bethard@email.arizona.edu

Abstract

Named Entity Recognition (NER) is a key component in NLP systems for question answering, information retrieval, relation extraction, etc. NER systems have been studied and developed widely for decades, but accurate systems using deep neural networks (NN) have only been introduced in the last few years. We present a comprehensive survey of deep neural network architectures for NER, and contrast them with previous approaches to NER based on feature engineering and other supervised or semi-supervised learning algorithms. Our results highlight the improvements achieved by neural networks, and show how incorporating some of the lessons learned from past work on feature-based NER systems can yield further improvements.

1 Introduction

Named entity recognition is the task of identifying named entities like person, location, organization, drug, time, clinical procedure, biological protein, etc. in text. NER systems are often used as the first step in question answering, information retrieval, co-reference resolution, topic modeling, etc. Thus it is important to highlight recent advances in named entity recognition, especially recent neural NER architectures which have achieved state of the art performance with minimal feature engineering.

The first NER task was organized by Grishman and Sundheim (1996) in the Sixth Message Understanding Conference. Since then, there have been numerous NER tasks (Tjong Kim Sang and De Meulder, 2003; Tjong Kim Sang, 2002; Piskorski et al., 2017; Segura Bedmar et al., 2013; Bossy et al., 2013; Uzuner et al., 2011). Early NER systems were based on handcrafted rules, lexicons, orthographic features and ontologies. These systems were followed by NER systems based on feature-engineering and machine learning (Nadeau and Sekine, 2007). Starting with Collobert et al. (2011), neural network NER systems with minimal feature engineering have become popular. Such models are appealing because they typically do not require domain specific resources like lexicons or ontologies, and are thus poised to be more domain independent. Various neural architectures have been proposed, mostly based on some form of recurrent neural networks (RNN) over characters, sub-words and/or word embeddings.

We present a comprehensive survey of recent advances in named entity recognition. We describe knowledge-based and feature-engineered NER systems that combine in-domain knowledge, gazetteers, orthographic and other features with supervised or semi-supervised learning. We contrast these systems with neural network architectures for NER based on minimal feature engineering, and compare amongst the neural models with different representations of words and sub-word units. We show in Table 1 and Table 2 and discuss in Section 7 how neural NER systems have improved performance over past works including supervised, semi-supervised, and knowledge based NER systems. For example, NN models on news corpora improved the previous state-of-the-art by 1.59% in Spanish, 2.34% in German, 0.36% in English, and 0.14%, in Dutch, without any external resources or feature engineering. We provide resources, including links to shared tasks on NER, and links to the code for each category of NER system. To the best of our knowledge, this is the first survey focusing on neural architectures for NER, and comparing to previous feature-based systems.

Proceedings of the 27th International Conference on Computational Linguistics, pages 2145–2158
Santa Fe, New Mexico, USA, August 20-26, 2018.

We first discuss previous summary research on NER in section 2. Then we explain our selection criterion and methodology for selecting which systems to review in section 3. We highlight standard, past and recent NER datasets (from shared tasks and other research) in section 4 and evaluation metrics in section 5. We then describe NER systems in section 6 categorized into knowledge-based (section 6.1), bootstrapped (section 6.2), feature-engineered (section 6.3) and neural networks (section 6.4).

2 Previous surveys

The first comprehensive NER survey was Nadeau and Sekine (2007), which covered a variety of supervised, semi-supervised and unsupervised NER systems, highlighted common features used by NER systems during that time, and explained NER evaluation metrics that are still in use today. Sharnagat (2014) presented a more recent NER survey that also included supervised, semi-supervised, and unsupervised NER systems, and included a few introductory neural network NER systems. There have also been surveys focused on NER systems for specific domains and languages, including biomedical NER, (Leaman and Gonzalez, 2008), Chinese clinical NER (Lei et al., 2013), Arabic NER (Shaalan, 2014; Etaiwi et al., 2017), and NER for Indian languages (Patil et al., 2016).

The existing surveys primarily cover feature-engineered machine learning models (including supervised, semi-supervised, and unsupervised systems), and mostly focus on a single language or a single domain. There is not yet, to our knowledge, a comprehensive survey of modern neural network NER systems, nor is there a survey that compares feature engineered and neural network systems in both multi-lingual (CoNLL 2002 and CoNLL 2003) and multi-domain (e.g., news and medical) settings.

3 Methodology

To identify articles for this survey, we searched Google, Google Scholar, and Semantic Scholar. Our query terms included *named entity recognition*, *neural architectures for named entity recognition*, *neural network based named entity recognition models*, *deep learning models for named entity recognition*, etc. We sorted the papers returned from each query by citation count and read at least the top three, considering a paper for our survey if it either introduced a neural architecture for named entity recognition, or represented a top-performing model on an NER dataset. We included an article presenting a neural architecture only if it was the first article to introduce the architecture; otherwise, we traced citations back until we found the original source of the architecture. We followed the same approach for feature-engineering NER systems. We also included articles that implemented these systems for different languages or domain. In total, 154 articles were reviewed and 83 articles were selected for the survey.

4 NER datasets

Since the first shared task on NER (Grishman and Sundheim, 1996)[1], many shared tasks and datasets for NER have been created. CoNLL 2002 (Tjong Kim Sang, 2002)[2] and CoNLL 2003 (Tjong Kim Sang and De Meulder, 2003)[3] were created from newswire articles in four different languages (Spanish, Dutch, English, and German) and focused on 4 entities - PER (person), LOC (location), ORG (organization) and MISC (miscellaneous including all other types of entities).

NER shared tasks have also been organized for a variety of other languages, including Indian languages (Rajeev Sangal and Singh, 2008), Arabic (Shaalan, 2014), German (Benikova et al., 2014), and slavic languages (Piskorski et al., 2017). The named entity types vary widely by source of dataset and language. For example, Rajeev Sangal and Singh (2008)'s southeast Asian language data has named entity types person, designation, temporal expressions, abbreviations, object number, brand, etc. Benikova et al. (2014)'s data, which is based on German wikipedia and online news, has named entity types similar to that of CoNLL 2002 and 2003: PERson, ORGanization, LOCation and OTHer. The shared task[4] or-

[1]Shared task: https://www-nlpir.nist.gov/related_projects/muc/
[2]Shared task: https://www.clips.uantwerpen.be/conll2002/ner/
[3]Shared task: https://www.clips.uantwerpen.be/conll2003/ner/
[4]Shared task: http://bsnlp.cs.helsinki.fi/shared_task.html

ganized by Piskorski et al. (2017) covering 7 slavic languages (Croatian, Czech, Polish, Russian, Slovak, Slovene, Ukrainian) also has person, location, organization and miscellaneous as named entity types.

In the biomedical domain, Kim et al. (2004) organized a BioNER task on MedLine abstracts, focusing on protien, DNA, RNA and cell attribute entity types. Uzuner et al. (2007) presented a clinical note de-identification task that required NER to locate personal patient data phrases to be anonymized. The 2010 I2B2 NER task[5] (Uzuner et al., 2011), which considered clinical data, focused on clinical problem, test and treatment entity types. Segura Bedmar et al. (2013) organized a Drug NER shared task[6] as part of SemEval 2013 Task 9, which focused on drug, brand, group and drug_n (unapproved or new drugs) entity types. (Krallinger et al., 2015) introduced the similar CHEMDNER task [7] focusing more on chemical and drug entities like trivial, systematic, abbreviation, formula, family, identifier, etc. Biology and microbiology NER datasets[8] (Hirschman et al., 2005; Bossy et al., 2013; Delėger et al., 2016) have been collected from PubMed and biology websites, and focus mostly on bacteria, habitat and geolocation entities. In biomedical NER systems, segmentation of clinical and drug entities is considered to be a difficult task because of complex orthographic structures of named entities (Liu et al., 2015).

NER tasks have also been organized on social media data, e.g., Twitter, where the performance of classic NER systems degrades due to issues like variability in orthography and presence of grammatically incomplete sentences (Baldwin et al., 2015). Entity types on Twitter are also more variable (person, company, facility, band, sportsteam, movie, TV show, etc.) as they are based on user behavior on Twitter.

Though most named entity annotations are flat, some datasets include more complex structures. Ohta et al. (2002) constructed a dataset of nested named entities, where one named entity can contain another. Strassel et al. (2003) highlighted both entity and entity head phrases. And discontinuous entities are common in chemical and clinical NER datasets (Krallinger et al., 2015). Eltyeb and Salim (2014) presented an survey of various NER systems developed for such NER datasets with a focus on chemical NER.

5 NER evaluation metrics

Grishman and Sundheim (1996) scored NER performance based on *type*, whether the predicted label was correct regardless of entity boundaries, and *text*, whether the predicted entity boundaries were correct regardless of the label. For each score category, *precision* was defined as the number of entities a system predicted correctly divided by the number that the system predicted, recall was defined as the number of entities a system predicted correctly divided by the number that were identified by the human annotators, and (micro) F-score was defined as the harmonic mean of precision and recall from both type and text.

The *exact match* metrics introduced by CoNLL (Tjong Kim Sang and De Meulder, 2003; Tjong Kim Sang, 2002) considers a prediction to be correct only when the predicted label for the complete entity is matched to exactly the same words as the gold label of that entity. CoNLL also used (micro) F-score, taking the harmonic mean of the exact match precision and recall.

The *relaxed F1* and *strict F1* metrics have been used in many NER shared tasks (Segura Bedmar et al., 2013; Krallinger et al., 2015; Bossy et al., 2013; Delėger et al., 2016). Relaxed F1 considers a prediction to be correct as long as part of the named entity is identified correctly. Strict F1 requires the character offsets of a prediction and the human annotation to match exactly. In these data, unlike CoNLL, word offsets are not given, so relaxed F1 is intended to allow comparison despite different systems having different word boundaries due to different segmentation techniques (Liu et al., 2015).

6 NER systems

6.1 Knowledge-based systems

Knowledge-based NER systems do not require annotated training data as they rely on lexicon resources and domain specific knowledge. These work well when the lexicon is exhaustive, but fail, for example, on every example of the drug_n class in the DrugNER dataset (Segura Bedmar et al., 2013), since drug_n

[5]Shared task: `https://www.i2b2.org/NLP/Relations/`
[6]Shared task: `https://www.cs.york.ac.uk/semeval-2013/task9/index.html`
[7]Similar datasets can be found here: `http://www.biocreative.org`
[8]Shared task: `http://2016.bionlp-st.org/tasks/bb2`

is defined as unapproved or new drugs, which are by definition not in the DrugBank dictionaries (Knox et al., 2010). Precision is generally high for knowledge-based NER systems because of the lexicons, but recall is often low due to domain and language-specific rules and incomplete dictionaries. Another drawback of knowledge based NER systems is the need of domain experts for constructing and maintaining the knowledge resources.

6.2 Unsupervised and bootstrapped systems

Some of the earliest systems required very minimal training data. Collins and Singer (1999) used only labeled seeds, and 7 features including orthography (e.g., capitalization), context of the entity, words contained within named entities, etc. for classifying and extracting named entities. Etzioni et al. (2005) proposed an unsupervised system to improve the recall of NER systems applying 8 generic pattern extractors to open web text, e.g., *NP is a <class1>*, *NP1 such as NPList2*. Nadeau et al. (2006) presented an unsupervised system for gazetteer building and named entity ambiguity resolution based on Etzioni et al. (2005) and Collins and Singer (1999) that combined an extracted gazetteer with commonly available gazetteers to achieve F-scores of 88%, 61%, and 59% on MUC-7 (Chinchor and Robinson, 1997) location, person, and organization entities, respectively.

Zhang and Elhadad (2013) used shallow syntactic knowledge and inverse document frequency (IDF) for an unsupervised NER system on biology (Kim et al., 2004) and medical (Uzuner et al., 2011) data, achieving 53.8% and 69.5% accuracy, respectively. Their model uses seeds to discover text having potential named entities, detects noun phrases and filters any with low IDF values, and feeds the filtered list to a classifier (Alfonseca and Manandhar, 2002) to predict named entity tags.

6.3 Feature-engineered supervised systems

Supervised machine learning models learn to make predictions by training on example inputs and their expected outputs, and can be used to replace human curated rules. Hidden Markov Models (HMM), Support Vector Machines (SVM), Conditional Random Fields (CRF), and decision trees were common machine learning systems for NER.

Zhou and Su (2002) used HMM (Rabiner and Juang, 1986; Bikel et al., 1997) an NER system on MUC-6 and MUC-7 data, achieving 96.6% and 94.1% F score, respectively. They included 11 orthographic features (1 numeral, 2 numeral, 4 numeral, all caps, numerals and alphabets, contains underscore or not, etc.) a list of trigger words for the named entities (e.g., 36 trigger words and affixes, like *river*, for the location entity class), and a list of words (10000 for the person entity class) from various gazetteers.

Malouf (2002) compared the HMM with Maximum Entropy (ME) by adding multiple features. Their best model included capitalization, whether a word was the first in a sentence, whether a word had appeared before with a known last name, and 13281 first names collected from various dictionaries. The model achieved 73.66%, 68.08% Fscore on Spanish and Dutch CoNLL 2002 dataset respectively.

The winner of CoNLL 2002 (Carreras et al., 2002) used binary AdaBoost classifiers, a boosting algorithm that combines small fixed-depth decision trees (Schapire, 2013). They used features like capitalization, trigger words, previous tag prediction, bag of words, gazetteers, etc. to represent simple binary relations and these relations were used in conjunction with previously predicted labels. They achieved 81.39% and 77.05% F scores on the Spanish and Dutch CoNLL 2002 datasets, respectively.

Li et al. (2005) implemented a SVM model on the CoNLL 2003 dataset and CMU seminar documents. They experimented with multiple window sizes, features (orthographic, prefixes suffixes, labels, etc.) from neighboring words, weighting neighboring word features according to their position, and class weights to balance positive and negative class. They used two SVM classifiers, one for detecting named entity starts and one for detecting ends. They achieved 88.3% F score on the English CoNLL 2003 data.

On the MUC6 data, Takeuchi and Collier (2002) used part-of-speech (POS) tags, orthographic features, a window of 3 words to the left and to the right of the central word, and tags of the last 3 words as features to the SVM. The final tag was decided by the voting of multiple one-vs-one SVM outputs.

Ando and Zhang (2005a) implemented structural learning (Ando and Zhang, 2005b) to divide the main task into many auxiliary tasks, for example, predicting labels by looking just at the context and masking

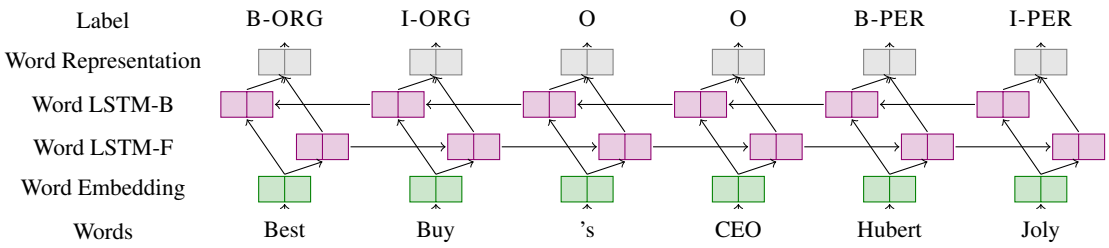

Figure 1: Word level NN architecture for NER

the current word. The best classifier for each auxiliary task was selected based on its confidence. This model had achieved 89.31% and 75.27% F score on English and German, respectively.

Agerri and Rigau (2016) developed a semi-supervised system[9] by presenting NER classifiers with features including orthography, character n-grams, lexicons, prefixes, suffixes, bigrams, trigrams, and unsupervised cluster features from the Brown corpus, Clark corpus and k-means clustering of open text using word embeddings (Mikolov et al., 2013). They achieved near state of the art performance on CoNLL datasets: 84.16%, 85.04%, 91.36%, 76.42% on Spanish, Dutch, English, and German, respectively.

In DrugNER (Segura Bedmar et al., 2013), Liu et al. (2015) achieved state-of-the-art results by using a CRF with features like lexicon resources from Food and Drug Administration (FDA), DrugBank, Jochem (Hettne et al., 2009) and word embeddings (trained on a MedLine corpus). For the same task, Rocktäschel et al. (2013) used a CRF with features constructed from dictionaries (e.g., Jochem (Hettne et al., 2009)), ontologies (ChEBI ontologies), prefixes-suffixes from chemical entities, etc.

6.4 Feature-inferring neural network systems

Collobert and Weston (2008) proposed one of the first neural network architectures for NER, with feature vectors constructed from orthographic features (e.g., capitalization of the first character), dictionaries and lexicons. Later work replaced these manually constructed feature vectors with word embeddings (Collobert et al., 2011), which are representations of words in n-dimensional space, typically learned over large collections of unlabeled data through an unsupervised process such as the skip-gram model (Mikolov et al., 2013). Studies have shown the importance of such pre-trained word embeddings for neural network based NER systems (Habibi et al., 2017), and similarly for pre-trained character embeddings in character-based languages like Chinese (Li et al., 2015; Yin et al., 2016).

Modern neural architectures for NER can be broadly classified into categories depending upon their representation of the words in a sentence. For example, representations may be based on words, characters, other sub-word units or any combination of these.

6.4.1 Word level architectures

In this architecture, the words of a sentence are given as input to Recurrent Neural Networks (RNN) and each word is represented by its word embedding, as shown in Figure 1.

The first word-level NN model was proposed by Collobert et al. (2011)[10]. The architecture was similar to the one shown in Figure 1, but a convolution layer was used instead of the Bi-LSTM layer and the output of the convolution layer was given to a CRF layer for the final prediction. The authors achieved 89.59% F1 score on English CoNLL 2003 dataset by including gazetteers and SENNA embeddings.

Huang et al. (2015) presented a word LSTM model (Figure 1) and showed that adding a CRF layer to the top of the word LSTM improved performance, achieving 84.26% F1 score on English CoNLL 2003 dataset. Similar systems were applied to other domains: DrugNER by Chalapathy et al. (2016) achieving 85.19% F1 score (under an unofficial evaluation) on MedLine test data (Segura Bedmar et al., 2013), and medical NER by Xu et al. (2017) achieving 80.22% F1 on disease NER corpus using this architecture. In similar tasks, Plank et al. (2016) implemented the same model for multilingual POS tagging.

[9]Code: `https://github.com/ixa-ehu/ixa-pipe-nerc`
[10]Code: `https://ronan.collobert.com/senna/`

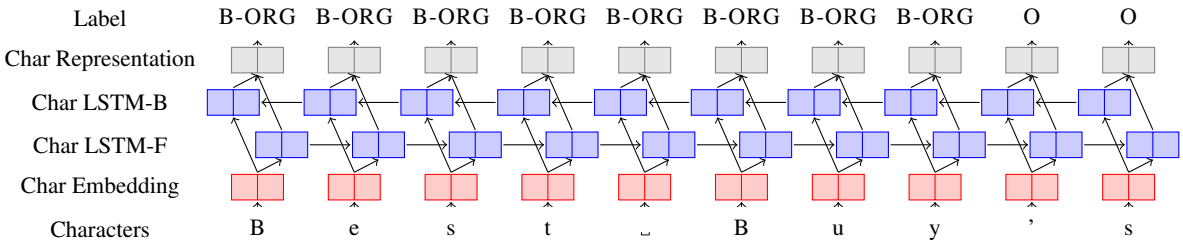

Figure 2: Character level NN architecture for NER

With slight variations, Yan et al. (2016) implemented word level feed forward NN, bi-directional LSTM (bi-LSTM) and window bi-LSTM for NER of English, German and Arabic. They also highlighted the performance improvement after adding various features like CRF, case, POS, word embeddings and achieved 88.91% F1 score on English and 76.12% on German.

6.4.2 Character level architectures

In this model, a sentence is taken to be a sequence of characters. This sequence is passed through an RNN, predicting labels for each character (Figure 2). Character labels transformed into word labels via post processing. The potential of character NER neural models was first highlighted by Kim et al. (2016) using highway networks over convolution neural networks (CNN) on character sequences of words and then using another layer of LSTM + softmax for the final predictions.

This model was implemented by Pham and Le-Hong (2017) for Vietnamese NER and achieved 80.23% F-score on Nguyen et al. (2016)'s Vietnamese test data. Character models were also used in various other languages like Chinese (Dong et al., 2016) where it has achieved near state of the art performance.

Kuru et al. (2016) proposed CharNER [11] which implemented the character RNN model for NER on 7 different languages. In this character model, tag prediction over characters were converted to word tags using Viterbi decoder(Forney, 1973) achieving 82.18% on Spanish, 79.36% on Dutch, 84.52% on English and 70.12% on German CoNLL datasets. They also achieved 78.72 on Arabic, 72.19 on Czech and 91.30 on Turkish. Ling et al. (2015) proposed word representation using RNN (Bi-LSTM) over characters of the word and achieved state of the art results on POS task using this representation in multiple languages including 97.78% accuracy on English PTB(Marcus et al., 1993).

Gillick et al. (2015) implemented sequence to sequence model (Byte to Span- BTS) using encoder decoder architecture over sequence of characters of words in a window of 60 characters. Each character was encoded in bytes and BTS achieved high performance on CoNLL 2002 and 2003 dataset without any feature engineering. BTS achieved 82.95%, 82.84%,86.50%,76.22% Fscore on Spanish, Dutch, English and German CoNLL datasets respectively.

6.4.3 Character+Word level architectures

Systems combining word context and the characters of a word have proved to be strong NER systems that need little domain specific knowledge or resources. There are two base models in this category. The **first type of model** represents words as a combination of a word embedding and a convolution over the characters of the word, follows this with a Bi-LSTM layer over the word representations of a sentence, and finally uses a softmax or CRF layer over the Bi-LSTM to generate labels. The architecture diagram for this model is same as Figure 3 but with the character Bi-LSTM replaced with a CNN[12].

Ma and Hovy (2016) implemented this model to achieve 91.21% F1 score on the CoNLL 2003 English dataset and 97.55% POS-tagging accuracy on the WSJ portion of PTB (Marcus et al., 1993). They also showed lower performance by this model for out of vocabulary words.

Chiu and Nichols (2015) achieved 91.62% F1 score on the CoNLL 2003 English dataset and 86.28% F score on Onto notes 5.0 dataset (Pradhan et al., 2013) by adding lexicons and capitalization features to

[11]Code: `https://github.com/ozanarkancan/char-ner`
[12]Code: `https://github.com/LopezGG/NN_NER_tensorFlow`

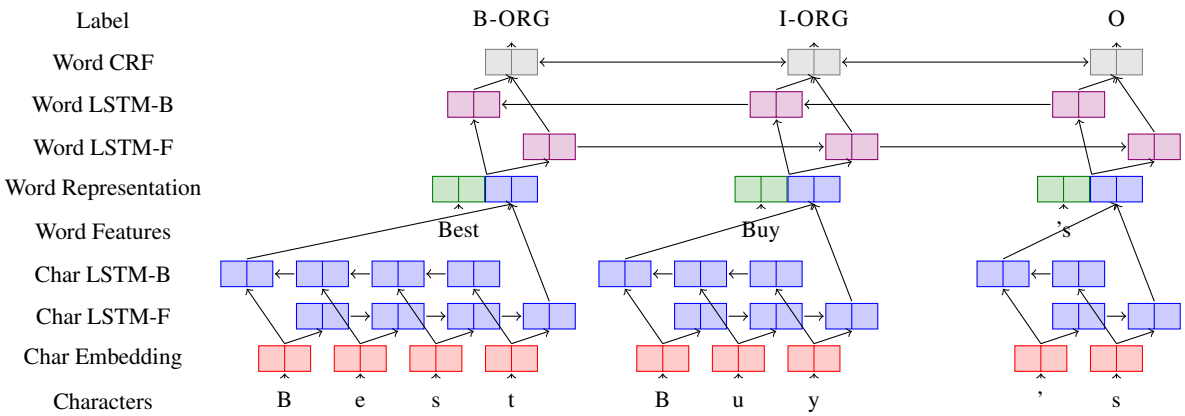

Figure 3: Word+character level NN architecture for NER

this model. Lexicon feature were encoded in the form or B(begin), I(inside) or E(end) PER, LOC, ORG and MISC depending upon the match from the dictionary.

This model has also been utilized for NER in languages like Japanese where Misawa et al. (2017) showed that this architecture outperformed other neural architectures on the *organization* entity class.

Limsopatham and Collier (2016) implemented a character+word level NER model for Twitter NER (Baldwin et al., 2015) by concatenating a CNN over characters, a CNN over orthographic features of characters, a word embedding, and a word orthographic feature embedding. This concatenated representation is passed through another Bi-LSTM layer and the output is given to CRF for predicting. This model achieved 65.89% F score on segmentation alone and 52.41% F score on segmentation and categorization.

Santos and Guimaraes (2015) implemented a model with a CNN over the characters of word, concatenated with word embeddings of the central word and its neighbors, fed to a feed forward network, and followed by the Viterbi algorithm to predict labels for each word. The model achieved 82.21% F score on Spanish CoNLL 2002 data and 71.23% F score on Portuguese NER data (Santos and Cardoso, 2007).

The **second type of model** concatenates word embeddings with LSTMs (sometimes bi-directional) over the characters of a word, passing this representation through another sentence-level Bi-LSTM, and predicting the final tags using a final softmax or CRF layer (Figure 3). Lample et al. (2016)[13] introduced this architecture and achieved 85.75%, 81.74%, 90.94%, 78.76% Fscores on Spanish, Dutch, English and German NER dataset respectively from CoNLL 2002 and 2003.

Dernoncourt et al. (2017) implemented this model in the NeuroNER toolkit[14] with the main goal of providing easy usability and allowing easy plotting of real time performance and learning statistics of the model. The BRAT annotation tool[15] is also integrated with NeuroNER to ease the development of NN NER models in new domains. NeuroNER achieved 90.50% F score on the English CoNLL 2003 data.

Habibi et al. (2017) implemented the model for various biomedical NER tasks and achieved higher performance than the majority of other participants. For example, they achieved 83.71 F-score on the CHEMDNER data (Krallinger et al., 2015).

Bharadwaj et al. (2016)[16] utilized phonemes (from Epitran) for NER in addition to characters and words. They also utilize attention knowledge over sequence of characters in word which is concatenated with the word embedding and character representation of word. This model achieved state of the art performance (85.81% F score) on Spanish CoNLL 2002 dataset.

A slightly improved system focusing on multi-task and multi-lingual joint learning was proposed by Yang et al. (2016) where word representation given by GRU (Gated Recurrent Unit) cell over characters plus word embedding was passed through another RNN layer and the output was given to CRF models trained for different tasks like POS, chunking and NER. Yang et al. (2017) further proposed transfer

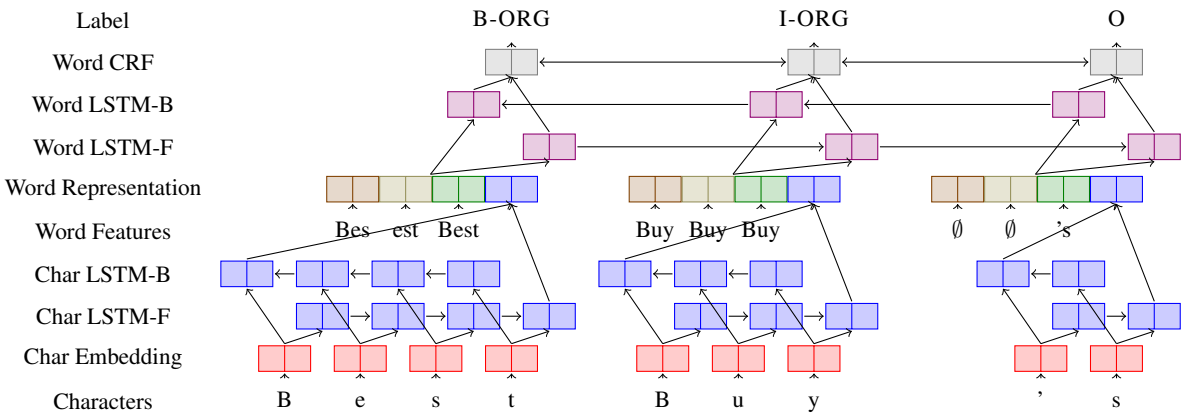

Figure 4: Word+character+affix level NN architecture for NER

learning for multi-task and multi-learning, and showed small improvements on CoNLL 2002 and 2003 NER data, achieving 85.77%, 85.19%, 91.26% F scores on Spanish, Dutch and English, respectively.

6.4.4 Character + Word + affix model

Yadav et al. (2018) implemented a model that augments the character+word NN architecture with one of the most successful features from feature-engineering approaches: affixes. Affix features were used in early NER systems for CoNLL 2002 (Tjong Kim Sang, 2002; Cucerzan and Yarowsky, 2002) and 2003 (Tjong Kim Sang and De Meulder, 2003) and for biomedical NER (Saha et al., 2009), but had not been used in neural NER systems. They extended the Lample et al. (2016) character+word model to learn affix embeddings[17] alongside the word embeddings and character RNNs (Figure 4). They considered all n-gram prefixes and suffixes of words in the training corpus, and selected only those whose frequency was above a threshold, T. Their word+character+affix model achieved 87.26%, 87.54%, 90.86%, 79.01% on Spanish, Dutch, English and German CoNLL datasets respectively. Yadav et al. (2018) also showed that affix embeddings capture complementary information to that captured by RNNs over the characters of a word, that selecting only high frequency (realistic) affixes was important, and that embedding affixes was better than simply expanding the other embeddings to reach a similar number of hyper-parameters.

7 Discussion

Table 1 shows the results of all the different categories of systems discussed in section 6 on the CoNLL 2002 and 2003 datasets. The table also indicates, for each model, whether it makes use of external knowledge like a dictionary or gazetteer. Table 2 presents a similar analysis on the DrugNER dataset from SemEval 2013 task 9 (Segura Bedmar et al., 2013).

Our first finding from the survey is that feature-inferring NN systems outperform feature-engineered systems, despite the latter's access to domain specific rules, knowledge, features, and lexicons. For example, the best feature-engineered system for Spanish, Agerri and Rigau (2016), is 1.59% below the best feature-inferring neural network system, (Lample et al., 2016), and 1.65% below the best neural network system that incorporates lexical resources (Bharadwaj et al., 2016). Similarly, the best feature-engineered system for German, Agerri and Rigau (2016), is 2.34% below the best feature-inferring neural network system, Lample et al. (2016). The differences are smaller for Dutch and English, but in neither case is the best feature-engineered model better than the best neural network model. In DrugNER, the word+character NN model outperforms the feature engineered system by 8.90% on MedLine test data and 3.50% on the overall dataset.

Our next finding is that word+character hybrid models are generally better than both word-based and character-based models. For example, the best hybrid NN model for English, Chiu and Nichols (2015), is 0.52% better than the best word-based model, Huang et al. (2015), and 5.12% better than the best character-based model, (Kuru et al., 2016). Similarly, the best hybrid NN model for German, Lample et

Table 2: DrugNER results on the MedLine and DrugBank test data (80.10% and 19.90% of the test data, respectively). The Yadav et al. (2018) experiments report no decimal places because they were run after the end of shared task, and the official evaluation script outputs no decimal places.

al. (2016), is 2.64% better than the best word-based model, Yan et al. (2016), and 2.54% better than the best character-based model, (Kuru et al., 2016). In DrugNER, the word+character hybrid model is better than the word model by 14.25% on MedLine test data and 1.81% on DrugBank test data.

Our final finding is that there is still interesting progress to be made by incorporating key features of past feature-engineered models into modern NN architectures. Yadav et al. (2018)'s simple extension

of Lample et al. (2016) to incorporate affix features yields a very strong new model, achieving a new state-of-the-art in Spanish, Dutch, and German, and performing within 1% of the best model for English.

8 Conclusion

Our survey of models for named entity recognition, covering both classic feature-engineered machine learning models, and modern feature-inferring neural network models has yielded several important insights. Neural network models generally outperform feature-engineered models, character+word hybrid neural networks generally outperform other representational choices, and further improvements are available by applying past insights to current neural network models, as shown by the state-of-the-art performance of our proposed affix-based extension of character+word hybrid models.

Abstract

A bottleneck problem with Chinese named entity recognition (NER) in new domains is the lack of annotated data. One solution is to utilize the method of distant supervision, which has been widely used in relation extraction, to automatically populate annotated training data without human-cost. The distant supervision assumption here is that if a string in text is included in a predefined dictionary of entities, the string might be an entity. However, this kind of auto-generated data suffers from two main problems: incomplete and noisy annotations, which affect the performance of NER models. In this paper, we propose a novel approach which can partially solve the above problems of distant supervision for NER. In our approach, to handle the incomplete problem, we apply partial annotation learning to reduce the effect of unknown labels of characters. As for noisy annotation, we design an instance selector based on reinforcement learning to distinguish positive sentences from auto-generated annotations. In experiments, we create two datasets for Chinese named entity recognition in two domains with the help of distant supervision. The experimental results show that the proposed approach obtains better performance than the comparison systems on both two datasets.

1 Introduction

In recent years, deep learning approaches have achieved great progress in the task of named entity recognition (NER) (Collobert et al., 2011; Chiu and Nichols, 2015). The standardized approach is that using BiLSTMs for encoding and then applying CRF for jointly label decoding (Huang et al., 2015; Lample et al., 2016). In addition, BiLSTMs and CNNs are employed to model character- or word-level representations (Ma and Hovy, 2016).

Most previous studies on NER focus on a certain set of predefined NER types, such as organization, location, person, date, and so on, where a certain amount of labeled data is provided to train the models. However, different applications require particular entity types, such as "Brand" and "Product" in E-commerce domain, and "Company" for finance industry. Considering the high cost of human annotation, it may not be feasible to annotate large amounts of labeled data for each new NER type, but small-scale data is available at some time.

As an alternative solution, distant supervision can automatically generate large-scale labeled data for new-type NER without human-cost. The idea of distant supervision has widely used in the task of relation extraction (Mintz et al., 2009; Riedel et al., 2010; Zeng et al., 2015). For relation extraction, at first we have a knowledge base. If two entities e_1 and e_2 have relation r according to the knowledge base, then we populate this knowledge and assume the relation between e_1 and e_2 is r in the sentences that contain the both entities. In this way, we can produce a lot of labeled data for model training.

Similarly, in our task, we first acquire a dictionary containing a list of the new-type entities. Then, we automatically generate large-scale labeled data by assuming that each entity mention in a sentence is a positive instance of the corresponding type according to the dictionary. Figure 1(a) shows an example

Proceedings of the 27th International Conference on Computational Linguistics, pages 2159–2169
Santa Fe, New Mexico, USA, August 20-26, 2018.

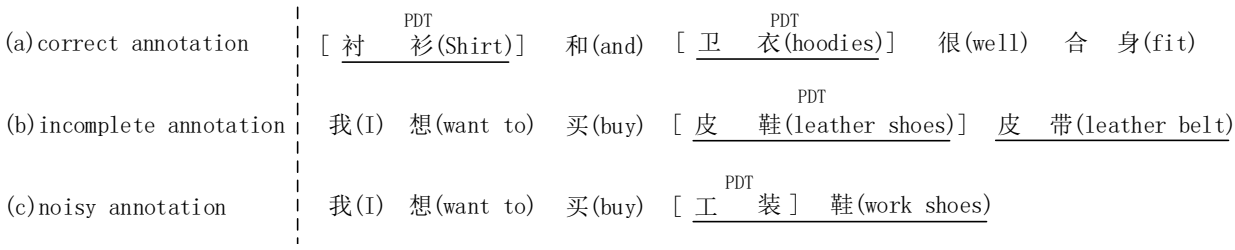

Figure 1: Examples generated by distant supervision, where "PDT" means a product name tagged by the distant supervision and one string with underline should be an entity of product.

that is regarded as a positive instance with two "Product" names are correctly matched by the distant supervision method.

However, in practice we find that the automatically labeled NER data suffers from two problems, i.e., *incomplete annotation* and *noisy annotation*, which negatively affect the performance of NER systems. The incomplete annotation problem means that not every entity has been labeled in the way of distant supervision. For example, "皮鞋(leather shoes)" is included in the dictionary, while "皮带(leather belt)" is not included. Thus in Figure 1(b), "皮鞋(leather shoes)" is annotated as a PDT, but "皮带(leather belt)" is not annotated. The noisy annotation problem means that the matched entity does not correspond to entity definition, such as Figure 1(c), where "工装鞋(work shoes)" is a product, but only the first two characters "工装(fatigue clothes)" are matched by the dictionary because "工装鞋(work shoes)" is not included in the dictionary. Obviously, such false labeled examples certainly provide wrong supervision during model training if we directly use the automatically generated data.

In this paper, we propose an approach to handle the two problems of distantly supervised NER data. As for the incomplete annotation problem, we treat the data as partially annotated data based on the extended CRF-PA model that can directly learn from partial annotations (PA) (Tsuboi et al., 2008). The noisy annotation problem is also ubiquitous in distantly supervised for relation extraction, and researchers try to address this issue by using reinforcement learning (RL) technology to select positive instances (Feng et al., 2018). Inspired of their work, we design an instance selector to obtain clean instances from distantly supervised NER data.

In summary, we make the following contributions:

- We propose a novel approach for new-type named entity recognition, which firstly combines the advantages of both partial annotation learning and reinforcement learning, to handle the problems of incomplete annotation and noisy annotation brought by distant supervision.
- We create two datasets for Chinese named entity recognition with the help of distant supervision in e-commerce and news domains. The experimental results on the newly created datasets show that the proposed approach performs better than the comparison systems.

2 Basic Settings

2.1 Distantly Supervised NER Data

Here we focus mainly on the Chinese NER, which is more difficult than NER for other languages such as English for the lack of morphological variations such as capitalization and in particular the uncertainty in word segmentation. To get a good tagger for new entity types in new domains, we perform distant supervision to acquire labeled data for Chinese NER.

Initially, we have a small set of labeled seed data $\mathcal{H}$ for new entity types, and large-scale unlabeled data pool $\mathcal{U}$. We collect named entities to construct dictionary $\mathcal{D}$, and use the entries of $\mathcal{D}$ to match the strings of the sentences in $\mathcal{U}$ by the method of distant supervision. Then we obtain a set of sentences containing at least one matched strings, and the set is denoted as $\mathcal{A}$. The purpose in this paper is that we make full use of $\mathcal{H}$ and $\mathcal{A}$ to build a NER system.

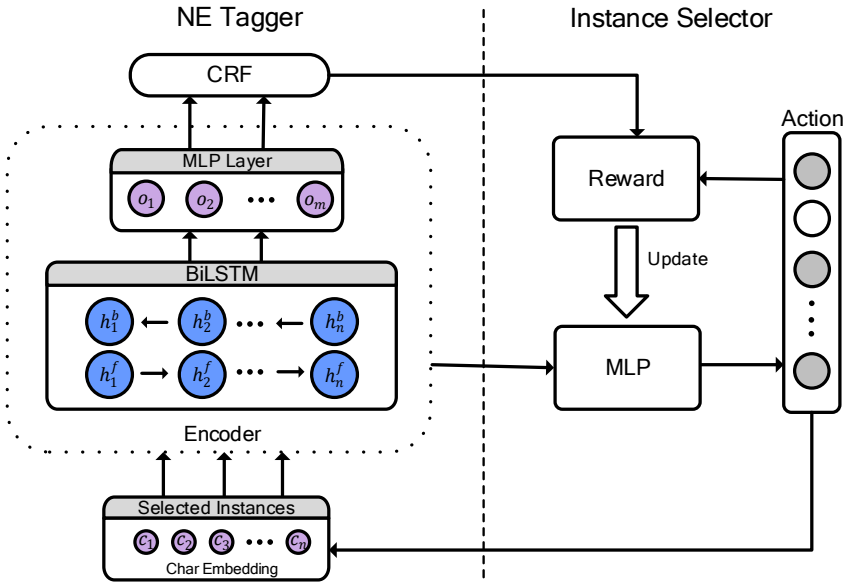

Figure 2: The framework of the proposed model, which consists of two parts. The right instance selector is a policy network, which chooses sentences from candidate dataset to expand training data to improve the left NE Tagger. The instance selector is trained based on the reward provided by NE Tagger.

In this paper, we treat Chinese NER task as a sequence labeling problem. We exploit the traditional BIO schema to represent the tags of sentences. Concretely, we tag the beginning character of an entity by "B-XX", the other characters of this entity by "I-XX", and the character as "O" if it is not inside an entity, where "XX" is the type of entities.

2.2 The Baseline LSTM-CRF

Given a sentence $x = c_1 c_2 \cdots c_n$, the goal is to assign an unique tag y_i for Chinese character c_i in the sentence. In general, the model predicts the entities in the sentence x by estimating the probability $p(y|x)$, where y is a possible label sequence for sentence x. The final output y_{max} of the system for one sentence is the label sequence with the maximum probability.

Here, we present a new NE tagger based on the LSTM-CRF model of Lample et al. (2016), which achieves the state-of-the-art performance in the NER task. Following Peng and Dredze (2015a), we represent Chinese characters as vectors and feed them into BiLSTM layer in the Chinese NER task. The left part of Figure 2 shows the framework of our baseline LSTM-CRF based NE tagger.

The input layer. For each input sentence $x = c_1 c_2 \cdots c_n$, we map serialized characters into a list of vectors $\mathbf{x}_1 \mathbf{x}_2 \cdots \mathbf{x}_n$ with an embedding layer including a lookup table as its key parameter. Following Lample et al. (2016), the lookup table is initialized with embeddings pre-trained on a large-scale raw corpus and is further fine-tuned during our training process.

The BiLSTM layer. With vector sequence $\mathbf{x}_1 \mathbf{x}_2 \cdots \mathbf{x}_n$ from input layer, we apply a bidirectional LSTM layer to encode the semantic dependency which provides high level features. The LSTM incorporates a memory-cell to solve the exploding and diminishing gradients of basic RNNs (Graves and Schmidhuber, 2005). For each character c_t in the sentence, we can obtain the output features $\mathbf{h}_t$ by concatenating $\overrightarrow{\mathbf{h}}_t$ and $\overleftarrow{\mathbf{h}}_t$, which computed in turn and in reverse to represent its left and right context. What's more, dropout (Srivastava et al., 2014) is applied to the outputs of the BiLSTM layer to avoid overfitting.

The MLP layer. Then, we employ a multi-layer perceptron (MLP), also known as feed-forward neural networks, to compute the scores of all labels at each position t, denoted as $\mathbf{o}_t$,

$$\begin{aligned} \mathbf{h}_t^{\text{mlp1}} &= \mathbf{W}^{\text{mlp1}} \mathbf{h}_t + \mathbf{b}^{\text{mlp1}} \\ \mathbf{o}_t &= \mathbf{W}^{\text{mlp2}} \mathbf{h}_t^{\text{mlp1}} + \mathbf{b}^{\text{mlp2}} \quad t \in [1, n] \end{aligned} \tag{1}$$

where $\mathbf{W}^{\text{mlp1/mlp2}}$ and $\mathbf{b}^{\text{mlp1/mlp2}}$ are the parameters.

The CRF layer. Finally, we adopt a CRF layer to derive the conditional probability of a label sequence y as follows:

$$\begin{aligned} p(y|x) &= \frac{e^{\text{score}(x,y)}}{\sum_{\bar{y}\in\mathbf{Y}_x} e^{\text{score}(x,\bar{y})}} \\ \text{score}(x,y) &= \sum_{t=1}^{n}(o_{t,y_t} + T_{y_{t-1},y_t}) \end{aligned} \tag{2}$$

where T_{y_{t-1},y_t} represents the transmission score from y_{t-1} to y_t, and $\mathbf{Y}_x$ are all candidate label sequences of input sentence x.

During evaluation, we adopt the minimum Bayes risk (MBR) decoding to find the optimal label sequence as follows:

$$\begin{aligned} y^* &= \arg\max_{y} \big(\sum_{t=1}^{n} p(y_t|x,t)\big) \\ p(y_t|x,t) &= \sum_{\bar{y}\in\mathbf{Y}_x,\bar{y}_t=y_t} p(\bar{y}|x) \end{aligned} \tag{3}$$

where $p(y_t|x,t)$ is the marginal probability of tagging the t-th position in x as y_t.

Training objective. In order to maximize the probability of the correct label sequence, we exploit a negative log-likelihood objective as the loss function:

$$\text{loss}(\Theta, x, y) = -\log p(y|x) \tag{4}$$

where Θ is the set of baseline model parameters.

3 Our Approach

This section describes our approach for new-type NER via distant supervision. To handle the problem of incomplete and noisy annotations, we propose a novel model for NER task. As shown in Figure 2, the framework of our model consists of two modules: the NE Tagger built on the idea of partial annotation learning to reduce the effect of unknown-type characters, the instance selector which chooses positive sentences from a candidate set and provides them to the NE Tagger.

3.1 LSTM-CRF-PA for Incomplete Annotation

It is inappropriate to regard those characters as non-entities, although they can not be matched according to the dictionary. It is a common problem known as false negative instance which may misguide model if we arbitrarily label them as "O". Therefore, we consider that each non-matched character can be annotated as any proper label. For example in Figure 3, except that "皮鞋 (leather shoes)" have definite labels, all of the remaining characters can be labeled as "B-PDT", "I-PDT" and so on. In other words, we denote a set of label sequences $\mathbf{z}$ for every distantly supervised sentence, whose probability is naturally the sum of probability of each possible label sequence $\tilde{y}$ in $\mathbf{z}$. We expand the original model for this situation and apply softmax over all candidate output label sequences, thus the probability of a distantly supervised instance is computed as follows:

$$p(\mathbf{z}|x) = \sum_{\tilde{y}\in\mathbf{z}} p(\tilde{y}|x) = \frac{\sum_{\tilde{y}\in\mathbf{z}} e^{\text{score}(x,\tilde{y})}}{\sum_{\bar{y}\in\mathbf{Y}_x} e^{\text{score}(x,\bar{y})}} \tag{5}$$

We exploit a negative log-likelihood objective as the loss function. Therefore, the loss function of our model with CRF-PA can be computed as follows:

$$\text{loss}(\Theta, x, \mathbf{z}) = -\log p(\mathbf{z}|x) \tag{6}$$

Figure 3: An example instance which is partially annotated. "PDT" means product name and "SPC" means specification name.

where Θ is the set of all NE tagger parameters.

In particular, if the sentence is annotated by hand and each character has definite label, the set $\mathbf{z}$ includes only one label sequence. Thus the above objective function is also suitable for supervised instances. We use standard back-propagation method to minimize the loss function of the NE tagger.

3.2 Instance Selector for Noisy Annotation

Our goal is to train an agent as an instance selector with reinforcement learning (RL) technology. Following Feng et al. (2018), the agent interacts with the environment and makes a decision at the sentence-level. We merge the initial hand-tagged seed set $\mathcal{H}$ and the distantly supervised set $\mathcal{A}$ into a candidate dataset $\mathcal{C}$. At each episode, we collect a random-size bag of instances $\mathcal{B}$ from $\mathcal{C}$. All the supervised instances in the current bag are default to be selected without decisions of agent. For each distantly supervised instance in the current bag, the agent makes an action from set of $\{1, 0\}$ to decide whether to select this instance or not. The agent receives the reward when all the actions have been completed. The reward represents the feedback of actions on this bag and will be used to update agent. The goal of agent is to decide actions that enable to maximize the reward.

State representation. In our view, the state s_t represents the current instance along with its label sequences. We represent the state as a vector $\mathbf{S}_t$, which consists of the following information: (1) The serialized vector representations of current instance, which are observed from the BiLSTM layer of baseline model. (2) The label scores calculated with output of the MLP layer from the shared encoder (denoted as $\mathbf{o}_t$ in Formula 1) and annotation of this instance, which means the tag-conditional noise of the distantly supervised annotation. More specifically, if a character is a part of an entity and annotated as a definite label (such as "皮" and "鞋" in Figure 3), the score of this position is the corresponding value in $\mathbf{o}_t$. Otherwise, we compute it by averaging the scores of all labels in $\mathbf{o}_t$. In this way, the dimension of the label scores vector is equal to the uniform length of sentences and will be concatenated with the first part.

Policy network. The agent decides an action $a_t \in \{0, 1\}$ to indicate whether the selector will select the t-th distantly supervised instance. The action value is sampled by the selector as $A_\Theta(s_t, a_t)$ where Θ is a multi-layer perceptron (MLP) with the parameter $\{\mathbf{W}, \mathbf{b}\}$. We adopt a logistic function as the policy function:

$$A_\Theta(s_t, a_t) = a_t\sigma(\mathbf{W} * \mathbf{S}_t + \mathbf{b}) + (1 - a_t)(1 - \sigma(\mathbf{W} * \mathbf{S}_t + \mathbf{b})) \tag{7}$$

where $\mathbf{S}_t$ is the state vector, and $\sigma(.)$ is the sigmoid function.

Reward. The reward is used to evaluate the ability of current NE tagger to predict labels of each character. The model receives a delayed average reward when it finishes all the selections in current bag, and before that the reward of each action is zero. The current bag $\mathcal{B}$ consists of two subsets: hand-tagged sentences $\tilde{\mathcal{H}}$ and distantly supervised instances $\tilde{\mathcal{A}}$. Now that the NE tagger calculates conditional probability for every sentence of bag $\mathcal{B}$, the reward can be computed on the set of selected distantly

supervised instances $\tilde{\mathcal{A}}_s$ and all the hand-tagged sentences:

$$r = \frac{1}{|\tilde{\mathcal{A}}_s| + |\tilde{\mathcal{H}}|}\Big(\sum_{x_j, \mathbf{z} \in \tilde{\mathcal{A}}_s} \log p(\mathbf{z}|x_j) + \sum_{x_k, y \in \tilde{\mathcal{H}}} \log p(y|x_k)\Big) \tag{8}$$

Different from the work of Feng et al. (2018), we have a set of supervised data. Our selector can be trained along the guidance of these prior knowledge about which sentences are labeled correctly. Therefore, the reward will become dependable and oriented, and it can guide the selector to maximize likelihood of all the instances in training dataset.

Selector Training. We use policy gradient method (Sutton et al., 2000) to optimize the policy network to maximize the reward of selections. For each random-sized bag $\mathcal{B}$, the feedback of every action $r(a_t)$ is same as average reward r. We compute the gradient and update the selector as follows:

$$\Theta = \Theta + \alpha \sum_{t=1}^{|\tilde{\mathcal{A}}|} r(a_t) \nabla_\Theta \log A_\Theta(s_t, a_t) \tag{9}$$

3.3 Joint Training

The parameters of the NE tagger and instance selector are learned iteratively. In each round, the selector first selects $\mathcal{A}_s$ from $\mathcal{A}$ and merges them with supervised sentences for the tagger. Meanwhile, the parameters of the NE tagger are learned from the newly training data and the tagger provides feedback reward to the selector to optimize its policy function.

4 Experiment

4.1 Datasets

We use two datasets in the experiments: one is from e-commerce domain and another is from news domain.

EC: In e-commerce domain (EC), we have five types of entities: Brand, Product, Model, Material, and Specification on user queries. This data contains 2,400 sentences tagged by annotators. We split the data into three sets: 1,200 sentences for training, 400 for dev, and 800 for testing. We collect a list of entities to construct dictionary from the training data. To reduce the effect of ambiguities, we remove the entry that belongs to more than one type, or it is a number or single character. Finally, the dictionary has 927 entries (included as EC.dic in supplementary materials). We perform distant supervision on raw data to obtain 2,500 sentences.

NEWS: For news domain, we use a NER data from MSRA, which was used in Sighan-bakeoff (Levow, 2006). We only test our systems on the type of PERSON. We randomly select 3,000 sentences as training dataset, 3,328 as dev data, and 3,186 as testing data. The rest set is used as raw data, having 36,602 sentences. We collect a list of person names from the training data. To increase the coverage, we add an additional names to the list. Finally, the list has 71,664 entries (included as NEWS.dic in supplementary materials). We perform distant supervision on raw data to obtain 3,722 sentences.

Embedding: In our approach, we need to map Chinese characters into vector representations by the lookup table, which can be initialized either by random or pre-trained. Many previous works (Lample et al., 2016; Peng and Dredze, 2015b) have shown that pre-trained embeddings on large-scale unlabeled corpus enable to initialize the table and observe efficiently improvements. Therefore, we collect one million sentences from the user-generated text in Internet, and pre-trained embeddings with the tool `word2vec`[1]. We set the embedding dimension as 100, the minimum frequency of occurrence as 5, and the window size of 5.

4.2 Settings

For evaluation, we use the entity-level metrics of Precision (P), Recall (R), and their F1 values in our experiments, treating one tagged entity as correct only when it matches the gold entity exactly.

There are several hyper-parameters in our models. We set them empirically by the development performances. The instance selector is a multi-layer perceptron with 100 units in each hidden layer. We use Adam (Kingma and Ba, 2014) to train the instance selector with the learning rate 0.001. For the parameters of the tagger, we set the character embedding dimension as 100, the dimension sizes of hidden features as 200. We exploit online training with a mini-batch size 128 to learn model parameters. The max-epoch iteration is set by 800, and the best-epoch model is chosen according to the development performances. We use RMSprop (Tieleman and Hinton, 2012) with a learning rate 0.001 to update model parameters. We adopt the dropout technique to avoid overfitting by a drop value of 0.2 at the training stage.

4.3 Baselines

We build four systems based on our proposed approach and a dictionary-based baseline system, listed as follows:

- Dict-based: The collected entity dictionary is directly used to match the strings in the testing data.
- LSTM-CRF: the baseline model described in Section 3.2.
- LSTM-CRF-PA: the system trained on $\mathcal{H}$ and $\mathcal{A}$ with CRF-PA learning, but without instance selector.
- LSTM-CRF+SL: the system trained on $\mathcal{H}$ and $\mathcal{A}$ with instance selector, but without CRF-PA learning.
- LSTM-CRF-PA+SL: our final system trained on $\mathcal{H}$ and $\mathcal{A}$ with CRF-PA learning and instance selector.

Table 3: Results for varing percent of training data on the EC dataset.

4.4 Results

In this section, we show the model performances of our proposed systems and the other systems mentioned above. Table 1 shows the experimental results on the EC data and Table 2 shows the results on the NEWS data, respectively.

The low recall scores of Dict-based systems show that the coverage of the dictionaries is low even we have more than 70K person-names for the NEWS data. Compared with LSTM-CRF trained on $\mathcal{H}$, LSTM-CRF system trained on $\mathcal{H}$ and $\mathcal{A}$ provides much lower performance on two datasets. These facts indicate that the data generated by distant supervision contains many noises that affect the performance of the models. LSTM-CRF-PA yields better performance than LSTM-CRF trained on $\mathcal{H}$, showing +0.89 F1 improvement on EC and +1.93 F1 on NEWS. This indicates that CRF-PA learning can reduce the effect of incomplete annotation.

From the tables, we find that compared with LSTM-CRF-PA, LSTM-CRF-PA+SL obtains absolute improvements of +1.37 and +0.84 F1 points on EC and NEWS, respectively. Overall, our final system (LSTM-CRF-PA+SL) achieves better improvement with +2.26 and +2.77 F1 on EC and NEWS respectively over our baseline system LSTM-CRF. These facts show that the RL-based instance selector can provide additional help to CRF-PA learning.

We further investigate the effect of different sizes of human-annotated data. We randomly select 25% and 50% sentences from human-annotated data $\mathcal{H}$ as training data and build new dictionaries of entities based on them respectively. The new dictionaries are used to generate distantly supervised annotated data. Table 3 shows the results on the EC dataset, where the first two lines are for 25%, the third and fourth lines are for 50%, and the last two are for 100%. From the table, LSTM-CRF-PA+SL performs better performance than the baseline system, showing +4.72 F1 improvement on 25% and +2.48 improvement on 50%, respectively. This indicates that with smaller human-annotated data, our proposed approach can provide relatively larger improvement.

5 Related Work

Our approach is to utilize partial annotation learning and reinforcement learning to perform new-type named entity recognition in new domains. Several previous studies relevant to our approach have been conducted.

NER. Most early studies treated NER task as the sequence labeling problem based on a large annotated corpus with supervised methods, such as HMM, MEMM (Hai and Ng, 2002) and CRF (Lafferty et al., 2001). Recently, neural networks have been explored by researchers (Collobert et al., 2011; Lample et al., 2016), and applied to reduce the weakness of feature sparsity problem and heavy feature engineering (Cai and Zhao, 2016). Those models have the similar architecture for decoding and feature extraction, which is chosen as our baseline model. In order to overcome the challenge of data deficient, some approaches based on weakly supervised learning (Nadeau et al., 2006; Riloff and Jones, 1999) have been proposed and successfully expand training data and feature space. However, it is difficult to implement these methods on Chinese tasks because of the lack of morphological variations such as capitalization and in particular the uncertainty in word segmentation, and it may cause large number of matching errors.

Under reasonable assumptions, OOV features should not be forced into certain tag. What's more, joint models have also obtained great performance (Qian and Liu, 2013; Finkel and Manning, 2009).

Learning from PAs. Learning from PAs has always been an attractive idea, since it usually requires much less or even none human annotation effort to obtain partially annotated data than fully annotated data, especially for complex tasks like sequence labeling. Li et al. (2012) propose to only manually annotate the most uncertain word boundaries in a sentence for Chinese word segmentation in order to reduce annotation cost. Tsuboi et al. (2008) extend the standard CRF to directly learn from incomplete annotations for sequence labeling tasks. This work refers to their model as *CRF-PA*. Jiang et al. (2013) propose to derive segmentation boundaries from implicit information encoded in web texts, such as anchor texts and punctuation marks, and use them as partially labeled training data in Chinese word segmentation. Liu et al. (2014) and Yang and Vozila (2014) further improve the work of Jiang et al. (2013) by employing the more sophisticated CRF-PA model. Marcheggiani and Artières (2014) systematically compare a dozen uncertainty metrics in token-wise active learning with CRF-PA for several sequence labeling tasks. Li et al. (2016b) propose a coupled sequence labeling approach for exploiting heterogeneous data by treating the single-sided annotations as PAs for the task of joint word segmentation and POS tagging. In this work, we for the first time apply the CRF-PA model to NER, and employ distance supervision to produce partially annotated NE data.

Reinforcement Learning. In recent years, reinforcement learning has become an issue in research, and applied successfully to many tasks. In text generation community, a deep Q-learning is served by Guo (2015) as generative model to improve the seq2seq model, which completes the process of decoding by Iteration. Li et al. (2016a) show how to apply deep reinforcement learning to model future reward in chatbot dialogue and capture the impact of this conversation in the future. Dethlefs (2010) aim to optimize the integration of NLG tasks that are inherently different in nature by learning a generation policy with reinforcement learning. For computer vision, Yeung et al. (2017) propose a reinforcement learning-based formulation select the right examples for training a classifier from noisy web search results. To more fine-grainedly select high-quality training sentences from noisy data, Feng et al. (2018) train an instance selector based on a policy function with reinforcement learning, which is inspirational to our model.

6 Conclusion

This paper presents a new approach to utilize the data generated by distant supervision to perform new-type named entity recognition in new domains. We adopt partial annotation learning to address the problem of incomplete annotation and design the instance selector to choose positive sentences to reduce the effect of noisy annotation. The instance selector is based on reinforcement learning and obtains the feedback reward from the NE tagger. When tested on two newly created datasets, our systems provide better performance than the comparison systems. The data and code is available at `https://github.com/rainarch/DSNER`.

Abstract

In this paper, we present a novel model for entity disambiguation that combines both local contextual information and global evidences through Limited Discrepancy Search (LDS). Given an input document, we start from a complete solution constructed by a local model and conduct a search in the space of possible corrections to improve the local solution from a global view point. Our search utilizes a heuristic function to focus more on the least confident local decisions and a pruning function to score the global solutions based on their local fitness and the global coherences among the predicted entities. Experimental results on CoNLL 2003 and TAC 2010 benchmarks verify the effectiveness of our model.

1 Introduction

The goal of entity disambiguation is to link a set of given query mentions in a document to their referent entities in a Knowledge Base (KB). As an essential and challenging task in Knowledge-Base Population (KBP) for text Analysis (Ji et al., 2014; Heng et al., 2015), entity disambiguation has attracted many research efforts from the NLP community. Recently, deep learning based approaches have demonstrated strong performances on this task (Ganea and Hofmann, 2017; Sil et al., 2018).

A main challenge for entity disambiguation is to best identify and represent the appropriate context, which can be local or global. Different methods have been proposed to capture and represent different types of contexts. Textual context has been heavily investigated for local models that score each query's candidates independently. Representations of the textual contexts range from weighted combination of the word embeddings based on attention (Ganea and Hofmann, 2017), to more fine-grained contextual representations using recurrent neural networks (Sil et al., 2018). The global context of other entities in the document has also been studied for a more global and joint prediction view on the problem. Ganea and Hofmann (2017) use a Conditional Random Field (CRF) based model to capture the interrelationship among entities in the same document, whereas Globerson et al. (2016) introduce a soft k-max attention model to weigh the importance of other entities in the document in making prediction for any given query.

Working with the recently proposed models, we observe that local models that employ an appropriate attention mechanism often have a solid linking performance. In a single document, there are often a small number of hard queries for which the local model fails to make a correct decision. We conjecture that if some of these mistakes can be corrected, a global model that enforces coherence among entities will be able to propagate these corrections to improve the overall solution quite effectively.

This inspires us to consider the Limited Discrepancy Search (LDS) framework (Doppa et al., 2014), which conducts a search over possible corrections on a complete output with the goal of improving the final output. Critically, LDS works well for cases where only a small number of local corrections are needed to reach a good global solution. This nicely matches up with our observation of the behavior of entity disambiguating models.

Proceedings of the 27th International Conference on Computational Linguistics, pages 2170–2180
Santa Fe, New Mexico, USA, August 20-26, 2018.

In this paper, we propose a LDS based global entity disambiguating system. Given a document and its query mentions, our system first applies a local disambiguation model to produce an initial solution. We then use LDS to conduct a shallow search in the space of possible corrections (with the focus on hard/least confident mentions) to find a better solution. Evaluation on CoNLL 2003 and TAC 2010 shows that our method outperforms the current state-of-the-art models. We also conduct an extensive ablation study on different variants of our model, providing insight into the strength of our method.

2 Proposed Approach

We are given a document D containing n mentions $[x_1, ...x_n]$. We assume that all mentions are linkable to a Knowledge Base (KB) by excluding the NILL mentions. We are interested in finding a joint assignment of all mentions to $\mathbf{Y} = [y_1, ...y_n]$ of referent entities to maximize the following score:

$$s(\mathbf{Y}) = \sum_{i=1}^{n} \psi(x_i, y_i) + \sum_{i=1}^{n} \sum_{j=1:j\neq i}^{n} \phi(y_i, y_j) \quad (1)$$

where function $\psi(x_i, y_i)$ gives the local compatibility score between the mention x_i and its candidate y_i and $\phi(y_i, y_j)$ indicates the amount of relatedness between the assigned candidates y_i and y_j. Optimizing this objective, however, is NP-hard. In this work, we develop a LDS-based search strategy for optimizing this objective.

2.1 Overview of the Approach

Given a document with n mentions, we initialize the search with a solution acquired based solely on the local scoring function $\psi(\cdot, \cdot)$. We then conduct a greedy beam search in the space of possible discrepancies (changes/corrections) to this initial solution while focusing on mentions with least confident local scores in the hope of finding a better solution. Fig 1 shows the overview of our search framework

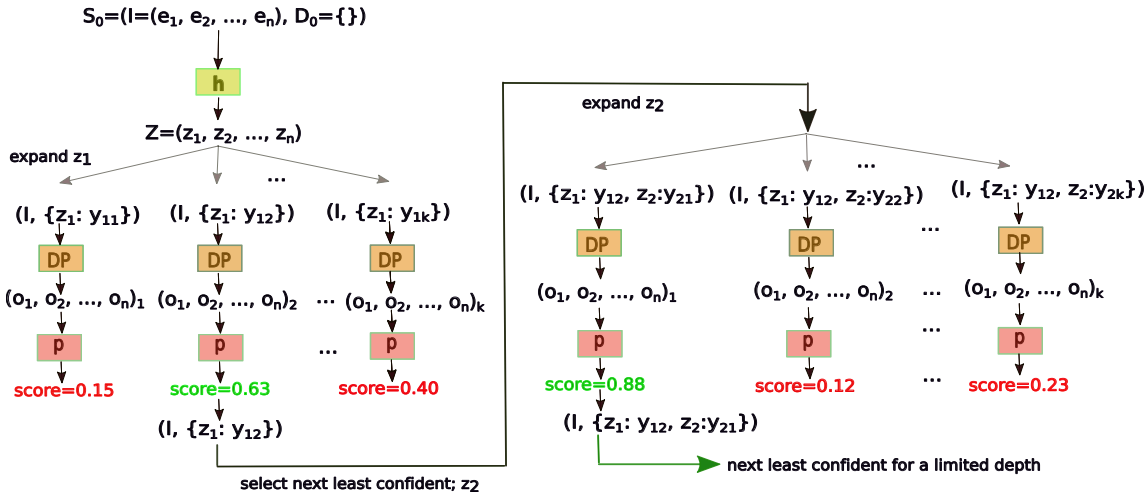

Figure 1: The general framework of our proposed model with beam size b=1.

for beam size $b = 1$. Each state S_i is a pair (I, D_i) where $I = (e_1, e_2, ..., e_n)$ is the initial solution given by the local model and D_i is the discrepancy set for state S_i. For example, a discrepancy set $\{x_{k_1} : y_{k_1}, x_{k_2} : y_{k_2}\}$ contains two discrepancies, changing the assignment for mentions x_{k_1} and x_{k_2} from e_{k_1} and e_{k_2} in I to y_{k_1} and y_{k_2} respectively. Starting with initial state (I,), we utilize a heuristic function h (Section 2.3.2) to sort the mentions in the increasing order of their local confidence. Let $(z_1, ..., z_n)$ be the ordered mentions where z_1 is the least confident mention. Each iteration of the greedy beam search explores and prunes the space of discrepancy sets as follows:

We select the least confident mention z_1 and expand state $(I, \{\})$ to k new states $(I, \{z_1 : y_{1j}\})$ for $j = 1 \cdots k$ where y_{1j} is the j^{th} candidate for mention z_1 (we consider top k most probable candidates). Each

expanded state $(I, \{z_1 : y_{1j}\}), j = 1, \ldots, k$ is given to a Discrepancy Propagator (DP) (Section 2.3.1) to get its discrepancy set propagated throughout the document and produce an updated complete solution $(o_1, ...o_n)_j$, for $j = 1, \ldots, k$. Utilizing a trained pruning function p (Section 2.3.3) we then rank the k complete solutions and prune them to top b states (b is beam size).

The search continues with the next least confident mention z_2 as shown in Fig 1. Each iteration increases the size of the discrepancy set by one. Note that a mention is not repeated in a discrepancy set. We consider two different strategies for terminating the search depending on the used heuristic function h (Section 2.3.3). Each strategy causes the search to terminate at different depth (length) of the discrepancy set. The output of the search is selected by the pruning function p from the last set of complete solutions.

In the following, we will first explain our **local model** ($\psi(\cdot, \cdot)$) for producing the initial solution. We will then introduce our LDS search framework, and its key components including the **Discrepancy Propagator** to propagate a set of discrepancies to other mentions in the document; the **Heuristic Function** to compute the local confidence of the mentions in the document and identify the least confident ones; and finally the **Pruning Function** to guide the search and select the final solution.

2.2 Local Model

Our local model utilizes contextual, lexical and prior evidences to compute the compatibility score $\psi(x_i, y_i)$ for assigning candidate y_i to mention x_i. These evidences are extracted and used as follows:

2.2.1 Contextual Evidence

Given a query mention, a key challenge for the local model is to identify a minimum but sufficient contextual evidence to disambiguate the query. We first extract all sentences in the document relevant to the query mention. This is achieved by applying CoreNLP (Manning and McClosky, 2014) to perform coreference resolution to all mentions in the document and extract all sentences containing a mention in the query's coreference chain.

The set of sentences are then concatenated to form the context for the query; $w_i = [w_{i1}, ...w_{im}]$, where $w_{ij} \in R^d$ is the embedding of the j-th word in the context. We then use an attention model introduced by (Ganea and Hofmann, 2017) to compress the context into a single embedding. Specifically, we define the contextual representation $c_i \in R^d$ for mention x_i with candidate set $\{y_{i1}, y_{i2}, ...y_{ik}\}$ over context w_i as

$$c_i = \sum_{l=1}^{m} \alpha_{il} w_{il} \tag{2}$$

The weight vector α is computed using the following attention considering all k entity candidates:

$$\alpha_i = \textbf{softmax}([\max_{j \in 1..k} y_{ij}^T A w_{i1}, ..., \max_{j \in 1..k} y_{ij}^T A w_{im}]) \tag{3}$$

where A is a learned matrix that scores the relatedness between word and entity. This attention model computes the relatedness of each word with all of the entity candidates and takes the max as the score for each word. The scores of all context words are then passed through softmax to compute their weight. Under this model, if a word is strongly related to one of the candidates, it will be given a high weight. Subsequently, using c_i we define the following contextual features for candidate y_{ij} as $f_{ij}^{(c)} = [y_{ij}^T B c_i; y_{ij}^T B; c_i]$, where B is a learned $R^d \times R^d$ matrix. Note that $f_{ij}^{(c)} \in R^{2d+1}$.

2.2.2 Lexical Evidence

The contextual features extracted above ignores any lexical/surface information between query mention and entity title, which can be useful. To this end we include some lexical features to our local model including variants of the edit distance between the surface strings of the mention and the candidate title, whether their surface strings follow an acronym pattern and etc. Detailed list can be found in the Table 1(a). The extracted features are scalar real values. We use RBF binning (Sil et al., 2018) to transform each scalar to a 10-d vector. Hence for each query x_i and candidate y_{ij} we have lexical vector feature $f_{ij}^{(l)} \in R^{10 \times |f|}$ where $|f|$ is the number of features listed in Table 1(a).

(a)

mention: m = [m_1, ... m_a], **entity title:** e = [t_1, ... t_b]
f_1: mention length = a
f_2: entity title length = b
f_3: $\sum_{i=1}^{b}$ (occurrence counts of t_i in the document)
f_4: m is acronym
f_5: e is acronym
f_6: m and e acronym patterns are exact match
f_7: m and e are non-acronyms and exact match
f_8: min-edit(m, e)
f_{10}: sum of partial min edits: $\sum_{i=1}^{a}(\min_{j=1}^{b}(\text{min-edit}(m_i, t_j)))$

(b)

local score for mention m: l = **sotmax**([$\psi(x_i, y_{i1})$, ... $\psi(x_i, y_{ik})$])
f_1: max(l)
f_2: second-max(l)
f_3: entropy(l)
f_4: m is an acronym
f_5: length(m)

Table 1: (a) list of lexical features in the local model (b) list of the features to learn heuristic function h_2

2.2.3 Prior Evidence

We consider $p(e|m)$, the prior probability that an entity e is linked to a mention string m as prior evidence. This is computed using hyper-link statistics from Wikipedia and aliases mapping from (Hoffart et al., 2011) obtained by extending the means tables of YAGO (Hoffart et al., 2013). The $p(e|m)$ is also transformed to a 10-d vector using RBF binning (Sil et al., 2018) to create prior feature $f_{ij}^{(p)} \in R^{10}$.

2.2.4 Overall local model

The contextual, lexical and prior features are concatenated and fed through a Multi Layer Perceptron (MLP) with 2 hidden layers (relu, 200-d and 50-d respectively) to produce a final local score for all candidates as follows:

$$\psi(x_i, y_{ij}) = \sigma(W_s[f_{ij}^{(c)}; f_{ij}^{(l)}; f_{ij}^{(p)}] + b_s) \tag{4}$$

Where W_s and b_s are weight and bias parameters for the MLP. The learning of the model is two tiered. We first pre-train the matrices A and B using the cross-entropy loss by using **softmax**($[y_{ij}^T B c_i]_{j \in 1..k}$) as the predicted probability for each candidate for mention x_i, Keeping A and B fixed, we then train the MLP weights with a drop-out rate of 0.7 minimizing again the cross-entropy loss. Note that we use the entity embeddings produced by (Ganea and Hofmann, 2017) and the word embeddings produced by (Mikolov et al., 2013) using skip-gram model.

2.3 Global Model via LDS

Our local model primarily focuses on the textual context of each mention in making its decisions and ignores the relationship between mentions. Our global model takes as input the local predictions for all the mentions in a single document and constructs a globally coherent final solution using Limited Discrepancy Search. Before we introduce our LDS search procedure, we will first describe the discrepancy propagator which is critical toward achieving an efficient search space.

2.3.1 Discrepancy Propagator

The purpose of the discrepancy propagator is to allow the influence of the local changes to propagate to other parts of the solution, thus reducing the necessary number of discrepancies needed. Our discrepancy propagator is essentially a new scoring function that evaluates each candidate for a given mention not only based on the local compatibility but also the global coherence among the predictions.

Given that not all mentions in a document need to be related to one another, for each mention x_i we construct an entity context E_i considering a window of 30 mentions centered at query mention x_i. Given the current entity assignment $e_1, e_2, ...e_n$ to the mentions in the document, the entity context for mention x_i will be $E_i = e_{i-15}..., e_{i-1}, e_{i+1}, ...e_{i+15}$.
For a given mention x_i and its entity context E_i, the new score of a candidate y_{ij} is defined as:

$$g(x_i, y_{ij}) = \psi(x_i, y_{ij}) + \frac{1}{|E_i|} \sum_{e \in E_i} \phi(e, y_{ij}) \tag{5}$$

In equation 5, the score of a candidate now considers both its local score ψ as well as its average coherence with the other predictions in its entity context. The coherence score ϕ between two entities e and y_{ij} is defined as:

$$\phi(e, y_{ij}) = e^T C y_{ij} + w^T r(e, y_{ij}) \tag{6}$$

where e and y_{ij} are entity embeddings and $r(e, y_{ij})$ is a vector of three pairwise features between the two entities: log transformed counts of co-ocurrences, shared in-links and shared out-links; $C \in R^{d \times d}$ and $w \in R^3$ are learned weights.

The score given by equation 5 is fed through a softmax activation to assign probabilities to each candidate of x_i. We train W and c in a mention-wise procedure using cross entropy loss. Specifically for each mention x_i we use ground truth entities for the other mentions in E_i and update weights of C and w such that the true candidate of x_i gets higher score than its false candidates.

Note that we do not intend to use this scoring function to do joint inference on all mentions. Instead, it is used with LDS to propagate the discrepancies to the output of all related mentions as follows. Given the original solution $e_1, e_2, ...e_n$ and a set of discrepancies $\{x_k : y_k\}$, we first update e_k to y_k. Then we re-evaluate equation 5 for all mentions that have y_k in their entity context to produce a complete solution based on new entity context containing y_k.

2.3.2 Heuristic Function

The heuristic function takes the initial solution and sort all the mentions based on their prediction confidence. In this work we consider two heuristic functions for computing the prediction confidence of the local model. For a given query x_i, our first heuristic function h_1 computes its confidence simply by taking the max of the local scores normalized by a softmax funtion:

$$h_1(x_i) = \textbf{max}(\textbf{softmax}([\psi(x_i, y_{i1}), ...\psi(x_i, y_{ik})])) \tag{7}$$

where $\psi(x_i, y_{ij})$ is the local score for candidate y_{ij}.

For our second heuristic function h_2, we learn a binary classifier (a two layer MLP) to produce local confidence for each mention x_i. The binary classifier utilizes the features listed in Table 1(b). Each feature value is transformed into a 10-d vector using RBF binning (Sil et al., 2018). The training samples for the binary classifier are generated from the prediction of the local model on the training set. One training example is generated for each local prediction — if the local model is correct about its decision then the label for the sample is 1. In order to balance the positive and negative training samples, we randomly sub-sample positive local predictions. For each local prediction, the learned classifier outs a probability of its being correct, which is used as the confidence score.

2.3.3 Pruning Function

At each iteration of the search, each beam is expanded to k new states. Following the expansion, the DP is applied to the $b \times k$ expanded nodes and re-evaluates equation 5 for all mentions with updated entity contexts due to the discrepancies. It hence propagates the discrepancies and produces a complete solution. Subsequently, the pruning function evaluates each of the $b \times k$ complete solutions and reduces the expansion list to the beam size b.

The pruning function is similar to equation 5 but scores all the mentions collectively. Given all the mentions in the document $x_1, ..., x_n$ and their predicted entities denoted as $o = o_1, ..., o_n$, our pruning function scores the solution o as follows:

$$s(o) = \sum_i \psi(x_i, o_i) + \sum_{(o_i \in E_j \text{ or } o_j \in E_i)} \phi_g(o_i, o_j) \tag{8}$$

Where constraint ($o_i \in E_j$ or $o_j \in E_i$) indicates that we consider relation among pair of entities (o_i, o_j) if they are in the entity context of one another. Here ϕ_g takes the same form as equation 6 but uses a different set of weights C_g and w_g.

Despite the similarity in forms, the pruning function serves a different purpose from that of equation 6 and requires different training. We train the pruning function by reducing it to a rank learning problem.

Specifically, in training, we collect all the complete solutions that are considered in each pruning step, and compute their hamming losses from the ground truth. Given a set of solutions in a pruning step, we will create ranking pairs to require the solution with the least hamming loss to score higher than all the others. Given a ranking pair, o^t and o^f, assuming o^t has lower hamming loss than o^f, we use the following ranking loss for training:

$$max\left(0, \Delta(o^t, o^f) - s(o^t) + s(o^f)\right) \tag{9}$$

where $\Delta(o^{(t)}, o^{(f)})$ is the absolute difference of the hamming-loss between $o^{(t)}$ and $o^{(f)}$. This loss function penalizes the scoring function if it fails to score o^t higher than o^f by a margin specified by $\Delta(o^{(t)}, o^{(f)})$.

Terminating the search. We consider two different strategies for terminating the search depending on the heuristic function in use. When using h_1 as the heuristic function, search terminates when we reach a depth limit τ (a maximum τ discrepancies). The strategy with h_2 uses a flexible depth. For this strategy, we terminate the search when discrepancies have been introduced for all queries that are predicted to be incorrect by h_2.

3 Experiments

3.1 Data Sets

We use two datasets CoNLL 2003 (Hoffart et al., 2011) and TAC 2010 (Ji et al., 2010) for evaluation. The CoNLL dataset is partitioned into train, test-a and test-b with 946, 216 and 231 documents respectively. Following our baselines we only use 27816 mentions with valid links to the KB. The TAC 2010 dataset is yet another popular NED dataset released by the Text Analysis Conference (TAC). The dataset contains training and test set with 1043 and 1013 documents respectively. Similar to CoNLL we only consider linkable mentions in TAC and report our performance on 1020 query mentions in the test set.

To learn and tune the parameters of the local models for CoNLL and TAC we use their own training and development splits. However, to learn and tune the parameters of the global model (the discrepancy propagator, the heuristic and pruning functions) we only use the CoNLL training and dev-sets.

The number of queries per document in the test sets of the CoNLL and TAC are approximately 20 and 1 respectively. In order to have a global setup for TAC we apply CoreNLP (Manning and McClosky, 2014) mention extractor to the test documents of TAC and perform joint disambiguation of the extracted mentions together with the query mentions, increasing the number of mentions to approximately 4 per document. We only report the performance on the query mentions with the given standard ground truth by TAC.

3.2 Hyper-parameters and Dimensions

Our model settings for the hyper-parameters and dimensionality of the embeddings and weights are as follows: We use entity/word embeddings of 300-d. We learned the embeddings using the mechanism proposed by (Ganea and Hofmann, 2017). We use 2-layers MLPs for the local model and the heuristic h_2 with hidden layer sizes 200×50 and 100×20 for each respectively. The RBF binning always transfers a scalar to 10-d. Although we analyze and compare different configurations for beam-size and depth limit in section 3.4, we use beam size 5 and flexible depth limit τ with heuristic h_2 in our reported results.

3.3 Results

To evaluate the model performance we use the standard micro-average accuracies of the top-ranked candidate entities. We use different alias mappings for TAC and CoNLL. Specifically, for TAC we only use anchor-title alias mappings constructed from hyper-links in the Wikipedia. For CoNLL, in order to follow the experimental setup reported by (Sil et al., 2018), in addition to the alias mappings of Wikipedia anchor-titles, we use the mappings produced by (Pershina et al., 2015) and (Hoffart et al., 2011).

Tables 2(a) and (b) show our performance on the CoNLL and TAC datasets for our local and global models along with other competitive systems respectively. The prior state of the art performances on

these two datasets are achieved by (Sil et al., 2018). The results show that our global model outperforms all the competitors for both CoNLL 2003 and TAC 2010. It is interesting to note that our local model is solid, but is noticeably inferior to the stat-of-the-art local model. With an even stronger local model like that of (Sil et al., 2018), one can potentially expect our LDS-based global model to push the state-of-the-art even further.

3.4 Ablation Study and Performance Analysis

For ablation we analyze the impact of the features and search. We also analyze the behavior of our model based on the rarity of the entities.

3.4.1 Feature Analysis

We study the impact of features on the local and global models. For the local model, starting with only considering the contextual evidence as described in Section 2.2.1, we see that the performance steadily increases as we add the prior and lexical features. As shown in tables 3(a) and (b) the prior and lexical features have very strong impact on TAC. The binning technique that projects the prior and lexical features to 10 dimensions gives an average of 0.94% and 0.61% percentage points for TAC and CoNLL respectively.

For the global model, entity pair compatibility is computed using both entity embeddings and log transformed counts of co-occurences, shared in-links and shared out-links. Using these features leads to a gain of 1.1% and 0.43% in accuracy for CoNLL and TAC respectively compared to the global model using only the embeddings in equation 6.

Table 3: The performance of variants of our Local/Global models on CoNLL 2003 and TAC-2010

3.4.2 Search Analysis

In the last two rows of Table 3, we list variants of our model where LDS search is removed. Specifically, given the initial local solution, our discrepancy propagator (equation 5) can be applied without any discrepancy to re-evaluate the candidates for all mentions and obtain a more globally compatible solution. Naturally, one can repeat this for multiple iterations till convergence, which gives us an alternative global model that does not rely on search. We consider this model and show its single iteration performance (-LDS + 1-step global prop.) as well as its converged performance (-LDS + conv. global prop.) in Table 3.

