence resulting from split. The second version, PorSimplesSent2, has 4,968 pairs and, for split sentences, selects only the simplification with greatest score after applying a linear combination of total number of words and word overlapping count, as exemplified in the following. The third version, PorSimplesSent3, disregard all the split sentences and has 2,600 pairs.

Types of Pairs	PorSimplesSent1	PorSimplesSent2	PorSimplesSent3
Original-Natural	3,535	2,372	1,543
Natural-Strong	4,976	1,501	782
Original-Strong	2,105	1,095	275
TOTAL	10,616	4,968	2,600

Table 6: Distribution of pairs by level in the three versions of PorSimplesSent.

For example, given an Original sentence (O) simplified into two sentences in Natural level (N1 and N2):

- (O): O dormitório, de aproximadamente cinco metros por cinco metros, completa-se com um guarda-roupas de duas portas, uma mesa, um frigobar e um aparelho de ar-condicionado. (The dormitory, approximately five meters by five meters, is complete with a two-door wardrobe, a table, a minibar and an air-conditioner.)
- (N1): O dormitório tem mais ou menos cinco metros por cinco metros. (length: 11 words; overlapping: 7 words; score: 11+7=18) (The dormitory is about five meters by five meters.)
- (N2): O dormitório se completa com um guarda-roupas de duas portas, uma mesa, um frigobar e um aparelho de ar-condicionado. (length: 19 words; overlapping: 19 words; score: 19+19=38) (The dormitory is complete with a two-door wardrobe, a table, a minibar and an air-conditioning unit.)

For PorSimplesSent1, we generated 2 pairs: O-N1 and O-N2. For PorSimplesSent2, we generated 1 pair: O-N2. The original was paired with the sentence N2, which presented a score of 38, against a score of 18 of the sentence N1. For PorSimplesSent3 we did not generate any pair with these sentences.

4 Corpus Validation

4.1 Method

To validate the corpus and to contribute with an initial baseline for the task in Portuguese, we evaluated a simple, but successful approach, inspired by Vajjala and Meurers (2016) —

the pair-wise ranking. For sentential complexity, each sentence should receive a score from an ordinal list of complexity, which could be 1 to n, being n the most difficult. Once the ranking method receives a pair of sentences (with feature vectors) it will predict which one is simpler than the other. The problem of sentential complexity is reduced to the comparison of sentences pairs taken from a pool of sentences where the objective is to rank them according to their complexity, trying to minimize inversion of ranks. As these authors, we also chose the RankSVM algorithm implemented in SVM$^{\text{Rank}}$ (Joachims, 2006)[4], which presented the best results among the algorithms tested for the task in English. We gave the rank value 2 to the complex side and value 1 to the simplified side of each sentence pair.

4.2 Features

For this experiment, we evaluated previously the sets of Original, Natural and Strong simplified sentences of PorSimples Corpus, using two publicly available NLP tools for Portuguese to extract textual metrics, which can be used to aid the automated analysis of text readability: Coh-Metrix-Port 2.0[5] (Scarton et al., 2010; Aluísio and Gasperin, 2010) and Coh-Metrix-Dementia[6] (Aluísio et al., 2016), both based on Coh-Metrix (Graesser et al., 2004). Also, we were inspired by another tool named AIC[7], built in PorSimples project which defined several syntactic metrics to be used in evaluation of text readability. Then we chose the 17 features that presented a clear tendency (increase or decrease, depending on the feature) in the three levels compared (see Table 7 and 8) in order to train a predictor.

Table 7 shows mean values of syntactic metrics for Original (O), Natural (N) and Strong (S) sentence levels in PorSimples corpus. In the table, S stands for Number of Sentences, CpS for Clauses per Sentence, ApC for Apposition per Clause, DD for Dependency Distance, MaxNP and MeanNP for Max and Mean Noun Phrase, SC for Subordinate Clauses, MVPpS for Mean Verb Phrase per Sentence, NIV for Non Inflected Verbs, PSR for Postponed Subject Ratio and ISC for Infinite Subordinate Clauses.

Table 8 shows mean values of lexical and psycholinguistic metrics for Original (O), Natural (N) and Strong (S) sentence levels in PorSimples corpus. In the table, WpS stands for Words per sentence, SpCW for Syllables per Content Words and WbMV for Words before Main Verbs.

L	S	CpS	ApC	DD	MaxNP	MeanNP	SC	MVPpS	NIV	PSR	ISC
O	2372	2.62	0.07	48.24	9.87	5.84	0.38	2.24	0.31	0.085	0.179
N	3535	1.95	0.02	28.39	7.35	4.79	0.26	1.71	0.22	0.051	0.124
S	2402	1.74	0.01	22.16	6.48	4.39	0.24	1.55	0.21	0.052	0.117

Table 7: Distribution of corpus sentences according to the level (L) of simplification - Syntactic Metrics.

L	WpS	SpCW	WbMV	Yngve	Frazier	Honoré	Brunet
O	21.01	2.86	6.16	2.89	7.38	1214.16	40.29
N	14.77	2.74	4.09	2.43	6.64	727.87	51.44
S	12.79	2.76	3.73	2.32	6.48	563.98	52.14

Table 8: Distribution of corpus sentences according to the level (L) of simplification - Lexical, Psycholinguistic and the Classic Syntactic Metrics of Yngve and Frazier.

The features are from three different groups: 1-4 are lexical; 5-16 measures syntactic complexity, and the last one is a psycholinguistic measure of working memory overload:

[4] `https://www.cs.cornell.edu/people/tj/svm_light/svm_rank.html`
[5] http://143.107.183.175:22680
[6] http://143.107.183.175:22380
[7] http://conteudo.icmc.usp.br/pessoas/taspardo/NILCTR0808.pdf

1. **Syllables per content word**: Average number of syllables per content word;
2. **Words per sentence**: Number of words in the sentence;
3. **Brunet**: Classic formula, its a type token ratio form less sensitive to text size (Thomas et al., 2005);
4. **Honoré**: Classic formula similar to Brunet but vocabulary-based (Thomas et al., 2005);
5. **Mean verb phrase per sentence**: Measures the quantity of verb phrases per sentence (implemented via tagger, counts verbs in a sentence);
6. **Yngve**: Measures how much a syntactic tree escapes from the pattern that tend to have branches to the right (Yngve, 1960);
7. **Frazier**: A bottom-up approach to calculate syntactic complexity of a sentence (Frazier, 1985);
8. **Dependency distance**: Calculates dependency distances in the syntactic tree; as dependency distances grows, the text complexity grows together;
9. **Apposition per clause**: Number of appositions in the sentence divided per number of clauses;
10. **Clauses per sentence**: Number of clauses in a sentence (implemented via parser Palavras (Bick, 2000); counts main verbs, excluding auxiliary verbs);
11. **Max noun phrase**: Maximum length of noun phrase in a sentence, calculated in words;
12. **Mean noun phrase**: Mean of noun phrase length in a sentence, calculated in words;
13. **Postponed subject ratio**: Occurrence of Verb-Subject order instead of canonical Subject-Verb order, calculated in relation to the total number of clauses;
14. **Subordinate clauses**: Proportion of subordinate clauses to the total number of clauses;
15. **Infinite subordinate clauses**: Proportion of subordinate clauses made by verbs in infinitive, gerund and past participle form;
16. **Non-inflected verbs**: Number of verbs that have not been inflected, that is, which are in infinite form: infinitive, gerund and past participle;
17. **Words before main verb**: Number of words before the main verbal phrase.

4.3 Evaluation

The 10-fold cross validation accuracy results are displayed in Table 9. As baselines for our tests, we chose four unique features and evaluated them individually on SVM^{Rank}: a) Words before main verb, b) Clauses per sentence, c) Syllables per content word and d) Tokens per sentence. The last line shows the results of our method with 17 features, detailed in Section 4.2.

Features	PorSimplesSent1	PorSimplesSent2	PorSimplesSent3
Words before main verb	45.13%	36.29%	23.06%
Clauses per sentence	59.02%	41.28%	11.32%
Syllables per content word	54.80%	50.90%	46.33%
Tokens per sentence	80.74%	69.35%	40.76%
All 17 features	**83.39%**	**74.20%**	**53.67%**

Table 9: Baselines and first experiment results (accuracy), using SVMRank.

In **PorSimplesSent1**, as expected, using just the number of tokens per sentence it is possible to achieve more than 80% of accuracy. This is because this dataset includes all sentences that are result of split operations, so the majority of simplified sentences are small parts from the original ones. The **PorSimplesSent3**, which has only full sentences, disregarding those that suffered split, is the most difficult to rank. Besides having the smallest number of pairs, PorSimplesSent3 has some simplified sentences that are bigger than the original ones. The **PorSimplesSent2**, on its turn, is a middle term between the previous two: it has split sentences, but only the longest sentence derived from the split is paired with the original sentence. Therefore, we have chosen the dataset PorSimplesSent2 to be our gold standard for sentential complexity task in Portuguese.

Our model with 17 features presents improvement over the strongest baseline (Tokens per Sentence): 2.65 in PorSimplesSent1, achieving 83.39% accuracy; 4.85 in PorSimplesSent2, achieving 74.20% accuracy; and 12.91 in PorSimplesSent3, achieving 53.67% accuracy.

4.4 Error Analysis

We performed a manual analysis, trying to understand the errors made by our model, in order to improve it with new features. Building on the syntactic and lexical operations used to annotated the PorSimples corpus, but now with focus on operations at the sentence level, we proposed a set of 14 labels to annotate the errors. Table 10 shows the errors found after this analysis.

Label Description	**Qty**	**%**
1 Replacement by word of the same grammatical class, including multiword discourse markers	169	28.89
2 Replacement by word of different grammatical class, without specifying the classes involved	19	3.25
3 Replacement by paraphrase (one word by several words)	111	18.97
4 Removal of clause	6	1.03
5 Removal of syntactic constituent (subject, adverbial adjunct, etc.)	8	1.37
6 Removal of words	31	5.30
7 Removal of parentheses	10	1.71
8 Insertion of words	33	5.64
9 Change in the order of constituents (such as putting the subject first and the adverb last)	44	7.52
10 Change to active voice	21	3.59
11 Change to synthetic (shortest) passive voice form (by means of passivizating particle “se”)	3	0.51
12 Change from direct to indirect speech	2	0.34
13 Rephrasing	48	8.21
14 ERROR (equal sentences or alignment error, which will be excluded from the corpus)	80	13.68

Table 10: List of Errors used to annotate 418 sentence pairs of PorSimplesSent3.

We annotated 209 of the 418 sentence pairs of PorSimplesSent3 for which our model missed the prediction. The annotation performed by two annotators was double blind and multi-label. A discussion on the pairs presenting annotation disagreement helped to clarify doubts on the annotation process and to assign commonly agreed labels. After that, the remaining sentence pairs were divided into two parts and each part was assigned to only one annotator.

The analysis of these numbers lead us to cogitate which features and metrics might be significant to improve the performance of our ranking model, initially trained with 17 linguistic and psycholinguistic features. Both most frequent labels, 1 and 3, relate to lexical substitution. Example 1 below shows a pair of sentences annotated only with the label 1.

Example 1

- (O): Quem é contra diz que os cães sujam a praia e colocam em risco a saúde dos veranistas. (Those who are against say that the dogs dirty the beach and put at risk the health of the vacationers.)

- (N): Quem é contra diz que os cães sujam a praia e colocam em risco a saúde das pessoas. (Those who are against say that the dogs dirty the beach and put at risk the health of the people.)

The only difference between the two sentences is the pair of words "veranistas" versus "pessoas", in a hyponym relationship. Example 2 brings a pair annotated with label 3. It shows 2 substitutions by paraphases, here understood as a word replaced by several ones, similar in meaning: "possibilitar" by "tornará possível" and "hepática" by "do fígado".

Example 2

- (O): A descoberta possibilitará que pessoas com dano no fígado usem as próprias células-tronco para produzir células hepáticas. (The discovery will enable people with liver damage to use their own stem cells to produce hepatic cells.)
- (N): A descoberta tornará possível que pessoas com dano no fígado usem as próprias células-tronco para produzir células do fígado. (The discovery will make it possible for people with liver damage to use their own stem cells to produce liver cells.)

As many sentence pairs differ by only one word, readability measures to compare words are essential to decide which is the easiest sentence. Word frequency and psycholinguistic properties of words (as age of acquisition, familiarity, concreteness, imageability) may be useful for this purpose. Additionally, there are several resources that may be used to design new metrics to deal with similar words and paraphases. For Portuguese, there are different similar projects of wordnets, among which stand out the OpenWordNet-PT (de Paiva et al., 2012), as the most complete with manual revision, and the CONTO.PT (Gonçalo Oliveira, 2016), built semi-automatically in order to comprise a greater number of words, and which describes itself as a diffuse wordnet. There is also the PPDB (Paraphrase Database), a resource that contains paraphrases in several languages, including Portuguese, automatically extracted from bilingual corpora (Ganitkevitch and Callison-Burch, 2014). Paraphrase in the context of PPDB refers to expressions or equivalent words. As it was generated automatically, the PPDB also contains some false positives. The resource is available in six different sizes: the difference is that larger sets extracted paraphrase rules with less confidence.

For features other than the lexical ones, a very promising research avenue is to test simplified sentences with human readers to confirm whether they are simpler than their original counterparts or not (using eye-trackers). This is relevant because many simplification operations we use are inspired in the literature regarding English language simplification and we need more evidence related to Portuguese language. The error analysis, therefore, provided important insights for future work aiming to increase the accuracy of our model in the dataset made available with this paper. Besides that, 80 pairs were dropped from our dataset because they contain nearly identical sentences or completely different sentences (improperly paired due to alignment error). Therefore, all the three totals in Table 6 were reduced by 80, resulting in 10,536, 4,888, and 2,520 sentences, respectively.

5 Conclusions

In this paper, we presented a new resource to evaluate the task of sentence readability for Portuguese language - the corpus PorSimplesSent. This dataset is larger, in terms of sentence pairs, than a similar corpus for the English language (cg. (Vajjala and Meurers, 2016)), and it is the first resource of this kind for Portuguese language, therefore we believe we can have a blossom of future research for this task. Moreover, we made available four baselines for the corpus and an approach based on pairwise ranking to compare two versions of a sentence. Our model uses 17 lexical, syntactic and psycholinguistic features and identifies the readability level of sentence pairs with an accuracy of 74.2%; an improvement of 2.65 on the strongest baseline. We believe there is plenty of room for improvement of our model and we hope this task receive a lot of attention from researchers devoted to Portuguese language NLP as well. The corpus is made publicly available at `http://www.nilc.icmc.usp.br/nilc/index.php/tools-and-resources`. As for future work, we will enlarge the number of features to build an improved model to evaluate the task and organize a shared task using it in an NLP conference.

Abstract

This paper proposes to perform natural language inference with *Word-Pair-Dependency-Triplets*. Most previous DNN-based approaches either ignore syntactic dependency among words, or directly use tree-LSTM to generate sentence representation with irrelevant information. To overcome the problems mentioned above, we adopt *Word-Pair-Dependency-Triplets* to improve alignment and inference judgment. To be specific, instead of comparing each triplet from one passage with the merged information of another passage, we first propose to perform comparison directly between the triplets of the given passage-pair to make the judgment more interpretable. Experimental results show that the performance of our approach is better than most of the approaches that use tree structures, and is comparable to other state-of-the-art approaches.

1 Introduction

Natural language inference (NLI) refers to the following task: given a text passage *P* (*Premise*) (which might have more than one sentence) and a text passage *H* (*Hypothesis*), whether we can infer *H* from *P*, i.e., identifying a specific relationship among *entailment*, *neutral* and *contradiction*. It has many applications such as question answering (Bhaskar et al., 2013; Harabagiu and Hickl, 2006), information extraction (Romano et al., 2006), machine translation (Pado et al., 2009), automatic text summarization (Harabagiu et al., 2007) and so on. Some evaluations about this task have been organized in the past decades, such as the PASCAL Recognizing Textual Entailment (RTE) Challenge (Dagan et al., 2005), SemEval-2014 (Marelli et al., 2014) and RITE (Shima et al., 2011).

Many previous approaches adopt statistical frameworks (Heilman et al., 2010; Kouylekov and Magnini, 2005). However, neural network approaches have emerged after Stanford Natural Language Inference (SNLI) dataset (Bowman et al., 2015) was released. Most of them adopt an increasingly complicated network structure to represent text passages, and then predict the relationship between them (Bowman et al., 2016; Liu et al., 2016b). However, *P* might include extra words which are not directly related to *H*. Actually, only the words in *P* that are associated with the words in *H* should be paid attention to. Those relevant words should be emphasized more while the irrelevant words should be less weighted during decision making. Therefore, some approaches (Parikh et al., 2016; Chen et al., 2017a) adopt attention mechanism to implicitly align the words between two passages to yield a better performance. This idea is very similar to how human make the entailment judgment, and the result shows that it is very effective for performing natural language inference on SNLI corpus in which most words in *H* can find their corresponding ones in *P*.

Proceedings of the 27th International Conference on Computational Linguistics, pages 414–425
Santa Fe, New Mexico, USA, August 20-26, 2018.

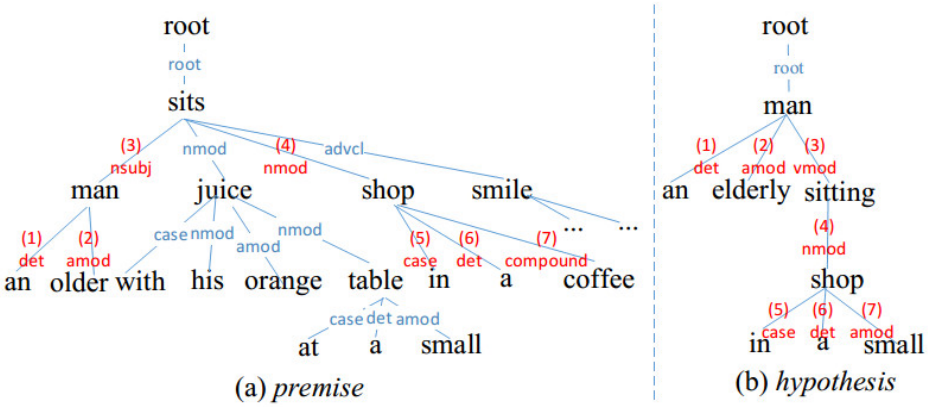

Figure 1. Dependency trees[1] for **Premise** "*An older man sits with his orange juice at a small table in a coffee shop while employees in bright colored shirts smile in the background."* and **Hypothesis** *"An elderly man sitting in a small shop.*" The relationship between them is "*neutral*".

However, after having analyzed some errors generated from an attention-based approach (Parikh et al., 2016), we find that it will introduce mis-alignment and might cause wrong inference. Although context information is used to alleviate this problem, it still cannot handle long distance dependency. Take the following sentence pair as an example (The benchmark is *neutral*):

Premise: *An older man sits with his orange juice at a small table in a coffee shop while employees in bright colored shirts smile in the background.*

Hypothesis: *An elderly man sitting in a small shop.*

The attention-based approach (Parikh et al., 2016) cannot catch the relation between "shop" and "small" in P precisely (which is important for the prediction). In this example, the relationship between *P* and *H* will be predicted as "*entailment*", because all the words in *H* can be found in *P*, although the word "*small*" in these two sentences does not modify the same thing (e.g., "*small*" modifies "*table*" in *premise* while modifies "*shop*" in *hypothesis*).

The above example clearly shows that a sentence is not a set of independent words. It is a sequence of words with syntactic relationship. Based on this observation, we propose to adopt the *Word-Pair Relation-Head-Dependent* (*RHD*) triplet[2] for conducting alignment and comparison. Furthermore, Parikh et al. (2016) and other previous models only compare each word in *H* with the vector merged from all the words in *P* according to their associated alignment scores, and vice versa. However, as shown in Figure 1, human compares *H* and *P* mainly based on *Structure Analogy* (Du et al., 2016; Gentner 1983; Gentner & Markman, 1997) instead of the merged meaning which will not only import irrelevant text but also lose information during merging. Consequently, only words with closely related syntactic/semantic roles (of the aligned predicates) should be compared.

Therefore, we first create two sets of *RHD* from *P* and *H* to denote their corresponding structures, and then perform comparison between triplets in *P* and those in *H*. Accordingly, two *RHD* triplets should be aligned if their relations are related and their head-words are aligned (e.g., the triplets with the same indexes are aligned in Figure 1). Particularly, when two *RHD* triplets are compared, each part of *RHD* triplet (i.e., *Relation, Head*, and *Dependent*) should be compared separately. Besides, as the words of some triplet pairs possess reversed head-dependent relations (e.g., the *Dependent* in "(*nsubj, sits, man*)" is linked to the *Head* in "(*vmod, man, sitting*)", as shown by the triplet pair with index 3 in Figure 1), we introduce *cross-comparison* to compare the *Head* from "(*nsubj, sits, man*)" with the *Dependent* from "(*vmod, man, sitting*)", and vice versa.

[1] The words in black represent the nodes of the dependency tree, and the string on each line represents the dependency relation between two nodes. The red relation denotes that its associated triplet is important in making the judgment. Links with the same indexes indicates that they are aligned and compared when judged the result by human.

[2] Each *RHD* triplet is denoted by "(*rel, head, dep*)", where *head* and *dep* denote the *head-word* and the *dependent-word* of the dependency relation, respectively; and *rel* denotes the dependency relation between *head* and *dependent*.

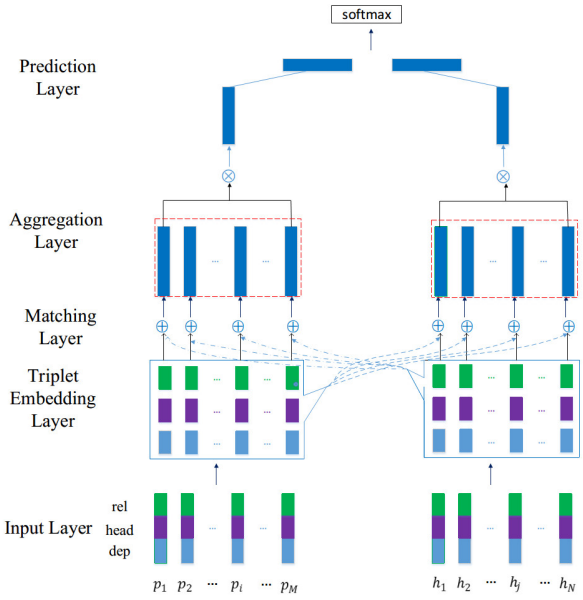

Figure 2: The skeleton of the proposed approach. The *rel*, *head* and *dep* of the triplet are represented with green, purple, and light-blue colors, respectively. Also, $\oplus$ denotes the *Comparison* operation between triplets (see section 2.2.2 for "Matching layer"), while $\otimes$ denotes the *Aggregation* operation (see section 2.2.3 for "Aggregation layer"). Besides, the left part and the right part in *Matching Layer* represent *P-aligned-to-H* and *H-aligned-to-P*, respectively.

Our contributions are summarized as follows: (1) The *RHD* triplet is first proposed to be the alignment and comparison unit in the neural network for NLI. In this way, the corresponding words could be aligned and compared more precisely. (2) Instead of comparing one *RHD* triplet of *H* with the merged meaning of all the *RHD* triplets in *P* (and vice versa), we propose to directly compare each *RHD* triplet of *H* with another *RHD* triplet of *P*; and each part in *RHD* triplet is compared separately. (3) We propose to use *cross-comparison* to compare the related words with different syntactic/semantic roles.

2 Proposed Approach

In our model, we first transform *P* and *H* into two sets of *RHD* triplets. For each *RHD* triplet of *P*, we compare it with another *RHD* triplet of *H* (without merging) to generate an *individual comparison vector* (and vice versa). Afterwards, we use a *self-attention* mechanism to align and sum them to yield the *one-side merged comparison vector* between a triplet and the triplet set of the other side. Last, we aggregate those *one-side merged comparison vectors* to give the overall entailment judgment.

Figure 2 shows the skeleton of the proposed approach. It consists of the following 5 layers: (1) *Input Layer*, which initializes the embedding of the words and relations; (2) *Triplet Embedding Layer*, which is used to adapt the input embedding to yield a better representation for this task; (3) *Matching Layer*, which performs comparison within each *RHD* triplet pair, scores the alignment weights, and sum those *individual comparison vectors* to generate the *one-side merged comparison vector* between each triplet with the triplet set of the other side; (4) *Aggregation Layer*, which aggregates the *one-side merged comparison vectors* to get a *directional comparison vector* for each comparing direction; and (5) *Prediction Layer*, which uses two separated *directional comparison vectors* and a feed-forward neural network classifier to predict the overall judgment.

Our model is symmetric about *P* and *H*. So for simplicity, we only describe the left parts which mainly about comparing each unit of *P* with *H*. Right part is exactly the same except that the roles of *P* and *H* are exchanged.

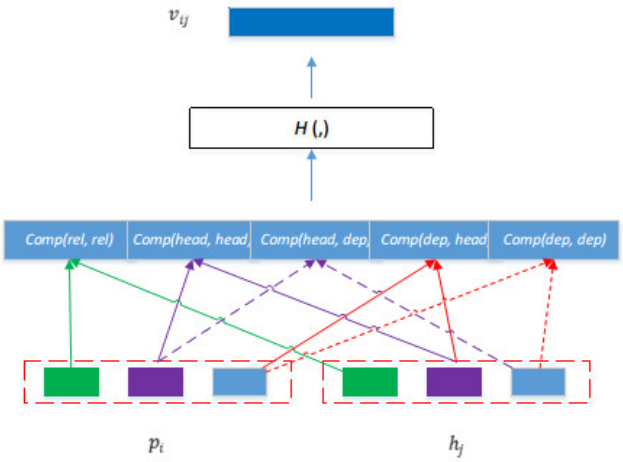

Figure 3: An illustration for the comparison between a triplet p_i in *Premise* and a triplet h_j in *Hypothesis*. The *rel*, *head* and *dep* of the triplet are represented with green, purple, and light-blue colors, respectively. *Comp(,)* indicate the comparison function denoted in equation (2). *H*(,) is a multilayer perception denoted in equation (4). The green solid-line, purple solid-line and red solid-line represent the comparison of pair (*rel, rel*), (*head, head*) and (*dep, dep*), respectively. The purple dot-line represents the cross-comparison of pair (*head, dep*), and red dot-line represents the cross-comparison of pair (*dep, head*).

2.1 Input Layer Generation

We first use a dependency parser[3] to transform *P* and *H* into two sets of *RHD* triplets. We define $\hat{P} := (p_1, p_2, \cdots, p_{\mathrm{m}})$ and $\hat{H} := (h_1, h_2, \cdots, h_{\mathrm{n}})$ be two sets of *RHD* triplets, while p_i and h_j denote the i^{th} *RHD* triplet and the j^{th} *RHD* triplet in *P* and *H*, respectively; also, *m* and *n* indicate the number of associated triplets in *P* and *H*, respectively. We then instantiate the *Input Layer* with the corresponding *word-embeddings* and *rel-embedding* of *RHD* triplets (For conciseness, we will let *rel/head/dep* denote both the original meaning and the corresponding embedding interchangeably from now on). Each $head, dep \in R^{d_w}$ is a word embedding of dimension d_w which is initialized with pre-trained GloVe word embedding (Pennington et al., 2014), while $rel \in R^{d_r}$ is a relation embedding vector of dimension d_r and is initialized randomly with a standard normal distribution (Please note, only rel will be tuned later during training). Each triplet-embedding will be presented as a triplet which contains three embedding corresponding to *rel*, *head* and *dep* respectively.

2.2 Network Architecture

2.2.1 Triplet Embedding Layer

As we fix the value of word embedding during training, in order to obtain better relation/word embedding representations to compare for this task, we use a simple feed-forward structure to adapt the three parts of the triplet to the task. The computations are as follows:

$$\begin{aligned} rel &= W_r * rel_{in} + b_r \\ head &= W_w * head_{in} + b_w \\ dep &= W_w * dep_{in} + b_w \end{aligned} \tag{1}$$

where * is the multiplication of matrices, $rel_{in} \in R^{d_r}$, $head_{in} \in R^{d_w}$ and $dep_{in} \in R^{d_w}$ are the input embedding-vectors from *Input Layer*, $rel \in R^{d_r}$, $head \in R^{d_w}$ and $dep \in R^{d_w}$ are the new representations generated, $W_r \in R^{d_r \times d_r}$, $W_w \in R^{d_w \times d_w}$, $b_r \in R^{d_r}$, $b_w \in R^{d_w}$ are the weight matrices to be learned. Here, all the *rel* share the same weight matrices, while all the words share the same weight matrices.

[3] http://nlp.stanford.edu/software/lex-parser.shtml#Download

2.2.2 Matching Layer

This layer is the core of our model. It is mainly used to perform the individual comparison between two triplets and use associated alignment weights to focus on the individual-comparisons of the preferred alignments. In this step, we will use a *one-side merged comparison vector* to represent each comparison result of one triplet with the triplet-set of another side. For a triplet p_i from *Triplet Embedding Layer*, it has three parts: $rel_{p_i} \in R^{d_r}$, $head_{p_i} \in R^{d_w}$ and $dep_{p_i} \in R^{d_w}$; and for h_j, it has $rel_{h_j} \in R^{d_r}$, $head_{h_j} \in R^{d_w}$ and $dep_{h_j} \in R^{d_w}$.

Figure 3 shows how the *individual comparison-vector* of one triplet-pair is generated. The vector $v_{ij} \in R^d$ denotes the comparison result between triplet p_i and a triplet h_j from $\hat{H}$, while *d* is the dimension of hidden layer. During comparison, each component of the triplet (i.e., *rel*, *head* and *dep*) is compared independently, as shown in the figure. Here, the comparing function is denoted as *comp(,)* in equation (2). *G* is a multi-layer perceptron with one hidden layer and a *Relu* activation.

$$comp(v_1, v_2) = G([v_1; v_2; v_1 - v_2; v_1 \odot v_2]) \tag{2}$$

Where v_1 and v_2 are any two embedding vectors. The notation ";" (within the bracket-pair in the above equation) denotes *Concatenation*; also, '$-$' and '$\odot$' are the *difference* and *element-wise product* of vectors respectively. Then we can get the comparison results in Figure 3 as follows:

$$\begin{aligned}
\overline{rel_{ij}} &:= comp\left(rel_{p_i}, rel_{h_j}\right) \\
\overline{head_{ij}} &:= comp\left(head_{p_i}, head_{h_j}\right) \\
\overline{head_x_{ij}} &:= comp\left(head_{p_i}, dep_{h_j}\right) \\
\overline{dep_{ij}} &:= comp\left(dep_{p_i}, dep_{h_j}\right) \\
\overline{dep_x_{ij}} &:= comp\left(dep_{p_i}, head_{h_j}\right)
\end{aligned} \tag{3}$$

Where $\overline{head\_x_{ij}}$ and $\overline{dep\_x_{ij}}$ are the results of *cross-comparison*. Please note that the comparison functions with the same input arguments share the same set of parameters in *G*. For example, all the functions *comp*(*head*, *head*) share a set of parameters while all *comp*(*head*, *dep*) share another set of parameters. After we obtain the comparison results of these components, we can incorporate them to yield the triplet *individual comparison vector* v_{ij} between p_i and h_j as follow.

$$v_{ij} = H([\overline{rel_{ij}}; \overline{head_{ij}}; \overline{head\_x_{ij}}; \overline{dep_{ij}}; \overline{dep\_x_{ij}}]) \tag{4}$$

Here *H* is a multi-layer perceptron with two hidden layers and a *Relu* activation. Afterwards, we need to generate the *alignment weight* e_{ij} between triplet p_i and triplet h_j to extract the key information for judgment. Most of the previous models (Chen et al., 2017a; Parikh et al., 2016) use the multiplication of two semantic unit vectors as their alignment weights. However, we find the individual comparison here can describe the relatedness of those triplet-pairs better. Consequently, we generate the *alignment weights* using these *individual comparison vectors* with a self-attention mechanism as follows.

$$e_{ij} = W_{s2}\tanh(W_{s1}v_{ij}) \tag{5}$$

Where $W_{s1} \in R^{d \times d}$ and $W_{s2} \in R^{d \times 1}$ are weight matrices to be learned. Then we use e_{ij} to obtain the *one-side merged comparison vectors* $O_{i,H}$ from various v_{ij} as follow.

$$O_{i,H} = \sum_{j=1}^{l_h} \frac{exp(e_{ij})}{\sum_{k=1}^{l_h} exp(e_{ik}))} v_{ij} \tag{6}$$

Where $O_{i,H}$ is the *one-side merged comparison vector* between p_i and the whole set H, l_h is the number of *RHD* triplets in H; $O_{P,j}$ (the right part in Figure 2) is defined similarly between h_j and the whole P.

2.2.3 Aggregation Layer

In this layer, we aggregate all the *one-side merged comparison vectors* $O_{i,H}$ and $O_{P,j}$ (obtained above) to generate the final comparison vector for these two different directions between P and H. Like the previous approaches (Chen et al., 2017a; Parikh et al., 2016), we aggregate the information by summation and max pooling:

$$\begin{aligned} O_{P,sum} &= \sum_{i=1}^{l_p} O_{i,H}, \qquad O_{P,max} = \max_{i=1}^{l_p} O_{i,H}, \qquad O_P = [O_{P,sum}; O_{P,max}] \\ O_{H,sum} &= \sum_{j=1}^{l_h} O_{P,j}, \qquad O_{H,max} = \max_{j=1}^{l_h} O_{P,j}, \qquad O_H = [O_{H,sum}; O_{H,max}] \end{aligned} \tag{7}$$

Where l_p and l_h are the numbers of triplets in P and H, respectively. We get the *overall comparison vector* O_P by concatenating the summation $O_{P,sum}$ and the max pooling $O_{P,max}$ using the *one-side merged comparison vectors of P* (and vice versa). Afterwards, we use these *overall comparison vectors* to predict the relationship in the next section.

2.2.4 Prediction Layer

From the above section, we have obtained O_P and O_H, which are the *overall comparison vectors* from $\hat{P}$ to $\hat{H}$ and from $\hat{H}$ to $\hat{P}$, respectively (i.e., the *overall comparisons* in two different directions). We then concatenate them and use a multi-layer perceptron classifier Q (it has two hidden layers with *Relu* activation and a *softmax* output layer) to generate the final overall judgment vector $\hat{y}$ (as shown in Eq. (8)), where $\hat{y} \in R^C$ (C equals the number of classes) are the scores for each class. The predicted class can be got by setting $y = \text{argmax}_i \hat{y}_i$. When we train the model, we use multi-class cross-entropy loss with dropout regularization (Srivastava et al., 2014).

$$\hat{y} = Q([o_P; o_H]) \tag{8}$$

3 Experiments

3.1 Dataset

We adopt both *SNLI* (Bowman et al., 2015) corpus[4] and *MultiNLI* (Williams et al., 2018) corpus[5] to test the performance. They are briefly introduced as follows.

SNLI - It contains 570k sentence pairs. The sentence pairs in this corpus are labelled with one of the following relationships: *entailment*, *contradiction*, *neutral* and "-", where "-" means that it lacks of consensus from human annotators. In our experiments, we follow Bowman et al. (2015) to delete those sentence pairs labelled with "-". Consequently, we end up with 549,367 pairs for training, 9,842 pairs for development and 9,824 pairs for testing.

MultiNLI - This corpus has 433k sentence pairs, which are collected from broad range of genre of American English such as written non-fiction genres (e.g. SLATE, OUP), spoken genres (TELEPHONE, FACE-TO-FACE), less formal written genres (FICTION, LETTERS), and that specialized on for 9/11. For the training set of this corpus, it selects half of the genres to create in-domain (matched) and out-domain (mismatched) development/test sets. Since the test set labels of this corpus are not released, the test performance is obtained through submission to Kaggle.com[6].

Table 2. Performance on MultiNLI

3.2 Details of training

In order to initialize the words in the triplets, we used 300 dimensional Glove embedding (Pennington et al., 2014). For the relation vectors (the dimension is set to 20), we use a standard normal distribution to randomly initialize the values and then normalize each vector. Besides, for OOV words, we follow (Parikh et al., 2016) to initialize them by randomly selecting one from 100 random vectors. During the training, the word embedding including the 100 random vectors for OOV words are fixed while the embedding of the relations will be updated. The dimensions of the Triplet embedding Layer for relation and head/dependent-words are set to 20 and 300, respectively. And the dimensions of other hidden layers are set to 1,024. Besides, *Adadelta* method (Zeiler, 2012) is adopted for optimization, and the batch size is 32, the dropout ratio is 0.2, while the learning rate is 0.1.

3.3 Results and Analysis

Table 1 shows the results of different models on SNLI. The first group includes two baseline classifiers presented by Bowman et al. (2015). In model (1), they use LSTM to learn a representation for the passage, and then use the representation of the passage-pair to predict the judgment label. Model (2) uses a

traditional statistical classifier to predict the label with some handcrafted features such as the overlapped words, negation detection, etc.

In the second group, Model (3) and model (4) are two models based on passage encoding with tree structure. In model (3), Mou et al. (2016) considers tree-based CNN to capture passage-level semantics, while Bowman et al. (2016) use parsing and interpretation within a single tree-sequence hybrid model in model (4).

In the next group, models (5)-(11) are inter-passage attention-based models which are similar to ours. Model (5) and model (6) are LSTMs with word-by-word attention. In model (7), Parikh et al. (2016) decompose each passage into a set of words and then compare two word-sets of the passage-pair. They further improve the performance by adding intra-passage attentions in model (8). Our model is inspired by their approach. Specifically, in models (9)-(11): Zhao et al. (2016) adopt tree-LSTM and attention mechanism based on binary tree to generate semantic units and compare; Munkhdalai and Yu (2016) constructs a full n-ary tree to improve the performance, while Chen et al. (2017a) use a syntactic tree-LSTM to extract the inner dependency relations in the passage and compare between the passage-pair.

Table 1 shows that our model achieves an accuracy of 87.4%, which outperforms most of those models with tree structure (even those with complicated network architectures (Munkhdalai and Yu, 2016; Zhao et al., 2016)), and our model is more interpretable than the other models which are based tree structure. Specifically, our performance is better than Parikh et al. (2016) significantly though our model is inspired by theirs.

In the first group of Table 2, models (1)-(6) show some published best performances on MultiNLI. And models (7)-(9) are some ensemble models which have a very complicated network architecture. From this table, we can see that our performance is better than models (1)-(5) on matched set (even outperforms the ensemble models (7) and (8)), and better than models (1)-(5) on mismatched set. Please note that the structure of our model is more interpretable than that of others.

	Train Acc.	Test Acc.
Original model	90.3	87.4
(1) merged comparison	89.3	84.5
(2) replace self-attention with inter-attention	92.1	86.6
(3) remove cross-comparison	88.3	86.5

Table 3. Ablation study on SNLI set

3.4 Ablation analysis

Table 3 examines the effect of each major component. In order to check whether the strategy of performing individual comparison between *RHD* triplets works well in this task, model (1) directly compares one triplet with the merged representation from the triplet-set of the other side (in the Matching Layer). In this model, we compute one representation for each triplet by concatenating its three parts, align between these triplet representations of the sentence pair, and then compare each triplet with the merged representation from the triplet-set of the other sentence as in (Parikh et al., 2016). It shows that the proposed individual comparison strategy gives a better result.

In model (2), instead of using self-attention to generate the alignment weight between one triplet pair, we first yield a semantic vector representation for each triplet by concatenating their three parts and processing it with a linear transform. And then we use the multiplication of the vector representations of each triplet-pair as their alignment weight (as adopted in (Parikh et al., 2016)). When we do this alteration, the accuracy drops to 86.6% on the test set. This again proves that adopting individual comparison for each triplet-pair can describe their relatedness more accurately.

Last, we remove *cross-comparison* from our approach and list the result in model (3) to check the effect of this component. This component is mainly used to compare the words which are similar in semantics but play different syntactic/semantic roles. It shows that when we remove this component, the accuracy drops to 86.5%.

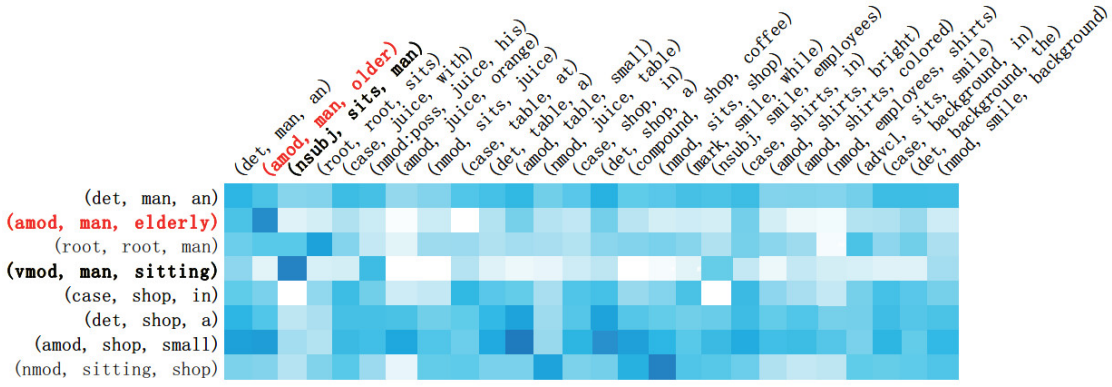

Figure 4. Triplet alignment weights for the triplet-pair in Figure 1. The darker color represents greater value. The triplets for *P* are on the top, and the triplets for *H* are on the left.

3.5 Visualization of Triplet Alignment

Figure 4 shows the alignment weights e_{ij} (i.e., the degree of relatedness between the triplets within the same sentence pair) of the example in Figure 1. In this figure, a darker color corresponds to a larger value of e_{ij}. From this figure, we can see that the related triplets do have larger alignment weights between them. For example, compared with other triplets of *H*, triplet (*amod, man, elderly*) in *H* (the red entry at the left of Figure 4) is more related to (*amod, man, older*) of *P* (the red entry at the top), which is echoed with a darker corresponding cell in Figure 4. Similarly, the corresponding cell for (*nsubj, sits, man*) of *P* and (*vmod, man, sitting*) of *H* shows a darker color, which also meets human judgment. This clearly shows that the alignment weights between these two triplet sets reflect the human interpretation closely.

4 Related Work

Early approaches for natural language inference usually adopted statistical models such as SVM (Joachims, 1998), CRF (Hatoriet et al., 2009) and so on, which employed hand-crafted features, and utilized various external resources and specialized sub-components such as *negation detection* (Lai and Hockenmaier, 2014; Levy et al., 2013). Besides, all the adopted datasets are very small.

After the SNLI corpus (Bowman et al., 2015) was released, a lot of work about natural language inference based on neural networks have been published in recent years (Bowman et al., 2016; Liu et al., 2016; Liu et al., 2016b; Munkhdalai and Yu, 2016; Mou et al., 2015; Sha et al., 2016). Basically, those neural network based approaches could be classified into 2 categories: (1) Merely computing the passage-embedding without introducing alignment (between the words in the sentences), and then comparing these passage-embedding to get the prediction (Bowman et al., 2016, Mou et al., 2016). (2) Decomposing the passage into some semantic units, comparing each semantic unit with the passage of the other side and then aggregating these comparisons (Parikh et al., 2016; Wang et al., 2017).

Within the first category, Bowman et al. (2015) used two LSTMs to get the representations of *P* and *H,* respectively. They then compare the vector representation of these two passages to predict the relationship between *P* and *H*. Besides, Bowman et al. (2016) used tree-LSTM to encode the representation of the passage. Although it uses the dependency relation in the passages to generate the representation, it cannot point out the difference among different words and is unable to catch the key information in the prediction step.

For the second category, Zhao et al. (2017) used the intermediate representations from tree-LSTM to compare *P* and *H*. It compares each node representation with the merged representation of the other passage, and generates the result bottom-up. In this way, it can extract the dependency relations in the passages and compare semantics in different granularities. However, they adopt the tree-LSTM to bottom-up generate the intermediate representations, and then directly compare each unit with the merged representation of the other passage. As the result, they cannot catch the key information and filter out irrelevant text.

Different from them, we transform *P* and *H* into two sets of *RHD* triplets, instead of comparing one *RHD* triplet of *P* with the merged information of the whole *H* (and vice versa), we directly compare a

RHD triplet of *P* with another *RHD* triplet of *H* to obtain the *individual comparison vector* (without merging). Specifically, when comparing two *RHD* triplets, each part in *RHD* triplet (i.e., *rel, head*, and *dep*) is compared separately and *cross-comparison* is adopted between nodes. Furthermore, we generate more precise alignment weights with these *individual comparison vectors* and self-attention mechanism. Consequently, our model is more interpretable than the previous models.

5 Conclusion

Inspired by how human judge the entailment relationship between the given *Premise (P)* and *Hypothesis (H)* text passages, we propose to transform the passages into two sets of word-pair dependency triplets, and then directly compare each triplet with every triplet from the other side to get the *individual comparison vector*. In this way, we can filter out the irrelevant information and judge the relationship between two passages more precisely. In order to further improve the comparison precision, we compare each part (i.e., "*rel*, *head*, and *dep*") of triplet separately and adopt *cross-comparison* to compare the related words which are with different syntactic/semantic roles. As these *individual comparison vectors* can describe the relatedness of the triplet-pair well, we use them and self-attention mechanism to generate the alignment weights between triplets from each passage. Afterwards, we use the alignment weights to incorporate these *individual comparison vectors* to yield the *one-side merged comparison vector* of one *RHD* triplet with the *RHD* triplet set of the whole other side. Finally, we aggregate those *one-side merged comparison vectors* to conduct the final overall entailment decision.

Abstract

Distantly supervised relation extraction greatly reduces human efforts in extracting relational facts from unstructured texts. However, it suffers from noisy labeling problem, which can degrade its performance. Meanwhile, the useful information expressed in knowledge graph is still underutilized in the state-of-the-art methods for distantly supervised relation extraction. In the light of these challenges, we propose CORD, a novel **CO**ope**R**ative **D**enoising framework, which consists two base networks leveraging text corpus and knowledge graph respectively, and a cooperative module involving their mutual learning by the adaptive bi-directional knowledge distillation and dynamic ensemble with noisy-varying instances. Experimental results on a real-world dataset demonstrate that the proposed method reduces the noisy labels and achieves substantial improvement over the state-of-the-art methods.

1 Introduction

Relation extraction aims to discover the semantic relationships between entities. Recently, it has attracted increasing attention due to its broad applications in many machine learning and natural language processing tasks such as Knowledge Graph (KG) construction (Shin et al., 2015), information retrieval (Kadry and Dietz, 2017), and question answering (Abujabal et al., 2017).

Distant supervision is one of the most important techniques in practice for relation extraction due to its ability to generate large-scale labeled training data automatically by aligning KGs to text corpus. Despite its effectiveness, it suffers from noisy labeling problem such as false negative examples, which can severely degrade its performance. To alleviate this limitation, multi-instance learning and probabilistic graphical models have been widely explored by existing work (Riedel et al., 2010; Hoffmann et al., 2011; Surdeanu et al., 2012). Due to the success of deep learning, there has been increasing interest in applying deep neural networks to solve this problem. Zeng et al. (2015) proposed a piecewise CNN model combining multi-instance paradigm, Lin et al. (2016) and Lin et al. (2017) introduced sentence-level and multi-lingual attention to alleviate the side-effect caused by noisy instances, and Luo et al. (2017) further modeled noises explicitly.

However, most existing studies reduce noises by leveraging information within text corpus, ignoring the relational facts expressed in other information sources, such as KG triples or semi-structured tables. Leveraging various information sources simultaneously, which takes full advantage of diverse and supplementary information in different sources, is beneficial to reduce noisy labels for distant supervision. To be more specific, we transform each sentence into entity sequence based on KG information, which is helpful to locate critical entities and adjust word-based network when their predictions are not consistent.

Moreover, by incorporating information from other sources, distantly supervised relation extraction methods can better handle "Not A relation" (NA) class, which is the main reason for the noisy label problem. The large proportion of NA instances is typical in distantly supervised relation extraction task, and it's non-trivial to characterize the NA patterns only based on text-corpus information. By considering

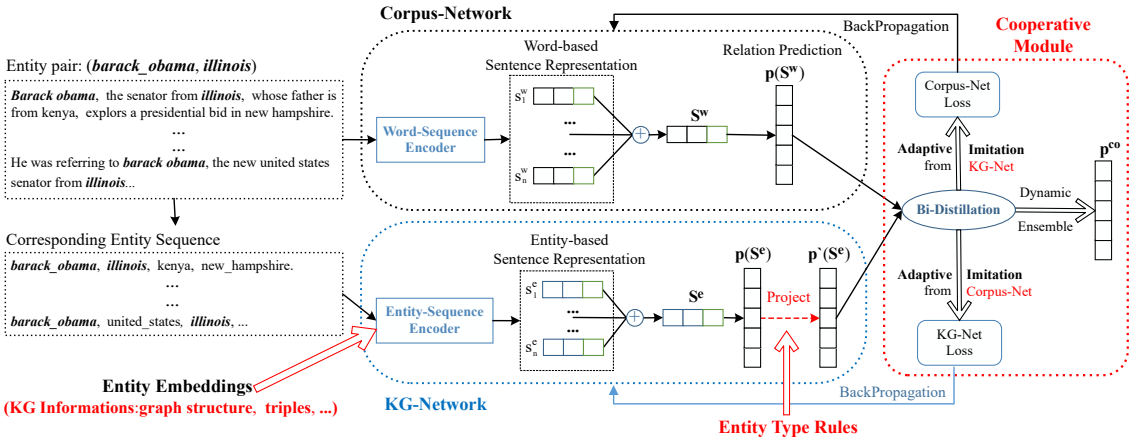

Figure 1: Overview of the proposed Cooperative Denoising Framework.

the information from KG, entity sequence can easily discriminate NA from other relations, since entities appeared in NA sentence usually are not connected in KG.

Motivated by the above observations, we propose a novel cooperative denoising framework (see Figure 1) to leverage the corpus-based and KG-based information. Specifically, we design two base networks, Corpus-Net and KG-Net, which are modeled with two separate Gated Recurrent Unit (GRU) networks, to predict relations using word-sequence and entity-sequence respectively. For KG-Net, we employ network embedding and KG embedding methods to pre-train the entity embeddings, and then project the prediction to a logic rule regularization subspace. Afterward, we design a cooperative module which involves the interactive learning between the two base networks with an adaptive bi-directional knowledge distillation mechanism, and the predictions of the base networks are dynamically integrated by an ensemble method. The key insight is that the base networks trained on different sources can learn complementary information, and thus the cooperative learning can benefit from the complementarity of different expressions of the same relational fact.

Our main contributions are as follows:

- We explore the feasibility of distantly supervised relation extraction by leveraging the information from different sources cooperatively.
- We devise a bi-directional knowledge distillation mechanism to enhance each base network via supplementary supervision.
- We design an adaptive imitation rate setting and a dynamic ensemble strategy to guide the training procedure and help the prediction of noisy-varying instances.
- The experimental results on a benchmark dataset show that the proposed method has robust superiority over compared methods.

2 Methodology

In this paper, we focus on the task of distantly supervised relation extraction. Our goal is to predict relation r for a given entity pair $< e_1, e_2 >$. The proposed framework CORD conducts with multi-instance learning, i.e., we take a bag of sentences mentioning both entity e_1 and e_2 as input, and we compute the probabilities for each relation expressed by this bag as output.

As Figure 1 shows, given a collection of sentences containing the target entity pair, we first transform each sentence into its distributed word-sequence and entity-sequence representations, and predict relation respectively using the attention weighted representation via a multi-instance learning mechanism. We also project the prediction of KG-Net to a logic rule regularization subspace. Then, we train the two base networks simultaneously with a bi-directional knowledge distillation method, in which the predictions of KG-Net and Corpus-Net are used as soft labels for each other. The final prediction is the ensemble

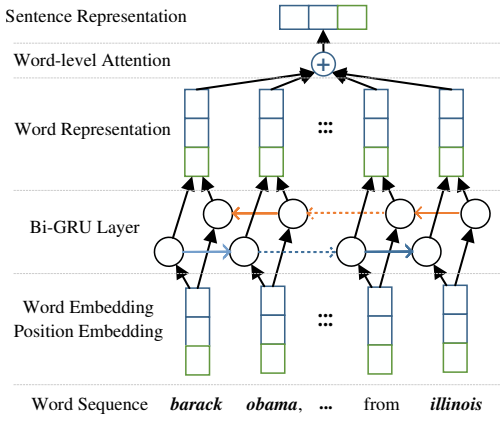

Figure 2: Word-Sequence Encoder.

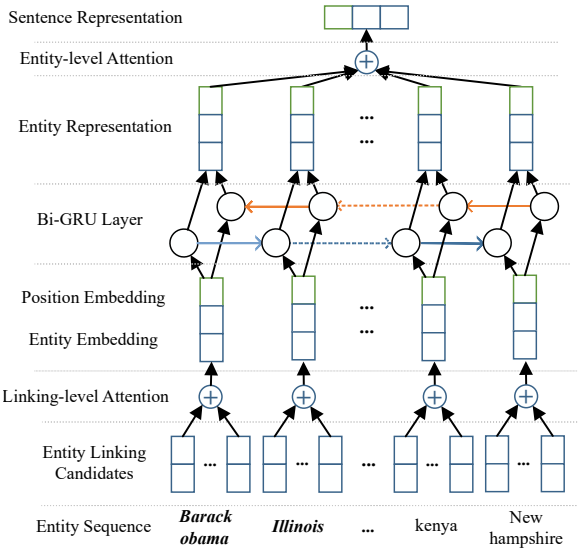

Figure 3: Entity-Sequence Encoder.

of the two base networks, and their weights in the ensemble are dynamically adjusted. In the rest of this section, we elaborate each component of CORD in detail.

2.1 Corpus-Network

We first introduce the word-sequence encoder shown in Figure 2, which transforms each sentence s_i to corresponding word-based sentence representation $\mathbf{s_i^w}$.

Input Representation Each word in the sentence is mapped to a low-dimensional embedding $w_i \in \mathbb{R}^{d_w}$ through a word embedding layer, where d_w denotes the size of the embedding. Similar to Zeng et al. (2014) and Lin et al. (2016), we encode the relative distances to entity e_1 and e_2 as $p_i \in \mathbb{R}^{2d_p}$, where $2d_p$ is the size of the position embedding. The distances are helpful in emphasizing how informative the word is thereby enabling better discrimination for relation extraction. We concatenate word vector w_i and position vector p_i as $\mathbf{w_i} = w_i \| p_i$, $\mathbf{w_i} \in \mathbb{R}^{d_w+2d_p}$, and feed words input $\mathbf{s_i} = \{\mathbf{w_1}, \ldots, \mathbf{w_n}\}$ to Bi-GRU layer.

Bi-directional GRU Layer We employ bi-directional GRU to encode patterns in $\mathbf{s}_i$ into a hidden representation $\mathbf{s_i^w} = \{h_1^f \| h_T^b, \ldots, h_T^f \| h_1^b\}$, which is obtained by concatenating each forward state h_j^f and backward state h_{T-j+1}^b at step j given input $\mathbf{s}_i$, $\mathbf{s_i^w} \in \mathbb{R}^{2d_h}$ and d_h means the hidden size of GRU. The forward sequence $[h_1^f, h_2^f, \ldots, h_T^f]$ and backward sequence $[h_1^b, h_2^b, \ldots, h_T^b]$ are calculated by GRU (Cho et al., 2014).

Hierarchical Attention As Figure 2 and Figure 1 show, we apply hierarchical attention for Corpus-Net involving word and sentence levels respectively. The motivation is that the semantic meaning of a sentence bag representation is gathered by vectors in different levels from the bottom to up, and the vectors in different context do not contribute equally. Some words express targeted relation more relevantly than others in a sentence. Furthermore, since we concatenate position vector to each word, a word with different distance is also importance-varying. As for sentence-level attention, it can reduce the weights of the sentences that suffer from wrong-labeling and improper-bagging (i.e., express inconsistent relations) problems. Inspired by Lin et al. (2016), we calculate the aggregation of different level attentions with unified form as:

$$\mathbf{X} = \sum_{i=1}^{n} a_i \mathbf{x}_i; \qquad a_i = \frac{exp(\mathbf{x_i A r})}{\sum_{j=1}^{n} exp(\mathbf{x_j A r})}, \tag{1}$$

where $\mathbf{x_i}$ is individual input vector in different levels, $\mathbf{X}$ is the corresponding sum of them, $\mathbf{r}$ is randomly initialized global relation vector. Note that we set different $\mathbf{r}$ and weighted diagonal matrix $\mathbf{A}$ for different attention levels.

Finally, the Bi-GRU output of each word $\mathbf{w_i}$ is gathered to sentence representation $\mathbf{s^w}$, and then to the bag-wise representation $\mathbf{S^w}$. We feed the resulting vector $\mathbf{S^w}$ to a *Softmax* classifier.

Prediction With $\mathbf{S^w}$ as input, the condition probability of each relation j is calculated as:

$$\mathbf{p_j}(\mathbf{S^w}) = \frac{\exp(o_j)}{\sum_{i=1}^{n_r} \exp(o_i)}; \qquad \mathbf{o} = \mathbf{W}\mathbf{S^w} + \mathbf{b}, \tag{2}$$

where $\mathbf{o} = [o_1, \ldots, o_{n_r}]$ is calculated with coefficient matrix $\mathbf{W} \in \mathbb{R}^{n_r \times (2d_h)}$ and bias $\mathbf{b} \in \mathbb{R}^{n_r}$. n_r is the number of relations and o_j measures how well $\mathbf{S^w}$ matches relation j.

2.2 KG-Network

Besides Corpus-Net, we propose another base network to incorporate information of KG. The entity-sequence encoder transforms each sentence s_i to entity-based sentence representation $\mathbf{s_i^e}$ as illustrated in Figure 3.

Input Representation One of the key challenges of leveraging KG information is identifying what information to use. Here we employ an extensible manner by using different entity embedding methods. For instance, *network embedding* methods such as DeepWalk (Perozzi et al., 2014) primarily encode graph structure information, while *knowledge embedding* methods such as TransE (Bordes et al., 2013) usually focus on triples information, we can flexibly use one of them or merge them together. Specifically, we link the detected entity names in sentences to the Freebase5M (Bordes et al., 2015) by n-gram text matching, and use the DeepWalk and TransE embeddings of linked entity candidates denoted as $\{e_{1,1}, e_{1,2}, \ldots, e_{m,k-1}, e_{m,k}\}$, where k is the amount of candidates for each entity, m is the amount of entities appearing in sentence.

In addition, we use the position vectors of Corpus-Net for KG-Net because the word-based distances are more discriminative than the entity-based distances. To be specific, the transformation between them is not one-to-one mapping because different word-sequences may result in the same entity-sequence and hence loss of information, e.g., "Obama flew to the US" and "Obama left the US" are both mapped to "Obama, US".

Bi-GRU and Attention Then we employ a similar architecture of the Bi-GRU component and the attention aggregation of Corpus-Net. As shown in Figure 3, the linked candidates $\{e_{i,1}, \ldots, e_{i,k}\}$ are aggregated to e_i for each entity, then entity vectors $\{e_1, \ldots, e_m\}$ and position vectors $\{p_1, \ldots, p_m\}$ are concatenated in element-wise and as input to Bi-GRU layer. The Bi-GRU outputs are gathered to $\mathbf{s^e}$ with entity-level attention, then to $\mathbf{S^e}$ with bag-level attention, and fed to a *Softmax* classifier similar to Corpus-Net.

External Rule Knowledge We regard the patterns learned automatically from word and entity sequences as internal knowledge and manage to transfer external human knowledge such as logic rules into the base network. Furthermore, the KG-specific rules can be incorporated into Corpus-Net gradually by bi-distillation and vice versa.

Here we concentrate on relation-specific type rules because: (1) We observe some typical false predictions which could be corrected with type rules (e.g., it is unreasonable to predict two person entities as relation *place of birth* whose tail type cannot be a *person*). (2) We can automatically obtain large-scale type resources because most KG reserved this information. For example, in Freebase, we can collect the types of entities located in *type/instance* field and the relation-specific type constraints located in *rdf-schema#domain* and *rdf-schema#range* fields.

To be specific, given all types (an entity can have many types) for an entity pair j as $t_{j,1}$ and $t_{j,2}$, we design the logic rule for each relation i as $T_{i,1}\ and\ T_{i,2}\ are\ not\ missing \implies (T_{i,1} \in t_{j,1}) \wedge (T_{i,2} \in t_{j,2})$ where $T_{i,1}$ and $T_{i,2}$ are the relation-specific type constrains for relation i. Here we apply probabilistic soft logic (Bach et al., 2017) to encode rules flexibly, i.e., the rule scores are continuous truth values in the internal $[0, 1]$ rather than $\{0, 1\}$ and logic $\wedge$ denotes averaging of truth values.

Moreover, considering type granularity, i.e., type information that is usually specified with hierarchy form (e.g., /people/person/spouse), we divide the number of matched levels (fields) of the type hierarchy by field amount as the value of $(T_i \in t_j)$ to gain fine-grained features.

Finally, with prediction $\mathbf{p}(\mathbf{S^e})$ from *Softmax* classifier, we use a posterior regularization fashion (Hu et al., 2016) to project $\mathbf{p}(\mathbf{S^e})$ into a constrained subspace $\mathbf{p}'(\mathbf{S^e})$ as follows:

$$(\mathbf{p}'(\mathbf{S^e}))^* \propto \mathbf{p}(\mathbf{S^e}) \times \mathrm{e}^{s_r}, \qquad s_r = -\sum_{i=1}^{l} C\lambda_i(1 - r_i(\mathbf{S^e})), \tag{3}$$

where λ_i is confidence of each rule, C is regularization parameter and s_r is rule score factor, which indicates how $\mathbf{S^e}$ satisfies the rules. This is the closed-form solution obtained by solving an optimization problem which finds the optimal $\mathbf{p}'(\mathbf{S^e})$ fitting rules meanwhile staying to $\mathbf{p}(\mathbf{S^e})$. We set λ_i as $\mathbf{p}_i(\mathbf{S^e})$, i.e., the higher probability classifier predicts (believes), the stronger effect rule-constraint takes for relation i. We can design other rules and enable to scale with similar manner.

2.3 Cooperative Module

In this section, we introduce how to ensemble two base networks cooperatively.

Bi-directional Knowledge Distillation We observe that KG-Net and Corpus-Net have different hard examples and different wrong predictions, i.e., for the same sentence bag, Corpus-Net may predict higher probability than KG-Net and sometimes, the contrary (we demonstrate the differences in Experiments Section). This observation encouraged us to train them cooperatively with mutual knowledge supplementation.

We devise a bi-directional knowledge distillation method to enhance their supervision information in label space. Specifically, the two base networks learn with the hard label $\mathbf{y}$ from distant supervision. Meanwhile, we set the predicted probability of the two base networks $\mathbf{p}^c$ and $\mathbf{p}^k$ as soft label to each other simultaneously:

$$L_c = \sum_{i=1}^{N}(\ell(\mathbf{y}_i, \mathbf{p}_i^c) + \pi_c \ell(\mathbf{p}_i^k, \mathbf{p}_i^c)), \qquad L_k = \sum_{i=1}^{N}(\ell(\mathbf{y}_i, \mathbf{p}_i^k) + \pi_k \ell(\mathbf{p}_i^c, \mathbf{p}_i^k)), \tag{4}$$

where ℓ is cross entropy loss, π is imitation rate, and N is batch size. We update the model parameters by minimizing L_c and L_k with Adam (Kingma and Ba, 2014) optimizer.

The learning process can be regarded as the fact that the two base networks not only learn from the coarse-grained hard label which is one-hot and low entropy, but also learn from the teacher network which expresses specific supplementary knowledge and dependencies between relations with soft label. For example, label $[0.3, 0.2, 0.9]$ is more informative than $[0, 0, 1]$.

Also note that the early base network is not reliable and gives low quality knowledge through soft label, so we pre-train the two base networks separately with certain steps before mutual learning.

Adaptive Imitation Rate The classification difficulty of the two base networks is varying with different entity pair bag instance, sometimes KG-Net is a better qualified teacher for Corpus-Net and sometimes vice versa. To transfer more reliable knowledge of each base network to another and train them more effectively, we set the imitation weights as following:

$$\pi_c = \frac{\ell(\mathbf{y}_i, \mathbf{p}_i^k)}{\ell(\mathbf{y}_i, \mathbf{p}_i^c) + \ell(\mathbf{y}_i, \mathbf{p}_i^k)}, \qquad \pi_k = \frac{\ell(\mathbf{y}_i, \mathbf{p}_i^c)}{\ell(\mathbf{y}_i, \mathbf{p}_i^c) + \ell(\mathbf{y}_i, \mathbf{p}_i^k)}, \tag{5}$$

where π_c and π_k are inversely proportional to the hard-label loss of each other, i.e., the smaller the loss is, the more qualified is the base network as teacher toward each other. In addition, from the perspective of optimization, the adaptive imitation can prevent the gradient from being dominated by ill-classified examples and hence be able to train the model effectively.

Later, in Section 3.4, we will demonstrate the effectiveness of the adaptive imitation rate by comparing with the fixed setting.

Dynamic Ensemble Prediction The final prediction $\mathbf{p}^{co}$ of the CORD framework is an ensemble of the two base networks predictions $\mathbf{p}^c$ and $\mathbf{p}^k$ because each of them has its strong points. We propose a dynamic ensemble strategy considering that (1) A high type-rule score indicates KG-Net may classify current sentence bag well because the predictions of the classifier satisfy the rules; (2) Ideally, entity

name in a sentence should be linked to only one entity in KG, so the KG-Net would be more confused with more linked candidates. Thus, with the above two factors, we can specify the dynamic ensemble prediction $\mathbf{p}^{co}$ as follows:

$$\mathbf{p}^{co} = (1 - w_k)\mathbf{p}^c + w_k\mathbf{p}^k, \qquad w_k = \alpha + \beta(\frac{s_r}{n_r} - \frac{n_c}{n_e \times N_e}), \tag{6}$$

where α is the empirical KG-Net base weight, β is the wave range. They can be set as the ratio of some evaluation indicators (such as F-score) of separate-trained base network. Then the prediction weight of KG-Net $w_k \in [\alpha - \beta, \alpha + \beta]$ depends on the normalized ($\in [0, 1]$) rule score factor and candidates score, i.e., average rule score per-relation and number of candidates per-entity dividing N_e, which is the upper limit on the number of candidates for linking. And s_r is the rule score factor in Eq. 3, n_r, n_c n_e are the amounts of relations, all entities candidates and gathered entities in sentence respectively.

As a comparison, we also deploy a naive baseline using static ensemble weight and report the results in Section 3.4.

3 Experiments

In this section, we aim to evaluate the effectiveness of the proposed CORD framework. We conduct an overall performance comparison with baseline methods and perform a comprehensive examination of the KG-Net and the Cooperative Module.

3.1 Experiment setup

Dataset and Evaluation Metrics We conduct experiments on the widely used benchmark dataset NYT10 (Riedel et al., 2010), which is built by aligning triples in Freebase to the New York Times corpus and contains 53 relations. There are 522,611/172,448 sentences, 281,270/96,678 entity pairs, and 18,252/1,950 relation mentions in train/test dataset respectively. Following previous works (Mintz et al., 2009; Lin et al., 2016), we evaluate our method in the held-out evaluation with P-R curve and P@N metric without expensive human evaluations.

Parameter Settings We set the embedding dimensions as 5, 50, 64, 64 for position, word2vec, DeepWalk and TransE respectively. For both base networks, we set the cell size of GRU as 230, learning rate as 0.001, dropout probability as 0.5 and batch size as 20. For the cooperative module, we set the base weight α and wave range β as 0.4, 0.2 respectively, and fixed w_k as 0.4 for ensemble comparison.

3.2 Comparison with Baseline Methods

We compare our approach with three traditional feature-based methods and two state-of-art neural-based methods.

Feature-based Methods *Mintz* (Mintz et al., 2009) is a multiclass logistic regression model; *MultiR* (Hoffmann et al., 2011) is a probabilistic graphical model which can handle overlapping relations; *MIML* (Surdeanu et al., 2012) is also a probabilistic graphical model but using a multi-instance multi-label paradigm.

Neural-based Methods *CNN+ATT* (Lin et al., 2016) is a sentence-level attention model based on CNN, which can dynamically reduce the weights of noisy instances; *PCNN+ATT* (Lin et al., 2016) achieves state-of-art results by applying sentence-level attention to the piecewise max pooling model, PCNN (Zeng et al., 2015).

The precision-recall curve results are shown in Figure 4, where *Base-Net-Corpus* and *Base-Net-KG* are our best results for the two base networks with independent training, *CORD* is the cooperative training and dynamic ensemble results. For the aforementioned five methods, we directly use the results reported in (Lin et al., 2016).