From the results we can see that a single iteration of the global propagation was able to significantly improve the initial local solution, but later iterations lead to very mild gain. This is because after the first propagation the convergence is almost immediate and there is a limited improvement after the first iteration. In contrast, our search based global model is able to achieve significant further performance gain 1.3% for CoNLL and 1.68% for TAC. The reason is that with local discrepancies introduced by LDS, we force the solution to escape the current local optimum and search for better ones.

Additionally, several parameters/choices in the search can potentially impact the performance: the beam size b, the depth of search, and the different heuristics for prioritizing the discrepancy locations. The following set of experiments explore these choices of parameters:

Beam size. We compare model with beam size $b = 5$ and a simple greedy model with $b = 1$. For CoNLL 2003 and TAC-2010, the model with $b = 5$ gives a gain of 0.24% and 0.13% compared to the greedy. Increasing the size of the beam further beyond 5 did not show significant gain.

Depth of search. For heuristic h_1, we use a fixed depth strategy. In particular, given a document with n mentions, we consider two different depth limits: $\tau = 25\%n$ and $\tau = 50\%n$, which lead to an average depth of 5 and 10 per document respectively. For heuristic h_2, the depth is flexible and determined by the number of mentions that are predicted to be incorrect by h_2. This strategy leads to an average depth of 4. In Tables 4 (a) and (b), we report the confusion matrices given by h_1 applied to the local prediction on test-b of CoNLL 2003 with $\tau = 25\%n$ and $\tau = 50\%n$ respectively. In these tables correct/incorrect mean whether the local prediction is correct or not (comparing to the ground truth). Therefore the first cell with value 1134 indicates that there are 1134 mentions in test-b that are correctly predicted by the local model, but deemed as among the top 25% least confident mentions (aka the hard queries) by h_1. The confusion matrix for a good heuristic will have small diagonal values and large anti-diagonal values.

In Table 4 (c), we apply heuristic h_2 to the same data with flexible depth. These results show that heuristic h_2 gives the best precision as well as recall of the real mistakes made by the local model.

$\tau = 25\%n$	r $\leq 25\%$	r $> 25\%$
correct	1134	2937
incorrect	276	136

(a)

$\tau = 50\%n$	r $\leq 50\%$	r $> 50\%$
correct	2071	2000
incorrect	331	81

(b)

τ=flexible	label=0	label=1
correct	805	3266
incorrect	333	79

(c)

Table 4: Confusion Matrices for (a) using heuristic h_1 with $\tau = 25\%n$, (b) heuristic h_1 with $\tau = 50\%n$ and (c) heuristic h_2 with flexible τ.

Models	Heuristic	Depth (τ)	Beam Size (b)	In-KB acc %
Global + LDS	h_1	$\tau = 25\%n$	1	93.88
Global + LDS	h_1	$\tau = 25\%n$	5	94.12
Global + LDS	h_1	$\tau = 50\%n$	5	94.23
Global + LDS	h_2	flexible	5	94.44

Table 5: CoNLL 2003 Test-b

In Table 5, we report the performance of our model on CoNLL 2003 with different choices for the heuristic, search depth, and beam size. The results show that using a beam of size 5 improves upon single greedy search, and using heuristic h_2 with flexible depth gives the best performance in terms of both prediction accuracy and efficiency (due to smaller search trees). When h_1 is used, doubling the depth of the search tree brings about only a marginal improvement in accuracy at the cost of doubling the search depth and thus the prediction time.

3.4.3 Performance Analysis Based on Entity Rarity

We also analyze the behavior of the coherent global models based on the rarity of the entities for the given mention. Specifically, we measure the rarity of e for given query mention m by $p(e|m)$, as defined in 2.2.3, scaled to (0, 100). To this end we quantize the value of rarity measure into different bins. For each bin we compute the difference of accuracy between a coherent global model and the local model. Two coherent models are considered here; a global model without LDS (-LDS + conv.global prop in Table 3) and global model with LDS using h_2. Figure 2 shows the difference of accuracy between the global and local models per bin. As shown in this figure both global models achieve gains mostly on bins with small $p(e|m)$, which are related to the mentions with rare true entity. Additionally, the impact of

the global model when LDS is used is more significant, especially for the mentions whose true entities are most rare according to $p(e|m)$.

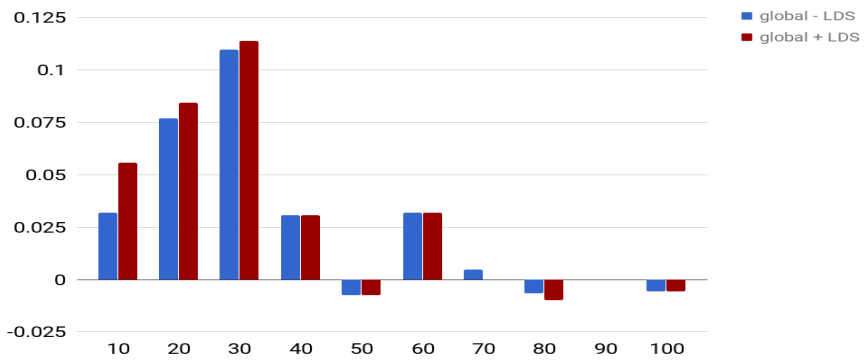

Figure 2: Global accuracy minus local accuracy per bin of rarity measure $p(e|m)$ which is scaled to (0, 100) for two coherent global models; model without LDS and model with LDS.

4 Related Work

Deep learning has been leveraged in recent local and global models. In local models Sun et al. (2015) use neural tensor networks to model mention, context and entity embeddings. Ganea and Hofmann (2017) develop an attention based model to weigh the importance of the words in the query document. The model by Sil et al. (2018) utilizes neural tensor network, multi-perspective cosine similarity and lexical composition and decomposition. In global models, the early models (Milne and Witten, 2008; Ferragina and Scaiella, 2010) decomposes the problem over mentions. Hoffart et al. (2011) use an iterative heuristic to prune edges among mention and entity. Cheng and Roth (2013) use an integer linear program solver and Lev-Arie Ratinov and Anderson (2011) apply SVM to use relation scores as ranking features.

In recent global models, Personalized PageRank (PPR) (Jeh and Widom, 2003) is adopted by several studies (Han and Sun, 2011; He et al., 2013; Alhelbawy and Gaizauskas, 2014; Pershina et al., 2015). Yamada et al. (2016) extend the skip-gram model (Mikolov et al., 2013) to learn the relatedness of entities using the linking structure of the KB. Ganea and Hofmann (2017) use a Conditional Random Field (CRF) based model to capture the interrelationship among entities in the same document whereas Globerson et al. (2016) introduce a soft k-max attention model to weight the importance of other entities in the document in making prediction for any given query.

In our proposed global model we address the intractable global optimization in a search framework. Specifically we use Limited Discrepancy Search (Doppa et al., 2014). Initialized with a local solution, LDS only explores a small number corrections to the hard queries. The propagation of the corrections enables the correction of other mistakes (even those with high local confidence) and allows us to reach high quality solutions with shallow searches. Moreover, the heuristic to prioritize the discrepancies can noticeably reduce the time without hurting the performance.

5 Conclusions

In this paper we study the problem of entity disambiguation. We are inspired by the observation that local models in this task tend to produce reasonable solutions, such that with only a small number of corrections and a proper propagation of these corrections throughout the document, one can quickly find superior solutions that are globally more coherent.

Based on this observation, we propose a search based approach that starts from an initial solution from a local model, and uses Limited Discrepancy Search (LDS) to search through the space of possible corrections with the goal of improving the linking performance. The experimental results show that our global model improves the state of the art on both the CoNLL 2003 and TAC 2010 benchmarks. For future research, we are interested in further understanding of the strengths and weaknesses of the LDS-based approach for different types of queries and entities. We are also interested in applying different local models to initialize the LDS search.

Abstract

In this paper, we propose to use a sequence to sequence model for Named Entity Recognition (NER) and we explore the effectiveness of such model in a progressive NER setting – a Transfer Learning (TL) setting. We train an initial model on source data and transfer it to a model that can recognize new NE categories in the target data during a subsequent step, when the source data is no longer available. Our solution consists in: (i) to reshape and re-parametrize the output layer of the first learned model to enable the recognition of new NEs; (ii) to leave the rest of the architecture unchanged, such that it is initialized with parameters transferred from the initial model; and (iii) to fine tune the network on the target data. Most importantly, we design a new NER approach based on sequence to sequence (Seq2Seq) models, which can intuitively work better in our progressive setting. We compare our approach with a Bidirectional LSTM, which is a strong neural NER model. Our experiments show that the Seq2Seq model performs very well on the standard NER setting and it is more robust in the progressive setting. Our approach can recognize previously unseen NE categories while preserving the knowledge of the seen data.

1 Introduction

Standard NER models are trained and tested on data with the same NE label set. In this paper, we explore a progressive setting, where (i) in the initial step, the model is trained on a dataset D_{S} with certain NE categories; and (ii) in the subsequent step, we further train the model on a dataset D_{T} containing all categories from D_{S} along with the new ones, without using the examples from D_{S} since we assume they are no longer available. Our goal is to learn to recognize the new NE categories in D_{T} while keeping the knowledge of previously seen categories.

This study is motivated by the application of NER model in industry scenarios, where different companies may aim to recognize different types of NEs in the text. For example, users interested in finance would probably target entities such as companies or banks while other users interested in politics would target entities such as senators, bills, ministries, etc. Nevertheless, there are certain types of commonly-seen NE categories such as locations or dates that most users would like to recognize. These common NEs are typically provided with more available labeled data. Hence, methods that can utilize such data in new domains are rather useful. Additionally, the possibility to only use the models trained on such data is very important as it avoids the NER designer to deliver most training data to the user for adaptation in new domains. The setting above describes a TL problem, where the domain remains unchanged but the output space of the task changes: a graphical illustration of our progressive task is shown in Fig. 1.

Since the current state-of-the-art of NER is provided by neural models (Lample et al., 2016; Chiu and Nichols, 2016), we focus on them. In particular, we implement a baseline model with a bidirectional LSTM (BLSTM) as it is effective and does not require a heavy feature engineering for the task. BLSTM achieves competitive performance in comparisons with many other more complex state-of-the-art models, being much less complex. A drawback of such model is that, although its prediction takes the

Santa Fe, New Mexico, USA, August 20-26, 2018.

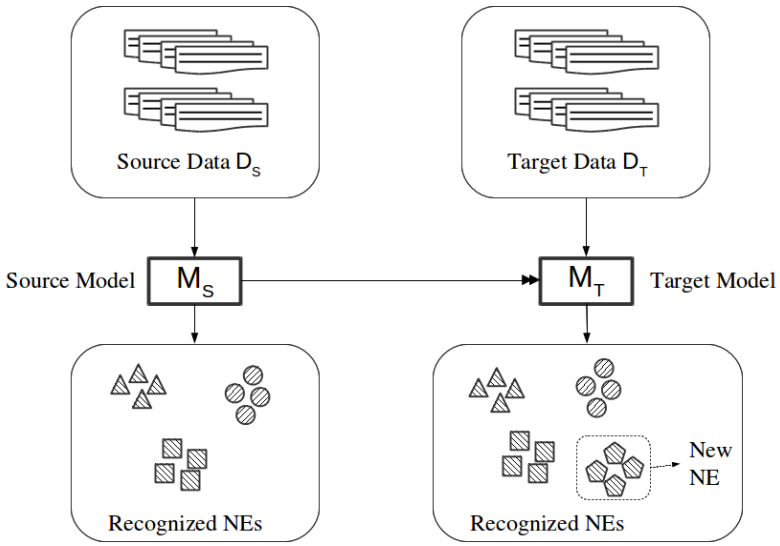

Figure 1: Progressive NER task setting.

surrounding context of the input word into account, it does not explicitly model the dependencies of the label sequence. To better capture these dependencies, we propose the use of Seq2Seq models for NER.

We speculate that Seq2Seq models can be suitable for our NER task for the following reasons: (i) they can be used to translate from a source language (the word sequence) to the target language (the label sequence); and (ii) on the decoder side, the current prediction is able to take the previous prediction into account, by feeding the previous output together with current input. This is an important property to build NERs, since the output sequence has some dependency assumptions among them (e.g., B-LOC cannot be followed by I-PER). Intuitively, Seq2Seq models can separate the mapping from input to output into two steps: encoding the information from input to an intermediate hidden space, and decoding the intermediate information to the output space. When the output space changes, as in our experiment, the model ought to better leverage the use of previously learned knowledge since the encoding of the input is still similar to the previous task.

Our solution to the task consists in (i) modifying the output layer of the model by adding neurons for the new NE category; (ii) transferring the parameters in the source model trained on data D_S to the target model that is trained on data D_T; and (iii) fine-tuning the obtained network on the target data. As for the proposed Seq2Seq model, we modify the output layer only on the decoder side. We conduct extensive experiments on progressive NER, analyzing the performance of both models. Our main contribution is twofold, we show that the Seq2Seq model is: (i) effective for the NER task, and (ii) more robust in the progressive NER setting as it does not forget previously learned knowledge about seen NE categories.

2 Related Work

In this section, we report related works on current state-of-the-art models for standard NER task, as well as the related works in the Transfer Learning and Progressive Learning areas.

2.1 Neural Models for NER

Early works on NER focused on engineering useful linguistic features for the task (Chieu and Ng, 2003; Carreras et al., 2003; Florian et al., 2003). The recent advances in the deep learning brought about new methods and produced a higher performance for the task. Current state-of-the-art models on standard NER are mostly neural models, in particular, Recurrent Neural Networks. These models incorporate word (sometimes also character) level embeddings and/or additional morphological word features for recognizing NE. Examples include CRF (Conditional Random Fields) over BLSTM (Bidirectional LSTM) model proposed by Lample et al. (2016) and BLSTM with Convolutional character feature extractor proposed by Chiu and Nichols (2016). We implement a BLSTM as the baseline model for pro-

gressive NER since it is an effective model that does not require a heavy feature engineering for the task. The performance of BLSTM model are reported in different works (Lample et al., 2016; Chiu and Nichols, 2016): this also makes it easier for us to conduct a comprehensive comparison with other works.

2.2 Seq2Seq Models

Although not previously used for NER task, Seq2Seq models have seen a great success in various applications, such as Neural Machine Translation by (Bahdanau et al., 2014; Luong et al., 2015), Speech Recognition (Lu et al., 2016; Zhang et al., 2017), Question Answering (Yin et al., 2016; Zhou et al., 2015) and so on. The idea of Seq2Seq model is to map a variable length source sequence to a fixed length vector representation by the encoder, and then remap it back to a variable length target sequence by the decoder. The Seq2Seq model was proposed by Cho et al. (2014) to learn phrase representations to be used in statistical Machine Translation. They reported empirical improvement of log-linear model performance while incorporating conditional probability of phrase pairs computed by the Seq2Seq model as additional features. Sutskever et al. (2014) also proposed a more general end-to-end approach to learn to map source sentences in one language into the translated sentences in the other.

To mitigate the bottleneck caused by mapping into a fixed-length vector, attention mechanism was proposed by Bahdanau et al. (2014). The attention mechanism works as a soft-alignment for the related parts in the source and target sequence. It is achieved by conditioning the prediction on a context vector that is calculated by the weighted sum of the encoder hidden states. Luong et al. (2015) further proposed global attention and local attention, to explore the effectiveness of different attention mechanisms. Our proposed model for NER is the same Seq2Seq architecture as proposed by Bahdanau et al. (2014), except that we use LSTM units for the encoder and decoder instead of simple RNN units. We also enforce an explicit alignment between the input word sequence and the output label sequence because the source and target sequences have a one-to-one mapping in the NER task.

2.3 Transfer Learning and Progressive Learning

Most machine learning methods assume the data for training and testing has the same feature space and distribution. TF is a technique that emerges to relax this assumption, allowing previously-learned knowledge to be used for a new task or in a new domain (Pan and Yang, 2010). Neural networks-based TL has proven to be very effective for image recognition (Donahue et al., 2014; Razavian et al., 2014). As for NLP, Mou et al. (2016) showed that TL can also be applied successfully on semantically equivalent NLP tasks. TL was applied on NER too, to transfer model and features on NER dataset with different NE entities (Qu et al., 2016; Kim et al., 2015).

Our learning paradigm falls in a more specific TL category – Progressive Learning. The Progressive Learning technique is adopted in multi-class classification by Venkatesan and Er (2016). They remodeled a network architecture (a single layer feed-forward network) by increasing the number of new neurons and interconnections while encountering unseen class labels in the dataset. The effectiveness of this technique is shown on several classic classification datasets. Our task is a sequence labeling task, where the independence assumption of output labels in a sequence does not hold. Hence, it cannot be treated as a set of classification tasks. We implement more sophisticated models and prove that the effectiveness of progressive learning techniques still holds.

3 Problem Formulation

In standard NER tasks, the model learns to maximize the conditional probability $P(Y|X)$ where $X = x_1, x_2, ..., x_n$ ($x_i \in \mathcal{X}$) is the input word sequence and $Y = y_1, y_2, ..., y_n$ ($y_i \in \mathcal{Y}$) is the output label sequence. $\mathcal{X}$ and $\mathcal{Y}$ represent the input and output space respectively. In our setting, in the initial step, the NER system is trained on the source dataset, D_{S}, which has C NE classes. Then, in the subsequent step, the model is presented with only the target dataset, D_{T}, which contains new examples annotated with the NE classes from the initial step and the E new classes. The initial model needs to adapt to be able to recognize the new E classes.

4 Models

We implemented (1) a BLSTM model, and (2) an attention-based Seq2Seq model for progressive NER. The input and output representation of both models is the expected to be the same.

4.1 Word & Character Embeddings

A word in the input sequence is represented by both its word-level and character-level embeddings. For the word-level representation, we use pretrained word embeddings to initialize an embedding lookup table to map the input word x (represented by an integer index) to a vector $\boldsymbol{w}$.

A character-level representation is typically used because the NER task is sensitive to the morphological traits of a word such as capitalization. They were shown to provide useful information for NER (Lample et al., 2016). We use a randomly initialized character embedding lookup table and then pass the embeddings to a character-level BLSTM (the details are described in Sec. 4.2) to obtain character level embedding $\boldsymbol{e}$ for x.

The complete representation of the t-th word $\boldsymbol{x}_t$ in the input sequence is the concatenation of its word-level embedding $\boldsymbol{w}_t$ and character-level embedding $\boldsymbol{e}_t$.

4.2 Bidirectional LSTM

BLSTM model is composed of a forward LSTM ($\overrightarrow{\text{LSTM}}$) and a backward LSTM ($\overleftarrow{\text{LSTM}}$), which read the input sequence (represented as word vectors described in the previous subsection) in both left-to-right and reverse order. The output of the BLSTM $\boldsymbol{h}_t$ is obtained by the concatenation of forward and backward output: $\boldsymbol{h}_t = [\overrightarrow{\boldsymbol{h}_t}; \overleftarrow{\boldsymbol{h}_t}]$, where

$$\overrightarrow{\boldsymbol{h}_t} = \overrightarrow{\text{LSTM}}(\boldsymbol{x}_t, \overrightarrow{\boldsymbol{h}}_{t-1})$$

and

$$\overleftarrow{\boldsymbol{h}_t} = \overleftarrow{\text{LSTM}}(\boldsymbol{x}_t, \overleftarrow{\boldsymbol{h}}_{t+1})$$

$\boldsymbol{h}_t$ captures the left and right context for $\boldsymbol{x}_t$ and is then fed into a fully-connected layer. The output of the fully connected layer is $\boldsymbol{p}_t$. The final prediction is obtained with a softmax over all possible tags as

$$\text{P}(y_t = m|\boldsymbol{p}_t) = \frac{e^{W_{o,m}\boldsymbol{p}_t}}{\sum_{m' \in M} e^{W_{o,m'}\boldsymbol{p}_t}},$$

where W_o are parameters to be learned and M represents the set of all the possible output labels.

In the case of character-level BSLTM, the forward and backward LSTMs take the sequence of character vectors $[\boldsymbol{z}_1, \boldsymbol{z}_2, ..., \boldsymbol{z}_k]$ as input, where k is the number of characters in a word. The final character level embedding $\boldsymbol{e}_t$ for a word at time t is obtained by concatenating $\overrightarrow{\boldsymbol{e}_t}$ and $\overleftarrow{\boldsymbol{e}_t}$.

4.3 Attention-based Encoder-Decoder

LSTM units are used in both encoder and decoder. On the encoder side, we use a BLSTM to capture the left and right context information of a word in the input sequence. The input to the encoder is the concatenation of word and character level embedding for each word, as the same as that for the BLSTM described above. The output $\boldsymbol{h}_t = [\overrightarrow{\boldsymbol{h}_t}; \overleftarrow{\boldsymbol{h}_t}]$ of the BLSTM at each time step t is later used for attention calculation. On the decoder side, we use a single layer LSTM that generates label predictions step by step from the start to the end of the sentence. The last hidden state of the forward encoder RNN ($\overrightarrow{\boldsymbol{h}_t}$) is used as the initial decoder hidden state. At each decoding time step, the decoder hidden state $\boldsymbol{s}_t$ is calculated by $\boldsymbol{s}_t = \sigma(\boldsymbol{s}_{t-1}, \boldsymbol{c}_t, y_{t-1}, \boldsymbol{h}_t)$, where $\boldsymbol{s}_{t-1}$ is the previous decoder hidden state, $\boldsymbol{c}_t$ is the context vector and y_{t-1} is the previous prediction. $\boldsymbol{c}_t$ is calculated as weighted sum of the encoder hidden state sequence as follows: $\boldsymbol{c}_t = \sum_{j=1}^{T} \alpha_{ij} \boldsymbol{h}_j$, where T is the total length of a sentence. The weight α_{ij} is obtained by applying a scoring function on the previous decoder hidden state $\boldsymbol{s}_{t-1}$ and the aligned encoder hidden state $\boldsymbol{h}_j$. More details on how attention is calculated can be found in the work of Bahdanau et al. (2014).

Since we have a specific sequence to sequence task, where each element of the input at a position t maps to an element of the output at the same position t, we define an explicit alignment between encoder and decoder by feeding the encoder hidden state $\boldsymbol{h}_t$ at time t to the decoder. We also restrict the decoder to output exactly T label predictions by restricting the recurrent step of decoder LSTM as T. This ensures the one-to-one mapping between the input words and the output labels. The final prediction of y_t is made by passing s_t to a fully-connected layer and then applying a softmax function over the output of this layer (the same as described in Sec. 4.2).

4.4 Progressive Adaption

Our proposed method for progressive NER is through pre-training a source model, transferring parameters to the target model and then fine-tuning such model. In the initial step, the model is trained on labeled source data until the optimal parameters $\hat{\theta}^{\mathrm{S}}$ are obtained and saved. $\hat{\theta}^{\mathrm{S}}$ include the parameters regarding the output layer $\hat{\theta}^{\mathrm{S}}_{output}$ and those regarding all the other layers $\hat{\theta}^{\mathrm{S}}_{-output}$.

To recognize the new NE categories, the major modification is made on the fully-connected layer after the BLSTM, i.e., the output layer of the network. In the BLSTM architecture, the fully-connected layer maps the output $\boldsymbol{h}$ of BLSTM to a vector $\boldsymbol{p}$ of size nC. n is a factor depending on the tagging format of the dataset (e.g., $n = 4$ if the dataset is in the BIOES format [1], since for each NE category, there would be 4 output labels *B-NE*, *I-NE*, *E-NE* and *S-NE*). To recognize the target NEs, we build the same model architecture for all layers before the output layer and initialize all their parameters by $\hat{\theta}^{\mathrm{S}}_{-output}$ obtained in the initial step. We extend the output layer with nE nodes, where E is the number of new NE categories. These are initialized with weights drawn from the random distribution $X \sim \mathcal{N}(\mu, \sigma^2)$, where μ and σ are the mean and standard deviation of the pre-trained weights in the same layer. [2] This way, the associated weight matrix of the fully-connected layer $\mathbf{W}^s_o$ also updates from the original shape $nC \times p$ to a new matrix $\mathbf{W}^{s'}_o$ of shape $(nC + nE) \times p$. Note that $\hat{\theta}^{\mathrm{S}}_{output}$ and $\hat{\theta}^{\mathrm{S}}_{-output}$ are essentially the weights in the matrix $\mathbf{W}^s_o$ and $\mathbf{W}^s_{-o}$. The new model parameters are updated in the same way as in the initial step.

5 Experiments

5.1 Data

We used the CONLL 2003 NER dataset[3] by modifying it to suit our experiment settings. The original dataset includes news articles with four types of named entities – organization, person, location and miscellaneous (represented by `ORG`, `PER`, `LOC`, and `MISC`, respectively). The `O` label indicates tokens that do not belong to any of these four named entities. The entity labels are annotated in BIOES format.

For the purpose of our experiment, we shuffle and divide the training set into 80%/20% partitions as D_{S} and D_{T} for the initial and the subsequent steps, as we assume that the size of the target data would be less than that of the source data. The validation and the test sets are the same in both steps in terms of the sentence instances, but different in label annotation. In particular, we create four datasets by (i) selecting one of the four categories as the new NE category to be recognized in the subsequent step; and (ii) substituting the labels of such category with `O` (not an entity) in D_{train_S}, D_{valid_S} and D_{test_S}. For example, when we use `LOC` as the new NE, we replace all the `LOC` label annotations with `O`, where they appear in D_{train_S}, D_{valid_S} and D_{test_S}. Instead, in D_{train_T}, D_{valid_T} and D_{test_T}, we keep `LOC` label annotation as is. A summary of label statistics for each case is shown in Table 1.

Apart from dividing the dataset into two components D_{S} and D_{T}, we do not perform any specific pre-processing of the dataset, except for replacing all digits with 0 to reduce the size of the vocabulary.

[1] The BIOES format (short for Begin, Inside, Outside, End and Single) is a common tagging format for tagging tokens.

[2] We initialize the weights using the approach producing the higher accuracy on the validation set. Our initizialization options are (i) set all parameters to zeros; (ii) using the random distribution $X \sim \mathcal{N}(\mu, \sigma^2)$, where $\mu = 0.0$ and $\sigma = 1.0$; and (iii) using the random distribution $X \sim \mathcal{N}(\mu, \sigma^2)$, where μ and σ are the mean and standard deviation of the pre-trained weights in the same layer.

Table 2: Value range and final value of hyperparameters for the BLSTM and the Seq2Seq models.

5.2 Models

We use 100 dimension GLOVE pretrained embedding[4] to initialize the word embedding lookup table. Since we do not lowercase the tokens in the input sequences, the words without direct mappings to the pretrained word embeddings are initialized as their lowercase counterparts, if found in the pretrained word embeddings. We replace the infrequent words, i.e., appearing less than two in the training set or in the test set, with *<UNK>*. The word embedding for *<UNK>* is randomly initialized by drawing from a uniform distribution between $[-0.25, 0.25]$.

We perform hyperparameter optimization by a Random Search (Bergstra and Bengio, 2012) on different intervals for each hyperparameter for both models, including the size for the character and word level embeddings of the BLSTMs, the batch size, the learning rate, the dropout rate and the maximum value for gradient clipping. Tab. 2 shows the intervals and the final values for each hyperparameter, where the final values are the ones giving the best performance on the validation set (D_{valid_S}) in each experiment setting.

5.3 Training

Both models are implemented in PyTorch (Paszke et al., 2017). [5] We use Stochastic Gradient Descent with a momentum of 0.9 to minimize the multi-class cross entropy. We apply dropout layer in both models to control overfitting. During each step, we allow a maximum epoch number of 200. The early stopping of the training is enforced if the F1 score on the validation set does not improve for 30 epochs. From our preliminary experiments, we found out that keeping the transferred parameters fixed during the subsequent step usually produces worse results for both models. Thus, in the subsequent step, the transferred parameters are not fixed but updated together with the rest of the network. We evaluate the F1 score of the models using the CONLL script.

Table 4: Test F1 of the Seq2Seq model on each category.

5.4 Results

Our baseline BLSTM model performs in-line with the BLSTM models reported by Lample et al. (2016) or by Chiu and Nichols (2016). We obtained an overall F1 score of 89.74 on traditional setting of NER. The Seq2Seq model outperformed the baseline model by 1.24 points in F1, reaching 90.98. The latter is comparable to some of the state-of-the-art results reported on the CONLL dataset.

5.4.1 Performance on Source Data

The performance of the BLSTM and Seq2Seq models in our progressive learning setting is shown in tables 3 and 4, respectively. Sub-level tables (a), (b), (c) and (d) report the test F1 in different experiment settings – recognizing different target new NE in the subsequent step. *Init.* indicates the F1 scores in the initial step, while *Sub.* indicates the scores in the subsequent step. *Rand.* reports the test F1 scores obtained by the same model architecture but with randomly initialized parameters and trained with all the target data in the subsequent step.

The training in the initial step and for the model with randomly initialized parameter in the subsequent step can be seen as a standard NER task. We further report a comparison of the performance of both models in the initial step as well as with the randomly initialized parameters in Figure 2. We can see that the Seq2Seq model outperforms the BLSTM model in all experiment settings. This supports our argument that the Seq2Seq model can be a better approach for the NER task than BLSTM due to its ability to exploit the previous predicted labels.

5.4.2 Transferred Parameters vs. Randomly Initialized Parameters

By construction, there is always a label disagreement between the data of the initial and of the subsequent steps for the new NE, as it is annotated as `O` in the data for the initial step. We can derive some interesting observations from the comparison between the F1 of the model using randomly initialized parameters (Column *Rand.* in each table) and the F1 of the model using transferred parameters in the subsequent step (Column *Sub.* in each table). In almost all cases, using transferred parameters produces better performance, by around 2 to 3 points in F1. In terms of the target new NE category, the models using transferred parameters are able to perform better than the models with only randomly-initialized parameters. This is because we allow the transferred parameters to be updated together with the other model parameters in the subsequent step. Such approach can recover from the adverse knowledge learned in the initial step with regard to treating the target new label as `O`. The only exception is when using `MISC` as target new NE. The F1 obtained by randomly initialized parameters for both BLSTM and Seq2Seq model is higher than the one obtained by the models using transferred parameters. This may be explained by the fact that the `MISC` category is a collection of NEs that do not fit into other categories. Thus, the context of such NEs may vary a lot from one to another, making the recovery from the previously-learned adverse knowledge on this NE category more challenging, e.g., its new context and information in the subsequent step are sparser.

We allow a maximum of 200 epochs in the subsequent step while forcing the training to stop when the F1 score on the validation set does not improve for more than 30 epochs. Even if we increase the training epochs to 60 for the model using randomly initialized parameters, transferred parameters still perform better. We also observed that the model with transferred parameters converges faster during the subsequent training, in around 20 epochs. This suggests that our progressive learning technique enables the models to more accurately predict the new categories and in a shorter time. That is, the transferred parameters not only help the model to reach a superior performance, but also provide a better initialization for the model to converge faster.

5.4.3 Original NE Classes vs. New Target NE Class

The improvement or decrease of the F1 for the original NE categories is an indicator of how well the model is able to preserve the learned knowledge transferred from the initial step. In Table 5, we report the difference of test F1 between the initial and the subsequent steps, for each of the original NE categories, using the BLSTM and Seq2Seq models. In this table, lower value means a lower loss in the F1 score, i.e., the model is better in preserving the performance on the NE categories that are seen in the initial step. In almost all cases, the Seq2Seq model suffers less degradation in F1. In some cases, the Seq2Seq model is able to further learn from the subsequent data and achieve better performance on these original NE categories. For example, when using `PER` as the new NE category, the Seq2Seq model is able to improve the performance on `LOC` and `MISC`, while the BLSTM model decreases its F1.

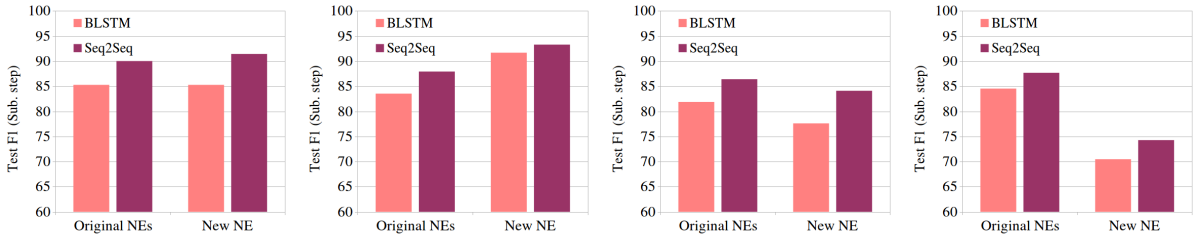
The ability of the model in terms of learning to recognize the new NE category is directly reflected by the test F1 score in the subsequent step of the target NE category of different settings, as shown in

	LOC as new NE		PER as new NE		ORG as new NE		MISC as new NE	
	BLSTM	Seq2Seq	BLSTM	Seq2Seq	BLSTM	Seq2Seq	BLSTM	Seq2Seq
MISC	2.51	2.03	1.69	-0.07	0.79	-0.88	-	-
ORG	1.23	1.07	0.66	0.71	-	-	0.79	0.79
PER	-0.28	-0.07	-	-	0.15	0.12	0.26	0.11
LOC	-	-	0.30	-0.09	1.35	-0.03	1.09	0.17

Table 5: Difference of the test F1 score from the initial step to the subsequent step (lower value is better, while a negative value means that the model is able to further improve).

	BLSTM	Seq2Seq
LOC	88.58	91.33
PER	91.96	93.30
ORG	77.61	84.11
MISC	70.48	74.28

Table 6: Test F1 on the new target NE in the subsequent step.



(a) LOC as new NE (b) PER as new NE (c) ORG as new NE (d) MISC as new NE

Figure 3: Test F1 scores obtained on the original NEs and the target new NE by the BLSTM and the Seq2Seq model.

Table 6. As it is evident from the table, in all cases, the Seq2Seq model produces better test F1 scores by 2 to 3 points at least. In the case of ORG label, the performance of the Seq2Seq model surpasses that of the BLSTM model by nearly 7 points. By comparing both the performance on the original labels and on the target new label, as shown in Figure 3, we see that the performance of Seq2Seq model is better than the baseline BLSTM in both the original and the new NE classes. It can be concluded that Seq2Seq model is more robust in the subsequent step regarding recognizing the new target NE category while it does not degrade the performance of the original NE categories.

6 Conclusions

In this work, we propose to use attention-based Seq2Seq models for both standard NER task as well as the progressive NER task, which is a more practical scenario of industry level applications of NER. We argue that the Seq2Seq model is suitable for both settings. Our experimental results support our claim as the Seq2Seq model outperforms BLSTM in both standard and progressive NER settings. Further analyses show that the Seq2Seq model is better in both preserving the knowledge learned from the source data, and in learning the new knowledge from the target data. We also demonstrated the effectiveness of the proposed progressive learning technique in the NER task. In future work, we would like to experiment with other datasets as well as extend our methods to target data that is only annotated with the new NE category. It would be also interesting to apply our model and technique to other areas such as domain adaptation or few-shot learning.

Responding E-commerce Product Questions via Exploiting QA Collections and Reviews

Qian Yu, Wai Lam, Zihao Wang
Department of Systems Engineering and Engineering Management
The Chinese University of Hong Kong
{yuqian, wlam, zhwang}@se.cuhk.edu.hk

Abstract

Providing instant responses for product questions in E-commerce sites can significantly improve satisfaction of potential consumers. We propose a new framework for automatically responding product questions newly posed by users via exploiting existing QA collections and review collections in a coordinated manner. Our framework can return a ranked list of snippets serving as the automated response for a given question, where each snippet can be a sentence from reviews or an existing question-answer pair. One major subtask in our framework is question-based response review ranking. Learning for response review ranking is challenging since there is no labeled response review available. The collection of existing QA pairs are exploited as distant supervision for learning to rank responses. With proposed distant supervision paradigm, the learned response ranking model makes use of the knowledge in the QA pairs and the corresponding retrieved review lists. Extensive experiments on datasets collected from a real-world commercial E-commerce site demonstrate the effectiveness of our proposed framework.

1 Introduction

Many E-commerce sites provide product information on product pages. Under a particular product page, users can ask questions about the corresponding product. Other experienced or qualified users can voluntarily provide answers. Thus, for each product, a product-specific question-answer (QA) collection is commonly available in E-commerce sites. However, the amount of QA pairs in the QA collection associated with a product is small since it is product-specific. In addition to the QA collection, users may write reviews about the product and a product-specific review collection is also commonly available. Figure 1 depicts an example, from a real-world E-commerce site, of a product page of a bluetooth car device. In this product page, the middle region contains the question-answer collection. The bottom region contains the review collection. Users may browse those two information sources for obtaining useful or insightful information about the corresponding product.

Both information sources mentioned above would be helpful for providing instant responses to questions newly posed by users about the corresponding product. Consider a new question "Is this device compatible with 2004 VW Jetta SportWagen?", a semantically similar question can be found in the existing QA collection of this product. Specifically the first question is a good match with the new question. Thus, the user posed answer for that question can be extracted as the response. On the other hand, consider another new question "Can I use iPhone 4s with it?". This new question cannot match any existing question well. In spite of that, the review sentence "My iPhone 4S connected with the unit and uploaded my contacts with no issues." found in the review collection of the corresponding product can provide informative content which can be retrieved as a response.

In this paper, we investigate the problem of responding E-commerce product questions newly posed by users. We aim at providing responses before any answer is posed by other users. Such kind of instant responses can improve user satisfaction. As aforementioned, two commonly available information

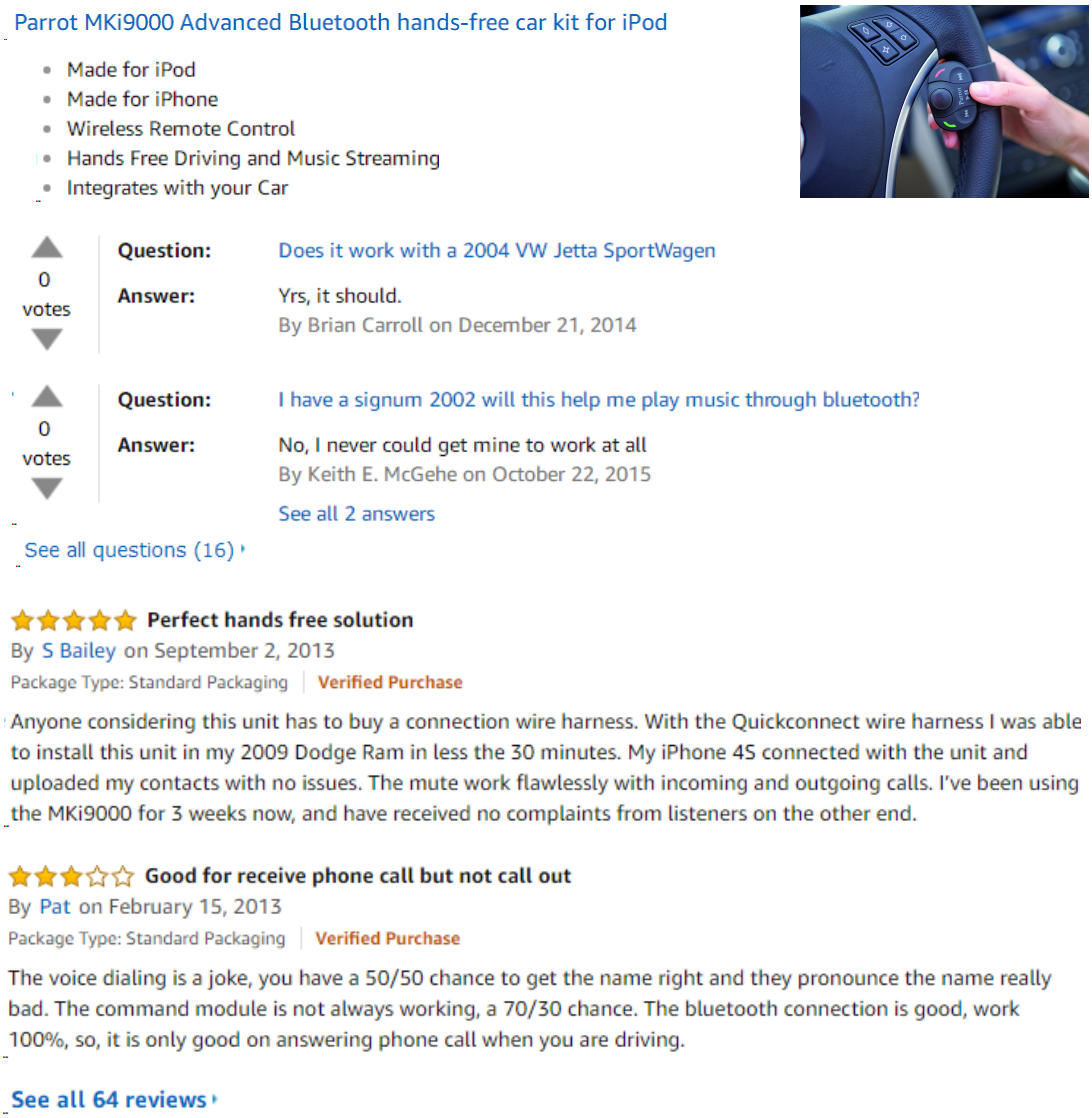

Figure 1: A product page of a bluetooth car device.

sources, namely, question-answer collections and review collections contain valuable information for generating instant responses for product questions. Consequently, given a question, our framework can return a ranked list of snippets serving as the automated response, where each snippet can be a sentence from reviews or an existing question-answer pair.

Community Question Answering (CQA) approaches can be employed, but they can only make use of the QA collection of the corresponding product, which typically contains just a small amount of QA pairs. Furthermore, similar questions associated with other products are not helpful due to different product specifications. Another limitation of CQA methods is that they cannot make use of the review collection which is another important information source for generating responses. Another possible approach is to employ a question answering learning approach such as QA-LSTM (Tan et al., 2016). But these QA models typically cannot effectively exploit reviews due to the heterogeneous nature of answer collections and review collections. Recently a chatbot for E-commerce sites known as SuperAgent has been developed (Cui et al., 2017). SuperAgent considers both QA collections and reviews when answering questions. However, it employs separated modules for each of the information sources without mutual coordination. Moreover, it requires external knowledge and a large volume of annotated data. Some models based on Mixture of Expert (MoE) (McAuley and Yang, 2016; Wan and McAuley, 2016) are proposed for handling product questions. Although the learning procedures of these models involve

QA collections and reviews, these models assume that the candidate answer set only comes from existing QA pairs containing the correct answers. Such setting is not practical for instant response generation.

We propose a new framework which is able to automatically respond product questions newly posed by users via exploiting question-answer collections and review collections in a coordinated manner. One major subtask in our framework is question-based response review ranking which aims at extracting reviews that are suitable for providing the response to the given question. Learning for response review ranking in this problem setting is challenging since no labeled review sample is available. The existing QA pairs in the corresponding QA collection contains knowledge for response ranking. These QA pairs and the corresponding retrieved review lists can be exploited as distant supervision for question-based response ranking. The relationship between such available QA pairs and reviews can be modeled for facilitating the learning of question-based review ranking.

2 Related Work

Product question answering is an emerging topic. Yu et al. (2012) extract hierarchical structure from the product review collection, and then select sentences from reviews based on the structure. Their model only focuses on review collections. Community Question Answering (CQA) (Zhou et al., 2011) approaches can be adopted to tackle this problem. For example, Zhou et al. (2015) propose to learn continuous word embeddings based on the QA corpus incorporating metadata such as category information, and the learned word embedding can be applied for question retrieval in CQA platform. Chen et al. (2018) encode the question text together with users' social interactions for handling the lexical gap among questions. A random walk based learning method is designed to facilitate the similarities evaluation via the recurrent neural network. One shortcoming of these CQA methods for tackling the task of E-commerce product questions is that they can only make use of the typically small QA collection of the corresponding product, and similar questions associated with other products are not helpful due to different specifications.

QA models (Shen et al., 2017; Yang et al., 2016) try to capture the relation between questions and answers. QA-LSTM (Tan et al., 2016) is developed for question answer matching via bidirectional LSTM with max pooling. The QA model proposed in (Wang and Jiang, 2016) also utilizes LSTM. Learning-to-rank model has also been adopted in some method for question-answer matching, such as in (Surdeanu et al., 2008). Generally existing QA models cannot handle the heterogeneous nature of answer collections and review collections in the problem setting investigated in this paper. McAuley and Yang (2016) propose to exploit product reviews for answer prediction via a Mixture of Expert (MoE) model. This MoE model makes use of a review relevance function and an answer prediction function. One restriction of this model is that it can only be used for answer selection given a candidate answer set. Although the QA collections and review collections are involved in the learning procedures, one assumption is that a candidate answer set containing the correct answers is available for answer selection. Such setting is not practical for instant response generation. In addition, both the above mentioned models only make use of information from reviews, while existing question-answer pairs of the corresponding product are ignored. A chatbot for E-commerce sites known as SuperAgent has been developed (Cui et al., 2017). SuperAgent considers both QA collections and reviews when answering questions. However, there is no mutual coordination for the response generation from different information sources, and the response from SuperAgent cannot be presented as a ranked list of snippets. Moreover, the training procedures of some modules in this system require external knowledge and a large volume of annotated data, including a set of similar question pairs.

3 Our Proposed Framework

3.1 Framework Overview

Our proposed framework exploits QA collections and review collections for instant responses of E-commerce product questions newly posed by users. The output is a ranked list of snippets providing relevant information related to the response of the question. Each snippet can be a sentence from reviews

or an existing QA pair. There are two main components in our framework, namely, response review ranking component and response generation component.

The response review ranking component tackles a major subtask whose aim is to extract response reviews that are suitable for providing the response to the given question. Learning for response review ranking in this problem setting is challenging and it cannot be handled by supervised learning. The reason is that there is no ground truth question-based reviews which can be used for training. The existing QA pairs and the corresponding retrieved review lists contains knowledge for response review ranking. To learn a question-based review ranking model, the relationship between the available QA pairs and reviews needs to be modeled. To this end, we develop a distant supervision paradigm for incorporating the knowledge contained in QA collections into response review ranking. An adapted Learning to Rank (LTR) method is designed in this distant supervision paradigm.

The aim of the response generation component is to generate a list of snippets which serve as the response of a given question newly posed by a user. Both the existing question-answer pairs in the QA collection of the corresponding product and question-based ranked reviews from the review collection of the corresponding product are considered in a coordinated manner. Semantically similar questions are extracted, if exist, via processing the question-answer pairs in the QA collection. The retrieved question-answer pairs are reformulated based on the corresponding review collection, and then integrated into the response review ranking model.

3.2 Response Review Ranking Model

As mentioned above, the aim of response review ranking is to extract reviews that can provide the response to a given question. Consider a E-commerce product t with the corresponding review collection R_t. Given a new question q_0 associated with this product, we wish to obtain the score $S(q_0, r)$ for each review $r \in R_t$. Based on this score, a ranked list of response reviews $L_{r|q_0} = (r_{1|q_0}, r_{2|q_0}, ...)$ can be obtained. A learning model is designed for tackling this subtask. Different from answer selection in CQA, response review ranking cannot be tackled via supervised learning. Suppose we have an existing question q in the question collections, the only available data is the question-answer pair (q, a) while no ground truth question-review pair (q, r) is available for the learning of this component. This setting makes this subtask challenging. Thus, we model the relationship between (q, a) pairs of the corresponding product t and the review set R_t. Such modeling can be regarded as a distant supervision paradigm based on the knowledge in the existing QA pairs for the learning of question-based response review ranking. In this way, we exploit the knowledge in QA pairs in the corresponding QA collection and learn the response review ranking model $p(r|q) \triangleq S(q, r)$, where $S(q, r)$ is the ranking score of the review r given the question q. An adapted Learning to Rank (LTR) method is designed in this distant supervision paradigm, with various types of features are designed.

3.2.1 Distant Learning Paradigm

Training Instance Preparation for Question-based Response Review Ranking. From the QA collections, we can obtain question-answer pairs. Each question-answer pair can provide knowledge about the corresponding product, and neither the question nor the answer alone is adequate for conveying the same semantics as the question-answer pair. We use question-answer pairs as queries for retrieving and ranking reviews, and the top ranked reviews are utilized as the training data for the question-based LTR model.

Given a question-answer pair (q, a), the review collection of the corresponding product is processed. We employ the Positional Language Model (PLM) (Lv and Zhai, 2009) to rank the reviews using (q, a) as the query. Formally, given a review r and a term position k, the PLM of r at this position is:

$$p(w|r, k) = \frac{c'(w, k)}{\sum_{w' \in V} c'(w', k)} \quad (1)$$

where $c'(w,k)$ is the pseudo word count of the word w at the position k:

$$c'(w,k) = \sum_{j=1}^{|r|} c(w,j) f(k,j) \tag{2}$$

and $f(k,j)$ is a weight given to another position. Basically, the closer are the position k and j, the larger value is assigned by $f(k,j)$. In our implementation, we use the Gaussian kernel for $f(k,j)$ as mentioned in (Lv and Zhai, 2009). To obtain an available relevant review ranking list, we design a modified relevance score of PLM:

$$S((q,a),r) = \max_{i\in[1,|r|]} \{S(q,r,i) + S(a,r,i)\} \tag{3}$$

$$= \max_{i\in[1,|r|]} \left\{ -\sum_{w\in V} p(w|q) \log \frac{p(w|q)}{p(w|r,i)} - \sum_{w\in V} p(w|a) \log \frac{p(w|a)}{p(w|r,i)} \right\} \tag{4}$$

We denote the review ranking list based on (q,a) as

$$L_{r|q,a} = (r_{1|q,a}, r_{2|q,a}, ..., r_{n|q,a}) \tag{5}$$

where $r_{i|q,a}$ is the i-th review sentence ranked by the question-answer pair (q,a). The top ranked reviews in this QA-based review ranking list $L_{r|q,a}$ are more relevant to (q,a) and are useful for capturing the knowledge of response review ranking. Thus, we truncate the review ranking list via retaining only the top M ranked reviews as the response reviews.

Since our goal is question-based review ranking, each $L_{r|q,a}$ is integrated with the question q and a training instance is packaged as $(q, L_{r|q,a})$. Here the answer is removed from the training instance even though it participates in the generation of $L_{r|q,a}$. The reason is that there is no available answer for questions newly posed by users during operation or testing. The response review ranking ability of the question-answer pair (q,a) is captured in the response review ranking list $L_{r|q,a}$, and this training instance can be utilized to guide the review ranking based on only the question text. Another issue about the training instance preparation is that different answers have different quality in regard to the question, and the instance based on answers with high quality should have more influence on the learning of the response review ranking model. To achieve this goal, for each question q, we sample training instances from its related response review ranking set $\{L_{r|q,a_1}, L_{r|q,a_2}, ...\}$. The sampling probability of the ranking list $L_{r|q,a_i}$ is the probability of the answer a given the question q, namely $p(a|q)$. We utilize a learning-to-rank model trained with the QA collections to generate $p(a|q)$, and this model makes use of the features as described in Section 3.2.2.

Question-based Learning to Rank. Based on the sampled $L_{r|q,a}$ instances, we utilize the pair-wise learning to rank model to make use of these response review ranking lists to the maximum extent. For each question-review pair, we make use of the features presented in Section 3.2.2. These features are concatenated as a vector denoted as $f^q(r)$. The details about this designed features will be described in Section 3.2.2.

Suppose for two response review r_i and r_j, we obtain the feature vectors $f^q(r_i)$ and $f^q(r_j)$. The probability that the review r_i is ranked higher than the review r_j is formulated as:

$$P^q_{ij} = P(r_i \rhd r_j) = \frac{1}{1 + e^{-\beta[f^q(r_i) - f^q(r_j)]}} \tag{6}$$

To learn a probability model for question-base review ranking, we minimize the cross entropy of the ranking probability generated from the model and the ranking probability from the training instances. Formally, the objective function can be written as:

$$O = -\bar{P_{ij}} \log P_{ij} - (1 - \bar{P_{ij}}) \log(1 - P_{ij}) \tag{7}$$

In our implementation, we utilize the training method with boosting in LambdaMART (Wu et al., 2010) to update the parameters in our response review ranking model.

3.2.2 Feature Design

We describe the features utilized in our LTR models.

- **Features based on Likelihood.** Generation likelihood (Jin et al., 2002) plays an important role in information retrieval. Two related features are designed, namely, the question likelihood given review and the review likelihood given question. For a question q and a review r, the question likelihood can be computed by multiplying the likelihood of query terms w given r, denoted as $p_\lambda(w|r)$. The likelihood is smoothed by Jelinek-Mercer method:

$$p_\lambda(w|r) = (1-\lambda)p(w|r) + \lambda p(w|C_r) \tag{8}$$

  where $p(w|C_r)$ is the probability of the term w in the review collection. Similarly, we can formulate the second feature about the likelihood of the reviews given the question q.

- **Features based on Aspect-based Similarity.** For text data from E-commerce platforms, aspects are an important concept which captures features or attributes about products. Two features related to aspects are designed. The first feature is derived from the aspect discovery model based on Latent Dirichlet Allocation (LDA) (Zhao et al., 2010). Trained with the text collection containing reviews, questions and answers, this model can transform each given text into an aspect representation. Let the representations for a question q and a review r be denoted as $v(q)$ and $v(r)$. We employ the cosine similarity score of these two representations to model the aspect-based similarity between the question and the review. The second feature is based on the Restricted Boltzmann Machine (RBM) (Wang et al., 2015) trained as an aspect modeling. The learned hidden representation from RBM contains aspect information and can be obtained efficiently. Similar to the aspect-based similarity in the first feature, we can also compute a similarity score based on the RBM as the second feature.

- **Features based on Word Embedding** Word embedding techniques map each term to a distributed representation capturing semantics of text. Three features are designed according to different types of word embedding. For the first two features, we adopt a set of pre-trained word embedding, known as Global Vectors for word representation (GloVe)(Pennington et al., 2014). Given a question $q = (t_1^q, t_2^q, ...)$, each term t_i^q in q can be represented as a word embedding denoted as $v(t_i^q)$. Then the question q can be represented as the average of each term representation. The review sentence is also represented in the same way. Then the first feature is obtained by computing the inner product of these two representations reflecting the semantic similarity between the question q and the review r. Another representation of question is to use the largest value in each dimension among all the term vectors as the value of the corresponding dimension in the question representation. Then the second feature can be obtained in a similar manner. Besides the pre-trained word embedding, we also implement an autoencoder with the reconstruction function as the objective function. This autoencoder is trained via the collection of reviews, questions and answers, for capturing the intrinsic elements of text useful for reconstruction. In this way, we obtain a new embedding of questions and reviews, and the corresponding similarity score can be obtained as the third embedding-based feature.

- **Features based on Word Count** Some simple features also contribute to some extent. These features include the word count of a review, the ratio of the review word count and the question word count, and the number of matched words between the question and the review.

3.3 Response Generation

As mentioned above, the aim of the response generation component is to generate a ranked list of snippets treated as the response to the given question. The snippets are extracted from the existing QA collection and the review collection of the corresponding product. To obtain this snippet ranking list, we integrate the question-answer pair result and the review ranking result in a unified ranking model so that the heterogeneous nature between these two collections can be handled in a coordinated manner.

Consider an E-commerce product t with the QA collection Q_t and the review collection R_t. Given a question q_0 associated with this product newly posed by a user, we retrieve semantically similar questions from the QA collection Q_t via searching the question-answer pairs. Specifically, we utilize the Positional Language Model (PLM) (Lv and Zhai, 2009) for question retrieval and obtain a ranked list of retrieved existing questions denoted by $L_{q^*,a^*|q}$. The next step is to utilize the trained LTR model described in Section 3.2 to reformulate each retrieved QA pair $(q_i, a_i) \in L_{q^*,a^*|q}$. The rationale is to narrow the syntactic gap between the QA pairs and the review collection so that QA pairs and reviews can be ranked in a unified model. Suppose that given the new question, we retrieve a similar QA pair (q_1, a_1). We then use (q_1, a_1) as the query to retrieve and rank the reviews in the review collection R_t, and obtain the top ranked reviews $\{r_{1|q_1,a_1}, r_{2|q_1,a_1}, ..., r_{M|q_1,a_1}\}$ in $L_{r|q_1,a_1}$. The reformulation method is designed as follows:

$$r_{q_i,a_i} =< q_i, a_i, \lambda \cdot r_{1|q_i,a_i}, \lambda \cdot r_{2|q_i,a_i}, ... > \tag{9}$$

where $< a, \lambda \cdot b >$ stands for concatenating the bag-of-word model of the two text a and b, and λ is the weight of b for the concatenation. Then we use the trained response review ranking model described in Section 3.2 to rank all the snippets in the set:

$$T = \{r_{q_1,a_1}, r_{q_2,a_2}, ..., r_{q_N,a_N}, \{r\}\} \tag{10}$$

where r_{q_i,a_i} is the pseudo review based on the reformulated QA pairs.

4 Experiments

4.1 Data Collections

We conduct our experiments using two datasets from a real-world E-commerce site, namely *Amazon.com*[1]. The first dataset is from the product category "Cell Phones & Accessories" and the second dataset is from the category "Clothing, Shoes & Jewelry". These two datasets were originally collected by McAuley et al. (McAuley and Yang, 2016; Wan and McAuley, 2016) containing a large number of products, question-answer pairs [2], and reviews [3]. For each product category, we randomly select around 50 questions to form the testing set, and conduct annotations so that these questions can be used for evaluation purpose. The remaining questions are retained as the training set. Regarding the annotation of the testing questions, consider each testing question, we collect the existing QA collection of the corresponding product. Then we examine each QA pair and annotate whether it is semantically similar to a given testing question. Similarly we collect the existing review collection of the corresponding product. We examine each review and annotate whether it can be used as a response for a given testing question. The detailed statistics of the datasets is depicted in Table 1.

Table 1: Statistics of the Datasets

Category	Cell Phones & Accessories	Clothing, Shoes & Jewelry
# of product	10320	2871
# of question	60791	17233
# of review	3447249	5748920
Ave. length of question	12.4	15.2
Ave. length of review sentence	13.9	14.1
# of question for testing	53	55
# of question w/ response reviews	53	55
# of question w/ similar QA Pairs	12	20

[2] http://jmcauley.ucsd.edu/data/amazon/qa/

[3] http://jmcauley.ucsd.edu/data/amazon/

4.2 Experiment Settings

We conduct sentence segmentation for the reviews. Terms in text such as review sentences, questions, and answer are lemmatized. Stopwords and punctuations are removed. The parameter value of M in Section 3.2 is set to 50. In Jelinek-Mercer smoothing method for LM, the interpolation parameter λ is set to 0.8. For both LDA and RBM in Section 3.2.2, the dimension of hidden layer is set to 10. For pre-trained word embedding, 300-dimension GloVe embeddings are utilized. In the autoencoder for word embedding, the dimension of hidden layer is set to 10.

We implement several baseline and state-of-the-art models to compare with our proposed framework.

- **Language Model (LM)**(Jin et al., 2002). We regard the given new question as the query, and calculate the query likelihood from each review and each question-answer pair via a language model. The list of output snippets are ranked by the question likelihood.

- **Positional Language Model (PLM)** (Lv and Zhai, 2009). Similar to LM, PLM models each document and provides query likelihood considering positional information. The list of output snippets are ranked by the positional question likelihood.

- **QA-LTR** (Surdeanu et al., 2008). QA-LTR is a supervised learning-to-rank model for answer selection, making use of a large volume labeled question-answer pairs. The original QA-LTR model is designed for online QA collections. Hence some features are not suitable. We implement QA-LTR with features replaced by our designed features described in Section 3.2.2. We expand the existing collection of question-answer pairs by including some relevant reviews to form the positive instance training set. Specifically, given a question q in the training set with its answer set A_q, we add similar reviews as candidate answers into A_q. For each $a \in A_q$, we retrieve k review sentences that have the largest similarity to a, denoted as $\{r_1^a, r_2^a, ..., r_k^a\}$. These retrieved reviews are added into the answer set A_q of the question q. We set k to 2 which yields the best performance.

- **QA-LSTM** (Tan et al., 2016). QA-LSTM is one of the state-of-the-art representation learning models for question answering matching. Equipped with bidirectional LSTM and maximum pooling, QA-LSTM has been applied to answer selection. In our experiment, we utilize this model to obtain semantic representation of questions and reviews, and to estimate the matching score given a question q_0 and a review r_0. Similar as in the training of QA-LSTM, the positive instances also include reviews via expanding the existing answer set for each question.

- **Ours.** It denotes our proposed framework.

The evaluation metrics are Normalized Discounted Cumulative Gain (NDCG), Mean Average Precision (MAP), and Mean Reciprocal Rank (MRR). We conduct the t-test for the results to compare the performance improvement over QA-LSTM and QA-LTR, with the significance level being 0.05.

4.3 Product Question Response Performance

Table 2: Response Performance. †, ‡ indicate that Ours is statistical significant at the significance level of 0.05 over QA-LSTM and QA-LTR respectively.

	Cell Phones & Accessories			Clothing, Shoes & Jewelry		
Model	NDCG	MAP	MRR	NDCG	MAP	MRR
LM	0.298	0.137	0.247	0.305	0.146	0.261
PLM	0.307	0.148	0.260	0.321	0.178	0.294
QA-LTR	0.369	0.177	0.403	0.392	0.192	0.320
QA-LSTM	0.397	0.184	0.390	0.407	0.211	0.367
Ours	$0.493^{\dagger\ddagger}$	$0.236^{\dagger\ddagger}$	$0.532^{\dagger\ddagger}$	$0.424^{\ddagger}$	$0.247^{\dagger\ddagger}$	$0.492^{\dagger\ddagger}$

The result is shown in Table 2 for the two product categories. We can observe that our proposed model "Ours" outperforms all the other models. It is statistical significant that our proposed framework

is better than QA-LSTM and QA-LTR. The results indicate that traditional information retrieval method cannot effectively handle the product question response. The reason is that our target is to find the review sentences or existing question-answer pairs that can answer the given question, instead of just retrieving relevant text for the question. The semantic relationship between questions and reviews cannot be modeled via information retrieval models. QA models, namely, QA-LTR and QA-LSTM are not effective as compared to our proposed framework despite the fact that QA models have been previously utilized for review ranking. It reveals that existing QA models have limitation when handling the heterogeneous nature of the review collections and the QA collections. In contrast, the distant supervision paradigm in our framework is more suitable. One main advantage of our proposed paradigm is that it can exploit both information sources in a coordinated manner.

Table 3: Response Performance with different amount of training data.

	Cell Phones & Accessories			Clothing, Shoes & Jewelry		
Model	NDCG	MAP	MRR	NDCG	MAP	MRR
Ours w/ all training data	0.493	0.236	0.532	0.424	0.247	0.492
Ours w/ 1/2 training data	0.483	0.219	0.521	0.421	0.230	0.479
Ours w/ 1/3 training data	0.470	0.201	0.492	0.401	0.215	0.440
Ours w/ 1/4 training data	0.403	0.189	0.453	0.365	0.157	0.398

In addition, we evaluate the performance of our framework under different amount of training data, and the result is presented in Table 3. "Ours w/ 1/n training data" stands for our proposed framework trained with only 1/n of all the training data. We can observe that even when we use a partial amount of the training data, the performance of the response generation does not drop significantly. It demonstrates that our proposed framework can effectively make use of the available training data including QA pairs and QA-based review ranking.

4.4 Case Study

We present a sample case study to gain more insights. Table 4 contains a response snippet list produced from our framework given a new question. The product is a cable and the new question is about how to use the cable for photo transfer to a Mac. The snippets in the response are compposed of review sentences and an existing QA pair. Specifically, the first ranked snippet is a question-answer pair talking about transferring photos from a mobile phone to a Mac. The following snippets come from reviews and they mention that the cable is not for data transferring. Thus, the user can receive informative response extracted from both the review collection and the QA collection associated with the corresponding product.

Table 4: A case study.

Newly posed question
Does anyone know if this cord will work to transfer photos by USB to a Mac? or is it just PC? Thanks!
Response Snippet List
Q: What do I need to get to transfer photos from phone to a Mac if this cable won't work? A: Not quite sure to be honest but maybe if the phone supports like sending emails then you can send your photos through email and download the photos onto your Mac from your email if the cable doesn't work but it should.
It would be nice if it could be used to transfer pictures, but if it can they sure do not make it easy.
Read all descriptions carefully because some of the cables are USB charging cables and do not transfer data!
This is not a data cable.

5 Conclusions

We propose a framework for instant product question response considering two common information sources, namely, existing QA collections and review collections. Our framework exploits both information sources in a coordinated manner. The distant supervision paradigm is adopted for handling a major subtask of question-based response review ranking. Extensive experiments demonstrate the effectiveness and stability of the proposed framework.

{skhosla,nchhaya,kchawla}@adobe.com

Abstract

Human communication includes information, opinions and reactions. Reactions are often captured by the affective-messages in written as well as verbal communications. While there has been work in affect modeling and to some extent affective content generation, the area of affective word distributions is not well studied. Synsets and lexica capture semantic relationships across words. These models, however, lack in encoding affective or emotional word interpretations. Our proposed model, Aff2Vec, provides a method for enriched word embeddings that are representative of affective interpretations of words. Aff2Vec outperforms the state-of-the-art in intrinsic word-similarity tasks. Further, the use of Aff2Vec representations outperforms baseline embeddings in downstream natural language understanding tasks including sentiment analysis, personality detection, and frustration prediction.

1 Introduction

Affect refers to the experience of a feeling or an emotion (Scherer et al., 2010; Picard, 1997). This definition includes emotions, sentiments, personality, and moods. The importance of affect analysis in human communication and interactions has been discussed by Picard (1997). Historically, affective computing has focused on studying human communication and reactions through multi-modal data gathered via various sensors. The study of human affect from text and other published content is an important topic in language understanding. Word correlation with social and psychological processes is discussed by Pennebaker (2011). Preotiuc-Pietro et al. (2017) studied personality and psycho-demographic preferences through Facebook and Twitter content. Sentiment analysis in Twitter, with a detailed discussion on human affect (Rosenthal et al., 2017) and affect analysis in poetry (Kao and Jurafsky, 2012) have also been explored. Human communication not only contains semantic and syntactic information but also reflects the psychological and emotional states. Examples include the use of opinion and emotion words (Ghosh et al., 2017). The analysis of affect in interpersonal communication such as emails, chats, and longer articles is necessary for various applications including the study of consumer behavior and psychology, understanding audiences and opinions in computational social science, and more recently for dialogue systems and conversational agents. This is an open research space today.

Traditional natural language understanding systems rely on statistical language modeling and semantic word distributions such as WORDNET (Miller, 1995) to understand relationships across different words. There has been a resurgence of research efforts towards creating word distributions that capture multi-dimensional word semantics (Mikolov et al., 2013a; Pennington et al., 2014). Sedoc et al. (2017b) introduce the notion of affect features in word distributions but their approach is limited to creating enriched representations and no comments on the utility of the new word distribution is presented. Beyond word-semantics, deep learning research in natural language understanding is focused towards sentence representations using encoder-decoder models (Ahn et al., 2016), integration of symbolic knowledge to language models (Vinyals et al., 2015), and some recent works in augmenting neural language modeling with affective information to emotive text generation (Ghosh et al., 2017). These works, however, do

Figure 1: t-SNE for significant affect words: The graphs show the distribution of sample words from Sedoc et al (2017b). The variance in the visualization illustrates the perturbation introduced by distributional schemes discussed in this paper. Vanilla GloVe embeddings show 'disappointed' near 'delighted', while these are separated in the ⊕Affect representations.

not introduce distributional affective word representations that not only reflect affective content but are also superior for related downstream natural language tasks such as sentiment analysis and personality detection.

We introduce Aff2Vec, affect-enriched word distributions trained on lexical resources coupled with semantic word distributions. Aff2Vec captures opinions and affect information in the representation using post-processing approaches. Figure 1 illustrates how Aff2Vec captures affective relationships using a t-SNE visualization of the word space. Even though Aff2Vec is trained on the Valence-Arousal-Dominance dimensions, our approach is generalizable to any other affect spaces. Our experiments show that Aff2Vec outperforms vanilla embedding spaces on both intrinsic word-similarity tasks as well as extrinsic natural language applications. The main contributions of this paper include:

- **Aff2Vec:** Affect-enriched word representations using post-processing techniques. We show that Aff2Vec outperforms the state-of-the-art in both intrinsic word similarity metrics as well as downstream natural language tasks including Sentiment analysis, Personality detection, and Frustration detection in interpersonal communication.

- **ENRON-FFP Dataset:** We introduce the ENRON-FFP Email dataset with Frustration, Formality, and Politeness tags gathered using a crowd-sourced human perception study.

The remainder of the paper is organized as follows. The prior art for enriched word distributions is discussed in Section 2. Aff2Vec is introduced in Section 3. We present a crowd-sourcing study for the ENRON-FFP Dataset in Section 4 and Section 5 discusses the experimental setup. Section 6 presents the evaluation of Aff2Vec for various intrinsic and extrinsic tasks. A discussion on the distributional word representations is presented in Section 7 before the conclusion in Section 8.

2 Related Work

The use of lexical semantic information (lexical resources) to improve distributional representations is recent. Methods like (Yu and Dredze, 2014; Xu et al., 2014; Bian et al., 2014; Kiela et al., 2015) achieve improved representations by using word similarity and relational knowledge to modify the prior or add a regularization term. We call such methods 'pre-training methods', as they alter the training process for word representations. Such methods require a change in the loss function while training the embeddings, hence are computationally expensive.

The other set of word distribution enhancements are done post-training. These methods aim to include external information using normalizations and modifications to the vanilla word distributions. Methods such as Retrofitting (Faruqui et al., 2015), which try to drag similar words closer together (where notion of similarity is taken from word relation knowledge found in semantic lexica (e.g. WordNet)) fall in this category. Counterfitting (Mrkšic et al., 2016) on the other hand, initiates from SimLex-999 tuned

embeddings, injects antonym and synonym constraints to improve word representations. This paper introduces post-training techniques on vanilla, retrofitted and counterfitted embeddings to include affective information in the distributions. Our work falls in the post-training category, hence no direct comparison with the pre-trained approaches is presented in this paper.

Recent work has explored approaches to adapt general-purpose lexica for specific contexts and affects. Studies have recognized the limited applicability of general purpose lexica such as ANEW (Bradley and Lang, 1999) to identify affect in verbs and adverbs, as they focus heavily on adjectives. Recognizing that general-purpose lexica often detect sentiment which is incongruous with context, Ribeiro et al. (2016) proposed a sentiment-damping method which utilizes the average sentiment strength over a document to damp any abnormality in the derived sentiment strength. Similarly, Blitzer et al. (2007) argued that words like 'predictable' induced a negative connotation to book reviews, while 'must-read' implied a highly positive sentiment. This paper doesn't focus on building yet another affect lexicon but studies the consequences of including affect information in distributional word representations that aim at defining relational relationships across all words in large contexts and vocabularies.

Automatic expansion of affect rating has been approached with the intuition that words closer in the distributional space would have similar ratings (Recchia and Louwerse, 2015; Palogiannidi et al., 2015; Vankrunkelsven et al., 2015; Köper and Im Walde, 2016). Recent work by Sedoc et al. (2017b) uses Signed Spectral Clustering to differentiate between words which are contextually similar but display opposite affect. Wang et al. (2016) use a graph-based method inspired by label propagation. While our approach follows the nature of the task defined in Sedoc et al. (2017b), we propose a generalized method to enrich content with affective information. Instead of only focusing on distinguishing the polarities, our method incorporates both semantic and affect information. Hence, creating embeddings that can also be used for semantic similarity tasks. Note that Sedoc et al. do not include any semantic information in their modeling.

3 Aff2Vec: Affect–enriched Word Distributions

Aff2Vec aims at incorporating affective information in word representations. We leverage the Warriner's lexicon (Warriner et al., 2013) in the Valence-Arousal-Dominance space for this work. The proposed work is generalizable to other affect spaces (Refer Appendix A for experiments with different dimensions.). This section presents two approaches for affect–enrichment of word distributions.

Warriner's lexicon: We use the Warriner's lexicon (Warriner et al., 2013) in this work. This is a affect lexicon with $13,915$ English words. It contains real-valued scores for valence, arousal, and dominance (VAD) on a scale of $1-9$ each. 1, 5, and 9 correspond to the low, moderate (i.e. neutral), and high values for each dimension respectively. For out-of-dictionary words, such as stop words or proper nouns, we assume a neutral affect vector $\vec{a} = [5, 5, 5]$.

3.1 Affect-APPEND ($\oplus$ Affect)

Consider word embeddings W, the aim is to introduce affective information to this space using the affect embedding space, A. The word vectors W, each with dimension D, are concatenated with affect vectors A with dimension F, thus resulting in a $D + F$ dimensional enriched representation. The process for this concatenation is described here:

1. Normalize word vector W and affect vector A using their L2-Norms (Equation 1). This reduces the individual vectors to unit-length.

$$x_i = \frac{x_i}{\sqrt{\sum_{k=1}^{D} x_{ik}^2}} \ \forall x_i \in W, \quad a_i = \frac{a_i}{\sqrt{\sum_{k=1}^{F} a_{ik}^2}} \ \forall a_i \in A \tag{1}$$

2. Concatenate the regularized word vectors x_i with regularized affect vectors a_i.

$$WA(w) = W(w) \oplus A(w) \tag{2}$$

3. Standardize (variance 1 , mean 0) the $D + F$ dimensional embeddings to achieve standard normal distribution.

$$y_i = \frac{y_i - \mu}{\sigma} \quad \forall y_i \in WA \tag{3}$$

where, μ and σ represent the mean and standard deviation respectively.

4. The enriched space WA is then reduced to original D dimensional vector. We use Principal Component Analysis for the dimensionality reduction.

3.2 Affect-STRENGTH

In this approach, the strength in the antonym-synonym relationships of the words is incorporated to the word distribution space. Hence, we leverage the retrofitting algorithm (Faruqui et al., 2015) as shown below. [1]

Retrofitting: Let $V = \{w_1, w_2, w_3, ..., w_n\}$ be a vocabulary and Ω be an ontology which encodes semantic relations between words present in V (e.g. WORDNET). This ontology Ω is represented as an undirected graph (V, E) with words as vertices and (w_i, w_j) as edges indicating the semantic relationship of interest. Each word $w_i \in V$ is represented as a vector representation $\hat{q}_i \in R^d$ learnt using a data-driven approach (e.g. Word2Vec or GloVe) where d is the length of the word vectors.

Let $\hat{Q}$ be the matrix collection of these vector representations. The objective is to learn the matrix $Q = (q_1, ..., q_n)$ such that the word vectors (q_i) are both close to their counterparts in $\hat{Q}$ and to adjacent vertices in Ω. The distance between a pair of vectors is defined to be Euclidean, hence the objective function for minimization is

$$\Psi(Q) = \sum_{i=1}^{n} \left[\alpha_i \|q_i - \hat{q}_i\|^2 + \sum_{(i,j)\in E} \beta_{ij} \|q_i - q_j\|^2 \right] \tag{4}$$

where, α and β are hyper parameters and control the relative strengths of the two associations. Ψ is a convex function in Q and its global optimal solution can be found by using an iterative update method. By setting $\frac{\partial \Psi(Q)}{\partial q_i} = 0$, the online updates are as follows:

$$q_i = \frac{\sum_{j:(i,j)\in E} \beta_{ij} q_j + \alpha_i \hat{q}_i}{\sum_{j:(i,j)\in E} \beta_{ij} + \alpha_i} \tag{5}$$

We propose two ways to modify β_{ij} in equation 4 in order to incorporate affective strength in the edge weights connecting two retrofitted vectors to each other.

Affect-cStrength ($*$ cStrength): In this approach, the affective strength is considered as a function of all F affect dimensions.

$$S(w_i, w_j) = 1 - \frac{\|a_i - a_j\|}{\sqrt{\sum_{f=1}^{F} max\_dist_f^2}} \tag{6}$$

where, a_i and a_j are F dimensional vectors in A and max_dist_f is defined as the maximum possible distance between two vectors in f^{th} dimension ($= 9.0 - 1.0 = 8.0$ for VAD dimensions).

Affect-iStrength ($*$ iStrength): Here, each dimension is treated individually. For every dimension f in A, we add an edge between neighbors in the Ontology Ω where the strength of that edge is given by $S_f(w_i, w_j)$:

$$S_f(w_i, w_j) = 1 - \frac{|a_{if} - a_{jf}|}{max\_dist_f}, \quad S(w_i, w_j) = \sum_{f=1}^{F} S_f(w_i, w_j) \tag{7}$$

β_{ij} from equation 5 is normalized with this strength function as $\beta_{ij} = \beta_{ij} * S(w_i, w_j)$, where $S(w_i, w_j)$ is defined by either Affect-cStrength or Affect-iStrength.

Frustration: High Agreement	Please see announcement below. Pilar, Linda, India and Deb, please forward to all of your people. Thanks in advance, adr	(0, 0, 0, 0, 0, 0, 0, 0, 0, 0)
Formality: Low Agreement	I talked with the same reporters yesterday (with Palmer and Shapro). Any other information that you can supply Gary would be appreciated. Steve, did Gary A. get your original as the CAISO turns email? GAC	(0, 0, -1, 1, 1, 1, 0, -1, -2, -1)
Politeness: High Agreement	John, This looks fine from a legal perspective. Everything in it is either already in the public domain or otherwise non-proprietary. Kind regards, Dan	(1, 1, 1, 1, 1, 1, 1, 1, 2, 1)

We introduce an email dataset, a subset of the ENRON data (Cohen, 2009), with tags about interpersonal communication traits: Formality, Politeness, and Frustration. Along with the content of the emails, the dataset also provides user and network level information for email exchanges between Enron employees.

Human Perceptions and Definitions: *Tone* or affects such as frustration and politeness are highly subjective. In this work, we do not attempt to introduce or standardize an accurate definition for frustration (or formality and politeness). Instead, we assume that these are defined by human perception and each individual may differ in their understanding of these metrics. This approach of using untrained human judgments has been used in prior studies of pragmatics in text data (Pavlick and Tetreault, 2016; Danescu-Niculescu-Mizil et al., 2013) and is a recommended way of gathering gold-standard annotations (Sigley, 1997). The tagged data is then used to predict the formality, frustration, and politeness tags using Aff2Vec embeddings.

Dataset Annotation: We conducted a crowd-sourced experiment using Amazon's Mechanical Turk[2]. The analysis presented in this section is based on $1,050$ emails that were tagged across multiple experiments[3]. Table 1 provides the statistics of the annotated data. We follow the annotation protocol of the Likert Scale (Allen and Seaman, 2007) for all three dimensions. Each email is considered as a single data point and only the text in the email body is provided for tagging. Frustration is tagged on a 3 point scale with neutral being equated to 'not frustrated'; 'frustrated' and 'very frustrated' are marked with -1 and -2 respectively. Formality and politeness follow a 5 point scale from -2 to $+2$, where both extremes mark the higher degree of presence and absence of the respective dimension. Table 3 shows example emails from the dataset.

Inter-annotator Agreement: To measure whether an individual's intuition of the affect dimensions is consistent with other annotators' judgment, we use inter-class correlation[4] to quantify the

ordinal ratings. This measure accounts for the fact that we may have different groups of annotators for each data point. Each data point has 10 distinct annotations. Agreements reported are 0.506 ± 0.05(for 3 class), 0.73 ± 0.02(for 5 class), and 0.64 ± 0.03(for 5 class) for frustration, formality, and politeness respectively. The agreement measures are similar to those reported for other such psycholinguistic tagging tasks.

5 Experiments

Two sets of experiments are presented to evaluate Aff2Vec embeddings[5] - Intrinsic evaluation using word similarity tasks and extrinsic evaluation using multiple NLP applications. We focus on 3 vanilla word embeddings: GloVe (Pennington et al., 2014), Word2Vec-SkipGram[6] (Mikolov et al., 2013b) and Paragram-SL999 (Wieting et al., 2015); and their retrofitted (Faruqui et al., 2015) and counterfitted (Mrkšic et al., 2016) versions. The vocabulary and embeddings used in our experiments resonate with the experimental setup by Mrkšić et al.(2016) ($76,427$ words).

5.1 Intrinsic Evaluation

Word similarity is a standard task used to evaluate embeddings (Mrkšic et al., 2016; Faruqui et al., 2015; Bollegala et al., 2016). In this paper, we evaluate the embeddings on benchmark datasets given in Table 2. We report the Spearman's rank correlation coefficient between rankings produced by our model (based on cosine similarity of the pair of words) against the benchmark human rankings for each dataset.

5.2 Extrinsic Evaluation

Although intrinsic tasks are popular, performance of word embeddings on these benchmarks does not reflect directly into the downstream nlp tasks (Chiu et al., 2016). Gladkova and Drozd (2016) and

Batchkarov et al. (2016) suggest that intrinsic tasks should not be considered as gold standards but as a tool to improve the model. Therefore, we test the utility of Aff2Vec on 4 distinct natural language understanding tasks:

Affect Prediction (FFP-Prediction): The experiment is to predict the formality, politeness, and frustration in email. We introduce the ENRON-FFP dataset for this task in section 4. A basic CNN model is used for the prediction (Refer to Appendix B.4 for hyper-parameters and model details). The purpose of this experiment is to evaluate the quality of the embeddings and not necessarily the model architecture. The CNN is hence not optimized for this task. Embeddings trained on the ENRON dataset (ENRON-Trainable) are used as a baseline.

Personality Detection: This task is to predict human personality from text. The big five personality dimensions (Digman, 1990) are used for this experiment. The 5 personality dimensions include Extroversion (EXT), Neuroticism (NEU), Agreeableness (AGR), Conscientiousness (CON), and Openness (OPEN). Stream-of-consciousness essay dataset by Pennebaker et al. (1999) contains $2,468$ anonymous essays tagged with personality traits of the author. We use this dataset for the experiment. Majumder et al (2017) propose a CNN model for this prediction. We use their best results as baseline and report the performance of Aff2Vec on their default implementation[7].

Sentiment Analysis: The Stanford Sentiment Treebank (SST) (Socher et al., 2013) contains sentiment labels on sentences from movie reviews. This dataset in its binary form is split into $6,920$ training, 872 validation, and $1,821$ test set samples. We report the performance on a Deep Averaging Network (DAN)(Iyyer et al., 2015)[8] with default parameters on the SST dataset and compare against refined embeddings specifically created for sentiment analysis. Implementation by Yu et al (2017) is used for the refined embeddings[9].

Emotion Intensity Task (WASSA): WASSA shared task on emotion intensity (Mohammad and Bravo-Marquez, 2017) requires to determine the intensity of a particular emotion (anger, fear, joy, or

sadness) in a tweet. This intensity score can be seen as an approximation of the emotion intensity of the author or as felt by the reader. We train a BiLSTM-CNN–based model for this regression task with embedding dimensions as features (Refer to Appendix B.3 for model details). Vanilla embeddings are used as a baseline for this experiment.

5.3 Qualitative Evaluation: Noise@k

Affect-enriched embeddings perform better as they move semantically similar but affectively dissimilar words away from each other in the vector space. We demonstrate this effect through two measures that capture noise in the neighborhood of a word.

Polarity-Noise@k (PN@k) (Yu et al., 2017) calculates the number of top k nearest neighbors of a word with opposite polarity for the affect dimension under consideration.
Granular-Noise@k (GN@k) captures the average difference between a word and its top k nearest neighbors for a particular affect dimension (f).

$$GN_i@k = \frac{\sum_{j \in kNN_i} |a_i f - a_j f|}{k} \tag{8}$$

where, a_i, a_j are F-dimensional vectors in A and kNN_i denotes the top k nearest neighbors of word i. This is done for each word in the affect lexicon.

6 Results

All experiments are compared against the vanilla word embeddings, embeddings with counterfitting, and embeddings with retrofitting.

Table A.1 summarizes the results of the **Intrinsic word–similarity tasks**. For the pre-trained word embeddings, Paragram-SL999 outperformed GloVe and Word2Vec on most metrics. Both retrofitting and counterfitting procedures show better or at par performance on all datasets except for WordSim-353. Addition of affect information to different versions of GloVe consistently improves performance

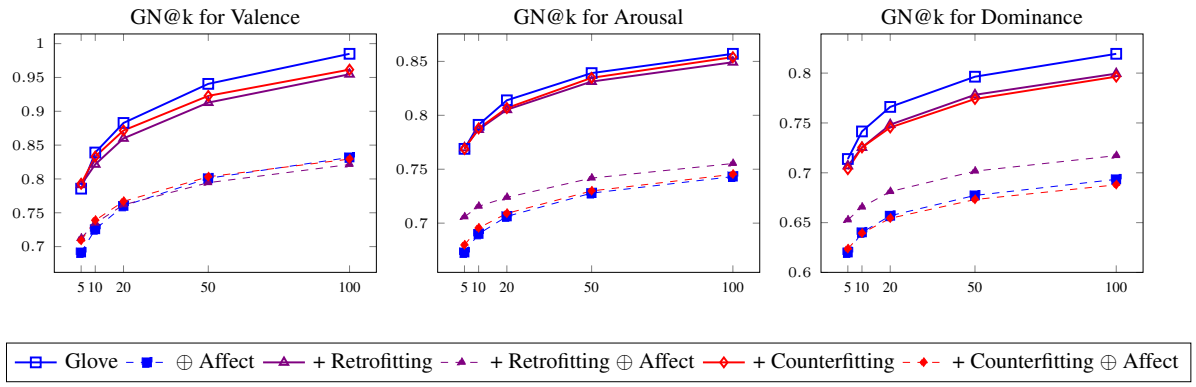

Figure 2: Variation of Granular Noise with different k values for GloVe and Affect-APPEND variants

whereas the only significant improvement for Paragram-SL999 variants is observed on the SimLex-999 and SimVerb-3500 datasets. To the best of our knowledge, $\rho = 0.74$ reported by Mrkšić et al. (2016) represents the current state-of-the-art for SimLex-999 and inclusion of affect information to these embeddings yields higher performance ($\rho = 0.75$). Similarly, for the SimVerb-3500 dataset, Paragram+Counterfitting⊕Affect embeddings beat the state-of-the-art scores[10]. Amongst Affect-APPEND and Affect-STRENGTH, Affect-APPEND out performs the rest in most cases for GloVe and Word2Vec. However, Affect-STRENGTH variations perform slightly better for the Paragram embeddings.

The results for the **Extrinsic tasks** are reported in Table 5. We report the performance for GloVe and Word2Vec with Affect-APPEND variants[11]. For FFP-Prediction, Affect-APPEND gives lowest Mean Squared Error for Frustration and Politeness. However, in the case of Formality, the counterfitting variant reports the lowest error. For the personality detection task, Affect-APPEND variants report best performance for NEU, AGR, and OPEN classes. For CON, Glove beats the best results in (Majumder et al., 2017). Evaluation against the Sentiment Analysis(SA) task shows that Affect-APPEND variants report highest accuracies. The final experiment reported here is the WASSA-EmoInt task. Affect-APPEND and retrofit variants out-perform the vanilla embeddings.

To summarize, the extrinsic evaluation supports the hypothesis that affect–enriched embeddings improve performance for all NLP tasks. Further, the word similarity metrics show that Aff2Vec is not specific to sentiment or affect-related tasks but is at par with accepted embedding quality metrics.

Qualitative Evaluation: Table 6 reports the average *Polarity-Noise@10* and *Granular-Noise@10* for GloVe, Word2Vec, and Paragram-SL999 variants. Note that lower the noise better the performance. Affect-APPEND reports the lowest noise for all cases. This shows that the introduction of affect dimensions in the word distributions intuitively captures psycholinguistic and in particular polarity properties in the vocabulary space. The rate of change of noise with varying k provides insights into (1) how similar are the embedding spaces and (2) how robust are the new representations to the noise i.e. how well is the affect captured in the new embeddings. Figure 2 shows the granular noise@k for valence, arousal, and sominance respectively. Noise@k for the Aff2Vec i.e. the Affect-APPEND variants, specifically, ⊕Affect and Couterfitting⊕Affect has lower noise even for a higher k. The growth rate for all variants is similar and reduces with an increase in the value of k. A similar behavior is observed for Polarity-Noise@k.

7 Discussion

Experiments give an empirical evaluation of the proposed embeddings, none of these provide an insight about the change in the distributional representations of the associated words. Semantic relationship

[11]Results for Paragram are reported in the supplement.

Table 7: Top-5 NN for 'Good' and 'Bad' for variants of GloVe, SentiWordNet and Aff2Vec

Model	Good	Bad
GloVe	[*great*, *nice*, *excellent*, *decent*, *bad*]	[*terrible*, *awful*, *horrible*, *wrong*, *thing*]
⊕ Affect	[*great*, *nice*, *excellent*, *decent*, *pretty*]	[*awful*, *terrible*, *horrible*, *wrong*, *crappy*]
+ Retrofitting	[*great*, *decent*, *nice*, *excellent*, *pretty*]	[*wrong*, *awful*, *terrible*, *horrible*, *nasty*]
+ Retrofitting ⊕ Affect	[*nice*, *great*, *decent*, *excellent*, *pretty*]	[*awful*, *wrong*, *nasty*, *terrible*, *horrible*]
+ Counterfitting	[*decent*, *nice*, *optimum*, *presentable*, *exemplary*]	[*rotten*, *shitty*, *horrid*, *naughty*, *lousy*]
+ Counterfitting ⊕ Affect	[*nice*, *decent*, *optimum*, *presentable*, *dignified*]	[*rotten*, *shitty*, *horrid*, *lousy*, *naughty*]
Senti-WordNet[12]	[*commodity*, *full*, *estimable*, *beneficial*, *adept*]	[*regretful*, *badly*]
Warriner's Lexicon	[*grandmother*, *healing*, *cheesecake*, *play*, *blissful*]	[*jittery*, *fuss*, *incessant*, *tramp*, *belligerent*]

capture the synonym like information. We study how the **neighborhood** of a certain word changes based on the different word distribution techniques used to create the corresponding representations. Table 7 shows the top five nearest neighbors based on the representations used. While SENTI-Wordnet represents synonyms more than affectively similar words, the affect–enriched embeddings provide a combination of both affective and semantic similarity. The variance in the ranking of words depicts how different schemes capture the intuition of word distributions. Such an analysis can be used to build automated natural language generation and text modification systems with varying objectives.

8 Conclusion

We present a novel, simple yet effective method to create affect–enriched word embeddings using affect and semantic lexica. The proposed embeddings outperform the state-of-the-art in benchmark intrinsic evaluations as well as extrinsic applications including sentiment analysis, personality detection, and affect prediction. We introduce a new human-annotated dataset with formality, politeness, and frustration tags on a subset of the publicly available ENRON email data. We are currently exploring the effect of dimension size on the performance of the enriched embeddings as well as the use of Aff2Vec for complex tasks such as text generation.

Appendix A Generalization of Affect and Emotion Dimensions

Apart from the Warriner's lexicon (Warriner et al., 2013) which is in the VAD space, we experimented with the NRC Affect Intensity lexicon by Mohammad (2013) and Ekman's Six emotions from IMS EmoInt Norms dataset[13](Köper et al., 2017; Ekman, 1992). The NRC lexicon has 4 dimensions whereas the Ekman has 6 dimensions. Table A.1 shows the intrinsic word similarity measures for both these affect spaces. The enriched embeddings reported here are based on Affect-APPEND. We report variants of the lexica with vanilla embeddings and their retrofitted and counterfitted versions. The intrinsic metrics improve over the vanilla embeddings with the Aff2Vec versions. Note that the improvement achieved here is slightly lower than those achieved with the VAD space.

This analysis supports the hypothesis that Aff2Vec is generalizable to other dimension spaces and not restricted to a specific affect distribution.

Table A.1: Intrinsic Evaluation: Word Similarity–We report the Spearman's correlation coefficient (ρ) against NRC as well as Ekman's dimensions. The results show that Aff2Vec variants improve performance consistently

Model	**Word Similarity**

Appendix B Model and Architecture Details

The architecture and hyperparameter details of various models used in the extrinsic evaluation tasks are presented here.

B.1 Sentiment Analysis

We use a Deep Average Network (`https://github.com/miyyer/dan`) with default parameters on binary Stanford Sentiment Treebank (Manning et al., 2014) for this task. Results reported in the paper are accuracies averaged across 5 independent runs.

[13]`http://www.ims.uni-stuttgart.de/forschung/ressourcen/experiment-daten/IMS_emoint_norms.tar.gz`

B.2 Personality Detection

A Convolutional Neural Network(CNN)-based model proposed by Mujumder et al (2017) is used in this paper to evaluate the performance of Aff2Vec embeddigns on the Personality Detection task. We use their Github implementation (`https://github.com/SenticNet/personality-detection`) with *Filter = True, Classifier = MLP, Convolution-Filter = [1,2,3] and Cross-Validation = 10*.

B.3 Emotion Intensity Task (WASSA)

For the WASSA EmoInt-2017, we train a BiLSTM-CNN model with word embeddings as input features. The model is trained separately for each emotion. The network architecture is explained in Table B.1. We use Adam as the optimizer and report Pearson's correlation coefficient(ρ), averaged across 5 independent runs.

Table B.1: BiLSTM-CNN Architecture for WASSA EmoInt-2017

Layer	**Properties**

Dropout	0.2
BiLSTM	$units = 80$
Dense	$size = 50$
Activation	$relu$
Dropout	0.3
Dense	$size = 1$

Table B.2: CNN architecture for FFP-Prediction

Layer	**Properties**
2D Convolution	$filters = 5, kernel\_size = 10X5$
Activation	$relu$
2D Max_pooling	$pool\_size = 5X5, sride = 5$
Dense	$size = 50$
Activation	$relu$
Dropout	0.2
Dense	$size = 1$

B.4 Affect Prediction (FFP-Prediction)

We implement a basic CNN-based model for Formality, Frustration and Politeness prediction on Enron-FFP dataset introduced in the paper. The network architecture is shown in Table B.2. We use Rectified Linear Unit (ReLU) as the activation throughout and Stochastic Gradient Descent(SGD) as the optimizer. A mean squared loss is used for regression. We report mean square error averaged across 10 independent runs. Standard deviation for the reported MSE values is of the order of 10^{-3}.

Aspect-based summarization of pros and cons in unstructured product reviews

Abstract

We developed three systems for generating pros and cons summaries of product reviews. Automating this task eases the writing of product reviews, and offers readers quick access to the most important information. We compared SynPat, a system based on syntactic phrases selected on the basis of valence scores, against a neural-network-based system trained to map bag-of-words representations of reviews directly to pros and cons, and the same neural system trained on clusters of word-embedding encodings of similar pros and cons. We evaluated the systems in two ways: first on held-out reviews with gold-standard pros and cons, and second by asking human annotators to rate the systems' output on relevance and completeness. In the second evaluation, the gold-standard pros and cons were assessed along with the system output. We find that the human-generated summaries are not deemed as significantly more relevant or complete than the SynPat systems; the latter are scored higher than the human-generated summaries on a precision metric. The neural approaches yield a lower performance in the human assessment, and are outperformed by the baseline.

1 Introduction

Reviews posted on Web-based consumer platforms such as Amazon[1] and Trustpilot[2] form a valuable source of information prior to buying a product or hiring a service. Especially when a multitude of reviews of a specific product are gathered, the different experiences enable the consumer to obtain a well-informed conception of the qualities and deficiencies of the respective article. However, achieving a coherent view of a product tends to be challenging when a high volume of reviews diverge in focus and sentiment. A system that can summarize the reviews of a product would therefore be a valuable asset to these platforms. This work describes the implementation and evaluation of both a supervised and an unsupervised approach to aspect-based sentiment analysis, with a focus on Dutch product reviews of electric devices.

We create summaries that zoom in on the pros and cons of the product that are mentioned in a review. Platforms that include product reviews commonly employ a pros and cons template to enable the authors of reviews themselves to summarize their review text. Although such a procedure could lead to

Santa Fe, New Mexico, USA, August 20-26, 2018.

appropriate summaries, only a minority of users make the effort to fill in the pros and cons.[3] On the one hand, this behavior underlines the need for a tool to generate a summary when the writer chooses not to. On the other hand, the review texts that do include pros and cons as explicated by the writer offers the train and test labels to employ a supervised learning framework. We will study the potential of using these user-generated summaries by training a neural-network implementation to generate the appropriate summary as output to the review text as input. This approach will be compared to a knowledge-driven approach based on syntactic patterns.

Aspect-based sentiment analysis from product reviews, of which the detection and summarization of pros and cons is an instance, is a challenging task due to the freedom that the user has when writing a review. In this case, the freedom applies to both the pros and cons the user chose to mention, and to the phrasings used to express these pros and cons. In addition, different types of products are reviewed with a focus on different aspects. For this reason, aspect-based sentiment analysis is commonly approached as a bounded task, with a focus on a specific product or service with predefined aspects. In contrast, we leverage the pros and cons that writers attach to their review, resulting in a more dynamic approach that can cope with any set of reviews, irrespective of the product or service, as long as example summaries are available. While the pros and cons as put forward by the users offers a gold standard for evaluation, we also include a human evaluation in which the qualities of both the system-generated summaries and the human-generated summaries are assessed.

This study offers the following contributions:

- We provide new insights into the utility of author-contributed pros and cons for automatically summarizing product reviews;
- We compare a neural learning approach with a linguistic pattern-driven approach;
- A novel evaluation is proposed that uses the author-assigned pros and cons as gold standard;
- The quality of the author gold standard is compared to system output through human evaluation.

After discussing related work, this paper will proceed with a description of the methods. Subsequently, the experimental set-up will be outlined, followed by the results. The paper ends with a conclusion and discussion.

2 Related Work

Studies in aspect-based sentiment analysis can roughly be divided into rule-based and machine learning-based approaches. Rule-based approaches implement searching for combinations of aspects and evaluations on the sentence level. Such combinations are commonly identified based on syntactic patterns (Poria et al., 2014; Zhang et al., 2014; Chinsha and Joseph, 2015; Rana and Cheah, 2015; Yan et al., 2015) while the evaluation is scored based on a sentiment lexicon (Chinsha and Joseph, 2015; Rana and Cheah, 2015; Poria et al., 2014), a PageRank-based procedure (Yan et al., 2015), or optimization based on review labels (Zhang et al., 2014). We apply a knowledge-driven approach to aspect-based sentiment analysis, comparable to the approach by Rana and Cheah (2015). Candidate phrases are identified based on predefined syntactic patterns and a sentiment lexicon is used to identify patterns that likely signify a pro or con.

Utilizing the pros and cons in product reviews as training data, we also apply a machine-learning based approach, using neural networks. Neural models have become popular for text classification tasks (Socher et al., 2013; Zhang et al., 2015; Conneau et al., 2016) in recent years. These models have the advantage that they generally require little feature engineering. The downside is that they are slow to train and test and require large amounts of training data. More recently, it has been shown that shallow neural models obtain performance on par with deep learning methods, while being much faster and less

[3] Of the reviews that are used in our study, only 30% include pros and/or cons. A full overview of the reviews is given in Table 2

data hungry. The higher representational power of these deep methods is not required for relatively simple tasks such as sentiment classification (Joulin et al., 2016).

Few studies on aspect-based sentiment analysis make use of the pros and cons that are given by the writers themselves to summarize their review. Closest to our work in this respect is the contribution by Kim and Hovy (2006), who align pros and cons with the most likely related sentence in their review text by a maximum entropy model. The output is used as training data to predict the pros and cons for reviews that were not summarized as such by the writer. In comparison to Kim and Hovy (2006), we leverage author-based pros and cons both as training labels and as test labels during evaluation. In addition, we evaluate these pros and cons along with system-generated pros and cons, thereby providing insight into the quality of these kinds of labels for training and evaluating aspect-based sentiment analysis of product reviews.

3 Method

3.1 System 1: Syntactic patterns of subjective phrases (SynPat)

The knowledge-driven SynPat system[4] tracks and matches syntactic cues towards aspect evaluations in reviews (Rana and Cheah, 2015). The system consists of two stages. First, a review is scanned for particular syntactic patterns based on a set of rules. Second, each candidate that is found during the first stage is matched with a lexicon of subjective words to confirm that the phrase indicates valence.

Part-of-speech tags and grammatical phrases are extracted from each review text by means of Frog[5], an off-the-shelf NLP system for Dutch (Van den Bosch et al., 2007). We matched the automatic analyses with a set of syntactic patterns of which the lexical realizations (the words associated with the PoS-tags) may reflect statements on the valence of an aspect. Examples of patterns and example lexical realizations are given in Table 1.

To assess the presence and direction of the valence in the lexical realizations (henceforth referred to as phrases) found with matching syntactic patterns, we matched them to the Duoman subjectivity lexicon (Jijkoun and Hofmann, 2009). This a lexicon of nouns and adjectives rated by human annotators as 'Very negative', 'Negative', 'Neutral', 'Positive' and 'Very positive'. We labeled each phrase with a positive or very positive word as 'pro', and each phrase with a negative or very negative word as 'con'. Phrases in which no word has a positive or negative valence in Duoman lexicon were discarded, as well as phrases that matched an equal amount of positive and negative words. A phrase that carries a combination of a 'positive' and 'very negative' is labeled as 'con', while phrases with a 'very positive' and 'negative' word are labeled as 'pro'.

Syntactic pattern	Example (Dutch)	Example English	Valence word	Pro/con
ADJ	fantastisch	fantastic	fantastic	Pro
ADJ-N	klein zuigmondje	small nozzle	small	Con
ADJ-N-N	heerlijk kopje espresso	delicious cup of espresso	delicious	Pro
ADJ-ADJ-N	onhandige extra handeling	inconvenient additional action	inconvenient	Con
ADJ-V	mooi uitgevoerd	nicely rendered	nicely	Pro
ADJ-Prep-N	goed van smaak	good flavor	good	Pro

Table 1: Examples of syntactic patterns extracted in the SynPat system (ADJ=Adjective, N=Noun, V=Verb, Prep=Preposition), their lexical realization (phrase)

3.2 System 2: Shallow neural classification

To explore the possibility of training a classification system end-to-end without feature engineering we choose to train a shallow neural network on the aspect summarization task. We treat reviews as bags of words and feed word embeddings to the neural classifier. Given the constructed sentence vector, the

[4]The implementation of the system can be found on github: `https://github.com/fkunneman/Product_review_summary/blob/master/synpat.py`

[5]`http://applejack.science.ru.nl/languagemachines/software/frog/`

classifier tries to predict the correct labels. Here, the labels are the human generated aspect sentences. We treat each aspect as a potential class to predict. The chosen architecture is similar to Joulin et al. (2016) which is a modification of the cbow model by Mikolov et al. (2013), but instead of predicting a hidden word, a hidden class is predicted. We use softmax to compute the probability distribution over the aspect classes. The model is trained using stochastic gradient descent and a linearly decaying learning rate. To pretrain the model we use 320-dimensional word embeddings derived from the corpora from the web (COW) introduced in Tulkens et al. (2016).

3.3 System 3: Shallow neural classification with clustering

Because users can state positive and negative aspects in any way they want, we end up with a large number of classes in a long-tail distribution. From inspection of the development data we observe that many of the different classes are in fact paraphrases of the same semantic content ('great coffee', 'coffee tastes great', etc.) To try to alleviate this problem, we add a preprocessing step where we cluster the aspect summaries based on averaging over word embedding vectors. Using k-means clustering we then cluster the summaries into distinct clusters and take the centroid as the label. We then try to predict these labels using the same shallow neural classifier.

4 Experimental Set-up

4.1 Data

We crawled product reviews from the Dutch platform 'kieskeurig.nl', which features consumer reviews for a diversity of electric devices. A screen shot of a typical consumer review is presented in Figure 1. Typically, such a review consists of a written text, a summary of the written text in the form of pros and cons, a review score and, occasionally, scores on predefined aspects such as design and ease of use. We are interested in the review text and the accompanying pros and cons.

Figure 1: Example of a review placed on kieskeurig.nl. 'Pluspunten' are pros, 'Minpunten' cons.

We crawled the reviews for the four most frequently reviewed product types: smartphones, vacuum cleaners, deep fryers and espresso machines.[6] The statistics of the resulting dataset are presented in Table 2. We observe that a significant part of the reviews are written without summing up explicit pros and cons. In addition, pros are more common than cons. About 35% of the reviews are accompanied by one or more explicated pros, while cons are present for 22% of the reviews.

4.2 Procedure

The review texts summarized with pros and cons were utilized as instances to train our systems with, and to test them intrinsically on held-out data from the same source. In order to tune the neural networks, we

[6]Due to privacy regulations, we are not allowed to publicly share this data.

Device	# reviews	# reviews with at least one pro	# reviews with at least one con	# reviews with both pros and cons	# reviews with either a pro or a con
Smartphone	5,133	1,007	703	697	1,012
Deep fryer	4,040	1,526	1,039	1,019	1,536
Vacuum cleaner	2,623	1,026	730	715	1,041

Smartphone	809	101	102	1,012
Deep fryer	1,228	154	154	1,536
Vacuum cleaner	832	104	105	1,041
Espresso machine	793	99	100	986

Table 3: Overview of the data used in the experimental set-up

split the reviews into training (80%), development (10%) and test (10%) instances. The resulting dataset is presented in Table 3.

The unsupervised SynPat system was applied directly to the test set. The hyperparameters of the two shallow neural systems were set using the development set. We trained for 30 epochs using a learning rate of 0.5 and the softmax loss function. For k-means clustering we set $k = 100$.

We compared the performance of the three systems to the performance of a baseline system based on string matching. This works as follows. All pros and cons contained in the training reviews of a specific device are saved as possible descriptions of unseen reviews. For a given unseen review, all known pros and cons from the training reviews are matched with the text. The baseline selects as summary the pros and cons of which an above-threshold proportion of words is seen in the text. The threshold value is empirically decided based on the development set: the threshold that leads to the pros and cons that are closest to the actual given pros and cons is selected and used for the predictions on the test set.[7]

4.3 Evaluation

We evaluated the systems in two ways: a gold standard assessment based on the pros and cons given by the writers of the reviews and a human evaluation in which the pros and cons given by the systems as well as the writers themselves are assessed by human annotators.

4.3.1 Evaluation 1: Gold standard

For the gold standard evaluation, we assessed the pros and cons extracted by a system as their closeness in characters to the author-based pros and cons.[8] Due to the variance in these pros and cons, which are given by the author in a free-text input field, it is infeasible to make direct matches between two sets of pros and cons. Slight grammatical differences between target and prediction would be assessed as a false prediction in such a procedure. Alternatively, we made use of the FuzzyWuzzy string matching library for python.[9] At the basis of this implementation is a computation of the edit distance between two strings using the Ratcliff–Obershelp pattern recognition algorithm (Ratcliff and Metzener, 1988). In this algorithm, the edit distance between two strings is computed by dividing the number of matching characters with the total number of characters. The FuzzyWuzzy library is particularly adequate for

[7]The implementation of the baseline can be found on github: `https://github.com/fkunneman/Product_review_summary/blob/master/baseline.py`

[8]The implementation of evaluation 1 can be found on github: `https://github.com/fkunneman/Product_review_summary/blob/master/evaluation1.py`

[9]`https://github.com/seatgeek/fuzzywuzzy`

assessing the distance between longer phrases, as it expands the core pattern recognition algorithm with two heuristics. The first is to overrule the strong penalization of two strings with a differing length by assigning a more positive score if one of the two strings is a substring of the other. The second heuristic assures that the order of word tokens is not of influence to the edit distance, by separately assessing the intersection of tokens between two phrases as two unordered sets.

Using the FuzzyWuzzy string matching procedure, the quality of the systems are assessed in the following way, for each review in the test set:

1. The pros and cons suggested by the system and the ones given by the user are aligned such that a predicted pro is matched with only one gold standard pro, the most similar one, and a predicted con is matched with only one gold standard con. Two predicted pros or cons can not be aligned with the same gold standard pro or con; the pair with the highest similarity is aligned.

2. Apart from string matching, we employed a heuristic for matching values of pros and cons that refer to 'Nothing'. This is the most common value (especially to the cons field), and is often given by not filling in anything or using words like 'geen' ('none') and 'nog niets gevonden' ('nothing found yet'). The heuristic assures that such values were matched. Such matches were given the optimal similarity score.

3. Aligned pairs with a similarity that surpasses a given threshold are scored as 'true positives'. Other pairs are scored as false positives (for system-generated pros and cons) and false negatives (for user-generated pros and cons). Pros and cons that are not aligned are also scored as 'false positives' and 'false negatives'

4. A precision, recall and F1-score for the summary of each single review is calculated based on the counts of true positives, false positives and false negatives. After all reviews in the test set are processed this way, an aggregate precision, recall and F1-score of the system is calculated.

In this evaluation procedure, true positives are assigned when the similarity between a target pro or con and a predicted pro or con surpasses a given threshold. To obtain insight into the influence of the threshold value, we will run the evaluation with different thresholds that cover the total spectrum of possible edit distance scores. The range of thresholds spans from 0 (no similarity at all) to 100 (complete similarity). Precision, recall and F1-score is calculated separately per review rather than adding up all true positives, false negatives and false positives, so as to avoid the influence of imbalance in the number of pros and cons per review.

4.3.2 Evaluation 2: Human assessment

In addition to a gold standard evaluation, we asked human annotators to assess the quality of review summaries. Apart from the pros and cons generated by the baseline system, SynPat, Neural and Neural_Clust, we included the pros and cons given by the authors themselves (the gold standard pros and cons) in this evaluation. This can give insight into the absolute quality of the gold standard, and its quality with respect to the systems. This kind of experimentally collected (human) judgments is often used in the evaluation of automatically generated text (Gatt and Krahmer, 2018).

We randomly selected twenty reviews from the test set, equally distributed over the four devices 'vacuum cleaner', 'deep fryer', 'espresso machine' and 'smartphone' (e.g.: five reviews per device). Each review was included five times in the evaluation set: linked with the pros and cons generated by each of the four systems as well as the pros and cons given by the author of the review. This led to a total of 100 instances. We divided them into five chunks of twenty instances to be presented to human annotators, which would include all twenty unique review texts presented with the pros and cons of one of the five sources (equally distributed over the twenty reviews). Each chunk of twenty review-system combinations was assessed by the same ten human annotators, enabling us to calculate the agreement between each annotator pair.

Annotators were recruited through the Radboud Research Participation System[10], a university-based platform that helps researchers finding student participants for their studies. For the assessment of twenty review texts, participants could choose to receive one student credit or a voucher worth ten Euros. In total, fifty human annotators assessed the quality of the pros and cons of twenty review texts. For each of these instances, the annotator was asked to assess both the relevance and the completeness of the given pros and cons with respect to the review text. Relevance was assessed by deciding for each of the given pros and cons whether they are actually discussed (literally or paraphrased) in the review text. Completeness was assessed by indicating, on a scale from 1 to 7, the extent to which the given summary covers all pros and cons that are mentioned in the review text. Relevance can be seen as an estimator of precision; completeness is a human-assessed approximation of recall.

A completeness and relevance score per review-system combination was computed as the average of the ten human assessments. The score per system is calculated as the average of these averages.

5 Results

An overview of the number of (aligned) predictions by system is presented in Table 4. Recall that the pros and cons in the predicted and gold standard summaries are aligned based on string matching and a heuristic for the most common phrases to express that there is no pro or con. In the latter case, the highest similarity score of 100 is assigned to the alignment. We therefore present the average similarity of aligned pros and cons with and without the ones aligned based on this 'empty' heuristic.

The baseline is characterized by a high number of predictions and alignments. The proportion of predictions that are aligned is, however, the lowest. Most of these alignments are based on string matching, which has the highest average similarity (50.5) of all systems. The SynPat system makes the least predictions, but yields a relatively high proportion of alignments and a high number of reviews with an aligned prediction. The average similarity of the alignments is slightly lower than the baseline. The Neural system yields the lowest number of aligned pros and cons based on string matching (468), but the highest number of alignments based on the 'empty' heuristic. The percentage of reviews with an alignment is low at 81%, which is due to the high amount of falsely predicted 'empties'. This seems to be the default option for Neural when certainty for other pros or cons is low. The Neural_clust system makes aligned predictions for most of the reviews, at an average string similarity of 44.43.

System	Predicted pros and cons	Aligned pros and cons (string matching)	Aligned pros and cons ('empty' heuristic)	# reviews aligned (% of total)	Avg. similarity	Avg. similarity (without 'empty')
Baseline	3,877	1,469	79	432 (94%)	52.50	50.05
SynPat	1,712	1,101	83	442 (96%)	51.41	48.42
Neural	1,844	468	159	375 (81%)	58.58	44.99
Neural_clust	1,844	1,228	109	456 (99%)	48.96	44.43

Table 4: Overview of predictions and alignments by system for all reviews (# target reviews: 461, # target pros and cons: 2060, similarity scaled 0-100).

5.1 Gold standard

A similarity threshold decides which pros and cons predicted by a system are assessed as matches (true positives) with a gold standard pro or con. The resulting F1-scores by threshold value are presented in Figure 2 (vacuum cleaner), Figure 3 (smartphone), Figure 4 (deep fryer) and Figure 5 (espresso machine).

The curves for most systems are showing a steep drop in performance around a threshold of 30, after which the scores are more stable between 50 and 70 and steadily decrease towards an F1-score of about 0.1 at 100. The SynPat and Neural_clust systems yield the highest performance between a threshold value of 0 and 30–40 for all systems, indicating that these systems make the most predictions that are

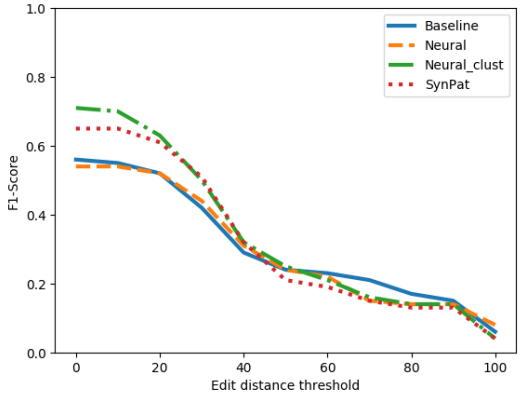

Figure 3: Performance by similarity threshold on smartphone reviews

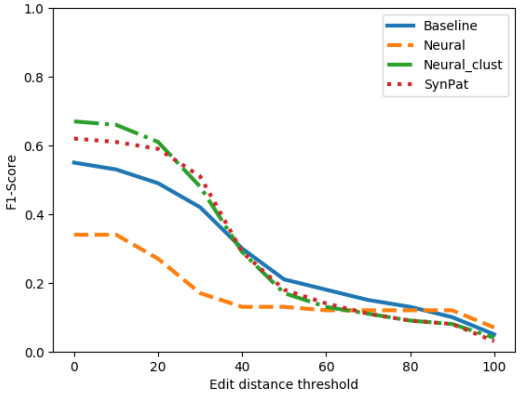

Figure 4: Performance by similarity threshold on deep fryer reviews

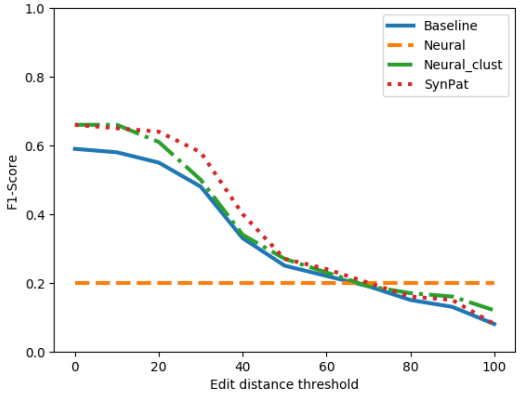

Figure 5: Performance by similarity threshold on espresso machine reviews

somewhat similar to one of the gold standard pros or cons. The F1-scores of all systems are closer to each other at distance thresholds of over 40. The baseline system outperforms the other systems between the threshold values of 60 and 80. The Neural system is generally outperformed at threshold values below 60 (except for the smartphone reviews). The clustering of pros and cons seems to be useful for this approach. Upon closer inspection, the flat line for the Neural system on the espresso machine reviews (Figure 5) is due to the exclusive prediction of 'Nothing' for cons.

5.2 Human assessment

A report of the human assessments of the pros and cons given by each system, as well as the writers of the reviews themselves, is given in Table 5. A Cohen's Kappa (Cohen, 1960) agreement was calculated between the relevance assessments of pros and cons of each pair of annotators. The average agreement on relevance was $\kappa = 0.56$. The agreement over the completeness assessment of pros and cons between each annotator pair was calculated as a weighted Cohen's Kappa. The average agreement for completeness was $\kappa = 0.30$. These Kappa-values suggest a moderate agreement between human judges.

Inspection of Table 5 reveals that the reviewers' summaries were judged to be the most complete at an average score of 4.60, although the differences with the average score of SynPat (4.06) and the Baseline (3.90) appear to be small. Apparently, reviewers themselves often do not cover all pros and cons that they mention in their review text. The relevance of their pros and cons (0.61) is lower than the best system, SynPat (0.67), although this difference is again small. The baseline system lags behind in terms of relevance. The scores of the two Neural systems are lower than the scores of the other systems for both completeness and relevance, and are close to each other.

We conducted two one-way Analyses of Variance (ANOVAs) to test for statistical significance of the

	Completeness	Relevance
Baseline	3.90 (0.90)	0.44 (0.17)
SynPat	4.06 (1.15)	0.67 (0.25)
Neural	2.74 (0.86)	0.25 (0.14)
Neural_clust	2.37 (0.62)	0.18 (0.10)
Reviewers summary	4.60 (1.13)	0.61 (0.25)

Table 5: Outcomes of the human assessment of the pros and cons generated by each system and the writers of the reviews themselves for 20 reviews. Completeness is rated on a scale from 1 to 7, and is reported as the average completeness of the 20 reviews (standard deviation between brackets). Relevance is rated as the proportion of pros and cons that are deemed relevant to a review text, on a scale from 0 to 1, reported as the average relevance of the 20 reviews (standard deviation between brackets).

completeness and relevance assessments. The ANOVA for completeness confirmed that the systems were not rated equally on this dimension, $F(4, 95) = 23.98, p < .001$. All pairwise comparisons (using the Tukey HSD method) were statistically significant at $p < .05$, except the comparisons between the human gold standard and SynPat, between human gold standard and baseline, and between SynPat and baseline (confirming that the three highest rated approaches performed statistically equally well) and between the two neural systems (confirming that neither neural method outperformed the other in terms of completeness). The ANOVA for relevance similarly showed that not all systems performed equally well, $F(4, 95) = 18.61, p < .001$, with all pairwise comparisons (Tukey HSD) statistically signifcant at $p < .05$, except the ones between the human gold standard and SynPat (confirming that SynPat performs on a par with human reviewers), and between the two neural methods.

5.3 Analysis

We set out to investigate the strength of each system by counting the overlap of their predictions for each of the test reviews. To focus on the most sensible predictions, we only selected the predictions with a similarity of > 50 with one of the gold standard pros and cons. An overview of the overlap is presented in a Venn diagram in Figure 6.

The diagram shows a predominantly disjoint pattern, with only 3.6% of the correctly predicted pros and cons generated by all four systems. The combination of three systems with most correct predictions that a fourth system has not generated (5.8%) is formed by the baseline, SynPat and Neural_clust. In most of these cases, the Neural system has falsely predicted 'empty' as con. The most overlapping combination of systems is the combination baseline–SynPat, with 120 predictions (11.6%). Both systems are based on matching phrases, while the Neural systems operate at the sentence level. Apparently, a good part of the pros and cons can best be detected on the phrase level.

6 Conclusion and Discussion

We presented three systems for generating pros and cons summaries of product reviews: a system based on syntactic phrases and a valence lexicon (SynPat), a neural-network-based system trained on bag-of-words in the review text as input and the pros and cons listed by the writer as output (Neural), and the same system trained on clusters of similar pros and cons based on word embeddings (Neural_clust). These systems were applied on reviews of vacuum cleaners, smartphones, deep fryers and espresso machines. We find that the pros and cons assigned by the authors themselves are not deemed by human annotators as more relevant or complete than the summaries extracted by the SynPat system. In fact, the SynPat system is assessed as offering more relevant pros and cons than the human summaries (though not significantly more). The neural-network approaches yield a lower performance in the human assessment, and are also outperformed by the baseline.

The lower performance of the neural-network approaches is likely due to the formulation of the task as a classification task of a text (either encoded as a bag-of-words or as centroids of word embedding clusters) into many different output classes. Moving from this discriminatory approach to a generative

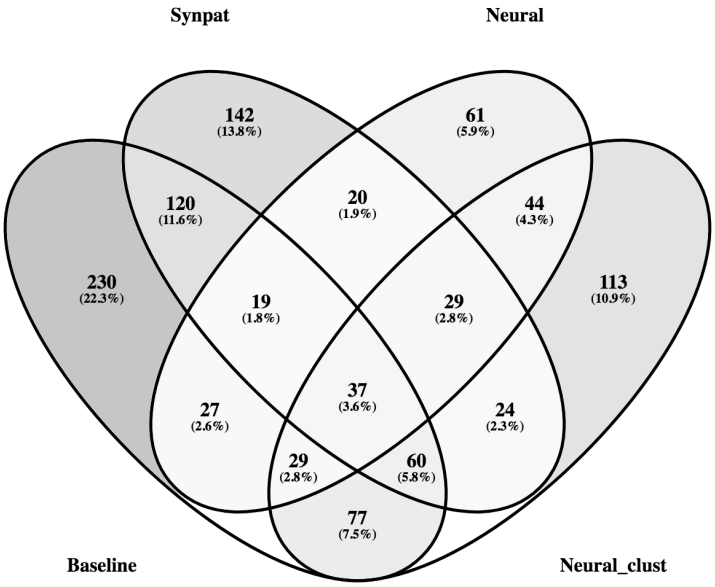

Figure 6: Venn diagram of the overlap between predicted pros and cons by each system which match the gold standard pros and cons at a similarity score of > 50.

approach may be a next step to attain better performances.

Our results show that human performance is imperfect as well. The SynPat system is assessed as not significantly worse than humans, and is even slightly more precise. The upper bound that the best systems appear to touch in Figures 2 to 5, an F1-score of about 0.7, must therefore be bounded by the variance and imperfect completeness (recall) and relevance (precision) of the human summaries we took as gold standard. In line with this finding, the moderate Cohen's Kappa scores that describe the agreement of human annotators on assessing the link between pros and cons and a review text ($\kappa = 0.56$ for relevance and $\kappa = 0.30$ for completeness) underlines the subjective nature of this task. In future work, subjectivity can be reduced (and thereby human agreement increased) by employing a stricter definition of when elements in a review text reflect a pro or con.

Finally, in future work we intend to move beyond extractive summarization of pattern-matched phrases. A strong assumption of the SynPat system is that pros and cons are consecutive word sequences that can be extracted literally from the full review, while pros and cons could be expressed in ways that transcend mere word n-grams. This calls for a richer encoding of the full review text, likely between the level of n-grams and the full bag-of-words. The sentence may be a good domain to target.

Abstract

Sentiment composition is a fundamental sentiment analysis problem. Previous work relied on manual rules and manually-created lexical resources such as negator lists, or learned a composition function from sentiment-annotated phrases or sentences. We propose a new approach for learning sentiment composition from a large, unlabeled corpus, which only requires a word-level sentiment lexicon for supervision. We automatically generate large sentiment lexicons of bigrams and unigrams, from which we induce a set of lexicons for a variety of sentiment composition processes. The effectiveness of our approach is confirmed through manual annotation, as well as sentiment classification experiments with both phrase-level and sentence-level benchmarks.

1 Introduction

Many sentiment analysis systems rely primarily on the sentiment of individual words. However, precise sentiment analysis often requires lexical-semantic knowledge that goes beyond word-level sentiment, even when dealing with short phrases such as bigrams. Phrases may be idiomatic, in which case their polarity cannot be inferred from the sentiment of their constituent words, e.g., *black market*, *on track*, and *let down*. The sentiment of most phrases, however, is *compositional*, namely, it can be determined from the interaction between their constituents.

Sentiment composition is a fundamental problem in sentiment analysis. It involves a variety of semantic phenomena, the most studied of which are *valence shifters* (Polanyi and Zaenen, 2004) that reverse sentiment polarity, e.g., ***not*** *happy*, ***hardly*** *helpful*, ***decrease*** *unemployment*, or change its intensity (***deeply/somewhat*** *disappointed*). Sentiment composition also needs to resolve the polarity of phrases containing opposing polarities, such as *cure cancer*, *sophisticated crime*, and *fake success*. Another, less studied type of sentiment composition is expressions such as *high income*, *long queue*, and *fast learner*, that include gradable adjectives. The sentiment of these expressions cannot be derived from the sentiment of their individual words (none of which have clear sentiment in the above examples). While they can be treated as fixed expressions, similar to idioms, it is beneficial to exploit their semantic compositionality. For example, for a given word *w*, the polarity of *high w*, *higher w*, and *increasing w* is likely to be the same, and opposite to the polarity of *low/lower w*. This allows more robust sentiment learning, as well as sentiment inference for such expressions.

Previous approaches for sentiment composition relied on hand-written lists of negation words and composition rules. Such knowledge is hard to acquire and is typically incomplete. Other approaches aim to learn sentiment composition from sentiment-labeled texts. However, sentiment-labeled texts might not be available for certain domains or languages.

In this work we propose a new approach for learning sentiment composition. We define a set of *sentiment composition classes* that cover a variety of sentiment composition processes, and propose a novel method for automatic acquisition of lexicons for each of these classes from a large corpus. For

Santa Fe, New Mexico, USA, August 20-26, 2018.

example, our method learns that words like *reduce* and *preventing*, when applied to a negative expression, change its polarity from negative to positive (e.g., *preventing violence*). It also learns that the positive sentiment of words like *strong* and *incredibly* is overridden when composed with a negative expression (e.g., *strong disapproval*). In addition, we learn composition lexicons for specific gradable adjectives, e.g., words *w* such that *high w* is positive (*morale, standard, competitiveness*), or negative (*cost ,anxiety, noise*).

Unlike previous approaches, our method does not require sentiment-labeled texts, or manually-created sentiment composition lexicons. The only annotated input required is a sentiment lexicon for individual words. We train an n-gram sentiment classifier on the input sentiment lexicon, using a novel sentiment-oriented phrase embedding that is very efficient to compute and scales well for very large corpora. The classifier is then applied to a large lexicon of bigrams, as well as to the unigrams they are made of. Finally, we induce from the automatically generated sentiment lexicon of bigrams and unigrams a set of fine-grained lexicons for sentiment composition.

The accuracy of the resulting sentiment composition lexicons is confirmed via manual assessment. We also show their contribution to both phrase-level and sentence level sentiment analysis. Our results illustrate the value of our automatically-generated sentiment lexicons for investigating sentiment composition phenomena. We made both these sentiment lexicons and the resulting composition lexicons publicly available, to facilitate further research on sentiment composition.[1]

2 Related Work

Many of the previous works on sentiment analysis include some treatment of valence shifters, based on manual lists of negators, intensifiers, etc. (Wilson et al., 2005; Kennedy and Inkpen, 2006; Taboada et al., 2011). Moilanen and Pulman (2007) apply manually-composed syntactic rules for sentiment composition over the syntactic parse. Neviarouskaya et al. (2010) manually created a lexicon with fine-grained categories for sentiment composition such as *propagation* and *domination* which may resolve conflicting sentiments. Schulder et al. (2017) applied an SVM classifier with linguistic features to bootstrap manual construction of a verbal polarity shifters lexicon. Some researchers, like Choi and Cardie (2008), combined manual composition rules with machine learning.

Other works aimed to learn a sentiment composition function from sentiment-labeled phrases or sentences by employing conditional random fields (Nakagawa et al., 2010), compositional matrix-space models (Yessenalina and Cardie, 2011), statistical parsing (Dong et al., 2015) and recursive neural networks (Socher et al., 2013; Tai et al., 2015). Several researchers aimed to learn sentiment shifters from sentiment-labeled texts, e.g. Ikeda et al. (2008), Noferesti and Shamsfard (2016).

In contrast to previous methods, our method does not require sentiment-labeled texts or feature engineering. It also does not rely on manually-composed lexicons of negators, propagators or dominators, but rather learns such lexicons automatically.

Kiritchenko and Mohammad (2016) wrote that *"lexicons that include sentiment associations for multi-word phrases as well as their constituent words can be very useful in studying sentiment composition"*. They manually developed such a lexicon for a few hundreds of bigrams and trigrams with opposing sentiments (each phrase has both negative and positive words), and experimented with both supervised and unsupervised methods for classifying and ranking the sentiment of these phrases. Their work has shown that rules based on part-of-speech patterns and unigram sentiment strengths are not sufficient for determining the sentiment of phrases with opposing sentiments. This motivated the current work, which is focused on learning lexical knowledge for sentiment composition.

Following Kiritchenko and Mohammad, we also build a sentiment lexicon for phrases and their constituent words, but our lexicon is built automatically, and is three orders of magnitude larger (over 250,000 bigrams). The size of the lexicon makes it suitable for learning lexical knowledge for sentiment composition.

[1] Available at `http://www.research.ibm.com/haifa/dept/vst/debating_data.shtml`

3 Method

Our method for learning sentiment composition lexicons comprises the following steps:

1. Train an n-gram sentiment classifier on a given sentiment lexicon for unigrams.
2. Use the sentiment classifier to automatically generate large sentiment lexicons of bigrams and unigrams.
3. Extract sentiment composition lexicons based on statistics from the bigram and unigram sentiment lexicons.

The rest of the section describes each of the above steps.

3.1 The Sentiment Classifier

Following previous work (Amir et al., 2015; Rothe et al., 2016; Bar-Haim et al., 2017b), we train a sentiment classifier on a sentiment lexicon, where the word's polarity is taken to be the label, and the word embedding is the feature vector. We use the publicly-available sentiment lexicon of Hu and Liu (2004) (hereafter, HL). After removing 224 multi-word expressions, the lexicon contains 6,565 words.

The above previous work focused on learning sentiment of unigrams, and optionally of multi-word expressions (conflated into single tokens), and used word2vec embeddings (Mikolov et al., 2013). In contrast, we are interested in learning sentiment composition from bigrams, and therefore we are mostly interested in compositional bigrams, and aim to construct a sentiment lexicon that contains hundreds of thousands of them. Due to bigram sparsity, learning their embeddings requires a very large corpus.

We use in this work a proprietary English corpus containing news articles and other types of publications from over 10,000 sources. The size of this corpus is in the order of 10^{11} tokens. While word2vec is known as a scalable method for deriving word embeddings, applying it to a corpus of this size is still computationally expensive.

We therefore opted for a more lightweight method for computing sentiment-oriented embeddings. Our method is inspired by the classical work of Turney and Littman (2003), who learned word sentiments based on their pointwise mutual information (PMI) with seed sentiment words. Our method represents each n-gram (unigram or bigram) as a 6,565 dimensional vector of its *Positive PMI (PPMI)* (Levy et al., 2015) with all the words in the HL lexicon. PPMI is defined for phrases u,v as

$$PPMI(u,v) = max(0, log\frac{f(u,v)\cdot N}{f(u)\cdot f(v)}), \quad (1)$$

where $f(u)$ and $f(v)$ are the number of sentences that contain u and v in the corpus, respectively, $f(u,v)$ is the number of sentences in which u and v co-occur, and N is the number of sentences in the corpus. u and v are said to co-occur if they are found in the same sentence, within a maximum distance of 10 tokens from each other, and have no overlap. We define $PPMI(u,u) = 0$ for any u.

We convert these sparse word vectors into dense embeddings as follows. First, we train a linear SVM[2] on the PPMI vectors of the words in HL, and apply it to a large lexicon of unigrams (to be described in the next section). We then select the 2,500 most positive words and 2,500 most negative words as predicted by the classifier (words in the HL lexicon were ignored). Based on the PPMI vectors of these 5,000 selected words, we learn a projection from the 6,565 dimensional space into a reduced space of 100 dimensions. Let M be a 5,000 $\times$ 6,565 matrix whose rows are the representations of the selected words. We compute the truncated Singular Value Decomposition (Deerwester et al., 1990) for M, $M_d = U_d \cdot \Sigma_d \cdot V_d^T$, with $d = 100$, following the notation of Levy et al. (2015). A PPMI row vector x for any new n-gram u (not in HL) can then be projected into the reduced space by taking the product $x \cdot V_d$. The resulting dense representation is much more compact, and is expected to work better for lower-frequency bigrams with sparse PPMI vectors.

[2]We used LIBSVM, (Fan et al., 2008).

#	Class	Condition UG1	Condition UG2	Predicted Bigram Polarity	
	Composition Classes				Sample match
1	REV$\oplus$	w	$\ominus$	$\oplus$	**combat** loneliness
2	REV$\ominus$	w	$\oplus$	$\ominus$	**lacked** courage
3	PROP$\oplus$	$w \wedge \ominus$	$\oplus$	$\oplus$	**overwhelming** success
4	PROP$\ominus$	$w \wedge \oplus$	$\ominus$	$\ominus$	**fresh** trouble
5	DOM$\oplus$	w		$\oplus$	**improving** nutrition
6	DOM$\ominus$	w		$\ominus$	**reckless** decision
	Adjective Classes				Sample match for (high,low)
7	ADJ(a_1,a_2)$\oplus\ominus$	$E(a_1)$	w	$\oplus$	high **morale**
8	ADJ(a_1,a_2)$\oplus\ominus$	$E(a_2)$	w	$\ominus$	low **morale**
9	ADJ(a_1,a_2)$\ominus\oplus$	$E(a_1)$	w	$\ominus$	higher **inflation**
10	ADJ(a_1,a_2)$\ominus\oplus$	$E(a_2)$	w	$\oplus$	lower **inflation**

Table 1: Definition of composition and adjective classes. Words in bold in the sample matches belong to the class.

The resulting 100-dimensional embeddings of the words in HL were used to retrain the SVM classifier. In order to assess the accuracy of the classifier, we performed a 100-fold cross validation experiment over HL words. For each fold, we removed from the training set words that have the same stem or lemma as any word in the test set. The classifier achieved high accuracy of 94.5%, confirming the effectiveness of our method.

3.2 Generating Sentiment Lexicons

Next, we created lexicons of unigrams and bigrams, computed their embeddings and applied the classifier to predict their sentiments. For the unigrams lexicon we selected words whose length is between 2 and 20 characters, are alphabetic and in WordNet (Miller, 1995), and their frequency in the corpus is at least 2000. This resulted in about 66,000 unigrams. For the bigram lexicon we selected bigrams that contain only unigrams from the unigram lexicon, and have minimum frequency of 250. The resulting lexicon of 2.8 million bigrams was still very noisy. In order to obtain a bigram lexicon of coherent phrases, we filtered out bigrams that the PMI between their unigrams is below 3.0. Finally, we only kept bigrams whose part-of-speech tag sequence form grammatical bigrams, e.g., *Adjective-Noun*, *Noun-Noun*, *Verb-Noun*, *Adverb-Adjective* etc. The resulting lexicon contains 262,555 bigrams. The classifier's real-valued predictions were normalized to the range of $[-1, 1]$. Unigrams that had sentiment in HL kept their original sentiment ($+1$ or -1).

3.3 Extracting Composition Lexicons

Finally, we define two types of classes that cover a variety of sentiment composition processes: *composition classes* model sentiment reversals and conflicting (opposing) sentiments; *adjective classes* determine the sentiment of phrases that contain specific gradable adjectives or their expansions. Our method learns a lexicon for each class, based on the unigram and bigram sentiment lexicons acquired in the previous step.

The classes are formally defined in Table 1. Each class definition has two parts: the *condition* for matching the class in a bigram, and the *predicted bigram polarity* (positive $\oplus$ or negative $\ominus$), in case the class is matched. The condition specifies in which unigram a word w from the class should be matched (the first unigram UG1 or the second unigram UG2), and optionally additional constraints on the other unigram. The table also shows a sample match for each class. For example, REV$\oplus$ (row 1 in the table) is a *Reverser*. Words in this class are matched in UG1, and if in addition UG2 is negative, the resulting bigram would be positive, e.g., ***combat*** *loneliness*. Similarly, REV$\ominus$ (row 2) flips the polarity from

positive to negative.

The other two types of composition classes are *Propagators (*PROP*)* and *Dominators (*DOM*)*. Propagators (rows 3-4) are sentiment words that, when followed by a word with opposite sentiment, "propagate" the sentiment of the other word to the bigram level, e.g., ***pure*** *vandalism*. Finally, dominators (rows 5-6) dictate the sentiment of the bigram, overriding any conflicting sentiment of the other unigram, if any.

Composition classes are extracted as follows. Let $C(c, w)$ be the set of bigrams in the bigram lexicon that satisfy the condition of class c for word w, and let $S(c)$ be the set of bigrams whose polarity is the one predicted by c. The precision of w with respect to c can be defined as:

$$P(c, w) = \frac{|S(c) \cap C(c, w)|}{|C(c, w)|} \tag{2}$$

The above formula gives uniform weights for all the bigrams in $C(c, w)$. However, we found that it is beneficial to also take into account the uncertainty stemming from the automatic sentiment prediction of the unigrams and bigrams. We do so by weighting each bigram according to strength of the predicted bigram sentiment, and for classes where the sentiment of UG2 is part of the match (REV and PROP), also according to the sentiment strength of UG2. Let $s(x)$ be the sentiment score of an n-gram x in the lexicon, and let wu be a bigram where UG1=w and UG2=u. The weighted formula is:

$$P(c, w) = \frac{\sum_{wu \in S(c) \cap C(c,w)} |s(u) \times s(wu)|}{\sum_{wu \in C(c,w)} |s(u) \times s(wu)|} \tag{3}$$

For DOM classes, we take $s(u) = 1$, since the sentiment of u is not part of the match. Weak sentiment of bigrams and unigrams (between -0.1 and 0.1 for unigrams, and between -0.05 and 0.08 for bigrams) is considered neutral sentiment.[3]

We include in c words w such that $P(c, w) > \alpha$ and $|C(c, w)| \geq k$. We use $|C(c, w)|$ as our confidence measure, by which we rank the words in each class. We took $(\alpha = 0.8, k = 10)$ for reversers and propagators, and $(\alpha = 0.95, k = 20)$ for dominators.[4]

Adjective classes are defined for specific pairs of opposing gradable adjectives (a_1, a_2) (rows 7-10). In this work we considered the pairs *(high, low)* and *(fast, slow)*. Since a_1 and a_2 are antonyms, we assume that if the bigram $a_1 w$ is positive, then the bigram $a_2 w$ is likely to be negative, and vice versa. We therefore learn two classes for each pair: ADJ(a_1,a_2)$\oplus\ominus$ contains words that are positive with a_1 and negative with a_2. ADJ(a_1,a_2)$\ominus\oplus$ contains words that are negative with a_1 and positive with a_2.

Adjective classes are learned as follows. We manually define a set of expansions $E(a)$ for each adjective a ($E(a)$ also includes a itself), e.g. *higher*, and *increasing* for *high*.[5] Let $B(a, w)$ be the set of all the bigrams in the lexicon such that UG1 is in $E(a)$ and UG2 is w. The score of a given word w with respect to the adjective pair (a_1,a_2) is defined as:

$$S_{(a_1,a_2)}(w) = \frac{\sum_{x \in B(a_1,w)} s(x)}{|B(a_1, w)|} - \frac{\sum_{x \in B(a_2,w)} s(x)}{|B(a_2, w)|} \tag{4}$$

We select for ADJ(a_1,a_2)$\oplus\ominus$ and ADJ(a_1,a_2)$\ominus\oplus$ words w with $S_{(a_1,a_2)}(w)$ above 0.1 or below -0.1, respectively, and use the absolute value of this score to rank the predictions.

4 Results

In this section we briefly describe the lexicons that were learned for each class by our method. Table 2 shows the number of words in each class. 2,783 words were learned in total. The biggest classes are the dominators, in spite of the higher thresholds that are applied to their results, compared to the reversers and the propagators. This happens because their matching condition is the weakest.

[3]The thresholds were determined heuristically by observing the resulting lexicons.

[4]α and k were selected heuristically by observing the resulting lexicons.

[5]The expansions we used are listed as part of the released dataset.

Class	Word Count
REV⊕	54
REV⊖	106
PROP⊕	48
PROP⊖	152
DOM⊕	666
DOM⊖	662
ADJ(*high,low*)⊕⊖	316
ADJ(*high,low*)⊖⊕	416
ADJ(*fast,slow*)⊕⊖	294
ADJ(*fast,slow*)⊖⊕	70
Total	2,783

Table 2: Number of words per class.

REV⊕		PROP⊕		DOM⊕	
less	wasteful	**critical**	acclaim	**unique**	culture
reduce	stress	**cloud**	solution	**beautiful**	gardens
reducing	inflammation	**proprietary**	insights	**wonderful**	atmosphere
preventing	violence	**complex**	ideas	**innovative**	approach
fewer	dropouts	**challenging**	endeavor	**digital**	capabilities
combat	inequality	**overwhelming**	victory	**excellent**	service
reduces	fraud	**invasive**	therapy	**strategic**	thinker
healthy	ageing	**intense**	commitment	**creative**	spirit
eliminate	racism	**strict**	compliance	**diverse**	environment
reduced	bureaucracy	**disruptive**	innovation	**good**	deeds
REV⊖		PROP⊖		DOM⊖	
poor	reputation	**pretty**	awful	**too**	often

negative	contribution	**hot**	mess	**dangerous**	situation
insufficient	protection	**clearly**	drunk	**violent**	outbursts

Table 3: Top-ranked words in each composition class.

Table 3 shows the top-ranked words in each composition class. Each class word (in bold), is followed by a sample UG2 match for that word and the class in the bigram lexicon. For example, ***critical*** *acclaim* is a bigram in $C(\text{PROP}\oplus, critical)$. For the propagator classes, we only show words in HL. These words have the strongest sentiment and therefore are the most challenging for opposing sentiment resolution. In addition, in the experiment to be described in Section 6.2, we use HL as our sentiment lexicon, so only propagators in HL will be matched. Interestingly, the classes learned for REV⊕ and for REV⊖ are disjoint, indicating that the reversers operating on positive words are rather different from those operating on negative words.

Table 4 shows the top-ranked words for adjective classes. For example, *high morale* is positive, and *low morale* is negative, while for *unemployment* it is the other way around.

ADJ(*high,low*)⊕⊖	ADJ(*high,low*)⊖⊕	ADJ(*fast,slow*)⊕⊖	ADJ(*fast,slow*)⊖⊕
morale	unemployment	economic	turns
productivity	poverty	broadband	temper
ceilings	crime	implementation	spiral
literacy	costs	loading	escalation
standards	anxiety	response	buck
quality	noise	progress	spreading
ethical	violence	wit	spread
profitability	debt	learner	breathing
visibility	inequality	reaction	escalates
competitiveness	handedness	growth	population

Table 4: Top-ranked words in adjective classes.

5 Manual Asssessment

We conducted manual assessment of the precision of each class, by measuring the fraction of bigrams that have the polarity predicted by the class, out of the bigrams matched by the class. To this end, we selected from the bigram lexicon a random sample of bigrams matched by each class. Recall that some of the classes require positive or negative sentiment in UG1 and/or UG2. Our goal is to estimate the precision of the predicted bigram polarity, given that the matching is correct. In order to avoid incorrect sentiment matches caused by errors in our automatically-learned unigram sentiment lexicon, we restricted here the sentiment matches to words from the HL lexicon. We sampled 100 bigrams for each composition class, except for PROP⊕, which only had 59 matching bigrams[6]. In addition, we sampled 100 bigrams for each adjective pair (conflating the positive and negative classes for each pair).

Each of the resulting 759 bigrams was annotated by three in-house human annotators, who were asked to assess the bigram sentiment (positive/negative/neutral). They also had the option to indicate that the bigram is an incomplete phrase. Fleiss' kappa (Fleiss, 1971) for inter-annotator agreement was 0.61, indicating *substantial agreement* (Landis and Koch, 1977). The gold label for each bigram was obtained by taking the majority annotation. Ties were adjudicated by one of the authors (34 in total). We then removed the 59 bigrams assessed as incomplete, and computed precision for each class over the remaining 700 bigrams.

The results are summarized in Table 5. The precision achieved by the various classes seems very promising, in particular considering that the only sentiment-annotated input for learning these classes was a unigram sentiment lexicon. Error analysis reveals that the vast majority of misclassifications (84.6%) were labeled as neutral by the majority of the annotators, and in 25.1% of them, one annotator agreed with the class prediction, and the other two were neutral.

The learned classes provide a good starting point for semi-automatic construction of composition lexicons. We believe that their quality can be easily improved with manual filtering of our results, which can be done rather quickly.

6 Experiments

In this section we demonstrate the contribution of the learned composition and adjective classes to both phrase-level and sentence-level sentiment classification tasks. In line with our method for learning the classes, we focus in this section on sentiment analysis methods that do not rely on sentiment-labeled phrases or sentences for training.

6.1 Phrase Polarity Classification

In this experiment we test the extracted lexicons for composition and adjective classes and the bigram sentiment lexicon on the Opposing Polarity Phrases (OPP) lexicon released by Kiritchenko and Mo-

[6]Note that for this class we require here that UG1 is negative in HL and UG2 is positive in HL.

Class	Precision		
	⊕	⊖	Total
REV	0.79	0.78	0.78
PROP	0.75	0.81	0.79
DOM	0.71	0.79	0.75
ADJ(*high,low*)			0.68
ADJ(*fast,slow*)			0.75
All			0.76

Table 5: Precision assessment.

Exp	Sentiment Score	Accuracy (All)	Coverage	Accuracy (Covered)
c0	Most polar unigram	0.668		
c1	Composition	0.713	0.355	0.761
c2	Bigram score	0.726	0.309	0.863
c3	Bigram score or Composition	0.746	0.541	0.807

Table 6: OPP bigram binary classification accuracy and coverage results.

hammad (2016), which consists of phrases with words of opposing polarity. The dataset contains the sentiment score of each n-gram, the part-of-speech tags of the constituent unigrams, and the sentiment of all the unigrams included in the phrases, with a total of 307 bigram and 262 trigram phrases with a non-zero sentiment score. The phrases were collected from Twitter and the sentiment scores were obtained by manual annotations. The purpose of the OPP lexicon is to train and test sentiment composition models for opposing polarity phrases and therefore it is suitable for testing our classes and bigram sentiment prediction methods. Kiritchenko and Mohammad tested both supervised and unsupervised methods for sentiment classification and ranking. Here, we focus on unsupervised classification of bigrams.

Table 6 shows our experimental results. The baseline, c0, is the best-performing unsupervised method reported by Kiritchenko and Mohammad. This method determines the bigram polarity according to the most polar unigram score. Then, in experiment c1 (*Composition*), we predict the sentiment of the bigram by trying to match each of the classes in the bigram according to the following order: ADJ, REV, PROP, DOM. The order is based on the match specificity of the other word in the bigram (the non-class word): ADJ requires a match in a small set of adjective expansions, REV and PROP only require a certain polarity (positive/negative), and DOM does not restrict the other word. The first class that is applicable for the bigram is selected. For the matched class, we predict the bigram sentiment according to the rules in Table 1. In our second experiment c2, we use the predicted bigram score, and in c3 we use the two methods in cascade: if the bigram score is not available, we try the composition method of c1. In all three experiments, we back off to the most polar unigram score (c0) in cases that the test bigram is not covered by our predictions, so the accuracy results under the *Accuracy (All)* column are reported over the complete dataset. The *coverage* of each method is defined as the fraction of predicted bigrams out of all the bigrams in the dataset. Finally, *Accuracy (Covered)* is the accuracy only for the bigrams covered by each of the methods c1-c3.

The best performance is achieved by configuration c3, which utilizes both the bigram sentiment scores and the composition and adjective classes. By combining the two methods, we are able to address both idiomatic phrases (e.g. *top gun*) and compositional phrases (e.g. *great loss*) in the OPP dataset. c3 achieves an absolute improvement of 7.8% in accuracy with respect to the baseline c0, over the whole dataset. The differences between c1-c3 and the baseline c0 are all statistically significant, with $p < 0.05$ for c1 and $p < 0.01$ for c2 and c3, according to McNemar's test (Everitt, 1992). The results show that our sentiment and composition lexicons are effective even in a domain such as Twitter, which is rather different from the corpus we used for learning.

	Positive			Negative				
	Precision	Reccall	F_1	Precision	Recall	F_1	Accuracy	Coverage
Baseline	0.703	0.462	0.558	0.810	0.525	0.637	0.761	0.653
+ADJ	0.703	**0.480**	**0.571**	**0.815**	**0.530**	**0.642**	0.764	**0.665**
+REV	**0.724**	**0.487**	**0.582**	**0.822**	**0.541**	**0.653**	**0.778**	**0.665**
+PROP	**0.724**	**0.488**	**0.583**	**0.823**	**0.545**	**0.656**	**0.778**	**0.667**
+DOM	**0.720**	**0.547**	**0.622**	0.820	**0.546**	**0.655**	0.772	**0.708**

+DOM	903	164	132	607	1160	808	352

Table 8: Impact of class matches.

6.2 Sentence Polarity

We further assess the contribution of the composition and adjective classes to a lexicon-based sentiment classification of sentences.

The baseline system matches terms from the HL lexicon in the sentence. If the number of positive matches is greater than negative matches, we predict positive; if there are more negative matches, we predict negative; otherwise we predict neutral.

We then add the classes incrementally. If a class is matched in a bigram, it may modify the sentiment of that bigram. For example, suppose that the sentence contains the bigram *preventing cancer*. The baseline system will match *cancer* from the HL lexicon in the bigram, giving it negative sentiment of -1. Then the word *preventing* from the class REV$\oplus$ will be matched (line 1 in Table 1), since it is followed by a negative unigram. As a result, the sentiment of the bigram will become positive, and will get the score 1. The classes were added in the same order as in the previous experiment: adjectives, reversers, propagators, and dominators. We do not allow mutiple classes to match the same bigram.

For testing these lexicons we use the Claim Stance Dataset introduced by Bar-Haim et al. (2017a). This dataset contains Pro and Con claims found in Wikipedia for 55 controversial topics, and also includes labels for sentiment. We chose this dataset due to its diversity - it covers a variety of topics, and since it was also approached with a lexicon-based sentiment analysis by Bar-Haim et al. This dataset has 2,252 claim sentences that contain sentiment annotations (1012 positive and 1240 negative). We ignore sentiment found in the sentiment target that is given by the Claim Stance Dataset.

Table 7 shows results for the sentiment prediction with the baseline and after the addition of each class. We use precision, recall, and F_1 to measure performance for positive and negative classes and *accuracy* and *coverage* to measure overall performance, following previous work on this dataset. Bar-Haim et al. define *accuracy* as $\frac{\#correct}{\#predicted}$ and *coverage* as $\frac{\#predicted}{\#sentences}$. If the system returns a neutral label it is not counted as a prediction. There is consistent improvement over the baseline and each of the classes contributes to some improvement. F_1 for the positive class continues to improve with each additional lexicon. The case is similar for negative F_1 and *accuracy*, which improve up to DOM.

In Table 8 we look closer at how the classes are being matched and the impact this has on sentiment prediction. The left side of the table reports the number of sentences with class matches and breaks down how often they help ($\uparrow$), hurt ($\downarrow$), or stay the same ($\leftrightarrow$) compared to the previous lexicon (e.g., ADJ vs the baseline). We see that for the first three classes we match fewer bigrams but consistently help sentiment prediction. Adding the DOM lexicon helps more than it hurts but the numbers are more

balanced. We also see more cases where the prediction remains the same. This is because much of the dominant sentiment learned is consistent with the original lexicon. For example, matching the dominator *good* in the bigram *good decision*, while a correct match, will have no effect on the bigram polarity, since *good* was already matched from the HL lexicon as a unigram.

Without manual labels for all bigrams, another option for roughly checking the quality of the bigram matches is to check if the sentiment of the bigram is consistent with that of the sentence. This is shown in the right side of Table 8 with a report of the bigram matches. Multiple bigrams can match in a sentence so there may be more bigram matches than sentence matches. If the bigram is given the same sentiment as the sentence we count it as consistent ($=$), otherwise inconsistent ($\neq$). This does not strictly mean that the bigram polarity is correct or not, but it does give us a rough idea if the sentiment is correct and if it helps improve the sentence sentiment prediction. The results show that all the classes are consistent with the sentence sentiment in most of the cases. The dominators have far more matches but they are also much noisier than the other classes.

7 Conclusion

We presented a new approach for learning sentiment composition from a large, unlabeled corpus, which only requires a word-level sentiment lexicon for supervision. Our method learns lexicons that can address important sentiment composition phenomena such as sentiment reversals and mixed sentiment expressions. Manual assessment of the predictions made by these classes showed promising results. The classes were also shown to improve both phrase-level and sentence-level sentiment classification.

The automatically learned sentiment lexicons of bigrams and unigrams proved to be very useful for research on sentiment composition. We made them publicly available, and hope it will promote further research in this area. It would also be interesting to apply our method to languages other than English. Finally, we would like to investigate how much our results can be further improved in a semi-supervised setting, where the automatically-acquired classes are filtered by human annotators.

Representations and Architectures in Neural Sentiment Analysis for Morphologically Rich Languages: A Case Study from Modern Hebrew

Adam Amram and **Anat Ben David** and **Reut Tsarfaty**
The Open University of Israel, University Road 1, Ra'anana
adam.amram@gmail.com, {anatbd,reutts}@openu.ac.il

Abstract

This paper empirically studies the effects of representation choices on *neural sentiment analysis* for Modern Hebrew, a *morphologically rich language* (MRL) for which no sentiment analyzer currently exists. We study two dimensions of representational choices: (i) the granularity of the input signal (token-based vs. morpheme-based), and (ii) the level of encoding of vocabulary items (string-based vs. character-based). We hypothesise that for MRLs, languages where multiple meaning-bearing elements may be carried by a single space-delimited token, these choices will have measurable effects on task perfromance, and that these effects may vary for different architectural designs: fully-connected, convolutional or recurrent. Specifically, we hypothesize that morpheme-based representations will have advantages in terms of their generalization capacity and task accuracy, due to their better OOV coverage. To empirically study these effects, we develop a new sentiment analysis benchmark for Hebrew, based on 12K social media comments, and provide two instances thereof: *token-based* and *morpheme-based*. Our experiments show that the effect of representational choices vary with architectural types. While fully-connected and convolutional networks slightly prefer token-based settings, RNNs benefit from a morpheme-based representation, in accord with the hypothesis that explicit morphological information may help generalize. Our endeavor also delivers the first state-of-the-art broad-coverage sentiment analyzer for Hebrew, with over 89% accuracy, alongside an established benchmark to further study the effects of linguistic representation choices on neural networks' task performance.

1 Introduction

Deep learning (Goodfellow et al., 2016) has seen a surge of interest in recent years, transforming all application domains of machine learning. In particular, *neural network* (NN) architectures currently dominate the development of models and applications in NLP, including syntactic parsing (Chen and Manning, 2014; Dyer et al., 2015; Durrett and Klein, 2015), sequence labeling (Grave, 2008), information extraction (Chen et al., 2015; dos Santos et al., 2015), text classification (Lai et al., 2015; Zhang et al., 2015) and sentiment analysis (Dos Santos and Gatti, 2014; Dong et al., 2014).

Much NN work in NLP has been conducted on English, which in turn raises the question whether these methods will be equally effective when applied to languages with different linguistic characteristics than English, and in particular, *Morphologically rich languages* (MRLs) (Tsarfaty et al., 2010). MRLs are languages where word structure holds substantial information, corresponding to multiple meaning-bearing units (morphemes) per space-delimited token. Furthermore, in MRLs word-order may be flexible. These properties may pose challenges to NN models which rely heavily on the *distributional* characteristics of the input tokens. While it is clear that *any* application of NN architectures to NLP may be non-trivial to design, and task performance may crucially depend on non-trivial architectural and modelling choices (Goldberg, 2015), we further ask: should these choices also be affected by the structure and properties of the language?

Proceedings of the 27th International Conference on Computational Linguistics, pages 2242–2252
Santa Fe, New Mexico, USA, August 20-26, 2018.

In this paper we attend to this question by empirically studying the effects of two dimensions of representational and modeling choices on *neural sentiment analysis* for Modern Hebrew — an MRL with interesting word-internal complexities and surface level ambiguity — and for which no sentiment analyzer currently exists.

We study two dimensions of representation choices: the first concerns the representation of the morphologically-rich input signal, *token-based* vs. *morpheme-based*, and the second concerns the level of encoding of the vocabulary items, which could be embedded as complete *strings* or as sequences of *characters*. We study these modeling choices for five architectures (a linear baseline and four NNs: fully-connected, convolutional, recurrent, and bi-directironal recurrent) to observe and analyze emerging trends in performance. In order to empirically evaluate the different models we develop a new and novel benchmark dataset for sentiment analysis in Hebrew, consisting of 12K user-generated comments on official Facebook pages of political figures. The sentiment of each comment has been manually coded by two trained human annotators, and the data themselves have been morphologically analysed and disambiguated, providing us with the opportunity to represent the input at different granularities.

Our experiments show that representation choices affect task performance, and these effects vary with the architectural type. While simple fully-connected and convolutional networks show advantages with the *token-based* representation, RNNs, in contrast, prefer *morpheme-based* settings and token-based bi-RNNs close much of the gap with the morphemes. This is the case for both the *string-based* and *char-based* encoding. We further show that, as in English, CNNs perform particularly well on Hebrew neural sentiment analysis, and conjecture that this is due to the tendency of CNNs to capture relatively large window sequences that are strong predictors, and these windows are, in turn, compatible with token-level granularity. Based on this investigation, we deliver the first sentiment analyser for Hebrew, with over 89% accuracy on analysing sentiment of user-generated comments, defining a new state-of-the-art for Hebrew NLP. A qualitative analysis of a sample of our best model's prediction errors shows that around a half of the remaining errors are also difficult for humans to classify, and require further work on integrating finer-grained aspects of the data.

Our contribution is then manifold. Firstly, we present empirical evidence to the varied effects that morphological information may have on different NN architectures. Secondly, we deliver a neural sentiment analyser for Hebrew, approaching 90% accuracy, on social media content. Finally, we provide a new manually annotated benchmark for Hebrew sentiment analysis, and a strong baseline for further investigation of the *task-representation-architecture* interplay and neural sentiment analysis in particular.

2 Task Description

Sentiment is a subjective attitude towards, for or against, a certain topic. The term *sentiment analysis* refers to the use of natural language processing and machine learning methods for the purpose of identifying or characterizing the sentiment expressed in a given piece of textual data (Pang and Lee, 2008). In this work we focus on sentiment analysis of social media content.

Due to their use by wide audiences, data extracted from social media are valuable sources for studying social, political and economic phenomena. One of the main motivations to analyze sentiment on the social web is *opinion mining*, an approach that challenges the traditional and dominant paradigms in political science, such as opinion polling, surveys or focus groups (Liu, 2012). Affect responses on social media have also been applied to study political behaviour (Ceron et al., 2014), determine organizational legitimacy (Etter et al., 2017), and even predict results of election campaigns (Tumasjan et al., 2010). While Twitter is a social media platform that lends itself naturally to sentiment analysis due to the short, informal character of tweets (Kouloumpis et al., 2011), various sentiment models analysed online conversations on other platforms (Paltoglou and Thelwall, 2012).

Open-source tools and sentiment analysis algorithms are available in several languages, including Arabic (Abdulla et al., 2013; Abdul-Mageed et al., 2014; Al Sallab et al., 2015), but as of yet no sentiment analysis tool is available for Hebrew. This represents a serious gap in the NLP technology available for Hebrew, and moreover, it places a significant barrier on the investigation of political situations through the unfolding conversations in the social web. Here we aim to leverage NN architectures for developing

a sentiment analysis tool for Modern Hebrew, in order to facilitate opinion mining in Israeli social media, and to expand the language technology available for the Hebrew-speaking research community. Since Twitter is not widely used for political discussion in Israel, we develop a new benchmark based on user comments to politicians' pages on Facebook, which is widely used in Israel by politicians and the public.

3 Data Representation

Previous work on *sentiment analysis* in general and on *neural sentiment analysis* in particular focused mainly on English data. Here, we consider Modern Hebrew, a Semitic language with very different characteristics than English. In particular, Hebrew is a *morphologically rich language* (MRL), of which word structure is internally complex and word order is quite flexible. How might these properties affect our modeling decisions when developing a NN-based sentiment analyzer for Hebrew?

Let us begin by theoretically considering the notion of an input token in Hebrew. Because of its rich morphology, any single space-delimited token in Hebrew may contain, in addition to its lexical content, functional clitics (prefixes and suffixes) that correspond to independent stand-alone words in English. To illustrate, the word "*wkftmkti*"[1] may be morphologically segmented into "*w*" (and) "*kf*" (when) "*tmkti*" (supported+1person), and be translated to "and when I supported". Without segmenting the raw tokens into these morphological units, the positive affinity of "*tmkti*" (supported+1person) may be lost on the model, which may have observed "*tmkti*" as a standalone token elsewhere, but not in this composition.

This situation is further complicated by the fact that Hebrew surface tokens are highly ambiguous. Due to the rich morphology and the lack of diacritics in standard textual data, a Hebrew space-delimited token may admit multiple different morphological analyses, only one of which is relevant in context (Tsarfaty, 2006). For example, the token "*frch*" may be a-priory analyzed as the simple verb "*frch*" (infested+3person) or as the sequences "*f*" (that) + "*rch*" (ran+3person+feminine) or "*f*" (that) + "*rch*" (wanted+3person+masculine). The latter analysis has a stronger affinity with positive sentiment than the others. This means that improper morphological disambiguation, or lack thereof, may undermine sentiment accuracy scores.

When constructing a vocabulary and defining the alphabet on which the NN will operate, we need to make representation choices that would be suitable for these properties of MRLs. In this paper we consider two dimensions of representational choices:

- **Input Items:** *Token-Based vs. Morpheme-Based.* First, we compare NN models trained on a signal consisting of the *raw tokens* with ones trained on sequences of *morphological segments* that represent standalone lexical and functional units. The hypothesis is that models trained on morphologically segmented input will provide better generalization capacity for the network and will thus improve the prediction accuracy.

- **Vocabulary Encoding:** *String-Based vs. Char-Based.* It has been proposed in previous work (Ling et al., 2015; Ballesteros et al., 2015) that combating the complexity of word structure in NN architectures may benefit from encoding the vocabulary using sub-words or character sequences. We thus contrast models that encode vocabulary items as complete strings to ones that encode a vocabulary of characters that are used to construct each of the strings.

The empirical investigation we conduct aims to empirically answer two questions: (i) would the choice of representation affect prediction accuracy? and, (ii) would the different representation choices affect different neural network architectures *in different ways*?

4 Data Preparation

In order to empirically evaluate task performance for the different representational choices and architectural design, we develop a new Hebrew benchmark for sentiment analysis and provide these annotated data in two different representational forms: a *token-based* and a *morpheme-based* version.

[1] We assume the transliteration of Sima'an et al. (2001).

Positive Sentiment	Negative Sentiment
"Ruvi, well done! Keep following your predecessor. Talk less and do more. You are the right person in the right timing."	"We should revenge the entire village of the kidnappers. Without fear. A government of cowards."
"Mr. President, you radiate peacefulness, humanism and security, and I hope this will soon be the case. Bless you. Mr. President, your vigorous actions create waves of connection and healing. I thank you for being my president."	"Shame on you! We don't care about your opinion! Constitutionally, the president should be a-political and your entire stupid post is wrapped with righteous politics. Shame on you and may this soon happen to your granddaughters".

Table 1: Inter-Annotator Agreement on the Rivlin's Annotated Corpus

Coder 1, Coder 2	N cases	Example	Explanation
Positive, Negative	26	"Terrible. May he rest in peace."	Mixed sentiment
Negative, Positive	14	"I am dreaming about peace and you are dreaming about football! A wasted dream!"	Potentially sarcastic
Neutral, Negative	2	"Daniel, this is not the time to generalize people despite of what you think of him. He's a Jew just like you and me."	Internal discussion among commenters
Neutral, Positive	2	"Mr. President, how can I arrange an appointment with you? I have been cherishing you for many years, since eleventh grade."	Off-topic
Positive, Neutral	4	"Mr. President, I would like to ask you to help the communities surrounding the Gaza Strip and to provide them with adequate housing and educational services for their children in safe places until genuine calm. This is not a matter of abandonment and Hamas propaganda is baseless."	Off-topic
Negative, Neutral	2	"Why not the length and breadth of it, Mr. President"	Potentially sarcastic

Table 2: Qualitative analysis of a sample of 50 comments for which there was no inter-rater agreement

Our data set consists of 12,804 user comments to posts on the official Facebook page of Israel's president, Mr. Reuven Rivlin. In October 2015, we used the open software application Netvizz (Rieder, 2013) to scrape all the comments to all of the president's posts in the period of June – August 2014, the first three months of Rivlin's presidency.[2] While the president's posts aimed at reconciling tensions and called for tolerance and empathy, the sentiment expressed in the comments to the president's posts was polarized between citizens who warmly thanked the president, and citizens that fiercely critiqued his policy. Of the 12,804 comments, 370 are neutral; 8,512 are positive, 3,922 negative.