Figure 4 demonstrates that: (1) The KG-Net achieves higher coverage than the feature-based methods, comparable precision with the *MultiR* and *MIML* and an obvious gap with other neural-based methods. This indicates that the KG-Net and feature-based methods can capture certain patterns effectively but with relatively low coverage. On one hand, the decent precision shows potentials of the KG-Net to capture patterns with entity-sequence and KG information. On the other hand, we suggest that the

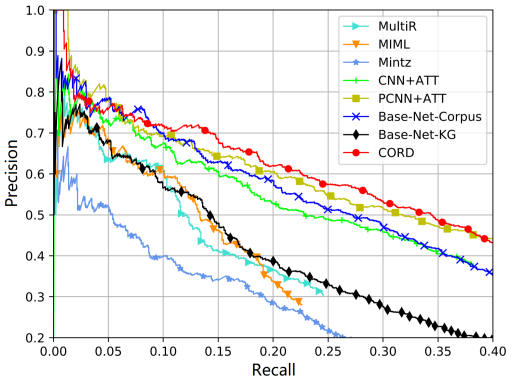

Figure 4: P-R Curve Comparison with Mintz, MIML, MultiR, CNN+ATT and PCNN+ATT.

weakness of the KG-Net might be caused by the sparsity of entity-sequence space (the dataset scales down after word-to-entity mapping), and we can enhance it by exploring other information such as relational paths (Lin et al., 2015; Zeng et al., 2017); (2) Corpus-Net achieves comparable results with *CNN+ATT* and *PCNN+ATT*, which reveals the effectiveness of Corpus-Net that could be the backbone of the CORD framework; (3) The CORD outperforms other methods on most recall area, demonstrating the effectiveness of our methods. Note that the CORD framework is significantly superior to the two separate trained base networks, especially in the rightmost area. This shows the cooperative module takes advantages of two base networks effectively and achieves better generalization. Also note that in the right-side area, CORD is still robust although the separate trained KG-Net is weak, which verifies the effectiveness of the CORD with different strengths of the base networks.

3.3 Performance of the KG Network

To evaluate the effect of incorporating KG information, we first compare P-R curve for different KG-Net setups, then we explore the benefit of using external logic rules and make a case study.

Comparison for Different Setups We experiment three KG-Nets without rule knowledge, using DeepWalk, TransE and their concatenation as entity embedding respectively. Based on whichever yields the best results, we experiment with rule knowledge and report results in Figure 5.

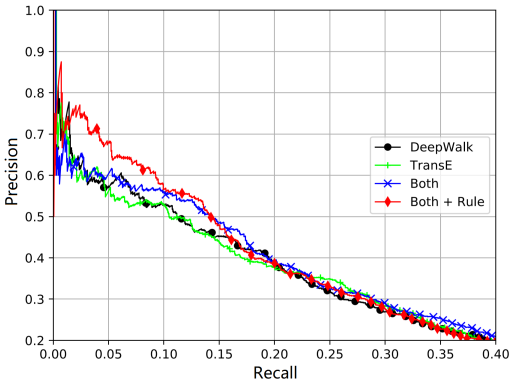

Figure 5: P-R Curve Comparison with Different Setup for the Base KG-Net.

From Figure 5, we can observe that: (1) The results of DeepWalk and TransE are slightly different and their concatenation improves, verifying the extendibility with different kinds of KG information embeddings; (2) After incorporating logic rules, the result is improved significantly as shown in left recall area, indicating that type-constraints helps to capture certain patterns more precisely.

Robustness on Long Tail Situation Efforts based on bag-level denoising such as sentence attention are liable to failure because of the long-tail situation in real-life datasets. For example, we observe that 77.63% entity pairs have only one relation instance in NYT10. We expect that supplementary external knowledge (logic rules) can enhance the robustness of this situation. We evaluate P@N of the KG-Net without rules $\mathbf{p}(\mathbf{S^e})$ and compare the rule-projected $\mathbf{p'}(\mathbf{S^e})$ on two kind of sentence amounts setup in

Table 1, where (≥ 1) means whole test dataset and (> 1) means filtering entity pairs which have only one instance.

	#Entity Pair Sentence	P@100 (%)	P@200 (%)	P@300 (%)	Average (%)
KG-Net	>1	60.2	54.0	46.4	53.5
	≥ 1	**60.3(+0.1)**	**51.5(-2.5)**	**46.0(-0.4)**	**52.6(-0.9)**
KG-Net + Rule	>1	69.2	57.0	48.6	58.3
	≥ 1	**73.5(+4.3)**	**60.4(+3.4)**	**51.7(+3.1)**	**61.9(+3.6)**

Table 1: P@N for Long Tail Situation.

From Table 1, we can observe that the KG-Net gets lower precisions (average reduces 0.9%) on the whole test data comparing with the filtered data. In contrast, the KG-Net with rules gets higher precisions on the whole test data because it can deal with noisy instances effectively in sentence-level and hence be more robust on long tail situation.

Case Study Here we pick an example instance in Table 2 to illustrate the effect of type rules. The KG-Net predicts wrong relation *place of death* probably because the appearance of entity *Joe Williams*. In contrast, it can predict correctly with the help of relation-specific type constraints.

	Predicted Relation	Relation-Specific Type
KG-Net	/people/deceased_person/place_of_death	/people/deceased_person, /location/location
KG-Net+ Rule	/location/location/contains	/location/location, /location/location
text	In ***Suffolk County***, ***Fire Island*** suffered the most damage, according to **Joe Williams**, commissioner of the county 's office of emergency management.	

Table 2: Effect of Type Constraint Rules. Bold indicates entity, italic indicates targeted entity pair.

3.4 Performance of the Cooperative Module

To investigate the effectiveness of the cooperative module, we compare the adaptive imitation rate with the fixed, the dynamic ensemble strategy with the static, and then perform a thorough case study.

Adaptive vs Fixed Imitation Rate We find that the adaptive imitation is crucial for the effective training of the CORD. To demonstrate this, we deploy some fixed imitation rate setups comparing the adaptive imitation rate. We set imitation rate (π_c, π_k) as $\{(0.5, 0.5), (0.6, 0.4), (0.4, 0.6)\}$, and report the loss curves of the dynamic, and only $(0.5, 0.5)$ for the fixed in Figure 6 because the other two have similar results.

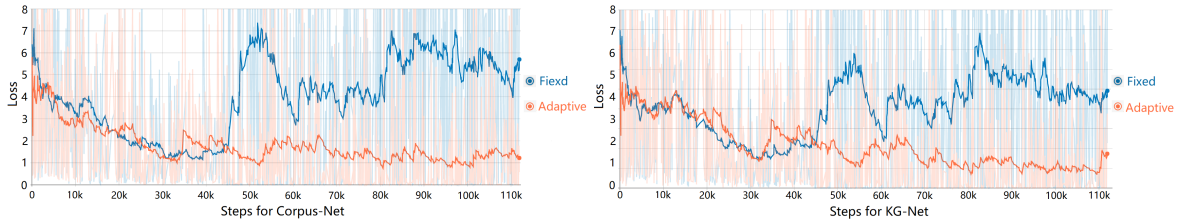

Figure 6: Loss for Adaptive and Fixed Imitation.

Figure 6 shows the remarkable difference between the fixed and the adaptive imitation, where the loss of the adaptive setting reduce gradually while the fixed fluctuates wildly. The waves of fixed KG-Net and fixed Corpus-Net are similar, meanwhile they mislead each other and the gradients are dominated by hard examples, resulting in the non-convergence. Conversely, the adaptive networks are trained effectively because the data speak for itself by providing loss values as clues to reveal the difficulty of predicting current instance. Note that the base networks are pre-trained independently and both descend gradually within the first 10k steps.

Dynamic vs Static Ensemble We also compare the dynamic ensemble strategy with the static and report their P@N results within identical base networks in Table 3. It shows that the dynamic outperforms the static and leverages the two base networks better. Note that the improvements decrease as recall

	P@100 (%)	P@200 (%)	P@300 (%)	Average (%)
Base-KG	64.0	55.2	49.3	56.2
Base-Corpus	77.3	72.0	66.5	73.9
Static	80.7	73.1	64.0	72.8
Dynamic	**84.5**	**76.0**	**66.7**	**76.1**

Table 3: P@N for Dynamic and Static Ensemble.

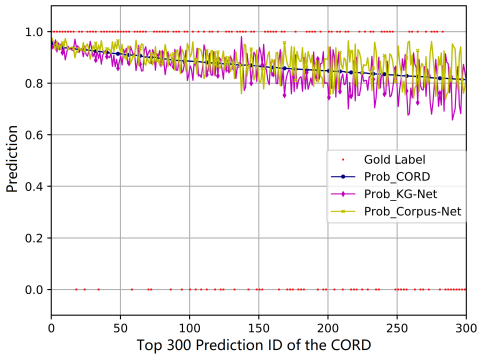

Figure 7: Top300 Predictions of the CORD.

increases, and the degree of decrease for the dynamic is less than the static, demonstrating the dynamic is more robust than the static.

Case Study To gain further insight about how the CORD works, we plot the top 300 predictions of the CORD in descending order, and compare it with its two base networks in Figure 7.

Figure 7 presents the predictions of KG-Net and Corpus-Net which go up and down around the CORD curve. The prediction differences between KG-Net and Corpus-Net are nonuniformly time-varying, indicating that some hard instances for KG-Net are easy to classify by Corpus-Net and vice versa. This supports again our view of employing adaptive imitation and dynamic ensemble.

To further demonstrate the different advantages of KG-Net and Corpus-Net, we choose two points which are predicted correctly and have significantly different values from Figure 7. The result is showed in Table 4, where prediction ID 137 and ID 257 have the different dominating network, KG-Net and Corpus-Net respectively.

ID in Figure 7	Prob-KG	Prob-Corpus	Relation	Text
137	0.9809	0.7591	location contains	when **Julian Resuello**, the mayor of ***San Carlos City*** in the northern ***Philippines***, was killed by gunmen at a campaign rally on April 28, his brother quickly stepped into his shoes.
257	0.6763	0.9583	place of death	***Ernst Haefliger***, a **Swiss** tenor who was most renowned as an interpreter of **German** art song and oratorio roles, died on Saturday in ***Davos***, **Switzerland**.

Table 4: Hard Example of KG and Corpus Net. Bold indicates entity, italic indicates targeted entity pair.

From Table 4, we can see that different networks contribute each other from the view of semantic: (1) KG-Net predicts relation *location contains* more accurately and Corpus-Net may fail if the wording of the sentence doesn't clearly state the relation between two entities. With the help of position and three entity embeddings, KG-Net can capture the relation-dependent features better from the view of graph structure. In contrast, Corpus-Net might be confused by the expression "the mayor of ..." and the uncorrelated latter part, "was killed by ..."; (2) Corpus-Net predicts relation *place of death* more accurately and KG-Net may fail if two entities are already known to be related by more than one relation. Here Corpus-Net provides reliable prediction because of the appearance of featured expression "died on ..." in the last sentence. Contrarily, KG-net may lack discriminative information and be confused by other possible relations such as *place of birth*, because the targeted person entity is followed by too many location entities.

4 Related Work

Relation extraction is one of the most important topics in NLP. Many approaches to relation extraction have been proposed, such as supervised classification (Zelenko et al., 2003; Bunescu and Mooney, 2005), bootstrapping (Carlson et al., 2010), distant supervision (Mintz et al., 2009; Krause et al., 2012; Min et al., 2013; Pershina et al., 2014; Ji et al., 2017), and generative model (Zhang et al., 2018). Among them,

distant supervision is popular as it is efficient to obtain large-scale training data automatically. However, it suffers from noisy labeling problem which severely degrades its performance.

To tackle this problem, Riedel et al. (2010; Hoffmann et al. (2011; Surdeanu et al. (2012) model distant supervision as a multi-instance learning problem under the at-least-one assumption and make it more practical. With the advances in deep learning, Zeng et al. (2015), Lin et al. (2016) and Lin et al. (2017) apply CNN and attention mechanism, Feng et al. (2017) further introduces memory network to reduce noises. Compared with these methods, the proposed framework leverages information from other sources such as KG and combine it with information from text corpus by knowledge distillation.

5 Conclusion

In this paper, we propose a novel neural relation extraction framework with bi-directional knowledge distillation to cooperatively use different information sources and alleviate the noisy label problem in distantly supervised relation extraction. Extensive experiments show that our framework can effectively model relation patterns between text corpus and KG information, and achieve the state-of-the-art results.

Abstract

Relation Classification aims to classify the semantic relationship between two marked entities in a given sentence. It plays a vital role in a variety of natural language processing applications. Most existing methods focus on exploiting mono-lingual data, e.g., in English, due to the lack of annotated data in other languages. In this paper, we come up with a feature adaptation approach for cross-lingual relation classification, which employs a generative adversarial network (GAN) to transfer feature representations from one language with rich annotated data to another language with scarce annotated data. Such a feature adaptation approach enables feature imitation via the competition between a relation classification network and a rival discriminator. Experimental results on the ACE 2005 multilingual training corpus, treating English as the source language and Chinese the target, demonstrate the effectiveness of our proposed approach, yielding an improvement of 5.7% over the state-of-the-art.

1 Introduction

Relation classification aims to identify the semantic relationship between two nominals labeled in a given sentence. It is critical to many natural language processing (NLP) applications, such as question answering and knowledge base population. For example, the following sentence contains an instance of the *Content-Container*(e_2,e_1) relation between two labeled entity mentions "e_1=*cartridge*" and "e_2=*ink*".

The [***cartridge***]$_{e_1}$ *was marked as empty, even with* [***ink***]$_{e_2}$ *in both chambers.*

An open challenge is how to train a model which is suitable for languages with insufficient available data of relation classification, since manual annotation is time-consuming and human-intensive. This makes it difficult to transferrably use the existing well-trained classification models in other languages.

To tackle this problem, we propose an adversarial feature adaptation approach to transfer latent feature representations from the source language with rich labeled data to the target language with only unlabeled data. Such an approach are both discriminative for relation classification and invariant across languages. This is largely motivated by the adversarial mechanism which has been effectively applied to measure the similarity between distributions in a variety of scenarios, such as domain adaptation (Bousmalis et al., 2016) and multi-modal representation learning (Park and Im, 2016).

In particular, we build two counterpart networks, using convolutional neural networks (CNNs), for source language and target language, to generate the latent feature representations respectively. Then, we use a rival discriminator to identify the correct source of feature representations. At the training step, the network of the source language is trained to maximize the performance on the annotated dataset, while the network of the target language is trained to imitate the feature representations of the source language by rival confusing the discriminator.

We perform the proposed approach on ACE 2005 multilingual training corpus by regarding English as the richly-labeled language (source) and Chinese as the poorly-labeled language (target). Our approach

*corresponding author

Proceedings of the 27th International Conference on Computational Linguistics, pages 437–448
Santa Fe, New Mexico, USA, August 20-26, 2018.

achieves an F1-score of 70.50% with a significant improvement of 5.7%, compared to the state-of-the-art method.

The main contributions of this study are as follows.

- We present a novel neural feature adaptation framework by leveraging a generative adversarial network to transfer feature representations from a richly-labeled language to a poorly-labeled language. To the best of our knowledge, this is the first study on feature adaptation for cross-lingual relation classification.
- Experimental results show that the latent feature representations can be effectively transferred from the source language to the target language. This enables the adaptation of the existing manually annotated resource in one language to a new language.
- In a slightly better scenario that there are a small-scale annotated data available in the target language, our adversarial feature adaptation approach can also be effectively cooperated with the supervised model to further improve the overall performance.

The rest of this paper is organized as follows. In Section 2, we overview the related work. In Section 3, we introduce details of the proposed adversarial feature adaptation approach. We show our experimental results and discussions in Section 4. Finally, we conclude the paper in Section 5.

2 Related Work

In this section, we briefly review the recent progress in cross-lingual relation classification and existing studies on adversarial adaptation.

2.1 Cross-lingual Relation Classification

Labeled data on relation classification are not evenly distributed among languages. While there are various of annotated datasets in English, such as the SemEval'10 Task-8 dataset (Hendrickx et al., 2010) and the SemEval'18 task-7 dataset (Gábor et al., 2018), annotated datasets in other languages are few.

Traditional studies for relation classification usually perform supervised machine learning models trained on mono-lingual labeled datasets, which either rely on a set of linguistic or semantic features (Kambhatla, 2004; Suchanek et al., 2006), or apply tree kernel-based features to represent the input sentences (Bunescu and Mooney, 2005; Qian et al., 2008). Recently, deep neural networks (Zeng et al., 2015; dos Santos et al., 2015) and attention mechanism (Wang et al., 2016) show the effectiveness in relation classification. However, the training of neural network relies on large-scale labeled instances. This makes it difficult to re-construct such classification models for the poorly-labeled language.

Most of existing studies have attempted to leverage parallel data or a knowledge-based system to transfer effective information from the richly-labeled language to the poorly-labeled language. Qian et al. (2014) proposed a bilingual active learning paradigm for Chinese and English relation classification with pseudo parallel corpora and entity alignment. Kim et al., (2014) proposed a cross-lingual annotation projection strategy by employing parallel corpora for relation detection. Faruqui and Kumar (2015) also present a cross-lingual annotation projection method by using machine translation results, rather than parallel data. Verga et al. (2016) performs multi-lingual relation classification by a knowledge base. Min et al. (2017) drive a classifier to learn discriminative representations by joint supervision of classification (softmax) loss and ideal representation loss.

Instead of exploiting external resources and manually selecting a closeness metric, we come up with an adversarial mechanism to provide an adaptive metric for feature adaptation from the richly-labeled language to the poorly-labeled language.

2.2 Adversarial Adaptation

Recently, the generative adversarial networks (GAN) have become increasingly popular, especially in the area of deep generative unsupervised modeling (Goodfellow et al., 2014; Makhzani et al., 2016). For adversarial adaptation, Ganin et al. (2017) proposed the domain adversarial neural networks (DANN) to

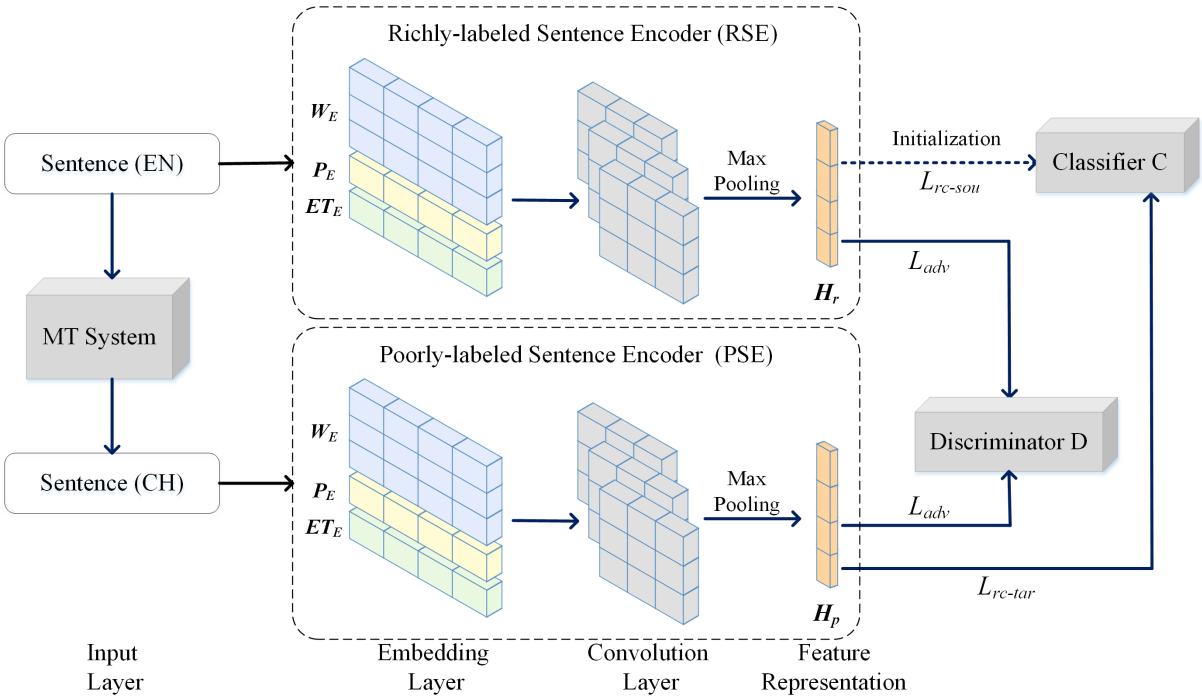

Figure 1: Architecture of the adversarial feature adaptation framework for cross-lingual relation classification.

learn discriminative but domain-invariant representations, transferring the information from the source domain to the target domain. Different from their study, our approach aims to find sharable language-independent latent feature representations for cross-lingual relation classification.

There have been some previous work applying adversarial adaptation technique to NLP tasks, such as that for sentiment analysis (Chen et al., 2016) and parsing (Sato et al., 2017). These studies learn the domain-invariant or domain-specific features by a shared network. Our work differs from them, since we force a second network with identical structure to learn the latent feature representations from the supervised network. Qin et al. (2017) propose a feature imitation approach. An adversarial mechanism is used between explicit and implicit discourse relation samples. Different from their study, we migrates the feature representations from one language to another (non-parallel). To the best of our knowledge, this is the first work to employ the adversarial feature adaptation for cross-lingual relation classification.

3 Adversarial Feature Adaptation for Cross-lingual Relation Classification

The common semantic information between different language motivates our adversarial feature adaptation approach. In this section, let us take a glance at the framework first, and then the relation classification networks (sentence encoders) and the adversarial training procedure.

Figure 1 illustrates the schematic overview of the framework which consists of four key components: 1) a Richly-labeled Sentence Encoder (RSE) with English sentences as the inputs, 2) a Poorly-labeled Sentence Encoder (PSE) which takes translated Chinese sentences as the input, 3) a language discriminator D distinguishing between the feature representations from the above two encoders, and 4) a relation classifier C to predict the relation label. In general, a GAN consists of a generative network G and a discriminator D, in which G generates instances by a distribution $P_{G(x)}$, and D aims to determining whether a instance is from $P_{G(x)}$ or the real data distribution $P_{data(x)}$. In our approach, the PSE is taken as the generative network which generates the feature representations $\boldsymbol{H_p}$ to confuse the discriminator.

In training step, the relation classifier aims to predict the labels, while the language discriminator attempts to distinguish between the feature representations extracted by the two sentence encoders ($\boldsymbol{H_p}$ or $\boldsymbol{H_r}$). In test step, we utilize the PSE to encode the input sentences in target language, and apply the same classifier to predict to relation labels.

3.1 Components

As a common neural network model that yields good performance for monolingual relation classification, we employ CNN to transform a sentence with pairs of entity mentions into a distributed representation $\boldsymbol{H}$. Note that, this plug-in architecture can also be implemented with the other networks, e.g., a long short-term memory network (LSTM)[1].

Embedding Layer

Following Zeng et al. (2014)'s work, we build an embedding layer to encode words, word positions, and entity types by real-valued vectors.

Given an input sentence $S = (w_1, w_2, ..., w_n)$, we first transform every word into a real-valued vector of dimension d_w using a word embedding matrix $\boldsymbol{W_E} \in \mathbb{R}^{d_w \times |V|}$, where V is the input vocabulary. Since the structures of RSE and PSE are the same, it is necessary if the word representations for both languages have a shared vocabulary. Therefore, bilingual word embeddings (Shi et al., 2015) are employed to map words from different languages into the same feature space.

To capture the informative features of the relationship between words and the entity mentions, we map the relative distances to entity mentions of each word to two real-valued vectors of dimension d_p using a position embedding matrix $\boldsymbol{P_E} \in \mathbb{R}^{d_p \times |D|}$, where D is the set of relative distances which are mapped to a vector initialized randomly (dos Santos et al., 2015). For each word, we obtain two position vectors with respect to the two entity mentions.

For each word, we also incorporate its entity type embedding to reflect the relationship between the entity type and the relation type. Each word is mapped to a real-valued vector using embedding matrix $\boldsymbol{ET_E} \in \mathbb{R}^{d_{et} \times |E|}$, where E is the set of entity types.

Finally, we represent a input sentence as a vector sequence $\mathbf{w}=\{\mathbf{w}_1, \mathbf{w}_2, ..., \mathbf{w}_n\}$ with the embedding dimension $d = (d_w + 2d_p + d_{et})$.

Convolution Layer

After encoding the input sentence, a convolution layer extracts local features by sliding a window of length w over the sentence and perform a convolution within each sliding window. The output for the ith sliding window is

$$\mathbf{p}_i = \mathbf{W_c}\mathbf{w}_{i-w+1:i} + \mathbf{b}, \tag{1}$$

where $\mathbf{w}_{i-w+1:i}$ denotes the concatenation of w word embeddings within the ith window, $\mathbf{W_c} \in \mathbb{R}^{d_c \times (w \times d)}$ is the convolution matrix and $\mathbf{b} \in \mathbb{R}^{d_c}$ is the bias vector (d_c is the dimension of output of the convolution layer).

Max-pooling Layer

We merge all local features via a max-pooling layer and apply a hyperbolic tangent function to obtain a fixed-sized final representations. The ith element of the output vector $\mathbf{x} \in \mathbb{R}^{d^c}$ is

$$[\mathbf{x}]_j = \tanh \max_i \mathbf{p}_{ij}. \tag{2}$$

Classifier and Discriminator

While the Classifier C is a fully-connected layer followed by a softmax classifier, the Discriminator D is a binary classifier which is implemented as a fully-connected neural network with a sigmoid activation function. Discriminator D takes the feature representations as input, to discriminate whether the feature representation comes from RSE or from PSE.

3.2 Adversarial Training

Although the aforementioned architecture could be applied to cross-lingual relation classification by leveraging the RSE module to train on source language and the MT module to translate the instances from

[1]As an alternative, a bidirectional LSTM (BiLSTM) is tried as the basic network. The experimental results are shown in Subsection 4.2.

Algorithm 1 Adversarial Training Procedure

Input: Training dataset

Output: RSE with classifier C

1: Initialize $\boldsymbol{\theta}_h$ and $\boldsymbol{\theta}_C$ by minimizing Eq.(3).
2: **repeat**
3: Train the discriminator D through Eq.(4)
4: Train PSE and classifier C through Eq.(7)
5: **until** convergence

the target language to the source language, there is no guarantee that the latent feature representations of the source language exist in the target language, or vice versa. On the other hand, the error propagation of MT module also should be considered. Therefore, we introduce adversarial training into our cross-lingual relation classification framework.

Algorithm 1 illustrates the adversarial training procedure. First, we pre-train the RSE and the classifier C by minimizing the relation classification (RC) loss function on source language (step line 1). Then we interleave the optimization of the adversarial loss function and the RC loss function on the target language at each iteration (step line 2-5). Finally, if the discriminator cannot tell the language of a input sentence using the adversarially trained features, then those features from PSE are effectively language-invariant. Upon successful training, the feature representations ($\boldsymbol{H_p}$) are thus encouraged to be both discriminative for relation classification and invariant across languages. Referring to the expression of Qin et al. (2017), the three loss function of our adversarial training are as follows.

RC Loss for Training on Source Language

We denote the parameters of the RSE and classifier C as $\boldsymbol{\theta}_r$ and $\boldsymbol{\theta}_C$, respectively, and the objective can be learned by minimizing the cross-entropy loss as

$$\mathcal{L}_{rc\text{-}sou}(\boldsymbol{\theta}_r, \boldsymbol{\theta}_C) = \mathbb{E}_{(\boldsymbol{x_e}, y)\sim data}\left[\mathcal{J}(C(H_r(\boldsymbol{x_e}; \boldsymbol{\theta}_r); \boldsymbol{\theta}_C), y)\right], \tag{3}$$

where $\mathbb{E}_{(\boldsymbol{x_e}, y)\sim data}[\cdot]$ denotes the expectation in terms of the data distribution, $\mathcal{J}(\boldsymbol{p}, y) = -\sum_k \mathrm{II}(y = k)\log p_k$ is the cross-entropy loss between predictive distribution $\boldsymbol{p}$ and ground-truth label y, $C(\boldsymbol{H_r}(\boldsymbol{x}))$ is the final prediction of classifier C when the input is the feature representation of RSE ($\boldsymbol{H_r}(\boldsymbol{x})$), $(\boldsymbol{x_e}, y)$ is the pair of input and output of relation classification model, where $\boldsymbol{x_e}$ is an English instance, and y is the relation label.

Adversarial Loss

The adversarial loss $\mathcal{L}_{adv}$ is used to train the discriminator D to make a correct estimation that where the feature representation comes from. Formally, the parameters of the discriminator D is denoted as $\boldsymbol{\theta}_D$. The training objective of D is to distinguish the input source of feature representation as far as possible:

$$\min_{\boldsymbol{\theta}_D} \mathcal{L}_{adv} = \mathbb{E}_{(\boldsymbol{x_e}, \boldsymbol{x_c}, y)\sim data}\left[\log(1 - D(\boldsymbol{H_r}(\boldsymbol{x_e}; \boldsymbol{\theta}_D))) + \log D(\boldsymbol{H_p}(\boldsymbol{x_c}; \boldsymbol{\theta}_D))\right], \tag{4}$$

where $D(\boldsymbol{H})$ denotes the output of discriminator D to estimate the probability that $\boldsymbol{H}$ comes from the RSE rather than the PSE, $C(\boldsymbol{H_l}(\boldsymbol{x}))$ is the final prediction of classifier C when the input is the feature representation of PSE ($\boldsymbol{H_l}(\boldsymbol{x})$), and $(\boldsymbol{x_c}, y)$ is the pair of input and output of relation classification model, where $\boldsymbol{x_c}$ is a translated Chinese instance.

RC Loss for Training on Target Language

We denote the parameters of the PSE as $\boldsymbol{\theta}_p$. The training objective is to minimize the discriminator's chance of correctly telling apart the features:

$$\mathcal{L}_p(\boldsymbol{\theta}_p) = \mathbb{E}_{\boldsymbol{x_c}\sim data}\left[\log D(\boldsymbol{H_p}(\boldsymbol{x_c}; \boldsymbol{\theta}_p))\right]. \tag{5}$$

The parameters of classifier C is denoted as $\boldsymbol{\theta}_C$. The training objective of C is to correctly classify

Relation Type	Source (EN)	Target (CH)		
	train	train	dev.	test

Total	10,124	7,556	1,092	2,055

Table 1: Discription of our datasets. The data in this tabel denote the number of samples of corresponding sets. The relation type "Other" means that the relation of entity mentions is not among the aforementioned six types.

relations. The objective can be learned by minimizing the cross-entropy loss:

$$\mathcal{L}_C(\boldsymbol{\theta}_C) = \mathbb{E}_{(\boldsymbol{x_c},y)\sim data}\left[\mathcal{J}(C(\boldsymbol{H_p}(\boldsymbol{x_c};\boldsymbol{\theta}_C), y)\right]. \tag{6}$$

Finally, we combine the above objectives Eq.(5) and (6) of the relation classifiers, and minimize the joint loss:

$$\min_{\boldsymbol{\theta}_p,\boldsymbol{\theta}_C} \mathcal{L}_{rc\text{-}tar} = \lambda\mathcal{L}_p(\boldsymbol{\theta}_p) + \mathcal{L}_C(\boldsymbol{\theta}_C) \tag{7}$$

where λ is a balancing parameters calibrating the weights of the classification loss and the feature-regulating loss.

4 Experimentation

In this section, we first describe our datasets, detailed settings, and evaluation metrics used in the experiments. Then we show the effectiveness of our adversarial feature adaptation framework for cross-lingual relation classification. Finally, we further investigate the semi-supervised settings, where a small amount of labeled data of the target language exists.

4.1 Experimental Settings

In this paper we regard English as the richly-labeled (source) language and Chinese as the poorly-labeled (target) language. Note that, in fact, our model could generalize to any pair of source and target languages in principle. We conduct our experiments on the commonly used ACE 2005 multilingual training corpus (Walker et al., 2006)[2] dataset. Table 1 shows the detailed descriptions of the datasets. We utilize all of the seven types of labeled relation mentions, and evaluate all of the systems by using the micro- and macro-F1 scores over the six types of relations excluding "Other". The English and Chinese datasets are not translation of each other.

We pre-train bilingual word embeddings by CLSim[3] (Shi et al., 2015), which provides 50-dimensional embeddings for 800k parallel sentence pairs. We set the dimensions of the position embeddings and the entity type embeddings to 20 and 30, respectively, with random initialization following a continuous uniform distribution. To obtain the translated sentence pairs automatically and easily, we employ the commercial Google Translate engine[4], which is a highly engineered machine translation system. The mention boundaries and the entity type tags are provided by the ACE 2005 multilingual training corpus.

Table 3: Performance of systems on the Chinese test sets of ACE 2005 multilingual training corpus for cross-lingual relation classification. CNN-GAN: our adversarail feature adaptation approach with a CNN sentence encoder; BiLSTM-GAN: similar as CNN-GAN, with a BiLSTM sentence encoder.

All the models are optimized using ADADELTA (Zeiler, 2012). We pick the parameters showing the best performance on the development set (in Column 4, Table 1) via early stopping, and report the scores on the test set (in Column 5, Table 1). Table 2 shows the best settings of model parameters in our experiments.

We compare with the following baselines for cross-lingual relation classification.

- **CNN-MT-Source** All the instances in the English training set (the "Source" Column in Table 1) are translated into Chinese (target language) by Google Translator. A CNN model with the same structure of PSE is trained by leveraging this new translated training data on Chinese.
- **CNN-MT-Target** Contrary to the **CNN-MT-Source**, all the instances in the Chinese test set (the "Target-test" Column in Table 1) are directly translated into English (source language) by Google Translator. A CNN model with the same structure of RSE is trained by leveraging the English training set.
- **BiLSTM-MT-Source** and **BiLSTM-MT-Target** They are similar to the settings of the **CNN-MT-Source** and the **CNN-MT-Target**, respectively. For further examining the robustness of our adversarial feature adaptation framework, we replace the sentence encoder networks (CNNs) with the BiLSTM networks for both RSE and PSE. The BiLSTM model is proposed by Zhang et al. (2015), which is one of the state-of-the-art mono-lingual relation classification system. For fair comparison, we only retain the word embeddings, the position embeddings, and the entity type embeddings.
- **BI-AL** This model is proposed by Qian et al. (2014), which is a bilingual active learning system for Chinese and English relation classification with pseudo parallel corpora and entity alignment.

4.2 Experimental Results

Adversarial Feature Adaptation

Table 3 shows a performance comparison of our adversarial feature adaptation models (*-GAN) with baselines. With the CNN-GAN system, we achieve a micro-F1 score of 68.41% and a macro-F1 score

Model (CH⇒EN)	Micro			Macro		
	P	R	F1	P	R	F1
CNN-MT-Source	64.86	73.53	68.92	64.18	72.13	67.93
CNN-MT-Target	68.08	72.60	70.27	66.60	71.11	68.78
BiLSTM-MT-Source	68.30	73.24	70.68	67.06	70.79	68.88
BiLSTM-MT-Target	66.85	71.56	69.12	66.30	70.74	68.45
CNN-GAN	71.65	**77.53**	**74.47**	69.51	**73.74**	**71.56**
BiLSTM-GAN	**72.20**	75.66	73.89	**69.69**	72.03	70.84

Table 4: Performance of systems on the opposite direction for cross-lingual relation classification, in which Chinese is treated as the source language and English is treated as the target language (contrary to Table 3). The partition of English dataset is the same as that in Table 1 (i.e. the training set 70%, the development set 10%, and the test set 20%).

of 70.50%, which outperform the active learning based system (BI-AL) with a relative improvement of about 5%. It indicates that our adversarial feature adaptation framework substantially outperforms the state-of-the-art model for cross-lingual relation classification without any annotated data on the target language.