We use a morphosyntactic parser called *yap* (*yet another parser*) (More and Tsarfaty, 2016) to morphologically analyze, disambiguate and segment all comments in our dataset. In the token-based representation, there is an average of 23 tokens per comment, and in the morpheme-based representation an average of 31 morphemes per comment. In terms of *out-of-vocabulary* (OOV) items, we observe a higher OOV rate in the token-based test set, 8.865% (2552 out of 28787), compared to the OOV rate 7.624% (1442 out of 18912) with the respective morpheme-based representation of the same set, as expected. So, at least in theory, a morpheme-based representation may better generalize from training instances, at least in cases where the composition of seen morphemes yields unseen tokens.

Data Annotation: A trained researcher examined each comment and determined its sentiment value, where comments with an overall positive sentiment were assigned the value 1, comments with an overall negative sentiment were assigned the value -1, and comments that are off-topic to the post's content were assigned the value 0. We validated the coding scheme by asking a second trained researcher to code the same data. There was substantial agreement between raters (N of agreements: 10623, N of disagreements: 2105, Coehn's Kappa = 0.697, p = 0).

Table 1 shows examples of positive and negative sentiment in clear cases of agreement between human annotators. We further examined the source of disagreements between the annotators. In a qualitative analysis of a sample of 50 comments for which there was disagreement between raters, summarized in

[2]It should be noted that the period of data collection was politically and socially charged. This has been due to a series of violent events that escalated fragile tensions with regards to Jewish-Arab relations in the region, including the kidnapping and murder of three teenagers living in the settlements of the West Bank, a revenge murder of an Arab teenager in East Jerusalem, a two-months war in Gaza, and a controversial wedding between a Jewish woman and an Arab man which sparked demonstrations led by extremist Jewish groups.

Table 2, we observe that the majority of the disagreement cases originated in comments that contained mixed sentiments, such as in the following:

- "Mr. President, every person has the right to decide on their lives, but converting to Islam in these crazy days, which is what her partner wanted, means that their offsprings will not be Jewish. You are talking about racism but they want to destroy us because we are Jews. Mr. President I wish you success, health and joy".

- "The hotheads, the enemy inside. The real enemy 'thanks' to whom we were scattered in all directions in the era of the Temple, the real enemy that might put us all in the grave".

In the first example, the commenter expresses a positive and respectful sentiment towards the president, but displays a negative sentiment towards conversion to Islam. In the second example, the sentiment can be interpreted in both directions. The content of the comment expresses negative sentiment towards the 'hot heads', but reading in also the context on the president's post, it actually expresses positive sentiment towards the idea that tolerance is better than hatred. It appears then that the unrestricted length and form of expression in Facebook comments makes the overall sentiment classification task more challenging.

Data Normalization and Two-Level Representation: We excluded from the dataset comments that do not contain any word in Hebrew. We also added spaces to separate Hebrew (or English) tokens, numbers, and punctuation symbols from one another in the text sequence. We then fed the raw tokens in our dataset to a morphological analysis and disambiguation parser (More and Tsarfaty, 2016), to build the respective morpheme-based representation. We split our dataset into a *train set* (80%) and a *test set* (20%) of sizes 10,244 and 2,560 comments, respectively. Out of the comments in the *train set*, 20% are reserved as *dev set* for evaluation and optimization after each epoch.

5 Neural Network Architectures for Sentiment Analysis

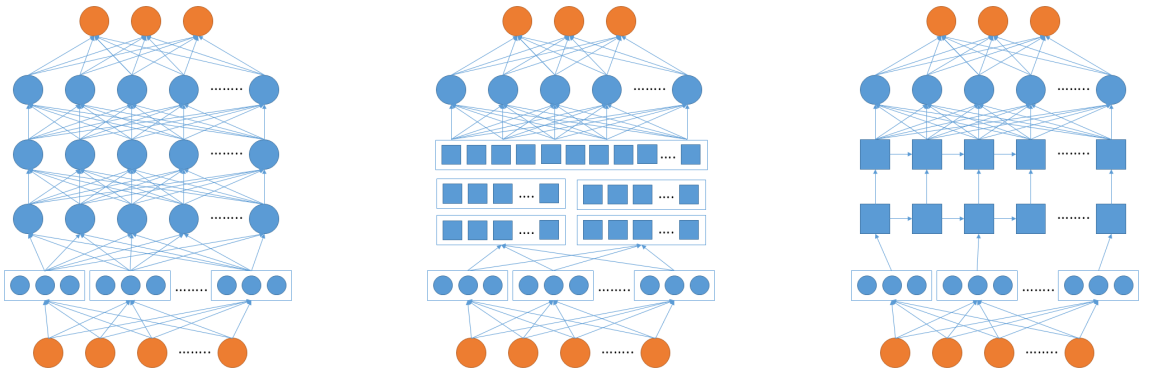
For each of the representation choices outlined above, we set out to compare and contrast the performance of different architectures. In all cases, we learn from our data a sentiment analysis function $f : x \rightarrow y$, where $x \in \mathcal{X}$ is a textual sequence which may be represented and encoded in the different ways discussed in Section 3, and $y \in \{$*positive, neutral, negative*$\}$ is a three-way classification of sentiment polarity.

We compare traditional linear models with non-linear models, contrasting different choices of NN architectures. Simple feed-forward fully-connected networks, such as the *multi-layer perceptron* (MLP), accept a sequence of items as input, which are then treated as features of the model (a *bag of words* (BOW) approach). They are simple to conceptualise and construct, however, the BOW representation, while highly sensitive to lexical content, is insensitive to any sequencing or ordering preferences. So, "The soup was not good, it was bad" may score the same as "The soup was not bad, it was good".

To capture some ordering information, it is customary to employ a feed-forward convolutional neural network (CNN) with a pooling layer. CNN architectures apply a non-linear function on a sliding window over words in the comment, and transform it to channel size vector. Then, a "pooling" operation combines the different vectors into a single channel size vector, that is in turn used for prediction. CNNs were previously shown to provide excellent performance on sentiment analysis of English (dos Santos et al., 2015). Would it be possible to replicate these achievements for Hebrew?

Ordering information may alternatively be captured by changing the network architecture to explicitely encode a sequence: this can be done using *recursive* or *recurrant neural networks* (RNNs). Indeed, various English sentiment analyzers assume RNNs at their backbone (Dong et al., 2014). For sentiment analysis we assume an RNN architecture, where the intermediate states throughout the sequence are used for prediction, loss calculation, and back propagation to update previous states.

In this work we consider a concrete implementation of RNNs — *Long Short-Term Memory* (LSTM) networks (Hochreiter and Schmidhuber, 1997) — which preserves gradients over time using functions that simulate logical gates (memory cells). At each input state, a gate is used to decide how much of the new input should be written to the memory cell, and how much of the current content of the memory



(a) The MLP Architecture (b) The CNN Architecture (c) The RNN Architecture

Figure 1: The Neural Network architectures in our experiments. All architectures started with an input vector of word/char index followed by an embedding layer with embedding size 300. In (a) we used 3 fully-connected layers, the first with 256 units, the second with 128 units and the third with 64 units. Each fully-connected layer has a dropout rate of 0.5. (b) uses 2 parallel convolution layers with 128 filters and kernel size of 3, 8 for *string-based* and 10, 30 for *char-based*. After the convolution, we apply max pooling with pooling size of 2. We then concatenate the results from previous layers and feed it to a fully-connected layer with 128 units and 0.5 dropout rate. (c) uses 2 layers of specific RNN implementations, LSTM or BiLSTM, followed by a fully-connected layer with 128 units and 0.5 dropout.

should be forgotten. Three gates are controlling for input, forget and output. Gate values are computed based on linear combinations of the current input and the previous state.

We also consider *Bidirectional-RNNs*, and in particular, a *Bidirectional-LSTM* (BiLSTM), which is a variant of LSTMs that has been shown to perform well on various sequence labeling and transduction tasks. BiLSTMs maintain two separate states for each input position, one forward and one backward. The forward and backward states are generated by two different LSTMs. The first LSTM is fed the input sequence as is, while the second LSTM is fed the input sequence in reverse. For morphologically rich sequences as discussed here, BiLSTMs may potentially capture the influence of prefixes and suffixes on upcoming content as well content that precedes them. At least in theory, such effects may help leverage morphological phenomena for classification.

6 Experiments

We set out to evaluate the effects of different input representation choices (Sections 3) and different architectural choices (Section 5) on neural sentiment analysis for Modern Hebrew. All of our models aim to learn the same objective function $f : x \rightarrow y$ where $x \in \Sigma^*$ is a sequence of vocabulary items over an alphabet Σ, encoded in the different ways detailed in Section 3. The output is a sentiment value $y \in \{positive, neutral, negative\}$.

We compare a traditional **Linear** basedline model to four different NN-based models: **MLP, CNN, LSTM** and **BiLSTM**. We implemented our models using Keras (Chollet, 2015) a high-level API with TensorFlow (Abadi et al., 2015) running as the backend engine. All models start with input represented by a vector of word/char index which is fed into an embedding layer, followed by the specific model layers (e.g. convolutional, RNN, etc.), and conclude with a softmax activation for the output. All of our NN models' architectures are depicted in Figure 1.

The **Linear** model contains a single fully-connected layer with 100 units and without activation. This is the only model that did not include an embedding layer and dropout regularization. The **MLP** model contains 3 fully-connected feed-forward layers, the first with 256 units, the second with 128 units and the third with 64 units. We apply dropout with rate of 0.5 on each fully-connected layer. Our **CNN** (ConvNet) contains two convolutional layers, one with kernel size 3 and the other with kernel size 8. After each convolutional layer there is a max pooling layer. These layers are followed by a fully-connected layer

(a) *String-based Vocabulary*					
Architecture: *Input Representation:*	**Linear**	**MLP**	**CNN**	**LSTM**	**BiLSTM**
Token-Based	68.20	**86.80**	**89.20**	85.20	87.40
Morpheme-Based	66.13	86.40	89.06	**86.20**	**87.50**
(b) *Char-based Vocabulary*					
Architecture: *Input Representation:*	**Linear**	**MLP**	**CNN**	**LSTM**	**BiLSTM**
Token-Based	**69.38**	74.60	82.40	69.50	73.70
Morpheme-Based	68.71	74.50	78.55	70.60	73.10

Table 3: Accuracy results (percentage of correct label predictions) for all architecture and representation choices on our test set; for (a) the *string-based* vocabulary, and (b) the *char-based* vocabulary (b).

with 256 units. For *char-based* we changed the kernel sizes to 10 and 30.[3] Our **RNN/BiRNN** Recurrent Neural Network architectures contain two specific RNN implementations (LSTM or BiLSTM) with 93 units followed by 1 fully connected layer with 256 units and 0.5 dropout rate.

All models use the cross-entropy loss for training and Adam optimizer (Kingma and Ba, 2014) to update models weights and biases. We set a learning rate of $1e-4$, and use batch size of 50 for training.

We evaluate two alternatives for representing the input: a *token-based* representation, where raw tokens are passed on as they are, and a *morpheme-based* representation, where the input signal is first morphologically disambiguated and is passed on as a sequence of morphological segments. From the train dataset we created a vocabulary Σ with 5K top items (tokens/morphemes). Then, we considered two alternatives of encoding the vocabulary items. A *string-based* encoding, where each of the tokens/morphemes is represented as a single item in the vocabulary, and a *character-based* representation assuming a narrower vocabulary, consisting of alphanumeric characters and special signals, and where each item (token or morpheme) is represented as a sequence of characters. The character set used in the vocabulary of our char-based models consists of 220 characters, including Hebrew letters, digits, and other characters such as white space and a new line character.

We set the comment length limit to 100 items (tokens or morphemes) in the *string-based* encoding and to 300 for *char-based* encoding. If a sequence was less than the limit, we padded it with the padding value, and if it is greater we trimmed it.

Results: Table 3(a) presents the results of the empirical comparison between our five architectures, in *token-based* vs. *morpheme-based* settings, for the *string-based* encoding of vocabulary items. When contrasting *token-based* and *morpheme-based* NN architectures in *string-based encoding*, the most striking outcome is that representation choices do have an effect on task performance, and that the difference in task performance varies across architectures.

First of all, we see that linear models, assuming a naïve classification architecture based on unigram features, perform roughly at the same level as a "majority vote" baseline, i.e., a classifier that would simply predict "positive" for all cases. In our data, "positive" constitutes 66.6% of the gold judgments. Yet, we observe a clear empirical advantage to the *token-based* representation over *morpheme-based* in this setting, perhaps since tokens allow more context to enter the classification — these tokens may essentially be seen as n-grams of morphological segments. Furthermore, in feed-forward networks, both fully-connected and convolutional, there is still an advantage to the token-based representation. We conjecture that this is due to the inherent order-insensitivity of these models. Morphological segments out of context may be less informative, and tokens capture more context of particular morphemes, where these larger "chunks" may exhibit particular ngrams that are strong predictors.

RNNs, in contrast, prefer the morpheme-based setting, and in the LSTM this is in a non-negligible margin. This is in line with our hypothesis that explicit modeling of morphology may capture interactions of elements in the sequence and allow for better generalization thereof. In contrast with MLPs and CNNs, RNNs consider the entire sequence for classification, and so it may be the case that previously unseen tokens in the sequence may undermine classification in token-based settings. This RNN representation

[3]This design outperformed CNNs with smaller (3,4,5) and larger (5,10,15) kernel sizes in our preliminary experiments.

can benefit from the more compact vocabulary of the morpheme-based models, and may also benefit from the decomposition of unknown tokens into potentially known morphemes to better generalize from seen sequences to unseen ones. That said, it is to note that token-based BiLSTM closes much of the gap with the morpheme-based setting, which suggests that the bidirectional representation of tokens perhaps already implicitly captures some aspects of tokens' internal decomposition and morphological signature.

The best result across all models is obtained with the token-based CNN. As in English, CNNs show excellent performance for this task, providing state of the art results for Hebrew sentiment analysis, above 89% accuracy. In particular, this is obtained in the token-based settings, where tokens are compatible with the "n-gram" views filtered through the convolution.

Table 3(b) presents the results of the same comparisons, for *char-based* vocabulary encoding. Interestingly, for the linear model the char-based representation outperforms the string-based counterpart, but these models still lag far behind the rest of the neural networks. With simple and convolutional feed-forward networks we continue to see that token-based representations outperform. Yet, in all cases, we see better scores for the parallel models in the *string-based* setting. RNNs are inferior to all CNNs and MLPs, still presenting an advantage to the morpheme-based representation, and almost no difference in the BiLSTM experiment. It seems that while characters may be able to capture some (morphological) regularities inside tokens, they are not very good at capturing the content of long character sequences.

For our best model overall, a token-based CNN in the string-based lexicon encoding, we compared the automatic prediction on a sample of 50 examples with the manually annotated sentiment. 26/50 (52%) of the mis-classifications are in cases when the human raters also happen to disagree, mostly due to mixed sentiment. This suggests that further improvement will require more sophisticated, aspect-based modeling, on finer-grained sentiment targets.

The main message coming out of this investigation is that the representation of linguistic items (tokens, words, morphemes) may influence the performance of NN-based architectures in the case of MRLs, and that the extent of the difference in performance depends on the type of architecture. It should be noted though that this outcome is — quite possibly — task-dependent. Sentiment analysis presents a three-way classification over complete sequences, for which long ngrams often seem to serve as good predictors. It may well be that for sequence transduction (as in SMT) or structure prediction (as in parsing) we will observe different trends in the influence of representation types on different languages and architectures.

Error Analysis: To gain further insight into the difference in task performance between different models and architectures, we performed a qualitative error analysis for 6 of our best models: the **MLP**, **CNN**, **LSTM** architecture, in *token-based* and *morpheme-based* settings, for the *string-based* lexicon.[4]

In general, all models are better at identifying positive sentiment than in identifying negative sentiment. The cases where both morpheme-based and token-based models correctly identified the *positive* sentiment constitute 91% of the *positive* comments in the MLP case, 93.8% in the CNN, and 94.1% in the LSTM. In contrast, morpheme-based and token-based models correctly identified *negative* sentiment only 27.8% of the *negative* comments in the MLP, 30.1% in CNN, and 48.1% in the LSTM. Cases where morpheme-based and token-based models wrongly identified a positive sentiment as negative one have different characteristics based on the architecture. In the MLP these are characterized by a double negation, and by addressing a third party. For CNN, comments that start with "Sorry, but.." are identified as negative, even when these happen to be positive. For the LSTMs, we see error in the prediction of positive sentiment in the case of extremely long comments, i.e., accuracy here is length sensitive.

We now turn to consider cases where the token-based models made the right prediction and morpheme-based models made the opposite prediction. The morpheme-based MLP wrongly identified a positive sentiment as a negative one in the case of short comments, many punctuations, and many negation elements. The CNN wrong classification of this type is characterized by a double negation, and also by addressing multiple parties in the same comment. For the RNN, this wrong prediction is again characterized by length — at moderate length of 12 morphemes the model often doesn't succeed in making the correct prediction. The opposite case, where morpheme-based models identify negative sentiment as a positive one has a different characterization in these architectures: in the MLP this is characterized

[4]For the complete report, confusion matrix, error characterization and translated examples, see our supplementary materials.

	MLP	CNN	LSTM
MB,TB-correct,pos	60.39 %	62.07%	62.4%
MB,TB-correct,neg	23.25%	24.14%	14.08%
MB,TB-should be pos	3.59% double negation	2.34% "sorry, but.."	2.12% very long comments
MB,TB-should be neg	4.2% honorary, criticism, !!!	3.125% sarcasm, irony	7.185% address+mixed modifiers
TB-pos MB-error,neg	1.09% short, honoraries+negations	0.39% double negation, third party	1.4% short-moderate length
TB-neg MB-error,pos	1.95% honorary title+negative words	2.3% mixed sentiments	0.93% honorary title+opposing words
MB-pos TB-error,neg	1.25% third party, neg words	1.52% direct address / "advise"	1.09 sequential short utterances
MB-neg TB-error,pos	1.36% third party ref	1.093% repetitions, moderate length	7.92% very short comments

Table 4: Qualitative Error Analysis and Confusion Quantitative Assessment on 2560 comments. TB denotes *token-based* and MB denote *morpheme-based* representation. We do not discuss neutral sentiment.

by kind and respectful words towards the president, alongside expressed criticism. For the CNN we see confused classification in comments that express mixed sentiments towards different topics. For the LSTM, we see the same pattern as the MLP; respectful attitude towards the president (Dear Mr. president, respected president) followed by an opinion which is opposed to the post's actual content.

Finally, cases where morpheme-based models made the right prediction and token-based models were erroneous, i.e., the cases that coincide with our linguistic hypothesis, can be characterized as follows. For the MLP, positive sentiments where identified as negative where the comments address a third party and also contain certain negation elements (i.e., "I choose Rivlin despite what Liberman says"). CNNs classified positive sentiments as negative where the comments directly address the president, proposing a sort of explicit "advice" ("Dear Mr. president we need to stop the violance"). The LSTM gets confused in cases of long comments consisting a sequence of very short utterances, typically also containing many negations and punctuation ("Me too. I'm opposed. Where do we go?" etc.) The opposite error also happens in the token-based models, where morpheme-based are correct. MLPs classify negative as positive where the comments do not address the president, but speak of a third party (the children, the soldiers, etc). Token-based CNNs mistakenly classify negative as positive in comments of moderate length (about 14 words) or those that have many repetitions ("sit down sit down sit down quietly and listen.."). The token-based LSTM is wrong in cases of *very* short comments, with only a handful of tokens.

All in all morpheme-based models do show advantages in identifying the correct sentiment of actual content (addressing of third parties, serving advise, etc.) beyond fixed expressions, and are better in classifying short texts or texts with repetitions. However it seems that the morpheme-based models do get more easily confused by the existence of negation elements, double negation, and many titles honoring the speaker (the president). These may steer the classification in a fairly rigid direction. Token-based models that consider larger n-grams, in particular in the context of CNN architectures, capture larger context windows, which currently present the best performance on Hebrew sentiment analysis.[5]

7 Discussion and Conclusion

Despite the great success of NN-based methods in NLP, the question of the interplay between *language type* and *architectural choices* has only been scarcely attended to, if at all. Yin et al. (2017), for instance, compare the strengths of different NN architectures for NLP tasks, but the discussion focuses solely on English. Dos Santos and Zadrozny (2014) propose char-based CNNs for NLP, but the benefits of the char-based modeling are not contrasted for different NN architectures and modeling. Finally, Al Sallab et al. (2015) contrast deep learning architectures for sentiment analysis in Arabic. They use a simple *bag of words* (BOW) approach without considering the MRL nature of the language, nor they are comparing different representation choices for their lexicon.

In this work we address neural sentiment analysis of Hebrew, a Semitic language known for its morphological complexities, and evaluate two choices of representing the input signal: (i) tokens vs. morphemes input, and (ii) string-based vs. char-based encoding. We experiment with different architectures: a linear model, feed-forward MLPs, CNNs, and (Bi)RNNs. We show that while linear models as

[5]Our data set, code, and models are publicly available at `https://github.com/omilab/Neural-Sentiment-Analyzer-for-Modern-Hebrew`.

well as MLPs and CNNs obtain higher accuracy at token-level granularity, RNNs prefer the morpheme-based settings. We further show that while char-based representation can in most cases dispense with morpheme-level information, it comes at a cost of an overall drop in accuracy. Our best model is a token-based CNN with above 89% on a new Hebrew benchmark based on social media content.

We believe that this investigation is only a first step in un-black-boxing the use of NN models for language processing tasks. Through this investigation, the two-level sentiment benchmark we deliver, and the strong baseline results we provide, we hope to encourage further investigation into the interplay between *task, language types* and *modeling choices* in general, and on NN models for MRLs in particular.

Acknowledgments

We thank Tzipy Lazar-Shoef for research assistance, and are thankful to three anonymous reviewers for their insightful comments. This research is funded by the Israel Science Foundation, ISF grant 1739/26, for which we are grateful.

Scoring and Classifying Implicit Positive Interpretations: A Challenge of Class Imbalance

Abstract

This paper reports on a reimplementation of a system on detecting implicit positive meaning from negated statements. In the original regression experiment, different positive interpretations per negation are scored according to their likelihood. We convert the scores to classes and report our results on both the regression and classification tasks. We show that a baseline taking the mean score or most frequent class is hard to beat because of class imbalance in the dataset. Our error analysis indicates that an approach that takes the information structure into account (i.e. which information is new or contrastive) may be promising, which requires looking beyond the syntactic and semantic characteristics of negated statements.

1 Introduction

Modeling inference is one of the most challenging tasks in computational linguistics, yet crucial for true natural language understanding. It requires looking beyond the literal meaning of statements and determining what exactly the author intends to convey. The position of *focus* (the new or contrastive information) in a sentence, for instance, is one pragmatic phenomenon that can affect its interpretation. The theory of alternative semantics (Rooth, 1992) assumes that the general function of focus is to evoke *alternatives*, i.e. a set of propositions potentially contrasting with the intended meaning of the sentence. A number of lexical items and constructions have been identified as focus-sensitive in English, such as *only*, *even*, *too*, counterfactual conditionals (*if*), frequency adverbs (*always*, *sometimes*, *often*) and negation. Their semantics depend on the information structure of the sentence; different choices of focus can result in different truth values. For example, Kawamura (2007) illustrates how focus contributes to the interpretation of negation in Sentence 1 below. In English, focus can be explicitly signaled prosodically, e.g. in the form of a strong pitch accent, or syntactically, e.g. by moving focused phrases to a special position in the sentence (Stevens, 2017). If no explicit signal is present, one has to rely on the context to determine which part of the sentence is in focus and, hence, what is its correct interpretation. This is a notoriously difficult task that so far has received little attention in the field.

   (c) We do not cover pragmatics in the lecture THIS SEMESTER.
   the lecture usually covers pragmatics, but not this semester

This paper reports on a reproduction study for the purpose of understanding the performance of a system on detecting implicit positive meaning from negated statements. Such a system could support a range of Natural Language Processing (NLP) technologies that require deep understanding of language, such as Recognizing Textual Entailment (RTE) and Question Answering (QA). The research that we reproduce

Proceedings of the 27th International Conference on Computational Linguistics, pages 2253–2264
Santa Fe, New Mexico, USA, August 20-26, 2018.

is that of Blanco and Sarabi (2016), who propose an interesting methodology to automatically generate positive interpretations from negated statements and score them according to their likelihood. We reflect on the definition of the task and the contribution of the different features to the performance of their system. Our findings show that the features they propose are not able to improve upon our baseline because of class imbalance. Based on an error analysis that we perform on the output of our baseline, we discuss future lines of research that take levels of informativeness into account, which we expect to be also applicable to related problems that have to do with implicit meaning and pragmatic phenomena. The remainder of this paper is structured as follows. In Section 2, we report on related work. Section 3 describes the dataset and the task as created, defined and performed by Blanco and Sarabi (2016). In Section 4, we report on the replication of the original experiment on our test set and the ablation tests on feature combinations against the baseline. In Section 5, we redefine the task as a classification task and apply an error analysis to understand system performance against the baseline and the role of the different features in the classification task. Our error analysis leads to a discussion reported in Section 6 and plans for future work. Section 7 summarizes our conclusions.

2 Related Work

The task of scoring implicit positive meanings from negated statements was preceded by the task of detecting the *focus of negation*. This task was pioneered by Blanco and Moldovan (2011), who argued that the *scope* and *focus* of negation are crucial for a correct interpretation of negated statements. Following Huddleston and Pullum (2002), they defined scope as "the part of the meaning that is negated" and focus as "the part of the scope that is most prominently or explicitly negated." More specifically, according to Blanco and Moldovan (2011), the focus of negation gives rise to implicit positive meaning. To capture this information, they created the PB-FOC corpus, which contains annotations for the focus of negation in the 3,993 verbal negations in PropBank (Palmer et al., 2005). Candidates for focus annotation were the verb itself or any of its semantic roles and annotators were instructed to choose only one.

The PB-FOC corpus was used in the first edition of the *SEM Shared Task, which was dedicated to resolving the scope (Task 1) and focus (Task 2) of negation (Morante and Blanco, 2012). Only one team (Rosenberg and Bergler, 2012) participated in the Focus Detection task. Their system, called CLaCs NegFocus, is rule-based and consists of three components: the identification of explicit negation cues (*not*, *nor* and *never*), the detection of the syntactic scope of negation, and the detection of the focus of negation using a set of four syntactic heuristics (e.g. "if an adverb directly precedes the negated verb and is connected through an *advmod* dependency relation to the negated verb, this adverb is annotated as the focus"). They report an F-measure of 0.584. Blanco and Moldovan (2013) report an F-measure of 0.641 with their system FOC-DET, which is trained with bagging over standard C4.5 decision trees using a set of features derived from gold syntactic annotation and semantic role labels. Whereas both CLaCs NegFocus and FOC-DET use only information from within the sentence, Zou et al. (2015) argue that contextual discourse information plays a critical role in negation focus identification and propose a word-topic graph model that uses this contextual information from both lexical and topical perspectives. They report an accuracy of 69.39 on PB-FOC.

PB-FOC has given rise to various alternative approaches to the annotation of focus and different definitions of the corresponding task. Blanco and Moldovan (2012) introduce the concept of granularity of focus and add fine-grained foci on top of the course-grained foci in PB-FOC; whereas coarse-grained focus includes all words belonging to a semantic role, fine-grained focus comprises fewer words within the semantic role (e.g. *We didn't get [an offer for <u>more than</u> $40]*$_{\text{FOCUS}}$), allowing for more specific implicit positive interpretations ("we got something, but not an offer for more than $40" versus "we got an offer for $40 or less"). Anand and Martell (2012) evaluated the annotations of PB-FOC, arguing that positive interpretations resulting from scalar implicatures and neg-raising predicates should be separated from those (indirectly) resulting from focus, and reannotated the corpus by using an alternative annotation approach that relies on relevant questions under discussion (QUDs).

Another criticism on PB-FOC was raised by Blanco and Sarabi (2016), who point out that the guidelines required the annotators to choose one semantic role as the focus, prioritizing "the one that yields the

most meaningful implicit [positive] information" in case of multiple candidates, but that it is not specified what "most meaningful" means. Therefore, they designed a new annotation task where several positive interpretations per negation (automatically generated by manipulating semantic roles) are scored according to their likelihood (see Section 3 for more details). Similar to the distinction between fine-grained and coarse-grained foci, Sarabi and Blanco (2016) propose to extract and score more fine-grained positive interpretations by manipulating syntactic dependencies instead of semantic roles. Sanders and Blanco (2016) further extend this approach of generating and scoring implicit positive interpretations by applying it to modal constructions.

3 Dataset and Task

The dataset created by Blanco and Sarabi (2016) contains 1,888 positive interpretations generated from 600 negated verbs in OntoNotes 5.0 (Hovy et al., 2006). These positive interpretations are automatically generated by first converting the negated statement into its positive counterpart by (1) removing the negation mark, (2) removing auxiliaries, expanding contractions and fixing third-person singular and past tense, and (3) rewriting negatively-oriented polarity-sensitive items (e.g. *anyone* becomes *someone*). From this positive counterpart, positive interpretations are generated by rewriting each semantic role or the (originally negated) verb. For example, ARG0-ARG4 are rewritten as *someone / some people / something*, and ARGM-TMP is rewritten as *at some point of time*. To illustrate, this results in the three positive interpretations listed for Sentence 2.

2. [The proper climatic conditions]$_{\text{ARG1}}$ don't [exist]$_{\text{V}}$ [in many places in the world]$_{\text{ARGM-LOC}}$.
   (a) The proper climatic conditions {some verb / action / state} in many places in the world.
   but not 'exist'
   (b) {someone / some people / something} exist in many places in the world.
   but not 'The proper climatic conditions'
   (c) The proper climatic conditions exist {somewhere}.
   but not 'in many places in the world'

On average, 3.15 positive interpretations are generated per negation, each of which is manually scored with a value between 0 and 5. A positive interpretation with a score of 5 is deemed very plausible given the context (i.e. the previous and next sentence), whereas a score of 0 indicates that this interpretation is highly implausible. Inter-annotator agreement is calculated using Pearson's correlation and is reported to be 0.761. The task is defined as a regression task, where each positive interpretation becomes an instance for which the system should produce a score.

3.1 Data releases

The dataset of scored positive interpretations is not publicly available, but the authors provided us with all their annotations. Blanco and Sarabi (2016) have used the CoNLL-2011 Shared Task distribution of OntoNotes[1] (Pradhan et al., 2011). In order to use the annotations for learning, both OntoNotes 5.0 and the CoNLL-2011 Shared Task release are required, since the latter contains all annotations but not the underlying words. The organizers of this shared task provide scripts and instructions to merge the annotations with the words in OntoNotes. Originally, the data was meant to be merged with the data from OntoNotes 4.0,[2] but it can also be used with OntoNotes 5.0,[3] which is the final release of the OntoNotes project. The resulting `.conll` files contain a merged representation of all the OntoNotes layers in CoNLL-style tabular format with one line per token, and with multiple columns specifying the annotations for each token. This format is similar to the CoNLL-formatted release of OntoNotes 5.0.[4] However, there are two important differences between the two CoNLL-formatted releases. First, for

CoNLL-2011 some of the documents were split into smaller parts to reduce the complexity of coreference annotation, which increases with the length of a document. Second, disfluencies in conversation data (e.g. restarts, hesitations), which are marked with a special EDITED phrase tag in the original OntoNotes parses, were removed. The splitting of documents and removal of disfluencies result in different sentence and token identifiers, since sentence numbering restarts for each document part and token count excludes disfluent tokens. Therefore, the CoNLL-2011 release is required for resolving the identifiers used in the positive interpretations dataset. However, the CoNLL-2011 release does not provide gold annotations for the complete dataset; for the test set used for this shared task, only automatic annotations are provided. The gold annotations required to replicate the experiment by Blanco and Sarabi (2016) were provided to us by the authors instead.

4 Regression Task: Scoring Positive Interpretations

The system for scoring the positive interpretations as reported in (Blanco and Sarabi, 2016) is not publicly available. However, since the authors provided us with the annotations and the required OntoNotes data, we were able to replicate their experiment for further analysis.

4.1 Experimental set-up

Simulating the approach reported by Blanco and Sarabi (2016), we trained a Support Vector Machine (SVM) for regression with RBF kernel using scikit-learn (Pedregosa et al., 2011) with the set of features

	Blanco & Sarabi	ANONYMIZED		
	Pearson's r	Pearson's r	Spearman's ρ	RMSE
BASELINE (MEAN)		**0.679**	**0.625**	**1.239**

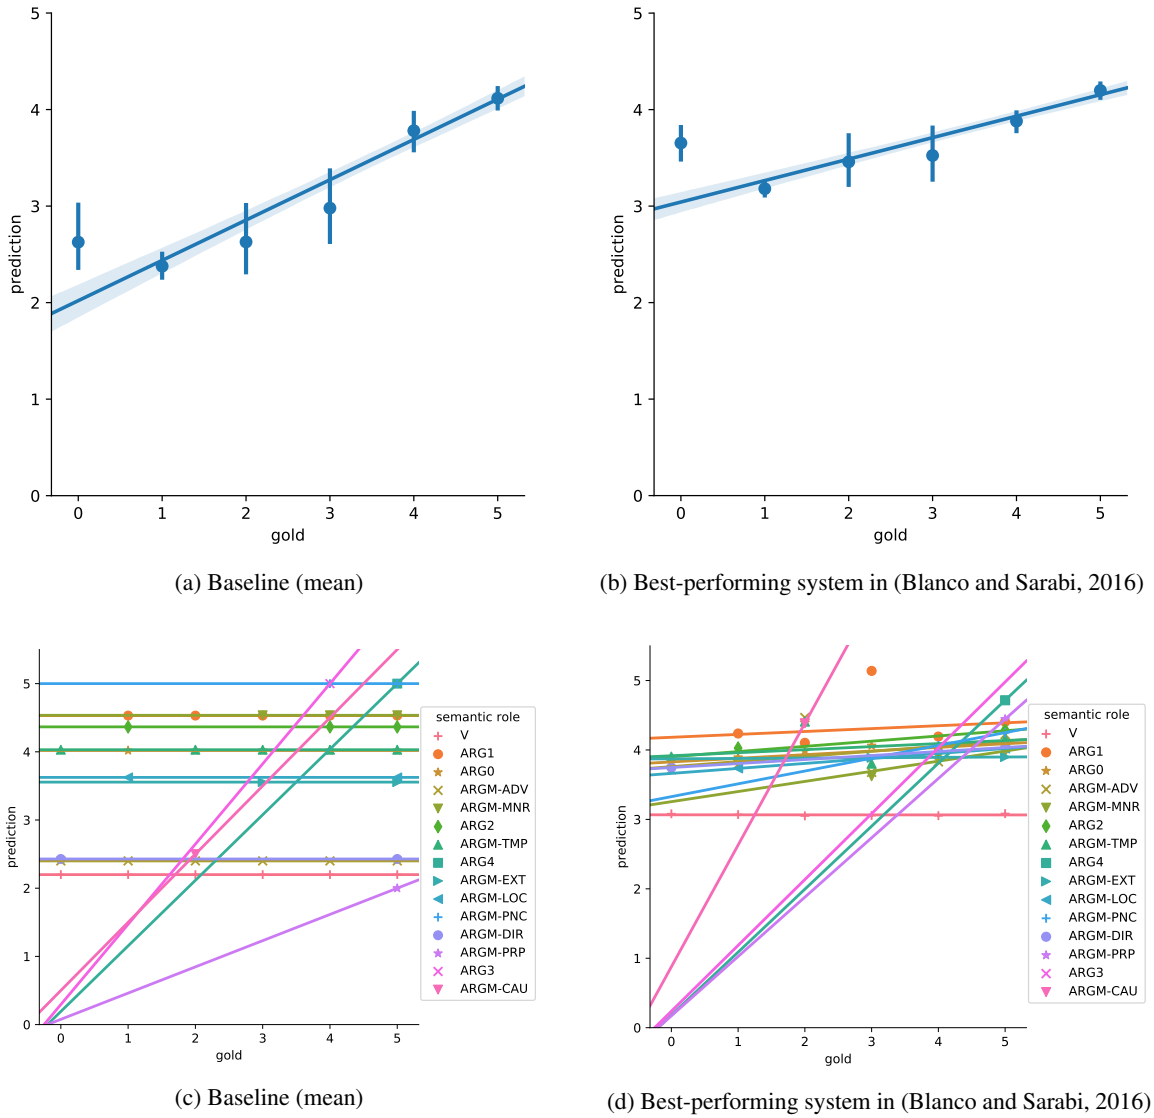
Table 3: Results of the Support Vector Machine (SVM) for regression with RBF kernel with different feature sets compared to those reported in (Blanco and Sarabi, 2016). All were statistically significant ($p < 0.001$), except those indicated with an asterisk.

presented in Table 1. Whereas Blanco and Sarabi (2016) report on results obtained with features extracted from gold-standard and predicted linguistic annotations, we only report on those obtained from the gold-standard annotations in the CoNLL-2011 dataset. We compare the results to a baseline system that simply takes the mean score of the semantic role from which the positive interpretation was generated as calculated over our train set (Table 2). Blanco and Sarabi (2016) evaluate their results using Pearson's correlation (r). However, we question the appropriateness of this evaluation measure, since Pearson's r assumes that the data is continuous and (at least approximately) normally distributed. Whereas the predicted scores are continuous indeed, the gold scores are rather ordinal of nature. Moreover, the data is not normally distributed, as can be seen in Figure 1. Therefore, we report our results using two additional evaluation measures: Spearman's correlation (ρ) with correction for ties, which can be used when the assumptions of Pearson's r are not met, and Root Mean Square Error (RMSE), which is the standard deviation of the residuals (prediction errors). RMSE is a measure of how spread out the residuals are; this way, it informs how concentrated the predicted scores are around the line of best fit. Lower values of RMSE indicate better fit, and since it is an absolute measure with the same units as the score being estimated, the values should be interpreted in the same range, in our case, between 0 and 5.

Unfortunately, due to time constraints, the authors were not (yet) able to provide us with the train/test splits as used in their paper. Therefore, we created our own test set using the same approach: we used a 80/20 split and made sure that all positive interpretations belonging to one negated verb were assigned to either the train or the test set.

4.2 Results

Table 3 presents the results of our experiments with the different combinations of feature sets on the regression task. We observe that, depending on the evaluation measure, different systems perform best. We also observe that our results are mostly comparable to those reported in (Blanco and Sarabi, 2016),



(a) Baseline (mean)

(b) Best-performing system in (Blanco and Sarabi, 2016)

(c) Baseline (mean)

(d) Best-performing system in (Blanco and Sarabi, 2016)

Figure 2: The upper figures show regression lines with a 95% confidence interval. The observations are collapsed in bins to plot an estimate of central tendency. The lower figures show regression lines per semantic role.

although just using the semrole_label as feature shows better results and is even the second-best system after our baseline, if we consider Pearson's *r* and the RMSE scores. This contradicts the finding of Blanco and Sarabi (2016), who found that considering all features yields the best performance. However, we emphasize that we tested on a different test set than Blanco and Sarabi (2016), so it is possible that this accounts for the differences in results. If we look at Spearman's ρ, the feature combination {semrole, verb-semrole} performs best, followed by {verb, semrole_label, verb-semrole, verbarg-struct}.

Figures 2a-2d visualize the regression lines for the baseline system and for the system that was reported as best-performing in (Blanco and Sarabi, 2016). We show both the overall tendency as the relation between the gold and the predicted scores per semantic role. As expected, Figure 2c shows flat lines for each semantic role, corresponding to the mean scores of each, except for those semantic roles that occur only once in the test set (ARG3, ARGM-CAU and ARGM-PRP) and ARG4, which is correctly scored as 5 in all cases. In contrast, Figure 2d shows more variation within most semantic roles (indicated by their slope), but in general, the predicted scores are too high, as can also be concluded from the overall overview in Figure 2b. In fact, the lowest predicted score according to this system is 2.96. The baseline seems to account a bit better for the lower and middle scores (the lowest predicted score is 2).

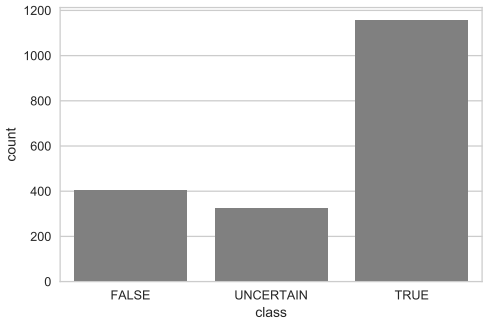


Figure 3: Overall distribution of the three classes in the complete dataset.

Table 4: Statistics of the three classes per semantic role in the train set. The most frequent classes per role (in bold) are used as a baseline.

5 Classification Task: Classifying Positive Interpretations as TRUE or FALSE

In a second experiment, we redefine the task as a classification task. We argue that the scores assigned to each positive interpretation in the dataset reflect the confidence of the annotators rather than what we are interested in predicting. In other words, in the end a binary classification system that can predict whether some positive meaning is implied in a negated statement or not would suffice in most real-world applications. Instead of predicting a score between 0 and 5, one option is thus to redefine the task as a binary classification problem where each positive interpretation is to be classified as either TRUE or FALSE. The original annotated scores can easily be divided: all scores between 0-2 become FALSE, and all scores between 3-5 become TRUE. However, intuitively, it is clear that the scores 2 and 3 are somewhat problematic in the sense that they present the middle cases that less clearly belong to either class. Therefore, these two scores could potentially make up their own class of UNCERTAIN. As can be seen in Figure 3, the UNCERTAIN class comprises a considerably large portion of the complete dataset.

5.1 Experimental set-up

We use the same sets of features to train an SVM with RBF kernel, but now for classification. We apply it to both the binary classification task (TRUE/FALSE) and the tertiary classification task (TRUE/FALSE/UNCERTAIN). The results are evaluated using precision, recall and F1-measure. We use weighted averaging for all scores, which accounts for class imbalance by computing the average of binary metrics in which each class' score is weighted by its presence in the true data sample. Our baseline system takes the most frequent class of the semantic role from which the positive interpretation was generated (corresponding to the classes in bold in Table 4 in both tasks).

5.2 Results

We summarize our results on both the tertiary and the binary classification tasks in Table 5. None of the feature combinations were able to beat the most-frequent baseline, which achieves an F1-measure of 0.725 with three classes and 0.840 with two classes. The differences with the second-best system, which uses only semrole_label as a feature, are small (0.721 and 0.834 respectively), but adding more features only appears to hurt performance. This is mostly in line with what we observed in the regression task. We analyzed the precision, recall and F1-measure per class for each of the feature combinations and observe that for most of them, the FALSE class performs 0.0 on each in both tasks, except for the better performing ones (indicated with bold scores in Table 5). Moreover, the UNCERTAIN class always performs 0.0 in the tertiary task, including the baseline. In the binary task, the baseline achieves 0.65 / 0.89 / 0.75 on precision, recall and F1-measure on the FALSE class and 0.95 / 0.81 / 0.87 on the TRUE class. In the tertiary task, the respective scores are 0.54 / 0.91 / 0.68 (FALSE) and 0.91 / 0.85 / 0.88 (TRUE).

Features	Tertiary Classification Precision	Recall	F1	Binary Classification Precision	Recall	F1
BASELINE (MOST FREQUENT)	**0.711**	**0.762**	**0.725**	**0.864**	**0.833**	**0.840**

Table 5: Results of the Support Vector Machine (SVM) for classification with RBF kernel with different feature sets on the classification task with three classes and with two classes.

5.3 Error analysis

The results on the classification task can easily be explained if we have another look at Figure 3 and Table 4. ARG0, ARG1 and V are by far the most frequent cases in the dataset and their classes are very imbalanced. ARGM-ADV, ARGM-CAU and ARGM-DIR are the only roles for which FALSE is the most frequent class and the classes are somewhat balanced, but these roles are not as well represented in the dataset. As expected, our error analysis on the results of the baseline show that the positive interpretations generated from the verb itself comprise the largest portion of classification errors: 39 out of 63 (62%) were incorrectly predicted as FALSE. This is followed by ARGM-ADV (16%, incorrectly predicted as FALSE), ARG1 (8%, TRUE), ARGM-TMP (5%, TRUE) and ARG0 (3%, TRUE). ARG2, ARGM-DIR, ARGM-LOC and ARGM-PRP were only misclassified once. From these results, we learn that the challenge of this task is to make a system perform well for the minority classes of each role. In other words, we need to know when the verb or ARGM-ADV results to TRUE and when the other roles result to FALSE.

We discuss some examples of misclassification. According to the gold annotations, the positive interpretation generated from the verb *create* in Sentence 3 results to TRUE. We argue that this is because the sentence contains *contrastive focus*. That is, *create* contrasts with another verb mentioned in the previous context: *enrich*. Evidence is provided by the subject being shared between the verbs, i.e. *a diversity of cultures*. Generally speaking, implicit positive meanings involving contrasting actions seem to be more easily evoked when the verb has a strong antonym, even if this is not explicitly mentioned in the context. For example, verbs like *win* (*lose*) or *like* (*dislike*) are more likely to give rise to alternatives than verbs that do not have a clear opposite meaning, such as *write*.

3. [A diversity of cultures]$_{\text{ARG0}}$ will only enrich a person, not **create** [a crisis of identity]$_{\text{ARG1}}$.
   A diversity of cultures will only enrich a person, {*some verb / action / state*} *a crisis of identity, but not 'create'*

Another observation in the TRUE positive interpretations generated from the verb, is that many of them contain coreferential expressions. For example, all semantic roles belonging to the negated verb in Sentence 4 consist of pronouns, indicating that the agent and patient have already been introduced in the previous context. The acceptability of this positive interpretation seems to be a result of *new information focus*, since the only 'new' information is the action expressed by the verb. This makes it more likely that the negation of the action is what the author intended to convey.

4. But [he]$_{\text{ARG0}}$ didn't **win** [it]$_{\text{ARG1}}$.
   But he {some verb / action / state} it, but not 'won'

Sentence 5, on the other hand, illustrates how information that is already introduced in the previous context is less likely to be in the pragmatic scope of negation. The ARG1, *the advance*, is coreferential with *gained* in the preceding context; the new, relevant information is the lack of participation of *many issues* in this advance. Therefore, in this case, the positive interpretation generated from this semantic role is FALSE instead of the more frequent TRUE class associated with ARG1.

5. But while the Composite gained 1.19, to 462.89, [many issues]$_{\text{ARG0}}$ didn't **participate** [in the advance]$_{\text{ARG1}}$.
   But while the Composite gained 1.19, to 462.89, many issues participated {in someone / some people / something}, but not 'in the advance'

6 Discussion and future work

The relation between information structure and inference is an interesting research area that needs further exploration in computational linguistics. Blanco and Moldovan (2011) laid some important groundwork for deriving implicit positive meaning from negations by trying to detect the (single) focus of negation. However, as correctly noted by Anand and Martell (2012), implicit positive meaning only indirectly results from focus. This is partially because, as Kawamura (2007) explains, negation does not *require* a focused element (in contrast to focus-sensitive elements such as *only*, *even* and *either*) and at the same time induces ambiguity in focus constructions. That is, negation without focus can still be grammatical; its absence simply produces a different interpretation. If the sentence *does* contain focus, negation yields a focus-associated reading (6a) and a non-associated reading (6b), as Kawamura (2007) illustrates with the example below. This ambiguity has been regarded as a result of the scope interaction of focus and negation (Jackendoff, 1972; Krifka, 2006).

6. John didn't criticize Mary [at the conference]$_{\text{FOCUS}}$.
   (a) John criticized Mary. It was not at the conference.
   (b) John did something other than criticizing Mary. It happened at the conference.

Therefore, we think Blanco and Sarabi (2016) improved upon the task by scoring each and every potential positive interpretation generated from the negation. The question remains, however, whether we really need to score positive interpretations on a scale from 0 to 5. We believe that, from an application perspective, classifying them as TRUE/FALSE (and optionally UNCERTAIN) is sufficient.

We have shown that class imbalance in the dataset is the reason why our baseline performs so well on the task, and that –even though there is no one-to-one correspondence between focus and implicit positive meaning– knowing which part of the proposition is new or contrastive seems to play a crucial role in correctly predicting the infrequent classes. We therefore argue that an approach to detecting implicit meaning should aim to include this pragmatic layer of information. The features described in this paper only partially capture this layer since they rely on explicit signals within the sentence (i.e. by determining which information is present and in what position), but they do not take context into account. However, we need more annotated data and more experiments to confirm our hypothesis.

Special cases of negation that we would like to highlight here are those that contain negatively-oriented polarity-sensitive items, such as *anyone*, *anything* or *either*. In the current definition of the task, these

items are rewritten to positively-oriented polarity-sensitive items (e.g. *anyone* becomes *someone*, *anything* becomes *something*) before generating the positive interpretations. For example, Sentence 7 would result in the interpretations 7a and 7b with this procedure. While 7a may be classified as UNCERTAIN (or, less likely, as TRUE), 7b will always be FALSE. Moreover, neither interpretations cover the actual meaning of the sentence. Instead, it should be interpreted as *"Kim read nothing"*, which in turn brings us to the next question: how to deal with other markers of negation, such as *nothing* or *nobody*? We suggest treating sentences with these kind of markers of negation or with negatively-oriented polarity-sensitive items both as special cases that probably do not need any annotation, since their correct interpretation directly follows from the meaning of the words.

7. Kim didn't read anything.
   (a) {*someone / some people / something*} *read something (but not Kim)*
   (b) *Kim read* {*something*}

Finally, while the task explored in this paper restricts itself to negation, it could possibly be extended to include also inferences resulting from focus in sentences without negation or with other focus-sensitive elements. As Kawamura (2007), among others, describes, the semantic effect of focus depends on the type of focus-sensitive elements present in the sentence. As noted above, some focus-sensitive elements require a focused element for their interpretation, while others do not. In addition, in sentences without focus-sensitive elements, focus-shift does not affect the truth conditions (even though intuitively the interpretations are different), whereas the truth conditions of sentences with a focus-sensitive element such as *only* do change. That is, if John reads something other than books in the bathroom, Sentence 8a and 8b can both be TRUE, while the focus-shift causes Sentence 9a to be FALSE.

8. (a) John reads [books]$_{\text{FOCUS}}$ in the bathroom.
   (b) John reads books [in the bathroom]$_{\text{FOCUS}}$.

9. (a) John only reads [books]$_{\text{FOCUS}}$ in the bathroom.
   (b) John only reads books [in the bathroom]$_{\text{FOCUS}}$.

This leaves us with many opportunities for future work to further investigate the inferences and truth conditions of sentences in relation to the interaction between focus and focus-sensitive elements.

7 Conclusion

We reimplemented a system for scoring implicit positive interpretations from negated statements for the purpose of understanding its performance, the task itself and the role that different features play. We have argued that the original task could be redefined as a classification task, where each positive interpretation is to be classified as TRUE or FALSE (optionally, with a third class of UNCERTAIN representing the middle cases). We showed that a simple baseline that takes the mean over the scores or the most frequent class per semantic role is hard to beat in both the regression and the classification tasks. Our error analysis indicated that improvements can only be achieved with a system that is able to account for the infrequent classes, and we hypothesize that modeling informativeness (e.g. new information or contrastive focus) may be useful in this respect. This would require looking beyond the syntactic and semantic characteristics of the proposition and taking the broader context into account. Our code is publicly available at `https://github.com/cltl/positive-interpretations`.

Abstract

The state-of-the-art methods for relation classification are primarily based on deep neural networks. This supervised learning method suffers from not only limited training data, but also the large number of low-frequency relations in specific domains. In this paper, we propose an exploratory relation classification method for domain knowledge harvesting. The goal is to learn a classifier on pre-defined relations while discovering new relations expressed in texts. A dynamically structured neural network is introduced to classify entity pairs to a continuously expanded relation set. We further propose the similarity sensitive Chinese restaurant process to discover new relations. Experiments conducted on a large corpus show that new relations are discovered with high precision and recall, illustrating the effectiveness of our method.

Title and Abstract in Chinese

基于领域知识获取的探索式神经网络关系分类

近几年来，关系分类任务主要利用神经网络模型来自动学习复杂的特征。然而这类监督式学习方法的局限性在于，首先它需要大量训练数据，其次特定领域存在长尾的低频关系无法被有效地预定义。在本论文中，我们提出了基于领域知识获取的探索式关系分类任务。它的目标在于学习预定义关系的分类器，同时从文本中发现新的语义关系。我们提出了一个动态结构的神经网络，它可以对持续扩充的关系集进行分类。我们进一步提出了相似度敏感的中餐馆过程算法，用于发现新关系。基于大语料库上的实验证明了该神经网络的分类效果，同时新发现的关系也有较高的准确率和召回率。

1 Introduction

Relation classification assigns semantic relation labels to entity pairs in texts. Besides traditional feature-based (Kambhatla, 2004) and kernel-based (Bunescu and Mooney, 2005) approaches, neural networks (NNs) are introduced to harvest relational facts in recent years. Classical architectures include convolutional neural networks (CNNs) (Zeng et al., 2014), recurrent neural networks (RNNs) (Xu et al., 2015), etc. However, above methods are still insufficient for domain knowledge acquisition due to two challenges: (i) most domain entities rarely occur in the corpus, hence pattern-based methods easily suffer from the feature sparsity problem; (ii) a domain knowledge graph tends to be incomplete w.r.t. relation labels and facts (Fan et al., 2017). As a result, unlabeled entity pairs are likely to be wrongly forced into existing relation labels by distant supervision approaches, instead of their true, unknown labels.

In this paper we propose a method, Exploratory Relation Classification (ERC), to populate domain knowledge graphs automatically. The goal of ERC is to not only classify entity pairs into a finite set of pre-defined relations, but also simultaneously discover previously unseen relation types and their respective instances from plain texts with high confidence. The resulting numbers of relation types and facts in the domain knowledge graph grow continuously.

Santa Fe, New Mexico, USA, August 20-26, 2018.

To solve ERC problem, we propose a Dynamic Structured Neural Network (DSNN). In the network, the convolutional and recurrent network units are employed to model local information such as syntactic and lexical features from the sentence level. For the context sparsity problem (Challenge (i)) an embedding layer is introduced to encode corpus-level semantic features of domain entities. The output classes of DSNN can be automatically expanded during the iterative training process, in order to classify entity pairs to both known and newly discovered relations. To explore new relations and corresponding instances, we introduce the similarity sensitive Chinese restaurant process (ssCRP) to generate clusters of entity pairs from unlabeled data that can not be classified into any known relations (Challenge (ii)). We can see that the DSNN only takes the training data of known relations directly derived from a domain knowledge graph without requiring any training data for new relations. Therefore, our approach is a very weakly supervised one with minimal human intervention.

The rest of the paper is organized as follows. Section 2 summarizes the related work and discusses relations between existing methods and ours. The detailed approach is introduced in Section 3, Section 4 and Section 5, with experiments presented in Section 6. Finally, we conclude this paper in Section 7.

2 Related Work and Discussion

In NLP research, feature-based (Kambhatla, 2004) and kernel-based (Bunescu and Mooney, 2005) methods have been proposed to utilize lexical, syntactic and semantic features for relation classification. In recent years, neural network based approaches are introduced to improve the performance. Word embeddings of entities are frequently used as inputs, instead of one-hot representations (Mikolov et al., 2013; Pennington et al., 2014). As shown in (Wang and He, 2016; Wang et al., 2017), word embeddings can be used for relation prediction. For neural network architectures, CNNs are capable of learning consecutive contexts of entities as local lexical features (Zeng et al., 2014; Vu et al., 2016), while RNNs exploit syntactic features by modeling long-term dependencies of sentences via memory units. The model of Long Short Term Memories (LSTMs) (Hochreiter and Schmidhuber, 1997) is an effective variant of RNNs to encode the shortest dependency path (SDP) between entity pairs (Xu et al., 2015; Shwartz et al., 2016). More recent work focuses on the design of integrated architecture, combining both CNNs and RNNs. Cai et al. (2016) propose a bidirectional recurrent CNN to model the directional information along the SDP forwards and backwards. The integrated neural network proposed by Raj et al. (2017) also experiments with attention-based pooling strategy for biomedical texts. Our model provides a more intuitive representation by feature concatenation instead of network layering, enabling the adaption of dynamic changes as new relations are discovered in iterations.

For relation discovery, one way is to formulate the task as open relation extraction (OpenRE) (Banko et al., 2007). Typical OpenRE systems include TextRunner (Banko et al., 2007), WOE (Wu and Weld, 2007), ReVerb (Etzioni et al., 2011), etc. Unlike approaches confined to a fixed set of pre-defined relations, these systems explore relations in a more general way. Contrary to the fact that the contexts for domain knowledge are sparse, the underlying idea of OpenRE is to identify phrases from sentences that are able to indicate unknown relations based on data redundancy. Therefore, OpenRE methods are not suitable for domain-specific knowledge harvesting within a limited text corpus. Similarly, Riedel et al. (2013) learn universal schemas by matrix factorization without pre-defined relations. An alternative way is to use clustering algorithms. Compared to standard clustering algorithms (e.g., KMeans), non-parametric Bayesian models (Rasmussen, 1999) are more suitable in our scenario, because they can automatically learn the number of clusters. Studies afterwards exploit data features for spatial and temporal data, such as distance dependent CRP (ddCRP) (Blei and Frazier, 2010), etc.

Our task is also related to a typical case of multi-class semi-supervised learning when unlabeled data contains unknown classes. We suggest that existing paradigms for this problem are not much useful for domain knowledge acquisition. Generally, distant supervision (Mintz et al., 2009) is employed to generate training data by aligning knowledge bases with free texts. But its strong alignment assumption may lead to noisy annotation results (Zhang and Wang, 2017). Traditional approaches assign new class labels to part of the unlabeled data on condition that none of the existing classes can fit the data well (Nigam et al., 2000; Dalvi et al., 2013). Therefore, considering the sparsity of domain knowledge, these

methods applied on such corpus will introduce plenty of small classes, which are in fact noises and thus meaningless. In contrast, our ssCRP-based approach works more effectively since we only discover one large class with confident instances in each iteration. Hence such noises in the data will not be forced to generate small classes and are automatically discarded when the last iteration stops.

3 Dynamic Structured Neural Network for ERC

In this section, we present the definition of the task ERC and a high level introduction of the DSNN approach.

3.1 Task Definition

Before introducing the training process of DSNN, we first provide some preliminaries. Denote entity pairs as $X^l = \{(e_1, e_2)\}$ with corresponding labels Y^l, and unlabeled entity pairs as $X^u = \{(e_1, e_2)\}$. Exploratory Relation Classification (ERC) task is defined as follows:

Definition 1. *Given labeled data (X^l, Y^l) and unlabeled data X^u, the goal of ERC is to train a model to predict the relations for entity pairs in X^u with $K + n$ output labels, where K denotes the number of pre-defined relations in Y^l, and n is the number of newly discovered relations which is unknown.*

3.2 An Overview of DSNN

Algorithm 1 shows the iterative training process of DSNN. In each iteration, the algorithm tries to detect a new relation from unlabeled data based on ssCRP, and expands the neural network structure to perform relation classification over existing and new relations. Briefly, it consists of three modules: base neural network training[1], relation discovery and relation prediction.

Algorithm 1 DSNN Training Process

Input: Entity pairs X^l and their labels Y^l, unlabeled entity pairs X^u, pre-defined relation set $R_{old} = \{r_1, \ldots, r_K\}$
Output: New relation set $R_{new} = \{r_{K+1}, \ldots, r_{K+n}\}$, populated labeled entity pairs X^l and their labels Y^l

Initialize $R_{new} = R_{old}, t = 1$
while no new relations can be discovered **do**
  // Base neural network training
  Train base neural network NN_t with X^l and Y^l
  // Relation discovery
  Generate candidate clusters $\{C_1, \ldots, C_m\}$ = *ssCRP*(X^u, X^l)
  C^* = *PickTheBestCluster*$(C_1, \ldots, C_m)$
  r^* = *MapToRelation*(C^*)
  if $r^* \notin R_{old}$ **then**
    $R_{new} = R_{new} \cup \{r^*\}$
  end if
  Label all entity pairs in C^* with relation r^* to be Y^*
  $X^l = X^l \cup C^*, Y^l = Y^l \cup Y^*, X^u = X^u \backslash C^*$
  // Relation prediction
  for each (e_1, e_2) in X^u **do**
    $\Pr(r|e_1, e_2, NN_t)$ =*PredictRelDistribution*$(e_1, e_2, R_{old}, NN_t)$
    if *NotNearUniform*$(\Pr(r|e_1, e_2, NN_t))$ **then**
      Label (e_1, e_2) with relation $\text{argmax}_{r^*} \Pr(r|e_1, e_2, NN_t)$ to be Y^*
      $X^l = X^l \cup \{(e_1, e_2)\}, Y^l = Y^l \cup Y^*, X^u = X^u \backslash \{(e_1, e_2)\}$
    end if
  end for
  $R_{old} = R_{new}, t = t + 1$
end while
return R_{new}, X^l, Y^l

In each iteration t, the first step is to train base neural network NN_t with training data X^l and Y^l. Note that in the first iteration, model NN_t is trained fully supervised. When $t > 1$, NN_t is trained semi-supervisedly, utilizing both labeled training data and new relations discovered in previous $t - 1$ iterations.

[1]In this paper, we refer to the structure of DSNN without the output layer expansion step as "base neural network". In each iteration, the training process of base neural network is the same despite the number of output units.

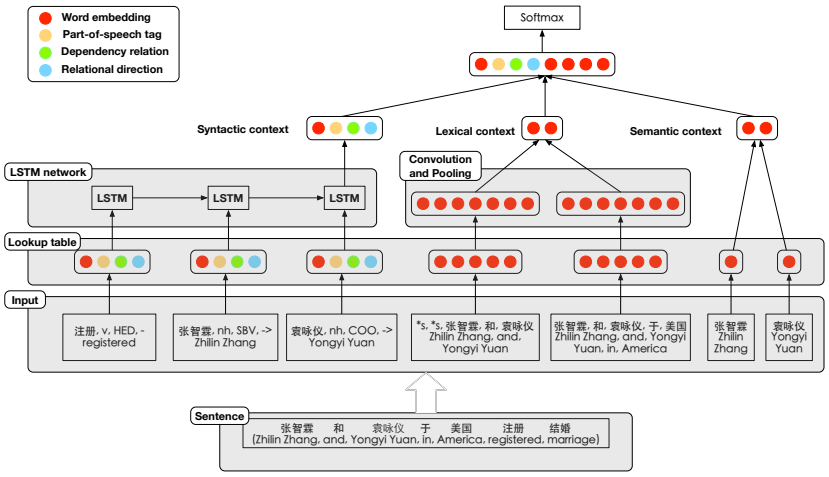

Figure 1: The architecture of the base neural network with k=2.

After NN_t is trained, ssCRP is employed to generate m clusters from X^u (i.e., $C_1, \ldots, C_m$), where each cluster represents the collection of entity pairs that are most likely to share the same underlying relation. We select the "best" cluster C^* from $C_1, \ldots, C_m$ based on the size and intra-cluster similarity, and map it to the relation r^*. r^* could either be one of the pre-defined relations, or a newly discovered relation. Either way, we update X^l and Y^l with C^* labeled as r^*, and remove them from X^u.

For unlabeled entity pairs $(e_1, e_2) \in X^u$, we use model NN_t to predict the probability distribution $\Pr(r|e_1, e_2, NN_t)$ over all possible relations. If the distribution is not "near uniform", the model is confident to predict the relation $r^* = \text{argmax}\Pr(r|e_1, e_2, NN_t)$. Hence, (e_1, e_2) will be labeled as r^* and added to labeled data (i.e., X^l and Y^l). Here, we only add unlabeled data with confident predictions to the training set, in order to avoid error propagation in a semi-supervised learning environment.

After the execution of the above three modules in one iteration, if a new relation is found with its seed relation instances (i.e., entity pairs), the structure of the neural network retrained in the next iteration will be adjusted dynamically with parameters updated.

4 The Architecture of the Base Neural Network

Base neural network takes texts with annotated entity pairs as input and classify them to a fixed relation set. It learns representation of texts by exploiting the following three contexts: (i) syntactic contexts; (ii) lexical contexts; and (iii) global semantic contexts. The overall architecture is illustrated in Fig. 1.

Syntactic contexts. Previous work exploits the shortest dependency path (SDP) (Bunescu and Mooney, 2005) to capture predicate-argument sequences (Cai et al., 2016; Xu et al., 2015; Shwartz et al., 2016). However, SDP can not handle the dependency relation properly between e_1 and e_2 due to the lack of the associated predicate. Consider the example in Fig. 2. Entities "张智霖 (Zhilin Zhang)" and "袁咏仪 (Yongyi Yuan)" are in the coordinate dependency relation via a direct arc. Thus, the SDP between two entities is "张智霖 (Zhilin Zhang) $\rightarrow$ 袁咏仪 (Yongyi Yuan)", which contains not much useful information. In this paper, we design a structure to capture the root verb along the dependency path, namely root augmented dependency path (RADP):

Definition 2. *An RADP is the combination of two subpaths derived from the dependency graph, one from e_1 to the root verb, and the other one from the root to e_2.*

Here, the RADP is "注册 (registered) $\rightarrow$ 张智霖 (Zhilin Zhang) $\rightarrow$ 袁咏仪 (Yongyi Yuan) ". Compared to SDP, it includes the extra root verb "注册 (registered)", a crucial complement indicating the relation "配偶 (spouse)" holds between two entities.

In the base neural network, each node along the RADP is considered as a syntactic unit (Shwartz et al., 2016) with four parts: 1) word embedding; 2) POS tag; 3) dependency relation, which is the label on the arc from the governing node; and 4) relational direction, one of the three labels "$\rightarrow$", "$\leftarrow$" and "—". Thus we present a syntactic unit as the concatenation of four parts: $\vec{v}_{syn} = [\vec{v}_{word}, \vec{v}_{pos}, \vec{v}_{rel}, \vec{v}_{dir}]$

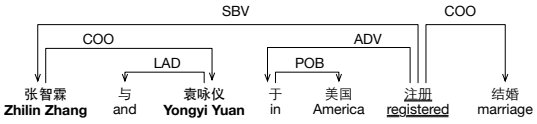

Figure 2: An example of the dependency graph.

where $\vec{v}_{word}$, $\vec{v}_{pos}$, $\vec{v}_{rel}$, $\vec{v}_{dir}$ are the embeddings of the word, POS tag, dependency relation and relational direction, respectively. $[\cdot]$ is the concatenation of embeddings. These embeddings are initialized as one-hot vectors except for $\vec{v}_{word}$, pre-trained on a large corpus.

We employ an LSTM network to handle the long-term dependencies. For an RADP with sequence $w_1, \ldots, w_j$, the corresponding embeddings $\vec{v}_{syn_1}, \ldots, \vec{v}_{syn_j}$ are fed into an LSTM network. The output vector $\vec{v}_{lstm}$ is the context vector modeling the syntactic features of the whole sequence.

Lexical contexts. Specific patterns around target entities can imply semantic relations between entity pairs (Hearst, 1992). Similar to previous research (Zeng et al., 2014; Vu et al., 2016), given a window size k, we define the lexical context of an annotated entity as k words ahead and k words following. Formally, the lexical context vector $\vec{v}_{con}$ is represented as follows: $\vec{v}_{con} = [\vec{v}_{w_{i-k}}, \ldots, \vec{v}_{w_{i-1}}, \vec{v}_{e_i}, \vec{v}_{w_{i+1}}, \ldots, \vec{v}_{w_{i+k}}]$ where $\vec{v}_{e_i}$ and $\vec{v}_{w_j}$ are embeddings of entity and context word at index i and j.

For entities e_1 and e_2 in the pair, $\vec{v}_{con_{e_1}}$ and $\vec{v}_{con_{e_2}}$ are fed into CNN units, respectively. After a convolutional layer and a max pooling layer, the resulting vectors are concatenated as $\vec{v}_{cnn}$.

Semantic contexts. The context-sparsity problem of domain knowledge motivates us to explore semantic contexts in the global corpus, instead of being limited to local features. Based on the distributional hypothesis, we train a Skip-gram model (Mikolov et al., 2013) to learn the distributional representations of words in a large corpus. For entity pair e_1 and e_2, the embeddings $\vec{v}_{e_1}$ and $\vec{v}_{e_2}$ are further concatenated to build the final representation of semantic contexts: $\vec{v}_{emb} = [\vec{v}_{e_1}, \vec{v}_{e_2}]$.

Prediction. The final context representation for prediction is the concatenation of three resulting vectors $\vec{v}_f = [\vec{v}_{lstm}, \vec{v}_{cnn}, \vec{v}_{emb}]$. Then we apply a *softmax* layer on $\vec{v}_f$ to predict the class distribution y: $\vec{y} = \text{softmax}(W \cdot \vec{v}_f + b)$ where W is the transformation matrix and b is the bias vector. The prediction of base neural network is the relation whose probability is maximal in $\vec{y}$.

5 Relation Discovery

To expand the output layer of base neural network, a clustering algorithm ssCRP is proposed to explore new relations from unlabeled data. In this part, we first introduce how the network expands, and briefly cover the basics of CRP, followed by the algorithm ssCRP in detail.

5.1 Network Expansion

After training base neural network, we take its final hidden layer as the representation for each entity pair, since it contains all high-level context features. The representations used as the input of ssCRP should be close to each other in the embedding space, if the same relation holds for these pairs.

In iteration t, ssCRP and the table selection process (to be discussed later) generate a cluster C^* from unlabeled data. Let r^* be the mapping relation that entity pairs in C^* hold, $\{r_1, \ldots, r_{K+l}\}$ be the K pre-defined relations and l new relations discovered in $t-1$ iterations. If $r^* \notin \{r_1, \ldots, r_{K+l}\}$, a new relation is found and base neural network trained in the next iteration $t+1$ expands its output layer with an extra class; otherwise, it remains the same with $K+l$ output classes. Fig 3 shows the base neural network and its expansion network.

5.2 Similarity Sensitive Chinese Restaurant Process

Preliminaries. The Chinese restaurant process (CRP) is a stochastic process, which groups customers into random tables where they sit (Aldous, 1985). Assume N_p denotes the number of customers sitting at table p, z_i denotes the index of the table where the i-th customer sits, and vector $\vec{z}_{-i}$ represents the

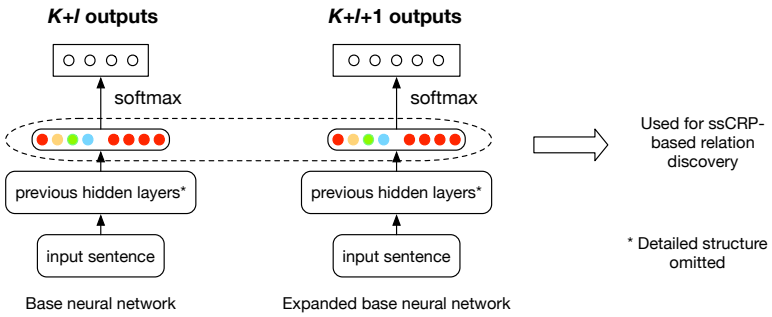

Figure 3: Base neural network and the expanded network.

table assignment for other customers. The distribution over table assignments is as follows:

$$\Pr(z_i = p \mid \vec{z}_{-i}, \alpha) \propto \begin{cases} N_p & \text{if } p \leq K \\ \alpha & \text{if } p = K+1 \end{cases} \tag{1}$$

where α is a scaling parameter and K is the number of occupied tables.

ssCRP. Although CRP can be applied for clustering in a non-parametric Bayesian fashion, it does not consider the similarity of relation instances. We observe that some extensions of CRP (e.g., ddCRP (Blei and Frazier, 2010)) leverage the distances between data points but they do not consider the iterative cluster generation process with pre-defined clusters. In this paper, we propose a similarity-based clustering algorithm especially designed for ERC, called similarity sensitive Chinese restaurant process (ssCRP).

In ssCRP, we turn the problem of table assignment into customer assignment. Unlike the CRP and ddCRP, we accommodate labeled data by initializing tables with K pre-defined classes. Customer i has the choice of sitting next to any customer j based on similarity, which leads to three cases: (i) i joins the table where j sits; (ii) i and an upcoming j generates a new table[2]; and (iii) i sits at an empty table alone. Case (i) is specifically introduced for task ERC due to the initialization of existing tables. Each table in case (i) can be represented as a virtual customer averaged from all its seated customers.

Denote $\eta = \{S, N, \alpha, \beta\}$ as the set of hyperparameters, where S is a similarity matrix between all customers, $N = (N_1, \cdots, N_K)$ is the size vector of existing K tables, α is the scaling parameter and β is a parameter balancing the weight of table size. The distribution of customer assignment c_i is:

$$\Pr(c_i = j \mid \eta) \propto \begin{cases} \alpha & \text{if } j \text{ is customer } i \text{ itself} \\ g(s_{ij}) & \text{if } j \text{ is an upcoming customer} \\ g(s_{ij})(1 + \beta \lg N_p) & \text{if } j \text{ is averaged from table } p \end{cases} \tag{2}$$

where g is a function modeling the cosine similarity s_{ij} between customer i and j. We design a magnifying function $g(s_{ij}) = -1/\ln s_{ij}$ where $s_{ij} > 0$, to increase the dissimilarity of inputs. The first two cases in Eq. (2) are derived from CRP. The third case gives existing tables additional weights to avoid generating too many small clusters. An alternative measuring system is to use the distance function $d_{ij} = 1 - s_{ij}$ and to apply different non-increasing functions to mediate the distances between customers. Given a parameter a, typical decay functions like window decay $f(d) = 1[d < a]$, exponential decay $f(d) = \exp(d/a)$ and logistic decay $f(d) = \exp(-d + a)/(1 + \exp(-d + a))$ are provided as alternatives (Blei and Frazier, 2010).

ssCRP-based relation discovery. The overall sampling and table selection process is illustrated in Fig. 4. In Step 1, we initialize fixed tables with classification results of labeled data. In Step 2, ssCRP draws customer assignments based on Gibbs sampling. Denote C_p as the collection of entity pairs w.r.t table p. Given the hyperparameter set η, the likelihood function of table p denoted by C_p is calculated as follows: $\Pr(C_p \mid \eta) = \prod_{i=1}^{|C_p|} \Pr(c_i^p \mid \eta)$ where c_i^p represents the customer assignment that customer i sits at table p.

[2]If the assignment of j is generated following i, then j is an upcoming customer w.r.t. i.

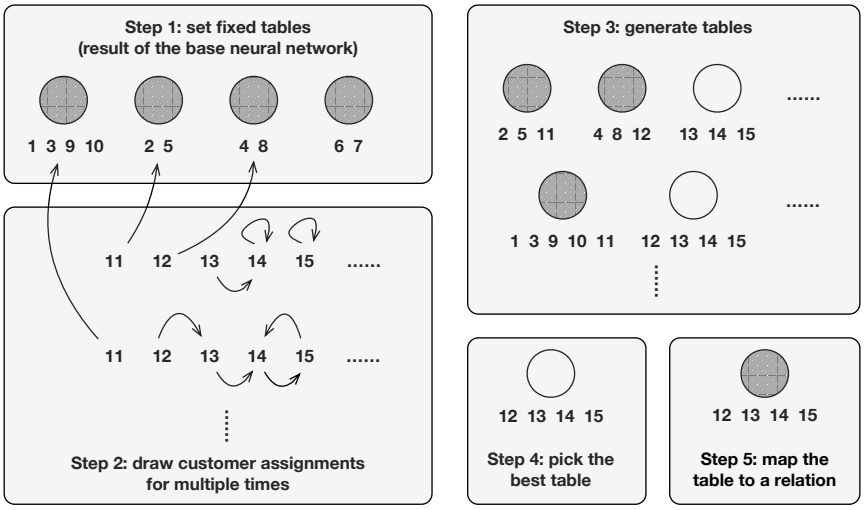

Figure 4: Relation discovery based on ssCRP. Circles with shadow are existing relations, while plain circles are new tables surrounded with customers representing entity pairs.

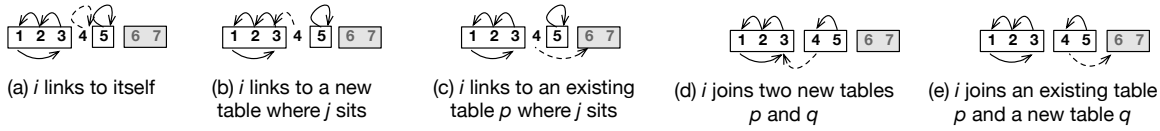

Figure 5: Five cases of customer assignment with $i = 4$ based on Gibbs sampling. Grey boxes are existing tables while white ones are generated new tables.

Given the rest of customer assignments $\mathbf{c}_{-i}$, customer assignment c_i can be divided into five cases (Blei and Frazier, 2010), generated by Gibbs sampling as Fig. 5 shows:

$$\Pr(c_i = j \mid \mathbf{c}_{-i}, \eta) \propto \begin{cases} \alpha & \text{(a)} \\ g(s_{ij}) & \text{(b)} \\ g(s_{ij})(1 + \beta \lg N_p) & \text{(c)} \\ g(s_{ij}) \frac{\Pr(C_p \cup C_q|\eta)}{\Pr(C_p|\eta)\Pr(C_q|\eta)} & \text{(d)} \\ g(s_{ij})(1 + \beta \lg N_p) \frac{\Pr(C_p \cup C_q|\eta)}{\Pr(C_p|\eta)\Pr(C_q|\eta)} & \text{(e)} \end{cases} \tag{3}$$

After this process, all customers are connected together with direct links from one to another or self-loops. New tables can be automatically generated by connected customers while existing tables are extended with new customers in Step 3. In our implementation, we run Gibbs sampling for multiple times to select the best configuration (i.e., largest likelihood), to enhance the fault tolerance.

Step 4 calculates a score for each table p considering pairwise similarities and table size, defined as:

$$score(p) = \frac{\lg N_p}{2\binom{N_p}{2}} \sum_{i=1}^{N_p} \sum_{j=1}^{N_p} s_{ij}(i \neq j) \tag{4}$$

where $\frac{1}{2\binom{N_p}{2}} \sum_{i=1}^{N_p} \sum_{j=1}^{N_p} s_{ij}(i \neq j)$ is the average pairwise similarity of instances in table p. $\lg N_p$ gives additional weight to large tables. It means the best table has similar relation instances and large size. The table with the highest $score(p)$ will be the selected cluster C^*. The last step (i.e., Step 5) maps the "best" cluster C^* to a semantic relation r^* with a proper relation predicate. The relation can be either a new one with confident seeds (i.e., entity pairs) or an existing relation extended with new entity pairs.

Predefined relations	执导 (directing)	演唱 (singing)	主演 (starring)	配偶 (spouse)
# Instances	633	648	1609	590

Table 1: The statistics of pre-defined relations extracted from (Fan et al., 2017).

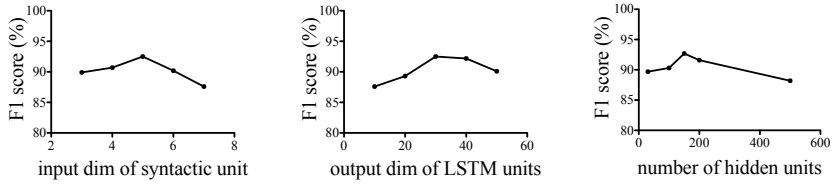

Figure 6: The effects of hyperparameters of the base neural network.

5.3 Relation Prediction

New relations generated via ssCRP only contain a small number of seed instances. To populate relations, part of unlabeled entity pairs will be assigned with labels based on model prediction, and added to the training set. To avoid error propagation, the algorithm requires that only if the prediction of DSNN is highly confident for an entity pair, can we add it to the training set.

Consider the distribution $[\Pr(r_1|e_1,e_2),\ldots,\Pr(r_{K+l}|e_1,e_2)]$ for entity pair (e_1,e_2). If it is "near uniform", none of the existing relation labels are confident enough to be the perfect fit. Goodness-of-fit tests are able to determine if the prediction follows uniform distribution (e.g. Kolmogorov-Smirnov test), but experiments show they do not work in this scenario (refer to Section 6.3). In this paper, we define a heuristic "Max-SecondMax" value to estimate the confidence score of a prediction:

$$conf(e_1,e_2) = \frac{\max([\Pr(r_1|e_1,e_2),\ldots,\Pr(r_{K+l}|e_1,e_2)])}{\text{secondMax}([\Pr(r_1|e_1,e_2),\ldots,\Pr(r_{K+l}|e_1,e_2)])} \tag{5}$$

where secondMax$(\cdot)$ is the second largest value of probabilities. If $conf(e_1,e_2)$ is no less than a given threshold τ, the label with the highest probability is indeed a convincing prediction. Such entity pairs will be added to labeled data together with their labels.

6 Experiments

In this section, we conduct extensive experiments for ERC task to evaluate our method and compare it with state-of-the-art approaches.

6.1 Datasets

We use distant supervision (Mintz et al., 2009) to create datasets. We choose four relations from an entertainment knowledge graph (Fan et al., 2017), and extract texts from Chinese Wikipedia where two entities from the same pair have joint occurrence. We manually check the correctness of relation labeling and remove annotation errors. In total, we have 3480 sentences with annotated entity pairs and relations, and spilt them into training data, testing data and validation data, with the proportion of 70%, 20% and 10%. The statistics of labeled data are summarized in Table 1. Similarly, two entities which do not appear in pairs of pre-defined relations are used for harvesting unlabeled data, which contains 3161 sentences.

6.2 Evaluation of Relation Classification

We implement base neural network with Keras[3] and use dependency parsing results generated by pyltp[4]. The word embeddings are initialized as 50 dimensions, trained on Chinese Wikipedia dump[5] via the Skip-gram model (Mikolov et al., 2013).

签约公司 (employed by)	144	制作公司 (produced by)	18

Table 3: Semantic relations discovered via ssCRP.