Moreover, we pay more attention to evaluate the proposed adversarial feature adaptation model against bidirectional MT-based baselines, including 1) translate the Chinses text into English, then leveraging the English relation classification model (trained on English dataset) to identify the entity type (CNN-MT-Target and BiLSTM-MT-Target), and 2) translate the English training set into Chinese, then train an Chinese relation classification model to classify the entity types (CNN-MT-Source and BiLSTM-MT-Source). Our approach improves about 2% of macro-F1 score over the machine translation based systems. Besides, the performances of CNN-MT-Source and CNN-MT-Target are comparative, which indicates that the translated direction may be insignificant for cross-lingual relation classification via MT.

We can also see that all of the CNN-based adversarial feature adaptation models achieve better results than the corresponding BiLSTM-based ones within the same settings. The reason might be that the BiLSTM is fitter for encoding order information and long-range context dependency for sequence labeling problem, while the CNN is suited to extracting local and position-invariant features. For relation classification, the essential features are always distributed around the entity mentions, which would be better utilized by CNN[5].

To validate the language independence of our feature adaptation framework, we also implement our adversarial feature adaptation systems and the MT-based systems in Table 1 on the same corpus from the opposite direction. Specifically, we regard Chinese as the source language and English as the target, then learn the feature representations from the Chinese dataset to predict the relation labels of the English dataset. Table 4 indicates that our approach also outperforms the baselines on learning the feature representations from Chinese to English. Besides, the results further validate the conclusions mentioned above: 1) Our system outperforms the MT-based systems for cross-lingual relation classification, and 2) the CNN-based systems achieve better performances than the BiLSTM-based systems in the same settings.

To further provide an empirical insight into the relationship between 1) the data size of labeled training set for supervised relation classification (the blue curve in Figure 2), and 2) the data size required by our adversarial feature adaptation system with only unlabeled sentences (the orange dashed curve in Figure 2), we simulate a supervised scenario by adding labeled Chinese instances for training a CNN-based relation classification system (CNN-CH in Table 5). We start from adding 100 labeled sentences and keep adding 100 sentences each time until 900. As shown in Figure 2, when adding the same number of labeled sentences, the CNN-CH system can better utilize the extra supervision. The margin is naturally decreasing as more supervision is incorporated, until the training set contains more than 700 instances.

[5]Yin et al. (2017) also demonstrated this conclusion for relation classification task.

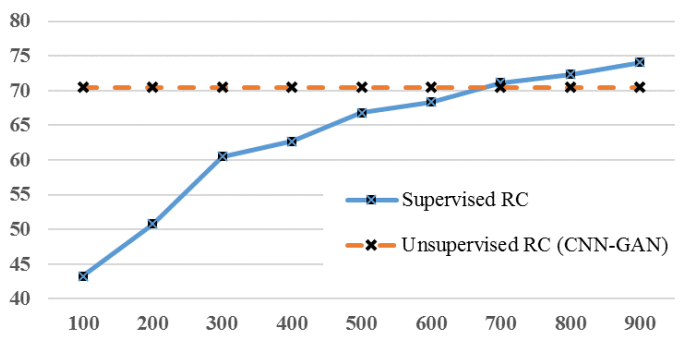

Figure 2: Comparison with a supervised relation classification system.

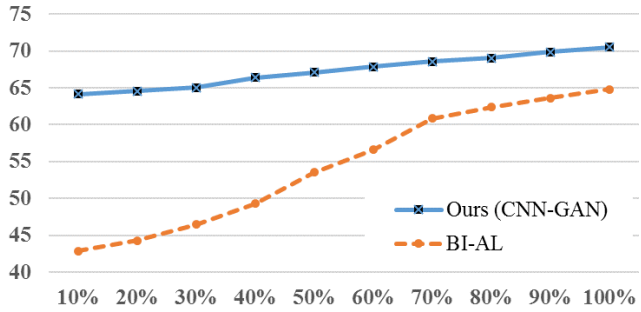

Figure 3: Comparison of the performances (macro-F1) when adding different sizes if labeled data of the source language from 10% to 100%.

It indicates that our adversarial feature adaptation system can achieve comparable performance to the supervised system trained on a small labeled dataset.

Another interesting find is that it seems a very small amount of supervision (e.g., 500 labeled instances) could significantly help the supervised relation classification system. However, it is worth noting that the manual annotation on such amount of dataset is still time-consuming and human-intensive, since the people should annotate not only the entity mentions and their relation, but also the external information such as the lexical or syntactic features if necessary.

Figure 3 compares the performances of our CNN-GAN system (the blue curve in Figure 3) and a bilingual active learning system BI-AL (Qian et al., 2014) (the orange dashed curve in Figure 3) when training with different sizes of labeled data from the source language. As we can see, the margin of our approach is not significant when the size of the source-language instances is relatively small. When using 10% of the training data, our system only declines 6.35% of performance (from 70.50% to 64.15%), while for the bilingual active learning system, the gap widens to 20.91% (from 64.80% to 42.89%). It indicates that our feature adaptation approach can efficiently utilize the translated supervision from the source language.

Semi-supervised Scenario

In this paper, we mainly focus on the the scenario of unsupervised cross-lingual relation classification, i.e., without any labeled dataset. However, for broader comparisons, we also test our framework when a few labeled training instances of the target language are available. Actually, our approach can be easily generalized to a semi-supervised setting. We employ a simple way that directly combine the softmax layers of the CNN-CH system and the CNN-GAN system, to integrate the supervision from target language into relation classification.

Table 5 lists the performances of these semi-supervised relation classification systems. We see that our ensemble model (*-CH-EN) which can employ not only the labeled data from the target language but from the source language, slightly improves over the supervised model (*-CH). It indicates that our

Model	P	R	F1
bilingual-Joint-IRL	**80.9**	77.1	78.9
CNN-CH	79.09	81.15	80.11
BiLSTM-CH	76.23	79.94	78.04
CNN-CH-EN	79.61	**81.65**	**80.62**
BiLSTM-CH-EN	77.55	79.50	78.52

Table 5: Performance of the semi-supervised relation classification systems. bilingual-Joint-IRL system: a bilingual approach by joint supervision of classification loss and ideal representation loss (Min et al., 2017); *-CH systems: A CNN/BiLSTM with the same architecture of our CNN/BiLSTM feature extractor (trained on 7,556 instances of the CH training set); *-CH-EN systems: a simple ensemble way that directly combine the softmax layers of the CNN-CH system (trained on 3,778 instances of the CH training set) and CNN-GAN system (trained on 3,778 instances of the EN training set).

adversarial model can transfer some useful knowledge and information from the source language to the target language for relation classification, by which both the language-specific and language-invariant features could be learned.

Besides, better ensemble methods could be attempted to exploit the information across language for semi-supervised relation classification. In addition, we see that our model has obtained improvement over the previous best-performing system (bilingual-Joint-IRL in Table 5) of semi-supervised relation classification.

5 Conclusion

In this paper we introduce an adversarial feature adaptation approach for cross-lingual relation classification without labeled dataset, which leverages the data on richly-labeled language to help relation classification on the poorly-labeled language. We evaluate our approach on ACE 2005 multilingual training corpus. Experimental results show that this approach can effectively transfer feature representations from a richly-labeled language to another poorly-labeled language, and outperforms several baselines including active learning models and highly competitive MT-based baselines. The code is available at `https://github.com/zoubowei/feature_adaptation4RC`.

Theoretically speaking, our adversarial feature adaptation approach can be flexibly implemented in the scenario of multiple languages, while this paper focuses on two languages of English and Chinese. Thus in future, we will extend this approach to more languages and explore its significance.

Abstract

Answering questions from university admission exams (Gaokao in Chinese) is a challenging AI task since it requires effective representation to capture complicated semantic relations between questions and answers. In this work, we propose a hybrid neural model for deep question-answering task from history examinations. Our model employs a cooperative gated neural network to retrieve answers with the assistance of extra labels given by a neural turing machine labeler. Empirical study shows that the labeler works well with only a small training dataset and the gated mechanism is good at fetching the semantic representation of lengthy answers. Experiments on question answering demonstrate the proposed model obtains substantial performance gains over various neural model baselines in terms of multiple evaluation metrics.

1 Introduction

Teaching a machine to pass admission exams is a hot AI challenge which has aroused a growing number of research (Guo et al., 2017; Cheng et al., 2016; Clark, 2015; Fujita et al., 2014; Henaff et al., 2016). Among these studies, deep question-answering (QA) task (Ferrucci et al., 2010; Wang et al., 2014) is especially difficult, aiming to answer complex questions via deep feature learning from multi-source datasets. Recently, a highly challenging deep QA task is from the Chinese University Admission Examination (*Gaokao* in Chinese), which is a national-wide standard examination for all senior middle school students in China and has been known as its large scale and strictness. This work focuses on *comprehensive question-answering* in Gaokao history exams as shown in Table 1[1], which accounts for the major proportion in total scoring and is extremely difficult in the exams. (Cheng et al., 2016) made a preliminary attempt to take up the Gaokao challenge, trying to solve *multiple-choice questions* via retrieving and ranking evidence from *Wikipedia* articles to determine the right choices. Differently, this task is to solve comprehensive questions and has to be based on knowledge representation and semantic computation rather than word form matching in the previous work.

Although deep learning methods shine at various natural language processing tasks (Wang et al., 2015; Zhang et al., 2016b; Qin et al., 2017; Cai et al., 2018; Zhang et al., 2018b; Huang et al., 2018; Zhang et al., 2018a; He et al., 2018; Zhang et al., 2018c; Li et al., 2018), they usually rely on a large scale of dataset for effective learning. The concerned task, unfortunately, cannot receive sufficient training data under ordinary circumstances. Different from previous typical QA tasks such as community QA (Zhang et al., 2016a) which can enjoy the advantage of holding a very large known QA pair set, the concerned task is equal to retrieving a proper answer from textbooks organized as plain texts with guidelines of very limited number of known QA pairs. In addition, the questions are usually given in a quite indirect way to ask students to dig the exactly expected perspective of the concerned facts. If such kind of perspective

[1]These examples are chosen as they are short, the average number of words in questions and answers are 22 and 47.

Proceedings of the 27th International Conference on Computational Linguistics, pages 449–461
Santa Fe, New Mexico, USA, August 20-26, 2018.

fails to fall into the feature representation for either question or answer, the retrieval will hardly be successful.

Q: “农民可能充当一种极端保守的角色，也可能充当一种具有高度革命性的角色。”试结合有关史实评析这一观点。 “Peasants may act as an extremely conservative role, or may be highly revolutionary.” Try to analyze this view in the light of the relevant historical facts. **A**: 农民阶级的经济地位和所处的时代条件决定了它可能充当一种具有高度革命性的角色。以太平天国运动为例，在斗争过程中颁布的《天朝田亩制度》就突出反映了农民阶级要求废除封建土地所有制的强烈愿望，表现出了高度的革命性。农民阶级存在的这种两面性是由其经济地位即受地主阶级压迫和小生产者的地位所决定的。 The economic and social conditions of peasants determine that they may act as a highly revolutionary role. Taking the Taiping Heavenly Kingdom movement as an example, the promulgated regulation “heavenly land system” reflected the peasant class’s demands and strong desire of abolishing the system of feudal land ownership, which shows a strong degree of revolution. The dual nature of the peasant class is also the result of its economic status, that is, under the oppression of the landlord class and the status of the small producers.
Q: 有人说“文艺复兴”是一场复古运动，你如何看待？如何评价其意义？ Some people think the Renaissance is a retro campaign. What’s your opinion and how to evaluate its historic significance? **A**: 文艺复兴运动从表面的含义来看，是一种复兴古希腊罗马时期的哲学、文学和艺术的活动，是一种复古运动，但从其深层的含义看，它却是一场思想解放运动，是一次思想领域里的变革。 The Renaissance is seemingly regarded as a retro movement of philosophy, literature and art of ancient Greece and Rome. However, it is actually an ideological liberation movement and a revolution of thoughts from a deeper inspection.

Table 1: Comprehensive question examples from Gaokao history exams.

Generally speaking, for the Gaokao challenge, knowledge sources are extensive and no sufficient structured dataset is available, while most existing work on knowledge representation focused on structured and semi-structured types (Khot et al., 2017; Khashabi et al., 2016; Vieira, 2016). With regard to the answer retrieval, most current research focused on the factoid QA (Dai et al., 2016; Yin et al., 2016), community QA (Zhang et al., 2017; Lu and Kong, 2017) and episodic QA (Samothrakis et al., 2017; Xiong et al., 2016; Vinyals et al., 2016). Compared with these existing studies, the concerned task is more compositive and more comprehensive and has to be done from unstructured knowledge sources like textbooks. Moreover, the answers of our Gaokao challenge QA task are always a group of detail-riddled sentences with various lengths rather than merely short sentences as focused on in previous work (Yin et al., 2016; Yih et al., 2014).

Recent research has turned to semi-supervised methods to leverage unlabeled texts to enhance the performance of QA tasks via deep neural networks (Yang et al., 2017; Lei et al., 2016). This task is somewhat different from previous ones that the expected extra labels are difficult to be annotated and the entire unlabeled data is kept in a very small scale, so that semi-supervised methods cannot be conveniently applied. Notably, one-shot learning has been proved effective for image recognition with few samples (Li et al., 2006), which is a strategy similar to people learning concept. As an implementation of one-shot learning, neural turing machine (NTM) was proposed (Santoro et al., 2016; Vinyals et al., 2016) and showed great potential by learning effective features from a small amount of data, which caters to our mission requirements. Inspired by the latest advance of one-shot learning, we train a weakly supervised classifier to annotate salient labels for questions using a small amount of examples. For question answering, we propose a cooperative gated neural network (CGNN) to learn the semantic representation and corresponding relations between questions and answers. We also release a Chinese comprehensive deep question answering dataset to facilitate the research.

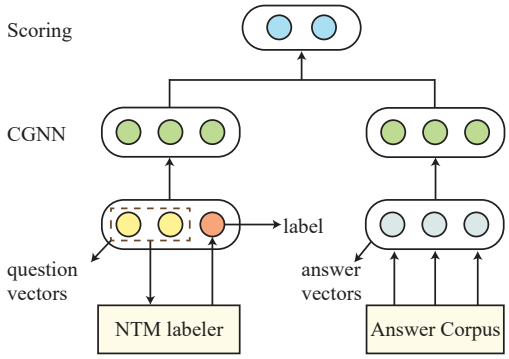

Figure 2: Model architecture.

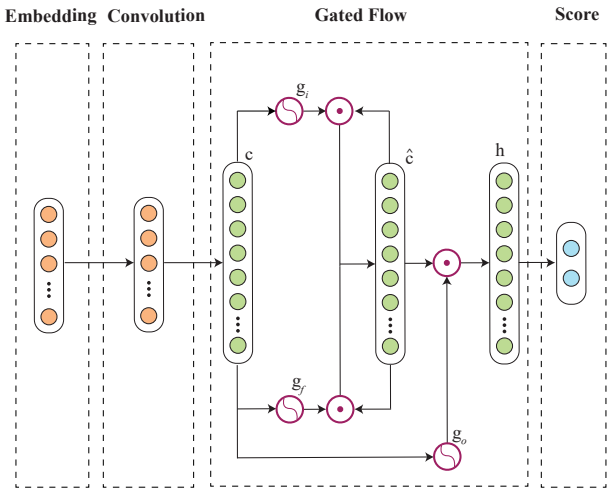

Figure 3: CGNN architecture.

The rest of this paper is organized as follows. The next section introduce our models, including retrieval model, CGNN, and NTM labeler. Task details and experimental results are reported in Section 3, followed by reviews of related work in Section 4 and conclusion in Section 5.

2 Model

The proposed hybrid neural model is composed of two main parts: cooperative gated neural network (CGNN) for feature representation and answer retrieval, and NTM as one-shot learning module for extra labeling. As shown in Figure 2, we use NTM to classify the question type and annotate the corresponding label. Then, the concatenated label vectors and question representation are fed to CGNN for jointly scoring candidate answers.

2.1 Main framework

For the QA task, the key problem is how to effectively capture the semantic connections between a question and the corresponding answer. However, the questions and answers are lengthy noisy, resulting in poor feature extraction. Inspired by the success of the popular gated mechanism (Wang et al., 2017a; Chen et al., 2016a; Lei et al., 2016) and the gradient-easing Highway Network (Srivastava et al., 2015), a CGNN is proposed to score the correspondence of inputted QA pairs. The architecture is shown in Figure 3.

Embedding Our model reads each word of questions and answers as the input. For an input sequence, the embedding is represented as $\mathbf{M} \in \mathbb{R}^{d \times n}$ where d is dimension of word vector and n is the maximum length. When using the NTM module for question type labeling, the question embedding will be refined as the concatenation of the label vectors and its original embedding. Considering the calculation efficiency, we specialize a max number of words for the input and apply truncating or zero-padding when needed.

Convolutional Layer Filter matrices $[\mathbf{W}_1, \mathbf{W}_2, \ldots, \mathbf{W}_k]$ with several variable sizes $[l_1, l_2, \ldots, l_k]$ are utilized to perform the convolution operations for input embeddings. Via parameter sharing, this feature extraction procedure is kept the same for questions and answers. For the sake of simplicity, we will explain the procedure for only one embedding sequence. The embedding will be transformed to sequences $\mathbf{c}_j (j \in [1, k])$:

$$\mathbf{c}_j = [\ldots; \tanh(\mathbf{W}_j \cdot \mathbf{M}_{[i:i+l_j-1]} + \mathbf{b}_j); \ldots]$$

where $[i : i+l_j-1]$ indexes the convolution window. Additionally, we apply wide convolution operation between embedding layer and filter matrices, because it ensures that all weights in the filters reach the entire sentence, including the words at the margins.

Gated Flow To highlight the key information and ignore irrelevant ones during convolution, we adopt an adaptive gated decay mechanism for gated information flow. Three gates are added to optimize the feature representation. These gates are only influenced by the original input through different parameters. Let $\hat{\mathbf{c}}_j^n$ denote n-gram features in c_j, the gates are formulated as

$$\mathbf{g}_i = \sigma(\mathbf{W}_i\hat{\mathbf{c}}_j^n + \mathbf{b}_i)$$
$$\mathbf{g}_f = \sigma(\mathbf{W}_f\hat{\mathbf{c}}_j^n + \mathbf{b}_f)$$
$$\mathbf{g}_o = \sigma(\mathbf{W}_o\hat{\mathbf{c}}_j^n + \mathbf{b}_o)$$

where σ denotes sigmoid function which guarantees the values in the gates are in [0,1] and $\mathbf{W}_i$, $\mathbf{W}_f$, $\mathbf{W}_o$, $\mathbf{b}_i$, $\mathbf{b}_f$, $\mathbf{b}_o$ are model parameters. The transformed inner cell is iteratively calculated by:

$$\hat{\mathbf{c}}_j^n = \hat{\mathbf{c}}_{j-1}^n \odot \mathbf{g}_i + \mathbf{g}_f \odot (\hat{\mathbf{c}}_{j-1}^{n-1} + \mathbf{W}_n)$$

where $\odot$ denotes element-wise multiplication and $\mathbf{W}^o$ is the parameter. Through gated flow, the vector $\mathbf{c}_t$ captures the filtered information. The output of our CGNN is $\mathbf{h}_j = \tanh(\hat{\mathbf{c}}_j^n) \odot \mathbf{g}_o$. The gates are used to route information through the flow. Although these gates are generated independently, they work cooperatively since they jointly control the information flow of inner-cells. This procedure will help select salient features. When there is one gate in our network, the model works similarly to the original highway network (Srivastava et al., 2015).

A *one-max-pooling* operation is adopted after the gated flow and the current state vector $\mathbf{s}_j$ is obtained through concatenating all the mappings for those k filters, we have $\mathbf{s}_j = \mathbf{max}(\mathbf{h}_j)$.

For discriminative training, we use a max-margin framework for learning (or fine-tuning) parameters θ. Specifically, a scoring function $\varphi(\cdot, \cdot; \theta)$ is defined to measure the similarity between the corresponding representations of questions and answers. In this work, we use cosine similarity for the measurement. Let $p = \{p_1, ...p_n\}$ denote the answer corpus and $a \in p$ is the answer to the question q_i, the optimal parameters θ are learned by minimizing the max-margin loss:

$$\max\{\varphi(q_i, p_i; \theta) - \varphi(q_i, a; \theta) + \delta(p_i, a)\}$$

where $\delta(.,.)$ denotes a non-negative margin and $\delta(p_i, a)$ is a small constant when $a \neq p_i$ and 0 otherwise.

2.2 Question Type Labeling

Since examinees studying for exams are required to understand the history knowledge from different sides, we exactly consider using especially-annotated labels as extra indicators for machines to capture such features. With external memory, NTM has shown great potential for one-shot learning (Santoro et al., 2016). As in Figure 3, an NTM consists of two primary components, controller and memory. The controller, often implemented as a recurrent neural network, interacts with an external memory module using soft *read heads* to retrieve representation from memory and *write heads* to store memory, respectively.

Controller The controller of NTMs can be implemented as either a recurrent neural network or a feed-forward neural network. Our model adopts LSTM cells as the implementation for the best performance (Graves et al., 2014).

$$\mathbf{i_t} = \sigma(\mathbf{W}_w^i\mathbf{w}_t + \mathbf{W}_h^i\mathbf{h}_{t-1} + \mathbf{b}_i)$$
$$\mathbf{f_t} = \sigma(\mathbf{W}_w^f\mathbf{w}_t + \mathbf{W}_h^f\mathbf{h}_{t-1} + \mathbf{b}_f)$$
$$\mathbf{u_t} = \sigma(\mathbf{W}_w^u\mathbf{w}_t + \mathbf{W}_h^u\mathbf{h}_{t-1} + \mathbf{b}_u)$$
$$\mathbf{c_t} = \mathbf{f}_t \odot \mathbf{c}_{t-1} + \mathbf{i}_t \odot \tanh(\mathbf{W}_w^c\mathbf{w}_t + \mathbf{W}_h^c\mathbf{h}_{t-1} + \mathbf{b}_c)$$
$$\mathbf{h_t} = \tanh(\mathbf{c}_t) \odot \mathbf{u}_t$$
$$\mathbf{o_t} = (\mathbf{h}_t \oplus \mathbf{m}_t)$$

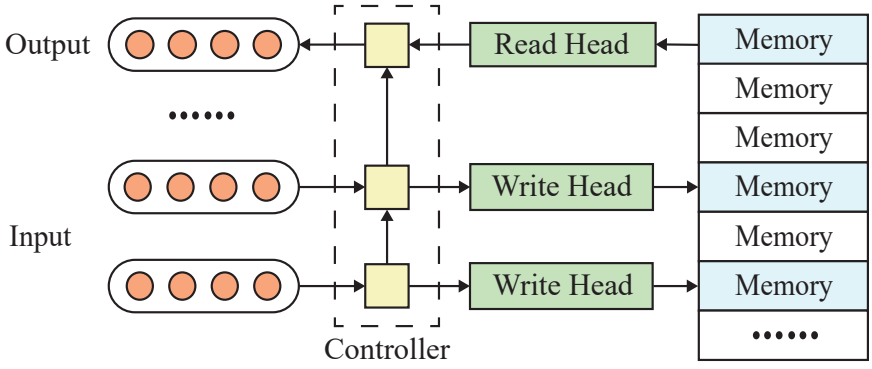

Figure 3: NTM architecture

where $\oplus$ denotes vector concatenation, and $\mathbf{i_t}, \mathbf{f_t}, \mathbf{u_t}, \mathbf{c_t}, \mathbf{h_t}$ are the input gates, forget gates, output gates, cell state and hidden state, respectively.

Given the input sequence, the controller computes the concatenated state sequence $\mathbf{o}_t$ by applying the formulation for each time step. Each word of the sequence is represented as word embedding. In order to simplify the calculation, we apply *one-max-pooling* to each input. As a result, each sequence is represented as a vector with the same dimension of word embedding.

Memory Manipulation We use a rectangular matrix $M \in \mathbb{R}^{N \times M}$ to denote the memory module. Given the read vector $\mathbf{r}_t$, the memory $\mathbf{m}_t$ is retrieved by:

$$\mathbf{m}_t = \mathbf{r}_t \mathbf{M}_t, \mathbf{r}_t = \frac{\exp(\mathbf{K}(\mathbf{k}_t, \mathbf{M}_t))}{\sum_j \exp(\mathbf{K}(\mathbf{k}_t, \mathbf{M}_t)}$$

where $\mathbf{r}_t$ is read vector and $\mathbf{K}$ is the similarity score. For writing, the memory is updated by

$$\mathbf{M}_t = \mathbf{M}_{t-1} \cdot (1 - \mathbf{w}_t \mathbf{e}_t) + \mathbf{w}_t \mathbf{c}_t$$

where $\mathbf{w}_t$, $\mathbf{e}_t$ and $\mathbf{c}_t$ represent the write vectors, erase vectors and content vectors respectively.

There are two categories for memory addressing mechanism of the original NTM: content-based addressing comparing each memory locations by some key $\mathbf{k}_t$ and a location-based addressing by shifting the heads, akin to running along a tape. However, the location-based addressing is not optimal for conjunctive coding of information independent of sequence. Following (Santoro et al., 2016), we use an addressing strategy called the Least Recently Used Access (LRUA).

Addressing The weight $\mathbf{u}_t$ is defined as follows,

$$\mathbf{u}_t = \gamma \mathbf{u}_{t-1} + \mathbf{r}_t + \mathbf{w}_t$$

where γ is a decay parameter. The least-used vectors, $\mathbf{v}_t$, are boolean variables. For a given time-step, each element of $\mathbf{v}_t$ is set to 0 if it is greater than the smallest element of $\mathbf{u}_t$, otherwise is 1. The write weights are obtained by

$$\mathbf{w}_t = \sigma(g_t)\mathbf{r}_{t-1} + (1 - \sigma(g_t))\mathbf{v}_{t-1}$$

where g_t is a scalar interpolation in the range (0,1) that blends the weights of previous read weights and previous least-used weights.

Learning For our labeling task, we define a cost function as the negative log-likelihood:

$$L(\theta) = -\sum_{n=1}^{N} \mathbf{y}_n log(Pr(\hat{\mathbf{y}}_n))$$

where $\mathbf{y}_n$ is the label and $\hat{\mathbf{y}}_n$ is the predicted one. After perspective detection, the label is then fed to the CGNN module as one-hot vectors and concatenated with the question representation.

	Train	Test
# QA pairs	964	965
Avg # words in questions	18	25
Avg # words in answers	46	48
Max # words in questions	478	482
Max # words in answers	4,652	4,387
# Candidate answer set	1,929	
# Vocabulary	10,806

.

3 Experiments

Corpus Gaokao challenge is an imitation of open-book examination for computers. Therefore, only quite a limited number of resources can be used, which makes common semi-supervised methods unlikely beneficial from large scale unlabeled data. In addition, all our source for the answer should come from standard textbook which contains unstructured plain texts as we initialized our system building.

The corpus is from the standard history textbook[2]. First, to compose an answer set, 1,929 text fragments[3] were extracted by human experts. Then equal numbers of questions were collected from past Gaokao exam papers, and their answers were manually assigned from the answer set to give 1,929 annotated QA pairs, which were equally split for training and test. All text fragments in either questions or answers are segmented into words using *BaseSeg* (Zhao et al., 2006). We publish it to research communities to facilitate the research [4]. Data statistics are in Table 2.

Embedding	Max number of words	$n = 100$
	Word embedding size	$d = 200$
CGNN	Hidden unit number	$h = 200$
	Initial learning rate	$lr = 10^{-3}$
	Regularization	$\nabla = 10^{-5}$
	Dropout	$p = 0.2$
	Filter Width	$k = 4$
NTM	Controller size	$s = 200$
	Read heads	$r = 4$
	Memory shape	$m = (128, 100)$
	Initial learning rate	$lr = 10^{-3}$

Class Labels	Answers
背景 Background	运用我们从古代诗文、戏曲、民间传说中已经学到的知识，举例说明中国古代自给自足的自然经济的状况。 Using the knowledge learned from ancient poetic proses, operas, and folklores, exemplify the situation of self-sufficiency of natural economy in ancient China.
原因 Cause	春秋战国时期是社会剧烈动荡的历史阶段，为什么在这样的时期会出现思想文化活跃的局面。 The Spring-autumn and Warring States Period was the historical stage of the violent social unrest. Why would there be an active ideological and cultural phenomenon in such a period?
主张 Claim	在启蒙运动中，众多的启蒙思想家的共性思想主张是什么？他们之间有何继承和发展。 During the Enlightenment, what is the common thought of those enlightening thinkers? What is the inheritance and development between them?
事实 Fact	“农民可能充当一种极端保守的角色，也可能充当一种具有高度革命性的角色。”试结合有关史实评析这一观点。 “Farmers may act as an extremely conservative role, or may be highly revolutionary.” Try to analyze this view in the light of the relevant historical facts.
意义 Influence	用历史唯物主义和辩证唯物主义的观点来分析古代雅典民主政治和罗马法发展的历程，了解它们对后世的作用和影响。 From the perspective of historical and dialectical materialism, analyze the history of Athens's democratic politics and the development of Rome law in ancient times, and understand their roles and influences on later generations.

Table 4: Examples of Text Fragments of 5 classes.

Setup For the sake of computational efficiency, a maximal length of 100 words for each text fragment is specialized and truncating or zero-padding will be applied as necessary. Word embedding is trained by word2Vector (Mikolov et al., 2013) using *Wikipedia* corpus[5].

The diagonal variant of AdaGrad (Duchi et al., 2011) is used for neural network training. Table 3 shows the hyper-parameters of our models. For other neural models, we fine-tune the hyper-parameters with the following range of values: learning rate $\in \{1e-3, 1e-2\}$, dropout probability $\in \{0.1, 0.2\}$, CNN filter width $\in \{2, 3, 4\}$. The hidden dimensions for all the neural networks are 200.

In the following experiments, we use NTM to annotate salient labels for each question. Then, the question representation and corresponding label vectors are concatenated and fed to CGNN for feature learning.

Labeling Examinees are required to understand the history knowledge from different sides. Thus, the solver should also be capable of capturing such kind of features. To specify a key perspective on historical questions, five classes[6] (*background, cause, claim, fact and influence*) are annotated as shown in Table 4. Note that such kind of annotation is even not easy for human annotators or history teachers and our complete set for all answers is very small (less than 2,000). At last, we have 80 answers per class annotated for a total number of 400, in which 50 are selected for training[7] and 350 for test. For our detailed case, our data is too precious to be used too many for training.

One-shot learning is supposed to effectively represent the questions in the feature space with a small set of training data. To evaluate its performance, we specify a fixed number of training data. At each epoch, NTM is randomly provided with a specific number (shot) of samples per class from training set according to the typical training setting of one-shot learning (Santoro et al., 2016). One-shot learning, in previous practice, usually still took a large candidate training set (i.e., hundreds) as input, though for

[5] https://dumps.wikimedia.org/

[6] These classes are determined according to national education quality control who requires every student should clearly distinguish these specific perspectives about history facts. More details are in Supplementary Materials.

[7] As our labeling is a five-class classification task, 50 samples therefore allow 10-shot learning per class at most.

Method	1-shot	2-shot	5-shot	10-shot
Naive Bayes	22.1	25.7	30.1	34.1
K-Means	12.5	15.7	15.8	16.1
SVM	19.1	21.8	30.2	**45.2**
Feedforward	20.1	22.7	21.3	21.6
LSTM	23.8	28.5	32.5	38.2
NTMs	**38.7**	**49.1**	**63.9**	**76.6**

Table 5: Accuracy for labeling task.

each class, only a small fixed number of shots (i.e., less than 10) were randomly selected and fed for learning. However, it is quite different from our data reality and we have to keep a least training set (10 for our case) for one-shot learning.

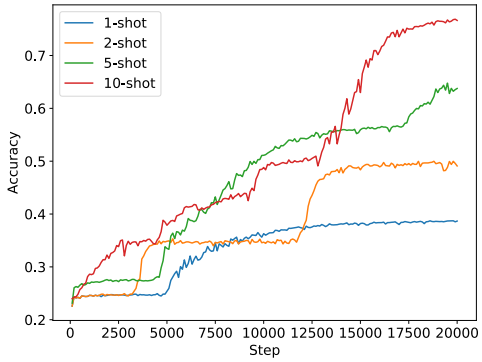

Figure 4: Labeling accuracy curve.

Method	Precision	Recall	F1-score
BM25	8.6 (8.7)	23.2 (23.7)	12.5 (12.7)
CNN	9.8 (27.0)	21.1 (45.0)	13.4 (33.8)
GRU	11.4 (32.9)	24.1 (50.4)	15.5 (39.8)
LSTM	8.4 (30.6)	21.2 (48.0)	12.0 (37.4)
+	**22.2**	**26.8**	**25.4**
CNN+Highway	15.8 (33.2)	30.5 (50.6)	20.8 (40.1)
CNN+GRU	17.4 (32.4)	31.1 (50.8)	22.3 (39.6)
CNN+LSTM	12.7 (27.5)	21.4 (47.0)	16.0 (34.7)
CGNN	**18.2 (33.7)**	**31.6 (51.6)**	**23.1 (40.8)**
+	15.5	20.0	17.7

Table 6: Answer retrieval performance without and with NTM labels (in brackets). "+" means the performance gains with the help of NTM labels.

Table 5 compares NTM with traditional classifiers (Naive Bayes, K-Means and SVM) and neural networks (Feedforward network and LSTM). All the baseline methods are fed the training instances as the same shot style of NTM and parameters are tuned for best performance.

Figure 4 illustrates NTM learning curves with different shots. The results show that NTM works effectively on a small amount of samples. With memory cells as well, LSTM is chosen as the baseline. The hidden layer dimension of the LSTM is 200, which is the same as the NTM controller size. The LSTMs are fed with the training instances as the same shot style of NTM. Results shown in Table 5 indicate only NTM provides satisfactory performance with the least input instances. The effectiveness of NTM may attribute to its capability of slowly learning the representations of raw data through weight updates, and rapidly binding relevant information after a single representation via an external memory. To that extend, the NTM could generalize the meta features of each question type and distinguish the perspectives. This indicates one-shot learning is able to lessen over-fitting issues from sparse features of limited data.

Answer Retrieval For a discriminative training, we add negative QA pairs by randomly selecting 20 false answers for each positive QA pairs in the original training set. For evaluation, all answers in the corpus are ranked to match each question. NTM labeler is from 10-shot training.

We use baselines including BM25 implemented by a standard search engine *Apache Lucene*[8] and other neural models, Convolutional Neural Network (CNN), LSTM, Gated Recurrent Unit (GRU). Our evaluation is based on the following metrics: Precision, Recall and F1-score, which are widely used for relevance evaluation.