We first study the effects of hyperparameters, i.e., the input dimension of syntactic unit d_{syn}, the output dimension of LSTM units d_{lstm} and the number of convolutional hidden units h. We tune these hyperparameters on the validation set and illustrate the F1 scores with different settings in Fig. 6. As we can see, the best performance is achieved when $d_{syn} = 5$ and $d_{lstm} = 30$. The base neural network shows signs of overfitting with h larger than 150. We heuristically set the window size $k = 5$ and train the network with 0.5 weighted L_2 regularization.

The second part is to evaluate the effectiveness of the proposed features. We implement several state-of-the-art methods of representing the embeddings of entity pairs: concatenation $\vec{v}_{e_1} \oplus \vec{v}_{e_2}$, difference $\vec{v}_{e_1} - \vec{v}_{e_2}$ and sum $\vec{v}_{e_1} + \vec{v}_{e_2}$ model (Baroni et al., 2012; Roller et al., 2014; Mirza and Tonelli, 2016). We train logistic regression and SVM with the combination of the above features. As Table 2 shows, both classifiers achieve the highest F1 scores when trained with all three features. Similar to observations (Mirza and Tonelli, 2016), the concatenated embeddings of entity pairs are the most effective.

The third part is the comparison of our model and other approaches. We implement the CNN-based model (Zeng et al., 2014) and keep the way they use features. Another competitor is the RNN-based model for hypernymy detection (Shwartz et al., 2016), which is modified slightly to classify more generalized semantic relations. We also evaluate the variations of base neural network during iterations, e.g. removing LSTM units (CNN+E) or the convolution layer (RNN+E). The results shown in Table 2 prove that our model has the best performance. The CNN-based models such as CNN+E and model (Zeng et al., 2014) are both significantly effective than RNN-based models, e.g. RNN+E and model (Shwartz et al., 2016). It suggests that lexical features are more effective than syntactic features. The embedding layer improves the performance in either situation due to the use of semantic features.

6.3 Evaluation of Relation Discovery

We first introduce the semantic relations found during the relation discovery process. Table 3 summarizes six relations discovered via ssCRP, containing 3048 instances. The sizes of relations are unbalanced due to the random selection of entity pairs in order to construct unlabeled data automatically.

As studied in previous research (Qiu and Zhang, 2014), OpenRE systems have low performance for Chinese due to flexible language expressions and low data redundancy. Hence, OpenRE methods are not treated as strong baselines for ERC task. To measure the effectiveness of ssCRP, we propose two baseline models following Balvi et al. (Dalvi et al., 2013) for multi-class semi-supervised learning task. Seeded KMeans proposed by Basu et al. (2002) is a clustering method using labeled data to guide the clustering process. We implement an exploratory version where a new centroid is initialized as the most centered data in each iteration. Another intuitive approach is semi-supervised EM-based Naive Bayes with empty

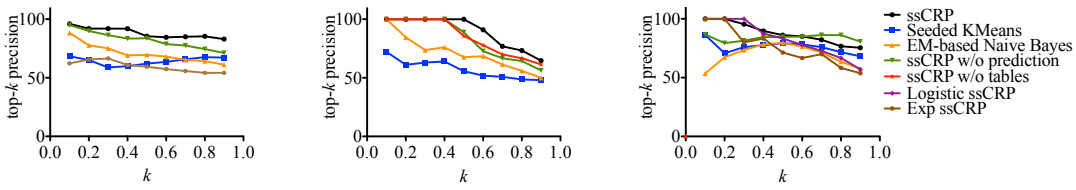

Figure 7: The top-k precisions (%) of three relations (series works, produced by, employed by) generated by various methods with different k.

Algorithm	# Instances	Precision (%)	Recall (%)	F1 (%)
Fit ssCRP	3161	31.0	35.7	33.2
Exploratory EM-based Naive Bayes	3161	70.7	40.2	52.8
Exploratory seeded KMeans	3161	80.5	53.0	63.9
ssCRP w/o tables	593	66.6	60.4	63.3
ssCRP w/o prediction	903	83.7	61.0	70.6
Exp ssCRP	3161	77.9	66.7	71.9
Logistic ssCRP	3161	81.4	66.9	73.0
Full implementation of ssCRP	3048	**83.1**	**68.4**	**75.0**

Table 4: Performance of different algorithms for relation discovery.

classes. The E-step starts with a random initialization of class assignment, and M-step retrains the model until convergence. We also try several variations of our model. For example, we replace the magnifying function with logistic decay (Logistic ssCRP) or exponential decay (Exp ssCRP) proposed in (Blei and Frazier, 2010). In relation prediction process, we make a comparison between the "Max-SecondMax" criterion and goodness-of-fit models such as Kolmogorov-Smirnov test with significance level of 0.05 (Fit ssCRP). Populating new clusters is essential for our model, so we conduct experiments of two related strategies, e.g. not allowing to join existing tables (ssCRP w/o tables) or removing the relation prediction process (ssCRP w/o prediction). We set $\tau = 2$ for all variations, fine tuned over the validation set.

The first experiment presents the top-k precision of newly found relations. Relation instances are sorted according to the cosine similarity between its embedding and averaged relation embedding. We ask human annotator to label whether the extracted top-k relations are correct or not, and evaluate the top-k precision with k ranging from 0.1 to 0.9, and show the results in Fig. 7. The illustrated relations achieve the best performance when they are generated by ssCRP, compared with other baseline models[6]. We heuristically choose $k = 0.4$ because the precision drops relatively faster when k is larger.

Next, we design a pairwise experiment to evaluate this non-standard clustering task. We manually construct a standard testing dataset by sampling pairs of instances from unlabeled data. For two entity pairs x_i and x_j with their respective sentences, we use the domain knowledge graph (Fan et al., 2017) as the ground truth to determine whether x_i and x_j have the same relation. We use Precision, Recall and F1 score as the evaluation metrics. We present the performance of ssCRP and other baseline models in Table 4. For two baseline models, exploratory seeded KMeans performs better than exploratory EM-based Naive Bayes. Experiments of ssCRP variations prove the effectiveness of our specially designed magnifying function and "Max-SecondMax" criterion. The reason that goodness-of-fit models fail is that they are sensitive to check whether the data follows uniform distribution or not, while our purpose is to select those with prominent peaks. Thus non-confident relation labels are assigned to unlabeled entity pairs roughly, increasing the number of false positive instances. For the strategies of table assignment and relation prediction process, the experimental results show that they not only populate new relations, but also improve the overall performance.

6.3.1 Error Analysis

To further obtain additional insights into our method, we study the errors in newly found relations and present three types of errors. A frequent type of confusion happens when entity pairs are closely related

[6]Some baselines do not generate certain relations, therefore these competitors are not included in corresponding figures.

under the same topic but not by the same relation, which accounts for 63.4% errors. For example, two entities involved with cooperation relation are be misclassified to the relation "团队成员 (group members)". Another 23.7% bad cases are due to the false positive results of NER where common nouns are mistaken as named entities, especially for specific names such as "黎明 (Ming Li, which also has the meaning of dawn)". The rest of errors result from the mixture of different grains of relation types. We observe that the relation "所属国家 (belong to the country)" contains a few instances where e_2 is not a country but a finer-grained city or a district.

7 Conclusion

In this paper, we propose the task of ERC to address the problem of domain-specific knowledge acquisition. We propose a DSNN model to address the task, consisting of three modules, an integrated base neural network for relation classification, a similarity-based clustering algorithm ssCRP to generate new relations and constrained relation prediction process with the purpose of populating new relations. Extensive experiments are conducted to evaluate the effectiveness of our approach.

Abstract

Finding names of people killed by police has become increasingly important as police shootings get more and more public attention (police killing detection). Unfortunately, there has been not much work in the literature addressing this problem. The early work in this field (Keith et al., 2017) proposed a distant supervision framework based on Expectation Maximization (EM) to deal with the multiple appearances of the names in documents. However, such EM-based framework cannot take full advantages of deep learning models, necessitating the use of hand-designed features to improve the detection performance. In this work, we present a novel deep learning method to solve the problem of police killing recognition. The proposed method relies on hierarchical LSTMs to model the multiple sentences that contain the person names of interests, and introduce supervised attention mechanisms based on semantical word lists and dependency trees to upweight the important contextual words. Our experiments demonstrate the benefits of the proposed model and yield the state-of-the-art performance for police killing detection.

1 Introduction

We study the problem of police killing detection from text. The key challenge is to be able to take a person name in the pool of documents (corpus) and automatically decide whether the corresponding person is killed by police or not based on the textual evidences in the corpus. For instance, the following sentence describes the police-caused death of "*Micah Jester*": "*Old **Micah Jester** was fatally shot by APD officers.*". This problem has drawn much public attention recently; however, it has not been investigated adequately by the natural language processing (NLP) community. To our knowledge, the only NLP work for police killing recognition so far is by (Keith et al., 2017) who rely on machine learning models to perform the automatic detection.

It is challenging to apply the machine learning models in this case as identifying police killings from text is a relatively new problem in machine learning research with no available training datasets to supervise the models. The only sources of supervision on which we can rely for this problem are the current databases that record the names of the police-killed victims in the past. Among these databases, the Fatal Encounters[1] (FE) database has emerged as the most comprehensive database with a relatively large number of recorded victims (over 23,000 victims). In order to take advantage of this database, (Keith et al., 2017) employs distant supervision (Craven et al., 1999; Mintz et al., 2009) that extracts person names from a corpus and aligns them with the victim names in the database. The matched names are considered as corresponding to people killed by police (positive entities) while the non-matched names constitute the negative examples in a binary classification problem for names in police killing detection. As the name itself does not carry much information, each extracted name is associated with the set of sentences in which the name appears in the corpus. This set of sentences is called the sentence container for the corresponding name (person). The sentence containers along with the distant supervision labels

[1]This database has been produced by D. Brian Burghart and colleagues by manually reading millions of news headlines and ledes.

Proceedings of the 27th International Conference on Computational Linguistics, pages 2277–2287
Santa Fe, New Mexico, USA, August 20-26, 2018.

(i.e, positive or negative) of the corresponding names would serve as the training data for the binary name classification problem.

An important characteristic of the sentence containers is that they might contain multiple sentences corresponding to the multiple appearances of the names in the corpus. Although all of these sentences mention the names of interests, some of them might not express police killing incidents. Consequently, it is crucial for the systems to be able to model the multiple sentences in the containers appropriately so that the correct sentences for police killing events can be captured to perform classification for the sentence containers of names. (Keith et al., 2017) solves this problem by introducing a latent variable for each sentence in the container of a name to predict whether the sentence describes the person as having been killed by police or not. Such latent variables are then modeled by sentence level classifiers (i.e, logistic regressions and convolutional neural networks) and aggregated for the final prediction for the name. (Keith et al., 2017) learns the parameters for the sentence classifiers via an Expectation Maximization (EM) based framework that alternates between estimating the latent variables and updating the model parameters. In (Keith et al., 2017), the authors demonstrate that the EM-based framework works well when the sentence level classifiers involve logistic regression with hand-crafted features. However, when deep learning models (i.e, convolutional neural networks) are employed for the sentence level classifiers, the performance of the EM-based framework drops significantly. We attribute this problem to the limitation of the EM-based framework to train the non-convex classifiers of deep learning, causing the inability to exploit the automatically learnt representations from deep learning and necessitating the use of complicated and laborious feature engineering.

In order to overcome this problem, we propose a novel deep learning framework for the problem of police killing recognition via hierarchical long short-term memory networks (LSTM) (Hochreiter and Schmidhuber, 1997; Yang et al., 2016). Our model does not make individual predictions on each sentence with the latent variables but involves a direct prediction to the name of interest based on its sentence container. Two layers of LSTMs are applied to model the sentence containers. The first LSTM layer learns the representations for the sentences in the containers by recurring over their words (the word level). The second LSTM layer, on the other hand, consumes the sentence representations (the sentence level) to produce container representations for police killing predictions. Attention mechanisms are then introduced into both LSTM layers to appropriately quantify the contribution of each word and sentence in the containers for the final predictions. This approach facilitates the modeling of multiple sentences in the containers, leading to the effective training of the deep learning models in a single framework and alleviating the reliance on manually designed features for this problem.

In the previous hierarchical LSTM models, attention scores are computed and normalized using the hidden representations of words and sentences generated by LSTMs (Yang et al., 2016). Unfortunately, for our problem of police killing recognition, this traditional attention computation tends to assign very high weight to the words in the names of interests and relatively low weights to the other important context words in the sentences. Such failure to adequately capture those context words would potentially lead to incorrect predictions for the containers. This problem is stem from the use of the position embeddings to specify the names of interests that might put too much emphasis on the current names. In order to solve this problem, we propose to integrate the supervised attention mechanisms into the hierarchical LSTM model that help to bias the attention scores toward the heuristically important words in the sentences (supervised attention) (Mi et al., 2016). In particular, we rely on linguistic intuitions to heuristically select the informative context words for the problem of police killing detection. These words are then used to guide the attention computation via penalizing the model parameters that generate low attention scores for such guidance words. We investigate several heuristics to choose the guidance words based on semantical word lists and dependency trees. The experiments show that the supervised attention mechanism with those heuristics helps to improve the performance of the hierarchical LSTM model and yield the state-of-the-art performance for the problem of detecting police killings. To the best of our knowledge, this is the first work that introduces supervised attention into the hierarchical LSTM models and employs semantical word lists and dependency trees to select guidance words.

2 Related Work

Although police killing recognition is a new task, it has some elements with the information extraction (IE) research of NLP that can be used to solve the task with some modifications. The most related IE task for police killing detection is event extraction that aims to detect events (i.e, marriage, attack, die etc.) in text (Li and Ji, 2014; Nguyen and Grishman, 2015b; Chen et al., 2015; Nguyen and Grishman, 2016b). Killings is one of the event types that the current event extraction systems can identify (Das et al., 2014; Li and Ji, 2014; Nguyen et al., 2016c), allowing the detection of police killing incidents when appropriate adaptations are introduced. Unfortunately, such adaptations result in poor performance for police killing recognition as shown in (Keith et al., 2017).

Distant supervision is another element of IE that is employed in this research to generate training data for police killing detection. In particular, distant supervision has been used to produce training data for relation extraction (Craven et al., 1999; Bunescu and Mooney, 2007; Mintz et al., 2009; Riedel et al., 2010; Surdeanu et al., 2012) and event extraction (Reschke et al., 2014).

Hierarchical deep learning techniques that model both the word and sentence levels have been employed for several NLP tasks, including relation extraction (Lin et al., 2016), question answering (Choi et al., 2017) and extractive summarization (Cheng and Lapata, 2016). Such work often uses convolutional neural networks to operate at the work level. This is different from our proposed model for police killing detection that employs LSTMs and supervised attentions to acquire sentence representations for police killing recognition. Perhaps the most related model to ours is (Yang et al., 2016) that utilizes hierarchical LSTMs for text categorization. Our model also relies on hierarchical LSTMs, but it is designed for police killing detection, characterizing position embeddings and supervised attentions to inject external knowledge (i.e, the heuristics for guidance words).

Finally, supervised attention mechanisms have been used recently for several natural language tasks. For machine translation, the attention guidance is based on word alignment (Mi et al., 2016; Liu et al., 2016) while entity mentions are chosen as the guidance words for event detection (Liu et al., 2017a). Our work in this paper is different as we consider supervised attention for police killing recognition using semantical word lists and dependency parsing trees (Schuster and Manning, 2016) to guide the attention components. Our model features hierarchical LSTMs to tackle distant supervision data that does not emerge in such prior work.

3 Model

We formalize the problem of finding people killed by police as follows.

Let D be a set of documents (corpus), $E = \{e_i\}_{i=1}^{N}$ be the set of entities (people) whose names appear in D (N is the number of the entities in E), and $C = \{c_i\}_{i=1}^{N}$ be the set of sentence containers for the entities in E (i.e, c_i is the set of sentences that contain the name of the entity e_i in D).

Each entity e_i in E has a label $y_{e_i} \in \{0, 1\}$, denoting whether e_i has been killed by police or not based on the distant supervision procedure (y_{e_i} is set to 1 if e_i is deemed to be killed by police via distant supervision and 0 otherwise). For convenience, let $Y = \{y_{e_i}\}_{i=1}^{N}$. Our goal is to use E, C and Y as training data to generate a model that can predict whether a new entity e is a victim of a police killing incident or not, given its sentence container c in some corpus. In machine learning, this essentially amounts to building models to estimate the probability $P(y_e = 1|c)$.

We will first introduce the hierarchical LSTM model for this problem, and then describe the supervised attention mechanisms with semantical word lists and dependency trees.

3.1 Hierarchical LSTMs

Each entity $e_i \in E$ along with its container $c_i \in C$ constitute an example for the model. Let $c_i = (s_{i,1}, s_{i,2}, \ldots, s_{i,L})$ be the list of sentences in c_i where L is the number of sentences and $s_{i,j}$ is the j-th sentence in the container c_i. Each sentence $s_{i,j}$ is in turn a word/token sequence: $s_{i,j} = (t_{i,j,1}, t_{i,j,2}, \ldots, t_{i,j,K})$ with K as the number of the tokens and $t_{i,j,k}$ as the k-th token in the sentence $s_{i,j}$. For each sentence $s_{i,j}$, let $k_{i,j}$ be the index of the name of the entity e_i (i.e, the token $t_{i,j,k_{i,j}}$). Note that the order of the sentences $s_{i,j}$ in c_i is obtained by sorting the sentences according to

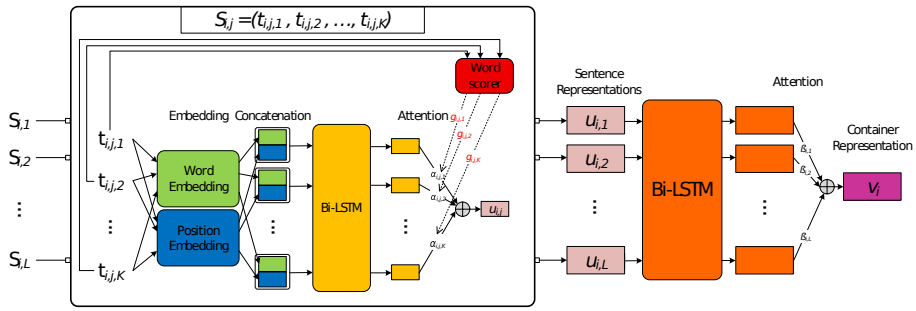

Figure 1: Hierarchical LSTMs with Supervised Attention for Police Killing Detection.

the download time of their corresponding documents in D^2. This helps to partially retain information about the order of being mentioned of the entities in the sentence containers in the corpus.

The hierarchical LSTM model in this work processes one entity e_i and its corresponding sentence container c_i at a time. For each entity e_i, the operation of the model can be divided into two main components: Embedding and Attention. Figure 1 shows an overview of the proposed model.

Embedding

In this component, each token $t_{i,j,k}$ of a sentence $s_{i,j}$ in c_i is transformed into an embedding vector $x_{i,j,k} = [q_{i,j,k}, p_{i,j,k}]$, which is the concatenation of the word embedding vector $q_{i,j,k}$ and the position embedding vector $p_{i,j,k}$ (Nguyen and Grishman, 2015a). These vectors are obtained as follows:

Word embedding vector: $q_{i,j,k}$ is obtained by taking the column vector corresponding to $t_{i,j,k}$ in the pre-trained word embedding matrix W_e (i.e, `word2vec` in our case): $q_{i,j,k} = W_e[t_{i,j,k}]$.

Position embedding vector: $p_{i,j,k}$ captures the relative distance $k - k_{i,j}$ from the token $t_{i,j,k}$ to the entity name token $t_{i,j,k_{i,j}}$ in the sentence: $p_{i,j,k} = W_d[k - k_{i,j}]$, the $(k - k_{i,j}) - th$ column in the position embedding matrix W_d (W_d is randomly initialized in this work) (Nguyen and Grishman, 2018).

Once each token $t_{i,j,k}$ has been transformed into a vector, the corresponding input sentence $s_{i,j}$ would become a sequence of vector $(x_{i,j,1}, x_{i,j,2}, \ldots, x_{i,j,K})$. This allows us to view the container c_i as an ordered list of vector sequences for its sentences $(s_{i,1}, s_{i,2}, \ldots, s_{i,L})$.

Attention

The attention component processes the list of vector sequences produced in the previous step for c_i at two levels (i.e, the word level and the sentence level) to produce a single representation vector for c_i.

The word level component consumes each vector sequence of c_i once at a time to compute the representation vector for the corresponding sentence. For a vector sequence $(x_{i,j,1}, x_{i,j,2}, \ldots, x_{i,j,K})$ of $s_{i,j}$, the model architecture consists of two LSTMs (Hochreiter and Schmidhuber, 1997) (i.e, the forward LSTM and the backward LSTM) that operate over two different directions of the vector sequence (bidirectional LSTMs) (Cho et al., 2014; Nguyen et al., 2016a). The resulting hidden vector sequences of the forward and backward LSTMs are concatenated at each position, generating the hidden vector sequence $(h_{i,j,1}, h_{i,j,2}, \ldots, h_{i,j,K})$ for the input vector sequence of $s_{i,j}$.

In order to combine the hidden vectors $h_{i,j,k}$, the attention mechanism computes the weighted sum of the hidden vectors to obtain a single representation vector for the input sentence $s_{i,j}$ (Bahdanau et al., 2015). Specifically, each hidden vector $h_{i,j,k}$ is given a weight $\alpha_{i,j,k}$ to estimate its contribution for the final representation of the container c_i for the problem of police killing recognition. In this work, the weight $\alpha_{i,j,k}$ is computed by:

$$\alpha_{i,j,k} = \frac{\exp(a_{i,j,k}^{\top} w_a)}{\sum_{k'} \exp(a_{i,j,k'}^{\top} w_a)} \quad (1)$$

where:

$$a_{i,j,k} = \tanh(W_{att} h_{i,j,k} + b_{att}) \quad (2)$$

[2]Such documents are retrieved via running pre-defined search queries once per hour throughout 2016 (Keith et al., 2017).

In such equations, W_{att}, b_{att} and w_a are the attention parameters at the word level that are learnt in the training process. Eventually, the representation vector $u_{i,j}$ of the sentence $s_{i,j}$ is:

$$u_{i,j} = \sum_k \alpha_{i,j,k} h_{i,j,k} \tag{3}$$

Once the word level component has been completed, every sentence $s_{i,j}$ in the container c_i would have a corresponding representation vector $u_{i,j}$. Such sentence representation vectors $u_{i,j}$ altogether form a new sequence of vector $(u_{i,1}, u_{i,2}, \ldots, u_{i,L})$ to represent the container c_i. At the sentence level, $(u_{i,1}, u_{i,2}, \ldots, u_{i,L})$ is processed in the same way we process the vector sequence $(x_{i,j,1}, x_{i,j,2}, \ldots, x_{i,j,K})$ at the word level to produce the sentence representation vector $u_{i,j}$. In particular, $(u_{i,1}, u_{i,2}, \ldots, u_{i,L})$ would be first passed to a bidirectional LSTM model to obtain the hidden vector sequence $(h_{i,1}, h_{i,2}, \ldots, h_{i,L})$. This is in turn fed into the attention component to obtain the attention weights $(\beta_{i,1}, \beta_{i,2}, \ldots, \beta_{i,L})$ (i.e, similar to Equations 1 and 2). Finally, we compute the vector representation v_i for the sentence container c_i via the weighted sum: $v_i = \sum_j \beta_{i,j} h_{i,j}$. As the sentences in c_i are sorted by their appearance time, the attentional bidirectional LSTMs at the sentence level attempt to estimate the contribution of each sentence $s_{i,j}$ in c_i for the representation vector v_i with respect to its past and future context information (i.e, the sentences before and after $s_{i,j}$ in c_i).

The container representation vector v_i for c_i allows us to compute the probability P_i of e_i being killed by police: $P_i = P(y_{e_i} = 1 \mid c_i) = \sigma(W_{out} v_i + b_{out})$ where W_{out} and b_{out} are the model parameters, and σ is the logistic function. In order to train the hierarchical LSTM model in this section, we use the cross-entropy between the predicted labels and the golden labels as the loss function:

$$L_c = -\sum_{e_i} y_{e_i} \log(P_i) + (1 - y_{e_i}) \log(1 - P_i) \tag{4}$$

3.2 Supervised Attention

The position embeddings $p_{i,j,k}$ in the initial representation vectors of the tokens is crucial to the hierarchical LSTM model as it helps to indicate the positions of the entity names of interests in the sentences. Technically, the position embeddings would tell the model to pay more attention to the words in the entity names by assigning higher attention weights to the representation vectors of the entity name tokens $h_{i,j,k_{i,j}}$ at the word level. Unfortunately, in the experiments, we find that this procedure might lead to extremely high weights for the tokens of the entity names, leaving essentially negligible weights for the other important context words in the sentences. The consequence is the incorrect predictions of the model for the entities in such situations. In order to solve this problem, in this work, we seek to use linguistic intuitions to obtain the rough estimations of the attention weights for the words in the sentences (intuitive attention weights), quantifying our belief about the importance of the words in the sentences for the problem of police killing recognition. The intuitive attention weights would then be used to guide the attention weights computed by the hierarchical LSTM model at the word level (i.e, Equation 1), penalizing the model parameters with significant difference between the two types of attention weights.

Formally, for an entity e_i with the sentence container c_i, suppose that we can obtain the intuitive attention weights $(g_{i,j,1}, g_{i,j,2}, \ldots, g_{i,j,K})$ for the tokens of every sentence $s_{i,j} = (t_{i,j,1}, t_{i,j,2}, \ldots, t_{i,j,K})$ in c_i ($\sum_k g_{i,j,k} = 1 \forall i, j$). The difference between the intuitive attention weights and the model attention weights in Equation 1 for e_i can be computed via the sum of the squared element difference: $L_i = \sum_{j,k} (g_{i,j,k} - \alpha_{i,j,k})^2$.

Our goal is to minimize this difference so that the model attention weights can encode our intuition about the importance of the words in the sentences. This essentially translates into an integrated loss function to train the hierarchical LSTM model, attempting to minimize the loss function in Equation 4 and the attention weight difference simultaneously: $L = L_c + \lambda \sum_i L_i$ where λ is a penalty coefficient to control the effect of the attention difference.

Generating Intuitive Attention Weights

The previous section has described the supervised attention mechanism for the hierarchical LSTM model. It remains to investigate the methods to obtain the intuitive attention weights. An important characteristics of the intuitive attention weights is that they should assign high weights to the linguistically important

words for police killing recognition. In this work, we first start by selecting the important words in the sentences based on our intuition. Afterward, non-negative scores are given to the selected words and their neighbors in the sentences, leaving zero scores for other words. These scores are then normalized to ensure a sum of 1. In order to generate the non-negative scores for the selected words and their neighbors, we employ a Gaussian distribution $\mathcal{N}(\mu, \sigma^2)$(Mi et al., 2016; Liu et al., 2017b) with the mean μ and the standard deviation σ so that the closer neighboring words would receive higher scores.

Selecting Important Words

This section presents two methods to select important words in the sentences of the containers for the problem of police killing detection. The first method relies on the semantical aspect while the second method concerns the syntactical heuristics. We will compare these methods in the experiments.

Semantical Aspect: The two concepts that are most related to our problem of police killing recognition would naturally be "*police*" and "*killing*". It is therefore intuitive to consider these two words ("*police*" and "*killing*") and their similar ones as the important words for our problem. Consequently, for every sentence in the containers, we search for such important words and use the matched word as the selected words. Following (Keith et al., 2017), we generate the lists of similar words for "*police*" and "*killing*" by looking up the nearest words in cosine distance via the word vectors pre-trained with `word2vec` and its corpus. Note that this method also includes the names of the entities e_i in the list of selected important words due to their roles in specifying the entities of interests in the sentences.

Syntactical Aspect: The semantical aspect with the lists of similar words for police killing detection might be helpful for the sentences that express a police killing instance (positive sentences) and contain the similar words. However, for the negative sentences that do not mention police killing incidents, the appearance of the similar words in the lists for "*killing*" and "*police*" might be harmful to the supervised attention mechanisms as the emphasis on such words might lead to an incorrect impression to consider the sentence as actually positive. For instance, consider the following negative sentence with the words in the similar word lists written in bold[3]:

*Marion **Police** Department have arrested **TARGET** , 20 , of Marion , in connection with the **fatal** hit.*

In this sentence, the extreme emphasis on "*Police*", "*TARGET*" and "*fatal*" might lead to the incorrect prediction that this sentence is expressing a fatal event caused by police. In order to overcome this issue, we observe that police killing recognition can be seen as a relation identification problem (Bunescu and Mooney, 2005), attempting to decide whether the entities of interests (i.e, the "*TARGET*") has a semantical relation of "*killed by*" with the similar words of "*police*" (if any) in the sentence or not. In such relation identification problem, it has been shown that the shortest dependency path connecting the two word of interests (i.e, the words "*TARGET*" and "*police*" in our case) in the dependency trees involve the most important context words for the problem (Bunescu and Mooney, 2005). Consequently, in this work, we propose to select the words along the shortest dependency paths between the entity name of interests (i.e, "*TARGET*") and the similar words of "*police*" in the sentence as the guidance words for the supervised attention mechanism for police killing recognition (dependency tress are obtained via Stanford CoreNLP (Schuster and Manning, 2016) in this work).

In the example sentence above, the shortest dependency path between "*TARGET*" and "*police*" is: *Police* $\rightarrow$ *Department* $\rightarrow$ *arrested* $\rightarrow$ *TARGET*. It is clear in this situation that the words along the path do not suggest a police-caused killing (i.e, not a "*killed by*" relation between "*TARGET*" and "*Police*"). Consequently, the attention of the models to such words would lead to a correct prediction in this case.

On the other hand, for the positive sentences, it might be the case that the words along the dependency paths help to include some words that are crucial to police killing prediction, but do not appear in the semantical word lists.

Baselines

For experimental purposes, we call the hierarchical LSTM model without supervised attention as "*H-LSTM*". The hierarchical LSTM model with the supervised attention mechanism would then be called

[3]Throughout this work, the names of the entities of interests would be replaced by "*TARGET*" while the other entity mentions in the sentences would be substituted by "*PERSON*" for generalization.

"*H-LSTM+SemAtt*" and "*H-LSTM+SynAtt*" depending on whether the semantical aspect (i.e, the lists of similar words) or the syntactical aspect (i.e, the dependency paths) is used to obtain the important words. In order to further demonstrate the benefits of supervised attention for police killing detection, we consider two more baseline models when the model attentions at the word level are excluded from "*H-LSTM+SemAtt*" and "*H-LSTM+SynAtt*", resulting in the models "*Mean+SemAtt*" and "*Mean+SynAtt*". In particular, in such models, the sentence representation vector $u_{i,j}$ for the sentence $s_{i,j}$ would not be obtained via the attention-based weighted sum in Equation 3. In contrast, $u_{i,j}$ would be computed using the mean vector of the vector set $\{h_{i,j,k_1}, h_{i,j,k_2}, \ldots, h_{i,j,k_I}\}$ from LSTMs where $k_1, k_2, \ldots, k_I$ are the indexes of the selected important words using the semantical or syntactical aspect for the sentence $s_{i,j} = (t_{i,j,1}, t_{i,j,2}, \ldots, t_{i,j,K})$: $u_{i,j} = 1/I \sum_{m=1}^{I} h_{i,j,k_m}$.

3.3 Training

We train all the models in this work using stochastic gradient descent with shuffled mini-batches, the Adam update rule, back-propagation and dropout. Non-embedding weights are also imposed to gradient clipping to rescale their $l2$-norms if they exceed a predefined threshold.

4 Experiments

4.1 Datasets and Parameters

We evaluate the models in this paper using the police killing dataset released by (Keith et al., 2017).

As there is no development data for this dataset, we divide the original training data into two parts, for which one part is used for training data while the other part functions as the development data. We use these newly-generated training data and development data to select the parameters for the models. For the comparison with the state-of-the-art models in (Keith et al., 2017), we utilize the original training data and test data with the chosen parameters from the development experiments to ensure a compatible comparison. We use the same procedure to split the original training data for development as those employed by (Keith et al., 2017) to generate the original dataset. In particular, we first sort all the positive entities in the original training data using the descending order of their death times. Afterward, we identify the death time of the entity at the bottom of the top 20% in the sorted list. The date we found is used as the split point. All the entities with the download time or death time after this date are utilized as the development data.

The parameters we found in the development experiments are as follow. The dimensionality parameters include: 8 dimensions for position embedding vectors, 300 dimensions for word embedding vectors, 256 hidden units for the LSTMs and 64 dimensions for the attention vectors. For supervised attention, the penalty coefficient λ is set to 1.0 while the neighbor window T for generating intuitive attention weights is 2. The threshold for gradient clipping is set to 5.0 while the dropout rate is 0.5. The mean and standard deviation of the Gaussian distribution have the values of $\mu = 0$ and $\sigma = 1.0$, respectively.

4.2 Evaluating the Models

We evaluate the models (i.e, *H-LSTM*, *H-LSTM+SemAtt*, *H-LSTM+SynAtt*, *Mean+SemAtt* and *Mean+SynAtt*) using the generated development data. Table 1 reports the performance.

Models	Precision	Recall	F1
H-LSTM+SynAtt	0.497	0.381	**0.431**
H-LSTM+SemAtt	0.366	0.504	0.424
H-LSTM	0.460	0.377	0.414
Mean+SynAtt	0.428	0.372	0.398
Mean+SemAtt	0.346	0.399	0.371

Table 1: Performance of the models on the development data. The comparisons in this table are significant with $p < 0.05$.

There are three major observations from the table. First, the performance of the baseline models *Mean+SynAtt* and *Mean+SemAtt* are much worse than the other models, demonstrating that the atten-

tions in Equation 1 are crucial to problem of police killing detection. Second, both *H-LSTM+SemAtt* and *H-LSTM+SynAtt* are better than *H-LSTM* (improvements of 1% and 1.7% on the absolute F1 scores for *H-LSTM+SemAtt* and *H-LSTM+SynAtt* respectively). This shows the benefits of the proposed supervised attention mechanisms with semantical and syntactical guidance in this work. Third, we see that *H-LSTM+SynAtt* outperforms *H-LSTM+SemAtt*, suggesting that the syntactical guidance with dependency trees are more effective than the semantical guidance with the word lists for supervised attention in our task. We also see that the recall of *H-LSTM+SemAtt* is much better than that of *H-LSTM+SynAtt*. We attribute this phenomenon to the fact that the dataset in (Keith et al., 2017) involves many sentences with the words in the similar words lists for "*police*" and "*killing*". This biases the supervised attention in *H-LSTM+SemAtt* to associate the appearance of such words with the positive entities and leads to the high recall for this method. Due to the poor performance of *Mean+SynAtt* and *Mean+SemAtt* in this development experiment, we only consider the other models (i.e, *H-LSTM*, *H-LSTM+SemAtt* and *H-LSTM+SynAtt*) in the following experiments.

4.3 Comparing to the State of the Art

This section compares our proposed models with the state-of-the-art models for police killing recognition. Such state-of-the-art models include *soft-RL* and *soft-CNN* that both apply the Expectation Maximization algorithm, but employ logistic regression and convolutional neural networks (respectively) for sentence classifiers (Keith et al., 2017). Table 2 shows the performance the models. Note that the performance in this section is obtained using the original training data and test data in (Keith et al., 2017).

As we can see from the table, the conclusions we have for the models *H-LSTM*, *H-LSTM+SemAtt* and *H-LSTM+SynAtt* in the previous section still hold in this case on the test data, thus further confirming those observations for police killing recognition. We also see that although *H-LSTM* does not use supervised attention, its performance is comparable with the best model *soft-LR* in (Keith et al., 2017). This is significant as *H-LSTM* does not employ any hand-crafted features while *soft-LR* needs to resort to complicated hand-designed features to perform well. The best performance is achieved with the *H-LSTM+SynAtt* model with an improvement of 3.3% in the absolute F1 measure over the best model *soft-LR* in (Keith et al., 2017). This testifies to the effectiveness of our proposed model in this work, featuring hierarchical LSTMs, supervised attention and syntactical guidance.

4.4 Analysis

In order to demonstrate the effectiveness of supervised attention and syntactical guidance for police killing detection, this section visualizes the attention weights $\alpha_{i,j,k}$ in Equation 1 for the words in several sentences in the test data.

The Effect of Supervised Attention

Figure 2 indicates the attention weights computed by the models *H-LSTM*, *H-LSTM+SemAtt* and *H-LSTM+SynAtt* for the words in an example sentence. This sentence corresponds to an entity in the test set that is correctly predicted (as being killed by police) by *H-LSTM+SynAtt*, but is incorrectly predicted by *H-LSTM* and *H-LSTM+SemAtt*. As we can see from the figure, *H-LSTM* fails in this case as it reserves a very high weight for the "*TARGET*" and essentially ignores the other words. This phenomenon is quite popular for *H-LSTM* and demonstrates the needs for supervised attention mechanisms as being motivated in the previous sections. In addition, *H-LSTM+SemAtt* cannot use this sentence as an evidence to make a

Models	Precision	Recall	F1	AUC
H-LSTM+SynAtt	0.442	0.288	**0.349**	**0.211**
H-LSTM+SemAtt	0.342	0.325	0.333	0.199
H-LSTM	0.419	0.259	0.320	0.194
soft-LR (EM)	0.447	0.243	0.316	0.193
soft-CNN (EM)	0.268	0.265	0.267	0.164

Table 2: Performance comparison on test data. AUC is the area under the precision/recall curve. The comparison in this table is significant with $p < 0.05$.

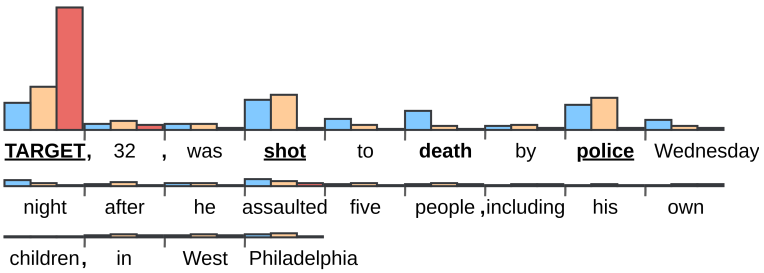

Figure 2: Attention weight visualization. The underlined and bold words are important words selected by *H-LSTM+SemAtt* and *H-LSTM+SynAtt* respectively. The blue, orange and red columns represents the word attention weights computed by *H-LSTM+SynAtt*, *H-LSTM+SemAtt*, and *H-LSTM* respectively. Weights of punctuations are not shown.

correct prediction in this case as it mainly attends to the words in the similar word lists (i.e,"*TARGET*", "*shot*" and "*police*") and misses the word "*death*". This is undesirable as "*death*" is the only clue showing that the victim of the shooting in this sentence is actually dead. *H-LSTM+SynAtt* is successful in this case as it is able to assign high weights to such important words along the dependency paths. This demonstrates our arguments in Section 3, showing the benefits of *H-LSTM+SynAtt* to suggest important words that cannot be captured by *H-LSTM+SemAtt* for police killing recognition.

Semantical vs. Syntactical Guidance

The previous part has shown the advantages of *H-LSTM+SynAtt* over *H-LSTM+SemAtt* for positive entities. This section focuses on the benefits of *H-LSTM+SynAtt* for the negative entities. Figure 3 illustrates the attention weights that *H-LSTM+SemAtt* and *H-LSTM+SynAtt* assign to the words of an example sentence in the test data.

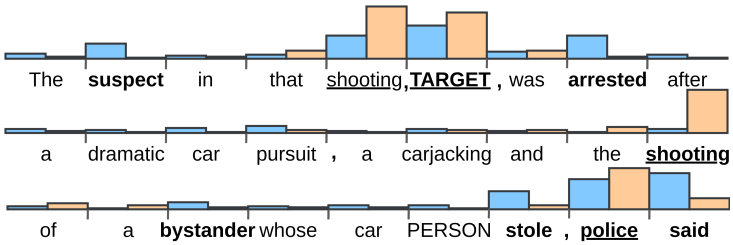

Figure 3: Attention weight visualization. The conventions in Figure 2 do apply here.

The entity of this sentence is negative that has been correctly recognized by *H-LSTM+SynAtt*, but has been incorrectly predicted by *H-LSTM+SemAtt*. As suggested in the figure, the failure of *H-LSTM+SemAtt* is due to its very high weights on "*shooting*", "*TARGET*" and "*police*", ignoring the effect of the words "*said*" and "*arrested*" that clearly negate the involvement of police in this shooting. *H-LSTM+SynAtt* can attend to such important words as they belong to the dependency paths between "*police*" and "*TARGET*" in this case.

5 Conclusions

We propose a novel deep learning model for the problem of police killing recognition. The proposed model involves hierarchical LSTMs to model the multiple sentences in the sentence containers of the entities. We introduce novel supervised attention mechanisms based on semantical and syntactical aspects for this problem. The experimental results demonstrate the effectiveness of the proposed models and lead to the state-of-the-art performance for police killing detection. In the future, we plan to apply the proposed method in a real system and extend it to other types of events (e.g, protests, epidemics).

Open Information Extraction from Conjunctive Sentences

Abstract

We develop CALM, a coordination analyzer that improves upon the conjuncts identified from dependency parses. It uses a language model based scoring and several linguistic constraints to search over hierarchical conjunct boundaries (for nested coordination). By splitting a conjunctive sentence around these conjuncts, CALM outputs several simple sentences. We demonstrate the value of our coordination analyzer in the end task of Open Information Extraction (Open IE).

State-of-the-art Open IE systems lose substantial yield due to ineffective processing of conjunctive sentences. Our Open IE system, CALMIE, performs extraction over the simple sentences identified by CALM to obtain up to 1.8x yield with a moderate increase in precision compared to extractions from original sentences.

1 Introduction

Open Information Extraction (Open IE) (Etzioni et al., 2008) extracts relational tuples from text in an unsupervised domain-independent manner, by identifying relational phrases and arguments from the sentences themselves. Recent work (Saha et al., 2017) has highlighted the lack of proper conjunction processing as the most significant source of missed yield in Open IE. We found Open IE 4.2 (Christensen et al., 2011; Pal and Mausam, 2016) and ClausIE (Corro and Gemulla, 2013) to frequently miss important extractions due to conjunctive relation phrases (see Table 1), and occasionally output conjunctive arguments, which are not ideal for readability or downstream applications (Angeli et al., 2015; Stanovsky et al., 2016a).

Most modern Open IE systems process dependency parses to obtain extractions. However, dependency parsers frequently make errors in resolving coordination ambiguity. Predicting the correct conjunct span is considered to be one of the biggest challenges for parsers (Ficler and Goldberg, 2016). The state of the art approach by Ficler and Goldberg (2016) trains an LSTM-based network for predicting the boundaries for the two conjuncts on either side of the coordinating conjunction, but does not handle cases where a conjunction coordinates more than two conjuncts.

Contributions: We propose a novel coordination analyzer called CALM (**C**oordination **A**nalyzer using **L**anguage **M**odel), which *corrects* the typical errors made by dependency parsers (specifically Clear parser, which is used in Open IE 4.2) using additional features and linguistic constraints. Under the intuition that one can split a conjunction to form multiple coherent simple sentences (see Table 2), CALM scores each simple sentence using a (modified) language model. It additionally employs several linguistic constraints to reduce errors further. An important linguistic constraint is that multiple coordination structures in a sentence must either be disjoint or completely nested. A key contribution of our work is operationalizing this constraint through a novel *hierarchical coordination tree*, which is helpful in sentences with multiple coordinations. Experiments on 577 conjunctive sentences in British News Corpus demonstrate that CALM improves upon the conjuncts from the parser, with significant benefits for sentences with multiple coordinations.

*Most work was done when Swarnadeep Saha was a graduate student at Indian Institute of Technology, Delhi.

Table 2: Simple sentences generated by our system for the conjunctive sentence in Table 1.

We use CALM's output for the goal of improving Open IE. Our system, CALMIE, splits a sentence into multiple simple sentences for each distributive coordination and pass those to two state-of-the-art Open IE systems, Open IE 4.2 and ClausIE. We call them CALMIE(O) and CALMIE(C) respectively. We evaluate on two different datasets and find that CALMIE(O) and CALMIE(C) always outperforms Open IE 4.2 and ClausIE respectively. CALMIE(O) particularly achieves 1.8x the yield with a 5 pt precision gain against Open IE 4.2 on a random sample of 100 conjunctive sentences from ClueWeb. Finally, we compare CALM with Ficler's system. On the subset of cases where a conjunction coordinates more than two conjuncts, our methods significantly outperform Ficler's, on an Open IE evaluation. We release our implementations of CALM, sentence splitter and CALMIE(O)[1] for further research.

2 Related Work

Open Information Extraction: Mausam (2016) surveys the progress in Open IE systems and its downstream applications (e.g., (Christensen et al., 2014; Stanovsky et al., 2015)). Existing Open IE systems are based on manually written patterns (Etzioni et al., 2011; de Sá Mesquita et al., 2013; Angeli et al., 2015), machine-learned patterns over bootstrapped training data (Mausam et al., 2012), sentence restructuring and decomposition (Bast and Haussmann, 2013; Schmidek and Barbosa, 2014), tree kernels (Xu et al., 2013) and simple inference (Bast and Haussmann, 2014). Some systems focus on specific kinds of extractions, e.g., noun-mediated (Pal and Mausam, 2016), numerical (Saha et al., 2017) and nested (Bhutani et al., 2016). We compare our methods to Open IE 4.2 (a combination of SRL-based IE (Christensen et al., 2011) and Relnoun (Pal and Mausam, 2016)) and ClausIE (Corro and Gemulla, 2013) – these outperformed others in a recent large-scale evaluation (Stanovsky and Dagan, 2016). ClausIE can also split some conjunctive clauses, thereby obtaining a higher yield.

There hasn't been any system with a specific focus on conjunctive sentences, which are recently found to be a reason for significant missed recall (Saha et al., 2017). While some of the missed recall is because of conjunctions appearing in arguments of extractions (extraction #6 in Table 1), which can be separated by reducing the argument spans (Stanovsky et al., 2016b), there are also important parts of the sentence which do not produce any extraction from either Open IE 4.2 or ClausIE (extraction #9, #10, #11 in

[1] CALMIE(O) is integrated into OpenIE 5.0, the latest software of OpenIE. It is publicly available at `https://github.com/dair-iitd/OpenIE-standalone`.

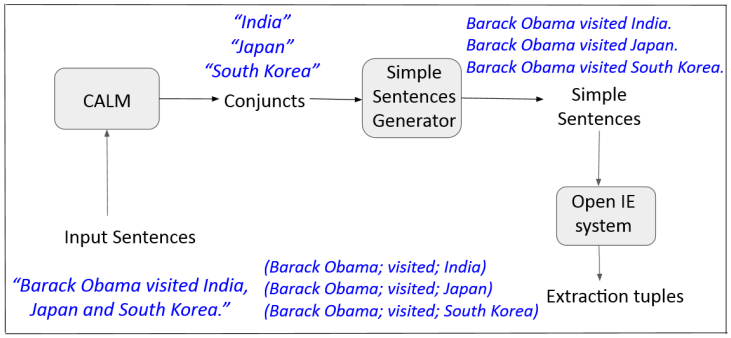

Figure 1: Flow diagram of CALMIE

Table 1), thereby motivating the need to split conjunctive sentences.

Conjunct Boundary Detection: Although co-ordination disambiguation has attracted attention of researchers over the years, it still remains one of the hardest problems to solve. Prior work has used two main principles for resolving ambiguities – (1) coordinated conjuncts have similar syntactic structures (Hogan, 2007; Shimbo and Hara, 2007; Hara et al., 2009; Hanamoto et al., 2012) and (2) replacing a full coordinated phrase with just one conjunct produces coherent (simple) sentences (Ficler and Goldberg, 2016).

The state-of-the-art coordination analyzer is by Ficler and Goldberg (2016), which uses LSTM-based components for operationalizing both these principles. It is a machine-learned model, which requires explicit annotation of coordination phrases for training (which isn't available in original Penn TreeBank). Importantly, it only outputs spans for the two conjuncts on either side of the conjunctive word and ignores any other conjuncts coordinated by the same word. Sentences often have a long list of comma separated conjuncts and not separating all of them would mean a substantial performance loss for end-tasks like Open IE.

In contrast, our approach eschews the first principle, as we find that it is not true often enough to be helpful. Our ranking of conjunct spans is based on the second principle (coherence of simple sentences). However, the search space is additionally restricted by various linguistic constraints for both single and nested coordination cases. Our system operates on top of Clear dependency parses (as opposed to constituency parses for Ficler's) and does not need any task-specific training data.

Sentence Simplification: CALM-based sentence splitting can be seen as a form of sentence simplification. Existing works on sentence simplification (Zhu et al., 2010; Vickrey and Koller, 2008; Vanderwende et al., 2007; Miwa et al., 2010) operate on top of syntactic parses, assuming them to be correct. CALM, on the other hand, corrects typical errors made by the parser to output corrected conjunction spans. These spans should naturally improve any sentence simplification task as well.

3 CALMIE

Figure 1 illustrates various steps of CALMIE. First, CALM identifies specific conjuncts to split the sentence into multiple simple sentences. Then an Open IE system acts on simple sentences to generate extractions. In this section we first focus on our key technical contribution, the coordination analyzer named CALM and conclude with a discussion on the generation of simple sentences.

3.1 CALM

CALM's goal is to output all *conjunct lists* from a sentence. For e.g., for sentence of Table 1, it should likely output five lists: (1) ⟨*'an American investor', 'co-founder of Microsoft'*⟩, (2) ⟨*'stepped down...2000', 'remained as...Craig Mundie'*⟩, (3) ⟨*'remained as chairman', 'created...Mundie'*⟩, (4) ⟨*'created...himself', 'transferred his...Mundie'*⟩, (5) ⟨*'Ray Ozzie', 'Craig Mundie'*⟩.[2]

[2]The conjunct lists #2, #3, #4 can change depending on the nesting level of the corresponding conjunctions.

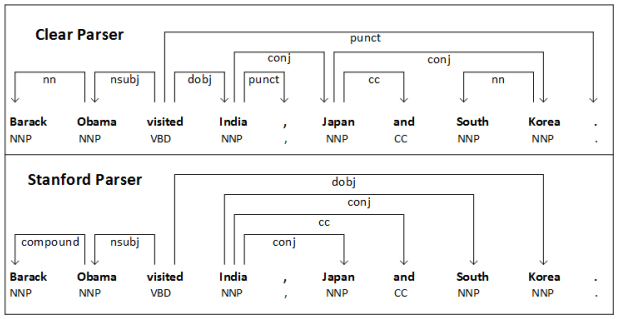

Figure 2: Clear and Stanford parses of a sample sentence

1. Generate the dependency parse of the sentence.
2. Find one of the conjunct heads through *'cc'* edge.
3. Find all other conjunct heads through *'conj'* edges.
4. Expand the conjunct heads to generate the conjuncts.

Table 3: Algorithm for Parser Baseline

We describe CALM's algorithm in two subsections. First, we describe CALM for a sentence that has only one coordinating conjunction (e.g., sentence of Figure 1). The case of multiple conjunctions, which may be nested (as in Table 1), is discussed in the latter subsection.

3.1.1 Single Coordinating Conjunction

We create a rule-based baseline to convert a dependency parse into a conjunct list (pseudo-code in Table 3). It finds various conjunct heads via *cc* and *conj* edges and expands the heads to generate conjunct spans. In the last step of the algorithm, while expanding on the conjunct heads, we don't expand on commas, the corresponding conjunction (*'and'*, *'but'*, etc) or any of the other conjunct heads.

We implement the baseline over Stanford[3] and Clear[4] parsers. Figure 2 shows that these dependency parsers have slightly different styles of notating conjuncts – Clear connects conjunct heads serially, whereas in Stanford parses one central conjunct heads connects to all others. Preliminary experiments reveal that Stanford parser makes many more mistakes than Clear. So we choose Clear parser for further algorithm design.

Analysis of Clear Parser-based Baseline Algorithm: Clear Parser identifies the conjunct heads correctly in most cases, but often makes mistakes in conjunct spans. We analyze a sample of 100 conjunctive sentences from BNC[5]. We find that 32 of them have correct parses with correctly identified conjuncts. Most correctly identified conjuncts are noun phrases (NP) while most incorrect ones involve verb phrases (VP). For e.g., in the sentence *"It also helps draw out toxins and excess oils."*, the NP conjuncts *'toxins'* and *'excess oils'* are identified correctly.

Our analysis also reveals that almost all wrong conjunct boundaries happen at the first and the last conjunct in the list, where the start of the first conjunct or the end of the last conjunct are identified incorrectly. Of the 68 incorrect parses, 57 of them have the first and last conjunct longer than necessary, suggesting that we can focus on shortening the first and last conjuncts. Further, out of these 57 sentences, 23 have a common NP subject distributed over multiple VPs and are wrongly represented in the parse. For e.g., in the sentence *"Angels danced in the air and settled reverently into their alcoves."*, the NP *'Angels'* incorrectly comes in the subtree of the VP *'danced in the air'*, leading to the generation of two conjuncts - *'Angels danced in the air'* and *'settled reverently into their alcoves'*. Most of the remaining 34 sentences also contain a phrase that is distributed over two VPs, but appears in the subtree of only one. For e.g., in the sentence *"He rejoices at the fact that they started off with smalltown views , and began thinking globally."*, the phrase *"that they"* appear in the subtree of *"started"*. Note that the conjuncts again are VPs. Finally, incorrect conjunct boundaries almost always result in the generation of ungrammatical simple sentences.

We design CALM on the basis of these observations – it shortens the first and last conjunct spans in a way that the resulting simple sentences are coherent, as evaluated by a language model.

Language-Model Based Algorithm: CALM needs to find the best start of the first conjunct and best end

	Example 1	Example 2
Sentence	She gasped as he reached out and clasped her shoulders.	Still dazed, the man eventually got himself home and called police.
Parser Baseline (Clear Parser)	1. She gasped as he reached out. 2. She gasped clasped her shoulders.	1. Still dazed, the man eventually got himself home. 2. called police.
+ Language Model	1. She gasped as he reached out. 2. She gasped **as he** clasped her shoulders.	1. Still dazed, the man eventually got himself home. 2. called police.
+ Constraints	1. She gasped as he reached out. 2. She gasped **as he** clasped her shoulders.	1. Still dazed, the man eventually got himself home. 2. **Still dazed, the man eventually** called police.

Table 4: Comparison of sentences generated using different algorithms on two conjunctive sentences.

of the last conjunct. It first generates candidates by successively shortening conjuncts from the respective ends, until a conjunct is shortened to a single word. For e.g., for the first conjunct in *"Angels..reverently"* sentence, the candidates are *'Angels danced in the air', 'danced in the air', 'in the air', 'the air'* and *'air'*.

For each candidate, it constructs simple sentences by replacing the complete coordination structure with each of its conjuncts. It scores the coherence of each simple sentence via LMScore, a language model based score, described below. It picks the best span based on maximizing the total LMScore (over all simple sentences).

To score the coherence of a simple sentence, we could simply use its language model probability – product of probabilities of each word given the entire sentence so far. Most language models approximate this via an n-gram probability for a *fixed* context window of length $n-1$, instead of taking the *entire* sentence so far.

However, using the language model score is ineffective for two reasons. First, we are comparing simple sentences of varying lengths, and language model scores will usually score shorter sentences higher (product of fewer probabilities). A possible correction is to take the $|s|^{th}$ root of the language model score, with $|s|$ being the sentence length. But, this isn't enough for a second, subtle reason.

Consider the incorrect span *'the air'* for the first conjunct, which results in the simple sentence *"Angels danced in settled reverently into their alcoves"*. Notice that the n-gram probability scores will typically assign high probabilities for the parts: *'Angels danced in'* and *'settled reverently into their alcoves'*, since they are bona fide parts of the original sentence. Only the part around the boundary (*'...in settled...'*) would hurt the grammaticality. However, taking the product over the *whole* simple sentence has the tendency that the probabilities around the intersection could get overpowered by high scores from the initial and ending parts of the sentence, yielding an overall high score for an ungrammatical sentence.

To correct for this, CALM only multiplies probabilities starting from the intersection point and upto n–1 words (and takes n–1$^{\text{th}}$ root). All omitted probabilities are simply the product of original sentence fragments and thus are unhelpful in disambiguating the boundary. E.g., for $n = 4$ our method LMScore computes the following product:

LMScore(*"Angels danced in settled...alcoves."*)
= [P(*'settled'* | *'Angels danced in'*)
× P(*'reverently'* | *'dance in settled'*)
× P(*'into'* | *'in settled reverently'*)]$^{1/3}$

In case k ($k < n$–1) probabilities are multiplied (for e.g., if a conjunct is too short), then CALM takes k^{th} root of the product.

Use of Linguistic Constraints: Although LMScore corrects many of the wrongly identified conjuncts, we observe some limitations too. In sentences with proper nouns, the n-gram probabilities are low and significantly decrease the overall score of the sentence. Sentences with multi-word named entities also should not be split. For e.g., in the sentence *"Donald Trump gave a speech and flew back to U.S.."*, the simple sentence *"Donald flew back to U.S.."* is grammatical yet undesirable – named entity *'Donald Trump'* should not be split. We further see some obvious grammatical errors in the generated sentences, with two linguistically incoherent adjacent verbs or a preposition *'to'* preceding a past tense verb in the generated sentences.

To correct such errors, CALM picks the candidate that has the highest LMScore without violating any of the following linguistic constraints:

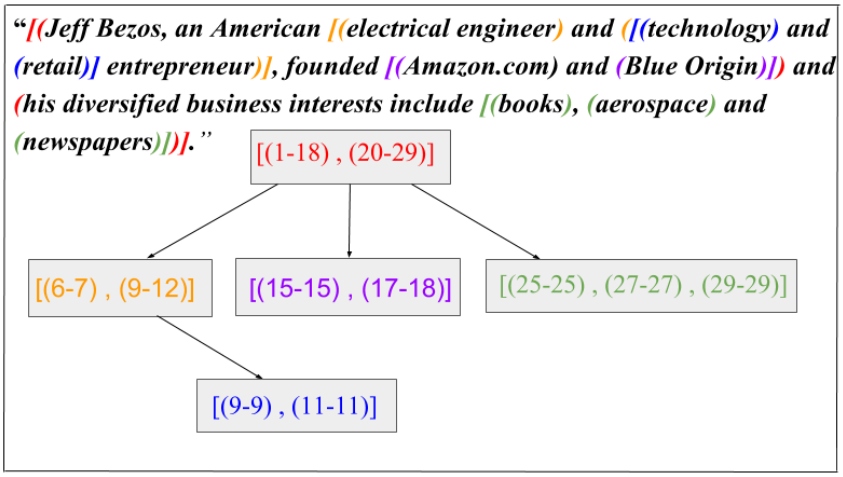

Figure 3: Hierarchical conjunct tree representation of a sentence with multiple conjunctions

1. Each simple sentence must have a subject. CALM looks for *nsubj* and *nsubjpass* dependency labels in the parse tree.
2. Named Entities (as identified by Stanford NER system[6]) should not be split.
3. If two verbs are adjacent, the first must be a light verb[7]. It handles ungrammatical sentences containing two adjacent incoherent verbs. For e.g., *"lives listening (to music)"* is nonsensical, but *"likes listening (to music)"* is not since *'like'* is a light verb.
4. A simple sentence should not have two consecutive occurrences of the same word.
5. Verb categories *VBD*, *VBZ* and *VBP* must precede a set of predefined POS tags[8]. English rarely allows a preposition, determiner or other such POS tags before the past/participle forms of a verb. However, language models do not always devalue these sentences. This constraint helps eliminate candidates that lead to such simple sentences.

3.1.2 Multiple Coordinating Conjunctions

When a sentence has multiple coordinating conjunctions, CALM identifies all coordination structures, i.e., the conjunct lists associated with each conjunction. Following English grammar, two coordination structures may have nothing in common (disjoint) or one conjunct list may be contained within the span of one of the conjuncts of another list (nested). For example, in sentence of Figure 3, the conjunct lists marked in yellow ({*'electrical engineer', 'technology and retail entrepreneur'*}) and green ({*'books', 'aerospace', 'newspapers'* }) are disjoint, while the one marked in blue ({*'technology', 'retail'*}) is nested within the second conjunct of yellow conjunct list.

Partial intersections, where one conjunct list is only partially contained in a conjunct of another list, are ungrammatical. CALM uses this knowledge as a search space constraint to jointly disambiguate all coordination structures in a sentence. We name this the *multiple conjunction constraint*. To operationalize this, we define a novel representation, *hierarchical coordination tree* (HCTree), for expressing the compositional containment between coordination structures.

An HCTree is a tree with each node representing a conjunct list for a single coordination structure, stored as a sequence of interval offsets. An edge from node A to B represents that B is fully contained within one of the conjuncts of A (nested case). Figure 3 illustrates an HCTree: *'electrical engineer'* is stored as interval 6-7, as it comprises sixth and seventh tokens in the sentence.

The number of legal HCTrees for a multiple conjunction sentence could be huge and a complete search over all tree structures and spans will be prohibitive. However, we reduce the search space by not performing a full search, as Clear parser usually returns a structurally accurate analysis, but, as before, makes errors in exact boundaries.

Use of Multiple Conjunction Constraint: CALM constructs an initial HCTree by converting the Clear parse into conjunct lists (using parser baseline), adding a node per conjunct list, and adding edges as per

[6] `https://nlp.stanford.edu/software/CRF-NER.shtml`
[7] We use the list of light verbs released by (Jain and Mausam, 2016) at `https://github.com/dair-iitd/kglr`.
[8] CC, CD, EX, NN, NNS, NNP, NNPS, PDT, PRP, RB, RBR, RBS, WDT, WP

containments in the parse. This provides us with a good structure for enforcing the multiple conjunction constraint. CALM keeps the HCTree structure constant, and re-evaluates the exact conjunct boundaries for each node in the tree.

In addition to providing a structure over all conjunct lists, an HCTree also imposes a natural order in which we could correct span errors. Typically, smaller conjuncts are easier to correct than longer ones. So, CALM makes a bottom up pass greedily correcting spans for the conjunct list in each node. As in previous subsection, a conjunct is only shortened. Moreover only start of first conjunct and end of last conjunct in a list are re-evaluated using the single-conjunction version of CALM.

Notice that shortening of a child conjunct doesn't hurt the consistency of an HCTree, since if a conjunct list was contained in a parent conjunct, then the shortened conjunct list is also contained in the same parent conjunct. However, the boundaries of child conjunct list impose an additional constraint on the candidate spans of the parent conjunct list – while shortening the parent conjunct, all child conjuncts must continue to be contained in it. Thus, when applying CALM at the parent node, this additional search constraint is imposed to maintain a valid HCTree.

3.2 Simple Sentences for Open IE

Once the spans of conjunct lists have been determined, the next task is to generate the simple sentences. Our Open IE system, CALMIE generates them in a top-down order of the HCTree. It starts with the original sentence. Now, at each level of the tree, it collects all the conjunct lists and generates all possible sentences out of the sentences generated from the previous level. Since at a particular level of the tree all conjunct lists are disjoint, generating simple sentences requires simply identifying parts of the sentence that do not belong to any conjunct list and concatenating them in order with a conjunct for each coordination structure. Note that it avoids generation of duplicate sentences by identifying which conjunct lists at a particular level are part of which simple sentences from the previous level and finally splitting only those. After processing the conjunct lists at the last level of the HCTree, we get all the simple sentences.

For Open IE, we wish to only produce those simple sentences, whose truth can be inferred from the original sentence. CALMIE doesn't split conjuncts coordinated by *'or'*, *'nor'*, and paired conjunctions like *'either-or'* and *'neither-nor'*. For e.g. splitting *"Adam's nationality is French or German."* will be inaccurate.

One common class of non-distributive coordination that cannot be split contains prepositions like *'between'* in connecting the conjuncts. For e.g. the sentence *"The world cup final was played between Germany and Argentina."* should not be split. Other examples aggregate information across conjuncts as in the sentence, *"The average of 3 and 5 is 4."* Thus, we create a list of triggers (*'between', 'among', 'total', 'sum', 'average','each other', ...*) using Thesaurus expansion of seed words which indicate non-distributive coordination . If the arguments of Open IE extractions on the original sentence contain any of the triggers, CALMIE does not split these conjuncts.

4 Experiments

We perform two sets of experiments. Section 4.1 evaluates CALM for coordination analysis task, and Section 4.2 demonstrates the performance increase, when using CALMIE for Open IE.

CALM's implementation uses the Berkeley Language Model,[9] which is based on the Google n-gram corpus. It uses Stupid Back-off smoothing (Brants et al., 2007) for infrequent n-grams. CALMIE runs Open IE 4.2 and ClausIE over the simple sentences generated in the previous section.

4.1 Experiments on Coordination Analysis

Previous work has given credit to a system only when both boundaries of a conjunct match exactly (Ficler and Goldberg, 2016). However, this is not ideal for downstream tasks like Open IE. Consider a sentence with polysyndetic coordination: *"Obama visited India and Japan and South Korea."*. Here, two analyses are equally good, depending upon whether we consider first conjunction as top-level or second, leading

Table 5: Results for simple sentence evaluation on British News Corpus. CALM obtains about 2 pt F-score improvement over Clear parser baseline. SC: Sentences with one conjunction, MC: Sentences with multiple conjunctions.

	(Ficler and Goldberg, 2016)	CALM
Precision	72.81	**75.12**
Recall	**72.61**	70.64
F1	72.7	**72.81**

Table 6: Results for conjunct boundary detection on Penn Treebank. CALM is competitive with state of the art.

to first conjunct being *'India'* or *'India and Japan'*, respectively. Such artifacts commonly happen when there are multiple conjunctions in a sentence, such as in Table 1.

In response, we evaluate a coordination analysis by generating the simple sentences and comparing them against the gold set of simple sentences. We split all coordinations (whether they are distributive or not) for this evaluation. For each conjunctive sentence, we compare its set of system-generated simple sentences with a gold set by first finding the best one-to-one mapping between the simple sentences in the two sets. Then for each mapping, precision is computed as the number of overlapping words upon the number of words in the predicted sentence. Recall is the number of overlapping words upon the number of words in the gold sentence. Notice that for the sentence above, all (correct) alternative analyses will yield the same simple sentences, obtaining perfect precision and recall scores.

We run our first set of experiments on all conjunctive sentences from British News Corpus test set.[10] It contains the gold parses for all sentences, which are used to generate the gold simple sentences. BNC testset has 577 conjunctive sentences – 391 with one conjunction and 186 with multiple conjunctions.

Table 5 compares the performances of all our algorithms on the whole BNC testset, and also individually on single and multiple conjunction sentences. We find that due to better conjunct heads identification, Clear parser does a much better job than Stanford parser in identifying conjunct boundaries. We get a point of F-score improvement by using language model over Clear parser baseline. Incorporating linguistic constraints yields another two-thirds of a point. More importantly, CALM obtains nearly 3.2 pt gain for sentences with multiple conjunctions; this highlights the value of our HCTree representation. Overall improvement of CALM over Clear baseline for the whole BNC is statistically significant using paired t-test with $p = 0.015$.

For sentences with a single conjunction, there is a slight drop in the final precision as compared to the parser baseline algorithm. Since we are only shortening the conjuncts, an already incorrect analysis can end up having even lesser number of common words with the gold sentence, reducing the precision. While the final precision is comparable, the recall improves significantly. This can be explained by examples in Table 4. E.g., in the second example, parser baseline has perfect precision, but low recall, due to missing words in the second simple sentence (*"called police"*). CALM corrects this by adding words in the sentence, increasing the recall to 1.0.

Comparison with Ficler's System: We also directly compare against Ficler's system on *their* dataset (Penn TreeBank). Recall that their evaluation metric is exact match of conjunct boundaries but only for the two conjuncts closest to the conjunction. We use their exact metric (Table 6) and find that CALM has slightly different characteristics – it has a higher precision and a lower recall; but, in aggregate it produces a similar F-score. Given that CALM is not trained directly (except for underlying parsers), we find it creditable that it can match performance of the state of the art system that was specifically trained on this data for this task. Unfortunately, their code isn't available for us to compare performance on BNC.

	Two Conjuncts		More than Two Conjuncts	
	[FG]	**[Cm[O]]**	**[FG]**	**[Cm[O]]**
Precision	**72.71**	72.35	74.50	**74.78**
Yield	323	**330**	346	**445**

Table 8: Open IE comparison on Penn TreeBank. [FG]: Ficler+Open IE 4.2, [Cm[O]]: CALMIE(O).

Error Analysis: CALM sometimes misses conjunctions in sentences due to the inaccuracy of parsers (absence of a 'cc' edge). A more common problem is that of missing contexts in sentences while splitting. E.g., from the sentence *"Two years ago we were carrying huge inventories and that was the big culprit ."*, CALM generates two simple sentences: *"Two years ago we were carrying huge inventories."* and *"that was the big culprit."*. Although the sentences are grammatically correct, we miss the phrase *"Two years ago"* in the second sentence. While this is a missing prefix problem, CALM often tends to miss important phrases in the suffix as well. E.g., for the sentence *"We want to see Nelson Mandela and all our comrades out of the prison."*, it misses the suffix phrase *"out of the prison"*. We believe fixing such problems will require better understanding of the semantics of the sentence.

4.2 Experiments on Open IE

We now evaluate the improvement in performance on the final task of Open IE using conjunctive sentences from three different datasets. We randomly sample 100 conjunctive sentences each from ClueWeb12 (CW)[11] and Open IE benchmarking dataset (NW) of Newswire and Wikipedia sentences (Stanovsky and Dagan, 2016). We consider a sentence conjunctive if its parse has a *cc* edge. Note that we could not use the whole of NW dataset since its gold set of extractions does not split conjunctions in arguments.

We also test on Penn Treebank (PTB) testset used for coordination evaluation in (Ficler and Goldberg, 2016). We report two sets of numbers from the dataset – for a random sample of 100 sentences with two conjuncts per conjunction, and all of 95 conjunctive sentences with more than 2 conjuncts per conjunction.

For CW and NW, we compare CALMIE(C) (CALM generated simple sentences passed through ClausIE) and CALMIE(O) (CALM generated simple sentences passed through Open IE 4.2) against two state-of-the-art Open IE systems, ClausIE and Open IE 4.2. These Open IE systems outperform others in a recent large-scale evaluation. Moreover, ClausIE also splits some conjunctive clauses, making it an especially suitable system for this comparison. As there is no automated way to check the correctness of an extraction, two annotators with NLP experience annotate the extractions for correctness. Each annotator annotated about 6000 extractions in total. We obtain an inter-annotator agreement of 97.2% across all the datasets and report the results on the subset where both agree. Table 7 lists the precision and yield on these test sets. Note that yield is equal to the number of correct extractions and is proportional to recall. It is normally used in Open IE where recall denominator is hard to compute.

On CW, CALMIE(C) and CALMIE(O) obtain 1.4x and 1.8x yields compared to ClausIE and Open IE 4.2 respectively. The respective precision gains are 2 and 5 points. On NW, CALMIE(C) and CALMIE(O) achieve 1.6x and 1.8x better yields with marginal precision gains compared to ClausIE and Open IE 4.2 respectively. All the improvements are statistically significant using paired t-test at $p < 10^{-4}$. We find that both Open IE 4.2 and ClausIE are unable to separate out extractions if the conjunctions are in the arguments. This largely accounts for CALMIE's massive yield improvement. Overall, we see substantial improvement in extractions of both Open IE 4.2 and ClausIE after the application of CALM.

Finally, we split the sentences in PTB sample into simple sentences using CALM and Ficler. Both sets of simple sentences are then fed to Open IE 4.2 for generating extractions, i.e., the pipeline after

[11] http://www.lemurproject.org/clueweb12.php

coordination analysis is the same. Table 8 shows that on sentences with two conjuncts per conjunction, the two sets of extractions are comparable. However, on 95 sentences with more than two conjuncts per conjunction, CALMIE(O) achieves 1.3x better yield than Ficler. This is due to Ficler's inability to separate out all the conjuncts.

Error Analysis: The single major challenge in Open IE over conjunctive sentences is in figuring out when not to split. For example, in *"Japan's domestic sales of cars, trucks and buses in October rose by 18%."*, no obvious trigger is present that can indicate non-distributive coordination. Another common class is organization names with *'and'* as part of their names. For e.g., in sentence *"The Perch and Dolphin fields moved their headquarters."*, *'Perch and Dolphin'* should not be split. Use of LEX system could help with better NER tagging (Downey et al., 2007). Finally, non-context free constructions need to be handled differently while splitting as in, *"Germany and Argentina beat Brazil and Netherlands in the semis respectively."* We believe that this remains one of the key future directions for improving the precision of our system.

5 Conclusions and Discussion

Coordination disambiguity is regarded as one of the hardest problems in NLP (Ficler and Goldberg, 2016). We develop CALM, a coordination analyzer that corrects the errors of Clear parser by using three insights: (1) splitting into coherent simple sentences, as judged by a modified language model score, (2) linguistically inspired constraints to obtain better conjunct spans, and (3) a novel hierarchical coordination tree data structure that enforces consistency among conjunct lists for multiple coordinations, leading to performance gain.

We split distributive coordinations to obtain simple sentences for running downstream Open IE. Our Open IE system, CALMIE, obtains enormously higher yields (upto 1.8 times) and comparable or better precisions for conjunctive sentences against state of the art Open IE systems. Empirical evaluation across multiple datasets demonstrate than CALM should likely improve any Open IE system. We also believe that CALM has value outside of Open IE, such as for Closed IE and sentence simplification.

CALM's insights are general, but its implementation is specific to Clear parser, which is used in Open IE 4.2. Minor modifications may be needed when correcting coordination errors in other parsers. In the future, we plan to use CALM to improve Clear parser itself.

A strength (and also weakness) of our work is that it is not an ML system. While we test CALM on several domains, it is conceivable that for some domains or genres, it does not perform as well. Embedding our ideas in the context of a learning system may obtain even better in-domain performance. One approach is to use CALM output as (hard or soft) constraint at inference time, similar to how CCMs use constraints while learning parameters. We also note that our main idea of splitting into simple sentences, may not always work, e.g., in the case of ellipsis and gaping. Such sentences are infrequent in our datasets; extending to these is another direction for the future.

We release Open IE 5.0 which integrates CALMIE(O) into the latest software of OpenIE. We also release the annotated datasets used for evaluating CALMIE(O) and the implementations of CALM and the sentence splitter which can be used for splitting conjunctive sentences in various downstream NLP tasks. All of these are publicly available for further research at `https://github.com/dair-iitd/OpenIE-standalone`.

Abstract

We present an Open Information Extraction (IE) approach that uses a two-layered transformation stage consisting of a clausal disembedding layer and a phrasal disembedding layer, together with rhetorical relation identification. In that way, we convert sentences that present a complex linguistic structure into simplified, syntactically sound sentences, from which we can extract propositions that are represented in a two-layered hierarchy in the form of *core relational tuples and accompanying contextual information* which are *semantically linked via rhetorical relations*. In a comparative evaluation, we demonstrate that our reference implementation Graphene outperforms state-of-the-art Open IE systems in the construction of correct n-ary predicate-argument structures. Moreover, we show that existing Open IE approaches can benefit from the transformation process of our framework.

1 Introduction

Information extraction (IE) turns the unstructured information expressed in natural language (NL) text into a structured representation (Jurafsky and Martin, 2009) in the form of relational tuples that consist of a set of arguments and a phrase denoting a semantic relation between them, e.g. ⟨*Barack Obama*; *served as*; *the 44th President of the US*⟩. Traditional IE systems have concentrated on identifying and extracting relations of interest by taking as input the target relations, along with hand-crafted extraction patterns or patterns learned from hand-labeled training examples. As this manual labor scales linearly with the number of target relations, such a supervised approach does not scale to large, heterogeneous corpora which are likely to contain a variety of unanticipated relations. To tackle this issue, Banko et al. (2007) introduced Open IE as a new extraction paradigm that allows for a domain-independent discovery of relations in large amounts of text by not depending on any relation-specific human input. Instead, detecting the relations is part of the problem. State-of-the-art Open IE systems (see Section 2) identify relationships between entities in a sentence by matching patterns over either shallow syntactic features in terms of part-of-speech (POS) tags and noun phrase (NP) chunks or dependency tree structures. However, particularly long and syntactically complex sentences pose a challenge for current Open IE approaches. By analyzing the output of such systems (see Figure 1), we observed three common shortcomings.

First, relations often span over long nested structures or are presented in a non-canonical form that cannot be easily captured by a small set of extraction patterns. Therefore, such relations are commonly missed by state-of-the-art approaches. Consider for example the first sentence in Figure 1 which asserts that ⟨*Sonia Sotomayor*; *became*; *the first Supreme Court Justice of Hispanic descent*⟩. This information is encoded in a complex participial construction that is omitted by both reference Open IE systems, OLLIE (Mausam et al., 2012) and ClausIE (Del Corro and Gemulla, 2013).

Second, current Open IE systems tend to extract propositions with long argument phrases that can be further decomposed into meaningful propositions, with each of them representing a separate fact. Overly specific constituents that mix multiple - potentially semantically unrelated - propositions are difficult

Figure 1: Comparison of the output generated by different state-of-the-art Open IE systems. Contextual arguments of Graphene are differentiated between simple textual arguments (S:) or arguments that link to other propositions (L:). Both contextual types are semantically classified by rhetorical relations.

to handle for downstream applications, such as question answering (QA) or textual entailment tasks. Instead, such approaches benefit from extractions that are as compact as possible. This phenomenon can be witnessed particularly well in the extractions generated by ClausIE ((8-10) and (16-21)), whose argument phrases frequently combine several semantically independent statements. For instance, the argument in proposition (8) contains three unrelated facts, namely a direct object ⟨*Sonia Sotomayor*⟩, a temporal expression ⟨*on May 26 2009*⟩ and a phrasal description ⟨*to replace David Souter*⟩ specifying the purpose of the assertion on which it depends.

Third, they lack the expressiveness needed to properly represent complex assertions, resulting in incomplete, uninformative or incoherent propositions that have no meaningful interpretation or miss critical information asserted in the input sentence. Most state-of-the-art systems focus on extracting binary relationships without preserving the semantic connection between the individual propositions. This can be seen in the second example in Figure 1. Here, the proposition ⟨*Congress and President Bush*; *fail to increase*; *the Treasury's borrowing capacity*⟩ is not asserted by the input sentence, but rather represents the precondition for the predication that ⟨*the funding*; *will be delayed*; ∅⟩. However, both state-of-the-art Open IE systems fail to accurately reflect this contextual information in the extracted relational tuples. While OLLIE completely ignores above-mentioned inter-proposition relationship in its

extractions, ClausIE incorporates this information in its argument phrases ((18) and (19)), yet producing over-specified components that is likely to hurt the performance of downstream semantic applications.

To overcome these limitations, we developed an Open IE framework that transforms complex NL sentences into clean, compact structures that present a canonical form which facilitates the extraction of accurate, meaningful and complete propositions. The contributions of our work are two-fold. First, to remove the complexity of determining intricate predicate-argument structures with variable arity from syntactically complex input sentences, we propose a two-layered transformation process consisting of a clausal and phrasal disembedding layer. It removes clauses and phrases that convey no central information from the input and converts them into independent sentences, thereby reducing the source sentence to its main information. In that way, the input is transformed into a **novel hierarchical representation in the form of core facts and accompanying contexts**. Second, we **identify the rhetorical relations by which core sentences and their associated contexts are connected in order to preserve their semantic relationship** (see the output of our reference Open IE implementation Graphene in Figure 1). These two innovations enable us to enrich extracted relational tuples of the form $\langle arg_1, rel, arg_2 \rangle$ with contextual information that further specifies the tuple and to establish semantic links between them, allowing to fully reconstruct the informational content of the input. The resulting representation of the source text can then be used to facilitate a variety of artificial intelligence tasks, such as building QA systems or supporting semantic inferences. The idea of generating a syntactically sound representation from linguistically complex NL sentences can be easily transported to other tasks than Open IE, e.g. it might be helpful for problems such as sentiment analysis, coreference resolution or text summarization.

2 Related Work

Learning-based approaches. The line of work on Open IE begins with TEXTRUNNER (Banko et al., 2007), a self-supervised learning approach which uses a Naive Bayes classifier to train a model of relations over examples of extraction tuples that are heuristically generated from sentences in the Penn Treebank using unlexicalized POS and NP chunk features. The system then applies the learned extractor to label each word between a candidate pair of NP arguments as part of a relation phrase or not. WOE (Wu and Weld, 2010) also learns an open information extractor without direct supervision. It makes use of Wikipedia as a source of training data by bootstrapping from entries in Wikipedia infoboxes to learn extraction patterns on both POS tags (WOE^{pos}) and dependency parses (WOE^{parse}). By comparing their two approaches, Wu and Weld (2010) show that the use of dependency features results in an increase in precision and recall over shallow linguistic features (though, at the cost of extraction speed). OLLIE follows the idea of bootstrap learning of patterns based on dependency parse paths. However, while WOE relies on Wikipedia-based bootstrapping, OLLIE applies a set of high precision seed tuples from its predecessor system REVERB to bootstrap a large training set. Moreover, OLLIE is the first Open IE approach to identify not only verb-based relations, but also noun-mediated ones.

Rule-based approaches. The second category of Open IE systems make use of hand-crafted extraction rules. This includes REVERB (Fader et al., 2011), a shallow extractor that applies a set of lexical and syntactic constraints that are expressed in terms of POS-based regular expressions. In that way, the amount of incoherent, uninformative and overspecified relation phrases is reduced. While previously mentioned Open IE systems focus on the extraction of binary relations, KRAKEN (Akbik and Löser, 2012) is the first approach to be specifically built for capturing complete facts from sentences by gathering the full set of arguments for each relation phrase within a sentence, thus producing tuples of arbitrary arity. The identification of relation phrases and their corresponding arguments is based on hand-written extraction rules over typed dependency information. EXEMPLAR (Mesquita et al., 2013) applies a similar approach for extracting n-ary relations, as it uses hand-crafted patterns based on dependency parse trees to detect a relation trigger and the arguments connected to it.