Table 6 presents the experimental results of all the models with and without NTM labels. All of the neural networks greatly outperform BM25 which is purely based on word form matching. In addition, NTM labeler boosts the performance of all the methods. For instance, our CGNN model has obtained 17.7% gains on the F1-score metric with the assistance of extra labeling. Furthermore, our model using CGNN and NTM labeler outperforms all the other baselines. This superior performance indicates that the one-shot learning strategy is competent for our deep QA task with only a small amount of data and

Cause	8.4	48.6	67.5	56.5
Claim	4.7	47.8	65.1	55.1
Fact	51.0	23.0	42.0	29.7
Influence	19.9	39.0	54.5	45.5

Table 7: Question type distribution and model performance of CGNN.

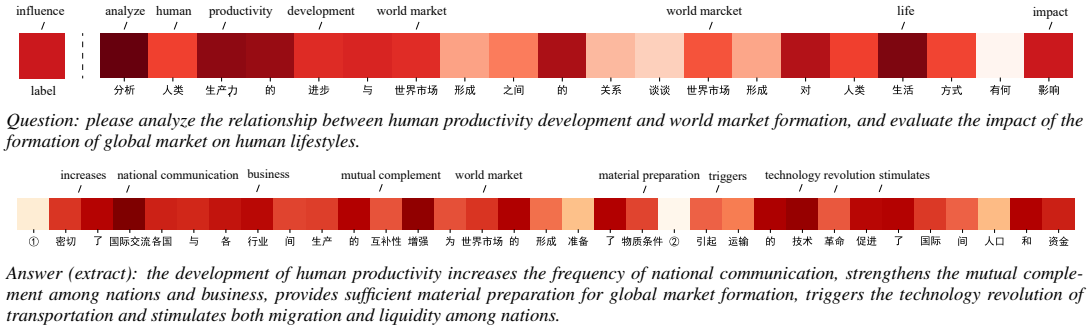

Figure 5: Visualization for question and answer representation weights after gated flow. The darker color means the higher weights.

the adoption of gated mechanism is also well-suited to work with CNN, adaptively transforming and combining local features detected by the individual filters. Table 7 shows question type distribution and the performance of CGNN. Our model performs well on most types but drops on *Fact* since these questions are diverse kinds of facts whose patterns are extremely hard to distinguish, even for human. This also shows our task is challenging.

Model Analysis The primary motivation of highway network is to ease gradient-based training of highly deep networks through utilizing gated units. When remaining one gate in our network, our model works similarly to the highway network. To compare different gated mechanisms, we carry out further experiments with the same CNN setting. As shown in Table 6, CGNN achieves the best performance in terms of all evaluation metrics, indicating our gated mechanism is well-suited to work with CNN, adaptively transforming and combining local features detected by the individual filters.

In order to give an insight into the effectiveness of the gated mechanism on information flow across neural network layers, we visualize the final weights for each word from question and answer after gated flow as shown in Figure 5. We can see that the key information (*human, productivity, development, world market, life and influence*) of the lengthy questions and answers will be given higher weights, especially the common words (*world market*) of the question and corresponding answer. Besides, the label in the question is also assigned a high attention, indicating the label works essentially.

4 Related Work

4.1 Question Answering

Various neural models have been proposed to tackle the tasks of QA task and related knowledge representation (Wang et al., 2017b; Chen et al., 2016b; Todor and Anette, 2018; Kundu and Ng, 2018). Previous work mainly focused on factoid questions, falling into the architecture of knowledge base embedding and question answering from knowledge base (Khashabi et al., 2016; Angeli et al., 2015). Yang et al. (2014) proposed a method that transforms natural questions into their corresponding logical forms and conducted question answering by leveraging semantic associations between lexical representations and knowledge base properties in the latent space. Yin et al. (2016) proposed an end-to-end neural model that can generate answers to simple factoid questions from a knowledge base. Nonetheless, the knowledge base construction requires a lot of human workload, and the related semantic parsing and knowledge representation will become much more complicated as the scale of the knowledge base increases.

For non-factoid QA, most work formulized it as a semantic matching task on sentence pairs by vector modeling. Different from answer retrieval from knowledge bases, this type of studies used vector to represent QA pairs and compare the distance in vector space to match answer text (Tan et al., 2015; Feng et al., 2015). However, the performance of these neural models greatly depends on a large amount of labeled data.

Our concerned task cannot be simply regarded as either factoid or non-factoid. In fact, questions in our task consist of both factoid and non-factoid ones with purely unstructured corresponding answers. Conventional networks might not be sufficient to represent these QA pairs and we need to seek more powerful models. A recent hot comprehensive QA task is the SQuAD challenge (Rajpurkar et al., 2016) which aims to find a text span from given paragraph to answer the question. However, our task is quite different from SQuAD. With sufficient learning data, neural models have shown satisfying performance in the SQuAD challenge. In real world practice, examinees are acquired to learn and comprehend meta-knowledge from textbooks so as to pass the exams through review and reasoning among the whole knowledge space instead of simply finding an answer span from a given paragraph, which shows to be challenging for neural networks.

4.2 Semi-supervised Learning

For real-world applications of specific domains, the datasets are always inadequate. Semi-supervised Learning methods have been extensively studied to make use of unlabeled data. A batch of models have been proposed based on representation learning (Yang et al., 2017; Lei et al., 2016). For question answering, current semi-supervised models generally use auto-encoder framework or generative model to obtain the representation of unlabeled data. However, these semi-supervised models can not be applied to generate labels for our raw QA pairs since our task requires diverse types of labels from discourse to sentence which are difficult to annotate, and it is more serious that the entire unlabeled data is also too small to support an effective semi-supervised learning. Thus, we must very carefully choose a proper learning strategy for our task.

Different from the above research line, one-shot learning belongs to a kind of weakly supervised method (Bordes et al., 2014) that was first proposed to learn information about object categories from one or only a few training images (Li et al., 2006). Recently, memory-based neural network models have greatly expanded the ways of storing and accessing information. Two promising neural networks with external memory have been proposed to connect deep neural network with one-shot learning. One is Neural Turing Machine (Graves et al., 2014), which can read or write the facts to an external differentiable memory. Santoro et al. (2016) proved it to be an effective method for image recognition. The other is Memory Network (Vinyals et al., 2016). The crucial difference between them is that the latter does not have a mechanism to modify the content of the external memory, which lets us choose the former as our one-shot learning implementation. Compared with previous methods for question answering, our model is more weakly supervised with a limited amount of training data. As to our best knowledge, this is the first attempt that adopts one-shot learning for a deep QA task by using NTM as automatic labeler.

5 Conclusion

This paper presents a neural model with NTM for a challenging deep question answering task from history examinations. Our experimental results show that the adopted CGNN together with other neural models works much better than BM25. With an NTM labeler, all the deep neural models are further enhanced. We also release a Chinese comprehensive deep question answering dataset and have launched a new research line for the Gaokao challenge and solve more complicated questions using deep neural networks to learn semantic representation while the previous work focused on choice questions using simple information retrieval methods (Cheng et al., 2016). In fact, open-domain questions that can often be distinguished into different aspects can always benefit from one-shot learnings over a few labeling samples, which has been verified the effectiveness in this paper by only relying on the least task-dependent assumptions.

Dynamic Multi-Level Multi-Task Learning for Sentence Simplification

Han Guo **Ramakanth Pasunuru** **Mohit Bansal**
UNC Chapel Hill
{hanguo, ram, mbansal}@cs.unc.edu

Abstract

Sentence simplification aims to improve readability and understandability, based on several operations such as splitting, deletion, and paraphrasing. However, a valid simplified sentence should also be logically entailed by its input sentence. In this work, we first present a strong pointer-copy mechanism based sequence-to-sequence sentence simplification model, and then improve its entailment and paraphrasing capabilities via multi-task learning with related auxiliary tasks of entailment and paraphrase generation. Moreover, we propose a novel 'multi-level' layered soft sharing approach where each auxiliary task shares different (higher versus lower) level layers of the sentence simplification model, depending on the task's semantic versus lexico-syntactic nature. We also introduce a novel multi-armed bandit based training approach that dynamically learns how to effectively switch across tasks during multi-task learning. Experiments on multiple popular datasets demonstrate that our model outperforms competitive simplification systems in SARI and FKGL automatic metrics, and human evaluation. Further, we present several ablation analyses on alternative layer sharing methods, soft versus hard sharing, dynamic multi-armed bandit sampling approaches, and our model's learned entailment and paraphrasing skills.

1 Introduction

Sentence simplification is the task of improving the readability and understandability of an input text. This challenging task has been the subject of research interest because it can address automatic ways of improving reading aids for people with limited language skills, or language impairments such as dyslexia (Rello et al., 2013), autism (Evans et al., 2014), and aphasia (Carroll et al., 1999). It also has wide applications in NLP tasks as a preprocessing step, for example, to improve the performance of parsers (Chandrasekar et al., 1996), summarizers (Klebanov et al., 2004), and semantic role labelers (Vickrey and Koller, 2008; Woodsend and Lapata, 2014).

Several sentence simplification systems focus on operations such as splitting a long sentence into shorter sentences (Siddharthan, 2006; Petersen and Ostendorf, 2007), deletion of less important words/phrases (Knight and Marcu, 2002; Clarke and Lapata, 2006; Filippova and Strube, 2008), and paraphrasing (Devlin, 1999; Inui et al., 2003; Kaji et al., 2002). Inspired from machine translation based neural models, recent work has built end-to-end sentence simplification models along with attention mechanism, and further improved it with reinforcement-based policy gradient approaches (Zhang and Lapata, 2017). Our baseline is a novel application of the pointer-copy mechanism (See et al., 2017) for the sentence simplification task, which allows the model to directly copy words and phrases from the input to the output. We further improve this strong baseline by bringing in auxiliary entailment and paraphrasing knowledge via soft and dynamic multi-level, multi-task learning.[1]

Apart from the three simplification operations discussed above, we also ensure that the simplified output is a directed logical entailment w.r.t. the input text, i.e., does not generate any contradictory or unrelated information. We incorporate this entailment skill via multi-task learning (Luong et al., 2015)

Proceedings of the 27th International Conference on Computational Linguistics, pages 462–476
Santa Fe, New Mexico, USA, August 20-26, 2018.

with an auxiliary entailment generation task. Further, we also induce word/phrase-level paraphrasing knowledge via a paraphrase generation task, enabling parallel learning of these three tasks in a three-way multi-task learning setup. We employ a novel 'multi-level' layered, soft sharing approach, where the parameters between the tasks are loosely coupled at different levels of layers; we share higher-level semantic layers between the sentence simplification and entailment generation tasks (which teaches the model to generate outputs that are entailed by the full input), while sharing the lower-level lexico-syntactic layers between the sentence simplification and paraphrase generation tasks (which teaches the model to paraphrase only the smaller sub-sentence pieces).

Finally, we also propose a multi-armed bandit approach that dynamically learns an effective schedule (curriculum) of switching between tasks for optimization during multi-task learning, instead of the traditional approach with a manually-tuned static (fixed) mixing ratio (Luong et al., 2015).

Empirically, we evaluate our system on three standard datasets: Newsela, WikiSmall, and WikiLarge. First, we show that our pointer-copy baseline is significantly better than sequence-to-sequence models, and competitive w.r.t. the state-of-the-art. Next, we show that our multi-level, multi-task framework performs significantly better than our strong pointer baseline and other competitive sentence simplification models on both automatic evaluation as well as on human study simplicity criterion. Further, we show that the dynamic multi-armed bandit based switching of tasks during training improves over the traditional manually-tuned static mixing ratio. Lastly, we show several ablation studies based on different layer-sharing approaches (higher versus lower) with auxiliary tasks, hard versus soft sharing, dynamic mixing ratio sampling, as well as our model's learned entailment and paraphrasing skills.

2 Related Work

Previous approaches to sentence simplification systems range from hand-designed rules (Siddharthan, 2006), to syntactic and lexical simplification via synonyms and paraphrases (Siddharthan, 2014; Kaji et al., 2002; Horn et al., 2014; Glavaš and Štajner, 2015), as well as treating simplification as a monolingual MT task, where operations are learned from examples of complex-simple sentence pairs (Specia, 2010; Koehn et al., 2007; Coster and Kauchak, 2011; Zhu et al., 2010; Wubben et al., 2012; Narayan and Gardent, 2014). Recently, Xu et al. (2016) trained a syntax-based MT model using the newly proposed SARI as a simplification-specific objective. Further, Zhang and Lapata (2017) used reinforcement learning in a sequence-to-sequence approach to directly optimize simplification metrics. In this work, we first introduce the pointer-copy mechanism (See et al., 2017) as a novel application to sentence simplification, and then use multi-task learning to bring in auxiliary entailment and paraphrasing skills.

Multi-task learning, known for improving the generalization performance of a task with related tasks, has successful application to many domains of machine learning (Caruana, 1998; Collobert and Weston, 2008; Girshick, 2015; Luong et al., 2015; Pasunuru and Bansal, 2017; Pasunuru et al., 2017). Although there are many variants of multi-task learning (Ruder et al., 2017; Hashimoto et al., 2017; Luong et al., 2015), our approach is similar to Luong et al. (2015), where different tasks share some common model parameters with alternating mini-batches optimization. In this work, we explore a multi-level (i.e., task-specific higher-level semantic versus lower-level lexico-syntactic layer sharing) and soft-sharing mechanism for improving sentence simplification via related tasks of entailment and paraphrase generation.

Recognizing Textual Entailment (RTE) is the task of predicting entailment, contradiction, or neutral relationships, and is useful for many downstream tasks like Q&A, summarization, and information retrieval (Harabagiu and Hickl, 2006; Dagan et al., 2006; Lai and Hockenmaier, 2014; Jimenez et al., 2014). Neural network models (Bowman et al., 2015; Parikh et al., 2016) and large datasets (Bowman et al., 2015; Williams et al., 2017) enabled recent strong progress. Recently, Pasunuru et al. (2017) and Guo et al. (2018) presented results using entailment generation as an auxiliary task for abstractive summarization; however, we use entailment as well as paraphrasing knowledge in a soft and multi-level layer sharing setup to improve sentence simplification.

Previous work (Barzilay and McKeown, 2001; Ganitkevitch et al., 2013; Wieting and Gimpel, 2017a) has developed methods and datasets for generating paraphrase pairs which can be useful for downstream applications such as question answering, semantic parsing, and information extraction (Fader et al., 2013;

Berant and Liang, 2014; Zhang et al., 2015). Wieting and Gimpel (2017a) recently introduced a large sentential paraphrase dataset via back-translation, and showed promising results when applied to learning sentence embeddings. In this work, we use this paraphrase dataset as an auxiliary generation task to improve our sentence simplification model by teaching it about paraphrasing in a multi-task setting.

Many control problems can be cast as a multi-armed bandits algorithm, where the goal of the agent is to select the arm/action from one of the M choices that gives the maximum expected future reward (Bubeck et al., 2012). Optimal control and reinforcement learning have been used to find the trade-off between exploitation and exploration, and yield theoretically-sound regret bounds, e.g., Boltzmann exploration (Kaelbling et al., 1996), UCB (Auer et al., 2002a), Thompson sampling (Chapelle and Li, 2011), adversarial bandits (Auer et al., 2002b), and information gain using variational approaches (Houthooft et al., 2016). Recently, Graves et al. (2017) use a non-stationary multi-armed bandit to automatically select the curriculum or syllabus that a neural network follows so as to maximize learning efficiency. Sharma and Ravindran (2017) use multi-armed bandit sampling to choose which domain data (harder vs. easier) to feed as input to a single model (using different Atari games), whereas we use multi-armed bandit sampling to decide the optimization curriculum (mixing ratio) among our three models for sentence simplification, entailment generation, and paraphrase generation (with different softly-shared layers).

3 Models

In this section, we first describe our sentence simplification baseline model with attention mechanism, which is further improved by pointer-copy mechanism. Later, we introduce our two auxiliary tasks (entailment and paraphrase generation) and discuss how they can share specific lower/higher-level layers/parameters to improve the sentence simplification task in a multi-task learning setting. Finally, we discuss our new multi-armed bandit based dynamic multi-task learning approach.

3.1 Pointer-Copy Baseline Sentence Simplification Model

Our baseline is a 2-layer sequence-to-sequence model with both attention (Bahdanau et al., 2015) and pointer-copy mechanism (See et al., 2017). Given the sequence of input/source tokens $x = \{x_1, ..., x_{T_s}\}$, the model learns an auto-regressive distribution over output/target tokens $y = \{y_1, ..., y_{T_o}\}$, which is defined as $P_{vocab}(y|x;\theta) = \prod_t p(y_t|y_{1:t-1}, x;\theta)$, where θ represents model parameters and $p(y_t|y_{1:t-1}, x;\theta)$ is probability of generating token y_t at decoder time step t given the previous generated tokens $y_{1:t-1}$ and input x. Given encoder hidden states $\{h_i\}$, and decoder's t^{th} time step hidden state (of last layer) s_t, the context vector $c_t = \sum_i \alpha_{t,i} h_i$, where the attention weights $\alpha_{t,i}$ define an attention distribution over encoder hidden states: $\alpha_{t,i} = \exp(e_{t,i}) / \sum_k \exp(e_{t,k})$, where $e_{t,i} = v_a^T \tanh(W_a s_t + U_a h_i + b_a)$. Finally, the conditional distribution at each time step t of the decoder is defined as $p(y_t|y_{1:t-1}, x;\theta) = \text{softmax}(W_s s'_t)$, where the final hidden state s'_t is a combination of context vector c_t and last layer hidden state s_t and is defined as $s'_t = \tanh(W_c[c_t, s_t])$, where W_s and W_c are trained parameters.

Pointer-Copy Mechanism: This helps in directly copying the words from the source inputs to the target outputs via merging the generative distribution and attention distribution (as a proxy of copy distribution). The goal of sentence simplification is to rewrite sentences more simply, while preserving important information; hence, it also involves significant amount of copying from the source. Our pointer mechanism approach is similar to See et al. (2017). At each time step of the decoder, the model makes a (soft) choice between words from the vocabulary distribution P_{vocab} and attention distribution P_{att} (based on words in the input) using the word generation probability $p_g = \sigma(W_g c_t + U_g s_t + V_g d_t + b_g)$, where $\sigma(\cdot)$ is sigmoid, W_g, U_g, V_g and b_g are trainable parameters, and d_t is decoder input. The final vocabulary distribution is defined as the weighted combination of vocabulary and attention distributions:

$$P_f(y) = p_g P_{vocab}(y) + (1 - p_g) P_{att}(y) \tag{1}$$

3.2 Auxiliary Tasks

Entailment Generation The task of entailment generation is to generate a hypothesis which is entailed by the given input premise. A good simplified sentence should be entailed by (follow from) the source

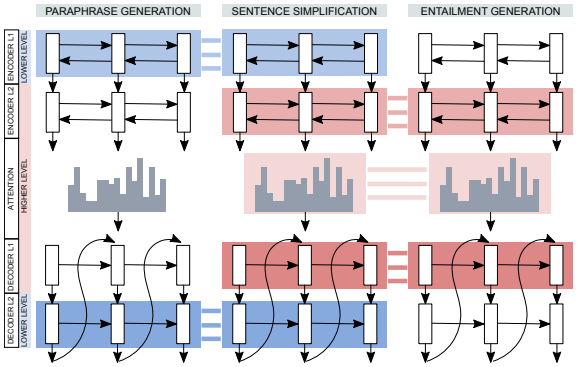

Figure 1: Overview of our 3-way multi-task model. Same color and dashed connections represent soft-shared parameters in different layers.

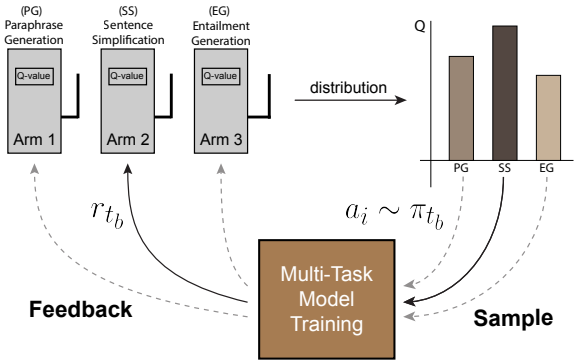

Figure 2: Overview of our multi-armed bandits algorithm for dynamic mixing ratio learning. It consists of a controller with 3 arms/tasks.

sentence, and hence we incorporate such knowledge through an entailment generation task into our sentence simplification task. We share the higher-level semantic layers between the two tasks (see reasoning in Sec. 3.3 below). We use entailment pairs from SNLI (Bowman et al., 2015) and Multi-NLI (Williams et al., 2017) datasets for training our entailment generation model, where we use the same architecture as our sentence simplification model.

Paraphrase Generation Paraphrase generation is the task of generating similar meaning phrases or sentences by reordering and modifying the syntax and/or lexicon. Paraphrasing is one of the common operations used in sentence simplification, i.e, by substituting complex words and phrases with their simpler paraphrase forms. Hence, we add this knowledge to the sentence simplification task via multi-task learning, by sharing the lower-level lexico-syntactic layers between the two tasks (see reasoning in Sec. 3.3 below). For this, we use the paraphrase pairs from ParaNMT (Wieting and Gimpel, 2017a). Here, again, we use the same architecture as our sentence simplification model.

3.3 Multi-Task Learning

In this subsection, we discuss our multi-task, multi-level soft sharing strategy with parallel training of sentence simplification and related auxiliary tasks (entailment and paraphrase generation).

The predominant approach for multi-task learning in sequence-to-sequence models is to directly hard-share all encoder/decoder layers/parameters (Luong et al., 2015; Johnson et al., 2016; Pasunuru and Bansal, 2017; Kaiser et al., 2017). However, this approach places very strong constraints/priors on the primary model to compress knowledge from diverse tasks. We believe that while the auxiliary tasks considered in this work share many similarities with the primary sentence simplification task, they are still different in either lower-level or higher-level representations (e.g., entailment will deal with higher-level, full-sentence logical inference, while paraphrasing will handle the lower-level intermediate word/phrase simplifications). In this section, we propose to relax the priors in two ways: (1) we share the model parameters in a finer-grained scale, i.e. layer-specific sharing, by keeping some of their parameters private, while sharing related representations; and (2) we encourage shared parameters to be close in certain distance metrics with a penalty term instead of hard-parameter-tying (Luong et al., 2015).

Multi-Level Sharing Mechanism Fig. 1 shows our multi-task model with parallel training of three tasks: sentence simplification (primary task), entailment generation (auxiliary task), and paraphrase generation (auxiliary task). Recently, Belinkov et al. (2017) observed that different layers in a sequence-to-sequence model (trained on translation) exhibit different functionalities: lower-layers (closer to inputs) of the encoder learn to represent word structure while higher layers (farther from inputs) are more focused on semantics and meanings (Zeiler and Fergus (2014) observed similar findings for convolutional image features). Based on these findings, we share the higher-level layers[2] between the entailment generation and sentence simplification tasks, since they share higher semantic-level language inference

[2]We found that sharing higher-level semantic layers (farther from input/output), i.e., encoder layer 2, attention, and decoder layer 1 (in Fig. 1), to work well. See Sec. 6 for ablations on alternative layer sharing methods.

skills (for full sentence-to-sentence logical directedness). On the other hand, we share the lower-level lexico-syntactic layers[3] between the paraphrase generation and sentence simplification tasks, since they share more word/phrase and syntactic level paraphrasing knowledge to simplify the smaller, intermediate sentence pieces. Sec. 6 present empirical ablations to support our intuitive layer sharing.[4]

Soft Sharing In multi-task learning, we can do either hard sharing or soft sharing of parameters. Hard sharing directly ties the parameters to be shared, and receives gradient information from multiple tasks. On the other hand, soft sharing only loosely couples the parameters, and encourages them to be close in representation space. Hence the soft sharing approach gives more flexibility for parameter sharing, hence allowing different tasks to choose what parts of their parameters space to share. We minimize the l_2 distance between shared parameters as a regularization along with the cross entropy loss. Hence, the final loss function of the primary task with a related auxiliary task is defined as follows:

$$L(\theta) = -\log P_f(y|x;\theta) + \lambda||\theta_s - \phi_s|| \tag{2}$$

where θ represents the full parameters of the primary task (sentence simplification), θ_s and ϕ_s are the subsets of shared parameters between the primary and auxiliary task resp., and λ is a hyperparameter.

Multi-Task Training We employ multi-task learning with parallel training of related tasks in alternate mini-batches based on a mixing ratio α_{ss}:α_{eg}:α_{pp}, where we alternatively optimize α_{ss}, α_{eg}, α_{pp} mini-batches of sentence simplification, entailment generation, and paraphrase generation, respectively, until all models converge. In the next section, we discuss a new approach to replace this static mixing ratio with dynamically-learned task switching.

3.4 Dynamic Mixing Ratio Learning

Current multi-task models are trained via alternate mini-batch optimization based on a task 'mixing ratio' (Luong et al., 2015; Pasunuru and Bansal, 2017), i.e., how many iterations on each task relative to other tasks (see end of Sec. 3.3). This is usually treated as a very important hyperparameter to be tuned, and the search space scales exponentially with the number of tasks. Hence, we importantly replace this manually-tuned and static mixing ratio with a 'dynamic' mixing ratio learning approach, where a controller automatically switches between the tasks during training, based on the current state of the multi-task model. Specifically, we use a multi-armed bandits based controller with Boltzmann exploration (Kaelbling et al., 1996) with an exponential moving average update rule.

We view the problem of learning the right mixing of tasks as a sequential control problem, where the controller's goal is to decide the next task/action after every n^s training steps in each task-sampling round t_b.[5] Let $\{a_1, ..., a_M\}$ represent the set of 3 tasks in our multi-task setting, i.e., sentence simplification, entailment generation, and paraphrase generation. We model the controller as a M-armed bandits, where it selects a sequence of actions/arms over the current training trajectory to maximize the expected future payoffs (see Fig. 2). At each round t_b, the controller selects an arm based on noisy value estimates and observes rewards r_{t_b} for the selected arm (we use the negative validation loss of the primary task as the reward in our setup). One problem in bandits learning is the trade-off between exploration and exploitation, where the agent needs to make a decision between taking the action that yields the best payoff on current estimates, or explore new actions whose payoffs are not yet certain. For this, we use the Boltzmann exploration (Kaelbling et al., 1996) with exponentially moving action value estimates. Let π_{t_b} be the policy of the bandit controller at round t_b, we define this to be:

$$\pi_{t_b}(a_i) = \exp(Q_{t_b,i}/\tau) \Big/ \sum_{j=1}^{M} \exp(Q_{t_b,j}/\tau) \tag{3}$$

[3]We found that sharing lower-level lexico-syntactic layers (closer to input/output), i.e., encoder layer 1 and decoder layer 2 (in Fig. 1), to work well. See Sec. 6 for ablations on alternative layer sharing methods.

[4]Note that even though entailment just tries to generate shorter, logical-subset sub-sentences, the overall saliency and quality of the simplified output is still balanced because the entailment task is flexibly (softly) shared with the paraphrasing and sentence simplification tasks, and the final model mixture is chosen based on simplification task metrics (see output examples in Fig. 4 where our multi-task model generates entailed sentences with important information).

[5]We set n^s to 10 to reduce variance of estimates, i.e., the bandit controller's task/action will be trained for 10 mini-batches.

where $Q_{t_b,i}$ is the estimated action value of each arm i at round t_b, and τ is the temperature.[6] If $Q_{0,i}$ is the initial value estimate of arm i, then $Q_{t_b,i}$ is the exponentially weighted mean with the decay rate α:

$$Q_{t_b,i} = (1-\alpha)^{t_b} Q_{0,i} + \sum_{k=1}^{t_b} \alpha(1-\alpha)^{t_b-k} r_k \tag{4}$$

To further help the exploration process, we follow the principle of optimism under uncertainty (Sutton and Barto, 1998) and set $Q_{0,i}$ to be above the maximum empirical rewards. Empirically, we show that this approach of 'dynamic mixing ratio' is equal or better than the traditional static mixing ratio (see Table 3). Also, we further show ablation study in Sec. 6 to show that this switching approach is better than the alternative approach of first using multi-armed bandits for finding an optimal 'final' mixing ratio and then re-training the model based on this bandits-selected mixing ratio.

4 Evaluation Setup

Datasets We first describe the three standard sentence simplification datasets we evaluate on: Newsela, WikiSmall, and WikiLarge; next, we describe datasets for our auxiliary entailment and paraphrase generation tasks. **Newsela** (Xu et al., 2015) is acknowledged as a higher-quality dataset for studying sentence simplifications, as opposed to Wikipedia-based datasets which automatically align complex-simple sentence pairs and have generalization issues (Zhang and Lapata, 2017; Xu et al., 2015; Amancio and Specia, 2014; Hwang et al., 2015; Štajner et al., 2015). Newsela consists of $1,130$ news articles, and we follow previous work (Zhang and Lapata, 2017) to use the first $1,070$ documents for training, and 30 documents each for development and test. **WikiSmall** (Zhu et al., 2010) contains automatically-aligned complex-simple sentences from the ordinary-simple English Wikipedias. The data has $89,042$ pairs for training and 100 for test. We use the 205-pairs validation set from Zhang and Lapata (2017). **WikiLarge** (Zhang and Lapata, 2017) is a larger Wikipedia corpus aggregating pairs from Kauchak (2013), Woodsend and Lapata (2011), and WikiSmall. We use the exact training/evaluation sets provided by Zhang and Lapata (2017). **SNLI and MultiNLI**: For the task of entailment generation, we use the Stanford Natural Language Inference (SNLI) corpus (Bowman et al., 2015) and MultiNLI (Williams et al., 2017). We use their entailment labeled pairs for our entailment generation task, following previous work (Pasunuru and Bansal, 2017). The combined SNLI and MultiNLI dataset has $302,879$ entailment pairs, out of which we use $276,720$ pairs for training, and the rest are divided into validation and test sets. **ParaNMT**: For the task of paraphrase generation, we use the back-translated paraphrase dataset provided by Wieting and Gimpel (2017a). The filtered version of the dataset has 5.3 million pairs of paraphrases.[7] We use 99% for training, and the rest are evenly divided into validation and test sets.

Evaluation Metrics Following previous work (Zhang and Lapata, 2017), we report all the standard evaluation metrics: SARI (Xu et al., 2016), FKGL (Kincaid et al., 1975), and BLEU (Papineni et al., 2002). However, several studies have shown that BLEU is poorly correlated w.r.t. simplicity (Zhu et al., 2010; Štajner et al., 2015; Xu et al., 2016). Moreover, Shardlow (2014) argues that FKGL (Kincaid et al., 1975), which measures readability of simpler output (lower is better), favors very short sentences even though longer/less coarse counterparts can be simpler. Further, Xu et al. (2016) argues that BLEU tends to favor conservative systems that do not make many changes, and proposes SARI metric which explicitly measures the quality of words that are added and deleted. SARI is shown to correlate well with human judgment in simplicity (Xu et al., 2016), and hence we primarily focus on this metric in our models' performance analysis.[8] Further, we also do human evaluation based on: Fluency ('is the output grammatical and well formed?'), Adequacy ('to what extent is the meaning expressed in the original sentence preserved in the output?') and Simplicity ('is the output simpler than the original sentence?'), following guidelines suggested by Xu et al. (2016) and Zhang and Lapata (2017).

[6] We tried decaying the temperature variable, but we didn't find this to very beneficial, so we instead fix this to 1.0.

[7] We chose ParaNMT over other paraphrase datasets (e.g. the phrase-to-phrase PPDB dataset (Ganitkevitch et al., 2013)), because ParaNMT is a sentence-to-sentence dataset and hence is a more natural fit for sentence-level multi-task RNN-layer sharing with our sentence-to-sentence simplification task.

[8] We use the JOSHUA package for calculating SARI and BLEU score following Zhang and Lapata (2017) and Xu et al. (2016). Our FKGL implementation is based on `https://github.com/mmautner/readability`.

Training Details All our soft/hard and layer-specific sharing decisions (Sec. 6) were made on the validation/dev set. Our model selection (tuning) criteria is based on the average of our 3 metrics (SARI, BLEU, 1/FKGL) on the validation set. Please refer to the appendix for full training details (vocabulary overlap, mixing ratios and bandit sampler decay rates and reward, WikiLarge pre-training, etc.).

5 Results

We evaluate our models on three datasets and via several automatic metrics plus human evaluation.[9]

Pointer Baseline First, we compare our pointer baseline with various previous works: PBMT-R (Wubben et al., 2012), Hybrid (Narayan and Gardent, 2014), SBMT-SARI (Xu et al., 2016)[10], and EncDecA, DRESS, and DRESS-LS (Zhang and Lapata, 2017). As shown in Table 1, our pointer baseline already achieves the best score in FKGL and the second-best score in SARI on Newsela, and also achieves overall comparable results on both WikiSmall and WikiLarge (see Table 2).

Multi-Task Models We further improve our strong pointer-based sentence simplification baseline model by multi-task learning it with entailment and paraphrase generation. First, we show that our 2-way multi-task models with auxiliary tasks (entailment and paraphrase generation) are statistically significantly better than our pointer baseline and previous works in both SARI and FKGL on Newsela (see Table 1).[11] Next, Table 1 and Table 2 summarize the performance of our final 3-way multi-level, multi-task models with entailment generation and paraphrase generation on all three datasets. Here, our 3-way multi-task models are statistically significantly better than our pointer baselines in both SARI and FKGL (with $p < 0.01$) on Newsela and WikiSmall, and in SARI ($p < 0.01$) on WikiLarge. Also, our 3-way multi-task model is statistically significantly better than the 2-way multi-task models in SARI and FKGL with $p < 0.01$ (see Table 1). In Sec. 6, we further provide a set of detailed ablation experiments investigating the effects of different (higher-level versus lower-level) layer sharing methods and soft- vs. hard-sharing in our multi-level, multi-task models; and we show the superiority of our final choice of higher-level semantic sharing for entailment generation and lower-level lexico-syntactic sharing for paraphrase generation.

Models	BLEU	FKGL	SARI
NEWSELA			
Static Mixing Ratio	11.86	1.38	32.98
Dynamic Mixing Ratio	11.14	1.32	33.22
WIKISMALL			
Static Mixing Ratio	29.70	6.93	28.24
Dynamic Mixing Ratio	27.23	5.86	29.58

Table 3: Results on dynamic vs. static mixing ratio (FKGL: lower is better).

Dynamic Mixing Ratio Models Finally, we present results on our 3-way multi-task model with the new approach of using 'dynamic' mixing ratios based on multi-armed bandits sampling (see Sec. 3.4).

[9] As described in Sec. 4, Newsela is considered as a higher quality dataset for text simplification, and thus we report ablation-style results (e.g., 2-way multi-task models and different layer-sharing ablations) and human evaluation on Newsela (since Wikipedia datasets are automatically-aligned). Moreover, we report SARI, FKGL, and BLEU for completeness, but as described in Sec. 4, SARI is the primary human-correlated metric for sentence simplification.

[10] We borrow the SBMT-SARI results for WikiLarge from Zhang and Lapata (2017).

[11] Stat. significance is computed via bootstrap test (Noreen, 1989; Efron and Tibshirani, 1994). Both our 2-way multi-task models are statistically significantly better in SARI and FKGL with $p < 0.01$ w.r.t. our pointer baseline and previous works. Note the discussion in Sec. 4 about why BLEU is not a good sentence simplification metric.

Models	HUMAN EVALUATION				MATCH WITH INPUT		
	Fluency	Adequacy	Simplicity	Average	BLEU (%)	ROUGE (%)	Exact Match (%)
Ground-truth	4.97	4.08	3.83	4.29	18.25	43.74	0.00
Hybrid	3.88	3.82	3.92	3.87	25.74	56.20	3.34
DRESS-LS	4.84	4.18	3.21	4.08	42.93	67.61	14.48
Pointer Baseline	4.61	3.94	3.99	4.18	30.80	60.56	10.68
3-way Multi-task	4.73	3.18	4.62	4.18	8.74	37.82	2.41

Table 4: Human evaluation results (on left) and closeness-to-input source results (on right), for Newsela.

As shown in Table 3, this dynamic multi-task approach achieves a stat. significant improvement in SARI as compared to the traditional fixed and manually-tuned mixing ratio based 3-way multi-task model: 33.22 vs. 32.98 ($p < 0.05$) on Newsela, and 29.58 vs. 28.24 ($p < 0.001$) on WikiSmall. Hence, this allows us to achieve better results while also avoiding the hassle of tuning on the large space of mixing ratios over several different tasks. In Sec. 6, we further provide ablation analysis to study whether the improvements come from the bandit learning this dynamic curriculum or from the bandit finding the final optimal mixing-ratio at the end of the sampling procedure (and also compare it to a random curriculum).

Human Evaluation We also perform an anonymized human study comparing our pointer baseline, our multi-task model, some previous works (Hybrid (Narayan and Gardent, 2014) and state-of-the-art DRESS-LS (Zhang and Lapata, 2017)), and ground-truth references (see left part of Table 4), based on fluency, adequacy, and simplicity (see Sec. 4 for more details about these criteria) using 5-point Likert scale. We asked annotators to evaluate the models (randomly shuffled to anonymize model identity) based on 200 samples from the representative and cleaner Newsela test set, and their scores are reported in Table 4. Our 3-way multi-task model achieves a significantly higher ($p < 0.001$) simplicity score compared to DRESS-LS, Hybrid, and our pointer baseline models. However, we next observe that our 3-way multi-task model has lower adequacy score as compared to DRESS-LS and the pointer model, but this is because our 3-way multi-task model focuses more strongly on simplification, which is the goal of the given task. Moreover, based on the overall average score of the three human evaluation criteria, our 3-way multi-task model is also significantly better ($p < 0.03$) than the state-of-the-art DRESS-LS model (and $p < 0.001$ w.r.t. Hybrid model).[12] Also, on further investigation, we found that a problem with the adequacy metric is that it gets artificially high scores for output sentences which are exact match (or a very close match) with the input source sentence, i.e., they have very little simplification and hence almost fully retain the exact meaning. In the right part of Table 4, we analyzed the matching scores of the outputs from different models w.r.t. the source input text, based on BLEU, ROUGE (Lin, 2004) and exact match. First, this shows that the ground-truth sentence-simplification references are in fact (as expected) very different from the input source (0% exact match, 18% BLEU, 44% ROUGE). Next, we find that our multi-task model also has low match-with-input scores (2% exact match, 9% BLEU, 38% ROUGE), similar to the behavior of the ground-truth references. On the other hand, DRESS-LS (and pointer baseline) model is generating output sentences which are substantially closer to the input and hence is not making enough changes (14% exact match, 43% BLEU, 68% ROUGE) as compared to the references (which explains their higher adequacy but lower simplicity scores).

6 Ablations and Analysis

In this section, we conduct several ablation analyses to study the different layer-sharing mechanisms (higher semantic vs. lower lexico-syntactic), soft- vs. hard-sharing, two dynamic multi-armed bandit approaches, and our model's learned entailment and paraphrasing skills. We also present and analyze some output examples from several models.[13] Note that all our soft and layer sharing decisions were strictly made on the dev/validation set (see Sec. 4).

[12]Note that our multi-task model is stat. equal to our pointer baseline on the overall-average score, showing the available trade-off between systems that simplify conservatively vs. strongly, based on one's desired downstream task application. Also refer to the high 'match-with-input' issue with the adequacy metric discussed next.

[13]Since Newsela is considered as the more representative dataset for sentence simplification with lesser noise and human quality (Xu et al., 2015; Zhang and Lapata, 2017), we conduct our ablation studies on this dataset, but we observed similar patterns on the other two datasets as well.

Models	Entailment	Paraphrasing
Ground-truth	N/A	62.1
Hybrid	34.8	74.1

Models	BLEU	FKGL	SARI
Final (High Ent + Low PP)	**11.86**	**1.38**	**32.98**
Both lower-layer	11.94	1.47	31.92
Both higher-layer	12.26	1.38	32.02
Swapped (Low Ent + High PP)	21.64	2.97	29.07
Hard-sharing	13.01	1.38	32.36

Table 5: Multi-task layer ablation results on Newsela.

Different Layer Sharing Approaches We empirically show that our final multi-level layer sharing method (i.e., higher-level semantic layer sharing with entailment generation, while lower-level lexico-syntactic layer sharing with paraphrase generation) performs better than the following alternative layer sharing methods: (1) both auxiliary tasks with high-level layer sharing, (2) both with low-level layer sharing, and (3) reverse/swapped sharing (i.e. lower-level layer sharing for entailment, and higher-level layer sharing for paraphrasing). Results in Table 5 show that our approach of high-level sharing for entailment generation and low-level sharing for paraphrase generation is statistically significantly better than all other alternative approaches in SARI ($p < 0.01$) (and statistically better or equal in FKGL).

Soft- vs. Hard-Sharing In this work, we use soft-sharing instead of hard-sharing approach (benefits discussed in Sec. 3.3) in all of our models. Table 5 also presents empirical results comparing soft- vs. hard-sharing on our final 3-way multi-task model, and we observe that soft-sharing is statistically significantly better than hard-sharing in SARI with $p < 0.01$.

Quantitative Improvements in Entailment We employ a state-of-the-art entailment classifier (Chen et al., 2017) to calculate the entailment probabilities of output sentence being entailed by the ground-truth.[14] Table 6 summaries the average entailment scores for the Hybrid, DRESS-LS, Pointer baseline, and 2-way multi-task model (with entailment generation auxiliary task), showing that the 2-way multi-task model improves in the aspect of logical entailment ($p < 0.001$), demonstrating the inference skill acquired by the simplification model via the auxiliary knowledge from the entailment generation task.

Quantitative Improvements in Paraphrasing We use the paraphrase classifier from Wieting and Gimpel (2017b) to compute the paraphrase probability score between the generated output and the input source. The results in Table 6 show that our 2-way multi-task model (with paraphrasing generation auxiliary task) is closer to the ground-truth in terms of the amount of paraphrasing (w.r.t. input) required by the sentence-simplification task, while the pointer baseline and previous models have higher scores due to higher amount of copying from input source (see 'Match-with-Input' discussion in Sec. 5, Table 4).

Addition/Deletion Operations We also measured the performance of the various models in terms of the addition and deletion operations using SARI's sub-operation scores computed w.r.t. both the ground-truth and source (Xu et al., 2016). Table 7 shows that our multi-task model is equal or better in terms of both operations.

Two Multi-Armed-Bandit Approaches As described in Sec. 3.4, our multi-armed bandit approach with dynamic mixing ratio during multi-task training learns a sufficiently good curriculum to improve the sentence simplification task (see Sec. 5). Here, we further show an ablation study on another alternative approach of using multi-armed bandits, where we record the last 10% of the actions from the bandit controller[15], then calculate the corresponding mixing ra-

[14]For this entailment analysis, we use ground-truth output as premise instead of input source, because: (1) entailment w.r.t. input source can give artificially high scores even when the output doesn't simplify enough and just copies the source (see the discussion in Sec. 5 and Table 4); (2) By transitivity, if output is entailed by ground-truth, which in turn is entailed by source, then output should also be entailed by source (plus, we want the output to be closer to ground-truth than to input source).

[15]We choose the last 10% to avoid the noisy action-value estimates at the start of the training.

tio based on this 10%, and run another independent model from scratch with this fixed mixing ratio. We found that the curriculum-style dynamic switching of tasks is in fact very effective as compared to this other 2-stage approach (33.22 versus 32.58 in SARI with $p < 0.01$). This is intuitive because the dynamic switching of tasks during multi-task training allows the model to choose the best next task to run based on the current state (as well as the previous curriculum path) of the model, as opposed to a fixed/static single mixing ratio for the full training period. In Fig. 3, we visualize the (moving averages of) probabilities of selecting each task, which shows that in the 0-1000 #rounds range, the bandit initially gives higher weight to the main task, but gradually redistributes the probabilities to the auxiliary tasks; and beyond 1000 #rounds, it then alternates switching among the three different tasks periodically. We also experimented with replacing the bandit controller with random task choices, and our bandit-controller achieves statistically significantly better results than this approach in both SARI and FKGL with $p < 0.01$, which shows that the path learned by the bandit controller is meaningful.

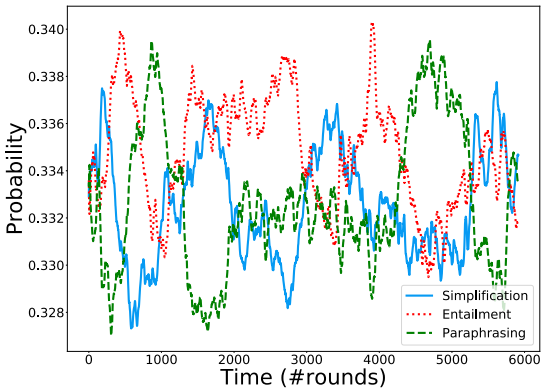

Figure 3: Task selection probability over training trajectory, predicted by bandit controller.

Multi-Task Learning vs. Data Augmentation To verify that our improvements come indeed from the auxiliary tasks' specific character/capabilities and not just due to adding more data, we separately trained word embeddings on each auxiliary dataset (i.e., SNLI+MultiNLI and ParaNMT) and incorporated them into the primary simplification model. We found that both our 2-way multi-task models perform stat. significantly better than these models (which use the auxiliary word-embeddings), suggesting that merely adding more data is not enough. Moreover, Table 5 shows that only specific intuitive (syntactic vs. semantic) layer sharing between the primary and auxiliary tasks helps results and not just adding data.

Output Examples Fig. 4 shows two output examples comparing DRESS-LS, pointer baseline, and multi-task models (and reference). We see that our multi-task model simplifies the input appropriately (similar extent to reference) while also keeping reasonably important information from the source. The pointer baseline and the DRESS-LS models simplify to a lesser extent and keep much more of the original input (as also suggested by our match-with-input investigation in Table 4).

Input: *he put henson in charge of escorting his slaves to his brother 's kentucky plantation .*
Reference: *he sent henson to take his slaves to kentucky .*

7 Conclusion

We presented a multi-level, multi-task learning approach to incorporate natural language inference and paraphrasing knowledge into sentence simplification models, via soft sharing at higher-level semantic and lower-level lexico-syntactic levels. We also introduced a multi-armed bandits approach for learning a dynamic mixing ratio of tasks. We demonstrated strong simplification improvements on three standard datasets via automatic and human evaluation, and also discussed several ablation and analysis studies.

A Appendix

A.1 Training Details

All LSTMs use hidden state size of 256. We train word vectors with embedding size of 128 with random initialization. We use gradient clipped norm of 2.0. Our model selection (tuning) criteria is based on the average of our 3 metrics (SARI, BLEU, 1/FKGL) on the validation set. The mixing ratios are α_{ss}:α_{eg}:α_{pp} = 6:1:3 for Newsela, 6:1:3 for WikiSmall, and 7:2:1 for WikiLarge. The soft-sharing coefficient λ is set such that we balance the cross-entropy and regularization losses (at convergence), which is 5×10^{-6} for Newsela, 1×10^{-6} WikiSmall, and 1×10^{-5} for WikiLarge. We train models from scratch for Newsela and WikiSmall (using Adam (Kingma and Ba, 2014) optimizer with learning rate of 0.002 and 0.0015, respectively). However, because of the large size and computation overhead for WikiLarge, we first pre-train both main and auxiliary models on their own domain until they reach 90%

convergence, and use these models to initialize the multi-task models, and set the learning rate to $1/10$ of its original default value (0.001). We set the decay rate α in the bandit controller to be 0.3. We use the negative validation loss as the reward at each sampling step to the bandit algorithm. The validation loss is divided by two as a smoothing technique.[16] All our soft/hard and layer-specific sharing decisions (Sec. 6) were made on the validation/dev set. We follow previous work (Zhang and Lapata, 2017) in their pre-processing and post-processing of named entities. We capped vocabulary size to be 50K and replaced less frequent words with UNK token.[17] Unlike previous work (Zhang and Lapata, 2017), we do not use UNK-replacement at test time, but instead rely on our pointer-copy mechanism. We use beam search with beam size of 5. All other details provided in our released code.

[16] This constant serves the same purpose as the temperature variable in the softmax function.

[17] We measured the vocabulary overlap between the main and auxiliary tasks, and found that "word-form-overlap" (percentage of unique word types in auxiliary task that also appear in the main task) to be 40.7% (entailment) and 41.0% (paraphrase), and "word-count-overlap" (percentage of words in auxiliary task that also appear in the main task, based on token frequency counts) to be 95.2% (entailment) and 94.9% (paraphrase). Hence, this suggests that only rare words (which make up for very few counts) aren't considered in training process, and our pointer mechanism handles these extra UNK words by copying the actual word-form from the source to the output.

Interpretation of Implicit Conditions in Database Search Dialogues

Abstract

Targeting the database search dialogue, we propose to utilise information in the user utterances that do not directly mention the database (DB) field of the backend database system but are useful for constructing database queries. We call this kind of information *implicit conditions*. Interpreting the implicit conditions enables the dialogue system more natural and efficient in communicating with humans. We formalised the interpretation of the implicit conditions as classifying user utterances into the related DB field while identifying the evidence for that classification at the same time. Introducing this new task is one of the contributions of this paper. We implemented two models for this task: an SVM-based model and an RCNN-based model. Through the evaluation using a corpus of simulated dialogues between a real estate agent and a customer, we found that the SVM-based model showed better performance than the RCNN-based model.

1 Introduction

The information that a dialogue system needs to extract from user utterances highly depends on its backend application. When being used as a natural language interface of a database system, the dialogue system should be able to extract pieces of information corresponding to the record fields of the database (DB) for constructing a query. There have been several attempts to extract this type of information from user utterances in database search dialogues. For instance, several studies (Raymond and Riccardi, 2007; Mesnil et al., 2015; Liu and Lane, 2016b) tried to extract values for the database field defined in the ATIS (The Air Travel Information System) corpus (Hemphill et al., 1990; Dahl et al., 1994) from the user utterances. The ATIS corpus includes a set of dialogues between users and an air travel system that were collected through the Wizard-of-Oz method. The tags that correspond to the backend database fields, e.g. departure city, arrival date, are annotated to the expressions in the user utterances. However, the utterances in real dialogues include information that does not always directly correspond to database fields but provides useful information for constructing database queries. It will be natural and more efficient if the dialogue system can utilise this type of information for retrieving the database. For instance, in real estate search dialogues, which is our target domain, the number of family members provides useful information for deciding the size of a house, but it is rarely a field of the real estate database as the number of family members is an attribute of the customer rather than that of houses. We call this type of information *implicit conditions* (Fukunaga et al., 2018).

To realise a dialogue system that can utilise the implicit conditions for the database search, we need to tackle the following two tasks.

(1) extracting pairs of a DB field and its value from user utterances that include the implicit conditions

(2) identifying the span in the utterance that represents the evidence for the DB field and value pair extraction

The task (1) provides useful information for efficiently constructing database queries from utterances that include the implicit conditions. The identified utterance span by the task (2) is helpful in constructing

Proceedings of the 27th International Conference on Computational Linguistics, pages 477–486
Santa Fe, New Mexico, USA, August 20-26, 2018.

clarification utterances by the system. As the task (1) requires a kind of inference to derive the DB field and value pair, the system interpretation is not necessarily correct. It will be safer and more natural to confirm the system interpretation with providing the evidence of that interpretation through clarification utterances. For instance, in the following dialogue fragment, the system inferred the DB field "number of rooms" and its value "one" from the user utterance. To ensure that this interpretation is correct, the system can add the evidence of the interpretation in the clarification utterance. This system utterance with the evidence is more natural than that without the evidence, i.e. "One bedroom place is large enough, isn't it?".

...

U: I will live alone.

S: As you live alone, one bedroom place is large enough, isn't it?

...

In such case, identifying that the span "live alone" is the evidence for extracting the DB field "number of rooms" and its value is worthwhile for constructing the clarification utterance.

We tackle the task (1) in two steps: extracting the DB field and extracting its value. In this paper, we first formalise the DB field extraction as a classification problem of user utterances into the DB fields. As we can derive multiple DB fields from a single utterance, the DB field extraction can be formalised as a multi-label classification. Furthermore, we solve the DB field classification together with the task (2), the evidence identification by adopting the method proposed by Lei et al. (2016). We put the DB field value extraction for the future work, as it requires the information of the database structure and its contents.

2 Related Work

The traditional pipeline for task-oriented dialogue systems consists of four modules: Natural Language Understanding (NLU), Dialogue State Tracking, Policy Learning and Natural Language Generation (Chen et al., 2017). The NLU task can be further divided into two tasks: intent detection and slot-filling. The intent detection classifies user utterances into the categories of user intention, e.g. request, question, inform and so on. The slot-filling extracts the semantic contents of user utterances in the form of slot-value pairs, e.g. the slot-value pairs From-Location="New York" and To-Location="Chicago" are extracted from "I'm going to go to Chicago from New York.". Regarding this general framework, our task corresponds to the slot-filling task. The slot-filling task can be formalised as a sequential labelling problem where each word in the target utterance is assigned an IOB tag of semantic slots (Ramshaw and Marcus, 1995). Recently, many studies adopt Recurrent Neural Network (RNN)(Mesnil et al., 2013; Yao et al., 2013; Mesnil et al., 2015; Vu et al., 2016; Jaech et al., 2016; Liu and Lane, 2016b; Liu and Lane, 2016a; Bapna et al., 2017) and Long Short-Term Memory (LSTM) (Yao et al., 2014; Hakkani-t et al., 2016) for the sequential labelling to achieve better performance. These methods, however, cannot identify semantic slots from the implicit condition which we are targeting, because they capture only explicitly mentioned semantic slots through the sequential labelling.

There are very few studies which address the task of predicting the users implicit condition in the task-oriented dialogue system. Celikyilmaz et al. (2012) proposed the method which predicts the user's preferred movie genre in the movie search domain. They estimate the movie genre that the user prefers from the user utterances that do not necessarily mention the movie genre. For instance, they estimate the comedy genre from the utterance "I wanna watch a movie that will make me laugh". Although the motivation of their work is almost the same as ours, their method estimates only a single attribute, i.e. the movie genre, and does not present the evidence for that estimate. Our method provides the evidence of the estimate at the same time and we deal with multiple attributes simultaneously.

In recent years, the end-to-end task-oriented dialogue systems which directly generate system utterances from user utterances are proposed. Eric et al. (2017) proposed an end-to-end dialogue system which accepts queries for the underlying knowledge base and returns the entities related to the users

Table 1: Database (DB) field tags

utterance. Their system works without an explicit NLU module. As is often the case for end-to-end systems, their system does not concern the reason why the system returns a certain result to a given query, i.e it does not provide any explanation for the response. Given a user utterance including implicit conditions, our system makes a kind of inference to construct a query to the DB. As there is no guarantee that the system always can make a correct inference, we need to prepare the explanation for the system inference or clarification to the user. Such functions are necessary for natural and efficient dialogues. They are, however, difficult to implement in the current end-to-end framework.

3 Data and Task Setting

We use a Japanese dialogue corpus developed by (Takahashi and Yokono, 2017) in this work. The corpus includes dialogues between pairs of crowd workers who play a real estate agent and their customer each. The dialogues were collected through a keyboard chat system. The goal of the dialogues is finding a dwelling that fulfils the customer needs. The agent does not search in a real database but completes the dialogue when having acquired the necessary information for search. In each dialogue, a customer was assigned one of ten predefined profiles and was instructed to interact with the agent regarding their assigned profile. The customer profile was not open to the agent. An example profile looks like "You are moving to a new place from your current studio apartment to live with your long-standing boyfriend. On this occasion, you want to improve your cooking skills, and thus you prefer a place equipped with an easy-to-use kitchen with a multi-burner range."

The corpus includes 968 dialogues and 29,058 utterances consisting of 14,571 agent utterances and 14,487 customer utterances. The average number of utterances in a dialogue is 29.5.

We assigned the DB field tag shown in Table 1 to each utterance in our past research (Fukunaga et al., 2018). The DB field tag set was designed based on the search conditions that are available for one of the established search sites for real estate in Japan[1]. In addition to these 38 tags, we defined the Other tag that does not fit into any of the DB fields, expecting that utterances with the Other tag contain the implicit conditions. When the annotators assigned the Other tag to an utterance, they were instructed to describe its content in the free format.

The task of the present work is to categorise customer utterances with the Other tag into the 38 DB field tags and to identify the span representing the evidence of that classification at the same time. The target customer utterances are coupled with their preceding consecutive agent utterances[2]. The customer utterance with the Other tag sometimes contains only confirmation, e.g. "Yes, please" for the agent question "You live with your wife?". To collect necessary information for classification in such cases, we add the preceding agent utterances to the target customer utterance. We call this a target utterance chunk. There are 2,642 target utterance chunks in total.

[1] http://suumo.jp

[2] When the target customer utterance with the Other tag is preceded by customer utterances without the Other tag, they are also included in the chunk.

4 Methods

We propose two models for our current task: a Support Vector Machine (SVM)-based model and a Recurrent Convolutional Neural Network (RCNN)-based model.

4.1 SVM-based model

We use SVM with a linear kernel for the first model. We build an SVM binary classifier for each DB field tag that judges whether the input target utterance chunk includes the information for that DB field or not. Thus we have 38 classifiers in total. Given an utterance chunk, the final output of the system is the list of the DB field tags of which classifier returns a positive judgement. As features for SVM, we use a bag-of-words in the utterance chunk. We ran the Japanese morphological analyser MeCab[3] on all utterance chunks and extracted nouns, verbs, adjectives and adverbs appearing more than once in the corpus. We replaced the occurrences of numbers and proper nouns with their abstraction symbol NUM and PROP. The dimension of the feature vector is 1,730.

To identify the evidence span in the utterance chunk, we collect the words of which learnt weight exceeds a certain threshold.

4.2 RCNN-based model

We extend the method proposed by Lei et al. (2016) to solve our task. Given a product review text as input, their method estimates the user rating for each aspect of the product by using regression and specify the text span for the evidence of that regression result. Their system consists of two components: a neural network for regression (Encoder) and the other neural network for identifying the evidence (Generator). These two components are trained simultaneously. The encoder is trained through supervised training being given correct ratings while the generator is trained through unsupervised training. They designed a loss function for the generator so that it prefers a shorter and consecutive span for the evidence. Assuming that the generator correctly identifies the evidence span, the encoder uses only words in the evidence span to estimate the rating. They aim at improving the generator performance indirectly through improving the encoder performance that is trained by supervised training.

To adopt Lei et al. (2016)'s method for our current task, we redesign the loss function for the encoder. We use the cross-entropy instead of the square error for the encoder loss function, as our task is the binary classification while Lei et al. (2016)'s is the regression. Let $\tilde{y}_i = \mathrm{enc}_i(\boldsymbol{z}_i, \boldsymbol{x}) \in \{0, 1\}$ is the result of classification for the i-th DB field tag where $\boldsymbol{x}$ is the input word sequence with length m and $\boldsymbol{z}_i = (z_{i1}, z_{i2}, \ldots, z_{im})$ is the binary vector denoting if the words are selected as the evidence. Note that $\mathrm{enc}_i(\cdot)$ uses only words in $\boldsymbol{x}$ of which corresponding values in $\boldsymbol{z}_i$ is one, and $\boldsymbol{z}_i$ is the output of the generator. Our loss function $\mathcal{L}_i(\boldsymbol{z}_i, \boldsymbol{x}, y_i)$ is defined in equation (1),

$$\mathcal{L}_i(\boldsymbol{z}_i, \boldsymbol{x}, y_i) = -(y_i \log(\tilde{y}_i) + (1 - y_i) \log(1 - \tilde{y}_i)), \tag{1}$$

where y_i is the correct classification. The generator loss function is the same as the original as shown in equation (2).

$$\Omega_i(\boldsymbol{z}_i) = \lambda_1 \|\boldsymbol{z}_i\| + \lambda_2 \sum_{t=1}^{m} |z_{it} - z_{i(t-1)}|. \tag{2}$$

We set z_0 to zero. The first factor promotes the evidence span to be shorter and the second promotes the span to be consecutive. We have two hyper-parameters λ_1 and λ_2 to adjust the balance between these two factors. The total cost function for the i-th DB field is

$$\mathrm{cost}_i(\boldsymbol{z}_i, \boldsymbol{x}, y_i) = \mathcal{L}_i(\boldsymbol{z}_i, \boldsymbol{x}, y_i) + \Omega_i(\boldsymbol{z}_i). \tag{3}$$

[3] http://taku910.github.io/mecab/

5 Experiments

5.1 Data

We divided 986 dialogues of the corpus into ten sets with carefully keeping the distribution of the customer profiles uniform in each set. We use the nine sets for training and the rest one set for testing. We further extracted the utterance chunks as described in 3. We removed the chunks that include the target utterances at the dialogue management level, e.g. greeting, prompting and concluding utterances. The training set has 2,379 utterance chunks and the test set has 263 utterance chunks.

The user utterance in each target utterance chunk has been annotated with the Other tag and its content description in our past work as explained in 3. In the present work, we annotated each utterance chunk with the correct answer of the classification task by mapping its content description onto some of the DB field tags. One utterance chunk can be assigned with more than one tag. For instance, a content description, "the number of people to live", which is assigned to an utterance, "I will live alone.", is mapped onto floor_plan and floor_area. The evidence span for each assigned DB field tag is also annotated in the chunk. These annotation tasks are done by one of authors.

5.2 Evaluation Measures

We use precision, recall and F-measure for the evaluation of the DB field classification. To evaluate the evidence span identification, we calculate F-measure on words, and BLEU (Papineni et al., 2002) and ROUGE (Lin and Hovy, 2003). In the evaluation of the evidence span identification, we evaluated only cases where the DB field was correctly classified. Let binary vectors $\tilde{\boldsymbol{z}} = (\tilde{z_1}, \tilde{z_2}, \cdots, \tilde{z_m})$ and $\boldsymbol{z} = (z_1, z_2, \cdots, z_m)$ be the estimated and true evidence spans respectively, where the vector element one represents that the corresponding word is selected for constituting the evidence. Given $\tilde{\boldsymbol{z}}$ and $\boldsymbol{z}$, the F-measure on words can be calculated by equation (5).

$$\mathrm{TP} = \sum_{t=1}^{m} \tilde{z}_t z_t, \quad \mathrm{FP} = \sum_{t=1}^{m} \tilde{z}_t (1 - z_t), \quad \mathrm{FN} = \sum_{t=1}^{m} (1 - \tilde{z}_t) z_t \tag{4}$$

$$\mathrm{F} = \frac{2\mathrm{TP}}{2\mathrm{TP} + \mathrm{FP} + \mathrm{FN}} \tag{5}$$

For calculating BLEU and ROUGE, we define the sets of n-grams in the estimated and true evidence span as $\tilde{G_n}$ and G_n respectively in equation (6) and (7).

$$\tilde{G}_n = \left\{ \{j\}_{j=t}^{t+n-1} \middle| \prod_{j=t}^{t+n-1} \tilde{z}_j = 1,\ 1 \le t \le m - n + 1 \right\} \tag{6}$$

$$G_n = \left\{ \{j\}_{j=t}^{t+n-1} \middle| \prod_{j=t}^{t+n-1} z_j = 1,\ 1 \le t \le m - n + 1 \right\} \tag{7}$$

Using these n-gram sets, we can calculate BLEU and ROUGE as the geometric means of P_n and Q_n as shown in equation (8) and (9). We use uni-grams and bi-grams for calculating BLEU and ROUGE, i.e. $n \le 2$.

$$\mathrm{BLEU} = \left(\prod_{n=1}^{2} P_n \right)^{1/2}, \quad P_n = \begin{cases} \dfrac{|\tilde{G}_n \cap G_n|}{|\tilde{G}_n|} & (|\tilde{G}_n| > 0 \wedge n = 1) \\ \dfrac{|\tilde{G}_n \cap G_n| + 1}{|\tilde{G}_n| + 1} & (\text{otherwise}) \end{cases} \tag{8}$$

$$\mathrm{ROUGE} = \left(\prod_{n=1}^{2} Q_n \right)^{1/2}, \quad Q_n = \begin{cases} \dfrac{|\tilde{G}_n \cap G_n|}{|G_n|} & (|G_n| > 0 \wedge n = 1) \\ \dfrac{|\tilde{G}_n \cap G_n| + 1}{|G_n| + 1} & (\text{otherwise}) \end{cases} \tag{9}$$

Table 3: Result of the evidence span identification

In equation (8) and (9), we add a smoothing constant. We do not introduce the brevity penalty into BLEU as we also use ROUGE in this evaluation.

5.3 Evaluation Settings

Due to the limitation of the data size, we evaluate the three DB fields: surrounding_facilities, floor_plan and floor_area, which are the three most dominant tags. The numbers of utterance chunks in the training set that are assigned these tags are 1,033 for surrounding_facilities, 974 for floor_plan and 964 for floor_area.

The RCNN-based model has two hyper-parameters λ_1 and λ_2 that control the balance between the span length and the constraints on the word sequence. To decide the values for these hyper-parameters, we randomly chose 200 utterance chunks from the training set of surrounding_facilities to make a development set, and trained the model with the rest of the training set and evaluated it with the development set. As a result, we found that $\lambda_1 = 0.021$ and $\lambda_2 = 0.003$ made the best performance on the development set. We use these hyper-parameter values for the other two DB fields. We also used the parameter values of the neural networks learnt in the development set as the initial parameter values. We used the existing word embeddings made from the Japanese Wikipedia articles[4]. The dimension size is 200.

The SVM-based model also has a hyper-parameter, i.e. the threshold weight for the evidence span identification. The words that have a higher weight than the threshold constitute the evidence. We used the same development set as the RCNN-based model to estimate this threshold. The word weight is normalised by equation (10). The estimated threshold was 0.58.

$$\hat{w} = \frac{w - w_{\min}}{w_{\max} - w_{\min}} \tag{10}$$

5.4 Experimental Results and Discussion

Table 2 and Table 3 shows the results of the DB field classification and the evidence span identification. Table 3 also includes the result of the SVM-based model that adopts a single word with the highest weight for the evidence (SVM_1). In both tasks, the SVM-based model outperformed the RCNN-based model.

DB field classification

Table 2 indicates that the SVM-based model is superior to the RCNN-based model in all evaluation measures. The RCNN-based model is trained to classify the utterance into a DB field by utilising only the fragments in the utterance identified as the classification evidence. That means the performance of the DB field classification depends on that of the evidence span identification. As shown in Table 3,

[4] http://www.cl.ecei.tohoku.ac.jp/~m-suzuki/jawiki_vector/

DB field	surrounding_facilities		floor_plan		floor_area	
overlap	TP	FN	TP	FN	TP	FN
Yes	73	17	86	10	75	11
No	14	9	3	5	14	3

Table 4: Categorisation of cases based on word overlap between the correct and predicted evidence spans

the word-wise F-measure of the evidence span identification is less than 0.5. This suggests that the RCNN-based model has to solve the DB field classification by using insufficient information, i.e. wrong evidence span.

To investigate the relation between the classification performance and the evidence spans, we counted the number of true-positive (TP) and false-negative (FN) cases in the result of the DB field classification by the RCNN-model. Table 4 shows the breakdown of the cases according to whether the predicted and correct evidence spans share at least one word. The row "Yes" shows the numbers of cases where at least one word is shared by both predicted and correct evidence spans and "No" shows that for no word overlap. For instance, in surrounding_facilities, 73 out of 90 (81%) "Yes" cases are correct (TP) while 14 out of 23 (60%) "No" cases are correct. This tendency is the same as in the other two DB fields. Table 4 suggests that the performance of the evidence span identification has a significant impact on that of the DB field classification in the RCNN-model.

However, Table 4 also shows that there are cases where the RCNN-model can correctly classify the DB fields even though it fails to identify the correct evidence spans. We investigated such 14 cases for the surrounding_facilities field (the cell intersecting "No" and "TP") to find words that are useful for the field classification but not included in the evidence spans. For instance, the word "near" appears in the positive examples twice as frequent as in the negative examples in our training data. This word can be a clue for the field classification although not being included in the evidence span. To improve the performance of the DB field classification, we need to extend the current model to incorporate such useful information on top of the information from the evidence spans.

We further investigated the individual error cases of the surrounding_facilities classification. We found errors due to the annotation inconsistency in 10 out of 25 FP cases in the RCNN-based model result and 11 out of 24 FP cases in the SVM-based model result. For instance, an utterance chunk in FP cases, "Do you have any preferences for location? — I prefer a suburb.", is annotated as a negative example, while the utterance chunk which has almost the same content, "What kind of property are you looking for? — I plan to move to a suburb in future.", is annotated as a positive example. When we assign the DB field to the utterance with the Other tag we regarded only the description for the Other tag, without referring to the original utterances. In the above example, the content description of the former utterance chunk is "rough area", while that of the latter is "living environment". Although the content of the utterances is the same, the difference of their description caused such inconsistent field assignment. Our future work includes implementing more solid annotation guideline that enables stable and consistent assignment of the correct DB field.

Evidence span identification

Table 3 shows that the SVM-based model is superior to the RCNN-based model in all DB fields and measures except for ROUGE.

Table 5 shows the average number of words and spans in the predicted and correct evidence of the evidence span identification.

As shown in Table 5, the number of words in the correct evidence spans is more than two on average. Therefore the SVM-based model selecting only one word as the evidence (SVM_1 in Table 3) cannot select enough words for the evidence. Setting an appropriate threshold on the learnt weight of each word (feature) improves both ROUGE and BLUE values. This implies that the learnt word weight can be a clue to choose words to constitute the evidence.