Clause-based approaches. Aiming to improve the accuracy of Open IE approaches, more recent work is based on the idea of incorporating a sentence re-structuring stage whose goal is to transform the original sentence into a set of independent clauses that are easy to segment into Open IE tuples. An

example of such a paraphrase-based Open IE approach is ClausIE, which exploits linguistic knowledge about the grammar of the English language to map the dependency relations of an input sentence to clause constituents. In that way, a set of coherent clauses presenting a simple linguistic structure is derived from the input. Then, one or more predicate-argument extractions are generated for each clause. In the same vein, Schmidek and Barbosa (2014) propose a strategy to break down structurally complex sentences into simpler ones by decomposing the original sentence into its basic building blocks via chunking. The dependencies of each two chunks are then determined using dependency parsing or a Naive Bayes classifier. Depending on their relationships, chunks are combined into simplified sentences, upon which the task of relation extraction is carried out. Angeli et al. (2015) present Stanford Open IE, an approach in which a classifier is learned for splitting a sentence into a set of logically entailed shorter utterances which are then maximally shortened by running natural logic inference over them. In the end, a small set of hand-crafted patterns are used to extract a predicate-argument triple from each utterance.

On the basis of such re-arrangement strategies for decomposing a complex input sentence into a set of self-contained clauses that present a linguistic structure that is easier to process for Open IE systems, we have developed an Open IE pipeline which will be presented in the following section.

3 Proposed Open IE Approach

We propose a method for facilitating the task of Open IE on sentences that present a complex linguistic structure. It is based on the idea of disembedding clausal and phrasal constituents out of a source sentence. In doing so, our approach identifies and retains the semantic connections between the individual components, thus generating a novel lightweight semantic Open IE representation.

We build upon the concept presented in Niklaus et al. (2016), who distinguish between core and contextual information in the context of sentence simplification. This is done by disembedding and transforming supplementary material expressed in phrases (e.g. spatial or temporal information) into standalone context sentences, thus reducing the input sentences to their key information (core sentences). In our work, we now port this idea to a broader scope by targeting clausal disembedding techniques for complex, nested structures. Furthermore, by converting the whole simplification process into a recursive process, we are able to generate a hierarchical representation of syntactically simplified core and contextual sentences (see center image of Figure 2). Moreover, this allows us to detect both local and long-range rhetorical dependencies that hold between nested structures, similar to Rhetorical Structure Theory (RST) (Mann and Thompson, 1988). As a consequence, when carrying out the task of Open IE on the compressed core sentences, the complexity of determining intricate predicate-argument structures is removed and the extracted propositions can be semantically linked and enriched with the disembedded contextual information. Our proposed framework uses a two-layered transformation stage for recursive sentence simplification that is followed by a final relation extraction stage. It takes a text document as an input and returns a set of hierarchically ordered and semantically interconnected relational tuples (see the output of Graphene in Figure 1). The workflow of our approach is displayed in Figure 2.

3.1 Transformation Stage

The core component of our work is the two-layered transformation stage where sentences that present a complex linguistic form are recursively transformed into simpler, compact, syntactically sound sentences with accompanying contextual information.

3.1.1 Concept of the Discourse Tree Creation

During the transformation process, we aim to identify intra-sentential semantic relationships which can later be used to restore semantic relations between extracted propositions. To capture these semantic relations, we employ a concept of RST, in which a document is represented as a hierarchy of consecutive, non-overlapping text spans (so-called Elementary Discourse Units (EDUs)) that are connected by rhetorical relations such as *Condition*, *Enablement* or *Background*. In addition, Mann and Thompson (1988) introduced the notion of *nuclearity*, where text spans that are connected by rhetorical relations are classified as either *nucleus*, when embodying the central part of information, or *satellite*, whose role is to further specify the nucleus.

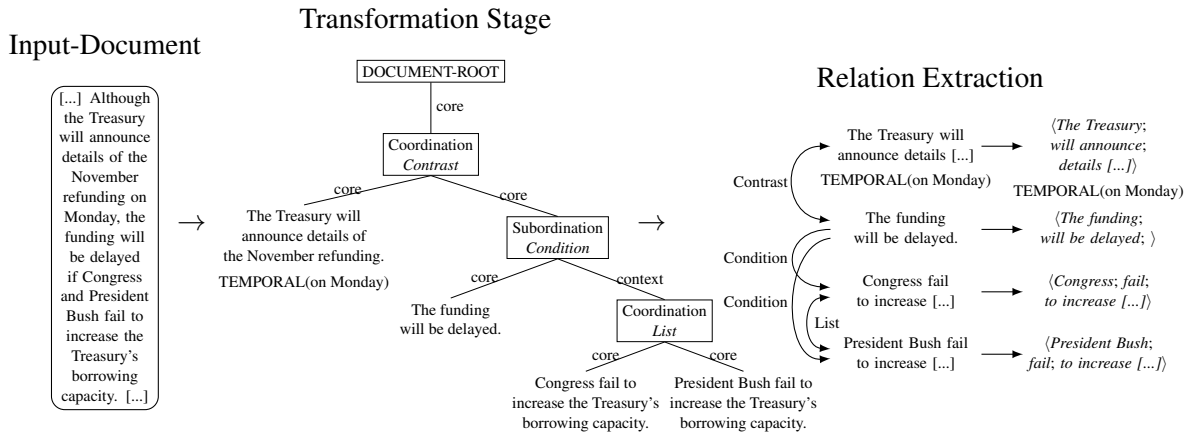

Figure 2: Extraction workflow for an example sentence.

We adapt the RST framework for our task of clausal sentence simplification, where the goal is to split up complex multi-clause sentences in a recursive fashion in order to obtain a hierarchical structure of the input similar to the diagrams used in RST. As opposed to RST, the resulting simplified sentences, which are represented as leaf nodes in the tree, cannot be specified prior to the transformation process, since they are not uniform and might require transformations (e.g. paraphrasing) for specific syntactic environments in which they occur. Therefore, the transformation process is carried out in a top-down fashion, starting with the input document and using a set of syntactic rule patterns that define how to split up, transform and recurse on complex syntactic sentence patterns (see Section 3.1.3). Each split will then create two or more simplified sentences that are connected with information about their constituency type (*coordinate* or *subordinate*) and identified rhetorical relation. The constituency type infers the concept of nuclearity, where coordinate sentences (which we will call *core* sentences) represent nucleus spans and subordinate sentences (*context* sentences) represent satellite spans. In this way, we obtain a hierarchical tree representation of the input document similar to RST. We will denote the resulting tree as a *discourse tree*.

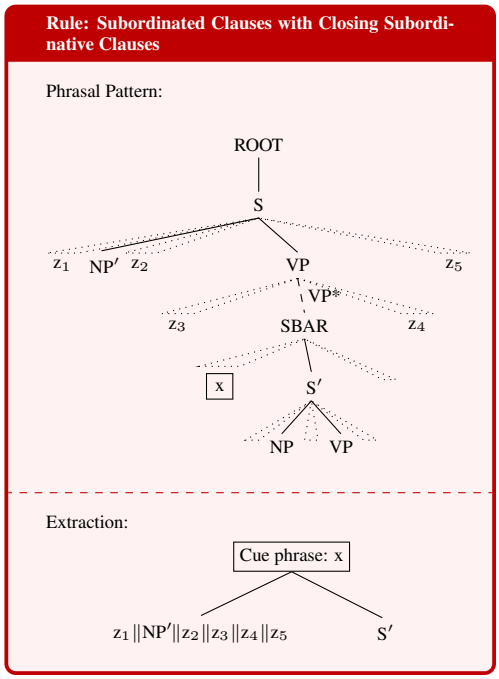

Figure 3: Rule for subordinated clauses with closing subordinative clauses ("||" denotes concatenation).

Note that our approach differs from RST in the following ways: 1) connected sentences do not have to be non-overlapping text spans; 2) our approach works in a top-down fashion where the final simplified sentences result from the transformation process, whereas in RST, the smallest elements of discourse (EDUs) are identified in advance.

3.1.2 Algorithm

The transformation algorithm (see Algorithm 1) takes as an input the document text as a string and outputs its discourse tree. In the initialization step (2), the discourse tree is set up in the form of a single, unclassified coordination node that represents the root of the document's discourse tree. It contains edges to every sentence that has been tokenized out of the document string, which are treated as coordinated leaf nodes. In this way, all sentences are considered as core sentences, thus being equally relevant.

Algorithm 1 Transformation Stage

Input: the document-string str
Output: the discourse tree $discourse\_tree$

1: **function** TRANSFORMATION(str)
2: $discourse\_tree \leftarrow$ initialize as a document root node with leaf-nodes for each sentence in str.
3: TRAVERSEDISCOURSETREE($discourse\_tree$)
4: $discourse\_tree \leftarrow$ further disembed contextual phrases (e.g. $temporal$, $spatial$) out of sentence leaves using the Sentence Simplification system proposed by Niklaus et al. (2016).
5: **return** $discourse\_tree$
6: **end function**

7: **procedure** TRAVERSEDISCOURSETREE($tree$)
8: ▷ Process leaves from left to right
9: **for** $leaf$ in $tree.leaves$ **do**
10: $match \leftarrow$ `False`
11: ▷ Check clausal transformation rules in fixed order
12: **for** $rule$ in $TRANSFORM\_RULES$ **do**
13: **if** $rule.pattern.matches(leaf.parse\_tree)$ **then**
14: $match \leftarrow$ `True`
15: **Break**
16: **end if**
17: **end for**
18: **if** $match ==$ `True` **then**
19: ▷ Disembedding / Simplification
20: $simplified\_sentences \leftarrow rule.disembed(leaf.parse\_tree)$
21: $new\_leaves \leftarrow$ convert $simplified\_sentences$ into leaf nodes. Nodes for subordinate sentences are labelled as `context`, else `core`
22: $new\_node \leftarrow$ create new parent node for new_leaves. If a context sentence is enclosed, the constituency is `subordinate`, else `coordinate`
23: ▷ Rhetorical relation identification
24: $cue\_phrase \leftarrow rule.extract\_cue(leaf.parse\_tree)$
25: $new\_node.relation \leftarrow$ match cue_phrase against a list of rhetorical cue words that are assigned to their most likely triggered rhetorical relation. Different cue word lists are used for different syntactic environments.
26: ▷ Recursion
27: $tree.replace(leaf, new\_node)$
28: TRAVERSEDISCOURSETREE(new_node)
29: **end if**
30: **end for**
31: **end procedure**

After initialization, the discourse tree is traversed and split up recursively in a top-down approach (3, 7). The tree traversal is done by processing sentence leaves in depth-first order, starting from the root node. For every leaf (9), we check if its phrasal parse structure matches one of the fixed ordered set of 16 hand-crafted syntactic rule patterns (see Section 3.1.3) that determine how a sentence is split up into two or more simplified sentence leaves (13). The first matching rule will be used, generating two or more simplified sentences (20) that will again be processed in this way. In addition to generating simplified sentences, each rule also determines the constituency type of the newly created node (22) and returns a cue phrase which is used as a lexical feature for classifying the type of rhetorical relation connecting the split sentences (24, 25). The algorithm terminates when no more rule matches the set of generated sentences. Finally, we use the sentence simplification system of Niklaus et al. (2016) to further disembed contextual phrases out of the simplified sentences from the discourse tree (4). The complete source code of our

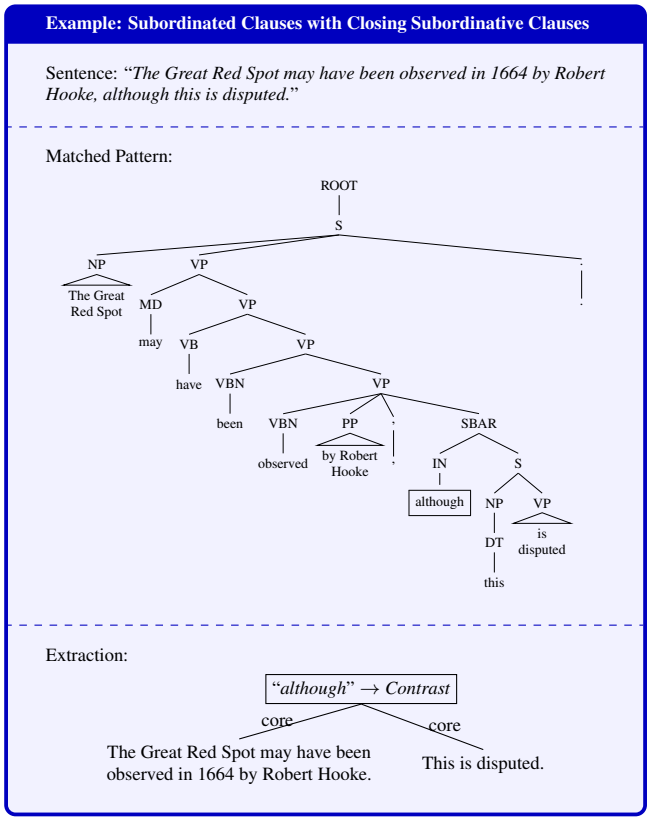

Figure 4: Example for subordinated clauses with closing subordinative clauses.

framework can be found online[1].

3.1.3 Transformation Rules

The set of hand-crafted transformation rules used in the simplification process are based on syntactic and lexical features that can be obtained from a sentence's phrase structure, which we generated with the help of Stanford's pre-trained lexicalized parser (Socher et al., 2013). These rules make use of regular expressions over the parse trees encoded in the form of Tregex patterns (Levy and Andrew, 2006). They were heuristically determined in a rule engineering process whose main goal was to provide a best-effort set of rules, targeting the challenge of being applied in a recursive fashion and to overcome biased or erroneous parse trees. During our experiments, we developed a fixed execution order of rules which achieved the highest F_1-score in the evaluation setting.

Each rule pattern accepts a sentence's phrasal parse tree as an input and encodes a certain parse tree pattern that, in case of a match, will extract textual parts out of the tree that are used to produce the following information:

Simplified sentences The simplified sentences are generated by combining extracted parts from the parse tree. Note that some of the extracted parts such as phrases also require to be arranged and complemented in a way so that they form grammatically correct sentences (*paraphrasing*), aiming for a canonical subject-predicate-object structure.

Constituency Our notion of constituency depicts the contextual hierarchy between the simplified sentences. If all sentences can be considered to be equally important, we will call it a *coordination*. In this case, all generated sentences are labeled as *core* sentences. Otherwise, i.e. if one sentence provides background information or further specifies another sentence, we use the term *subordinate* and label the sentence as *context* sentence. In most of the cases, our framework uses the syntactic information of coordinated and subordinated clauses to infer the same type of (semantic) constituency with respect to the rhetorical relations. An example where this does not apply are rules for identifying attributions. In these cases, we consider an actual statement (e.g. "*Economic activity continued to increase.*") to be more important than the fact that this was stated by some entity (e.g. "*This was what the Federal Reserve noted.*").

Classified rhetorical relation Both syntactic and lexical features are used during the transformation process to identify and classify rhetorical relations that hold between the simplified sentences. Syntactic features are manifested in the phrasal composition of a sentence's phrasal parse tree, whereas lexical features are extracted from the parse tree as so-called *cue phrases*. Cue phrases (often denoted as *discourse markers*) represent a sequence of words that are likely to include rhetorical cue words (e.g. "*because*", "*after that*" or "*in order to*") indicating a certain rhetorical relation. The way these cue phrases are extracted from a sentence's parse tree is specific to each rule pattern. For determining potential cue words and their positions in specific syntactic environments, we use the work of Knott and Dale (1994). The extracted cue phrases are then used to infer the kind of rhetorical relation. For this task, we use a predefined list of rhetorical cue words which are assigned to the rhetorical relation that they most likely trigger. The mapping of cue words to rhetorical relations was adapted from the work of Taboada and Das (2013). If one of these cue words is present in the cue phrase, the corresponding rhetorical relation is set between the newly constructed sentences.

An example for a transformation rule, targeting subordinate clausal constructions, is illustrated in Figure 3. Figure 4 shows its application to an example sentence. The full rule set can be found in the supplementary material online[2]. Here, a detailed example that demonstrates the process of turning a complex NL sentence into a discourse tree is provided, too.

3.2 Relation Extraction

[1] https://github.com/Lambda-3/Graphene

[2] https://github.com/Lambda-3/Graphene/tree/master/wiki/supplementary

The last step in our framework is realized by the actual relation extraction task. To do so, each of the previously generated leaf sentences is given as an input to any Open IE system that is able to extract one (or more) binary propositions from a given sentence. In order to map the identified rhetorical and contextual relationships from the discourse tree to the extracted propositions, we need to determine which of the extracted propositions embodies the main statement of the corresponding sentence. We use the following heuristic to decide whether an extracted proposition represents the main statement of the input sentence: 1) the head verb of the input sentence is contained in the relational phrase rel of the proposition $\langle arg_1; rel; arg_2 \rangle$ (e.g. $\langle$*Employees*; *are* nominated; *for the program*$\rangle$); or 2) the head verb of the input sentence equals the object argument arg_2 of the proposition (e.g. $\langle$*Employees*; *are*; nominated$\rangle$). We will denote any proposition that matches those criteria as a *representative* of the corresponding sentence. Once determined, the identified rhetorical and contextual relations that hold between two sentences from the discourse tree can be directly transferred as (semantically typed) additional arguments to the corresponding representatives, thus generating n-ary relations.

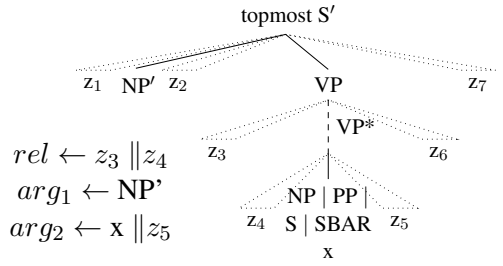

Figure 5: Graphene's default relation extraction pattern ("‖" denotes concatenation).

In this way, extractions from any Open IE system that uses our framework can be enriched with semantic information. An example of the semantically enriched output produced by the Open IE system OLLIE when using our framework as a preprocessing step is shown in Figure 6. In our baseline implementation Graphene, we use one syntactic rule pattern that operates on the sentence's phrase structure and identifies simple subject-predicate-object structures. The default pattern, which extracts one tuple for each sentence, is shown in Figure 5.

4 Evaluation

In order to evaluate the performance of our Open IE reference implementation Graphene, we conduct an automatic evaluation using the Open IE benchmark framework proposed in Stanovsky and Dagan (2016), which is based on a QA-Semantic Role Labeling (SRL) corpus with more than 10,000 extractions over 3,200 sentences from Wikipedia and the Wall Street Journal[3]. This benchmark allows us to compare our system with a variety of current Open IE approaches in recall and precision. Moreover, we investigate whether our two-layered transformation process of clausal and phrasal disembedding improves the performance of state-of-the-art Open IE systems when applied as a preprocessing step.

[3]available under `https://github.com/gabrielStanovsky/oie-benchmark`

4.1 Experimental Setup

To conduct an automatic comparative evaluation, we integrate Graphene into Stanovsky and Dagan (2016)'s Open IE benchmark framework, which was created from a QA-SRL dataset where every verbal predicate was considered as constituting an own extraction. Since Graphene's structured output is not designed to yield extractions for every occurrence of a verbal predicate, we use an alternative relation extraction implementation which is able to produce more than one extraction from a simplified core sentence. To match extractions to reference propositions from the gold standard, we use the method described in Stanovsky and Dagan (2016), following He et al. (2015) by matching an extraction with a gold proposition if both agree on the grammatical head of both the relational phrase and its arguments. Since n-ary relational tuples with possibly more than two arguments have to be compared, we assign a positive match if the relational phrase and at least two of their arguments match. Since the gold standard is composed of n-ary relations, we add all contexts (S) of an extraction as additional arguments besides arg_1 and arg_2. We assess the performance of our system together with the state-of-the-art systems ClausIE, OLLIE, OpenIE-4 (Mausam, 2016), PropS (Stanovsky et al., 2016), REVERB and Stanford Open IE.

After evaluating Graphene as a reference implementation of the proposed approach, we investigate how clausal and phrasal disembedding applied as a preprocessing step affects the performance of other Open IE systems. Therefore, we compare the performance of ClausIE, OLLIE, OpenIE-4, REVERB and Stanford Open IE on the raw input data with their performance when operating inside of our framework where they act as different relation extraction implementations that take the simplified sentences of the transformation stage as an input.

4.2 Results and Discussion

Figure 7 shows the precision-recall curve for each system within the Open IE benchmark evaluation framework. In our experiments, with a score of 50.1% in average precision, our reference implementation Graphene achieves the best performance of all the systems in extracting accurate relational tuples, followed by OpenIE-4 (44.6%) and PropS (42.4%). Considering recall, Graphene (27.2%) is able to compete with other high-precision systems, such as PropS (26.7%). However, it does not reach the recall rate of ClausIE (33.0%) or OpenIE-4 (32.5%). This lack in recall was expected, since Graphene was not designed to create fine-grained relations for every possible verb, as opposed to the gold standard, but rather determines the main relations with attached (contextual) arguments that often contain some of these verbal expressions. In an in-depth analysis of the output, we proved that only 33.72% of unmatched gold extractions were caused by a wrong argument assignment of Graphene. In the majority of cases (66.28%), Graphene did not extract propositions with a matching relational phrase. We further calculated that in 56.80% of such cases, the relational phrase of a missed gold standard extraction was actually contained inside an argument, e.g.:

"*Japan may be a tough market for outsiders to penetrate, and the U.S. is hopelessly behind Japan in certain technologies.*"

- Unmatched Gold-Extraction: ⟨*outsiders*; *may penetrate*; *Japan*⟩
- Graphene-Extractions:
  1. ⟨*Japan*; *may be*; *a tough market for outsiders to penetrate*⟩
  2. ⟨*the U.S.*; *is hopelessly behind Japan*; *in certain technologies*⟩

This number even grows to 67.89% when considering the lemmatized form of the head:
"*The seeds of "Raphanus sativus" can be pressed to extract radish seed oil.*"

- Unmatched Gold-Extraction: ⟨*radish seed oil*; *can be extracted*; *from The seeds*⟩
- Graphene-Extractions:
  1. ⟨*the seeds of "Raphanus sativus"*; *can be pressed*; *to extract radish seed oil*⟩

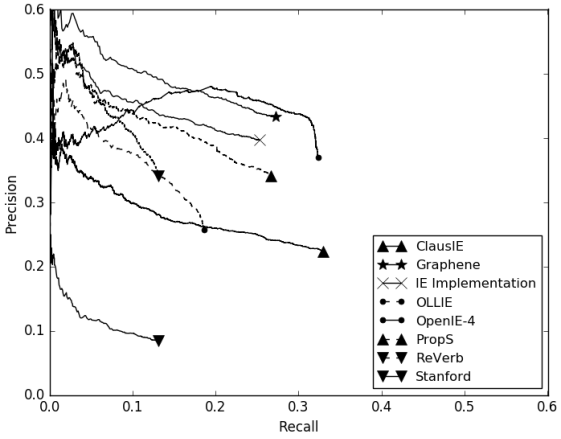

Figure 7: Performance of Graphene.

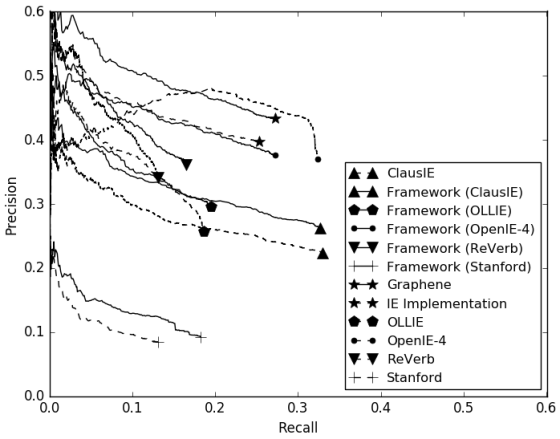

Figure 8: Improvements of state-of-the-art systems when operating as RE component of our framework.

Another 5.22% of unmatched relational phrases would have been recognized by Graphene if they were compared based on their lemmatized head.

Regarding the overall Area Under the Curve (AUC) score, OpenIE-4 is the best performing system with a score of 14.5%, closely followed by Graphene (13.6%), PropS (11.3%) and ClausIE (9.3%).

The precision-recall curve in Figure 8 shows that when using clausal and phrasal disembedding provided by our framework, all tested systems except for OpenIE-4 (-18%) gain in AUC. The highest improvement in AUC was achieved by Stanford Open IE, yielding a 63% AUC increase over the output of Stanford Open IE as a standalone system. AUC scores of OLLIE and REVERB improve by 34% and 22%. While OLLIE and REVERB primarily profit from a boost in recall (+4%, +26%), ClausIE mainly enhances precision (+16%). Furthermore, the performance of our reference relation extraction implementation increases both in precision (+10%) and recall (+8%) when applied as the relation extraction component inside of our system Graphene (+19% AUC).

5 Conclusion

In this paper, we introduce a novel Open IE approach that presents an innovative two-layered hierarchical representation of syntactically simplified sentences in the form of core facts and accompanying contexts that are semantically linked by rhetorical relations. In that way, the semantic connection of the individual components is preserved, thus allowing to fully reconstruct the informational content of the input.

The results of a comparative analysis conducted on a large-scale benchmark framework showed that with a score of 50.1%, our baseline system Graphene achieves the best average precision, while also providing a recall rate of 27.2% that is comparable to that of other high-precision systems. Moreover, we demonstrated that by using clausal and phrasal disembedding as a preprocessing step, the AUC score of state-of-the-art Open IE systems can be improved by up to 63%. In summary, we were able to show that by generating a two-layered representation of core and contextual information, the relations extracted by state-of-the-art Open IE systems can be semantically enriched without losing in precision or recall. Moreover, by using clausal and phrasal disembedding techniques, contextual information is detached from the core propositions and transformed into additional arguments, thus avoiding the problem of overspecified argument phrases and yielding a more compact structure. By enhancing the resulting syntactically sound sentence representation with rhetorical relations, semantically typed and interconnected relational tuples are created that may benefit downstream artificial intelligence tasks. In future work, we plan to evaluate the classification of the rhetorical relations, examine to what extent other NL Processing tasks such as QA systems may benefit from the results produced by our framework and investigate the creation of big knowledge graphs for QA by performing a large-scale Wikipedia extraction.

An Exploration of Three Lightly-supervised Representation Learning Approaches for Named Entity Classification

Ajay Nagesh and Mihai Surdeanu
University of Arizona, Tucson, AZ, USA
{ajaynagesh, msurdeanu}@email.arizona.edu

Abstract

Several semi-supervised representation learning methods have been proposed recently that mitigate the drawbacks of traditional bootstrapping: they reduce the amount of semantic drift introduced by iterative approaches through one-shot learning; others address the sparsity of data through the learning of custom, dense representation for the information modeled. In this work, we are the first to adapt three of these methods, most of which have been originally proposed for image processing, to an information extraction task, specifically, named entity classification. Further, we perform a rigorous comparative analysis on two distinct datasets. Our analysis yields several important observations. First, all representation learning methods outperform state-of-the-art semi-supervised methods that do not rely on representation learning. To the best of our knowledge, we report the latest state-of-the-art results on the semi-supervised named entity classification task. Second, one-shot learning methods clearly outperform iterative representation learning approaches. Lastly, one of the best performers relies on the mean teacher framework (Tarvainen and Valpola, 2017), a simple teacher/student approach that is independent of the underlying task-specific model.

1 Introduction

The paucity of labeled datasets presents tremendous challenges to training machine learning (ML) systems in the real world. Most natural language processing (NLP) tasks are data hungry. The recent success of deep learning for NLP tasks is at least partially due to the fact that such models are exposed to large quantities of labeled data. However, obtaining such rich labeled data is a costly proposition and seldom feasible in many realistic scenarios.

Semi-supervised learning (SSL) mitigates the supervision cost by combining a minimal amount of labeled data with a large amount of unlabeled data. In information extraction (IE), SSL often takes the form of bootstrapping, which starts with a few seed examples, e.g., "Barack Obama" as an example of a person's name, and continues with an iterative approach that alternates between learning extraction patterns such as word n-grams, e.g., the pattern "`@ENTITY , former president`" could be used to extract person names, and applying these patterns to extract the desired structures (entities, relations, etc.) (Riloff, 1996; Abney, 2007; Carlson et al., 2010b; Gupta and Manning, 2014; Gupta and Manning, 2015, inter alia). There are, however, two drawbacks to this direction. First, as learning in this iterative framework advances, the task often *drifts semantically* (Komachi et al., 2008) into a related but different space, e.g., from learning women names into learning flower names (McIntosh, 2010; Yangarber, 2003). Second, the statistics used to estimate the quality of the learned patterns are often *brittle* due to the sparsity of the extraction patterns.

Recently, several semi-supervised representation learning methods have been proposed to mitigate these issues. One direction learns custom representations for both patterns and the structures to be extracted to mitigate the sparsity mentioned above (see Section 4). A different direction, illustrated

Proceedings of the 27th International Conference on Computational Linguistics, pages 2312–2324
Santa Fe, New Mexico, USA, August 20-26, 2018.

by the ladder networks (LN) and mean teacher (MT) frameworks (Rasmus et al., 2015; Tarvainen and Valpola, 2017), replaces the iterative bootstrapping with one-shot learning driven by teacher/student architectures, trained to maximize consistency of predictions between the teacher and the student on the unlabeled data (Sections 5 and 6). Despite this progress, several important questions remain unanswered. First, most of these methods have been proposed for vision, and it is unclear how useful they are for lightly-supervised natural language processing tasks. Second, it is unknown how well these methods compare against "traditional" bootstrapping that does not use representation learning. Third, it is unclear how these representation learning methods compare against each other.

In this work, we answer the above questions by adapting all these methods to the same IE task, and performing a rigorous comparative analysis. Specifically, the contributions of this paper are the following:

- We are the first to adapt the mean teacher (MT) framework (Tarvainen and Valpola, 2017) to a semi-supervised IE task, in particular named entity classification (NEC).
- We implement and evaluate the three semi-supervised representation learning approaches summarized above for the same NEC task, using two distinct datasets (Pradhan et al., 2013; Tjong Kim Sang and De Meulder, 2003), the same inputs, and the same evaluation measures to understand how they compare both against each other and against more traditional semi-supervised NLP approaches.
- We perform a thorough comparative analysis of all these methods, which highlights several important observations. First, our analysis confirms that all these representation learning methods outperform state-of-the-art semi-supervised methods that do not rely on representation learning (Gupta and Manning, 2015; Gupta and Manning, 2014; Zhu and Ghahramani, 2002). Second, one-shot learning methods (the teacher/student approaches here) have superior performance compared to iterative representation learning approaches that are driven by objective functions tailored for the task at hand (e.g., which maximize the similarity of embeddings for entities in the same class). Lastly, the teacher/student approaches perform comparatively – each outperforms the other on one dataset – despite the fact that MT is a simpler framework than LN. That is, in the mean teacher framework both student and teacher are decoupled whereas in ladder networks there are connections between the two, which makes porting LNs to new tasks more difficult.

2 Related Work

There is a large body of work in semi-supervised learning for NLP, which encompasses many different types of techniques such as self-training or bootstrapping (Riloff, 1996; Abney, 2007; Carlson et al., 2010a; Carlson et al., 2010b; McIntosh, 2010; Gupta and Manning, 2015, inter alia), co-training (Blum and Mitchell, 1998), or graph-based methods such as label propagation (Delalleau et al., 2005). Among these, perhaps the most-widely adopted approach in the NLP field is bootstrapping, which has been used in many applications, including information extraction (Carlson et al., 2010a; Gupta and Manning, 2014; Gupta and Manning, 2015), lexicon acquisition (Neelakantan and Collins, 2015), named entity classification (Collins and Singer, 1999) and sentiment analysis (Rao and Ravichandran, 2009). However, as mentioned, most of these approaches suffer from brittle statistics due to the sparsity of the patterns learned, and from semantic drift, due to their iterative nature. The methods we investigate in this paper address these two limitations through representation learning and one-shot learning.

Auto-encoder frameworks have received considerable attention in the machine learning community recently. Such frameworks include recursive auto-encoders (Socher et al., 2011), denoising auto-encoders (Vincent et al., 2008), and others. They are primarily used as a pre-training mechanism before supervised training. Recently, such networks have also been used for semi-supervised learning as they are more amenable to combining supervised and unsupervised components of the objective functions (Zhai and Zhang, 2015).

Ladder networks (LN) are stacked denoising auto-encoders with skip-connections in the intermediate layers (Rasmus et al., 2015; Valpola, 2014). LNs have been shown to produce state-of-the-art perfor-

mance on both supervised and semi-supervised tasks on the MNIST dataset in image processing. Our work is among the first to apply LNs to NLP. While similar in spirit to Zhang et al. (2017), the only other work we found that applies a denoising auto-encoder to a semi-supervised spelling correction task, our work is much simpler, since it uses a multi-layer perceptron instead of convolution-deconvolution operations (see Section 5). Further, we demonstrate that LNs perform very well on a complex IE task, considerably outperforming several state-of-the-art approaches. In the same space, teacher-student networks have shown to provide state-of-the-art semi-supervised learning results on several image processing tasks. The most prominent example of such a network is the Mean Teacher framework (Tarvainen and Valpola, 2017).To our knowledge, we are the first to apply the MT framework to an IE task (Section 6).

Distributed representations of words serve as underlying representation for many NLP tasks. For example, Levy and Goldberg (2014a) generalized the `word2vec` algorithm (Mikolov et al., 2013) to use any arbitrary context instead of just individual words. Faruqui et al. (2015) demonstrated that embeddings learned without supervision can be retro-fitted to better conform to some semantic lexicon. Generating custom embeddings that encode more specific semantic properties has been shown to be useful for downstream tasks (Sharp et al., 2016). Riedel et al. (2013; Toutanova et al. (2015; Toutanova et al. (2016) used knowledge bases in conjunction with surface patterns to learn custom representations for relation extraction. Note, however, that most of these works that customize embeddings for a specific task rely on some form of supervision. In contrast, our approach that learns a custom representation for the NEC task is lightly supervised, with a only few seed examples per category (Section 4).

3 Task and Approaches

Named entity classification

We implement and evaluate the proposed semi-supervised learning approaches on the task of named entity classification (NEC), defined as identifying the correct label of an entity mention in a given context. In our setting, the context of a mention is defined as all the patterns that match that specific mention in its context. In this work, we consider patterns to be n-grams of size up to 4 tokens on either side of an entity. For instance, "`@ENTITY , former President`" is one of the patterns learned for the class `person`. Using all these patterns as input, the classifier must infer the mention's correct label. Importantly, the NEC task can be defined at mention level, i.e., as the classification of *individual mentions* of named entities as defined above, or at entity level, i.e., as the identification of all labels that apply to *all mentions* of a given entity jointly (e.g., "Washington" = {`person`, `location`}). Here we focus on mention classification, although in some of our evaluations we revert to entity classification, to be able to compare against other approaches.

Semi-supervised representation learning

We propose three representation learning approaches for the NEC task: (i) Embedding-based bootstrapping (Emboot), (ii) ladder networks (LN), and (iii) mean teacher (MT) architectures.

Emboot (Valenzuela-Escárcega et al., 2018) is an adaptation of iterative bootstrapping-based approaches, coupled with a component that learns custom representations (embeddings) for both the entities and the patterns learned. As mentioned, such iterative approaches suffer from semantic drift, i.e., as the learning advances, the learning often drifts into a related but different space. LN and MT are based on the emerging paradigm of teacher-student architectures: both approaches aim to reconcile differences between the teacher and the student models by minimizing a consistency cost when their predictions do not concur. Teacher-student architectures are more robust to semantic drift due to their single-shot semi-supervised learning algorithms.

Note that, of the above architectures, Emboot and MT additionally learn custom representations for the unsupervised data provided which could potentially be informative representations to be used in a downstream component aimed at interpreting the classifier decisions. Further, MT is the most flexible/customizable of all these architectures, as it is largely independent of the underlying task-specific model. We show in our experiments that this simplicity is coupled with good performance on two different datasets.

In the next three sections, we discuss each of these approaches in detail.

4 Embedding-based Bootstrapping (Emboot)

This algorithm (based on our earlier work (Valenzuela-Escárcega et al., 2018)) iteratively grows a pool of known entities (entPool$_c$) and patterns (patPool$_c$) for each category of interest c, and learns custom embeddings for both. These pools are initialized with a few seed examples (seeds$_c$) for each category. For example, in our experiments we initialize the pool for a `person names` category with 10 names such as *Bill Clinton* and *Mother Teresa*. Then the algorithm iteratively applies the following three steps for a specified number of epochs:

(1) *Learning custom embeddings*: The algorithm learns custom embeddings for all entities and patterns observed in the dataset, using the current entPool$_c$s. We train our embeddings for both entities and patterns by maximizing the objective function J:

$$J = \text{Skip-gram} + \text{Attract} + \text{Repel} \tag{1}$$

where the individual components of the objective function designed to model both the unsupervised, language model part of the task as well as the light supervision coming from the seed examples. The *Skip-gram* term is similar to Eq. 4 of Mikolov et al. (2013) (skip-gram with negative sampling), but, crucially, adapted to operate over *entities* (rather than words), and a context consisting of the bag of all *patterns* that match each entity (rather than context words). The *Attract* term, encourage entities or patterns in the same pool to be close to each other (*E.g.* two person entities should be attracted to each other), whereas the *Repel* term encourages that the pools be mutually exclusive, which is a soft version of the counter training approach of Yangarber (2003) or the weighted mutual-exclusive bootstrapping algorithm of McIntosh and Curran (2008) (e.g., person names should be far from organization names in the semantic embedding space). They are depicted by the following two equations:

$$\text{Attract} = \sum_{P} \sum_{x1,x2 \in P} \log(\sigma(V_{x1}^{\top} V_{x2})) \tag{2}$$

$$\text{Repel} = \sum_{\substack{P1,P2 \\ \text{if } P1 \neq P2}} \sum_{x1 \in P1} \sum_{x2 \in P2} \log(\sigma(-V_{x1}^{\top} V_{x2})) \tag{3}$$

where P is the entity/pattern pool for a category, $x1, x2$ are entities/patterns in said pool in Eq 2. and $P1, P2$ are different pools, and $x1$ and $x2$ are entities/patterns in $P1$, and $P2$, respectively.

(2) *Pattern promotion*: We generate the patterns that match the entities in each pool entPool$_c$, rank those patterns using point-wise mutual information (PMI) with the corresponding category, and select the top ranked patterns for promotion to the corresponding pattern pool patPool$_c$.

(3) *Entity promotion*: Entities are promoted to entPool$_c$ using a classifier that estimates the likelihood of an entity belonging to each class (Gupta and Manning, 2015). We differ from Gupta and Manning (2015) in that we use a multi-class classifier instead of many binary classifiers, and in the features used. Our feature set includes, for each category c: (a) edit distance between the candidate entity e and current e_cs $\in$ entPool$_c$, (b) the PMI (with c) of the patterns in patPool$_c$ that matched e in the training documents, and (c) similarity between e and e_cs in some semantic space. For the latter feature group, we use two sets of vector representations for entities. The first is the set of custom embedding vectors learned in step (1) for entities. The second includes pre-trained word embeddings (for multi-word entities, we simply average the embeddings of the component words). We use these vectors to compute the cosine similarity score of a given candidate entity e to the entities in entPool$_c$, and add the average and maximum similarities as features. The top 10 entities classified with the highest confidence for each class are promoted to the corresponding entPool$_c$ after each epoch.

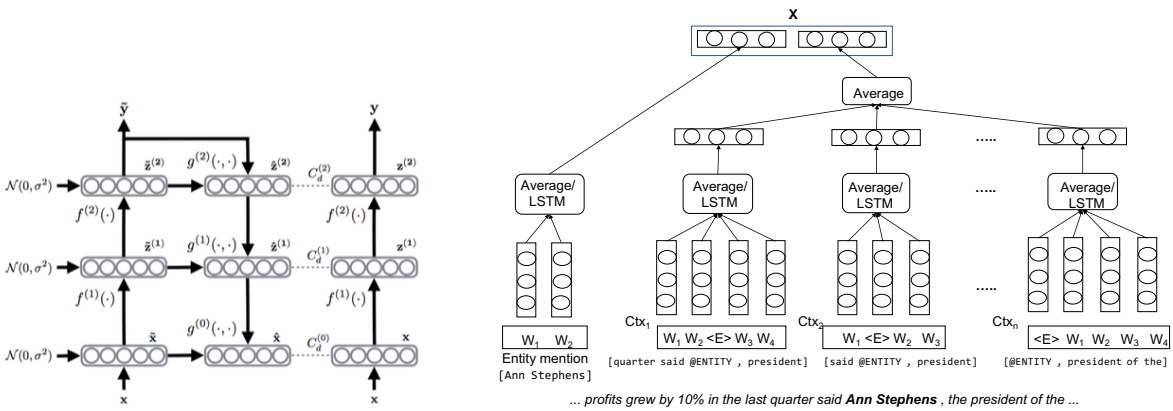

Figure 1: Architecture of the ladder network (Rasmus et al., 2015) (left), and network initialization of input vector X for the NEC task, where X captures the entity mention modeled and all the patterns matching it in the corresponding sentence (right).

5 Ladder Networks

Ladder networks (LN) (Rasmus et al., 2015) is a neural network architecture designed to use unsupervised learning as a scaffolding for the supervised task. It is a denoising autoencoder (DAE) with noise introduced in every layer. It consists of two sets of encoders, a clean one and another corrupted with noise, and a decoder. In addition, there are skip connections between the encoder and decoder (see left part of Figure 1). The ladder network is defined as follows:

$$\tilde{X}, \tilde{Z}^{(1)}, \dots \tilde{Z}^{(L)}, \tilde{y} = f_{corr}(X) \tag{4}$$

$$X, Z^{(1)}, \dots Z^{(L)}, y = f_{clean}(X) \tag{5}$$

$$\hat{X}, \hat{Z}^{(1)}, \dots \hat{Z}^{(L)} = g(\tilde{Z}^{(1)}, \dots \tilde{Z}^{(L)}) \tag{6}$$

where X, $\tilde{X}$ and $\hat{X}$ is an input datapoint, its corrupted version, and its reconstruction, respectively; $Z^{(l)}$ and $\tilde{Z}^{(l)}$ are clean and corrupted hidden representations in the l-th layer; and, lastly, y, $\tilde{y}$ are the clean and corrupted activations, converted to a probability distribution over the label set (using a softmax layer).

For our NEC task, X is the concatenation of an entity mention and its context embedding vectors, and y represents the mention's label (e.g., `person`). We initialize the words in the entities and patterns around them with pre-trained word embeddings. To obtain a single embedding for an entity mention and its context we: (a) average word embeddings to obtain a single embedding for the entity mention and each of its patterns; and (b) average the resulting pattern embeddings to produce the embedding of the corresponding context. We then concatenate the mention's embedding and context embedding to be given as input to the ladder network. This process is depicted schematically in the right part of Figure 1. We introduce noise by adding a random Gaussian to the pre-trained embeddings with a fixed mean and standard deviation.

The objective function is a combination of a supervised training cost and unsupervised reconstruction costs at each layer (including the hidden layers):

$$Cost = -\sum_{n=1}^{N} logP(\tilde{y_n} = y_n^* | X_n) + \sum_{n=N+1}^{M} \sum_{l=1}^{L} \lambda_l ReconstCost(Z_n^{(l)}, \hat{Z}_n^{(l)}) \tag{7}$$

where the first term is the supervised cross-entropy based on the N labeled datapoints $(X_1, y_1^*), (X_2, y_2^*), \dots (X_N, y_n^*)$, and the second term is the reconstruction loss on the M unlabeled datapoints $X_{N+1}, X_{N+2}, \dots X_{N+M}$, for each layer l. Typically $M \gg N$.

Pezeshki et al. (2016) analyze the different architectural aspects of LN and note that the lateral connections and corresponding reconstruction costs (second term in the above cost function) are critical for

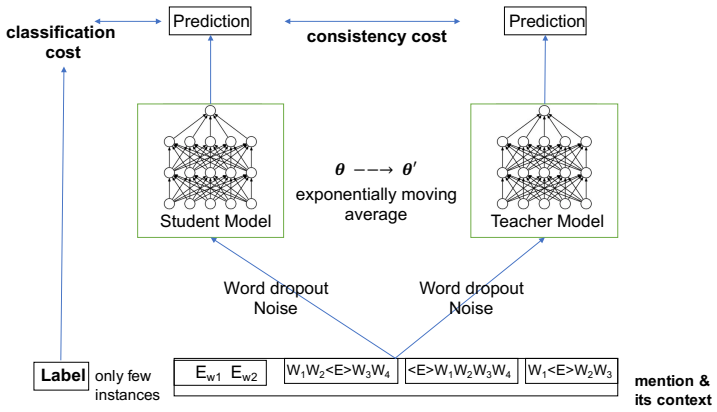

Figure 2: Mean Teacher architecture for the named entity classification task. E_{wi} are words contained in the current entity mention; W_i are words that occur in a pattern that matches the entity mention; and <E> is a placeholder token to indicate where the entity mention occurs inside a pattern.

semi-supervised learning. In other words, it is important for unlabeled data to be used for regularization to be able to learn good abstractions in the different layers. We have similar observations for the NEC task (see Experiments).[1]

6 Mean Teacher Framework

The mean teacher framework (Tarvainen and Valpola, 2017) belongs to a general class of teacher-student algorithms that learn with unlimited unlabeled data and limited supervision. The broad motivation behind MT is provided by the shortcomings of auto-encoders, which suffer from confirmation bias in semi-supervised settings, i.e., when they use their own predictions instead of gold labels (Tarvainen and Valpola, 2017; Laine and Aila, 2016). To mitigate confirmation bias, the teacher weights in MT are averaged over the training epochs, akin to the averaged perceptron. This provides a more robust scaffolding that the student model can rely on during training when gold labels are not available (Tarvainen and Valpola, 2017).

The MT architecture is summarized in Figure 2. It consists of two models with identical architectures where one is termed the teacher, and the other the student. The weights in the teacher network are set through an exponential moving average of the student weights. The input to both of these models is the same datapoint, which is augmented by some noise that is specific to each model. In the case of our NEC task, we introduce noise through random word dropout in the patterns that apply to an entity mention.

The MT algorithm is designed for semi-supervised tasks, where only a few of the data points are labeled. The cost function is a combination of two different type of costs: classification and consistency. The classification cost applies to supervised data points, and can be instantiated with any supervised cost function (e.g., we used categorical cross-entropy). The consistency costs is used for unlabeled data points, and aims to minimize the differences in predictions between the teacher and the student models. The consistency cost, J is:

$$J(\theta) = \mathrm{E}_{x,\eta',\eta}\left[\|f(x,\theta',\eta') - f(x,\theta,\eta)\|^2\right] \tag{8}$$

where this function is defined as the expected distance between the prediction of the teacher model (with weights θ' and noise η') and the prediction of the student model (with weights θ and noise η).

The student weights are updated via back propagation. The teacher weights are deterministically updated after each mini batch of gradient descent on the student, through an exponentially weighted moving average (EMA) from the previous iterations of the student, given by the following equation:

[1]LNs for semi-supervised named entity classification was presented by our earlier work (Nagesh and Surdeanu, 2018). In this work, we compare LNs with MT and provide a more in-depth analysis of these frameworks under the umbrella of teacher-student architectures.

$$\theta_t^{'} = \alpha\theta_{t-1}^{'} + (1-\alpha)\theta_t \quad (9)$$

where $\theta_t^{'}$ is defined at training step t as the EMA of successive weights θ (Tarvainen and Valpola, 2017).

We explored two different architectures for the student model:

Simple model (MT_simple): In this model, we used bag-of-word averaging to obtain embeddings for entity mentions and the patterns matching them. In particular, we: (a) average word embeddings to obtain a single embedding for the entity mention and each of its patterns; and (b) average the resulting pattern embeddings to produce the embedding of the corresponding context. We then concatenate the mention's embedding and context embedding to be given as input to the mean teacher framework. This process is depicted schematically in the right part of Figure 1. This replicates the input processing in LN.

Custom Embedding model (MT_custom): We use a bidirectional LSTM layer on top of the word embedding layer. We train a biLSTM on both the entity tokens and a separate LSTM for each of the pattern tokens. We average each of pattern LSTM representations and concatenate the entity and pattern representations as depicted in the right part of Figure 1. The addition of the LSTM layer, enables this model learn custom embeddings. These embeddings are further analyzed in Section 7.

For both student and teacher models, we initialized the words in the entity mentions and corresponding patterns with pre-trained word embeddings. We have a *linear-ReLU-linear* fully connected layers from the embedding layer before computing the loss.

7 Experiments

7.1 Experimental Setup[2]

Datasets: We used two datasets, the CoNLL-2003 shared task dataset (Tjong Kim Sang and De Meulder, 2003), which contains 4 entity types, and the OntoNotes dataset (Pradhan et al., 2013), which contains 11[3], both of which are benchmark datasets for supervised named entity recognition (NER). These datasets contain marked entity boundaries with labels for each marked entity. Here we only use the entity boundaries but *not* the labels of these entities during the training of our bootstrapping systems. To simulate learning from large texts, we ran the actual experiments on the *train* partitions.[4]

Baselines: We compared against two baselines:

Explicit Pattern-based Bootstrapping (EPB): This is our implementation of the state-of-the-art bootstrapping system of Gupta and Manning (2015), adapted to NEC. The algorithm grows a pool of known entities and patterns for each category of interest, from a few seed examples per category, by iterating between pattern promotion and entity promotion. The former is implemented using a ranking formula driven by the point-wise mutual information (PMI) between each pattern with the corresponding category; the top ranked patterns are promoted to the pattern pool in each iteration. The latter component promotes entities using a classifier that estimates the likelihood of an entity belonging to each class. Our feature set includes, for each category c: (a) edit distance between the candidate entity e and known entities for c; (b) the PMI (with c) of the patterns in the pool of c that matched e in the training documents; and (c) similarity between e and entities in c's pool in some semantic space.[5] Entities classified with the highest confidence for each class are promoted to the corresponding pool after each epoch.

[2]For ease of reproducibility, we release the code for the various semi-supervised learning algorithms at `https://github.com/clulab/releases/tree/master/coling2018-ssl-nec`

[3]We excluded numerical categories such as `DATE`.

[4]Although we run the evaluation on the train dataset, we do not use the labels present in it, as it is a semi-supervised task. In general, in any machine learning dataset, usually the test dataset is quite small compared to train. Since we wanted to analyze the performance in a larger context, we used the train dataset (without the labels).

[5]We used pre-trained word representations, averaged for multi-word entities, to compute cosine similarities between pairs of entities.

	CoNLL	*Ontonotes*
EPB	40.75	21.07
LP	26.07	19.40
Emboot	67.97	45.20
Ladder	68.92 (±2.9)	65.20 (±3.2)
MT_simple	69.50 (±2.7)	51.10 (±4.8)
MT_custom	66.81 (±3.5)	36.17 (±2.5)

Table 1: Overall Accuracies (entity-based)

	CoNLL	*Ontonotes*
Ladder	71.58 (± 1.6)	72.04 (± 0.7)
MT_simple	73.91 (± 3.4)	66.27 (± 1.9)
MT_custom	68.14 (± 4.3)	64.04 (± 3.8)

Table 2: Overall Accuracies (mention–based)

Label Propagation (LP): We used the implementation available in the `scikit-learn` package of the LP algorithm (Zhu and Ghahramani, 2002).[6] In each bootstrapping epoch, we run LP, select the entities with the lowest entropy, and add them to their top category. Each entity is represented by a feature vector that contains the co-occurrence counts of the entity and each of the patterns that matches it in text.[7]

Settings: For each entity mention, we consider a n-gram window of size 4 on either side as a pattern. We initialized the mention and contexts embeddings input to either the ladder network or the mean teacher as well as the baseline systems with pre-trained embeddings from Levy and Goldberg (2014b) (size 300d) as this gave us improved results on the baseline compared to vanilla `word2vec` initialization. We used a 600d dimensional embedding for each datapoint (300 each from entity and context concatenated). We used a 3-layer ladder network with dimensions 600-500-K where K is the number of labels present in the dataset. Further, we used a noise of 0.3 for the corrupted encoder and reconstruction cost for the 3-layers were 1000-10-0.1. In the custom embeddings architecture of the mean teacher framework we used an bi-directional LSTM of size 200d on the entities and the each of the patterns in the context. The hidden size of fully connected layer was set to 300. We used a random word dropout of size 1 on the patterns to be input to the student and the teacher. Following Tarvainen and Valpola (2017), in the MT runs, we set the consistency cost weight to 1 and consistency-rampup to 5. We set the supervised examples (mentions along their corresponding contexts and labels) randomly. For CoNLL we used 40 and Ontonotes 440 examples, with equal representation from their labels' set.

Note that both MT and LN classify individual mentions, whereas Emboot and the two baselines classify entities. To facilitate the comparison between MT and LN and the baselines, for MT and LN we generate entity-level predictions by averaging the scores of the top predictions of all mentions corresponding to the same entity, and then select the label with the highest score for each entity. Further, to create the precision/throughput curves we we sorted the predictions returned by the LN and MT in decreasing order of their activation scores, and introduce multiple cutout thresholds to generate the precision/throughput points for the curves. We ran the baselines until they predicted labels for all the entities. For the baselines, in each iteration we promoted 100 entities per category.[8]

To compare with the baselines, which classify entities rather than mentions, we sorted the predictions returned by the LN and MT in decreasing order of their activation scores and chose the most confident entity label (when all its mention scores were averaged). For each of the LN and MT results, we report averaged results of 5 random runs (along with the standard deviation).

7.2 Results and Observations

Tables 1 and 2 shows the overall accuracies of the various systems on entity-based and mention-based evaluations, respectively. The key observation is that there is a consistent improvement in performance in approaches that are based on representation learning (namely, Emboot [9], LN and MT) on both datasets compared to traditional bootstrapping techniques (EPB and LP). Furthermore, we observe that one-shot learning systems such as Ladder and MT have a clear edge over the embedding based iterative

[6] `http://scikit-learn.org/stable/modules/generated/sklearn.semi_supervised.LabelPropagation.html`

[7] We experimented with other feature values, e.g., pattern PMI scores, but all performed worse than raw counts.

[8] We also ran a cautious approach of promoting 10 entities per category per iteration and noticed that the former had slightly better performance.

[9] Note: The Emboot results are for 20 epochs only. As running more number of epochs to cover the entire dataset does not complete even after a long time and sometimes results in memory overflow in the current implementation.

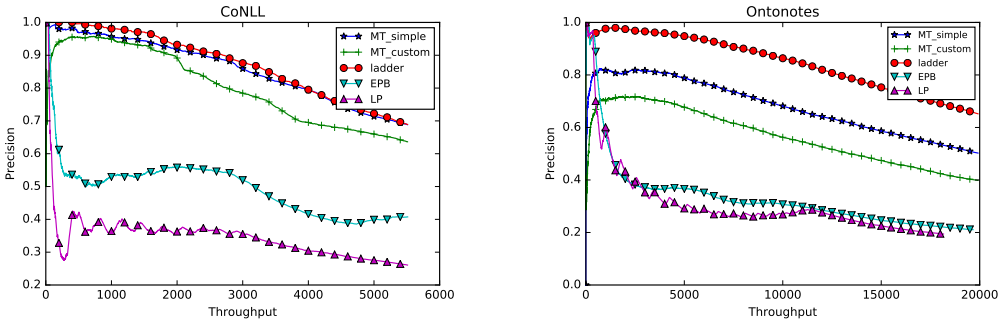

Figure 3: Overall results on the CoNLL (left) and Ontonotes (right) datasets. Throughput is the number of entities classified, and precision is the proportion of entities that were classified correctly.

bootstrapping (Emboot). To our knowledge, the results in Table 2 are the new state of the art for this semi-supervised NEC task.

While MT and LN outperform Emboot on both datasets, it is yet not fully clear why. As mentioned, MT and LN use one-shot learning whereas Emboot is iterative and, thus, more prone to semantic drift. However, a second potential cause for this difference is that MT and LN assemble their input representation from word-level embeddings, whereas Emboot learns from scratch embeddings for atomic entities and patterns, which forces it to work with sparser information. We leave this analysis, as well as efforts to align these three frameworks more closely, as future work.

Figure 3 shows the precision vs. throughput curves for the baselines, LN and MT approaches. We see that on both the datasets the one-shot learning methods outperform the iterative baselines by a large margin. Further we notice that both LN and MT variants are reasonably stable for most of the curve whereas EPB degrades quickly. Bootstrapping systems inherently suffer from semantic drift: as the iterations progress the system begins to drift into a different semantic space due to incomplete statistics and ambiguity (Komachi et al., 2008).

MT outperforms slightly LN on the CoNLL dataset, whereas LN performs better than MT on OntoNotes. We speculate that the latter result is caused by the fact that the space of hyper parameters were not sufficiently explored in the MT framework. For example, we ran LN for approximately 200 iterations, and we ran the MT experiments for 20 epochs. We will investigate a larger hyper parameter space in future work. However, the comparable performance of the two approaches is an encouraging result for MT, which is the simpler architecture of the two. With MT, we can "plug in" any task simply by generating a different input vector X (and, potentially, a different scheme to insert noise), whereas LN requires an adaptation of the entire architecture due to the tight connections between teacher and student.

Qualitative analysis: In Figure 4, we plot the t-SNE (van der Maaten and Hinton, 2008) projections of the learned custom embeddings from the MT framework. We contrast these projections with the t-SNE projections of the entities constructed by averaging the vectors present in the entity tokens, as provided by the pre-trained embeddings we used to initialize the various models. It is interesting to note that we can see clear clustering of the entities in both datasets for MT. The number of clusters is roughly equal to the number of classes present in the datasets. This is especially accentuated on the OntoNotes dataset.Upon closer observation on a small number of data points, we could ascertain that the clusters were semantically meaningful. On the other hand, we do not see such a clustering of the pre-trained embeddings (word2vec). This opens the gates for further investigation of these custom embeddings to construct interpretable deep learning models.

Amount of training data vs. accuracy: Table 3 lists the accuracies of LN and MT_simple approaches on all the data points, as we varied the amount of supervision. As expected, as we increase the amount of supervision, we observe improvements in accuracy. More importantly, the table shows both LN and MT outperform the overall accuracy of EPB (right-most points in Figure 3) with much fewer annotations (e.g., with 55 annotations in OntoNotes, LN and MT outperform the performance of EPB with 550

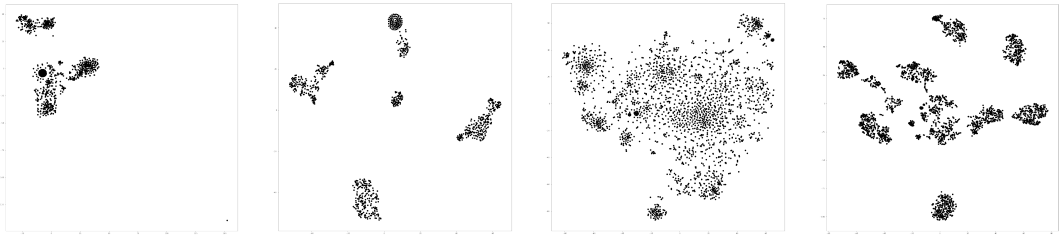

Figure 4: t-SNE projections of the learned embeddings of four models: (i) pre-trained word2vec on the CoNLL dataset; (ii) the custom MT model on CoNLL; (iii) pre-trained word2vec on OntoNotes; (iv) custom MT on OntoNotes.

annotated examples).

8 Conclusion

To our knowledge, this is the first work that rigorously analyzes several recent semi-supervised representation-learning approaches in the context of an information extraction task – named entity classification, in particular. To achieve this, we adapted two teacher-student methods that were initially proposed for image processing to the named entity classification task, and compared them against an iterative representation learning that learns custom embeddings for the underlying data, as well as other semi-supervised learning approaches that do not rely on representation learning. Our analysis, which was performed on two NEC datasets, highlighted several important observations, which, we believe, should inform the design of future semi-supervised IE systems. First, all representation learning methods investigated outperform state-of-the-art semi-supervised methods that do not rely on representation learning. Second, one-shot learning methods outperform iterative approaches, which suggests that one-shot learning is a practical solution to control for semantic drift. Third, the mean teacher framework performs comparatively similar to ladder networks, despite its simplicity and independence of the underlying task-specific model. These results advocate for a modular take on semi-supervised IE, where the learning is performed by a generic MT framework, which is then extended for specific tasks through independent components that model the corresponding data and task.

As part of future work, we would like to explore other tasks such as fine-grained entity typing, where the number of labels are an order of magnitude larger. Further, another interesting avenue for further research is to perform semi-supervised relation extraction, which is a significantly more challenging task and would be greatly benefited by such techniques.

Abstract

This survey discusses how recent developments in multimodal processing facilitate conceptual grounding of language. We categorize the information flow in multimodal processing with respect to cognitive models of human information processing and analyze different methods for combining multimodal representations. Based on this methodological inventory, we discuss the benefit of multimodal grounding for a variety of language processing tasks and the challenges that arise. We particularly focus on multimodal grounding of verbs which play a crucial role for the compositional power of language.

Title and Abstract in German

Multimodale konzeptuelle Verankerung für die automatische Sprachverarbeitung

Dieser Überblick erörtert, wie aktuelle Entwicklungen in der automatischen Verarbeitung multimodaler Inhalte die konzeptuelle Verankerung sprachlicher Inhalte erleichtern können. Die automatischen Methoden zur Verarbeitung multimodaler Inhalte werden zunächst hinsichtlich der zugrundeliegenden kognitiven Modelle menschlicher Informationsverarbeitung kategorisiert. Daraus ergeben sich verschiedene Methoden um Repräsentationen unterschiedlicher Modalitäten miteinander zu kombinieren. Ausgehend von diesen methodischen Grundlagen wird diskutiert, wie verschiedene Forschungsprobleme in der automatischen Sprachverarbeitung von multimodaler Verankerung profitieren können und welche Herausforderungen sich dabei ergeben. Ein besonderer Schwerpunkt wird dabei auf die multimodale konzeptuelle Verankerung von Verben gelegt, da diese eine wichtige kompositorische Funktion erfüllen.

1 Introduction

Natural languages are continually developing constructs that include numerous variations and irregularities. Modeling the subtleties of language in a formal, processable way has driven computational linguistics for decades. In recent years, distributional approaches have become the most widely accepted solution to model the associative character of word meaning (Harris, 1954; Collobert et al., 2011; Mikolov et al., 2013; Pennington et al., 2014). These approaches learn word representations in a high-dimensional vector space based on context patterns in large text collections. Machine learning researchers aim at reducing external knowledge to an absolute minimum and simply interpret language as a continuous stream of characters. From an engineering perspective, these data-driven approaches are highly attractive because they reduce the need of domain experts.

From a cognitive perspective, processing language in isolation without information on situational context seems to be an overly artificial setup. Human acquisition of semantic representations does not occur based on pure language input. The term conceptual grounding refers to the idea that language is

(a) Cross-modal transfer. Information from modality A is aligned to comparable information in B.

(b) Cross-modal interpretation. Relevant information in modality A is summarized and interpreted in modality B.

(c) Joint multimodal processing. Left: Modality A and B both contribute to a joint prediction. Right: Interactive exchange of information between modalities.

Figure 1: Information flow in multimodal tasks. Blue and yellow shapes refer to modality A and B.

grounded in perceptual experience and sensorimotor interactions with the environment (Barsalou, 2008). In its strictest interpretation, this embodied perspective implies that language production and language comprehension involve perceptual and motor simulations of the described situation (Goldman, 2006). An impressive number of recent neuroimaging studies indicate that processing a word activates areas in the brain that correspond to the associated sensory modality of its semantic category: action-related words like *kick* trigger activity in the motor cortex and object-related words like *cup* activate visual areas (Pulvermüller et al., 2005; Garagnani and Pulvermüller, 2016). While it remains a controversial question to what extent conceptual representations are actually shared across modalities (Louwerse, 2011; Leshinskaya and Caramazza, 2016), it has been widely accepted that conceptual and sensorimotor representations are tightly coupled and interact with each other. Cognitively plausible language processing should thus interpret language as one modality within a multimodal environment.

This survey discusses how recent developments in multimodal processing facilitate conceptual grounding of language. It intents to provide a bridge between the field of multimodal machine learning (Baltrušaitis et al., 2017) and the cognitive theories for grounding distributional semantics (Baroni, 2016). As this is a wide interdisciplinary topic which influences many subfields, we focus on multimodal grounding for computational linguistics. For a better understanding of the interaction between modalities, we categorize multimodal tasks according to the information flow between the modalities. In a second step, we analyze different methods for combining multimodal information. Based on this methodological inventory, we discuss the benefit of multimodal grounding for a variety of language processing tasks. In multimodal processing, grounding is usually limited to concrete concepts leading to a reduction of referential ambiguity. We provide a detailed analysis of the challenges that arise when multimodal grounding is extended to open-domain language settings. We particularly focus on multimodal grounding of verbs which is essential for the interpretation of sequences and the identification of relations between concepts.

2 Multimodal processing models

The term "multimodal" has been used in a broad range of different interpretations even in the computational linguistics literature alone. In the common interpretation, modalities refer to sensory input such as audio, vision, touch, smell, and taste. Other definitions stretch over different communicative channels such as language and gesture, or simply different "modes" of the same modality (e.g., day and night pictures). In this section, we analyze the flow of multimodal information in different multimodal tasks exemplified by three modalities: natural language encoded as texts, visual signals encoded as images or videos, and audio signals encoded as sound files. For an overview of the challenges and machine learning methods associated with each task, the interested reader is referred to Baltrušaitis et al. (2017). We propose a classification of multimodal tasks with respect to the information flow between modalities into cross-modal transfer, cross-modal interpretation, and joint multimodal processing. From a historical perspective, progress in multimodal processing can be aligned with cognitive theories of multimodal organization in the human brain.

2.1 Cross-modal transfer

In the 1980s and 90s, cognitive processing theories were heavily influenced by the theory of the modularity of mind (Fodor, 1985). It assumes that processing occurs in domain-specific encapsulated modules

that do not interact with each other. Earlier approaches to multimodal engineering have taken a similar modular perspective. They model the information flow in each modality separately and the final outcome is then transferred or aligned to another modality. We group tasks in which one modality serves as the interface to query or represent the content from another modality under the category of cross-modal transfer, see Figure 1a.

A classical example for cross-modal transfer are search and retrieval tasks. The human user provides a natural language description to query an artifact (i.e., an image, video, or audio file) from a database (Atrey et al., 2010). The cross-modal alignment between the query and the artifact requires query expansion and disambiguation for referential indexing. In speech-related transfer tasks, textual content needs to be mapped to audio samples. Speech synthesis transforms text into artificially generated phonemes for users who cannot read (Zen et al., 2009). The reverse task of transcribing audio and video content is addressed by approaches for speech recognition (Juang and Rabiner, 2005) and subtitle generation (Daelemans et al., 2004). For lipreading tasks, mute video input of people speaking is transformed into text representing their utterances (Ngiam et al., 2011).

In these cross-modal transfer tasks, synchronous processing of the input in one modality is not directly influenced by information from the output modality. The main challenge lies in finding appropriate translations or alignments from one modality to the other. Information from the output modality is mainly used for reranking of input hypotheses. This view corresponds to mental models of a language hub in the brain that does not directly incorporate perceptual information (Chomsky, 1986).

2.2 Cross-modal interpretation

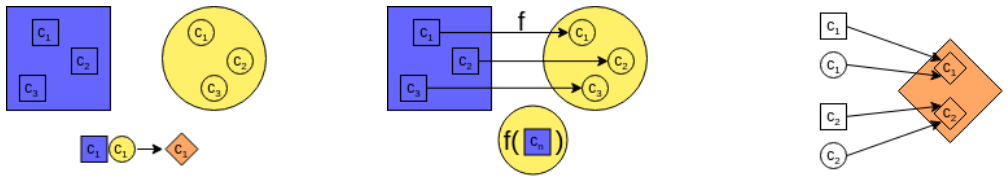
In order to explain how humans can select relevant information from perceptual input, the concept of attention has become very popular. Bridewell and Bello (2016) argue that attention serves as "a bottleneck for information flow in a cognitive system" that redirects mental resources. In multimodal processing, the concept of attention as a mediator between modalities is relevant for cross-modal interpretation. For these tasks, the goal is to obtain a compressed and structured intermediate representation of the input to generate a useful interpretation in the target modality. Attention mechanisms (Bahdanau et al., 2014) are used for the identification of relevant information, see Figure 1b.

A textual interpretation of a visually presented scene is generated in image captioning (Xu et al., 2015) and sketch recognition (Li et al., 2015). The goal is to identify relevant elements, group individual elements to semantic concepts, identify relations between concepts, and express these relations in natural language. The output sequence is generated while paying attention to different salient areas in the image. To our knowledge, a bidirectional information flow that includes cues from the language generation module in the image recognition process has not yet been implemented. However, semantic information could help to better direct the attention for image recognition, e.g., the generation of a verb like *eat* could constrain the visual recognition to edible objects as filler roles. Yatskar et al. (2016) propose the task of situation recognition to approximate this problem.

Complementary approaches attempt to generate visual representations to summarize documents and present the most relevant information in an intuitive way (Kucher and Kerren, 2015). The most popular approach are so-called word clouds which are frequency-based visualizations for topic modeling (Bateman et al., 2008). More recent approaches include semantic relations between words for a more conceptual-driven interpretation (Xu et al., 2016). Concept maps highlight structural relations between concepts in a graph-based visualization (Zubrinic et al., 2012). One key challenge for cross-modal interpretation tasks lies in the evaluation of the output because interpretations are by definition subjective and divergent solutions can be equally valid. Accumulations over various human ratings are currently considered to be better quality approximations than any automatic metrics (Vedantam et al., 2015).

2.3 Joint multimodal processing

Due to a wave of experimental findings that support the cognitive theory of embodied processing, the separating aspects between different modalities have become blurred (Pulvermüller et al., 2005). A similar development can be observed in multimodal machine learning. Tasks which explicitly require the combination of knowledge from different modalities gave rise to joint multimodal processing (Figure 1c). For



(a) Multimodal fusion. Concatenate known representations from modality A and B and apply dimensionality reduction.

(b) Mapping. Learn a mapping function f from modality A to B that can be applied on unknown concepts c_n.

(c) Joint learning. Optimize two objectives simultaneously: quality of unimodal representations and cross-modal alignment.

Figure 2: Methods for learning multimodal representations. Blue and yellow shapes indicate the representation space of modality A and B.

emotion recognition (Morency et al., 2011) or persuasiveness prediction (Santos et al., 2016), the actual content of an utterance and paraverbal cues (e.g., pitch, facial expression) need to be jointly evaluated. An ironic tone of voice might reverse the conceptual interpretation of the language content.

Recent work from the vision community goes one step further and tackles tasks that imperatively require an interactive flow of information. In visual question answering, a human user can ask questions about an image that the system should answer (Malinowski et al., 2015). This requires several steps: understanding the question, determining the salient elements in the image, interpreting the image with respect to the question, and generating a coherent natural language answer that matches the question. For this task, exchange of information between the modalities is crucial. In an overview, Wu et al. (2017) compare 29 approaches to visual question answering. 23 of these approaches use a joint representation of textual and visual information. The remaining 6 approaches organize the exchange either through a coordinated network architecture or through shared external knowledge bases. Novel interactive approaches make it possible to directly modulate the information flow in one modality by input from another modality (Vries et al., 2017) or by human feedback (Ling and Fidler, 2017).

The main challenge for joint processing lies in efficiently combining information from the modalities, so that redundant information is integrated without losing complementary cues. In human language understanding, this process seems to be performed in an effortless and highly accurate manner (Crocker et al., 2010). However, the underlying mechanisms of multimodal representations remain poorly understood. In Section 3, we discuss different methods for obtaining joint representations computationally.

3 Multimodal representation learning

Multimodal representations combine information from separate modalities. We discuss methods for representing known concepts, projecting information to represent unknown concepts, and for combining concept representations into compositional representations for sequences.

3.1 Concept representations

Even in unimodal tasks, researchers experiment with many different variations of representing concepts and their relations. Earlier work on multimodal representations used human-elicited visual features (Silberer and Lapata, 2012; Roller and Schulte Im Walde, 2013). Conveniently, integrating knowledge from different modalities has been facilitated due to the now common low-level representations of the input (also known as embeddings). Images are represented as groups of pixels, videos as series of image frames, audio data as windows of waveform samples, and language as sequences of distributional word representations. These values are then fed into a neural network that learns to compress and normalize the representation such that it better generalizes across input samples (Kiela and Bottou, 2014). A concept representation is usually obtained by averaging over many different samples for the concept (e.g., the concept *bird* is represented by averaging over the representation for n images showing a bird). The representations are expressed as high-dimensional matrices which can be projected into a common space. This approach facilitates a joint information flow between different modalities and has contributed to the growing success of multimodal processing.

Fusion The most intuitive approach is multimodal fusion (Figure 2a). Assuming that a unimodal vector representation v for the concept c and the modalities m_1 and m_2 exists, the multimodal representation v_{mm} consists of the concatenation $\frown$ of the two vectors weighted by a tunable parameter α:

$$v_{mm}(c) = \alpha \cdot v_{m_1}(c) \frown (1 - \alpha) \cdot v_{m_2}(c).$$

The concatenation occurs directly on the concept level and is thus called feature-level fusion or early fusion (Leong and Mihalcea, 2011; Bruni et al., 2011). In the case of pure concatenation, the unimodal representations reside in separate conceptual spaces. The concatenated representation for *cat* could give us the information that *cat* is visually similar to *panther* and textually similar to *dog*, but it is not possible to determine cross-modal similarity. In order to smooth the concatenated representations while maintaining multimodal correlations, dimensionality reduction techniques such as singular value decomposition (Bruni et al., 2014) or canonical correlation analysis (Silberer and Lapata, 2012) have been applied.

3.2 Projection

In practice, concepts that have a representation in one modality are not necessarily covered by representations in another modality. The projection of unseen concepts is known as zero shot learning. It can either be performed on a mapped or a joint representational space.

Mapping To overcome the lack of representations for one modality, several researchers proposed to map representations from one modality to the other (Figure 2b). The idea is to learn a mapping function f from m_1 to m_2 that maximizes the similarity between a known representation of c in m_2 and its projection from the representation in m_1: $c_{m_2} \sim f(c_{m_1})$.

The choice of the similarity and the loss measures for learning the mapping function vary. A max-margin optimization which maximizes the similarity between true pairs of concept representations (c_{m_1}, c_{m_2}) and minimizes the similarity for pairs with random target representations $(c_{m_1}, random_{m2})$ has been shown to be a good choice for image labeling (Frome et al., 2013). In this task, the mapping approach is applied in the image-to-text direction to classify unknown objects in images based on their semantic similarity to known objects (Socher et al., 2013) . Lazaridou et al. (2014) and Collell et al. (2017) proceed in the reverse text-to-image direction to ground words in the visual world. Similar propagation approaches had already been examined by Johns and Jones (2012) and Hill and Korhonen (2014), but they used human-elicited perceptual features from the McRae dataset (McRae et al., 2005) instead of automatically derived image representations.

Joint learning The mapping approaches assume a directed transformation from one modality to the other. Joint estimation approaches aim to learn shared representations instead (Figure 2b). An approach inspired by topic modeling interprets aligned data as a multimodal document and uses Latent Dirichlet Allocation to derive multimodal topics (Andrews et al., 2009; Feng and Lapata, 2010; Silberer and Lapata, 2012; Roller and Schulte Im Walde, 2013). Unfortunately, this approach cannot be easily used for zero shot learning. Lazaridou et al. (2015) enrich the skip-gram model by Mikolov et al. (2013) with visual features. Their model optimizes two constraints: the representation of concepts c with respect to their textual contexts (unsupervised skip-gram objective in m_1) and the similarity between word representations and their visual counterparts (supervised max-margin objective for (c_{m_1}, c_{m_2})). In their approach, the visual representations remain fixed, but the textual representations are learned from scratch. Silberer and Lapata (2014) go one step further and use stacked multimodal autoencoders to simultaneously learn good representations for each modality (unsupervised reconstruction objective for m_1 and m_2) and their optimal multimodal combination (supervised classification objective for (c_{m_1}, c_{m_2})). Both approaches implicitly also learn a mapping between the two modalities and can be adjusted to induce a directional projection for zero shot learning. Joint learning of multimodal representations is very popular in the vision community (Karpathy et al., 2014; Srivastava and Salakhutdinov, 2012; Ngiam et al., 2011).

3.3 Compositional representations

For tasks that require representing longer sequences, a naïve approach is sequence-level fusion. In this setting, the unimodal sequence representation is obtained by performing an arithmetic operation (e.g.,

average, max) over the concept representations for each word in the sequence. Multimodal fusion is then performed on this averaged representation (Glavaš et al., 2017; Bruni et al., 2014). Shutova et al. (2016) work with short phrases consisting of two words and directly learn phrase representations. Missing concept representations in one modality can be obtained by mapping functions (Botschen et al., 2018).

For image captioning approaches, representations for a pair of an image and the corresponding caption are learned jointly (Kiros et al., 2014; Socher et al., 2014). Pre-trained unimodal representations are fed into a neural network which is trained with the max-margin objective to distinguish between true and false captions for an image. The multimodal sequence representation can be obtained from the last hidden layer of the network. The introduction of attention variables can function as a mediator between the visual and the textual modality (see Section 2.2). For a more detailed overview of multimodal sequence representations in the vision community, the interested reader is referred to Wu et al. (2017). The approaches for compositional representations have focused on enriching noun and adjective meaning multimodally. The multimodal interpretation of verbs as an integral part of compositional sequences has not yet been thoroughly examined.

4 Multimodal grounding for language processing

The progress in joint multimodal processing and the increasing availability of multimodal datasets and representations open up new possibilities for grounded approaches to language processing. We review recent works for grounding concepts, grounding phrases, and grounding interaction. The challenges that arise from these efforts are discussed in Section 5.

4.1 Grounding concepts

Multimodal concept representations are motivated by the idea that semantic relations between words are grounded in perception. Being able to assess semantic relations between concepts is an important prerequisite for modeling generalization capabilities in language processing. The combination of the textual and the visual modality has received most attention for conceptual grounding, but perceptual information from the auditory and the olfactory channel have also been used for dedicated tasks (Kiela et al., 2015; Kiela and Clark, 2017). In order to provide a more concrete discussion, we focus on the combination of textual and visual cues for the remainder of the survey.

The quality of concept representations is commonly evaluated by their ability to model semantic properties. Different approaches to learning conceptual models are compared by their performance on similarity datasets, e.g., *WordSim353* (Finkelstein et al., 2002), *SimLex-999* (Hill et al., 2015), *MEN* (Bruni et al., 2012), *SemSim*, and *VisSim* (Silberer and Lapata, 2014)). These datasets contain pairs of words that have been annotated with similarity scores for the two concepts. Several evaluations of semantic models have shown that multimodal concept representations outperform unimodal ones (Feng and Lapata, 2010; Silberer and Lapata, 2012; Bruni et al., 2014; Kiela et al., 2014). Kiela et al. (2016) perform a comparison of different image sources and architectures and their ability to model semantic similarity. Despite the advantages of multimodal models in capturing semantic relations, it remains an open question whether they contribute to a cognitively more plausible approximation of human conceptual grounding. Bulat et al. (2017b) and Anderson et al. (2017) conduct experiments to label brain activity scans by human subjects with the corresponding concepts that elicited the brain activity. They compare different distributional semantic models and obtain mixed results. Bulat et al. (2017b) find that visual information is beneficial for modeling concrete words, whereas Anderson et al. (2017) conclude that textual models sufficiently integrate visual properties. Further interdisciplinary research involving computer science, neuroscience, and psycholinguistics is required to obtain a deeper understanding of cognitively plausible language processing (Embick and Poeppel, 2015).

4.2 Grounding phrases

Most experiments for conceptual grounding indicate that providing a multimodal representation for abstract concepts is significantly more challenging due to the lack of perceptual patterns associated with abstract words (Hill et al., 2014). For grounding phrases, the meaning for concrete and abstract concepts

need to be combined (see Section 3.3). Bruni et al. (2012) examine the compositional meaning of color adjectives and find that multimodal representations are superior in modeling color. However, they fail to distinguish between literal and non-literal usage of color adjectives (e.g., *green cup* vs *green future*).

Vivid imagery and synaesthetic associations play an important role in the interpretation of figurative language. In their influential theory of metaphor, Lakoff and Johnson (1980) argue that abstract concepts can be grounded metaphorically in embodied and situated knowledge. They assume that metaphors can be understood as a mapping from a concrete source domain to a more abstract target domain. For example, *time* is often viewed as a *stream* that *flows* in a direction. Turney et al. (2011) operationalize this theoretical account by identifying metaphoric phrases based on the discrepancy in concreteness of source and target term. Shutova et al. (2016) and Bulat et al. (2017a) build on their approach and use multimodal models for identifying metaphoric word usage in adjective-noun combinations. They show that words used in a metaphorical combination (*dry wit*) exhibit less similarity than words in non-metaphorical phrases (*dry skin*). We strongly believe that progress in multimodal compositional grounding will pave the way for a more holistic understanding of figurative language processing. As a prerequisite, multimodal grounding needs to be examined beyond the representation of concrete objects (see Section 5.2). Representing verbs, compositional phrases, and even full sentences by means of multimodal information has not yet been sufficiently examined.

4.3 Grounding interaction

The origins of grounding theories were initiated to account for situational language use and interaction. We distinguish two main scenarios for interactive language use: language learning and situational grounding of action descriptions.

Grounded language learning Language learning is deeply rooted in social interaction and initially emerges with respect to a concrete referential context (Tomasello, 2010). Children acquire language in interaction with their parents and foreign language learning proceeds much faster in an environment that forces the learner to interact in the foreign language (Nation, 1990). Usage-based approaches to language learning that account for the frequency and the quality of the language stimulus have a long tradition (Dale and Chall, 1948). Brysbaert and New (2009) have shown that frequency information grounded in auditory and visual communicative cues can better model human processing effects than frequency information extracted from purely textual corpora. Lazaridou et al. (2016) show that a multimodal distributional approach better approximates word learning from interactive child-directed input than unimodal approaches. The same model can also convincingly simulate word meaning induction by adults (Lazaridou et al., 2017a). Psycholinguistic research indicates that conceptual mapping modulated by visual properties is not only relevant for first language acquisition, but is also used as a means to establish cross-lingual links in foreign language learning (Beinborn et al., 2014). Bergsma and Van Durme (2011) and Vulić et al. (2016) take advantage of this observation and use multimodal representations to induce multilingual representations.