We formalised the evidence span identification as a binary classification of whether each word in the

	surrounding_facilities			floor_plan			floor_area		
	#words	#spans	#w/#s	#words	#spans	#w/#s	#words	#spans	#w/#s
SVM	1.60	1.54	1.04	2.48	2.33	1.07	2.49	2.32	1.07
RCNN	3.21	2.39	1.34	2.97	2.06	1.44	3.57	2.12	1.69

Prediction	Positive	SVM	102	64
		RCNN	92	144
	Negative	SVM	193	2,353
		RCNN	165	2,038

Table 6: Confusion matrix of the evidence span identification

utterance chunks belongs to the evidence or not. Table 6 shows the confusion matrix of the number of words constituting the evidence for the surrounding_facilities field. This matrix indicates that there are more false-negative cases than false-positive cases in both models. A dominant word type in the false-negative cases is Japanese particles, e.g. ga, ni, which indicate case marking. In other words, both models tend to skip these particles and to select the content words such as nouns and verbs. Although the particles are not important features of the classification since they appear in any class, it is desirable for dialogue systems to include them into the evidence so that they are used in the later stage of response generation, e.g. generating clarification utterances.

Through the investigation of the individual extracted evidence spans for the surrounding_facilities field by the RCNN-based model, we found that the model tends to extract the word just after the question mark "?" for all test cases. The question mark is the last word of the question by the real estate agent in most cases. The word "safety" which is the strong clue for surrounding_facilities appears just after the question mark at a rate of 41.3%. The model seems to have learnt this collocation. However, there are only 40.4% of test cases where the word just after a question mark belongs to the evidence span. This over-tuning degrades the performance of the evidence span identification.

The RCNN-based model is inferior to the SVM-based model in both tasks. Probably we need to have more data to train the neural network-based model; we used 2,379 utterance chunks for training classifiers while Lei et al. (2016) used about 80,000 to 90,000 reviews in the experiment.

6 Conclusion

Targeting the database search dialogue, we proposed to utilise information in the user utterances that do not directly correspond to the DB field of the backend database system. We call this kind of information *implicit conditions*. We formalised the interpretation of the implicit conditions as classifying user utterances into the related DB field while identifying the evidence for that classification at the same time. We implemented two models: an SVM-based model and an RCNN-based model. Through evaluation experiments on a corpus of simulated dialogues between a real estate agent and a customer, we found that the SVM-based model showed better performance than the RCNN-based model. This implies that the size of the corpus is too small to train the latter model. Furthermore, the error analysis on the DB field classification revealed that some errors occurred due to the annotation inconsistency. Our future work includes implementing more solid annotation guideline that enables stable and consistent assignment of the correct DB field.

While this paper focused on only finding DB field and its evidence from the utterance, we need to further extract the value for the field in order to generate database queries from the utterances.

Abstract

Automatic charge prediction aims to predict the final charges according to the fact descriptions in criminal cases and plays a crucial role in legal assistant systems. Existing works on charge prediction perform adequately on those high-frequency charges but are not yet capable of predicting few-shot charges with limited cases. Moreover, these exist many confusing charge pairs, whose fact descriptions are fairly similar to each other. To address these issues, we introduce several discriminative attributes of charges as the internal mapping between fact descriptions and charges. These attributes provide additional information for few-shot charges, as well as effective signals for distinguishing confusing charges. More specifically, we propose an attribute-attentive charge prediction model to infer the attributes and charges simultaneously. Experimental results on real-work datasets demonstrate that our proposed model achieves significant and consistent improvements than other state-of-the-art baselines. Specifically, our model outperforms other baselines by more than 50% in the few-shot scenario. Our codes and datasets can be obtained from https://github.com/thunlp/attribute_charge.

1 Introduction

The task of automatic charge prediction aims to train a machine judge to determine the final charges (e.g., *theft*, *robbery* or *traffic offence*.) of the defendants in criminal cases. As a representative subtask of legal judgment prediction, charge prediction plays an important role in legal assistant systems and can benefit many real-world applications. For example, it can provide a handy reference for legal experts (e.g., lawyers and judges) and improve their working efficiency. Meanwhile, it can supply ordinary people who are unfamiliar with legal terminology and complex procedures with legal consulting.

As a typical task in legal intelligence, automatic charge prediction has been studied for decades and most existing works formalize this task under the text classification framework. At the early stage, researchers pay great efforts to extract efficient features from text or case profiles. For example, some works (Liu et al., 2004; Liu and Hsieh, 2006) utilize shallow textual features, including characters, words, and phrases, to predict charges. Katz et al. (2017) predict the US Supreme Court's decisions with efficient features extracted from case profiles (e.g., dates, locations, terms, and types). All these approaches require numerous human effort to design features and annotate training instances. Besides, these methods are hard to scale to other scenarios. Inspired by the successful usage of deep neural networks on natural language processing tasks (Kim, 2014; Baharudin et al., 2010; Tang et al., 2015), researchers propose to employ deep neural networks to model legal documents. For example, Luo et al. (2017) propose an attention-based neural network for charge prediction by incorporating the relevant law articles.

However, charge prediction is still confronted with two major challenges which make it non-trivial:

*Indicates equal contribution.

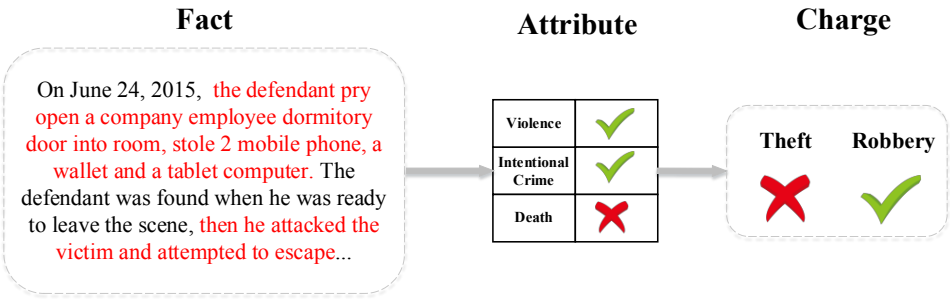

Figure 1: An illustration of the attribute-based charge prediction.

Few-Shot Charges. In practice, the case numbers of various charges are highly imbalanced. According to our statistics on a real-world dataset, the most frequent 10 charges (e.g., *theft*, *intentional injury*, and *traffic offence*.) cover 78.1% cases. On the contrary, the most low-frequency 50 (e.g., *scalping relics*, *disrupting the order of the court*, and *tax-escaping*.) charges only cover less than 0.5% cases and most of these charges own only around ten cases correspondingly. Previous works usually focus on these common charges and ignore the few-shot ones. Though deep neural models advance feature-engineering based charge prediction methods, they are unable to handle few-shot charges well due to the requirement of sufficient training data. Therefore, how to deal with these charges with limited cases is critical to a robust and effective charge prediction system.

Confusing Charges. Besides few-shot charges, there also exist many confusing charge pairs, such as (*theft*, *robbery*) and (*misappropriation of funds*, *embezzlement*). For each confusing pair, the definitions of two charges only differ in the verification of a specific act and the circumstances in corresponding cases are usually similar to each other. As illustrated in Fig. 1, many *robbery* case also contain the act of *theft*, and the existence of violence is the only key factor to distinguish these two charges. Thus, how to capture the crucial factors for distinguishing confusing charges is another challenge of charge prediction.

To address these issues, we propose to introduce discriminative legal attributes of charges into consideration and take these attributes as the internal mapping between facts and charge. More specifically, we select 10 representative attributes of charges, including *violence*, *profit purpose*, *buying and selling* and so on. Afterwards, we conduct a low-cost category-level annotation, i.e., for each charge, we annotate the value (including *yes*, *no*, or *not available*) of each attribute. This annotation indicates if an attribute is the essential condition of a charge.

With the attribute annotation of charges, we propose a novel multi-task learning framework to predict the attributes and charges of each case simultaneously. In this model, we employ attribute attention mechanism to capture the critical factual information relevant to a specific attribute. After that, we combine these attribute-aware representations with an attribute-free fact representation to predict the final charges. There are two reasons for introducing legal attributes into our charge prediction model. On one hand, these attributes can provide explicit knowledge about how to distinguish confusing charges. On the other hand, these attributes are shared by all charges, and the knowledge can transfer from high-frequency charges to low-frequency ones. Even for the few-shot charges, we can learn an efficient attribute-aware representation for prediction.

To investigate the advantage of our model on handling few-shot and confusing charges, we conduct experiments on three real-world datasets of Chinese criminal cases. Experimental results demonstrate that our model significantly and consistently outperforms other state-of-the-art models on all datasets and evaluation metrics. It is worth noting that, our model outperforms other baselines by more than 50% for the few-shot charges.

To summarize, we make three main contributions as follows:

(1) We are the first to focus on the few-shot and confusing problems in charge prediction. To address these issues, we introduce legal attributes of charges into charge prediction task for the first time.

(2) We propose a novel multi-task learning framework to infer the attributes and charges of a case jointly. To achieve it, we employ attribute attention mechanism to learn attribute-aware fact representa-

tions.

(3) We conduct efficient experiments on several real-world datasets, and our model significantly outperforms other baselines and achieves more than 50% improvements for few-shot charges.

2 Related Work

2.1 Zero-Shot Classification

Our work is relevant to zero-shot classification in computer vision. Many attribute-based models have been proposed under this task since attributes are shared among different classes and can offer an intermediate representation. Lampert et al. (2014) introduces direct attribute prediction(DAP) and indirect attribute prediction(IAP), and proposes attribute classifiers which can be pre-trained and dont need retraining when finding new suitable object class. Akata et al. (2013) proposes to transform the task of attribute-based classification to the label-embedding task. Jayaraman and Grauman (2014) introduces a random forest method stressing the unreliability of attribute prediction for unseen classes. They also extend it to the few-shot scenario.

Other than attributes, other external information can also be introduced to promote zero-shot classification. Elhoseiny et al. (2014) makes use of text description of the class label to transfer knowledge between text features and visual features. Zero-shot learning has also been used in applications besides object recognition, such as activity recognition (Zellers and Choi, 2017) and event recognition (Wu et al., 2014).

2.2 Charge Prediction

Researchers in the legal area have been working on automatically making the legal judgment for a long time. Kort (1957) applies quantitative methods to predict judgment by calculation numerical values for factual elements. Nagel (1963) makes use of correlation analysis to make predictions for reapportioning cases. Keown (1980) introduced mathematical models used for legal prediction such as linear models and the scheme of nearest neighbors. These methods are usually mathematical or quantitative, and they are restricted to a small dataset with few labels.

Since machine learning has been proven successful in many areas, researchers begin to formalize charge prediction as a text classification problem and make use of machine learning methods. Such work usually focuses on feature extraction from the case fact. Lin et al. (2012) fetches 21 legal factor labels for case classification. Mackaay and Robillard (1974) extracts N-grams and topics created by clustering semantically similar N-grams as features. Sulea et al. (2017) proposes a system based on SVM ensembles using the case description, ruling and time span of a case as input. However, these methods only extract shallow text features or manual labels which are hard to gather on a larger dataset. Whats more, the conventional models could not catch the subtle difference between similar crimes, thus they wouldnt perform well when the number of classes increases and more similar crimes appear.

With the successful usage of neural network methods on speech (Mikolov et al., 2011; Hinton et al., 2012; Dahl et al., 2012; Sainath et al., 2013), computer vision (CV) (Krizhevsky et al., 2012; Farabet et al., 2013; Tompson et al., 2014; Szegedy et al., 2015) and natural language processing (NLP) (Collobert et al., 2011; Kim, 2014; Bordes et al., 2014; Sutskever et al., 2014; Jean et al., 2015; Yang et al., 2016), researchers propose to employ neural models for legal tasks. Luo et al. (2017) proposes a hierarchical attentional network to predict charges and extract relevant articles jointly. However, this work only focuses on high-frequency charges, without paying attention to few-shot and confusing ones. To address these issues, we propose an attention-based neural model by incorporating several discriminative legal attributes.

3 Method

In this section, we propose a few-shot neural model which jointly models charge prediction task and legal attribute prediction task in a unified framework. In the following parts, we first introduce the discriminative charge attributes. Afterward, we give definitions of charge prediction and attribute prediction. Then

we describe the neural encoder of fact description and the attention-based attribute predictor. At last, we show the output layer and the loss function of our model.

3.1 Discriminative Charge Attributes

To distinguish confusing charges and provide additional knowledge for few-shot charges, we introduce 10 discriminative attributes for all the charges in Chinese criminal law. The detailed descriptions of these attributes are shown in Table 1. For each (*charge, attribute*) pair, it can be labeled as *Yes*, *No* or *NA*. For example, the charge of *manslaughter* should be labeled as *No* on *Intentional Crime*, *Yes* on *Death*, *NA* on *State Organ*. Note that, the fact-findings of a specific case can only be labeled as *Yes* or *No*. When convicting someone of a certain crime, the facts should conform to the description of the certain charge. Thus for a certain attribute, the label of a specific case and the label of the corresponding charge should be the same or not in conflict. In other words, for a certain attribute, the label of a case and the charge can only be (*Yes*, *Yes*), (*No*, *No*), (*Yes*, *NA*), or (*No*, *NA*). In practice, we conduct a low-cost annotation and annotate the attributes of 149 distinct charges manually. Then, we assign each case with the same attributes of its corresponding charge.

Attributes	Description
Profit Purpose	Whether the criminal commits a crime on the purpose of getting profit.
Buying and Selling	Whether the criminal has buying or selling behavior during the commission of the crime.
Death	Whether death is caused by the criminal.
Violence	Whether the criminal has the act of violence.
State Organ	Whether the case or the charge involves State organ or any functionary of a State organ.
Public Place	Whether the criminal commits a crime in a public place.
Illegal Possession	Whether the criminal commits a crime for the purpose of illegal possession.
Physical Injury	Whether a physical injury is caused by the criminal.
Intentional Crime	Whether the criminal commits an intentional crime.
Production	Whether the criminal commits a crime during the production.

Table 1: The descriptions of selected attributes.

3.2 Formalizations

3.2.1 Charge Prediction

The fact description of a case can be seen as a word sequence $\mathbf{x} = \{x_1, \ldots, x_n\}$, where n represents the sequence length, $x_i \in T$, and T is a fixed vocabulary. Given the fact description $\mathbf{x}$, the charge prediction task aims to predict a charge $y \in Y$ from a charge set Y.

3.2.2 Attributes Prediction

The attributes prediction task can be regarded as a binary classification task. It takes the same input sequence $\mathbf{x}$ as in the charge prediction task, and aims to predict the fact-findings of attributes $\mathbf{p} = \{p_1, \ldots, p_k\}$ according to the fact. Here, k is the number of selected attributes, and $p_i \in \{0, 1\}$ is the label for a certain attribute.

3.3 Fact Encoder

As illustrated in Fig. 2, fact encoder encodes the discrete input sequence into continuous hidden states. Here, we employ conventional Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) as fact encoder due to its ability to extract semantic meanings. LSTM is a variation of RNN and is capable of capturing long-term dependencies.

First, LSTM encoder converts each word $x_i \in \mathbf{x}$ into its word embedding $\mathbf{x}_i \in \mathbb{R}^d$, where d is the dimension of word embeddings. Then, we get the corresponding word embedding sequence as

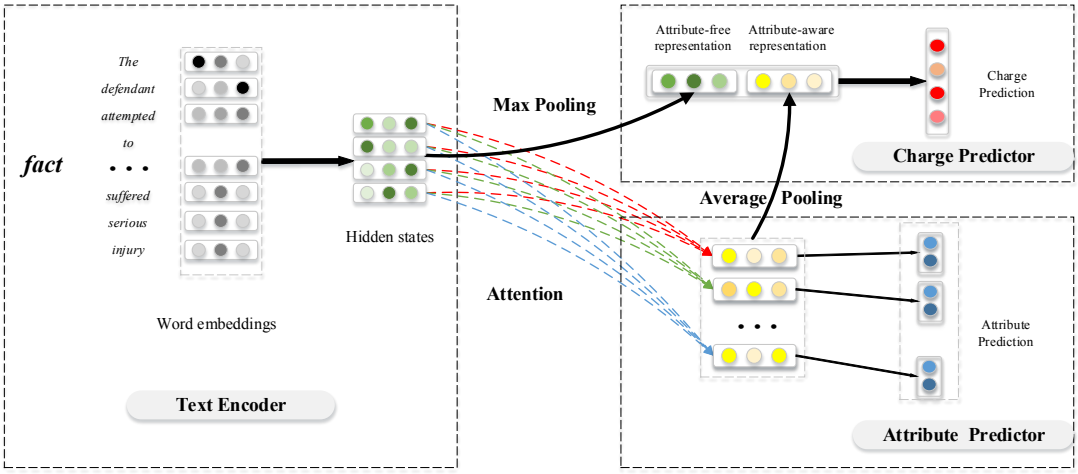

Figure 2: An illustration of the attribute-based charge prediction.

$\hat{\mathbf{x}} = \{\mathbf{x}_1, \ldots, \mathbf{x}_n\}$.

At each time step $t \in [1, n]$, the LSTM cell intakes $\mathbf{x}_t$, recalculates memory cell $\mathbf{c}_t$, and outputs new hidden state $\mathbf{h}_t$ as follows:

$$\begin{aligned}
\mathbf{f}_t &= \sigma\left(W_f \mathbf{x}_t + \mathbf{U}_f \mathbf{h}_{t-1} + \mathbf{b}_f\right), \\
\mathbf{i}_t &= \sigma\left(W_i \mathbf{x}_t + \mathbf{U}_i \mathbf{h}_{t-1} + \mathbf{b}_i\right), \\
\mathbf{o}_t &= \sigma\left(W_o \mathbf{x}_t + \mathbf{U}_o \mathbf{h}_{t-1} + \mathbf{b}_o\right), \\
\hat{\mathbf{c}}_t &= \tanh\left(W_c \mathbf{x}_t + \mathbf{U}_c \mathbf{h}_{t-1} + \mathbf{b}_c\right), \\
\mathbf{c}_t &= \mathbf{f}_t \odot \mathbf{c}_{t-1} + \mathbf{i}_t \odot \hat{\mathbf{c}}_t, \\
\mathbf{h}_t &= \mathbf{o}_t \odot \tanh\left(\mathbf{c}_t\right).
\end{aligned} \tag{1}$$

Here, $\mathbf{f}_t$, $\mathbf{i}_t$ and $\mathbf{o}_t$ represent forget gate, input gate, and output gate respectively. $\odot$ means element-wise multiplication and σ is the sigmoid activation function. W, U, and b are weight matrices and bias vectors. After processing all time steps, we get a hidden state sequence $\mathbf{h} = \{\mathbf{h}_1, \ldots, \mathbf{h}_n\}$. At last, we feed it into a max-pooling layer to get the attribute-free representation $\mathbf{e} = [e_1, \ldots, e_s]$ as

$$e_i = \max(\mathbf{h}_{1,i}, \cdots, \mathbf{h}_{n,i}), \forall i \in [1, s]. \tag{2}$$

Here, s is the dimension of hidden states.

3.4 Attentive Attribute Predictor

Given the fact description $\mathbf{x}$, the attribute predictor aims to predict the label of every attribute. Inspired by (Yang et al., 2016), we employ an attention mechanism to select relevant information from facts and generate attribute-aware fact representations.

As shown in Fig. 2, attribute predictor takes the hidden state sequence $\mathbf{h} = \{\mathbf{h}_1, \ldots, \mathbf{h}_n\}$ as input. Our attentive attribute predictor then calculates attention weights $\mathbf{a} = \{\mathbf{a}_1, \ldots, \mathbf{a}_k\}$ for all attribute, where $\mathbf{a}_i = [a_{i,1}, \ldots, a_{i,n}]$. $\forall i \in [1, k]$ and $j \in [1, n]$, $a_{i,j}$ is calculated by:

$$a_{i,j} = \frac{\exp(\tanh(\mathbf{W}^a \mathbf{h}_j)^T \mathbf{u}_i)}{\sum_t \exp(\tanh(\mathbf{W}^a \mathbf{h}_t)^T \mathbf{u}_i)}. \tag{3}$$

Here, $\mathbf{u}_i$ is the context vector of the i-th attribute to calculate how informative an element is to the attribute i, and $\mathbf{W}^a$ is a weight matrix that all attributes share. Afterwards, we get attribute-aware representations of fact $\mathbf{g} = \{\mathbf{g}_1, \ldots, \mathbf{g}_k\}$, where $\mathbf{g}_i = \sum_t a_{i,t} \mathbf{h}_t$. At last, with representations g, we project it into the label space and use softmax function to get the final prediction results $\mathbf{p} = [p_1, \ldots, p_k]$, where p_i is the prediction result of attribute i and is calculated by:

$$\begin{aligned}
\mathbf{z}_i &= \text{softmax}(\mathbf{W}_i^p \mathbf{g}_i + \mathbf{b}_i^p), \\
p_i &= \arg\max(\mathbf{z}_i).
\end{aligned} \tag{4}$$

Here, $\mathbf{z}_i$ is the prediction probability distribution on *Yes* and *No*. $\mathbf{W}_i^p$ and $\mathbf{b}_i$ are weight matrix and bias vector of attribute i.

3.5 Output Layer

To integrate the fact descriptions and fact-findings of all attributes, we use both attribute-free and attribute-aware representations to predict the final charge of a case in the output layer. The predicted distribution y over all charges is calculated as follows:

$$\begin{aligned} \mathbf{r} &= \frac{\sum_i \mathbf{g_i}}{k}, \\ \mathbf{v} &= \mathbf{e} \oplus \mathbf{r}, \\ y &= \text{softmax}(\mathbf{W}^y \mathbf{v} + \mathbf{b}^y). \end{aligned} \tag{5}$$

Here, $\mathbf{r}$ is the average of attribute-aware representations. $\mathbf{r}$ and $\mathbf{e}$ are concatenated into the final fact representation $\mathbf{v}$. $\mathbf{W}^y$ and $\mathbf{b}^y$ are weight matrix and bias vector in the output layer.

3.6 Optimization

The training objective of our proposed model consists of two parts. The first one is to minimize the cross-entropy between predicted charge distribution y and the ground-truth distribution $\hat{y}$. The other one is to minimize the cross-entropy between predicted distribution and the ground-truth fact-finding of each attribute.

The charge prediction loss can be formalized as:

$$\mathcal{L}_{charge} = -\sum_{i=1}^{C} y_i \cdot log(\hat{y}_i), \tag{6}$$

where y_i is the ground-truth label, $\hat{y}_i$ is prediction probability, and C is the number of charges.

As each attribute is equally important in the model, we can easily calculate the attribution loss by sum up the cross-entropy of all attributes. However, when the attribute of a specific charge is *NA*, the label of the corresponding cases can be *Yes* or *No*. Therefore, we only add up the cross-entropy to the attribute loss when this attribute of the charge belongs to *Yes* or *No*. At last, we formulate the attribute loss as:

$$\mathcal{L}_{attr} = -\sum_{i=1}^{k} I_i \sum_{j=1}^{2} z_{ij} \cdot log(\hat{z}_{ij}), \tag{7}$$

where I_i is an indicator function. $I_i = 1$ if the i-th attribute of current charge is labeled as *Yes* or *No*, and $I_i = 0$ otherwise. Obviously, z_i is the ground-truth label, and $\hat{z}_i$ is predicted probabilities distribution on *Yes* and *No*.

Considering the two objectives, our final loss function $\mathcal{L}$ is obtained by adding $\mathcal{L}_{charge}$ and $\mathcal{L}_{attr}$ as follows:

$$\mathcal{L} = \mathcal{L}_{charge} + \alpha \cdot \mathcal{L}_{attr}, \tag{8}$$

where α is a hyper-parameter to balance the weight of the two parts in the loss function.

4 Experiments

In order to investigate the effectiveness of our model on criminal charges prediction, we conduct experiments on several real-world datasets and compare our model with several state-of-the-art baselines.

4.1 Dataset Construction

Since there are no publicly available datasets in previous works for charges prediction, we collect criminal cases published by the Chinese government from China Judgments Online[1]. As each case is well-structured and divided into several parts such as fact, court view, and penalty result, we select the fact

[1] `http://wenshu.court.gov.cn`.

part of each case as our input. Besides, we can easily extract the charges from the penalty result by regular expression. We have manually checked the extracted charges and there are few mistakes.

Although there are some cases that contain multiple defendants and multiple charges in real-world, considering the task would be too complex to solve if these cases contained, we removed the cases which have more than one charges in a verdict. Besides, in order to examine the performance of our method on few-shot charges, we keep 149 distinct charges (near 3 times as compared with (Luo et al., 2017)) with at least 10 cases.

After preprocessing, we randomly select about $400,000$ cases and construct three datasets with different scales, denoted as **Criminal-S(small)**, **Criminal-M(medium)** and **Criminal-L(large)**. The three different datasets contain the same number of charges but the different number of cases. The detailed statistics are shown in Table 2.

Datasets	**Criminal-S**	**Criminal-M**	**Criminal-L**
train	$61,589$	$153,521$	$306,900$
test	$7,702$	$19,189$	$38,368$
valid	$7,755$	$19,250$	$38,429$

Table 2: The statistics of different datasets.

4.2 Attribute Selection and Annotation

As mentioned in previous part, we propose to introduce discriminative attributes to enhance charge prediction. To select these attributes, we first train a LSTM based charge prediction model and obtain the confusion matrix of predicted charges on validation set. Then, we filter out the confusing charge pairs and provide them to three master students majoring in criminal. According to these confusing charge pairs, they define 10 representative attributes to distinguish these confusing pairs.

With the selected 10 attributes, we conduct a low-cost annotation over all charges. Here, the low-cost annotation means we only need to annotate 10 attributes for 149 charges manually, rather than all cases. As the selected attributes are discriminative and unambiguous, we asked these annotators to reach an agreement for each annotation. Totally, we spent less than 10 hours for annotation.

4.3 Baselines

We employ several typical text classification models and one charge predicting model as baselines:

TFIDF+SVM: We implement term-frequency inverse document frequency (TFIDF) (Salton and Buckley, 1988) to extract features of inputs, and employ SVM (Suykens and Vandewalle, 1999) as the classifier.

CNN: We implement the CNN with multiple filter widths (Kim, 2014) as text classifier.

LSTM: We implement a two-layer LSTM (Hochreiter and Schmidhuber, 1997) with a max-pooling layer as the fact encoder.

Fact-Law Attention Model: Luo et al. (2017) propose an attention-based neural charge prediction model by incorporating relevant law articles.

4.4 Experiment Settings and Evaluation Metrics

As all the case documents are written in Chinese without word cutting, we employ THULAC (Sun et al., 2016) for word segmentation and set the maximum document length to 500. For the TFIDF+SVM model, we set the feature size to $2,000$. For other neural models, we employ Skip-Gram model (Mikolov et al., 2013) to pre-train word embeddings with the embedding size of 100. We set the hidden state size of LSTM to 100.For the CNN based models, we set the filter widths to $(2, 3, 4, 5)$ with each filter size to 25 for consistency. The weight α of the attribute loss is set to 1.

Note that, the representation size of our model turns into 200 after concatenation. For a fair comparison, we add a 100×200 fully connected layer between after the pooling layer in CNN and LSTM,

denoted as CNN-200 and LSTM-200.

We use Adam (Kingma and Ba, 2015) as the optimizer, and set the learning rate to 0.001, the dropout rate (Srivastava et al., 2014) to 0.5 and the batch size to 64. We employ accuracy (Acc.), macro-precision (MP), macro-recall (MR) and macro-F1 as our evaluation metrics.

4.5 Results and Analysis

Datasets	Criminal-S				Criminal-M				Criminal-L			
Metrics	Acc.	MP	MR	F1	Acc.	MP	MR	F1	Acc.	MP	MR	F1
TFIDF+SVM	85.8	49.7	41.9	43.5	89.6	58.8	5 0.1	52.1	91.8	67.5	54.1	57.5
CNN	91.9	50.5	44.9	46.1	93.5	57.6	48.1	50.5	93.9	66.0	50.3	54.7
CNN-200	92.6	51.1	46.3	47.3	92.8	56.2	50.0	50.8	94.1	61.9	50.0	53.1
LSTM	93.5	59.4	58.6	57.3	94.7	65.8	63.0	62.6	95.5	69.8	67.0	66.8
LSTM-200	92.7	60.0	58.4	57.0	94.4	66.5	62.4	62.7	95.1	72.8	66.7	67.9
Fact-Law Att.	92.8	57.0	53.9	53.4	94.7	66.7	60.4	61.8	95.7	73.3	67.1	68.6
Our Model	**93.4**	**66.7**	**69.2**	**64.9**	**94.4**	**68.3**	**69.2**	**67.1**	**95.8**	**75.8**	**73.7**	**73.1**

Table 3: Charge prediction results of three datasets.

As shown in Table 3, we can observe that our model significantly and consistently outperforms all the baselines. Almost all existing methods perform poorly under the macro-F1 metric, which indicates their shortage of predicting few-shot charges. Conversely, our model achieves promising improvements (7.9%, 4.4%, and 5.2% absolutely on three datasets respectively), which demonstrates the robustness and effectiveness of our model.

To further verify the advance of our model on dealing with few-shot charges, we show the performance on charges with different frequencies. As shown in Table 4, we divide the charges into three parts according to their frequencies. Here, the charges with ≤ 10 cases are low-frequency, and the charges with > 100 cases are high-frequency. From this table, we find that our model achieves more than 50% improvements than baseline method for the low-frequency (i.e., few-shot) charges, which verifies the effectiveness of our model on handling few-shot issues.

Charge Type	Low frequency	Medium frequency	High frequency
Charge Number	49	51	49
LSTM-200	32.6	55.0	83.3
Our Model	**49.7 (↑ 17.1%)**	**60.0 (↑ 5.0%)**	**85.2 (↑ 1.9%)**

Table 4: Macro-F1 values of various charges on Criminal-S.

Datasets	Criminal-S				Criminal-M				Criminal-L			
Metrics	Acc.	MP	MR	F1	Acc.	MP	MR	F1	Acc.	MP	MR	F1
Our model	93.4	**66.7**	**69.2**	**64.9**	94.4	68.3	**69.2**	**67.1**	**95.8**	**75.8**	**73.7**	**73.1**
w/o attention	**93.5**	63.4	60.1	60.0	94.7	**68.8**	58.2	60.9	94.9	70.9	54.4	58.6

Table 5: Experimental results of ablation test.

4.6 Ablation Test

Our method is characterized by the incorporation of attention mechanism and attribute-aware representations. Thus, we design ablation test respectively to investigate the effectiveness of these modules. When taken off the attention mechanism, for each attribute we replace attention mechanism with a fully connected layer. When taken off the attribute-aware representations (i.e., without concatenating the averaged

Task	Charge Prediction	Attribute Prediction on *physical injury*
Ground Truth	Intentional Injury	Yes
Our model	Intentional Injury	Yes
LSTM-200	Affray	N/A

Table 6: Charge and attribute prediction result of the selected case.

attribute-aware representation), our method degrades into a typical multi-task learning based on LSTM for both charge and attribute prediction.

As shown in Table 5, we can observe that the performance drops obviously after removing the attention layer or the concatenation. The macro-F1 decreases at least 4%. Therefore, it can be seen that both attention mechanism and attribute-aware fact representation play irreplaceable roles in our model.

4.7 Case Study

In this part, we select a representative case to give an intuitive illustration of how the predicted attributes help to promote the performance of charge prediction. In this case, the defendant is convicted of intentional injury. It is often hard to decide whether to judge a case as affray or intentional injury since they are both related to violence. One important difference between them is that intentional injury has the feature of physical injury, while affray does not.

So we believe the attribute physical injury is essential in the charge prediction of this case. As shown in Table 6, our model correctly predicts the label of *physical injury* as *Yes*, and consequently predicts the charge as *intentional injury*. In contrary, the model LSTM-200 predicts it as *affray* incorrectly. In addition, we visual the heat map of this case when predicting the attribute $intentionalinjury$. Words with deeper background color have higher attention weights. From this figure, we observe that the attention mechanism can capture key patterns and semantics relevant to current attribute.

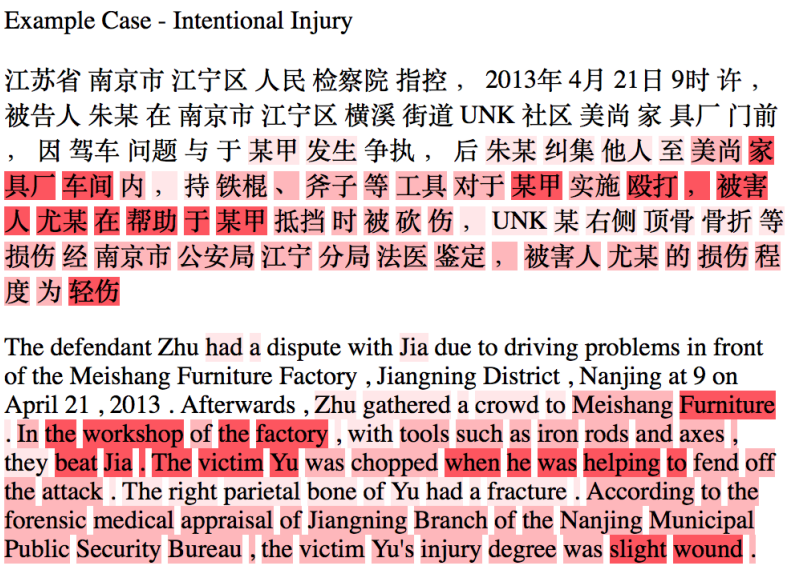

Figure 3: Visualization of attention mechanism.

.

5 Conclusion

In this work, we focus on the task of charge prediction according to the fact descriptions of criminal cases. To address the problem of prediction few-shot and confusing charges, we introduce discriminative legal

attributes into consideration and propose a novel attribute-based multi-task learning model for charge prediction. Specifically, our model learns attribute-free and attribute-aware fact representation jointly by utilizing attribute-based attention mechanism.

In future, we will explore the following directions:

(1) There are more complicated criminal cases, such as multiple defendants and charges. Thus, it is challenging to handle this general form of charge prediction.

(2) In this work, we only utilize several simple attributes of charges, while there exist more complex essential conditions of charges. How to take full usage of essential conditions of charges is expected to improve the interpretability of charge prediction models.

Abstract

In this paper, we propose a hybrid technique for semantic question matching. It uses a proposed two-layered taxonomy for English questions by augmenting state-of-the-art deep learning models with question classes obtained from a deep learning based question classifier. Experiments performed on three open-domain datasets demonstrate the effectiveness of our proposed approach. We achieve state-of-the-art results on partial ordering question ranking (POQR) benchmark dataset. Our empirical analysis shows that coupling standard distributional features (provided by the question encoder) with knowledge from taxonomy is more effective than either deep learning (DL) or taxonomy-based knowledge alone.

1 Introduction

Question Answering (QA) is a well investigated research area in Natural Language Processing (NLP). There are several existing QA systems that answer factual questions with short answers (Iyyer et al., 2014; Bian et al., 2008; Ng and Kan, 2015). However, systems which attempt to answer questions that have long answers with several well-formed sentences, are rare in practice. This is mainly due to some of the following challenges: (i) selecting appropriate text fragments from document(s), (ii) generating answer texts with coherent and cohesive sentences, (iii) ensuring the syntactic as well as semantic well-formedness of the answer text. However, when we already have a set of answered questions, reconstructing the answers for semantically similar questions can be bypassed. For each unseen question, the most semantically similar question is identified by comparing the unseen question with the existing set of questions. The question, which is closest to the unseen question can be retrieved as a possible semantically similar question. Thus, accurate semantic question matching can significantly improve a QA system. In the recent past, several deep learning based models such as recurrent neural networks (RNNs), convolution neural network (CNN), gated recurrent units (GRUs) etc. have been explored to obtain representation at the word (Mikolov et al., 2013; Pennington et al., 2014), sentence (Kim, 2014) and paragraph (Zhang et al., 2017) level.

In the proposed semantic question matching framework, we use attention based neural network models to generate question vectors. We create a hierarchical taxonomy by considering different types and subtypes in such a way that questions having similar answers belong to the same taxonomy class. We propose and train a deep learning based question classifier network to classify the taxonomy classes. The taxonomy information is helpful in taking a decision on semantic similarity between them. For example, the questions '*How do scientists work?*' and '*Where do scientists work?*', have very high lexical similarity but they have different answer types. This can be easily identified using a question taxonomy. Taxonomy can provide very useful information when we do not have enough data for generating useful deep learning based representations, which are generally the case with restricted domains. In such scenarios linguistic information obtained from the prior knowledge helps significantly in improving the performance of the system.

Proceedings of the 27th International Conference on Computational Linguistics, pages 499–513
Santa Fe, New Mexico, USA, August 20-26, 2018.

We propose a neural network based algorithm to classify the questions into appropriate taxonomy class(es). The information, thus obtained from taxonomy, is used along with the DL techniques to perform semantic question matching. Empirical evidence establishes that our taxonomy, when used in conjunction with Deep Learning (DL) representations, improves the performance of the system on semantic question (SQ) matching task.

We summarize the contributions of our work as follows: **(i)** We create a two-layered taxonomy for English questions; **(ii)** We propose a deep learning based method to identify taxonomy classes of questions; **(iii)** We propose a dependency parser based technique to identify the *focus* of the question; **(iv)** We propose a framework to integrate semantically rich taxonomy classes with DL based encoder to improve the performance and achieve new state-of-the-art results in semantic question ranking on benchmark dataset and Quora dataset; and finally **(v)** We release two annotated datasets, one for semantically similar questions and the other for question classification.

2 Related Works

Rapid growth of community question and answer (cQA) forums have intensified the necessity for semantic question matching in QA setup. Answer retrieval of semantically similar questions has drawn the attention of researchers in very recent times (Màrquez et al., 2015; Nakov et al., 2016). It solves the problem of *question starvation* in cQA forums by providing a semantically similar question which has already been answered. In literature, there have been attempts to address the problem of finding the most similar match to a given question, for e.g. Burke et al. (1997) and Mlynarczyk and Lytinen (2005). Wang et al. (2009) have presented syntactic tree based matching for finding semantically similar questions. 'Similar question retrieval' has been modeled using various techniques such as topic modeling (Li and Manandhar, 2011), knowledge graph representation (Zhou et al., 2013) and machine translation (Jeon et al., 2005). Semantic kernel based similarity methods for QA have also been proposed in (Filice et al., 2016; Croce et al., 2017; Croce et al., 2011).

Answer selection in QA forums is similar to the question similarity task. In recent times, researchers have been investigating DL-based models for answer selection (Wang and Nyberg, 2015; Severyn and Moschitti, 2015; Feng et al., 2015). Most of the existing works either focus on better representations for questions or linguistic information associated with the questions. On the other hand, the model proposed in this paper is a hybrid model. We also present a thorough empirical study of how sophisticated DL models can be used along with a question taxonomy concepts for semantic question matching.

3 Question Matching Framework

When framed as a computational problem, semantic question (SQ) matching for QA becomes equivalent to ranking questions in the existing question-base according to their semantic similarity to the given input question. Existing state-of-the-art systems use either deep learning models (Lei et al., 2016) or traditional text similarity methods (Jeon et al., 2005; Wang et al., 2009) to obtain the similarity scores. In contrast, our framework of SQ matching efficiently combines deep learning based question encoding and a linguistically motivated taxonomy. Algorithm 1 describes the precise method we follow. $Similarity(.)$ is the standard cosine similarity function. $fsim$ is focus embedding similarity which is described later in Section 4.4.

3.1 Question Encoder Model

Our question encoder model is inspired from the state-of-the-art question encoder architecture proposed by Lei et al. (2016). We extend the question encoder model of Lei et al. (2016) by introducing attention mechanism similar to Bahdanau et al. (2014) and Chopra et al. (2016). We propose the attention based version of two question encoder models, namely Recurrent Convolutional Neural Network (RCNN) (Lei et al., 2016) and Gated Recurrent Unit (GRU) (Chung et al., 2014; Cho et al., 2014).

A question encoder with attention does not need to capture the whole semantics of the question in its final representation. Instead, it is sufficient to capture a part of hidden state vectors of another question it needs to attend while generating the final representation. Let $\mathbf{H} \in \mathbb{R}^{d \times n}$ be a matrix consisting of

    RESULTS.append(result)
  return RESULTS

hidden state vectors $[h_1, h_2 \dots h_n]$ that the question encoder (RCNN, GRU) produced when reading the n words of the question, where d is a hyper parameter denoting the size of embeddings and hidden layers. The attention mechanism will produce an attention weight vector $\alpha_t \in \mathbb{R}^n$ and a weighted hidden representation $r_t \in \mathbb{R}^d$.

$$\begin{aligned} C_t &= tanh(W^H H + W^v(v_t \otimes I_n)) \\ \alpha_t &= softmax(w^T C_t) \\ r_t &= H\alpha^T \end{aligned} \tag{1}$$

where W^H, $W^v \in \mathbb{R}^{d \times d}$, are trained projection matrices. w^T is the transpose of the trained vector $w \in \mathbb{R}^d$. $v_t \in \mathbb{R}^d$ shows the embedding of token x_t and $I_n \in \mathbb{R}^n$ is the vector of 1. The product $W^v(v_t \otimes I_n)$ is repeating the linearly transformed v_t as many times (n) as there are words in the candidate question. Similarly we can obtain the attentive hidden state vectors $[r_1, r_2 \dots r_n]$. We apply the averaging pooling strategy to determine the final representation of the question.

Annotated data, $\mathscr{D} = \{(q_i, p_i^+, p_i^-)\}$ is used to optimize $f(p, q, \phi)$, where $f(.)$ is a measure of similarity between the questions p and q, and ϕ is a parameter to be optimized. Here p_i^+ and p_i^- correspond to the similar and non-similar question sets, respectively for question q_i. Maximum margin approach is used to optimize the parameter ϕ. For a particular training example, where q_i is similar to p_i^+, we minimize the max-margin loss $\mathcal{L}(\phi)$ defined as:

$$\mathcal{L}(\phi) = \max_{p \in Q'(q_i)} \left\{ f(q_i, p; \phi) - f(q_i, p_i^+; \phi) + \lambda(p, p_i^+) \right\} \tag{2}$$

where $Q'(q_i) = p_i^+ \cup p_i^-$, $\lambda(p, p_i^+)$ is a positive constant set to 1 when $p \neq p_i^+$, 0 otherwise.

3.2 Question Taxonomy

Questions are ubiquitous in natural language. Questions essentially differ on two fronts: semantic and syntactic. Questions that differ syntactically might still be semantically equivalent. Let us consider the following two questions:

- What is the number of new hires in 2018?
- How many employees were recruited in 2018?

Although the above questions are not syntactically similar but both are semantically equivalent and have the same answer. A well-formed taxonomy and question classification scheme can provide this information which eventually helps in determining the semantic similarity between the questions.

According to Gruber (1995), ontologies are commonly defined as specifications of shared conceptualizations. Informally, conceptualization is the relevant informal knowledge one can extract from their experience, observation or introspection. Specification corresponds to the encoding of this knowledge in representation language. In order to create a taxonomy for questions, we observe and analyze questions

Coarse Classes	Fine Classes
Quantification	Temprature, Time/Duration, Mass, Number, Age Distance, Money, Speed, Size, Percent, Rank/Rating
Entity	Person, Location, Organization, Animal, Technique Flora, Entertainment, Food, Abbreviation, Language Disease, Award/Title, Event, Sport/Game, Policy, Date Publication, Body, Thing, Feature/Attribute, Website Industry Sector, Monuments, Activity/Process, Other Tangible, Other Intangible
Definition	Person, Entity
Description	Reason, Mechanism, Cause & Effect, Describe Compare & Contrast, Analysis
List	Set of fine classes listed in the coarse classes *Quantification* and *Entity*
Selection	Alternative/Choice, True/False

Table 1: Set of proposed coarse and respective fine classes

from Stanford Question Answering Dataset (SQuAD) released by Rajpurkar et al. (2016) and question classifier data from Hovy et al. (2001) and Li and Roth (2002). The SQuAD dataset consists of 100,000+ questions and their answers, along with the text extracts from which the questions were formed. The other question classifier dataset contains $5,500$ questions. In the succeeding sub-section, we describe in details the coarse classes, fine classes and focus of a question. We have included an additional hierarchical taxonomy table with one example question for each class in the appendix section.

3.2.1 Coarse Classes

To choose the correct answer of a question one needs to understand the question and categorize the answer into the appropriate category which could vary from a basic implicit answer (question itself contains the answer) to a more elaborate answer (description). The coarse class of question provides a broader view of the expected answer type. We define the following six coarse class categories: *Quantification, Entity, Definition, Description, List* and *Selection*. *Quantification* class deals with the questions which look for a specific quantity as answer. Similarly *Entity, Definition, Description* class give the evidence that answer type will be entity, definition and a detail description, respectively. *Selection* class defines the question that looks for an answer which needs to be selected from the given set of answers. Few examples of questions along with their coarse class are listed here:

- **Quantity:** *Give the average speed of 1987 solar powered car winner?*
- **Entity:** *Which animal serves as a symbol throughout the book?*

3.2.2 Fine Classes

The coarse class defines the answer type at the broad level such as entity, quantity, description etc. But extracting the actual answer of question needs further classification into more specific answer types. Let us consider the following examples of two questions:

1. **Entity (Flora):** *What is one aquatic plant that remains submerged?*
2. **Entity (Animal):** *Which animal serves as a symbol throughout the book?*

Although both the questions belong to the same coarse class *entity* but they belong to the different fine classes, (*Flora* and *Animal*). Fine class of a question is based on the nature of the expected answer. It is useful in restricting the potential candidate matches. Although, questions belonging to the same fine class need not to be semantically same, questions belonging to the different fine classes rarely match. We show the set of the proposed coarse class and their respective fine classes in Table 1.

3.2.3 Focus of a Question

According to Moldovan et al. (2000), *focus* of a question is a word or a sequence of words, which defines the question and disambiguates it to find the correct answer the question is expecting to retrieve. In

the following example, *Describe the customer service model for Talent and HR BPO*, the term 'model' serves as the *focus*. As per Bunescu and Huang (2010b), *focus* of a question is contained within the noun phrases of a question. In the case of imperatives, the direct object (*dobj*) of the *question word* contains the *focus*. Similarly, in case of interrogatives, there are certain dependencies that capture the relation between the question word and its focus. The *dobj* relation of the root verb or *det* relation of *question word* for interrogatives contain the *focus*. Question word *how* has *advmod* relations that contain *focus* of the question. Priority order of the relations used to extract *focus* is obtained by observation on the SQuAD data. We depict the pseudo-code of the *focus* extraction method in the appendix section.

3.3 Question Classification

Question classification guides a QA system to extract appropriate candidate answer from the document/corpus. For example, the question *'How much does international cricket player get paid?'* should be accurately classified as the coarse class *quantification* and fine class *money* to further extract the appropriate answer. In our problem, we attempt to exploit the taxonomy information to identify the semantically similar questions. Therefore, the question classifier should be capable enough to accurately classify the coarse and fine classes of a reformulated question:

1. *What is the salary of an international level cricketer?*
2. *What is the estimated wage of an international cricketer?*

3.3.1 Question Classification Network

In order to identify the coarse and fine classes of a given question, we employ a deep learning based question classifier. In our question classification network CNN and bidirectional GRU has been applied sequentially. The obtained question vector is passed through a feed forward NN layer, and then through a softmax layer to obtain the final class of the question. We use two separate classifiers for coarse and fine class classification.

Firstly, an embedding layer maps a question $Q = [w_1, w_2 \dots w_n]$, which is a sequence of words w_i, into a sequence of dense, real-valued vectors, $E = [v_1, v_2 \dots v_n]$, $v_i \in \mathbb{R}^d$. Thereafter, a convolution operation is performed over the zero-padded sequence E^p. $F \in \mathbb{R}^{k \times m \times d}$, a set of k filters is applied to the sequence. We obtain convoluted features c_t at given time t for $t = 1, 2, \dots, n$.

$$c_t = tanh(F[v_{t-\frac{m-1}{2}} \dots v_t \dots v_{t+\frac{m-1}{2}}]) \tag{3}$$

Then, we generate the feature vectors $C' = [c'_1, c'_2 \dots c'_n]$, by applying max pooling on C. This sequence of convolution feature vector C' is passed through a bidirectional GRU network. We obtain the forward hidden states $\overrightarrow{h_t}$ and backward hidden states $\overleftarrow{h_t}$ at every step time t. The final output of recurrent layer h is obtained as the concatenation of the last hidden states of forward and backward hidden states.

Finally, the fixed-dimension vector h is fed into the softmax classification layer to compute the predictive probability $p(y = l|Q) = \frac{exp(w_l^T h + b_l)}{\sum_{i=1}^{L} exp(w_i^T h + b_i)}$ for all the question classes (coarse or fine). We assume there are L classes where w_x and b_x denote the weight and bias vectors, respectively and $x \in \{l, i\}$.

3.4 Comparison with Existing Taxonomy

In the Text REtrieval Conference (TREC) task, Li and Roth (2002) proposed a taxonomy to represent a natural semantic classification for a specific set of answers. This was built by analyzing the TREC questions. In contrast to Li and Roth (2002), along with TREC questions we also make a thorough analysis of the most recent question answering dataset (SQuAD) which has a collection of more diversified questions. Unlike Li and Roth (2002), we introduce the list and selection type question classes in our taxonomy. Each of these question types has its own strategy to retrieve an answer, and therefore, we put these separately in our proposed taxonomy. The usefulness of list as a different coarse class in semantic question matching can be understood considering the following questions:

1. *What are some techniques used to improve crop production?*
2. *What is the best technique used to improve crop production ?*

These two questions are not semantically similar as **(1)** and **(2)** belong to *list* and *entity* coarse classes, respectively. Moreover, Li and Roth (2002)'s taxonomy has overlapping classes (*Entity, Human and Location*). In our taxonomy we put all these classes in a single coarse class named *Entity*, which helps in identifying semantically similar questions better. We propose a set of coarse and respective fine classes with more coverage compared to Li and Roth (2002). Li and Roth (2002) taxonomy does not cover many important fine classes such as, *entertainment, award/title, activity, body* etc., under *entity* coarse class. We include these fine classes in our proposed taxonomy. We further redefine *description* type questions by introducing *cause & effect, compare and contrast* and *analysis* fine classes in addition to *reason, mechanism* and *description* classes. This finer categorization helps in choosing a more appropriate answer strategy for descriptive questions.

4 Experiments

4.1 Datasets

We perform experiments on three benchmark datasets, namely Partial Ordered Question Ranking (POQR)-Simple, POQR-Complex (Bunescu and Huang, 2010a) and Quora datasets. In addition to this, we also perform experiments on a new semantic question matching dataset (Semantic SQuAD[1]) created by us. In order to evaluate the system performance, we perform experiments in two different settings. The first setting deals with semantic question ranking (SQR) and the second deals with semantic question classification (SQC) with two classes (match and no-match). We perform SQR experiments on Semantic SQuAD and POQR datasets. For SQC experiments, we use Semantic SQuAD and Quora datasets.

4.1.1 Semantic SQuAD

We built a semantically similar question-pair dataset based on a portion of SQuAD data. SQuAD, a crowd-sourced dataset, consists of 100,000+ answered questions along with the text from which those question-answer pairs were constructed. We randomly selected $6,000$ question-answer pairs from SQuAD dataset and for a given question we asked 12 annotators[2] to formulate semantically similar questions referring to the same answers. Each annotator was asked to formulate 500 questions. We divided this dataset into training, validation and test sets of $2,000$ pairs each. We further constructed $4,000$ *semantically dissimilar* questions automatically. We use these $8,000$ question pairs ($4,000$ semantic similar questions pair from test and validation + $4,000$ semantically dissimilar pairs) to train the semantic question classifier for the SQC setting of the experiments. *Semantically dissimilar* questions are created by maintaining the constraint that questions should be from the different taxonomy classes. We perform 3-fold cross-validation on these $8,000$ question pairs.

4.1.2 POQR Dataset

POQR dataset consists of 60 groups of questions, each having a reference question that is associated with a partially ordered set of questions. Each group has three different sets of questions named as *paraphrase* ($\mathcal{P}$), *useful* ($\mathcal{U}$) and *neutral* ($\mathcal{N}$). For each given reference question q_r we have $q_p \in \mathcal{P}$, $q_u \in \mathcal{U}$, and $q_n \in \mathcal{N}$. As per Bunescu and Huang (2010a) the following two relations hold:

1. $(q_p \succ q_u | q_r)$: A *paraphrase* question is *'more useful than'* useful question.
2. $(q_u \succ q_n | q_r)$: A *useful* question is *'more useful than'* neutral question.

By transitivity, it was assumed by Bunescu and Huang (2010a) that the following ternary relation holds $(q_p \succ q_n | q_r)$: "A *paraphrase* question is *'more useful than'* a neutral question". We show the statistics of these datasets for *Simple* and *Complex* question types for two annotators (1, 2) in Table 2.

4.1.3 Quora Dataset

We perform experiments on semantic question matching dataset consisting of 404,290 pairs released by Quora[3]. The dataset consists of 149,263 matching pairs and 255,027 non-matching pairs.

[1]All the datasets used in the paper are publicly available at `https://figshare.com/articles/Semantic_Question_Classification_Datasets/6470726`

[2]The annotators are the post-graduate students having proficiency in English language.

Datasets	Simple		Complex	
	Simple-1	Simple-2	Complex-1	Complex-2
$\mathcal{P}$	164	134	103	89
$\mathcal{U}$	775	778	766	730
$\mathcal{N}$	594	621	664	714
Pairs	11015	10436	10654	9979

Table 2: Brief statistics of POQR datasets

4.2 Evaluation Scheme

We employ different evaluation schemes for our SQR and SQC evaluation settings. For the **Semantic SQuAD** dataset, we use the following metrics for ranking evaluation: Recall in top-k results (Recall@k) for $k = 1$, 3 and 5, Mean Reciprocal Rank (MRR) and Mean Average Precision (MAP). The set of all candidate questions in $2,000$ pairs of the test set is ranked against each input question. As we have only 1 correct match out of $2,000$ questions for each question in the test set, recall@1 is equivalent to precision@1. Given that we only have one relevant result for each input question, MAP is equivalent to MRR. We evaluate the semantic question classification performance in terms of accuracy. To ensure fair evaluation, we keep the ratio of semantically similar and dissimilar questions to be 1:1. In order to compare the performance on **POQR dataset** with the state-of-the art results, we followed the same evaluation scheme as described in Bunescu and Huang (2010a). It is measured in terms of 10-fold cross validation accuracy on the set of ordered pairs, and the performance is averaged between the two annotators (1,2) for the Simple and Complex datasets. For **Quora dataset**, we perform 3-fold cross validation on the entire dataset evaluating based on the classification accuracy only. We did not perform the semantic question ranking (SQR) experiment on Quora dataset as 149,263 $\times$ 149,263 ranking experiment for matching pairs takes a very long time.

4.3 Baselines

We compare our proposed approach to the following information retrieval (IR) based baselines:
1) TF-IDF: The candidate questions are ranked using cosine similarity value obtained from the TF-IDF based vector representation.
2) Jaccard Similarity: The questions are ranked using Jaccard similarity calculated for each candidate question with the input question.
3) BM-25: The candidate questions are ranked using BM-25 score, provided by Apache Lucene [4]

4.4 Experimental Setup

Question Encoder: We train two different question encoders (hidden size=300) on *Semantic SQuAD* and *Quora* datasets. For Semantic SQuAD dataset, we used $2,000$ training pairs to train the question encoder, as mentioned in Section 4.1.1. For Quora dataset we randomly selected $74,232$ semantically similar question pairs to train the encoder, and $10,000$ question pairs for validation. The best hyper-parameters for the deep learning based attention encoder are identified on validation data. Adam (Kingma and Ba, 2014) is used as the optimization method. Other hyper-parameters used are: learning rate (0.01), dropout probability (Hinton et al., 2012): (0.5), CNN feature width (2), batch size (50), epochs (30) and size of the hidden state vectors (300). This optimal hyper-parameter values are same for the attention based RCNN and GRU encoder. We train two different question encoders trained on *Semantic SQuAD* and *Quora* datasets. We could not train the question encoder on the **POQR dataset** because of the unavailability of sufficient amount of similar question pairs in this dataset. Instead we use the question encoder trained on the Quora dataset to encode the questions from POQR dataset.

Question Classification Network: To train the model we manually label (using 3 English proficient

[4] https://lucene.apache.org/core/

annotators with an inter-annotator agreement of 87.98%) a total of $5,162$ questions[5] with their coarse and fine classes, as proposed in Section 3.2. We release this question classification dataset to the research community. We evaluate the performance of question classification for 5-fold cross-validation in terms of F-Score. Our evaluation shows that we achieve 94.72% and 86.19% F-score on coarse class (6-labels) and fine class (72-labels), respectively. We use this trained model to obtain the coarse and fine classes of questions in all datasets.

We perform the SQC experiments with SVM classifier. We use *libsvm* implementation (Chang and Lin, 2011) with linear kernel and polynomial kernel of degree $\in \{2, 3, 4\}$. Best performance was obtained using linear kernel. Due to the nature of POQR dataset as described in Section $4.1.2$ in the paper we employ SVM^{light} [6] implementation of ranking SVMs, with a linear kernel keeping standard parameters intact. In our experiments, we use pre-trained Google embeddings provided by (Mikolov et al., 2013). The focus embedding is obtained through word vector composition (averaging).

5 Results and Analysis

5.1 Results

We present extensive results of semantic question ranking experiment on the Semantic SQuAD dataset in Table 4. In Tables 3, 4 and 5 the performnce results are reported on the respective dataset using the models **GRU**, **RCNN, GRU-Attention and RCNN-Attention** (c.f. Section 3.1). For all these models the results reported in the tables are based on the cosine similarity of the respective question encoder. The introduction of attention mechansim helps the question encoder in improving the performance. The attention based model obatins the maximum gains of 2.40% and 2.60% in terms of recall and MRR for the *GRU* model. The taxonomy augmented model outperforms the respective baselines and state-of-the-art deep learning question encoder models. We obtain the best improvements for the *Tax+RCNN-Attention* model, 3.75% and 4.15% in terms of Recall and MRR, respectively. Experiments show that taxonomy features assist in consistently improving the R@k and MRR/MAP across all the models.

Table 3: Semantic question ranking performance of various models on **POQR datasets**. All the numbers shows is in terms of accuracy.

Performance of the proposed model on POQR dataset are shown in Table 3. The '*overall*' column in Table 3 shows the performance average on simple-1,2 and complex-1,2 datasets. We obtain improvements (maximum of 1.55% with *GRU-Attention* model on Complex-1 dataset) in each model by introducing attention mechanism on both simple and complex datasets. The augmentation of taxonomy

[5] $4,000$ questions are the training set of Semantic SQuAD. Remaining $1,162$ questions from the dataset used in Li and Roth (2002)

[6] http://svmlight.joachims.org/

features helps in improving the performance further (8.75% with *Tax+RCNN-Attention* model on Simple dataset).

The system performance on semantic question classification (SQC) experiment with Semantic SQuAD and Quora datasets are shown in Table 5. Similar to ranking results, we obtain significant improvement by introducing attention mechanism and augmenting the taxonomy features on both the datasets.

Models	R@1	R@3	R@5	MRR/MAP

Tax + RCNN-Attention	82.25	83.17

Table 5: **Semantic Question Classification (SQC)** performance of various models on **Semantic SQuAD** and **Quora** datasets.

Sr. No.	Datasets	All	-CC	-FC	-Focus Word
1	Semantic SQuAD (SQR)	83.12	81.66	81.84	82.20
2	Semantic SQuAD (SQC)	82.25	80.85	81.19	81.13
3	POQR-Simple	83.82	80.85	81.44	82.57
4	POQR-Complex	83.71	81.04	81.97	82.19
5	Quora	83.17	80.93	81.75	82.24

Table 6: Feature ablation results on all datasets. **SQR** results are in **MAP**. The others results are shown in terms of **Accuracy**.

5.2 Qualitative Analysis

We analyze the obtained results by studying the following effects:

(1) Effect of Attention Mechanism: We analyzed hidden state representation the model is attending to when it is deciding the semantic similarity. We depicted the visualization (**in appendix**) of attention weight between two semantically similar question from Semantic SQuAD dataset. We observed that the improvement due to the attention mechanism in Quora dataset is comparatively less than the Semantic SQuAD dataset. The question pairs from Quora dataset have matching words, and the problem is more focused on difference rather than similar or related word. For example, for the questions "*How magnets are made?*" and "*What are magnets made of?*", the key difference is question words 'how' versus 'what', while the remaining words are similar.

(2) Effect of Taxonomy Features: We performed feature ablation study on all the datasets to analyze the impact of each taxonomy features. Table 4 shows the results[7] with the full features and after removing coarse class (-CC), fine class (-FC) and focus features one by one. We observed from Quora dataset that the starting word of the questions *(what, why, how etc.)* is a deciding factor for semantic similarity. As the taxonomy features categorize these questions into different coarse and fine classes, therefore, it helps the system in distinguishing between semantically similar and dissimilar questions. It can be observed from the results that the augmentation of CC and FC features significantly improves the performance

[7]The results are statistically significant as $p < 0.002$.

especially on Quora dataset. Similar trends were also observed on the other datasets.

5.3 Comparison to State-of-the-Art

We compare the system performance on POQR dataset with state-of-the-art work of Bunescu and Huang (2010a). Bunescu and Huang (2010a) used several cosine similarities as features obtained using bag-of-words, dependency tree, focus, main verb etc. Compared to Bunescu and Huang (2010a), our model achieves better performance with an improvement of 2.1% and 1.46% on simple and complex dataset respectively. A direct comparison to SemEval-2017 Task-3[8] CQA or AskUbuntu (Lei et al., 2016) datasets could not be made due to the difference in the nature of questions. The proposed classification method is designed for well-formed English questions and could not be applied to multi-sentence / ill-formed questions. We evaluate (Lei et al., 2016)'s model (RCNN) on each of our datasets and report the results in Section 5.1. Quora has not released any official test set yet. Hence, we report the performance of 3-fold cross validation on the entire dataset to minimize the variance. We can not directly make any comparisons with others due to the non-availability of an official gold test set.

5.4 Error Analysis

We observed the following as major sources of errors in the proposed system: **(1)** Misclassification at the fine class level is often propagated to semantic question classifier when some of questions contain more than one sentence. For e.g. "*What's the history behind human names? Do non-human species use names?*". **(2)** Semantically dissimilar questions having same function words but different coarse and fine class were incorrectly predicted as similar questions. It is because of the high similarity in the question vector and focus, which forces the classifier to commit mistakes. **(3)** In semantic question ranking (SQR) task, some of the questions with higher lexical similarity to the reference question are selected in prior to the actual similar question due to the high cosine similarity score with the reference question.

6 Conclusion

In this work, we have proposed an efficient model for semantic question matching where DL models are combined with pivotal features obtained from taxonomy. We have created a two layered taxonomy (coarse and fine) for questions in interest and proposed a deep learning based question classifier to classify the questions. We have established the usefulness of our taxonomy on two different task (SQR and SQC) on four different datasets. We have empirically established that effective usage of semantic classification and focus of questions helps in improving the performance of various on semantic question matching. Future work includes the efficient question encoders and handling community forum questions, which are often ill-formed, using taxonomy based features.

Appendices

A Proposed Taxonomy Table

	Coarse Classes	Fine Classes	Example
Non-Decision	**Quantification**	Temperature	What are the approximate temperatures that can be delivered by phase change materials?
		Time/Duration	How long did Baena worked for the Schwarzenegger/Shriver family?
		Mass	What is the weight in pounds of each of Schwarzenegger 's Hummers?
		Number	How many students are in New York City public schools?
		Distance	How many miles away from London is Plymouth?
		Money	What is the cost to build Cornell Tech?
		Speed	Give the average speed of 1987 solar powered car winner?
		Size	How large is Notre Dame in acres?
		Percent	What is the college graduation percentage among Manhattan residents?
		Age	How old was Schwarzenegger when he won Mr. Universe?
		Rank/Rating	What rank did iPod achieve among various computer products in 2006?
	Entity	Person	Who served as Plymouth 's mayor in 1993?
		Location	In what city does Plymouth 's ferry to Spain terminate?
		Organization	Who did Apple partner with to monitor its labor policies?
		Animal	Which animal serves as a symbol throughout the book?
		Flora	What is one aquatic plant that remains submerged?
		Entertainment	What album caused a lawsuit to be filed in 2001?
		Food	What type of food is NYC 's leading food export?
		Abbreviation	What does AI stand for?
		Technique	What is an example of a passive solar technique?
		Language	What language is used in Macedonia?
		Monuments	Which art museum does Notre Dame administer?
		Activity/Process	What was the name of another activity like the Crusades occurring on the Iberian peninsula?
		Disease	What kind of pain did Phillips endure?
		Award/Title	Which prize did Frederick Buechner create?
		Date	When was the telephone invented?
		Event	What event in the novel was heavily criticized for being a plot device?
		Sport/Game	Twilight Princess uses the control setup first employed in which previous game?
		Policy	What movement in the '60s did the novel help spark?
		Publication	Which book was credited with sparking the US Civil War?
		Body	What was the Executive Council an alternate name for?
		Thing	What is the name of the aircraft circling the globe in 2015 via solar power?
		Feature/Attribute	What part of the iPod is needed to communicate with peripherals?
		Industry Sector	In which industry did the iPod have a major impact?
		Website	Which website criticized Apple 's battery life claims?
		Other Tangible	In what body of water do the rivers Tamar and Plym converge?
		Other Intangible	The French words Notre Dame du Lac translate to what in English?
	Definition	Person	Who was Abraham Lincoln?
		Entity	What is a solar cell?
	Description	Reason	Why are salts good for thermal storage?
		Mechanism	How do the BBC 's non-domestic channels generate revenue?
		Cause & Effect	What caused Notre Dame to become notable in the early 20th century?
		Compare & Contrast	What was not developing as fast as other Soviet Republics?
		Describe	What do greenhouses do with solar energy?
		Analysis	How did the critics view the movie , " The Fighting Temptations "?
	List	Set of fine classes listed in the coarse classes *Quantification* and *Entity*	What are some examples of phase change materials? Which two national basketball teams play in NYC?
Decision	**Selection**	Alternative/Choice	Are the Ewell 's considered rich or poor?
		True/False	Is the Apple SDK available to third-party game publishers?

Table 7: The exemplar description of proposed taxonomy classes

B Algorithms

Algorithm 2 Question word extraction

```
procedure QUESTION WORD(QuesTokens)
    WhTags ← [WDT, WP, WP$, WRB]
    VbTags ← [VB, VBD, VBP, VBZ]
    for t ∈ QuesTokens do
        if t.POS ∈ WhTags then return t
    for t ∈ QuesTokens do
        if t.POS ∈ VbTags then return t
```

Algorithm 3 Focus Word Extraction

```
procedure FOCUS(QuesTokens)
    qw ← QUESTION WORD (QuesTokens)
    depP ← DependencyParse(QuesTokens)
    if qw is 'how' then
        return tail of 'advmod' of qw
    if qw.POS is V* then
        obj ← OBJECT(QuesTokens, qw)
        return obj
    if qw.POS is WH* then
        if 'root' is qw then
            nsubj ← tail of 'nsubj' of qw
            return nsubj
        else
            obj ← OBJECT (QuesTokens, 'root')
            return obj
    return <unk>
```

Algorithm 4 Object Extraction

```
procedure OBJECT(QuesTokens, qw)
    depP ← DependencyParse(QuesTokens)
    obj ← tail of 'det' of qw
    if obj not NULL then return obj
    obj ← tail of 'dobj' of qw
    if obj not NULL then return obj
    qw ← tail of 'conj:*' of qw
    obj ← tail of 'dobj' of qw
    if obj is NULL then
        comp ← tail of 'ccomp'/'xcomp' of qw
        obj ← tail of 'dobj' of comp
    return obj
```

C Additional Results

C.1 K-means Clustering

The k-means clustering was performed on the question representation obtained from the best question (RCNN-Attention) encoder of $2,000$ semantic question pairs. The clustering experiment was evaluated on the test set of Semantic SQuAD dataset (4000 questions). The performance was evaluated using the following metric:

$$\texttt{Recall} = \frac{100 \times \textit{no. of SQ pairs in same cluster}}{\textit{total no. of SQ pairs}} \tag{4}$$

K-means Clustering results are as follows: R@1:50.12, R@3:62.44 and R@5:66.58. As the number of clusters decreases `Recall` is expected to increase as there is higher likelihood of matching questions falling in the same cluster. `Recall` with $2,000$ clusters for $2,000$ SQ pairs i.e. 4,000 questions is comparable to Recall@1 as we have 2 questions per cluster on average, `Recall` with $1,000$ clusters is a proxy for Recall@3 and `Recall` with 667 clusters is comparable to Recall@5.

C.2 Semantic question classification (SQC) using IR-based Similarity

We have used TF-IDF, BM-25 and Jaccard similarity to classify a pair of question to similar or non-similar. We calculate the score between the question using the said algorithms thereafter a optimal thresholds are used to label a question pair as 'matching' or 'non-matching'. If the similarity score is greater than or equal to the threshold value we set the label 'matching' otherwise 'non-matching'. The optimal threshold value are calculated using the validation data. The optimal threshold value are given in the table 8.

Algorithm / Dataset	TF-IDF	BM-25	Jaccard Similarity
Semantic SQuAD Dataset	0.72	12.98	0.29
Quora Dataset	0.79	13.18	0.56

Table 8: IR based Optimal threshold value for each dataset

C.3 Attention Visualizations