Grounding sequences in actions Situational grounding of action descriptions requires the representation of sequences and their compositional interpretation. Regneri et al. (2013) build a corpus that grounds descriptions of actions in videos showing these actions. For the interpretation of sequences, evaluating verbs and their arguments plays a fundamental role. Yatskar et al. (2016) developed the *imSitu* dataset which consists of images depicting verbs and annotations which link the verb arguments to visual referents. This dataset can be used for the multimodal task of situation recognition (Mallya and Lazebnik, 2017; Zellers and Choi, 2017), and it serves as a multimodal resource for verb processing. Grounding verbs is particularly challenging because of the variety of their possible visual instantiations. For example, an image of an adult drinking beer has very little in common with a zebra drinking water.

Multimodal interpretation of sequences is highly relevant for robotics research (Chaplot et al., 2017). Mordatch and Abbeel (2017) examine the emergence of compositionality in grounded multi-agent communication. The language learned by artificial agents is not necessarily interpretable by humans. Lazaridou et al. (2017b) show that agents which develop their own language for representing concepts that are grounded in images infer similar taxonomic relations as humans. Their work suggests that the learned

concepts can even be mapped back into natural language. Agent-agent communication has already been examined in the talking head experiments, in which two agents learn to discriminate between objects and develop their own language of referring expressions (Steels and Vogt, 1997; Steels, 2002). Hermann et al. (2017) and Heinrich and Wermter (2018) explicitly focus on human-robot interaction and train their agent to associate natural language descriptions of actions with perceptual input from its sensors.

For experiments on grounded language understanding, the situational environment is usually artificially restricted to a very small domain. This confined setting facilitates the analysis of compositional expressions and their referential interpretation as complex object descriptions or action sequences. In open-domain language understanding, semantic disambiguation is even more challenging. Approaches using multimodal information for the disambiguation of concepts (Xie et al., 2017), named entities (Moon et al., 2018), and sentences (Botschen et al., 2018; Shutova et al., 2017) show promising tendencies, but the underlying compositional principles are not yet understood.

5 Challenges for grounded language processing

Multimodal grounding of language has been a longstanding goal of language researchers. The discussion has gained new momentum due to the recent developments in learning distributed multimodal representations. Most evaluations indicate that multimodal representations are beneficial for a variety of tasks, but explanatory analyses of this effect are still in a developing phase. In this section, we discuss open challenges that arise from existing work. For future work, we propose to examine multimodal grounding beyond concrete nouns and adjectives. In order to do this, larger multimodal datasets encompassing a wider range of word classes need to be build. These datasets would enable us to analyze compositional representations in more detail and to develop more elaborate models of selective multimodal grounding.

5.1 Combining complementary information

Different modalities contribute qualitatively different conceptual information. Bruni et al. (2014) argue that highly relevant visual properties are often not represented by linguistic models because they are too obvious to be explicitly mentioned in text (e.g., birds have wings, violins are brown). Textual models, on the other hand, provide a better intuition of taxonomic and functional relations between concepts which cannot easily be derived from images (Collell and Moens, 2016). Ideally, multimodal representations should integrate the complementary perspectives for a more coherent grounded interpretation of language. From a more skeptical perspective, Louwerse (2011) states that perceptual information is already sufficiently encoded in textual cues. In this case, the superior performance of multimodal representations that has been established by several researchers would mainly be due to a more robust representation of highly redundant information. The results by Silberer and Lapata (2014) and Hill et al. (2014) support the intuitive assumption that textual representations better model textual similarity and visual representations better model visual similarity. As the multimodal models improve on both similarity tasks, the integration of complementary information seems to be successful. Interestingly, both evaluations show that simply concatenating the two modalities already yields a quite competitive model. The reported findings have been evaluated on models working with human-annotated perceptual features. These features inherently represent taxonomic knowledge that cannot be directly inferred from visual input. It remains an open question to which extent automatically derived image representations can contribute complementary information when combined with textual representations. Most multimodal research to date focuses on the representation of individual concepts (nouns) and their properties (adjectives). The benefit of multimodal representations for language tasks going beyond concept similarity needs to be examined in more detail from both, engineering and theoretical perspectives.

Multimodal grounding of verbs Verbs play a fundamental role for expressing relations between concepts and their situational functionality (Hartshorne et al., 2014). The dynamic nature of verbs poses a challenge for multimodal grounding. To our best knowledge, only Hill et al. (2014) and Collell et al. (2017) consider verbs in their evaluation. They report that results for verbs are significantly worse, but

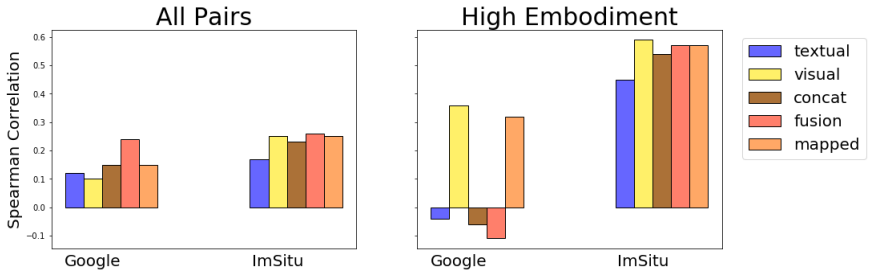


Figure 3: Illustration for the quality of verb representations indicated as Spearman correlation between the cosine similarity of verbs and their corresponding similarity rating in the *SimVerb* dataset.

do not elaborate on this finding. We present first steps towards an investigation of verb grounding.[1] Figure 3 illustrate the quality of verb representations in the most common publicly available approaches for multimodal representations. In line with previous work, the quality of the representations is evaluated as the Spearman correlation between the cosine similarity of two verbs and their corresponding similarity rating in the *SimVerb* dataset (Gerz et al., 2016). We compare the quality of 3498 verb pairs[2] in textual Glove representations (Pennington et al., 2014) and two visual datasets: the Google dataset that performed best in Kiela et al. (2016) and has the highest coverage for the verb pairs (493 pairs, 14%)[3] and the *imSitu* dataset which has been intentionally designed for verb identification (354 pairs, 10%). The results show that models which include visual information outperform purely textual representations for known concepts. However, the general quality of the verb representations is much lower than the quality reported for nouns. As a consequence, the mapping to unseen verb pairs yields unsatisfactory results for the full *SimVerb* dataset. Our encouraging results for the *imSitu* dataset indicate that it is recommended to directly obtain visual representations for verbs instead of projecting the meaning. Building larger multimodal datasets with a focus on verbs seems to be a promising strand of research for future work.

5.2 Imageability of abstract words

Conceptual grounding of language can be intuitively performed for concrete words that have direct referents in sensory experience. Bruni et al. (2014) and Hill and Korhonen (2014) show that multimodal representations are beneficial for evaluating concrete words, but have little to no impact on the evaluation of abstract words. Projecting unseen concepts into the representation space based on their relations to seen concepts in another modality provides an elegant method for zero shot learning, but it is questionable whether multimodal relations between concrete concepts are sufficient to infer relations between abstract concepts. Lazaridou et al. (2015) analyze projected abstract words by extracting the nearest visual neighbor from their multimodal representation. The neighbors were paired with random images and human raters judged how well each image represents the word. The hypothesis that concrete objects are more likely to be captured adequately by multimodal representations was confirmed. However, they also provide illustrating examples which represent abstract words like *together* or *theory* surprisingly well.

Embodiment of verbs From a multimodal perspective, verbs can be categorized according to their degree of embodiment. This measure indicates to which extent verb meanings involve bodily experience (Sidhu et al., 2014). We obtain embodiment ratings for 1163 pairs.[4] The class *high embodiment* contains pairs like *fall-dive* in which the embodiment of both verbs can be found in the highest quartile (135 pairs), *low embodiment* contains pairs with embodiment ratings in the lowest quartile (81 pairs) like *know-decide*.[5] Coherent with previous work on concrete and abstract nouns (Hill et al., 2014), it can be

[1]The pre-trained embeddings and the script to reproduce our results are available for research purposes: https://github.com/UKPLab/coling18-multimodalSurvey.

[2]Two pairs had to be excluded because *misspend* was not covered in the textual representations.

[3]The coverage in *WN9-IMG* (Xie et al., 2017) and the dataset used by Collell et al. (2017) is lower.

[4]`https://psychology.ucalgary.ca/languageprocessing/node/22`. We only include a pair, if an embodiment rating is available for both verbs.

[5]It should be noted that not all instances of the two classes are covered by the visual representations. The small number of instances might have an impact on the correlation values.

seen that visual representations better capture the similarity of verbs with a high level of embodiment. The mapped representations maintain this sense of embodiment, whereas the concatenated and fused representations better capture the similarity for verbs referring to more conceptual actions. This finding indicates that multimodal information is not equally beneficial for all words.

5.3 Selective multimodal grounding

The expressive power of language is essentially due to its combinatorial capabilities. Understanding how to combine concept representations to represent multi-word expressions or even full sentences has been a question of ongoing research in computational linguistics for decades. The inclusion of additional modalities further complicates this debate. Glavaš et al. (2017) and Botschen et al. (2018) obtain multimodal sentence representations by averaging over the multimodal representations for each word. They report improved results for the tasks of sentence similarity and frame identification. Our comparison above indicates that this superior performance is mainly due to a better representation of concepts. This raises the assumption that multimodal grounding should only be performed on selected words. Glavaš et al. (2017) propose to condition the inclusion of visual information on the prototypicality of a concept as measured by the image dispersion score (Kiela et al., 2014). This measure calculates the average pairwise cosine distance in a set of images to model the assumption that an image collection for an abstract concept like *happiness* is more diverse than for a concrete concept like *ladder*. Lazaridou et al. (2015) and Hessel et al. (2018) propose alternative concreteness measures based on the same idea. Unfortunately, these measures are highly dependent on the image retrieval algorithm which might be optimized towards obtaining a diverse range of images. Nevertheless, we assume that selective multimodal grounding constitutes a more plausible approach to sentence processing. Some functional words (e.g., locative expressions) might benefit from multimodal information, but it currently remains unclear how words with syntactic functions (e.g., coordinating expressions) should be represented visually.

6 Conclusion

We analyzed how multimodal processing has developed from transfer between encapsulated modalities to interactive processing over joint multimodal representations. These developments contribute to new avenues of research for grounded language processing. We strongly believe that the integration of multimodal information will improve our understanding of conceptual semantic models, figurative language processing, language learning, and situated interaction. Image datasets are often optimized towards providing a variety of visual instantiations. Developing algorithms for determining more prototypical visual representations could contribute to better grounding of verbs and might also serve as a criterion for selective multimodal grounding.

Acknowledgements

This work has been supported by the DFG-funded research training group "Adaptive Preparation of Information form Heterogeneous Sources" (AIPHES, GRK 1994/1) at Technische Universität Darmstadt. We thank Faraz Saeedan for his assistance with the computation of the visual embeddings for the imSitu images. We thank the anonymous reviewers for their insightful comments.

Abstract

Natural language inference (NLI) is the task of determining if a natural language hypothesis can be inferred from a given premise in a justifiable manner. NLI was proposed as a benchmark task for natural language understanding. Existing models perform well at standard datasets for NLI, achieving impressive results across different genres of text. However, the extent to which these models understand the semantic content of sentences is unclear. In this work, we propose an evaluation methodology consisting of automatically constructed "stress tests" that allow us to examine whether systems have the ability to make real inferential decisions. Our evaluation of six sentence-encoder models on these stress tests reveals strengths and weaknesses of these models with respect to challenging linguistic phenomena, and suggests important directions for future work in this area.

1 Introduction

Natural language inference (NLI), also known as recognizing textual entailment (RTE), is concerned with determining the relationship between a premise sentence and an associated hypothesis. This requires a model to make the 3-way decision of whether a hypothesis is true given the premise (*entailment*), false given the premise (*contradiction*), or whether the truth value cannot be determined (*neutral*). NLI has been proposed as a benchmark task for natural language understanding research (Cooper et al., 1996; Dagan et al., 2006; Giampiccolo et al., 2007; Dagan et al., 2013; Bowman et al., 2015; Nangia et al., 2017), due to the requirement for models to reason about several difficult linguistic phenomena[1] to perform well at this task (Bowman et al., 2015; Williams et al., 2017).

Due to its importance, significant prior work (Dagan et al., 2006; Dagan et al., 2009; Dagan et al., 2013; Marelli et al., 2014a) has focused on developing datasets and models for this benchmark task. Most recently, this task has been concretely implemented in the Stanford NLI (SNLI; Bowman et al. (2015)), and Multi-genre NLI (MultiNLI; Williams et al. (2017)) datasets, where crowdworkers are given a premise sentence and asked to generate novel sentences representing the three categories of entailment relations. Within the scope of these benchmark datasets, state-of-the-art deep learning-based sentence encoder models[2] (Nie and Bansal (2017), Chen et al. (2017), Conneau et al. (2017), Balazs et al. (2017), *inter alia*) have been shown to consistently achieve high accuracies, which may lead us to believe that these models excel at NLI across genres of text. However, machine learning models are known to exploit idiosyncrasies of how the data was produced, allowing them to imitate desired behavior using tricks such as pattern matching (Levesque, 2014; Rimell et al., 2009; Papernot et al., 2017). In NLI this arises when the test set contains many easy examples, and the extent to which difficult components of language understanding are required is masked within traditional evaluation. Therefore we ask a natural question:

*The first two authors contributed equally to this work.

[1]such as scope, coreference, quantification, lexical ambiguity, modality and belief.

[2]Sentence-encoder models are considered to be especially important to natural language understanding due to the requirement to represent sentences as fixed length vectors and perform reasoning based on these representations (Nangia et al., 2017). Thus, they will be our primary focus.

Proceedings of the 27th International Conference on Computational Linguistics, pages 2340–2353
Santa Fe, New Mexico, USA, August 20-26, 2018.

is good model performance on NLI benchmarks a result of sophisticated pattern matching, or does it reflect true competence at natural language understanding?

In this work, we propose an evaluation based on "stress" tests for NLI, which tests robustness of NLI models to specific linguistic phenomena. This methodology is inspired by the work of Jia and Liang (2017) (and other related work: §5), which proposes the use of adversarial evaluation for reading comprehension by adding a distracting sentence at the end of a paragraph (known as concatenative adversaries), and evaluating models on this test set. However, this evaluation scheme cannot easily be applied to NLI as i) the adversarial perturbations suggested are not *label preserving*, that is the semantic relation between premise and hypothesis will not be maintained by such edits, ii) the perturbations may decrease system performance but are not interpretable and iii) premise-hypothesis pairs in inference usually consist of a single sentence, but concatenative adversaries break this assumption. In addition, besides evaluating model robustness to *distractions* in the form of adversarial examples, we are also interested in evaluating model *competence* on types of reasoning necessary to perform well at the task.

The proposed method offers a fine-grained evaluation for NLI (with label-preserving adversarial perturbations when required), in the form of "stress tests". In the stress testing methodology, systems are tested beyond normal operational capacity in order to identify weaknesses and to confirm that intended specifications are being met (Hartman and Owens, 1967; Tretmans, 1999; Beizer, 2003; Pressman, 2005; Nelson, 2009). To construct these stress tests for NLI, we first examine the predictions of the best-performing sentence encoder model on MultiNLI (Nie and Bansal, 2017), and create a typology of phenomena that it finds challenging (§2). Based on this typology, we present a methodology to automatically construct stress tests, which may cause models that suffer from similar weaknesses to fail (§3). The resulting tests make it possible to perform evaluation on a phenomenon-by-phenomenon basis, which is not the case for Jia and Liang (2017).[3] We benchmark the performance of four state-of-the-art models on the MultiNLI dataset on our constructed stress tests (§4), and observe performance drops across stress tests. We view these results as a first step towards robust, fine-grained evaluation of NLI systems. To encourage development of models that perform true natural language understanding for NLI, we release our code and all stress tests for future evaluation. [4]

2 Weaknesses of State-of-the-art NLI

Before creating adversarial examples that challenge state-of-the-art systems, it is helpful to study what phenomena systems find difficult. To elucidate this, we conduct a comprehensive error analysis of the best-performing sentence encoder model for MutliNLI (Nie and Bansal, 2017). For this analysis, we sample 100 misclassified examples from both genre-matched and mismatched sets, analyze their potential sources of errors, and group them into a typology of common reasons for error.In the end, the reasons for errors can broadly be divided into the following categories,[5] with examples shown in Table 1:

1. **Word Overlap (29%)**: Large word-overlap between premise and hypothesis sentences causes wrong entailment prediction, even if they are unrelated. Very little word overlap causes a prediction of neutral instead of entailment.

2. **Negation (13%)**: Strong negation words ("no", "not") cause the model to predict contradiction for neutral or entailed statements.

3. **Antonymy (5%)**: Premise-hypothesis pairs containing antonyms (instead of explicit negation) are not detected as contradiction by the model.

4. **Numerical Reasoning (4%)**: For some premise-hypothesis pairs, the model is unable to perform reasoning involving numbers or quantifiers for correct relation prediction.

[3] Isabelle et al. (2017) have proposed a similar fine-grained evaluation approach for machine translation, but it requires the manual construction of examples, unlike our automatic approach.

[4] All stress tests and resources available at `https://abhilasharavichander.github.io/NLI_StressTest/`

[5] % indicates what proportion of examples from our error analysis on the matched development set, fall into each category. Results on the mismatched development set follow similar trends and are available in appendix A

Error	Premise	Hypothesis
Word Overlap (N→E)	And, could it not result in a decline in Postal Service volumes across–the–board?	There may not be a decline in Postal Service volumes across–the–board.
Negation (E→C)	Enthusiasm for Disney's Broadway production of The Lion King dwindles.	The broadway production of The Lion King is no longer enthusiastically attended.
Numerical Reasoning (C→E)	Deborah Pryce said Ohio Legal Services in Columbus will receive a $200,000 federal grant toward an online legal self-help center.	A $900,000 federal grant will be received by Missouri Legal Services, said Deborah Pryce.
Antonymy (C→E)	"Have her show it," said Thorn.	Thorn told her to hide it.
Length Mismatch (C→N)	So you know well a lot of the stuff you hear coming from South Africa now and from West Africa that's considered world music because it's not particularly using certain types of folk styles.	They rely too heavily on the types of folk styles.
Grammaticality (N→E)	So if there are something interesting or something worried, please give me a call at any time.	The person is open to take a call anytime.
Real World Knowledge (E→N)	It was still night.	The sun hadn't risen yet, for the moon was shining daringly in the sky.
Ambiguity (E→N)	Outside the cathedral you will find a statue of John Knox with Bible in hand.	John Knox was someone who read the Bible.
Unknown (E→C)	We're going to try something different this morning, said Jon.	Jon decided to try a new approach.

Table 1: Examples of misclassified samples for each error category (Gold Label→Predicted Label)

5. **Length Mismatch (3%)**: The premise is much longer than the hypothesis and this extra information could act as a distraction for the model.

6. **Grammaticality (3%)**: The premise or the hypothesis is ill-formed because of spelling errors or incorrect subject-verb agreement.

7. **Real-World Knowledge (12%)**: These examples are hard to classify without some real-world knowledge.

8. **Ambiguity (6%)**: For some instances, the correct answer is unclear to humans. These are the most difficult cases.

9. **Unknown (26%)**: No obvious source of error is discernible in these samples.

Some of our error categories such as real world knowledge are well-known "hard" problems. However, error categories such as negation scope and antonymy, are crucial for natural language understanding and been of significant interest to study in formal semantics (Kroch, 1974; Muehleisen, 1997; Murphy, 2003; Moscati, 2006; Brandtler, 2006). Some of these phenomena have long been suspected to be challenging for entailment models (Jijkoun and De Rijke, 2006; LoBue and Yates, 2011; Roy, 2017). In fact, at roughly the same time as this submission, Gururangan et al. (2018) corroborate our findings by identifying lexical choice such as negation words, as well as sentence length as biasing factors in NLI datasets.

3 Stress Test Set Construction

While the error analysis is informative for Nie and Bansal (2017), performing a manual analysis for every system is not scalable. To create an automatically calculable proxy, we focus on automatically constructing large-scale datasets (*stress tests*), which test NLI models on phenomena that account for most errors in our analysis. In particular, we generate adversarial examples which test "word overlap", "negation", "length mismatch", "antonyms", "spelling error" and "numerical reasoning".[6]

[6]Notably, we focus only on "spelling error" for "grammaticality". We omit "real world knowledge" as it is not trivial to create a large dataset without human input, the "ambiguity" category because it is unreasonable that models can handle such cases, and the "unknown" category because it does not correspond to a particular phenomenon.

Error Cat.	Premise	Hypothesis
Antonyms	I love the Cinderella story.	I hate the Cinderella story.
Numerical Reasoning	Tim has 350 pounds of cement in 100, 50, and 25 pound bags	Tim has less than 750 pounds of cement in 100, 50, and 25 pound bags
Word Overlap	Possibly no other country has had such a turbulent history.	The country's history has been turbulent and true is true
Negation	Possibly no other country has had such a turbulent history.	The country's history has been turbulent and false is not true
Length Mismatch	Possibly no other country has had such a turbulent history and true is true and true is true and true is true and true is true and true is true	The country's history has been turbulent.
Spelling Errors	As he emerged, Boris remarked, glancing up at teh clock: "You are early	Boris had just arrived at the rendezvous when he appeared

Table 2: Example constructions from stress tests

We organize our stress tests into three classes, based on their perceived difficulty for the model. The first class (*competence tests*) evaluates the model's ability to reason about quantities and understand antonymy relations. The second class (*distraction tests*), estimates model robustness to shallow distractions such as lexical similarity or presence of negation words. This category contains "word overlap", "negation" and "length mismatch" tests. The final class (*noise tests*) checks model robustness to noisy data and consists of our "spelling error" test. Our adversarial construction uses three techniques: heuristic rules with external knowledge sources (for competence tests), a propositional logic framework (for distraction tests) and randomized perturbation (for noise tests). The following subsections describe our stress test construction, with examples shown in Table 2.

3.1 Competence Test Construction

Antonymy: For this construction, we consider every sentence from premise-hypothesis pairs in the development set independently. We perform word-sense disambiguation for each adjective and noun in the sentence using the Lesk algorithm (Lesk, 1986). We then sample an antonym for the word from WordNet (Miller, 1995). The sentence with the word substituted by its antonym and the original sentence become a new premise-hypothesis pair in our set. This results in 1561 and 1734 premise-hypothesis pairs for matched and mismatched sets respectively.

Substituting a word with its antonym may not always result in a contradiction [7] . Hence, three annotators were provided 100 random samples from the stress test set to evaluate for correctness. At least two annotators agreed on 86% of the labels being contradiction. We also evaluated grammaticality of our constructions, with at least two annotators agreeing on 87% being grammatical.

Numerical Reasoning: Creating a stress test for numerical reasoning is non-trivial as most of the MultiNLI development set does not involve quantities. Hence, we extract premise sentences from AQuA-RAT (Ling et al., 2017a), a dataset specifically focused on algebraic word problems along with rationales for their solutions. However, word problems from AQuA-RAT are quite complicated[8] and general-purpose NLI models cannot reasonably be expected to solve them.

To generate a reasonable set of premise sentences, we first discard problems which do not have numerical answers or have long rationales (>3 sentences) as such problems are inherently complex. We then split all problems into individual sentences and discard sentences without numbers, resulting in a set of 40,000 sentences. From this set, we discard sentences which do not contain at least one named entity (we consider "PERSON", "LOCATION" and "ORGANIZATION"), since such sentences mostly deal with abstract concepts.[9] This results in a set of 2500 premise sentences. For each premise, we generate entailed, contradictory and neutral hypotheses using heuristic rules:

[7] Consider examples of sentences with modalities, belief, conjunction or even conversational text such as *"They can change the tone of people's voice yes."*, *"They can change the tone of people's voice no."*, coreference, word substitution in metaphors or failure of word sense disambiguation.

[8] Including concepts such as probability, geometry and theoretical proofs.

[9] For example, "Find the smallest number of five digits exactly divisible by 22, 33, 66 and 44".

1. **Entailment:** Randomly choose and change one numerical quantity from the premise, prefixing it with the phrase "less than" or "more than" based on whether the new number is higher or lower.
2. **Contradiction:** Perform one of two actions with equal probability: randomly choose a numerical quantity from the premise and change it, or randomly choose a numerical quantity from the premise and prefix it with "less than/ more than" without changing it.
3. **Neutral:** Flip the corresponding entailed premise-hypothesis pair.
Using these rules, we generate a set of 7,596 premise-hypothesis pairs testing models on their ability to perform numerical reasoning. We further instruct three human annotators to evaluate 100 randomly sampled examples for difficulty, grammaticality and label correctness (since the labels are automatically generated). At least two annotators agreed with our generated label for 91% of the samples. Additionally, at least two annotators agreed on 92% of the examples being grammatical, and 98% being trivial numerical reasoning for humans.

3.2 Distraction Test Construction

This class includes stress tests for "word overlap", "negation" and "length mismatch", which test model ability to avoid getting distracted by simple cues such as lexical similarity or strong negation words. Models usually exploit such cues to achieve high performance since they have strong but spurious correlations with gold labels, but reliance on shallow reasoning can be used to distract models easily, as we demonstrate. We use a framework inspired by propositional logic to construct adversarial examples.

Propositional Logic Framework: Assume a premise p and a hypothesis h. For entailment, $(p \Rightarrow h) \implies (p \wedge True \Rightarrow h)$ since $(p \wedge True = p)$. Similarly for contradiction, $(p \Rightarrow\Leftarrow h) \implies (p \wedge True \Rightarrow \Leftarrow h)$ and if p and h are neutral, they remain neutral. In other words, if the premise or hypothesis is in conjunction with a statement that is independently true in all worlds, the entailment relation is preserved.

The next step is to construct such statements whose values are true in all worlds (*tautologies*). We then define stress test accuracy for NLI as :

$$Adv(a) = \frac{1}{|D_{test}|} \sum_{i \in D_{test}} \mathbb{1}\{f(p, h, a) = c_i\}$$

where a is an adversarial tautology which can be attached as a conjunction to either the premise or hypothesis without changing the relation. We use this framework to construct distraction tests for "word overlap", "negation" and "length mismatch". For all sets, we use simple tautologies, which do not contain words that share any topical significance with the premise or hypothesis.

A natural concern is that statements obtained from such constructions are unnatural (Grice, 1975), making the NLI task more difficult for humans. To study this, we run a human evaluation where three annotators are shown premise-hypothesis pairs from these sets and instructed to label the relation. On word overlap, we find the provided label has 91% agreement with the gold label. For length mismatch, the provided label has 85% agreement with gold. This is similar to the agreement reported in Williams et al. (2017), leading us to believe the constructed examples are not too unnatural or difficult. The constructions also remain grammatical; after annotating 100 samples from our adversarially generated set, only two were deemed ungrammatical, and both were because of reasons unrelated to our perturbations. Specific details for our sets are as follows:
Word Overlap: For this set, we append the tautology *"and true is true"* to the end of the hypothesis sentence for every example in the MultiNLI development set.
Negation: For this set, we append the tautology *"and false is not true"*, which contains a strong negation word (*"not"*), to the end of the hypothesis sentence for every example in the MultiNLI development set.
Length Mismatch: For this adversarial set, we append the tautology *"and true is true"* five times to the end of the premise sentence for every example in the MultiNLI development set. We modify the premise sentence in this case as we hypothesize that errors in this category mainly arise due to the premise sentence being unwieldy.

System	Original MultiNLI Dev		Competence Test			Distraction Test						Noise Test	
			Antonymy		Numerical	Word Overlap		Negation		Length Mismatch		Spelling Error

Table 3: Classification accuracy (%) of state-of-the-art models on our constructed stress tests. Accuracies shown on both genre-matched and mismatched categories for each stress set. For reference, random baseline accuracy is 33%.

3.3 Noise Test Construction

This class consists of an adversarial example set which tests model robustness to spelling errors. Spelling errors occur often in MultiNLI data, due to involvement of Turkers and noisy source text (Ghaeini et al., 2018), which is problematic as some NLI systems rely heavily on word embeddings. Inspired by Belinkov and Bisk (2017), we construct a stress test for "spelling errors" by performing two types of perturbations on a word sampled randomly from the hypothesis: random swap of adjacent characters within the word (for example, *"I saw Tipper with him at teh movie."*), and random substitution of a single alphabetical character with the character next to it on the English keyboard. For example, *"Agencies have been further restricted and given less choice in selecting contractimg methods"*.

4 Experiments

4.1 Experimental Setup

We focus on the following sentence-encoder models, which achieve strong performance on MultiNLI:
Nie and Bansal (2017) (NB): This model uses a sentence encoder consisting of stacked BiLSTM-RNNs with shortcut connections and fine-tuning of embeddings. It achieves the top non-ensemble result in the RepEval-2017 shared task (Nangia et al., 2017).
Chen et al. (2017) (CH): This model also uses a sentence encoder consisting of stacked BiLSTM-RNNs with shortcut connections. Additionally, it makes use of character-composition word embeddings learned via CNNs, intra-sentence gated attention and ensembling to achieve the best overall result in the RepEval-2017 shared task.
Balazs et al. (2017) (RiverCorners - RC): This model uses a single-layer BiLSTM with mean pooling and intra-sentence attention.
Conneau et al. (2017) (InferSent - IS): This model uses a single-layer BiLSTM-RNN with max-pooling. It is shown to learn robust universal sentence representations which transfer well across several inference tasks.
We also set up two simple baseline models:
BiLSTM: The simple BiLSTM baseline model described by Nangia et al. (2017).
CBOW: A bag-of-words sentence representation from word embeddings.

4.2 Model Performance on Stress Tests

Table 3 shows the classification accuracy of all six models on our stress tests and the original MultiNLI development set. We see that performance of all models drops across all stress tests. On competence stress tests, no model is a clear winner, with **RC** and **CH** performing best on antonymy and numerical reasoning respectively. On distraction tests, **CH** is the best-performing model, suggesting that their gated-attention mechanism handles shallow word-level distractions to some extent. Interestingly, our

BiLSTM baseline is the second-best model on two out of three distraction tests. On the noise test, **CH**, **RC** and both baselines **[BiLSTM;CBOW]** do not show much performance degradation, most likely due to the benefit of subword modeling via character-CNNs and the use of mean pooling. We further analyze model performance on each class of tests.

4.3 Model Competence

Model Performance on Antonymy: Table 3 shows that all models perform poorly on antonymy. **RC** achieves the best performance, with 36.4% and 32.8% on matched and mismatched sets respectively which is just higher than random performance. Our analysis shows that models tend to overpredict entailment (due to a high amount of word overlap in this test). This accounts for, on average, 86.4% and 87.6% of total errors on matched and mismatched sets.[10]

We study which antonym pairs are easy and difficult for models by examining the errors of the best and worst performing models on this test **[RC;CH]**. On 982 samples where both models fail, we find 617 unique antonym pairs, and on 171 samples where both models succeed, we find 84 unique antonym pairs. 89.8% of the "easy" and 57.2% of the "hard" antonym pairs appear in a contradiction relation within the training data, suggesting that models succeed on easy antonym-pairs seen in the training data but struggle to generalize.

We were also curious about error variation by antonym type. We randomly sample 100 examples where both models fail and 100 samples where both succeed, and manually annotate whether the antonym present was gradable, relational or complementary. Among successful examples, 99% are complementary antonyms with only one relational antonym. Amongst the failure cases, 20% are relational antonym pairs, 73% are complementary and 7% are gradable, suggesting that models find relational and gradable antonyms hard, but get complementary antonyms both right and wrong. Finally, we examine differences between models by analyzing examples classified correctly by the best model which are not handled by the worst. We find that antonym pairs recognized by the weaker model occur, on average, nearly twice as often in the training data as antonym pairs recognized by the stronger model, suggesting that **RC** is able to learn antonymy from fewer examples (though these examples must be present in training data).

Model Performance on Numerical Reasoning: Table 3 shows that all models exhibit a significant performance drop on numerical reasoning, with none achieving an accuracy better than random (33%). We analyze the predictions of the best and worst performing models on this test **[BiLSTM;NB]**. The biggest source of common errors for both models (1703 out of 4337 errors) is misclassifying neutral pairs as entailment, which arises because our construction technique flips entailed premise-hypothesis pairs to create neutral pairs, leading to high word overlap for neutral pairs. Our constructions also lead to high word overlap for contradiction pairs, leading to a large number of C-E errors for both models (1695 out of 4337 errors). Thus, 78.3% of all errors are caused due to the models falsely predicting entailment. Most of the remaining errors are caused by entailment examples containing the phrases "more than" or "less than" being incorrectly classified as contradiction. This behavior could arise as these phrases are often used by crowdworkers to create contradictory examples in the original MultiNLI data, fooling models into marking examples with this phrase as "contradiction" without reasoning about involved quantities. Our observations suggest that models do not perform quantitative reasoning, but rely on word overlap and other shallow lexical cues for prediction.

4.4 Model Distraction

Our distraction tests are designed to check model robustness to: 1) decreasing lexical similarity between premise-hypothesis pairs, 2) strong negation words in sentence pairs.

Effect of Decreasing Lexical Similarity: Due to our construction methodology (appending tautologies), accuracy on *word overlap* and *length mismatch* demonstrates the effect of decreasing lexical similarity

[10] Detailed results from this analysis are provided in appendix B

System	MultiNLI Dev		Word Overlap		Length Mismatch	
	Mat	Mis	Mat	Mis	Mat	Mis
NB	33.2	33.1	43.2	38.3	46.0	46.9
CH	32.9	31.7	84.7	85.3	65.8	65.8
RC	37.1	39.1	74.3	83.3	74.2	79.5
IS	34.7	31.4	86.3	87.0	43.5	44.2
BiLSTM	38.5	37.9	83.2	81.9	75.9	79.1
CBOW	33.9	30.2	74.5	72.3	54.7	59.9

Table 4: % of FALSE NEUTRAL in total errors on MultiNLI development set, word overlap test and length mismatch test.

System	BiLSTM		NB	
	Mat	Mis	Mat	Mis
MultiNLI Dev	70.2	70.4	66.6	66.6
NEGATION	68.9	70.4	49.3	48.7
DIFF TAUT	49.0	49.3	49.9	49.7

Table 5: Effect of training on distraction data on original DEV set, original distraction set and new distraction set

on model performance. Table 3, shows accuracy decreases for all models on both tests. This drop is lower for **CH**, suggesting that their gated attention mechanism might help in focusing on relevant parts of the sentence.

The significant decrease in accuracy indicates that lexical similarity is a strong signal for entailment prediction, failing which models default to predicting neutral. To provide further justification, we compare the proportion of false neutral errors for all models on word overlap and length mismatch stress sets vs. the original MultiNLI development set. As shown in Table 4, we find it increases for all models on both sets.

Effect of Introducing Strong Negation Words: Table 3 shows results on negation, and we see that all state-of-the-art models perform poorly, with accuracies decreasing by 23.4% and 23.38%, on average, on matched and mismatched sets respectively. However, comparing the number of E-C (entailment predicted as contradiction) and N-C (neutral predicted as contradiction) errors for these models on the negation test vs. the original MultiNLI development set, we do not find an increase in these error types on negation. Instead, we observe an increase in false neutral errors for all models. This could occur due to the introduction of extra words ("false", "is" and "true") apart from "not", indicating that decreasing lexical similarity has a stronger effect on models than introducing negation.

4.5 Effect of Noise

Our noise test results in Table 3 show that **NB** and **IS** exhibit a huge decrease in accuracy, since both models rely on word embeddings. Other models show little performance degradation on this test. **CH** performs subword modeling via character-level CNNs, which provides robustness towards perturbation attacks. **RC** and **BiLSTM** perform well despite relying on word embeddings since both use mean pooling, which might reduce the effect of single-word edits on the final representation. **CBOW** is also very robust to this test, which can arise from the fact that it sums word embeddings to create the final sentence embedding, diluting the effect of changing a single word on final model performance[11].

4.6 Training with Distraction

Finally, we study the effect of training with distractions generated via our adversarial construction. We generate an equivalent sample with the negation distraction for every sample in the training data, and retrain **NB** and **BiLSTM** on the union of these examples and original training data.

We observe the performance of the trained models on three tests: the original MultiNLI development set, the negation stress test and a new distraction test creating using a different tautology *"green is not red"* (DIFF TAUT). We observe that **NB** shows performance degradation across all tests, but training

[11] We analyze difference in model performance across perturbation techniques such as adjacent character swapping, keyboard character swapping, function word and content word perturbations, but do not observe significant differences. Results from these experiments are included in appendix C.

BiLSTM on distraction data helps it become robust to the tautology it was trained on. However, it collapses when evaluated on a different tautology. Ignoring such distractions is something humans do naturally. Models should not have to train on the specific distraction to succeed on this evaluation.

5 Related Work and Discussion

Adversarial evaluation schemes have been proposed to evaluate model robustness on various NLP tasks. Smith (2012) discuss dangers of community-wide "overfitting" to benchmark datasets and emphasize the need to correlate model errors to well-defined linguistic phenomena to understand specific model strengths and weaknesses. Prior work (Rimell et al., 2009; Schneider et al., 2017) performed analyses of model errors in dependency parsing and information extraction. Motivated by this desideratum, we analyze errors in Multi-Genre NLI and automatically construct large stress sets to evaluate NLI systems on identified difficulties. This is analogous to recent work (Jia and Liang, 2017; Burlot and Yvon, 2017) on developing automated adversarial evaluation schemes for reading comprehension and machine translation. However, unlike these efforts, our stress tests allow us to study model performance on a range of linguistic phenomena. Unlike work on manual construction of small adversarial evaluation sets for various NLP tasks (Levesque, 2014; Mahler et al., 2017; Staliūnaite and Bonfil, 2017; Isabelle et al., 2017; Belinkov and Bisk, 2017; Bawden et al., 2017), our work focuses on a more exhaustive large-scale evaluation for NLI. It is interesting to note that Bayer et al. (2006) discuss the daunting cost of finding entailment pairs for NLI evaluation, but our techniques can be used to construct such pairs with low cost.

The NLI task attracted significant interest before datasets became large enough for the application of neural methods (Glickman et al., 2005; Harabagiu and Hickl, 2006; Romano et al., 2006; Dagan et al., 2006; Giampiccolo et al., 2007; Dagan et al., 2010; MacCartney, 2009; Zanzotto et al., 2006; Malakasiotis and Androutsopoulos, 2007; Haghighi et al., 2005; Angeli and Manning, 2014). de Marneffe et al. (2009) analyze the effect of multi-word expressions and find that they do not significantly affect the performance of NLI systems. Perhaps the closest to our contribution are the works of Cooper et al. (1996), which manually constructs sentences containing phenomena that NLI systems are expected to handle (FraCaS), and Marelli et al. (2014b), which constructs sentences that require compositional knowledge (SICK). Our constructions differ from SICK and FraCaS in several aspects. Since we use large datasets (Williams et al., 2017; Ling et al., 2017b) as base data, our sets are larger and more lexically diverse than both SICK (which used a seed set of 1500 sentences) and FraCaS (which was manually constructed). Secondly, while SICK uses handcrafted rules and incorporates linguistic phenomena, sentence-pairs are not constrained to exhibit only one phenomenon, which may introduce confounding factors during analysis. Though FraCaS follows the constraint of restricting sentence-pairs to exhibit only one phenomenon, it contains very few examples of each phenomenon. Conversely, our techniques generate large evaluation sets, with each set focusing on a single phenomenon, providing a testbed for fine-grained evaluation and analysis. Lastly, our stress tests are grounded in failings of current state-of-the-art models, rather than on phenomena hypothesized to be challenging for NLI models. Our evaluation sets also differ from the small portion of the MultiNLI development set annotated for challenging linguistic phenomena, as similar to SICK, each sentence pair is not constrained to exhibit a single phenomenon. In addition, presence of biases in the MultiNLI development and test data (Gururangan et al., 2018; Poliak et al., 2018) could also lead to models exploiting them as shallow cues for prediction (for example, the performance of baseline models on the subset of the MultiNLI dataset annotated for antonymy averages 67% , while the same baselines perform much worse on our antonymy stress-test).

We hope that insights derived from our stress tests will stimulate future research in NLI. One promising direction would be the development and investigation of more linguistically-motivated neural models on NLI (such as models which incorporate explicit negation scope information or semantic roles for example), as our stress tests now provide a framework for in-depth analysis of model performance and demonstrate significant room for improvement in these areas. While we benchmark the performance of state-of-the-art models on our stress tests, in the future, it would be interesting to investigate which architectural choices contribute to model successes and *why*. Another interesting research direction is the identification of "core competencies", such as quantitative reasoning or antonymy, which can

enhance model performance across multiple NLP tasks such as sentiment analysis, question answering and relation extraction and studying transfer of representations from "competent" models.

6 Conclusion

In this work, we present a suite of large-scale stress tests to perform targeted evaluation of NLI models, along with a set of techniques for their automatic construction. Our stress tests evaluate a model's ability to reason about quantities and antonymy (*competence tests*), its susceptibility to shallow lexical cues (*distraction tests*) and its robustness to random perturbations (*noise tests*). We benchmark the performance of four state-of-the-art sentence encoding models on our tests and find that they struggle on many phenomena, despite reporting high accuracy on NLI.

Overall, we consider the MultiNLI dataset to be a valuable resource for the NLP community, with entailment pairs drawn from several different genres of text. However, we argue that the community would benefit by having NLI models pass sanity checks, in the form of "stress tests", to ensure models evolve against exploiting simple idiosyncrasies of training data. Similar to Isabelle et al. (2017), we intend our stress tests to supplement existing NLI evaluation rather than replace it. In the future, we hope benchmarking model performance on stress tests in addition to standard evaluation criteria will provide deeper insight into model strengths and weaknesses, and guide more informed model choices. We would also like to note that the "stress test" evaluation paradigm that we propose for NLI can be further updated in the future when new forms of models are devised, increasing the coverage of the tests to cover problems of future models as well. We release all our stress tests and associated resources to the community to promote work on models that get us closer to true natural language understanding.

Appendix A. Error Analysis on Mismatched Set

Table 6 describes what proportion of misclassified examples from the mismatched set fall into each error category, as defined in the typology presented in §2.

Appendix B. Error Types on Antonymy

The high amount of word overlap in this test causes models to overpredict entailment, accounting for, on average, 86.4% and 87.6% of total errors on matched and mismatched sets respectively. We present the exact proportion of False Entailment and False Neutral errors in Table 7. Keep in mind there is only one gold class in this category: contradiction.

As expected, all four models make a high amount of false entailment errors because they notice high amounts of lexical similarity between the premise and the hypothesis.

Error Category	% of Misclassified Examples
Word Overlap	28
Negation	12
Antonymy	4
Numerical Reasoning	4
Length Mismatch	6
Grammaticality	4
Real-World Knowledge	14
Ambiguity	8
Unknown	20

Table 6: Distribution of misclassified examples from the MultiNLI mismatched development set.

System	C-E Errors		C-N Errors

IS	99.40	99.81	0.60	0.19

Table 7: Percentage of C-E and C-N errors on antonymy test.

Appendix C. Additional Experiments with Spelling Error Stress Tests

This stress test consists of an adversarial example set which tests model robustness to spelling errors. Spelling errors occur often in MultiNLI data, due to involvement of Turkers and noisy source text, which is problematic as some NLI systems rely heavily on word embeddings. We construct a stress test for "spelling errors" by performing two types of perturbations:

AdjSWAP: Swap adjacent characters in a single word sampled randomly from the hypothesis. For example, *"I saw Tipper with him at teh movie."*.

KBSWAP: Substitute a single alphabetical character randomly sampled from the hypothesis with the character next to it on the English keyboard. For example, *"Agencies have been further restricted and given less choice in selecting contractimg methods."* We additionally perform perturbations on only function words (conjunctions, pronouns and articles), and on only content words (nouns and adjectives) in the hypothesis to study the effects. We do not address perturbations in verbs and adverbs in the content word vs. function word analysis. The results are presented in Table 8.

Sys	ADJ SWAP		KB SWAP		CN SWAP		FN SWAP	
tem	**Mat**	**Mis**	**Mat**	**Mis**	**Mat**	**Mis**	**Mat**	**Mis**
NB	43.0	42.9	47.7	47.9	51.1	49.8	49.7	49.6
CH	68.24	68.1	68.5	68.3	68.3	69.1	69.9	70.3
RC	66.6	66.4	67.0	66.8	66.6	67.0	68.4	68.4
IS	57.8	58.6	57.7	58.7	58.3	59.4	57.5	57.6

Table 8: Model Performance on grammaticality test

We observe that there is no significant effect of perturbing a function word or a content word. One hypothesis is that content words can often be named entities for which the models do not find word embeddings. We also do not find a considerable difference in performance between the different kinds of perturbations but this is expected behaviour as most models use word embeddings, and these will just be categorized as unknown words.

Grounded Textual Entailment

Abstract

Capturing semantic relations between sentences, such as entailment, is a long-standing challenge for computational semantics. Logic-based models analyse entailment in terms of possible worlds (interpretations, or situations) where a premise P entails a hypothesis H iff in all worlds where P is true, H is also true. Statistical models view this relationship probabilistically, addressing it in terms of whether a human would likely infer H from P. In this paper, we wish to bridge these two perspectives, by arguing for a visually-grounded version of the Textual Entailment task. Specifically, we ask whether models can perform better if, in addition to P and H, there is also an image (corresponding to the relevant "world" or "situation"). We use a multimodal version of the SNLI dataset (Bowman et al., 2015) and we compare "blind" and visually-augmented models of textual entailment. We show that visual information is beneficial, but we also conduct an in-depth error analysis that reveals that current multimodal models are not performing "grounding" in an optimal fashion.

1 Introduction

Evaluating the ability to infer information from a text is a crucial test of the capability of models to grasp meaning. As a result, the computational linguistics community has invested huge efforts into developing textual entailment (TE) datasets.

After formal semanticists developed FraCas in the mid '90 (Cooper et al., 1996), an increase in statistical approaches to computational semantics gave rise to the need for suitable evaluation datasets. Hence, Recognizing Textual Entailment (RTE) shared tasks have been organized regularly (Sammons et al., 2012). Recent work on compositional distributional models has motivated the development of the SICK dataset of sentence pairs in entailment relations for evaluating such models (Marelli et al., 2014). Further advances with Neural Networks (NNs) have once more motivated efforts to develop a large natural language inference dataset, SNLI (Bowman et al., 2015), since NNs need to be trained on big data.

However, meaning is not something we obtain just from text and the ability to reason is not unimodal either. The importance of enriching meaning representations with other modalities has been advocated by cognitive scientists, (e.g., (Andrews et al., 2009; Barsalou, 2010)) and computational linguists (e.g., (Glavaš et al., 2017)). While efforts have been put into developing multimodal datasets for the task of checking Semantic Text Similarity Text (Agirre et al., 2017), we are not aware of any available datasets to tackle the problem of Grounded Textual Entailment (GTE). Our paper is a first effort in this direction.

Textual Entailment is defined in terms of the likelihood of two sentences (a premise P and an hypothesis H) to be in a certain relation: P entails, contradicts or is unrelated to H. For instance, the premise "People trying to get warm in front of a chimney" and the hypothesis "People trying to get warm at home" are highly likely to be in an entailment relation. Our question is whether having an image that illustrates the event (e.g., Figure 1a) can help a model to capture the relation. In order to answer this

Correspondence should be addressed to Raffaella Bernardi (raffaella.bernardi@unitn.it) and Albert Gatt (albert.gatt@um.edu.mt).

 The dataset, annotation and code is available from https://github.com/claudiogreco/coling18-gte.

Proceedings of the 27th International Conference on Computational Linguistics, pages 2354–2368
Santa Fe, New Mexico, USA, August 20-26, 2018.

(a) P: *A family in front of a chimney* and H: *A family trying to get warm*

(b) P: *People trying to get warm* and H: *People are outside on a chilly day*. TE: unrelated vs. GTE: related

Figure 1: Premise, Hypothesis and Image examples

question, we augment the largest available TE dataset with images, we enhance a state of the art model of textual entailment to take images into account and we evaluate it against the GTE task.

The inclusion of images can also alter relations which, based on text alone, would seem likely. For example, to a "blind" model the sentences of the sentence pair in Figure 1b would seem to be unrelated, but when the two sentences are viewed in the context of the image, they do become related.

A suitable GTE model therefore has to perform two sub-tasks: (a) it needs to ground its linguistic representations of P, H or both in non-linguistic (visual) data; (b) it needs to reason about the possible relationship between P and H (modulo the visual information).

2 Related Work

Grounding language through vision has recently become the focus of several tasks, including Image Captioning (IC, e.g. (Hodosh et al., 2013; Xu et al., 2015)) and Visual Question Answering (VQA, eg. (Malinowski and Fritz, 2014; Antol et al., 2015)), and even more recently, Visual Reasoning (Johnson et al., 2017; Suhr et al., 2017) and Visual Dialog (Das et al., 2017). Our focus is on Grounded Textual Entailment (GTE). While the literature on TE is rather vast, GTE is still rather unexplored territory.

Textual Entailment Throughout the history of Computational Linguistics various datasets have been built to evaluate Computational Semantics models on the TE task. Usually they contain data divided into entailment, contradiction or unknown classes. The "unknown" label has sometimes been replaced with the "unrelated" or "neutral" label, capturing slightly different types of phenomena. Interestingly, the "entailment" and "contradiction" classes also differ across datasets. In the mid-'90s a group of formal semanticists developed FraCaS (Framework for Computational Semantics). (Cooper et al., 1996)[1] The dataset contains logical entailment problems in which a conclusion has to be derived from one or more premises (but not necessarily all premises are needed to verify the entailment). The entailments are driven by logical properties of linguistic expressions, like the monotonicity of quantifiers, or their conservativity property etc. Hence, the set of premises entails the conclusion iff in all the interpretations (worlds) in which the premises are true the conclusion is also true; otherwise the conclusion contradicts the premises. In 2005, the PASCAL RTE (Recognizing Textual Entailment) challenge was launched, to become a task organized annually. In 2008, the RTE-4 committee made the task more fine-grained by requiring the classification of the pairs as "entailment", "contradiction" and "unknown" (Giampiccolo et al., 2008). The RTE datasets, unlike FraCaS, contain real-life natural language sentences and the sort of entailment problems which occur in corpora collected from the web. Importantly, the sentence pair relations are annotated as entailment, contradiction or neutral based on a likelihood condition: if a human reading the premise would typically infer that the conclusion (called the hypothesis) is most likely true (entailment), its negation is most likely true (contradiction) or the conclusion can be either true or false (neutral).

At SemEval 2014, in order to evaluate Compositional Distributional Semantics Models focusing on the compositionality ability of those models, the SICK dataset (Sentences Involving Compositional Knowledge) was used in a shared entailment task (Marelli et al., 2014). Sentence pairs were obtained through

[1] A cleanly processable version of it has been made available only recently: `http://www-nlp.stanford.edu/~wcmac/downloads/fracas.xml`

re-writing rules and annotated with the three RTE labels via a crowdsourcing platform. Both in RTE and SICK the label assigned to the sentence pairs captures the relation holding between the two sentences.

A different approach has been used to build the much larger SNLI (Stanford Natural Language Inference) dataset (Bowman et al., 2015): Premises are taken from a dataset of images annotated with descriptive captions; the corresponding hypotheses were produced through crowdsourcing, where for a given premise, annotators provided a sentence which is true or not true with respect to a possible image which the premise could describe. A consequence of this choice is that the contradiction relation can be assigned to pairs which are rather unrelated ("A person in a black wetsuit is surfing a small wave" and "A woman is trying to sleep on her bed"), differently from what happens in RTE and SICK.

Since the inception of RTE shared tasks, there has been an increasing emphasis on data-driven approaches which, given the hypothesis H and premise P, seek to classify the semantic relation (see (Sammons et al., 2012) for a review). More recently, neural approaches have come to dominate the scene, as shown by the recent RepEval 2017 task (Nangia et al., 2017), where all submissions relied on bidirectional LSTM models, with or without pretrained embeddings. RTE also intersects with a number of related inference problems, including semantic text similarity and Question Answering, and some models have been proposed to address several such problems. In one popular approach, both P and H are encoded within the same embedding space, using a single RNN, with a decision made based on the encodings of the two sentences. This is the approach we adopt for our baseline LSTM in Section 4, based on the model proposed by Bowman et al. (2015), albeit with some modifications (see also (Tan et al., 2016)). A second promising approach, based on which we adapt our state of the art model, relies on matching and aggregation (Wang et al., 2017). Here, the decision concerning the relationship between P and H is based on an aggregate representation achieved after the two sentences are matched. Yet another area where neural approaches are being applied to sentence pairs in an entailment relationship is generation, where an RNN generates an entailed hypothesis (or a chain of such hypotheses) given an encoding of the premise (Kolesnyk et al., 2016; Starc and Mladenić, 2017).

Vision and Textual Entailment In recent years, several models have been proposed to integrate the language and vision modalities; usually the integration is operationalized by element-wise multiplication between linguistic and visual vectors. Though the interest in these modalities has spread in an astonishing way thanks to various multimodal tasks proposed, including the IC, VQA, Visual Reasoning and Visual Dialogue tasks mentioned above, very little work has been done on grounding entailment. Interestingly, Young et al. (2014) has proposed the idea of considering images as the "possible worlds" on which sentences find their denotation. Hence, they released a "visual denotation graph" which associates sentences with their denotation (sets of images). The idea has been further exploited by Lai and Hockenmaier (2017) and Han et al. (2017). Vendrov et al. (2016) look at hypernymy, textual entailment and image captioning as special cases of a single visual-semantic hierarchy over words, sentences and images, and they claim that modelling the partial order structure of this hierarchy in visual and linguistic semantic spaces improves model performance on those three tasks.

We share with this work the idea that the image can be taken as a possible world. However, we don't use sets of images to obtain the visual denotation of text in order to check whether entailment is logically valid/highly likely. Rather, we take the image to be the world/situation in which the text finds its interpretation. The only work that is close to ours is an unpublished student report (Sitzmann et al., 2016), which however lacks the in-depth analysis presented here.

3 Annotated dataset of images and sentence pairs

We took as our starting point the Stanford Natural Language Inference (SNLI) dataset (Bowman et al., 2015), the largest natural language inference dataset available with sentence pairs labelled with entailment, contradiction and neutral relations. We augmented this dataset with images. It has been shown very recently that SNLI contains language bias, such that a simple classifier can achieve high accuracy in predicting the three classes just by having as input the hypothesis sentence. A subset of the SNLI test set with 'hard' cases, where such a simplistic classifier fails (hereafter SNLI$_{hard}$) has been released (Gururangan et al., 2018). Hence, in this paper we will report our results on both the full dataset and the hard

test set, but then zoom in on SNLI$_{hard}$ to understand the models' behaviour. We briefly introduce SNLI and the new test set and compare them through our annotation of linguistic phenomena.

3.1 Dataset construction

SNLI and SNLI$_{hard}$ test set The SNLI dataset (Bowman et al., 2015) was built through Amazon Mechanical Turk. Workers were shown captions of photographs without the photo and were asked to write a new caption that (a) is definitely a true description of the photo (entailment); (b) might be a true description of the photo (neutral); (c) is definitely a false description of the photo (contradiction). Examples were provided for each of the three cases. The premises are captions which come mostly from Flickr30K (Young et al., 2014); only 4K captions are from VisualGenome (Krishna et al., 2017). In total, the dataset contains 570,152 sentence pairs, balanced with respect to the three labels. Around 10% of these data have been validated (4 annotators for each example plus the label assigned through the previous data collection phase). The development and test datasets contain 10K examples each. Moreover, each Image/Flickr caption occurs in only one of the three sets, and all the examples in the development and test sets have been validated.

V-SNLI and V-SNLI$_{hard}$ test set Our grounded version of SNLI, V-SNLI, has been built by matching each sentence pair in SNLI with the corresponding image coming from the Flickr30K dataset; thus the V-SNLI dataset is slightly smaller than the original, which also contains captions from VisualGenome. V-SNLI consists of 565,286 pairs (187,969 neutral, 188,453 contradiction, and 188,864 entailment). Training, test, and development splits have been built according to the splits in SNLI. The main statistics of the splits of the dataset are reported in Table 1 together with statistics for the visual counterpart of Hard SNLI, namely V-SNLI$_{hard}$. By construction, V-SNLI contains datapoints such that the premise is always true with respect to the image, whereas the hypothesis can be either true (entailment or neutral cases) or false (contradiction or neutral cases.)

Split	# entailment	# contradiction	# neutral	# total
V-SNLI train	182,167	181,938	181,515	545,620
V-SNLI dev	3,329	3,278	3,235	9,842
V-SNLI test	3,368	3,237	3,219	9,824
V-SNLI$_{hard}$ test	1,058	1,135	1,068	3,261

Table 1: Statistics of the V-SNLI dataset.

3.2 Dataset annotation

For deeper analysis and comparison of the contents of SNLI and SNLI$_{hard}$, we have annotated the SNLI dataset by both automatically detecting some surface linguistic cues and manually labelling less trivial phenomena. Using an in-house annotation interface, we collected human judgments aiming to (a) filter out those cases for which the gold-standard annotation was considered to be wrong[2]; (b) connect the three ungrounded relations to various linguistic phenomena. To achieve this, we annotated a random sample of the SNLI test set containing 527 sentence pairs (185 entailment, 171 contradiction, 171 neutral), out of which 176 were from the hard test set (56 entailment, 62 contradiction, 58 neutral).

All the pairs were annotated by at least two annotators, as follows: (a) We filtered out all the pairs which had a wrong gold label (see Table 2 for details). When our annotators did not agree whether a given relation holds for a specific pair, we appealed to the corresponding five judgments coming from the validation stage of the SNLI dataset to reach a consensus based on the majority of labels. (b) We considered as valid any linguistic tag assigned by at least one annotator. Since the annotation for (a) is binary whereas for (b) it is multi-class, we used Cohen's κ for the former and also Scott's π and Krippendorff's α for the latter as suggested by Passonneau (2006). The inter-annotator agreement for the relation type (a) was $\kappa = 0.93$; for (b) linguistic tags it was $\pi = 0.63$, $\alpha = 0.61$, and $\kappa = 0.64$[3].

[2] An example of a wrong annotation is the pair *A white greyhound dog wearing a muzzle runs around a track* and *The dog is racing other dogs*, labelled as entailment in the SNLI test set.

[3] Inter-rater agreement was calculated using the NLTK implementation, `http://www.nltk.org`

	Ungrounded			Grounded		
	entailment	contradiction	neutral	entailment	contradiction	neutral
SNLI	7%	16%	2%	1%	1%	31%
SNLI$_{hard}$	6%	10%	1%	<1%	1%	20%

Table 2: Wrong gold-standard labels: Data for which the gold standard label was considered to be wrong (a) in the *ungrounded* setting or (b) correct in the ungrounded setting but not in the *grounded* one. We filter out the data in (a) and keep those in (b).

Tag	Description	Example
Paraphrase	Two-way entailment, i.e., H entails P and vice versa.	P: *A middle eastern marketplace*, H: *A middle eastern store*
Generalisation	One-way entailment, i.e., H entails P but not necessarily vice versa.	P: *A group of people on the beach with cameras*, H: *People are on a beach*.
Entity	P and H describe different entities (e.g., subject, object, location) or incompatible properties of entities (e.g., color).	P: *A dog runs along the ocean surf*, H: *A cat is running in the waves*.
Verb	The sentences describe different, incompatible actions.	P: *Military personnel are shopping*, H: *People in the military are training*.
Insertion	H contains details and facts not present in P (e.g., subjective judgments and emotions.)	P: *Woman reading a book in a laundry room*, H: *The book is old*.
Unrelated	The sentences are completely unrelated.	P: *A woman is applying lip makeup to another woman*, H: *The man is ready to fight*.
Quantifier	The sentences contain numbers or quantifiers (e.g., *all, no, some, both, group*).	P: *A group of people are taking a fun train ride*, H: *People ride the train*.
World knowledge	Commonsense assumptions are needed to understand the relation between sentences (e.g., if there are named entities).	P: *A crowd gathered on either side of a Soap Box Derby*, H: *The people are at the race*.
Voice	The premise is an active/passive transformation of the hypothesis.	P: *Kids being walked by an adult*, H: *An adult is escorting some children*.
Swap	The sentences' subject and object are swapped from P to H.	P: *A woman walks in front of a giant clock*, H: *The clock walks in front of the woman*.

Table 3: Tags used in manual annotation of a subset of the SNLI test set.

Linguistic phenomena Following the error analysis approach described in recent work (Nangia et al., 2017; Williams et al., 2018), we compiled a new list of linguistic features that can be of interest when contrasting SNLI and SNLI$_{hard}$, as well as for evaluating RTE models. Some of these were detected automatically, while others were assigned manually. Automatic tags included SYNONYM and ANTONYM, which were detected using WordNet (Miller, 1995). QUANTIFIER, PRONOUN, DIFF TENSE, SUPERLATIVE and BARE NP were identified using Penn treebank labels (Marcus et al., 1993), while labels such as NEGATION were found with a straightforward keyword search. The tag LONG has been assigned to sentence pairs with a premise containing more than 30 tokens, or a hypothesis with more than 16 tokens. Details about the tags used in the manual annotation are presented in Table 3.

We examined the differences in the tags distributions between the SNLI and SNLI$_{hard}$ test sets (Table 4). Interestingly, the hard sentence pairs from our random sample include proportionately more antonyms but fewer pronouns, as well as examples with different verb tenses in the premise and hypothesis, compared to the full test set. Furthermore, SNLI$_{hard}$ contains a significantly larger proportion of gold-standard labels which become wrong when the image is factored in (χ^2-test with $\alpha = 0.05$).

4 Models

In this section, we describe a variety of models that were compared on both V-SNLI and V-SNLI$_{hard}$, ranging from baseline models based on Bowman et al. (2015) to a state of the art model by Wang et al. (2017). We compare the original 'blind' version of a model with a visually-augmented counterpart. In what follows, we use *P* and *H* to refer to a premise and hypothesis, respectively.

LSTM baseline (Blind) This model exploits a Recurrent Neural Network with Long Short-Term Memory units (Hochreiter and Schmidhuber, 1997) to encode both P and H in 512D vectors. The two vectors

Table 4: Distribution of the automatic and manually assigned tags in the SNLI and SNLI$_{hard}$ test sets. Automatic tags are detected in the whole test set, manual ones are assigned to its random subset. Arrows ↑↓ signify a statistically significant difference in tag proportions between the datasets (Pearson's χ^2-test).

are then concatenated in a stack of three 512D layers having a ReLU activation function (Nair and Hinton, 2010), with a final softmax layer to classify the relation between the two sentences as entailment, contradiction or neutral. The model is inspired by the LSTM baseline proposed by Bowman et al. (2015)[4]. The model exploits the 300,000 most frequent pretrained GloVe embeddings (Pennington et al., 2014) and improves them during the training process. To regularize the model, Dropout (Srivastava et al., 2014) is applied to the inputs and outputs of the recurrent layers and to the ReLU fully connected layers with a keeping probability of 0.5. The model is trained using the Adam optimizer (Kingma and Ba, 2014) with a learning rate of 0.001 until its accuracy on the development set drops for three successive iterations.

V-LSTM baseline The LSTM model described above is augmented with a visual component following a standard Visual Question Answering baseline model (Antol et al., 2015). Following initial representation of P and H in 512D vectors through an LSTM, a fully-connected layer projects the L2-normalized 4096D image vector coming from the penultimate layer of a VGGnet16 Convolutional Neural Network (Simonyan and Zisserman, 2014) to a reduced 512D vector. A fully-connected layer with a ReLU activation function is also applied to P and H to obtain two 512D vectors. The multimodal fusion between the text and the image is obtained by performing an element-wise multiplication between the vector of the text representation and the reduced vector of the image. The multimodal fusion is performed between the image and both the premise and the hypothesis, resulting in two multimodal representations. The relation between them is captured as in the model described above. This model uses GloVe embeddings and the same optimization and procedure described above.

We have also adapted a state-of-the-art attention-based model for IC and VQA (Anderson et al., 2017; Teney et al., 2017) to the GTE task. It obtains results comparable to the V-LSTM. This lack of improvement might be due to the need of further parameter tuning. We report the details of our implementation and its results in the Supplementary Material.

BiMPM The Bilateral Multi-Perspective Matching (BiMPM) model (Wang et al., 2017) obtains state-of-the-art performance on the SNLI dataset, achieving a maximum accuracy of 86.9%, and going up to 88.8% in an ensemble setup. An initial embedding layer vectorises words in P and H using pretrained GLoVe embeddings (Pennington et al., 2014), and passing them to a context representation layer, which uses bidirectional LSTMs (BiLSTMs) to encode context vectors for each time-step. The core part of the model is the subsequent matching layer, where each contextual embedding or time-step of P is matched against all the embeddings of H, and vice versa. The output of this layer is composed of two sequences of matching vectors, which constitute the input to another BiLSTM at the aggregation layer. The vectors from the last time-step of the BiLSTM are concatenated into a fixed-length vector, which is passed to the final prediction tier, a two-layer feed-forward network which classifies the relation between P and H

[4]There are some differences between our baseline and the LSTM baseline used in (Bowman et al., 2015). In particular, we used the Adam optimizer instead of the AdaDelta optimizer, the ReLU activation function instead of the tanh activation function, 512D instead of 100D for the output dimension of LSTM units, and dropout in all fully-connected layers instead of L2 regularization. Our settings outperformed the original ones in our experiments.

via softmax. Matching is performed via a cosine operation, which yields an l-dimensional vector, where l is the number of perspectives. Wang et al. (2017) experiment with four different matching strategies. In their results, the best-performing version of the BiMPM model used all four matching strategies. We adopt this version of the model in what follows.

V-BiMPM model We enhanced BiMPM to account for the image, too. Our version of this model is referred to as the *V*-BiMPM. Here, the feature vector for an image is obtained from the layer before the fully-connected layer of a VGGnet-16. This results in a $7 \times 7 \times 512$ tensor, which we consider as 49 512-dimensional vectors. The same matching operations are performed, except that matching occurs between P, H, and the image. Since the textual and visual vectors have different dimensionality and belong to different spaces, we first map them to a mutual space using an affine transformation. We match textual and image vectors using a cosine operation, as before. Full details of the model are reported in the Supplementary Materials for this paper.

5 Experiments and Results

The models described in the previous sections were evaluated on both (V-)SNLI and (V-)SNLI$_{hard}$. For the visually-augmented models, we experimented with configurations where image vectors were combined with both P and H (namely P+I and H+I), or only with H (P and H+I). The best setting was invariably the one where only H was grounded; hence, we focus on these results in what follows, comparing them to "blind" models. In view of recent results suggesting that biases in SNLI afford a high accuracy in the prediction task with only the hypothesis sentence as input (Gururangan et al., 2018), we also include results for the blind models without the premise (denoted with [H] in what follows).

Table 5 shows the results of the various models on the full V-SNLI dataset. The same models are compared in Table 6 on V-SNLI$_{hard}$. First, note that the LSTM [H] model evinces a drop in performance compared to LSTM (from 81.49% to 68.49%), though the drop is much greater on the unbiased SNLI$_{hard}$ subset (from 60.99 to 25.57%). This confirms the results reported by Gururangan et al. (2018) and justifies our additional focus on this subset of the data.

The effect of grounding in these models is less clear. The LSTM baseline performs worse when it is visually augmented; this is the case of V-SNLI and, even more drastically, V-SNLI$_{hard}$. It is also true irrespective of the relationship type. On the other hand, the V-BiMPM model improves marginally across the board, compared to BiMPM, on the V-SNLI data. On the hard subset, the images appear to hurt performance somewhat in the case of contradiction (from 77.62% to 76.12%), but improve it by a substantial margin on neutral cases (from 59.36% to 63.67%). The neutral case is the hardest for all models, with the possible exception of LSTM [H] on the full dataset.

Overall, the results suggest that factoring in images either hinders performance (as in the case of the V-LSTM baseline), or helps only marginally (as in the case of V-BiMPM). In the latter case, we also observe instances where factoring in images hurts performance. In an effort to understand the results, we

turn to a more detailed error analysis of the V-BiMPM model, first in relation to the dataset annotations, and then by zooming in somewhat closer on V-SNLI$_{hard}$.

5.1 Error analysis by linguistic annotation label

Table 7: Accuracies obtained by BiMPM and V-BiMPM models on SNLI$_{hard}$, by annotation tags. Arrows ↑↓ signify a statistically significant difference in tag proportions between the datasets (Pearson's χ^2-test).

In Table 7, accuracies for the blind and grounded version of BiMPM are broken down by the labels given to the sentence pairs in the annotated subset of SNLI described in Section 3. We only observe a significant difference in the *Entity* case, that is, where the referents in P and H are inconsistent. Here, the blind model outperforms the grounded one, an unexpected result, since one would assume a grounded model to be better equipped to identify mismatched referents. Hence, in the following we aim to understand whether the models properly deal with the grounding sub-task.

5.2 Error analysis on grounding in the SNLI$_{hard}$

We next turn to the "hard" subset of the data, where V-BiMPM showed some improvement over the blind case, but suffered on contradiction cases (Table 6). We analysed the 207 cases in SNLI$_{hard}$ where the V-BiMPM made incorrect predictions compared to the blind model, that is, where the image hurt performance. These were annotated independently by two of the authors (raw inter-annotator agreement: 96%) who (a) read the two sentences, P and H; (b) checked whether the relation annotated in the dataset actually held or whether it was an annotation error; (c) in those cases where it held, checked whether including the image actually resulted in a change in the relation.

Table 8 displays the proportions of image mismatch and incorrect annotations. As the table suggests, in the cases where images hinder performance in the V-BiMPM, it is usually because the image changes the relation (thus, these are cases of image mismatch; see Section 1 for an example); this occurs in a large proportion of cases labelled as neutral in the dataset.

Inspired by the work in (Mironenco et al., 2017), we further explored the impact of visual grounding in both the V-LSTM and V-BiMPM by comparing their performance on SNLI$_{hard}$, with the same subset incorporating image "foils". Vectors for the images in the V-SNLI test set were compared pairwise using cosine, and for each test case in V-SNLI$_{hard}$, the actual image was replaced with the most dissimilar image in the full test set. The rationale is that, if visual grounding is really helpful in recognising the semantic relationship between P and H, we should observe a drop in performance when the images are

unrelated to the scenario described by the sentences. The results are displayed in Table 9, which also reproduces the original results on V-SNLI$_{hard}$ from Table 6 for ease of reference.

As the results show, models are not hurt by the foil image, contrary to our expectations. V-BiMPM overall drops just by 0.67% whereas V-LSTM drop is somewhat higher (-2.11%) showing it might be doing a better job on the grounding sub-task.

As a final check, we sought to isolate the grounding from the reasoning sub-task, focusing only on the former. We compared the models when grounding only the hypothesis [H+I], while leaving out the premise. Note that this test is different from the evaluation of the model using only the hypothesis [H]: Whereas in that case the input is not expected to provide any useful information to perform the task, here it is. As we noted in Section 3, by construction the premise is always true with respect to the image while the hypothesis can be either true (entailment or neutral cases) or false (contradiction or neutral cases). A model that is grounding the text adequately would be expected to confuse both entailment and contradiction cases with neutral ones; on the other hand, neutral cases should be confused with entailments or contradictions. Confusing contradictions with entailments would be a sign that a model is grounding inadequately, since it is not recognising that H is false with respect to the image.

As the left panel of Table 10 shows, V-BiMPM outperforms V-LSTM by a substantial margin, though the performance of both models drops substantially with this setup. The right panel in the table shows that neither model is free of implausible errors (confusing entailments and contradictions), though V-BiMPM makes substantially fewer of these.

6 Conclusion

This paper has investigated the potential of grounding the textual entailment task in visual data. We argued that a Grounded Textual Entailment model needs to perform two tasks: (a) the grounding itself, and (b) reasoning about the relation between the sentences, against the visual information. Our results suggest that a model based on matching and aggregation like the BiMPM model (Wang et al., 2017) can perform very well at the reasoning task, classifying entailment relations correctly much more frequently than a baseline V-LSTM. On the other hand, it is not clear that grounding is being performed adequately in this model. It is primarily in the case of contradictions that the image seems to play a direct role in biasing the classification towards the right or wrong class, depending on whether the image is correct.

In summary, two conclusions can be drawn from these results. First, in those cases where the inclusion of visual information results in a loss of accuracy, this is often due to the image resulting in a change in the original relation annotated in the dataset. A related observation is that using foil images results in a greater drop in performance on contradiction cases, possibly because in such cases, grounding serves to

identify a mismatch between the hypothesis and the scene described by the premise, a situation which is rendered opaque by the introduction of foils. Second, in those cases where improvements are observed in the state of the art V-BiMPM, the precise role played by the image is not straightforward. Indeed, we find that this model still marginally outperforms the 'blind', text-only model overall, when the images involved are foils rather than actual images.

We believe that further research on grounded TE is worthy of the NLP community's attention. While linking language with perception is currently a topical issue, there has been relatively little work on linking grounding directly with inference. By drawing closer to a joint solution to the grounding and inference tasks, models will also be better able to address language understanding in the real world.

The present paper presented a first step in this direction using a version of an existing TE dataset which was augmented with images that could be paired directly with the premises, since these were originally captions for those images. However, it is important to note that in this dataset premise-hypotheses pairs were not generated directly with reference to the images themselves. An important issue to consider in future work on GTE, besides the development of better models, is the development of datasets in which the role of perceptual information is controlled, ensuring that the data on which models are trained represents truly grounded inferences.

Appendix A: Bottom-up top-down attention (VQA)

We adapted the Visual Question Answering model proposed in (Anderson et al., 2017; Teney et al., 2017) to the Grounded Textual Entailment task. The model presents a more fine-grained attention mechanism which allows to identify the most important regions discovered in the image and to perform attention over each of them.

The model uses a a Recurrent Neural Network with Long Short-Term Memory units to encode the premise P and hypothesis H in 512D vectors. A bottom-up attention mechanism exploits a Fast R-CNN (Girshick, 2015) based on a ResNet-101 convolutional neural network (He et al., 2016) to obtain region proposals corresponding to the 36 most informative regions of the image. A top-down attention mechanism is used between the premise (resp. hypothesis) and each of the L2-normalized 2048D image vectors corresponding to the region proposals to obtain an attention score for each of them. Then, a 2048D image vector encoding the most interesting visual features for the premise (hypothesis) is obtained as a sum of the 36 image vectors weighted by the corresponding attention scores for the premise (hypothesis). A fully-connected layer with a gated tanh activation function is applied to the image vector of the most interesting visual features for the premise and for the hypothesis to obtain a reduced 512D vector for each of them. A fully-connected layer with a gated tanh activation function is also applied to the premise and to the hypothesis in order to obtain a reduced 512D vector for each of them.

The multimodal fusion between the premise (hypothesis) and the image vector of the most interesting visual features for the premise (hypothesis) is obtained by performing an element-wise multiplication between the reduced vector of the premise (hypothesis) and the reduced vector of the most interesting visual features for the premise (hypothesis). After that, the model feeds the concatenation of the two resulting multimodal representations to a stack of three 512D layers having a gated tanh activation function, with a final softmax layer to classify the relation between the two sentences as entailment, contradiction or neutral. This model uses GloVe embeddings and the same optimization tricks and procedure of the LSTM and V-LSTM models.

We report the accuracies of the VQA models against the various tests reported in the paper. For ease of comparison we reproduce the full table from the main paper, with the addition of the VQA results.

Appendix B: V-biMPM Model details

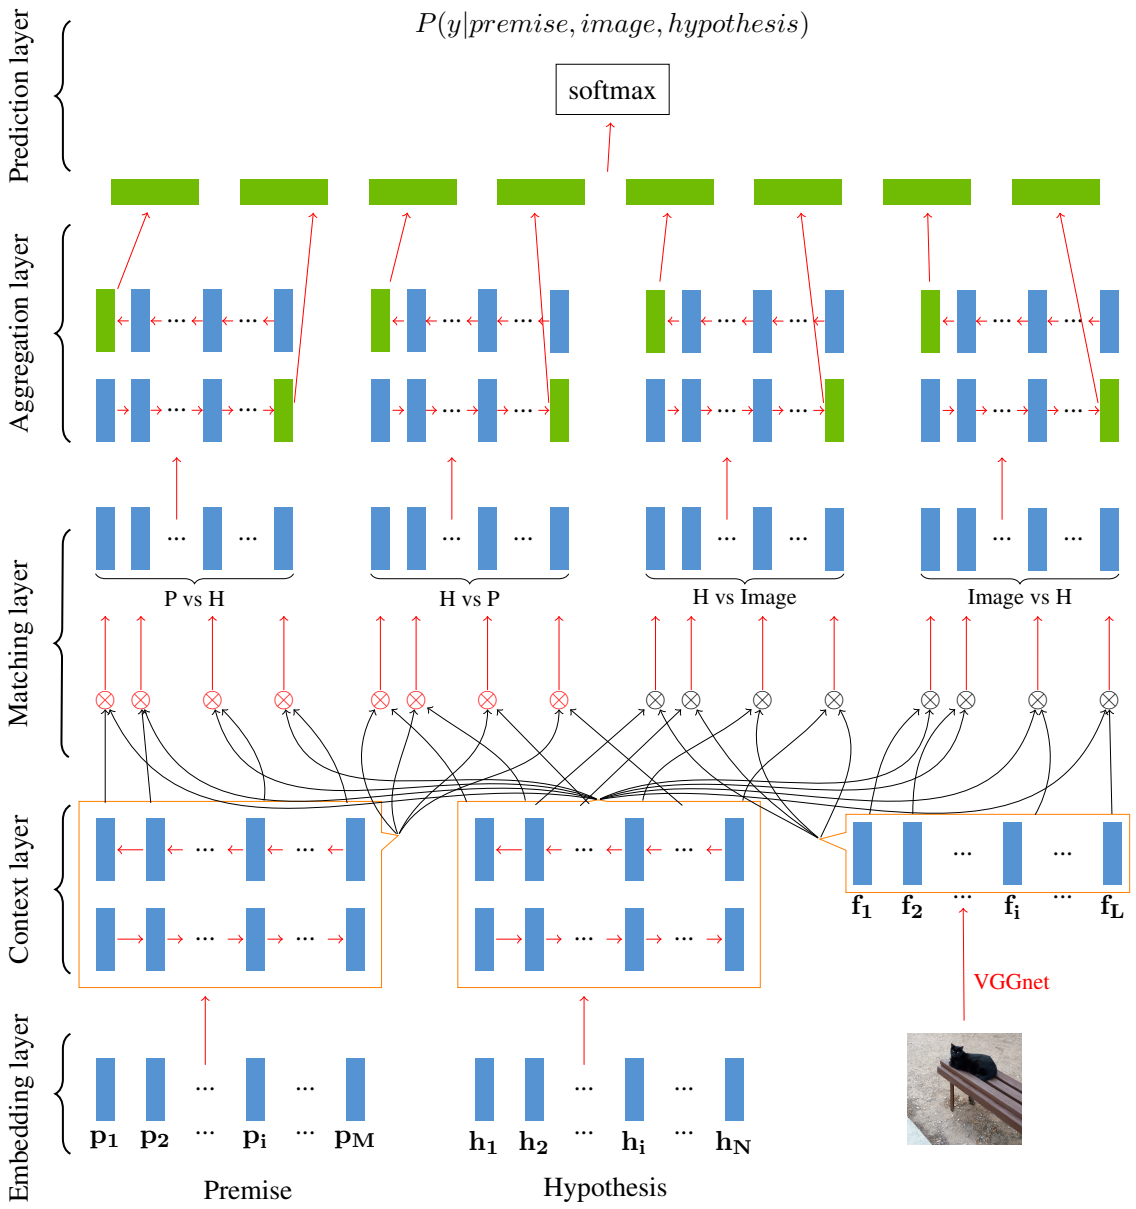

Figure 2: Vision-enhanced Bilateral Multi-Perspective Matching model (v-BiMPM).

Here, we report some further details of our implementation of the V-BiMPM model described in Section 4 of the main paper, based on the work of Wang et al. (2017). Our model is displayed in Figure 2.

The core part of the original BiMPM is the matching layer. Given two d-dimensional vectors v_P and v_H, each replicated l times (l is the number of 'perspectives') and a trainable $l \times d$ weight matrix W, matching involves a cosine similarity computation that yields an l-dimensional matching vector m, whose elements are defined as follows:

$$m_k = \textit{cosine}\left(W_k \circ v_P, W_k \circ v_H\right) \tag{1}$$

The matching operations included are the following:

1. *full-matching*, where each forward or backward contextual embedding of the premise P (resp. the hypothesis H) is matched to the last time-step of H (resp. P);

2. *max-pooling*, where each forward/backward contextual embedding of one sentence is compared to the embeddings of the other, retaining the maximum value for each dimension;

3. *attentive matching*, where first, the pairwise cosine similarity between forward/backward embeddings of P and H is estimated, before calculating an attentive vector over the weighted sum of contextual embeddings for H and matching each forward/backward embedding of P against the attentive vector;

4. *max-attentive matching*, a version of attentive matching where the contextual embedding with the highest cosine is used as the attentive vector, instead of the weighted sum.

The visually-augmented version of the original model, V-BiMPM, is displayed in Figure 2. To perform multimodal matching, the visual and textual vectors are mapped to a mutual space using the following affine transformation:

$$v_i = \mathbf{W}_t f_i + b_t; f_i \in \mathbb{R}^e; \mathbf{W}_t \in \mathbb{R}^{e \times d}; b_t, v_i \in \mathbb{R}^d \tag{2}$$

where $\mathbf{W}_t$, b_t, f_i, and v_i are the weight matrix, the bias, the input features and output features, respectively, and t is any text (P or H). Given weight matrices $\mathbf{W} \in \mathbb{R}^{l \times d}$ for text and $\mathbf{U}^{l \times d}$ for images, we compute the matching vector m between a textual vector v_t and image vector v_i as:

$$m_k = \textit{cosine}\left(W_k \circ v_t, U_k \circ v_i\right) \tag{3}$$

Abstract

Large scale knowledge graphs (KGs) such as Freebase are generally incomplete. Reasoning over multi-hop (mh) KG paths is thus an important capability that is needed for question answering or other NLP tasks that require knowledge about the world. mh-KG reasoning includes diverse scenarios, e.g., given a head entity and a relation path, predict the tail entity; or given two entities connected by some relation paths, predict the unknown relation between them. We present *ROPs*, recurrent one-hop predictors, that predict entities at each step of mh-KB paths by using recurrent neural networks and vector representations of entities and relations, with two benefits: (i) modeling mh-paths of arbitrary lengths while updating the entity and relation representations by the training signal at each step; (ii) handling different types of mh-KG reasoning in a unified framework. Our models show state-of-the-art for two important multi-hop KG reasoning tasks: Knowledge Base Completion and Path Query Answering.[1]

1 Introduction

Natural language understanding (NLU) is impossible without knowledge about the world. Large scale knowledge graphs (KGs) such as Freebase (Bollacker et al., 2008) are structures that store world knowledge. Unfortunately, KGs suffer from incomplete coverage (Min et al., 2013); e.g., Freebase contains Brandon Lee, but not his ethnicity.

The knowledge in KGs needs to be expanded to cover more facts; reasoning is one way to do so. For example, we could infer that *(Microsoft, ?, United States)* instantiates "CountryOfHQ" given the facts *(Microsoft, IsBasedIn, Seattle)* and *(Seattle, LocatedIn, United States)*; or we could infer Brandon Lee's ethnicity from his parents' ethnicity, i.e., answering the query *(Brandon Lee, Ethnicity, ?)* by facts *(Brandon Lee, Father, Bruce Lee)* and *(Bruce Lee, Ethnicity, Chinese)*. We refer to the two reasoning examples as "knowledge base completion (KBC)" and "path query answering (PQA)", respectively.

The most successful approach for modeling KGs is the *embedding approach*. It embeds KG elements (entities and relations) into low-dimensional dense vectors; controlling the dimensionality of the vector space forces generalization to new facts (Nickel et al., 2011).

In this work, we are mainly interested in three issues. (i) Compared to modeling one-hop KG paths, a bigger challenge is how to model multi-hop paths, e.g., the path query *(U.S.A, president→spouse→born_in, ?)* for the question "Where was the first lady of the United States born?" (ii) How can we address different KG reasoning problems driven by multi-hop paths in a universal paradigm rather than via different systems? (iii) How can we combine specific multi-hop KG reasoning tasks with generic KG representation learning, so that KG representation learning can either stand alone or be incorporated into diverse multi-hop KG-related NLU problems. We get inspiration from following two types of work.

First, *prior work in KG reasoning*. Guu et al. (2015) extend one-hop reasoning regimes such as TransE (Bordes et al., 2013) to multi-hop PQA. However, these basic one-hop models do not encode the relation

Proceedings of the 27th International Conference on Computational Linguistics, pages 2369–2378
Santa Fe, New Mexico, USA, August 20-26, 2018.

order when used in compositional training schemes. For example, path query q_1 = (h, $r_1 \rightarrow r_2 \rightarrow \cdots \rightarrow r_k$, ?) will be encoded into the same embedding as path query q_2 = (h, $r_2 \rightarrow r_1 \rightarrow \cdots \rightarrow r_k$, ?), resulting in (often incorrect) prediction of the same tail entity. Instead, the relation order should influence the prediction. This limitation in modeling multi-hop relation paths motivates the *RNN approach*: using recurrent neural networks (RNN (Elman, 1990)) to model relation paths (Neelakantan et al., 2015). Das et al. (2017) further extend this approach by incorporating entity information and apply it to multi-hop KBC. Intermediate entities should influence the reasoning decision. For example, given two paths with the same relation sequence: (Donald Trump, *child*, Ivanka Trump, *mother*, Ivana Trump) and (Donald Trump, *child*, Barron Trump, *mother*, Melania Trump), even though both paths have the relation sequence [$child$, $mother$], the relation between (Donald Trump, Melania Trump) is "spouse" while it does not hold between (Donald Trump, Ivana Trump) due to the intermediate entities: "Ivanka Trump" vs. "Barron Trump". Similarly, paths (JFK, $located\_in$, NYC, $located\_in$, NY) and (Yankee Stadium, $located\_in$, NYC, $located\_in$, NY) would predict the same score for target relation "airport_serves_place" if we do not consider that Yankee Stadium is not an airport (Das et al., 2017).

Second, *sequence labeling tasks* such as POS tagging, chunking and NER have been successfully addressed by RNNs (Huang et al., 2015; Lample et al., 2016). These approaches model the mechanism in a structure of form "input$_1$, tag$_1$, input$_2$, tag$_2$, input$_3$, tag$_3$, $\cdots$, input$_t$, tag$_t$", which resembles the structure of multi-hop KG paths.

Inspired by this prior work, we propose *ROP*, Recurrent One-hop Predictor. Given a head entity, ROP encodes a multi-hop sequence of relations and predicts a sequence of entities using an RNN. More formally, given relation sequence "$r_1, r_2, \cdots, r_t$" and the head entity e_h, ROP predicts the sequence $e_1, e_2, \cdots, e_t$, thus generating a complete KG path $e_h, r_1, e_1, r_2, e_2, \cdots, r_t, e_t$. Intuitively, our model memorizes history of path context; given a new relation, it predicts the next entity, then the memory is updated, and the process – given new relation, predicting new entity, updating memory – keeps going. Grouping step-wise updates in a chain gives our model two advantages. (i) A better vector space representation of KG entities and relations, with training signals either from in-path entities or from labels of reasoning tasks or from both. (ii) A unified approach for two different reasoning tasks (mh-KBC and mh-PQA) and state-of-the-art in each.

In summary, our contributions are: (i) ROP, a novel RNN sequence modeling of multi-hop KG paths that updates entity and relation embeddings by training signal at each step and leads to better KG embeddings; (ii) unified framework for solving different multi-hop reasoning tasks over KGs; (iii) showing the importance of modeling within-path entities in mh-PQA; (iv) state-of-the-art results for both mh-KBC and mh-PQA; (v) releasing an enhanced version of a mh-PQA dataset by adding within-path entities.

§2 introduces the mh-KBC and mh-PQA tasks. §3 discusses related work. §4 presents three ROP architectures and §5 evaluates them. §6 concludes.

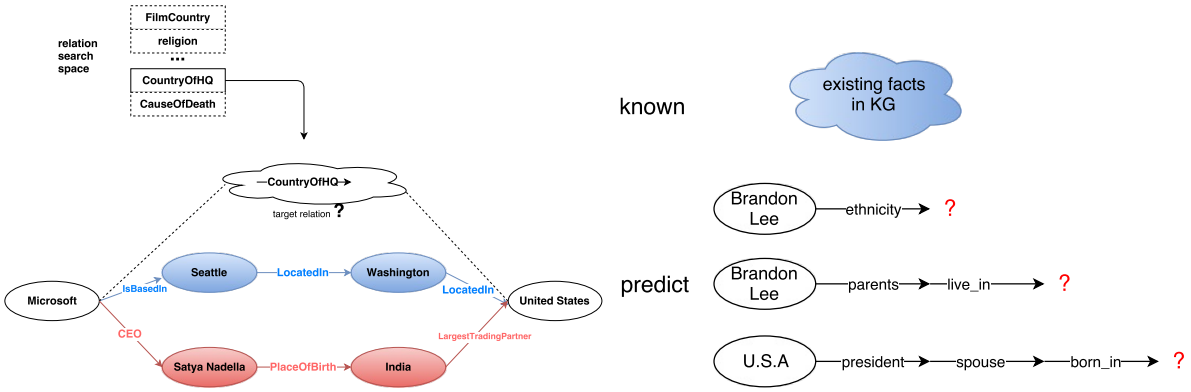
2 Multi-Hop Path Reasoning Tasks

We first give background on the two KG reasoning tasks we address in this work.

Knowledge Base Completion (mh-KBC). In mh-KBC, the goal is to predict new relations between entities using existing path connections. For example, *(A, LivesIn, B)* is implied, with some probability, from *(A, CEO, X)* and *(X, HQIn, B)*. This kind of reasoning lets us infer new or missing facts from KGs.

Figure 1(a) shows two paths between *Microsoft* and *United States*: *(Microsoft, IsBasedIn, Seattle, IsLocatedIn, Washington, IsLocatedIn, United States)* (blue) and *(Microsoft, CEO, Satya Nadella, PlaceOfBirth, India, LargestTradingPartner, United States)* (red). The task is then to predict the direct relation that connects *Microsoft* and *United States*; i.e., *CountryOfHQ* in this case. There can exist multiple long paths between two entities; the example shows that the target relation may only be inferrable from one path. The difficulty of finding the most informative path makes this task challenging.

Path Query Answering (mh-PQA). In mh-PQA, the goal is to *predict missing properties* of an entity, such as the earlier mentioned ethnicity of Brandon Lee. More generally, given an entity and relations of interest, predict what the target entity is, as Figure 1(b) shows. This task corresponds to answering



(a) Multi-hop knowledge base completion (b) Multi-hop path query answering

Figure 1: Multi-Hop Path Reasoning Tasks

compositional natural questions. For example, the question "Where do Brandon Lee's parents live?" can be formulated by the path query brandon_lee/parents/live_in. mh-PQA tries to find answers to the path queries and hence compositional questions. Unfortunately, KGs often have missing facts (edges), which makes mh-PQA a non-trivial problem.

A path query q_t consists of an initial anchor entity, e_h, followed by a sequence of t relations to be traversed, $p = (r_1, \cdots, r_t)$. Following (Guu et al., 2015), the answer or denotation of the query is the set of all entities that can be reached from e_h by traversing p.

3 Related Work

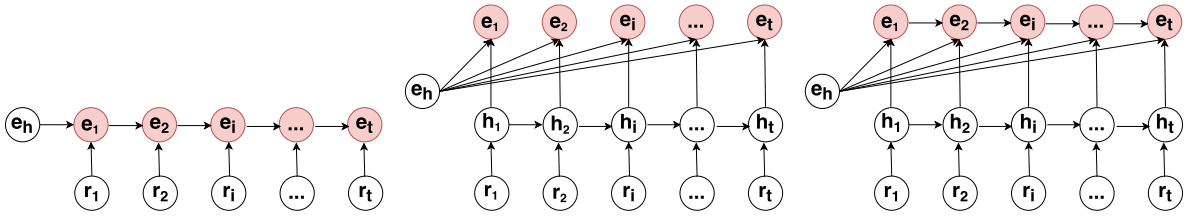
Here we focus on the multi-hop path reasoning literature. Some work (Neelakantan et al., 2015; Guu et al., 2015; Lin et al., 2015; Lin et al., 2016; Shen et al., 2016) does some composition over relation paths. Given relation path $p = (r_1, \cdots, r_t)$, the composition operation is *add* ($\mathbf{p} = \mathbf{r}_1 + \cdots + \mathbf{r}_t$), *multiplication* ($\mathbf{p} = \mathbf{r}_1 \cdots \mathbf{r}_t$) or an *RNN step*: $\mathbf{p}_i = \text{RNN}(\mathbf{p}_{i-1}, \mathbf{r}_i)$, where $\mathbf{p}_i$ is the accumulated relation information up to step i. Some work explores compositional encoding of long paths (Lin et al., 2016; Shen et al., 2016), but still performs reasoning in one-hop scenario. Neelakantan et al. (2015) use RNNs to model multi-hop paths.

Das et al. (2017) extend the RNN approaches by leveraging within-path entities into the encoding of inputs along with relations. We also include within-path entities, but we do not give them as inputs; instead, *we force our RNN to predict them as outputs and do updates at each step in the path*. This supports representation learning for KG entities and relations even without task-specific annotations. Toutanova et al. (2016) propose a dynamic programming algorithm to model both relation types and intermediate entities in the compositional path representations and test on WordNet and a biomedical KG. These two works address mh-KBC; for mh-PQA, there is no prior work on using within-path entities[2], including Das et al. (2017), in which the system uses within-path entities as input, while those entities are not available for testing. So Das et al. (2017) use RNN for mh-PQA to encode the relation sequence, but it does not incorporate the intermediate entities involved.

4 Recurrent One-Hop Prediction

We propose three ROPs, recurrent one-hop predictors, to model paths such as $p = (e_h, r_1, e_1, \cdots, r_i, e_i, \cdots, r_t, e_t)$. Entities and relations appear alternately in p; e_h and e_t are head and tail entities; t steps (hops) connect e_h and e_t; each step is a single fact triple (e_{i-1}, r_i, e_i). We stipulate $\mathbf{e}_i \in \mathbb{R}^{d_e}$ and $\mathbf{r}_i \in \mathbb{R}^{d_r}$. We allow $d_e \neq d_r$.

[2]Guu et al. (2015) attempt to measure how severe the cascading errors along the path are by reconstructing the intermediate entities along a path. Their operation only generates an evaluation score for the path representation. We instead turn this into a training objective to fine-tune the path representations.



(a) ROP_ARC1 (b) ROP_ARC2 (c) ROP_ARC3

Figure 2: Three recurrent one-hop predictors

Paths are encoded by GRUs (Cho et al., 2014):

$$\mathbf{g}_z = \sigma(\mathbf{x}_i\mathbf{U}^z + \mathbf{h}_{i-1}\mathbf{W}^z) \quad (1)$$
$$\mathbf{g}_r = \sigma(\mathbf{x}_i\mathbf{U}^r + \mathbf{h}_{i-1}\mathbf{W}^r) \quad (2)$$
$$\hat{\mathbf{h}}_i = \tanh(\mathbf{x}_i\mathbf{U}^q + (\mathbf{h}_{i-1} \circ \mathbf{g}_r)\mathbf{W}^q) \quad (3)$$
$$\mathbf{h}_i = (1 - \mathbf{g}_z) \circ \hat{\mathbf{h}}_i + \mathbf{g}_z \circ \mathbf{h}_{i-1} \quad (4)$$

where x is the input sequence with x_i at position i, h is the output sequence with h_i at position i. g_z and g_r are gates. All $\mathbf{U}$s and $\mathbf{W}$s are parameters. In following, *we define the whole Eqs. 1–4 as a single GRU step as*:

$$h_i = \text{GRU}(h_{i-1}, x_i) \quad (5)$$

Thus, we interpret each GRU step as a composition function of two objects: h_{i-1} and x_i.

We now introduce the three architectures ROP_ARC1, ROP_ARC2 and ROP_ARC3 that encode the context "$e_h, r_1, e_1, \cdots, r_i$" in different ways to predict entity e_i.

ROP_ARC1 (Figure 2(a)) models KG paths as:

$$\hat{\mathbf{e}}_0 = \mathbf{e}_h \quad (6)$$
$$\hat{\mathbf{e}}_i = \text{GRU}(\hat{\mathbf{e}}_{i-1}, \mathbf{r}_i) \quad (7)$$

$\hat{\mathbf{e}}_0$ is initialized to the embedding of the *true* head entity $\mathbf{e}_h$. At position $i, i > 0$, $\hat{\mathbf{e}}_i$ is the *predicted* entity embedding.

ROP_ARC1 is essentially a recurrent process with a pre-set starting state; the key is to use the head entity embedding $\mathbf{e}_h$ as the initialization of the hidden state of GRU. We hope this start point guides where the path goes and what state to reach at each position. As a result, *relations lie in the input space and entities lie in the hidden space*. All *predicted* entities $\hat{\mathbf{e}}_i$ will be compared with the gold intermediate entities $\mathbf{e}_i$, then the loss (red in Figure 2) is used to train the system.

ROP_ARC1 only encodes head entity e_h at the starting hidden state, possibly far from the tail entity e_t for long paths. Thus, e_h cannot provide effective guidance for prediction of e_t. This motivates ROP_ARC2, a modification of ROP_ARC1.

In **ROP_ARC2**, we want the head entity e_h to participate in the entity prediction at each step more directly and effectively. To this end, ROP_ARC2 first encodes the relation sequence as standard GRU:

$$\begin{aligned} \mathbf{h}_0 &= \mathbf{0} \\ \mathbf{h}_i &= \text{GRU}(\mathbf{h}_{i-1}, \mathbf{r}_i) \end{aligned} \quad (8)$$

$\mathbf{h}_0$ is initialized to $\mathbf{0}$. $\mathbf{h}_i$, $i > 0$, contains the information of the relation sequence $r_1, r_2, \cdots, r_i$ independent of the head entity e_h. To make sure the path reaches the correct state, ROP_arc2 then composes each h_i with e_h to predict e_i as:

$$\hat{\mathbf{e}}_i = \text{COMP}_1(\mathbf{e}_h, \mathbf{h}_i) \quad (9)$$

As composition function COMP_1 we use ADD (addition, as in TransE) or GRU (Eq 5).

In ROP_ARC2, head entity e_h directly participates in entity prediction at each step. Unfortunately, there is often another issue – head entity e_h may not match the hidden state h_i if they are far away from each other – h_i mainly encodes some latest relation inputs that are less related to the head entity. Besides, there is a second information source, in addition to e_h, that is clearly relevant for accurate prediction: the preceding predicted entity $\hat{e}_{i-1}$. But ROP_ARC2 does not make it available. Our solution is ROP_ARC3. This architecture predicts the next entity e_i using both e_h and $\hat{e}_{i-1}$, based on the intuition that e_i is directly related to its predecessor e_{i-1}.

ROP_ARC3 combines the benefits of ROP_ARC1 and ROP_ARC2. It encodes the relation sequence as in Eq 8 in ROP_ARC2, but composes head entity e_h as well as the *predicted* entity $\hat{e}_{i-1}$ with h_i to predict the entity e_i as:

$$\hat{\mathbf{e}}_i = \text{COMP}_2(\mathbf{e}_h, \hat{\mathbf{e}}_{i-1}, \mathbf{h}_i) \tag{10}$$

As composition function COMP_2, we use ADD (addition) or an extended GRU step, defined as:

$$\begin{aligned}
\mathbf{g}_{zh} &= \sigma(\mathbf{h}_i\mathbf{U}^{zh} + \mathbf{e}_h\mathbf{W}^{zh}) && (11)\\
\mathbf{g}_{rh} &= \sigma(\mathbf{h}_i\mathbf{U}^{rh} + \mathbf{e}_h\mathbf{W}^{rh}) && (12)\\
\mathbf{g}_{zp} &= \sigma(\mathbf{h}_i\mathbf{U}^{zp} + \hat{\mathbf{e}}_{i-1}\mathbf{W}^{zp}) && (13)\\
\mathbf{g}_{rp} &= \sigma(\mathbf{h}_i\mathbf{U}^{rp} + \hat{\mathbf{e}}_{i-1}\mathbf{W}^{rp}) && (14)\\
\hat{\mathbf{h}}_i &= \tanh(\mathbf{h}_i\mathbf{U}^{q} + (\mathbf{e}_h \circ \mathbf{g}_{rh})\mathbf{W}^{q_h} + (\hat{\mathbf{e}}_{i-1} \circ \mathbf{g}_{rp})\mathbf{W}^{q_p}) && (15)\\
\hat{\mathbf{e}}_i &= (1 - \mathbf{g}_{zh} - \mathbf{g}_{zp}) \circ \hat{\mathbf{h}}_i + \mathbf{g}_{zh} \circ \mathbf{e}_h + \mathbf{g}_{zp} \circ \hat{\mathbf{e}}_{i-1} && (16)
\end{aligned}$$

where super/subscript h refers to *head* entity and p refers to *prior* predicted entity $\hat{e}_{i-1}$.

In following work, we define Eqs. 11–16 as eGRU (extended GRU) step as:

$$\hat{\mathbf{e}}_i = \text{eGRU}(\mathbf{e}_h, \hat{\mathbf{e}}_{i-1}, \mathbf{h}_i) \tag{17}$$

We extend GRU into eGRU, so that one architecture can compose three objects: a hidden state h_i and two entity states e_h and $\hat{e}_{i-1}$.

Training. For the gold entity sequence $e_1, e_2, \cdots, e_t$, we define the **loss function** as the margin-based ranking criterion used in TransE (Bordes et al., 2013):

$$l_{\text{seq}} = \textstyle\sum_i \max(0, \alpha + \text{s}(\mathbf{e}_i^-, \hat{\mathbf{e}}_i) - \text{s}(\mathbf{e}_i, \hat{\mathbf{e}}_i)) \tag{18}$$

where α is the margin, e_i^- a negative sample for entity e_i and $\text{s}()$ a similarity function.

Discussion. The three ROP models *differ* in three aspects.

(i) ROP_ARC1 has only one composition process, i.e., GRU, to encode from head entity e_h to r_i; ROP_ARC2 and ROP_ARC3 each have two composition processes, one composes relation sequence $r_1, \cdots, r_i$ into hidden state $\mathbf{h}_i$, the other composes entities (e_h in ROP_ARC2, e_h and $\hat{e}_{i-1}$ in ROP_ARC3) with $\mathbf{h}_i$ to predict e_i.

Figure 2 shows that ROP_ARC1 uses the GRU hidden states as outputs to compare with gold entities. ROP_ARC2 and ROP_ARC3 instead compose their hidden states with head entity or preceding predicted entity to generate a new output space, then compare with gold entities.

(ii) ROP_ARC2 only uses the head entity e_h along with the current hidden state $\mathbf{h}_i$ to predict the next entity e_i whereas ROP_ARC1 and ROP_ARC3 in addition use the preceding predicted entity $\hat{e}_{i-1}$. Hence, ROP_ARC3 roughly uses the combined information of ROP_ARC1 and ROP_ARC2 to do the prediction.

(iii) GRUs like ROP_ARC2&ARC3 often zero-initialize first hidden state $\mathbf{h}_0$. Setting $\mathbf{h}_0$ to the head entity in ROP_ARC1 supports prediction of subsequent entities.

The ROP models are *similar* in three aspects.

(i) They model entities and relations in different spaces: relations are in the input space, entities are in hidden or output spaces. Our motivation is similar to SE, TransH and TransR (cf. §3).

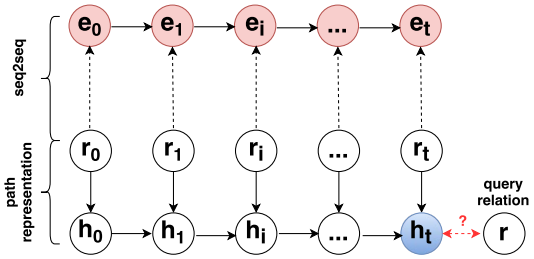


Figure 3: Architecture for mh-KBC task

(ii) The gating mechanism enables flexible compositions between entities and relations based on path context. In contrast, *one-hop KG embedding approaches model compositions statically as shared parameters and consider no context.*

(iii) Unlike Neelakantan et al. (2015), Guu et al. (2015) and Lin et al. (2015) (who also do some composition over relation paths), we finetune entity/relation embeddings in each step of the path. Our intuition is that many more training signals coming from each step of the sequence enable better learning of entity/relation embeddings. Das et al. (2017), as prior work that incorporates entities in the paths, only update the entity embeddings in the path once, when reaching the end of the path. We test this effect in our experiments.

5 Experiments

5.1 Knowledge Base Completion (mh-KBC)

Dataset. We use Das et al. (2017)'s dataset, in which there are 46 query relations, each has *train, dev and test* files containing positive and negative entity pairs (head entity, tail entity). Each entity pair is also provided with multiple multi-hop paths connecting them.

This is a binary classification task for each query relation: does the query relation hold between a pair of entities? The classifier builds a ranked list of entity pairs for corresponding query relation. Evaluation: mean average precision (MAP) across all 46 relations.

Task setup. We use ROP for mh-KBC. Figure 3 shows that we extend the basic ROP architecture (§4) by a GRU layer (bottom layer in Figure 3), denoted as GRU_r, that learns the representation of the relation sequence. Finally, we use $\mathbf{h}_t$ (the last hidden state of GRU_r, shown in blue in Figure 3) to match the query relation $\mathbf{r}$.[3]

Thus, the training loss of this task has two parts: one comes from the loss of ROP training (l_{seq}, Eq 18); the other is the prediction loss of query relation, denoted as l_{pred}. Our preliminary experiments always showed worse performance of ADD, so the first loss l_{seq} here only considers (e)GRU. The second loss is as in (Neelakantan et al., 2015); we show that our ROP part boosts the system as it enables relation paths to encode entity information with multiple updating – as opposed to a single update per path as in (Das et al., 2017). Similar to l_{seq}, we define:

$$l_{\text{pred}} = \sum_{j,i} \max(0, \beta + \text{s}(\mathbf{h}_j^-, \mathbf{r}) - \text{s}(\mathbf{h}_i, \mathbf{r})) \tag{19}$$

where $\mathbf{r}$ is the embedding of a query relation in Figure 3, $\mathbf{h}_i$ (resp. $\mathbf{h}_j^-$) is the representation of positive (resp. negative) path example i (resp. j), shown as $\mathbf{h}_t$ in Figure 3. In testing, all paths are ranked in terms of the given query relation.

The target relation is often not inferrable from all paths between head and tail (see Figure 1(a)); it can be entailed by a single path or a subset of paths. Hence, given the representation of a group of paths, how to match them with the representation of the target relation is a key problem. We use max (over all paths) because we found it works well in selecting the best path for the target relation. See last paragraph of §5.1 for discussion.

[3]Using the last hidden state in ROP (which participates in predicting the tail entity) to predict the query relation performed much worse. We suspect the finetuning by tail entity makes it not indicative for query relations.

Model	MAP
PRA (Lao et al., 2011)	64.43
PRA+ Bigram (Neelakantan et al., 2015)	64.93
RNN-path (Neelakantan et al., 2015)	68.43
RNN-path-entity (Das et al., 2017)	71.74
RNN-path-types (Das et al., 2017)	73.26
ROP_ARC1	74.23
ROP_ARC2	74.46
ROP_ARC3	**76.16**

Table 1: Results of mh-KBC task

We use AdaGrad (Duchi et al., 2011) with learning rate 0.1. Relation embedding dimension is 200, margins α and β are 0.5 (Eqs. 18–19), entity embedding dimension 200, batch size 20, negative sampling size 4. Longer paths are truncated to 8, the first 30 paths are kept for each entity pair.

Results. Table 1 compares our ROP systems to five baselines. RNN-path (Neelakantan et al., 2015) composes the relations occurring in a path using a vanilla RNN. It ignores all information about within-path entities and trains separate models per relation. RNN-path-entity (Das et al., 2017) models the path entities and improves the results. RNN-path-type (Das et al., 2017) further improves the result by representing entities with the sum of their type embeddings. Thus, RNN-path-type uses extra information, the entity types. Apart from these baselines, it is also feasible to compare with the baselines based on composition of one-hop triple-based embedding models. However, the performance of these baselines is very poor for this task (Neelakantan et al., 2015) and therefore, we do not include them in our comparison.

The performance order of our architectures for mh-KBC is ROP_ARC3 $>$ ROP_ARC2 $>$ ROP_ARC1. All our ROP systems are superior to the state-of-the-art. In particular, they are superior to RNN-path-type (Das et al., 2017), the state-of-the-art, even though we do not need and do not use information about the types of entities. Comparing ROP performance to RNN-path-entity is more fair, and this makes it even clearer that our modeling is effective. Das et al. (2017) encode entities along with relations into the path representation explicitly. Their motivation is that entity incorporation prevents prediction of the same target relation when relation sequences are the same, but path entities are different. Our ROP models achieve this implicitly, as the relation sequence can predict the entity sequence; this makes sure the representation of the relation sequence is specific to the entity sequence. As a result, the same goal can be achieved as (Das et al., 2017).

In (Das et al., 2017), an entity and a relation *are concatenated as a new unit* in the path; both entity and relation representations are trained based on the given gold relation as label. ROP predicts intermediate entities and updates the entity/relation embeddings and other parameters in each step; the training signals can come from the in-path target entities and from the reasoning task specific annotations. Thus, ROP makes use of the in-path structures to learn good quality entity/relation embeddings, which are further employed and finetuned to solve the reasoning problem.

This can also explain why max (over all paths) works well for us while Das et al. (2017) found Log-SumExp (over all paths) works better. As their system solely relies on target relations as training signals, max selection prevents all other paths from generating gradients to update, so max tends to select randomly in the initial stage. However, in our system, the representations of entities and relations get rich training signals at each path hop, so that the path representations are more reliable. Hence, max can select the most informative path and avoid misleading paths to support the claim of target relation. In a similar vein, max pooling is widely found more effective than mean/sum pooling for classification as this task mostly relies on the dominant features.

5.2 Path Query Answering (mh-PQA)

Dataset. We use the mh-PQA dataset released by Guu et al. (2015) and refer to it as *BaseKGP*[4]. BaseKGP contains paths like $e_h, r_1, r_2, \cdots, r_t, e_t$, where e_h and e_t are head and tail entities, connected

[4]Das et al. (2017) use a dataset based on the WordNet, however they conclude that the dataset is not an ideal test bed for mh-PQA due to some limitations: it is fairly small, with very short paths, few unseen paths during test time, and only one path between an entity pair. Therefore, we experiment on BaseKGP.

	#paths	#entities	#relations
train	6,266,058	75,043	26
dev	27,163	41,010	26
test	109,557	96,858	26

Table 2: Statistics of EnhancedKGP for mh-PQA

	methods	MQ	H@10
BaseKGP (baselines)	Comp-Bilinear	83.5	42.1
	Comp-Bilinear-Diag	84.8	38.6
	Comp-TransE	88.0	50.5
BaseKGP (our model)	ROP_ARC1	88.3	52.7
	ROP_ARC2 (ADD)	89.3	54.3
	ROP_ARC2 (GRU)	89.6	54.9
EnhancedKGP (our model)	ROP_ARC1	89.4	54.2
	ROP_ARC2 (ADD)	90.3	55.5
	ROP_ARC2 (GRU)	90.5	56.3
	ROP_ARC3 (ADD)	90.3	55.8
	ROP_ARC3 (eGRU)	**90.7**	**56.7**

Table 3: Results of mh-PQA

by relation sequence $r_1, \cdots, r_t$. There are 6,266,058/27,163/109,557 paths in train/dev/test.

BaseKGP is based on a Freebase subset released by Socher et al. (2013). The original subset contains a collection of Freebase triplets in form of (head, relation, tail). Guu et al. (2015) generated paths by traversing the triplet space. Paths in BaseKGP of form $e_h, r_1, r_2, \cdots, r_t, e_t$ do not contain intermediate entities. We create *EnhancedKGP* by enhancing each BaseKGP path *in train* as follows. We search entities at each step of a path by traversing the subset (Socher et al., 2013) until reaching the tail entity e_t. When there are multiple entity choices at a step, we randomly choose one. EnhancedKGP *train* has the same size as BaseKGP *train*, except that paths are filled by intermediate entities. Table 2 gives statistics. We will release EnhancedKGP, the first dataset for mh-PQA that includes within-path entities.

Task setup. We tune parameters on dev. We sample 10 negative entities for each ground truth entity in the path and use ranking loss (Eq 18) (with α=0.3, s() = cosine similarity). For testing, we ignore intermediate predicted entities and only output the tail entity. We update parameters – relation embeddings, entity embeddings (both dimension 300) and GRU parameters – using AdaGrad with learning rate 0.01 and mini-batch size 50.

We compare ROP with the three compositional training schemes *Bilinear*, *Bilinear-Diag* and *TransE* in (Guu et al., 2015). The compositional training of TransE, denoted as *Comp-TransE* in this work, is the state-of-the-art in mh-PQA. For ROP_ARC2, we report the performance of using ADD and GRU for COMP_1 in Eq 9. Similarly, for ROP_ARC3, we report the performance of using ADD and eGRU for COMP_2 in Eq 10.

In addition, to better investigate ROP models, we run them on both BaseKGP and EnhancedKGP. Note that since there are no intermediate entities in BaseKGP, ROP_ARC3 is reduced to ROP_ARC2. Hence, we report results on BaseKGP only for ROP_ARC1 and ROP_ARC2.

Two benchmark metrics are reported for this task (Guu et al., 2015): *hits at 10* (H@10), percentage of ground truth tail entities ranked in the top 10 of all retrieved; and *mean quantile* (MQ), normalized version of mean rank.

Results. Table 3 gives results for mh-PQA: top baselines on BaseKGP (block 1), ROP results on BaseKGP (block 2) and ROP results on EnhancedKGP (block 3). Overall, our ROP models all get new state-of-the-art by large margins (2–4% H@10 on BaseKGP, 4–6% H@10 on EnhancedKGP). The improvements of the second block over the first are evidence that recurrent neural networks are an appropriate paradigm in this task. The third block shows that encoding intermediate entities in an appropriate

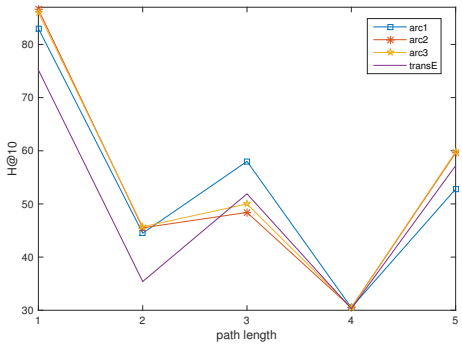

Figure 4: H@10 vs. path lengths on test set

way, like ROP does, can give a further boost.

Comparing ROP_ARC2 and ROP_ARC1, we realize that forwarding head entity e_h *directly* to predict each intermediate entity e_i is better than putting e_h as the start state of the GRU. We suspect this is due to the fact that the latest state of GRU is gradually less influenced by e_h when the following relation path is getting longer and longer. In ROP_ARC2, no matter how long the relation sequence $r_1, r_2, \cdots, r_i$ is, we always compose its whole representation $\mathbf{h}_i$ with the representation of e_h so that e_h can participate in the prediction of e_i more directly.

ROP_ARC3 further improves results by composing not only head entity e_h, but also the preceding predicted entity $\hat{e}_{i-1}$ with h_i to predict entity e_i. The result suggests that $\hat{e}_{i-1}$ provides critical information in this prediction process. This may be due to the property of RNN that latest inputs tend to be remembered better than old inputs, so the latest hidden state $\mathbf{h}_i$ is heavily influenced by the adjacent relations of position i; employing the preceding predicted entity $\hat{e}_{i-1}$ hence can help the prediction of e_i.

For composition, GRU/eGRU always surpass ADD – presumably due to the higher expressibility of (e)GRU's gating mechanism.

Performance vs. path lengths. Figure 4 graphs H@10 on different path lengths for our three ROP systems and the Comp-TransE baseline. We expected that H@10 should decrease gradually. However, Figure 4 shows that even-length paths are harder than odd-length ones. This surprising phenomenon is *due to a large number of inverse relations, as most inverse relations in BaseKGP are 1-to-N connections*.

The percentages of inverse relations in paths of length 1, 2, 3, 4, 5 are 0.0, 49.7, 38.3, 49.5 and 42.9, respectively. Spearman correlation coefficients between these percentages and system performance are always higher than 0.9. Thus, the more inverse relations, the worse performance. Unfortunately, to date there is no good way to model pairs of a relation $\mathbf{r}$ and its inverse $*\mathbf{r}$, e.g, "gender" and "*gender", as separate, yet at the same time as systematically related. Guu et al. (2015)'s TransE implementation enforces $*\mathbf{r}+\mathbf{r} = \mathbf{0}$. Figure 4 shows this is not as effective as expected, perhaps because it fails for 1-to-N projections. ROP treats inverse relations as independent, but we did not observe any worse performance. Better modeling of inverse relations is an interesting challenge for future work.

6 Conclusion

This work presented three ROP architectures for multi-hop KG reasoning. ROP models a KG path of arbitrary length as a pair of a relation sequence and an entity sequence, using the former to predict the latter by encoding and decoding step by step. Our neural sequential modeling of KG paths enables better learning of entity/relation embeddings because there are more training signals at each multi-hop path. ROPs showed state-of-the-art in two representative KG reasoning tasks, multi-hop KBC and multi-hop PQA. Incorporating knowledge from textual sources by initializing the entity embeddings with distributional representation of entities (Yaghoobzadeh and Schütze, 2015) could improve our results further, which we will explore in the future.

Abstract

We examine the utility of linguistic content and vocal characteristics for multimodal deep learning in human spoken language understanding. We present a deep multimodal network with both feature attention and modality attention to classify utterance-level speech data. The proposed hybrid attention architecture helps the system focus on learning informative representations for both modality-specific feature extraction and model fusion. The experimental results show that our system achieves state-of-the-art or competitive results on three published multimodal datasets. We also demonstrated the effectiveness and generalization of our system on a medical speech dataset from an actual trauma scenario. Furthermore, we provided a detailed comparison and analysis of traditional approaches and deep learning methods on both feature extraction and fusion.

1 Introduction

Understanding human conversation is fundamental for human-computer interaction (HCI) and artificial intelligence (AI). However, it is hard for a computer to precisely interpret human meaning because: 1. Giving computers the ability to interpret speech requires a complete understanding of how it works for a human. Unfortunately, we still cannot identify how humans understand the information during conversation. 2. It is hard to extract associated features; there is a gap between the extracted modality-specific features and the actual human state of mind. 3. During conversation, people often accept messages from multiple sources such as facial expression, gesture, linguistic content, and vocal signals. But how to integrate the heterogeneous inputs into a computer is still an open-ended question. In this paper, we focus on exploring and addressing the issues above on the spoken language classification task, which is the most commonly used method for human sentiment analysis, emotion recognition, and speech topic categorization.

Comprehending spoken language can be rephrased as analyzing vocal signals. A variety of research focuses on extracting the human meaning from audio data (Koolagudi et al., 2012; Busso et al., 2013; Mirsamadi et al., 2017). However, instead of directly processing audio information at the frame-level as a computer does, humans comprehend the meaning of utterances on the word-level, which can be seen as extracting meaning from linguistic content. It is natural for beginners in English to translate speech information into their native language word-by-word to understand the conversation, effectively using textual information for spoken language understanding. Based on this assumption, we propose a multimodal structure that considers both the audio signal and text as inputs to classify utterance-level speech data, where text data can be either transcribed speech or automatic speech-to-text output.

Another challenge for classifying spoken language is extracting the associated features. As mentioned in previous research (Poria et al., 2017a), traditional approaches used handcrafted features for both the text and audio branches, which cannot fully represent the high-level characteristics. Recent studies tried to overcome such issues with deep learning structures, including convolutional neural networks (CNNs)

Santa Fe, New Mexico, USA, August 20-26, 2018.

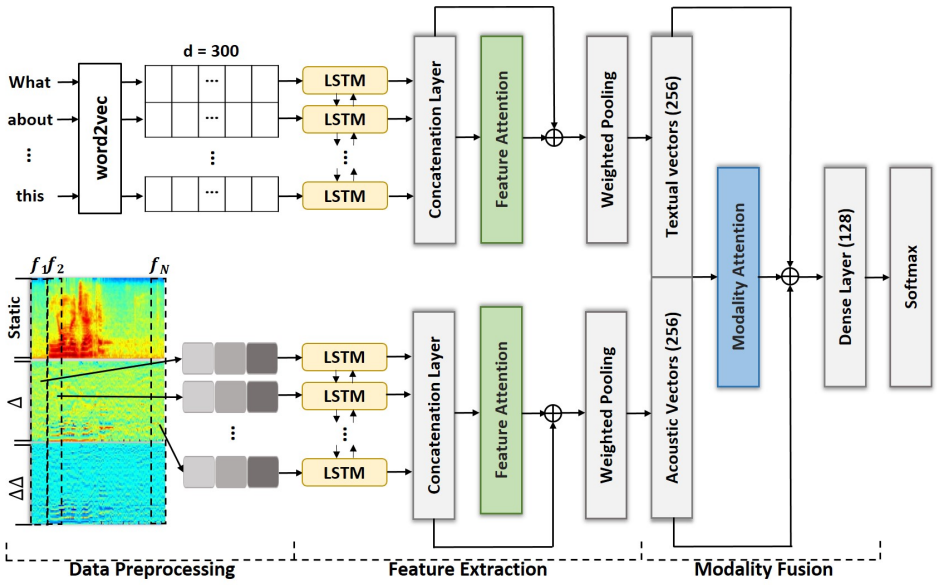

Figure 1: Overall system structure.

(Poria et al., 2015) and long short-term memory networks (LSTMs) (Zadeh et al., 2017). However, the words and audio frames should have different importance. For example, the word hate carries all the anger information in "I hate you". Even the same word or acoustic frame may have different contributions for different classes. To select the informative words and frames, we introduced an LSTM with an attention mechanism as the feature extractor on both the text and audio branches. A weighted pooling strategy was applied over the feature extractor to form a modality-specific feature representation. Compared to the previous research using independent software or networks to extract the modality-specific features, our system simultaneously tunes both the feature extraction and fusion modules, encouraging optimal feature learning.

Decision-level fusion is a commonly used strategy for fusing heterogeneous inputs, combining the independent modality outputs by using several specific rules. However, the lack of mutual association learning across modalities is a major limitation of applying decision-level fusion (Zhang et al., 2017). Feature-level fusion aims to fuse the extracted modality-specific features as a general feature vector, and so has the ability to learn correlations across modalities. Unfortunately, it is difficult to ensure data synchronization, as different features may consist of diverse time scales and formats (Poria et al., 2017a). To address the above issues, model-level fusion has been introduced, which generates a joint or shared feature representation consisting of both the feature-level fusion and decision-level fusion characteristics. Instead of using shallow structures in fusion as previous approaches did (Kim et al., 2013; Pang et al., 2015), we designed a modality attention fusion that allows system fusion at the feature-level and applies weighted modality scores over the extracted features to indicate the importance of different modalities. This keeps advantages of both feature-level and decision-level fusion.

We evaluated our system on three published multimodal datasets for spoken language understanding tasks, including speech sentiment analysis (CMU-MOSI and MOUD) and speech emotion recognition (IEMOCAP). Our system achieves state-of-the-art on CMU-MOSI and IEMOCAP, and competitive results on MOUD. We also generalize the system to classify speech content for utterance-level data on an an actual trauma resuscitation speech dataset (TRS). The results show that the proposed network improves performance on noisy data. Specifically, this paper addresses the following issues:

1. Does multi-source input data improve performance, and is it necessary to apply text information to a spoken language classification task?

2. Is the proposed attention-based LSTM structure helpful? Does extracting high-level representations perform better than low-level handcrafted features?

3. Is modality attention needed?

4. Is the proposed system enough to perform spoken language classification in a real scenario?

The paper is organized as follows: we present the related work in section 2. Section 3 describes the proposed network. We provide the experiments in section 4 and discuss the results in detail in section 5. We conclude in section 6.

2 Related Work

Previous works in spoken language classification focused on extracting acoustic features from different aspects of speech data (Koolagudi et al., 2012; Busso et al., 2013; Mirsamadi et al., 2017). While there is much previous research using audio-visual data on emotion recognition and sentiment analysis, only a few of them consider text as input. These approaches are difficult to generalize to spoken language understanding (due to the lack of visual data in many scenarios) and ignore the contribution of text. Recent studies on speech-based analysis have proposed to use both audio and text data for classification (Jin et al., 2015; Gu et al., 2018). However, they only applied the experiments to emotion recognition.

A variety of feature extraction strategies were proposed in the last decade. Early research used low-level acoustic descriptors and derivations (LLDs) with functional statistics as acoustic features (Rosas et al., 2013). For textual features, they used SVMs with bag of words (BoW) and part of speech (PoS) features in addition to low-level acoustic features (Rozgic et al., 2012; Rosas et al., 2013). Since low-level features represent limited high-level associations (Poria et al., 2015), various deep learning approaches have been proposed, like CNNs (Poria et al., 2016) and LSTMs (Gu et al., 2017b; Zadeh et al., 2017), to learn high-level representations. To further improve system performance, an attention mechanism was introduced in machine translation and text classification (Bahdanau et al., 2014; Yang et al., 2016)

There exist two commonly used fusion strategies in previous research: decision-level fusion and feature-level fusion. Specifically, Poria et al. (Poria et al., 2015, 2016) used a multiple kernel learning strategy to fuse the modality data on the feature-level. A decision-level fusion was applied by Wöllmer et al. (Wöllmer et al., 2013) that combines the results of the text and audio-visual modalities by a threshold score vector. Deep neural network fusion was proposed in a recent study to fuse the extracted modality-specific features (Zhang et al., 2017; Gu et al., 2018). More recent approaches introduced LSTM structures to fuse the features at each time step (Poria et al., 2017b; Chen et al., 2017)

3 Method

We introduce the design of the proposed architecture in this section (shown in Figure 1). There are three major parts of the system: the data preprocessing, feature extraction, and modality fusion.

3.1 Data Preprocessing

The system accepts raw audio signal and text as inputs. The data preprocessing module formats the heterogeneous inputs into specific representations, which can be effectively used in the feature extraction network. We embedded the words and extracted Mel-frequency spectral coefficients (MFSCs) from the text and audio inputs for the feature extraction module.

We first embedded each word into a 300-dimensional word vector by *word2vec*, which is a pre-trained word embedding dictionary trained on 100 million words from Google news (Mikolov et al., 2013). Compared to *GloVe* and *LexVec*, *word2vec* provides us the best performance. For all embedded vectors, we allow fine-tuning of the embedding layer via backpropagation during the training stage. We removed all punctuation, as spoken language does not provide tokens. Unknown words were randomly initialized and each sentence was represented as a $N \times 300$ matrix, where N is the number of the words for the given sentence.

Unlike most previous research extracting LLDs or using Mel-frequency cepstral coefficients (MFCCs) as the acoustic features (Poria et al., 2016; Mirsamadi et al., 2017), we represented the raw audio signal using MFSCs because: 1. MFSCs maintain the locality of the data by preventing new bases of spectral energies resulting from discrete cosine transform in MFCCs extraction (Abdel-Hamid et al., 2014). 2. Compared to the MFCCs that only have 39 dimensions for each audio frame, MFSCs allow more dimensions in the frequency domain that aid learning in deep models. 3. Instead of using MFCCs, voice

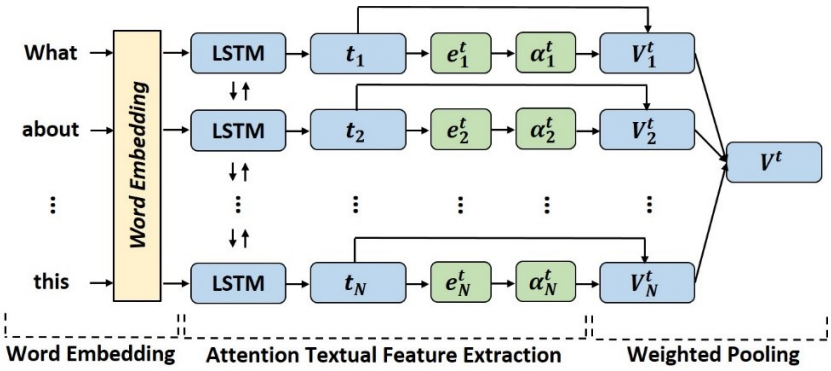

Figure 2: Textual feature extraction with attention.

intensity, pitch, etc. as in (Poria et al., 2017b) that need voice normalization and statistic computations, MFSC extraction does not require additional operations. As suggested in (Gu et al., 2017), we used 64 filter banks to extract static, delta (Δ), and double delta ($\Delta\Delta$) of the MFSCs as the MFSCs map. The final representation is a 3-D array with $64 \times F \times 3$ dimensions, where F is number of extracted MFSCs frames.

3.2 Textual Feature Extraction with Attention

We applied the LSTM structure with an attention mechanism to extract temporal associations and select informative words.

The textual feature extraction module consists of two parts. Firstly, it has a regular bidirectional LSTM structure used to generate the contextual hidden states for each word vector. Secondly, it has an attention layer connected to the bidirectional LSTM to provide a weight vector over the contextual hidden states to amplify the representative vectors. As shown in Figure 2, we fed the words into the bidirectional LSTM in sequence. Specifically,

$$t_i^{\rightarrow}, t_i^{\leftarrow} = bi\_LSTM(E_i), i \in [1, N]$$

where E_i is the embedded word vector of the ith word, bi_LSTM is the bidirectional LSTM, and $t_i^{\rightarrow}$ and $t_i^{\leftarrow}$ denote respectively the forward and backward contextual states of the given input word vector. Each contextual state is a word-level feature representation with forward and backward temporal associations. As not all words equally contribute to the final prediction, we added a learnable attention layer over the contextual states to denote the importance of the representations. As defined by (Bahdanau et al., 2014), we first computed the text attention energies (e_i^t) by:

$$e_i^t = tanh(W_t[t_i^{\rightarrow}, t_i^{\rightarrow}] + b_t), i \in [1, N]$$

Then, we calculated the text attention distribution (α_i^t) for word representations via a softmax function:

$$\alpha_i^t = \frac{exp(e_i^{t^\top} v_t)}{\sum_{k=1}^{N} exp(e_k^{t^\top} v_t)}$$

where W_t, b_t, and v_t are the learnable parameters. To form the final textual feature representation (V^t), we applied a weighted-pooling by computing a weighted sum of the text contextual states and the attention distribution:

$$V^t = \sum_{i=1}^{N} [t_i^{\rightarrow}, t_i^{\leftarrow}] \alpha_i^t$$

Unlike the systems that apply convolutional neural networks to extract the sentimental and emotional textual features using a fixed window size (Poria et al., 2015; Poria et al., 2017b), we used LSTM structures that can fully capture the sequential information with varying length and learn the temporal associations between words. We notice that Zadeh also applied LSTMs as the textual feature extractor

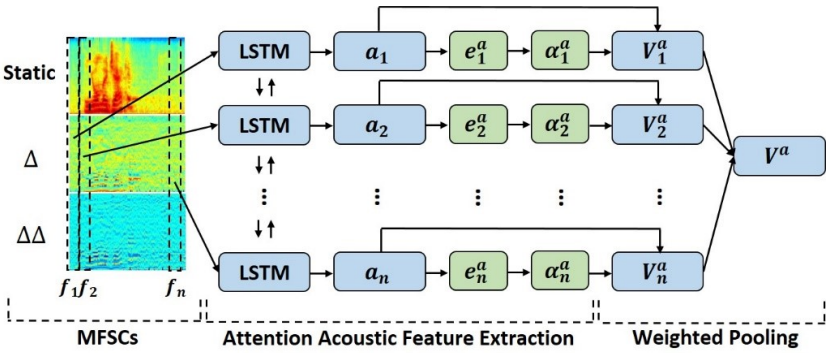

Figure 3: Acoustic feature extraction with attention.

(Zadeh et al., 2017). However, they used a mean-pooling strategy to form the final utterance-level feature representation by passing all the contextual states into the dense layer. This assumes all the outputs can correctly contribute to the final prediction. Unfortunately, as we know, even the same word may carry diverse information that may make a different contributions to the final prediction. The proposed attention layer allows the system to focus on the most informative words to further improve the representations.

3.3 Acoustic Feature Extraction with Attention

Similar to textual feature extraction, we also introduced a bidirectional LSTM with attention to focus on extracting informative contextual states on frame-level MFSCs.

Unlike the textual feature extraction that only has one channel (2D-array), the input MFSCs map is a 3D-array. We first concatenated the synchronized frames from static, delta, and double delta feature maps to form the input acoustic feature vector (A_j):

$$A_j = [s_j, \Delta_j, \Delta\Delta_j], j \in [1, F]$$

Again, we used the same approach as in textual feature extraction to compute the bidirectional acoustic contextual states $([a_j^{\rightarrow}, a_j^{\leftarrow}])$, acoustic attention energies (e_j^a), and acoustic attention distribution (α_j^a). The α_j^a can be understood as the importance score for the jth frame. We computed the weighted sum of the bidirectional acoustic contextual states and acoustic attention distribution as the final acoustic representation (V^a).

Unlike previous research that directly uses the acoustic LLDs as the extracted features (Degottex et al., 2014; Poria et al., 2016), the proposed architecture learns high-level acoustic associations. We didn't use convolutional neural networks to extract the acoustic features as in (Gu et al., 2017) because CNNs only capture spatial associations whereas acoustic data contains many temporal associations. The fixed window size of CNNs limits the temporal interaction extraction. As the number of audio frames is large (hundreds per sentence), the LSTM structure ensures the system captures long-term dependencies among the MFSCs frames. Even if a deep neural network was used for extracting the high-level associations on LLDs (Zadeh et al., 2017; Gu et al., 2018), the generation of attention over the extracted features is still desirable, as it can help indicate the importance at the frame-level. The weighted pooling based on the attention distribution makes sure the final acoustic feature representations contain the most informative features.

3.4 Modality Fusion

Simply concatenating the features cannot reveal the actual importance of different modalities; the same modality may have different contributions in different spoken language understanding tasks. For example, people rely more on the vocal delivery and acoustic characteristics to express their emotions, but linguistic content and text are more important to speech content classification. Even for the same task, the modality may have distinct influences on different categories. Acoustic information might provide useful information for the *Anger* class, but it is hard to distinguish *neutral* and *happy* without considering text. To make the system learn this difference, we proposed a modality attention fusion that puts an attention

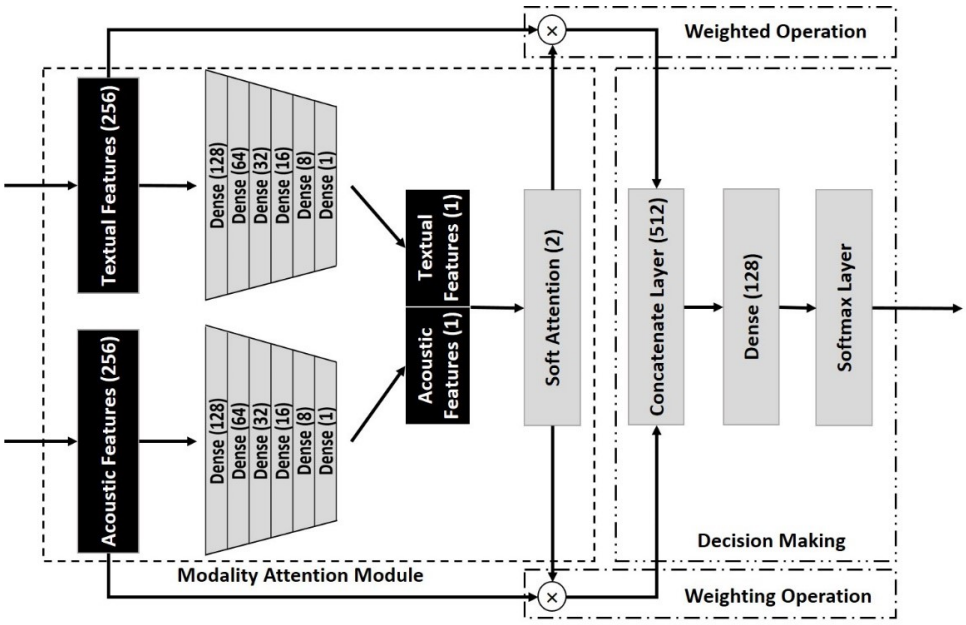

Figure 4: Modality Fusion

layer over the extracted modality-specific features, helping the system focus on the informative modality. It can be intuitively understood as giving a weighted score vector at the modality-level to indicate the importance of individual branches.

The proposed modality fusion consists of three major parts: a modality attention module, a weighted operation, and a decision making module. We first set up five dense layers after the attention layer to fuse the modality-specific features (as shown in figure 4). Then, we used softmax regression to generate the weighted score (s) for the given modality:

$$s = softmax(tanh(W_f[V_t^*, V_a^*] + b_f))$$

where W_f and b_f are the trainable fusion attention parameters, s is a n-dimension vector, and n=2 in this study (representing the text and audio modalities respectively). We computed a soft-attention over the original modality features and concatenated them. A dense layer was used to learn the associations across weighted modality-specific features by:

$$r = tanh(W_r[(1 + s_t)V^t, (1 + s_a)V^a] + b_r)$$

where r is the final representation, and W_r and b_r are the additional parameters for the last dense layer. We used $(1 + s)$ as the attention score to keep the original modality characteristics. We made the final decision by a softmax classifier using r as input.

4 Experiment

We evaluated the proposed system on three published multimodal datasets and an actual trauma resuscitation speech dataset. We compared our structure with the baselines from three major aspects: 1. proposed system vs previous methods; 2. low-level handcrafted features vs high-level features; 3. shallow fusion vs deep fusion. We also conducted an experiment on a trauma resuscitation speech dataset that uses speech-to-text results as text input to test the generalizability of the system.

4.1 Dataset

We selected three multimodal datasets that contain spoken language information. We used audio and text data as inputs in this study. Table 1 shows dataset details.

CMU-MOSI: This dataset is a multimodal sentiment intensity and subjectivity dataset consisting of 93 review videos in English with 2199 utterance segments (Zadeh et al., 2016). Each segment is labelled

by five individual annotators between -3 (strong negative) to +3 (strong positive). The aim of using this dataset is to extract the sentiments from spoken language information by applying the audio segments and the corresponding transcripts. We used binary labels (positive and negative) based on the sign of the annotations average. We used an 80-20 training-testing split that considers speaker independency. Specifically, there are 1755 utterances for training and 444 utterances for testing.

Dataset	Class	Speaker Independent	Training Set	Testing Set
CMU-MOSI	2	93 (74|19)	1755	444
IEMOCAP	4	151(121|30)	4295	1103
MOUD	2	79 (59|20)	322	115
TRS	7	50 (40|10)	7261	1843

Table 1: Dataset details.

IEMOCAP: The interactive emotional dyadic motion capture database is a multimodal emotion dataset including visual, audio, and text data (Busso et al., 2008). For this study, we only used the audio and text data and classified emotion at the utterance-level. We used the label agreed on by the majority and combined the *happy* and *excited* classes following previous research (Poria et al., 2016). The final dataset consists of four categories including 1591 *hap (happy+excited)*, 1054 *sad*, 1076 *anger*, 1677 *neutral*. We still used an 80-20 speaker independent data split. Table 1 shows the detailed separation.

MOUD: The MOUD dataset is a Spanish multimodal utterance-level dataset. Following previous research (Poria et al., 2016), we only consider the positive and negative labels during training and testing. Instead of translating the sentences into English as previous research did, we initialize the word embedding layer randomly.

In addition, we tested the generalizability of the proposed system on a trauma resuscitation speech dataset (TRS).

TRS: This dataset was collected from 50 actual trauma cases with 9104 utterance-level audio segments. For each segment, it contains one utterance with at least 2 seconds. The dataset contains the following utterance-level medical category labels: *airway*, *breathing*, *circulation*, *disability*, *exposure*, *secondary-survey*, and *others*. Each utterance was assigned one category by trauma experts. The audio data was collected by two shotgun microphones placed in the resuscitation room. We used two different transcripts as the text input: human transcribed text and speech-to-text transcript. These experiments can then evaluate the influence of noise in the text branch. We reserved 40 cases as the training set and the 10 others as the testing set.

4.2 Baselines

We first compared our system with several state-of-the-art methods.

SVM Trees: an ensemble of SVM trees was used for classifying concatenated bag-of-words and LLDs (Rozgic et al., 2012).

BL-SVM: extracted bag-of-words and low-level descriptors as textual and acoustic features, respectively. The model used an SVM classifier (Rosas et al., 2013).

GSV-eVector: this model used Gaussian Supervectors to select LLDs as acoustic features and extracted a set of weighted handcrafted vectors (eVector) as textual features. A linear kernel SVM was used as the final classifier (Jin et al., 2015).

C-MKL: the system used a multiple kernel learning structure as the final classifier (Poria et al., 2016). The model extracted textual and acoustic features by using a convolution neural network and OpenSMILE software, respectively.

TFN: a tensor fusion network was used to fuse the extracted features from different modalities (Zadeh et al., 2017).

WF-LSTM: a word-level LSTM with temporal attention structure to predict sentiments on the CMU-MOSI dataset (Chen et al., 2017).

BC-LSTM: a bidirectional LSTM structure to learn contextual information among utterances (Poria et al., 2017b).

Approach	CMU-MOSI		IEMOCAP		MOUD		TRS	
	Acc	W-F1	Acc	W-F1	Acc	W-F1	Acc	W-F1
SVM Tree	67.3	66.1	66.4	66.7	60.4	50.4	58.4	45.7

BC-LSTM	72.4	72.6	70.8	70.8	72.4	72.4	67.9	64.4
H-DMS	70.4	70.2	70.2	69.8	68.4	67.6	66.7	64.3
Our Method	**76.2**	**74.8**	**72.1**	**72.2**	**72.8**	**73.0**	**69.4**	**66.0**

Table 2: Proposed system vs previous methods. Acc = accuracy (%). W-F1 = weighted F1 score.

H-DMS: a hybrid deep multimodal structure to extract and fuse the textual and acoustic features on the IEMOCAP dataset (Gu et al., 2018).

We further tested the performance of models using different feature extraction methods.

BoW: using bag-of-words as the textual features to make the final prediction (Wöllmer et al., 2013).

WEV: directly using word embedding vectors as the textual features (Zadeh et al., 2018).

CNNs-t: Convolutional neural networks were used for extracting the textual features based on embedding word vectors (Poria et al., 2015).

LSTM-t: using an LSTM structure to learn contextual word-level textual features (Gu et al., 2017b).

OpenSimle: extracts 6373 low-level acoustic features from an entire audio clip (Poria et al., 2017b).

COVAREP: extracts low-level acoustic features including MFCCs, pitch tracking, glottal source parameters, peak slope, and maxima dispersion quotients (Chen et al., 2017).

CNNs-a: using convolutional neural networks on extracted MFSCs (Gu et al., 2017).

LSTM-a: using an LSTM structure to learn the temporal associations based on LLDs extracted by OpenSmile (Gu et al., 2018).

To make the comparison more reasonable, we introduced a shallow fusion and a deep fusion that combines with the previous feature extraction strategies to make the final predictions.

SVM: an SVM was trained on modality-specific features or concatenated features for classification.

DF: a deep neural network with three hidden layers was trained as the fusion module and a softmax classifier was used for decision-making.

4.3 Implementation

We implemented the system in Keras using the Tensorflow backend. Instead of directly training the entire network, we first pre-trained the feature extraction networks by using two individual softmax classifiers. Then, we tuned the entire network by combining the feature extraction module and modality fusion module. The system was trained on a GTX 1080 GPU with 32GB RAM. We set 256 as the dimension for the bidirectional LSTM. We selected the ReLU activation function except for the attention layers. To overcome overfitting and internal covariate shift (Ioffe and Szegedy, 2015), we applied dropout and batch normalization after the bidirectional LSTM layer and attention layers. We initialized 0.01 as the learning rate, used the Adam optimizer, and binary/categorical cross-entropy loss. We further split 20 percent of the data from the training set as validation and used mini-batch size 8. To make a fair comparison between the proposed system and baselines, we re-trained all models on the same training-testing set split (shown in Table 1). We directly built the models for the baselines that provided the source code. For the rest, we re-implemented the models based on the methods described in their papers.

5 Experiment Result

We first compared the performance of the proposed system with the previous methods. The result shows that our system achieves state-of-the-art on all three published datasets. Specifically, we achieved 76.2% accuracy and 74.8 weighted F1 score on CMU-MOSI, outperforming the previous methods by a margin

Table 3: Detailed comparison on CMU-MOSI (CM) dataset and IEMOCAP (IE) dataset (accuracy percentage). OS* = OpenSmile. COV* = COVAREP. ATFE = proposed attention based textual feature extraction. AAFE = proposed attention based acoustic feature extraction. MAF = modality attention fusion.

of 2.3% to 7.8%, which demonstrates the effectiveness of the proposed architecture. Compared to the traditional approaches using low-level handcrafted features and shallow fusion strategies (GSV-eVector and SVM Trees), the proposed method shows a significant performance improvement on IEMOCAP (9.3% and 8.7% accuracy gain, respectively). Experiments also indicate that our system performs better than the deep approaches (including C-MKL, TFN, H-DMS), showing the necessity of learning attentive information on feature extraction and fusion levels. Our approach achieves a competitive result (72.8% accuracy) on the MOUD dataset. We further re-implemented all previous methods on the TRS dataset, and our system reports the best performance in terms of both accuracy (69.4%) and weighted F1 score (66.0).

We further compare low-level vs high-level features and shallow vs deep fusion. We re-trained all the individual feature extraction baselines and fusion structures on both IEMOCAP and CMU-MOSI with the same training-testing split. As shown in Table 3 (a), (b), and (c), we made several different combinations of the feature extraction baselines with fusion baselines. We first evaluated the performance of unimodal and multi-modal systems. From Table 3 (a), in all of combinations, multi-modal systems performed better than unimodal ones. In general, the performance of text is similar to that of audio on the IEMOCAP dataset, but text dominates the system performance on MOSI. This might because humans rely more on vocal delivery to express emotions, but less on sentiments. Combining textual and acoustic modalities using an ATFE+AAFE structure leads to 9.6% performance boost on IEMOCAP, which proves the necessity of using multimodal inputs in spoken language understanding. However, there is only 1.7% accuracy improvement on CMU-MOSI by using a multimodal structure. This might because humans express their attitudes without using many vocal characteristics.

Table 3 (b) compares the different feature extraction methods. Compared to traditional textual feature extraction (BoW), the deep models achieve better performance by extracting high-level associations on both datasets. It worth mentioning that directly using the word vectors extracted by *word2vec* model as textual features (WEA+SVM) cannot outperform CNN and LSTM word vector feature extractors (CNNs-t+SVM and LSTM-SVM). This observation demonstrates the necessity of extracting high-level features. On IEMOCAP, the high-level acoustic features extracted by CNNs-a and LSTM-a achieves 59.9% and 60.5% accuracy, outperforming the low-level handcrafted acoustic features (OpenSimle+SVM and COVAREP+SVM) between 1.7% to 7.8% in accuracy. We notice that applying the LSTM architecture over the LLDs gives a 2.4% accuracy increase compared to directly using the LLDs

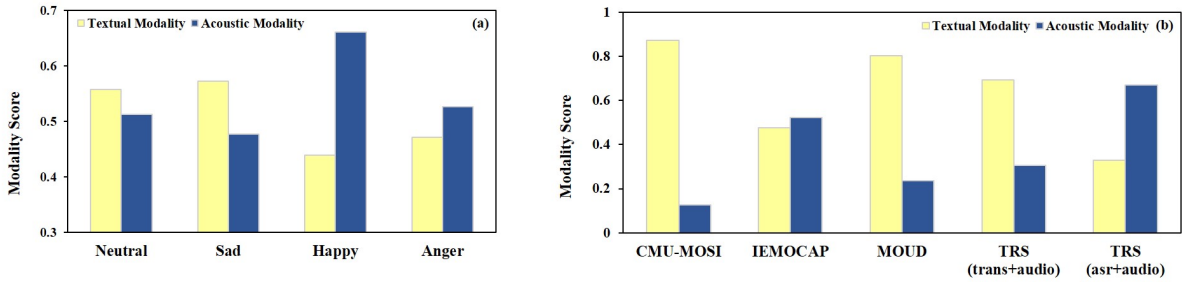

Figure 5: The weighted scores of modality attention. (a) Modality attention scores of different categories on IEMOCAP. (b) Modality attention scores of different datasets.

on CMU-MOSI, which shows that modeling the temporal associations improve system performance. As expected, the proposed attention-based textual and acoustic feature extraction performs the best on each individual branch. Based on the above observations, we conclude that learning the high-level features from textual and acoustic data improves the system performance, and that the proposed attention-based LSTM structure indeed helps extract associated features.

Compared to the performance of shallow fusion (SVM) in Table 3 (c), deep fusion (DF) gives a significant performance improvement on combinations that use deep feature extractors (CNNs, LSTM, and proposed attention structure), demonstrating that extracting associations across modality-specific features indeed helps the final decision-making. The modality fusion outperforms both shallow fusion (directly using SVM classifier) and deep fusion (DF) on diverse feature extraction combinations. Using an MAF structure instead of SVM and DF brings 5.1% and 1.4% accuracy gain on CMU-MOSI, respectively. To further compare, we visualized the weighed scores from the modality attention on different datasets and categories (shown in Figure 5). We computed the average scores of one hundred random testing samples from each category and dataset. The results indicate the proposed modality attention can learn the distinct scores on different categories and datasets.

We further tested the generalization of the proposed system by applying it to the TRS dataset. Instead of just using the transcribed speech text, we fed the raw audio data into the IBM Watson speech to text API to automatically recognize speech (ASR). From Table 3 (d), using the ASR text leads to a 19.1% accuracy decrease compared to the transcribed text on unimodal systems. However, the multimodal structure only has a 10.5% accuracy drop. These observations indicate that the multimodal system is tolerant to noisy data, demonstrating the generalizability of the proposed multimodal architecture with modality attention.

6 Conclusion

In this paper, we introduced a hybrid attention based multimodal architecture for different spoken language understanding tasks. Our system used feature attention and modality attention to select the representative information at both the feature-level and modality-level. The proposed modality attention fusion overcomes the limitations from feature-level and decision-level fusion by performing feature-level fusion with modality scores over the features. We evaluated our system on three published datasets and a trauma resuscitation speech dataset. The results show that the proposed architecture achieves state-of-the-art performance. We also demonstrated the necessity of applying a multimodal structure, extracting high-level feature representations, and using modality attention fusion. The generalization testing established that our system has the ability to handle actual speech data.

Abstract

This paper explores the influence of spelling errors on lexical variation measures. Lexical variation measures such as Type-Token Ration (TTR) and Yule's K are often used for learner English analysis and assessment. When applied to learner English, however, they can be unreliable because of the spelling errors appearing in it. Namely, they are, directly or indirectly, based on the counts of distinct word types, and spelling errors undesirably increase the number of distinct words. This paper examines the hypothesis that lexical variation measures become unstable in learner English because of spelling errors. Specifically, it tests the hypothesis on English learner corpora of three groups (middle school, high school, and college students). To be precise, it estimates the difference in TTR and Yule's K caused by spelling errors, by calculating their values before and after spelling errors are manually corrected. Furthermore, it examines the results theoretically and empirically to deepen the understanding of the influence of spelling errors on them.

Title and Abstract in French

Une exploration de l'influence des erreurs orthographiques sur les mesures de variation lexicale

Cet article explore l'influence des erreurs orthographiques sur les mesures de variation lexicale. Les mesures de variation lexicale telles que le rapport type-occurrence (*Type-Token Ratio*; TTR) et le K de Yule sont souvent employées pour analyser et évaluer l'anglais d'apprenants langue seconde. Lorsqu'on les applique a l'anglais d'apprenants, elles peuvent cependant s'avérer peu fiables du fait des erreurs orthographiques que l'on y rencontre. De fait, elles se fondent directement ou indirectement sur le décompte des types de mots diffŕents, et les erreurs orthographiques augmentent artificiellement le nombre de mots différents. Cet article examine l'hypothèse selon laquelle les mesures de variation lexicale deviennent instables sur l'anglais d'apprenants à cause des erreurs orthographiques. Il teste cette hypothèse sur des corpus d'anglais d'apprenants de trois groupes (élèves de collège, de lycée, et étudiants à l'université). Plus précisément, il estime la différence causée par les erreurs orthographiques sur le TTR et le K de Yule en calculant leurs valeurs avant et après correction manuelle des erreurs orthograpiques. Il examine de plus ces résultats théoriquement et empiriquement pour approfondir notre compréhension de l'influence des erreurs orthographiques sur ces mesures.

1 Introduction

Vocabulary richness measures are often used for learner language analysis and assessment as in the work by Arnaud (1984), Attali and Burstein (2006), Ishikawa (2015), Gregori-Signes and Clavel-Arroitia (2015), and Šišková (2012). Among a wide variety, Type-Token Ratio (TTR), which is defined as the

Proceedings of the 27th International Conference on Computational Linguistics, pages 2391–2398
Santa Fe, New Mexico, USA, August 20-26, 2018.

number of distinct words divided by the total number of words, is probably the most popular one because of its readiness; it is often used in the related research areas including the work as just mentioned above. Many modifications have been made to it, resulting in, for example, Guiraud's R (Guiraud, 1959), Herdan's C (Herdan, 1960), and Malvern and Richard's D (Malvern et al., 2004), to name a few (see Malvern et al. (2004) for the information about other measures). Another well known measure is Yule's K (Yule, 1944; Tanaka-Ishii and Aihara, 2015), which has the nice property that it is stable with respect to text length.

When applied to learner English[1], however, they might be unreliable because of spelling errors appearing in it. Typically, directly or indirectly, vocabulary richness measures including TTR and K are based on the number of distinct words in the target text. Here, it should be emphasized that the more spelling errors occur, the more (superficially) distinct words tend to appear (and thus, the greater number of distinct words). In the view of vocabulary richness, however, spelling errors derived from a canonical spelling should be treated as one word type. For example, the word *because* is mistakenly spelt as *becose*, *becouse*, and *becous* in learner English and they would unnecessarily increase the value of TTR if they were individually counted as unique word types. With the accumulation of the influence, vocabulary richness measures will likely deviate from their true values. A similar argument can be made about K that also uses the statistics on distinct words in the target text (in a different way, though).

Granger and Wynne (1999) have already pointed out this problem. They actually reported on the difference in TTR between an original text and its spelling-error-corrected version. At the same time, their report is not complete in that they only targeted spelling errors whose edit distance is within one from their correct spelling. Considering that spelling errors exist whose edit distance is more than one, one should adequately take care of all spelling errors in the target text to estimate accurately their influence on vocabulary richness measures. As Arnaud (1984) show (and also we will in Sect. 2), it is not straightforward to determine which type of spelling error to correct and how.

Apart from TTR, as far as we know, no one has yet revealed their influence on other lexical variation measures such as K. It would be especially interesting to see how they affect K which is stable with respect to text length.

In view of this background, in this paper, we explore the influence of spelling errors on TTR and K. Specifically, we explore the following hypothesis:

> **Hypothesis**: Lexical variation measures become unstable in learner English because of spelling errors.

to augment the findings Granger and Wynne (1999) showed. We test this hypothesis on English learner corpora of three groups (middle school, high school, and college students). To be precise, we estimate the differences in TTR and K caused by spelling errors by calculating their values before and after spelling errors are manually corrected. In addition, we examine the results theoretically and empirically to deepen our understanding of the influence of spelling errors on TTR and K.

The rest of this paper is structured as follows. Section 2 describes the corpus data we used in this work. It also explores the spelling errors we targeted. Section 3 describes the method we used to investigate the influence of spelling errors on TTR and K. Section 4 shows the results. Section 5 investigates them to discuss the influence of spelling errors on lexical richness theoretically and empirically.

2 Data and Spelling Errors

We use for our investigation English learner corpora of three groups ranging over middle school, high school, and college students whose mother tongue is all Japanese[2]. They consist of essays written on different topics; their statistics are shown in Table 1. Note that the essays in each group are written on different topics and thus it would be difficult to make intra-group comparisons; our emphasis here is on the inter-group comparisons before and after spelling error correction.

[1] In this paper, *learner English* refers to English as a Foreign Language.

[2] Because of the copyright, not all the corpus data can be open to the public. However, we have released a part of it with the information about spelling errors and their corrections to the public. It corresponds to the Konan-JIEM (KJ) learner corpus, which is available at `http://http://www.gsk.or.jp/en/catalog/gsk2016-b/`.

Group	# essays	# words	# errors	# topics	Av. edit distance[3]
Middle school	384	21,324	583	3	1.33
High school	251	23,561	680	3	1.37
College	438	37,774	1,271	14	1.42
TOTAL	1,073	82,659	2,534	20	1.38

Table 1: Basic Statistics on the Corpus Data.

To measure the difference, one has to determine which types of spelling errors should be corrected; we identified 13 error types in the corpora. Table 2 shows them with their acronyms and short explanations (e.g., RE for *Real word spelling error*).

Based on the taxonomy, we test two ways of correcting spelling errors to measure the difference. The first is to correct all 13 error types. The second is to classify them into three groups: those corrected, not corrected, and not counted. The first group (those corrected) consists of SP, PC, OC, GC, and NM. Spelling errors in these types would unnecessarily increase the number of distinct words if they were not corrected and left as they are. The second only consists of RE as in *Their is a house.* $\rightarrow$ *There is a house.* For this type of error, the writer might not know the correct word, and thus they should be left as is. Considering this, this type of error is not corrected (and thus it is counted as a unique word type). The rest (the third group) are those that do not exist in the English language. Therefore, they are not considered in calculating TTR and K. Namely, they are not included in the number of distinct words nor in the total number.

3 Method

We first applied the following preprocessing steps to the target corpora. We respectively used the sentence splitter and the tokenizer in Stanford Parser 3.5.0 (Chen and Manning, 2014) to split the essays into sentences and then into word tokens. We converted all word tokens into lowercase. After this, we removed those tokens containing no English alphabet letter from the corpora. In addition, we removed spelling errors whose correct spellings were not identified.

After this, we calculated TTR and K for the three corpora before and after spelling error correction. We tested two ways of correcting spelling errors as described in Sect. 2. Namely, we corrected all 13 types of errors and also only a part of them. We excluded mistakenly concatenated and split words from spelling errors. The former are word form errors that should be spelled with more than one word token as in *highschool* $\rightarrow$ *high school*. The latter are those that should spelled as one word token as in *grand father* $\rightarrow$ *grandfather*. We then compared the resulting TTR and K with those for the original corpora.

We used the following definitions for TTR and K. Let N be the total number of words in the target corpus, V be the number of distinct words in it. Then, TTR is defined as

$$\text{TTR} = \frac{V}{N}. \tag{1}$$

Also, let $V(m, N)$ $(1 \leq m \leq N)$[4] be the number of words appearing m times in a corpus whose total number of words is N. Then, K is defined as

$$K = c[-\frac{1}{N} + \sum_{m=1}^{N} V(m, N)(\frac{m}{N})^2] \tag{2}$$

where c is a constant enlarging of the value of K. Note that the larger the value of TTR is, the richer the vocabulary is and that the opposite holds for K. Also note that the symbols introduced here will be used again to discuss the results in Sect. 5.

[3]The average was calculated for spelling errors falling into SP error types, excluding those whose correct forms were unknown.

[4]Theoretically, m ranges between one and N. In practice, however, $V(m, N)$ tends to be zero for large values of m.

Error code	Explanation	Treatment
SP	Spelling that does not exist in English. e.g., I am a *sistem* engineer.	✓
PC	Inappropriate plural form conjugation. e.g., I didn't do *anythings*.	✓
OC	Over-regularized morphology. e.g., I *gived* her her hat.	✓
GC	Conjugation error other than the above two. e.g., I am *driveing*.	✓
NM	Spelling error in names. e.g., I went to *Desneyland*.	✓
RE	Real word spelling error (i.e., context sensitive error). e.g., *Their* is a house.	×
RO	Romanized Japanese. e.g., I ate an *omusubi*.	-
SR	Romanized Japanese that has no equivalent English expression. e.g., I went to *Hukuoka*. or that becomes proper English if transliterated. e.g., I ate *susi*.(susi → sushi).	-
CW	Coined word that is not used in English. e.g., I want to be a *nailist*.	-
FW	Foreign words other than Japanese. e.g., I have an *Arbeit*.	-
AL	Non-American (e.g. British English) spelling. e.g., It's my *favourite*.	-
AB	Improper abbreviation that is not used in English. e.g., I went to *USJ*.	-
O	Other than the above.	-

Table 2: Spelling Error Taxonomy and its Treatment: Each symbol denotes as follows: ✓: corrected; ×: not corrected; -: not counted.

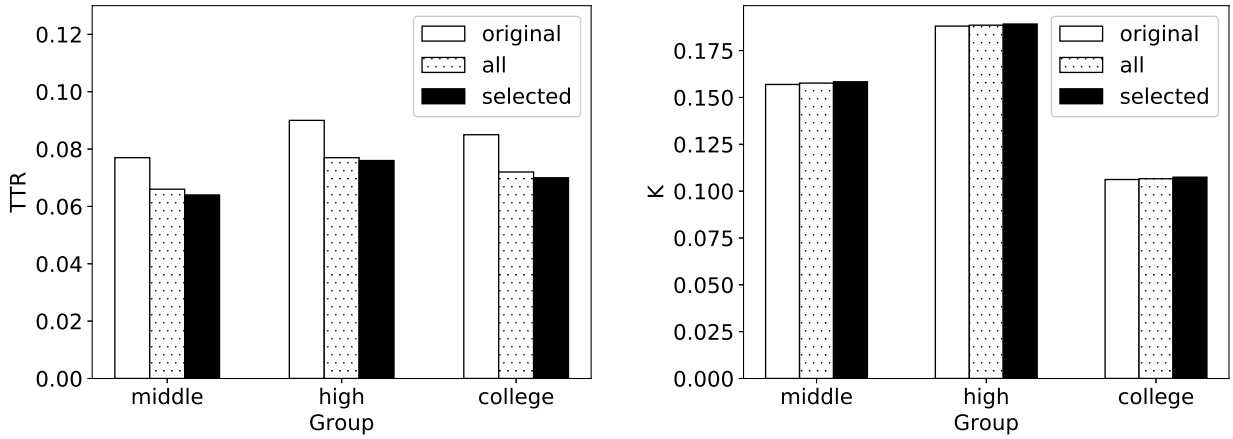
4 Results

Figure 1 shows the results. Figures 1–(a) and 1–(b) show the differences in TTR and K, respectively. The horizontal and vertical axes correspond to the three groups of the writers and the values of TTR and K, respectively. The labels *original*, *all*, and *selected* refer to the original corpus, the one where all 13 types of spelling errors are corrected, and the one where spelling errors are partly corrected, respectively.

Figure 1–(a) reveals that across the three groups, the difference in TTR is relatively large. For example, even the smallest difference, which is between *original* and *all* in *college*, approximately amounts to 16%. In *selected*, because the total number of words are slightly different (because of the not-counted spelling errors), one should be careful about its comparison with the other two. Having said that, it would be safe to say that there are at least some differences in TTR between them. These results imply that one would get varying values of TTR regardless of how he or she corrects spelling errors.

Here, note that although one might expect the values of TTR to decrease in order of *original*, *selected*, and *all*, it is not the case in the results. This is because there exist not-counted spelling errors in *selected*, which decreases both the number of distinct words and the total number of words.

Contrary to our expectation, Fig. 1–(b) reveals that almost no difference is observable in K. This applies to all groups with both ways of spelling error treatment; the difference is not more than 1% in all cases. This empirically shows that K is highly stable with respect to spelling errors.



(a): Difference in TTR.

(b): Difference in K.

Figure 1: Differences in TTR and K caused by Spelling Errors.

To sum up, the results give double answers to the hypothesis introduced in Sect. 1. TTR becomes unstable in learner English because of spelling errors. In contrast, this is not the case with K. In the next section, we explore the results theoretically and empirically to deepen our understanding of these phenomena.

5 Discussion

In this section, we explore why the influence of spelling errors is large in TTR and is very small in K. We begin with TTR, which is relatively easy to analyze, and then move on to K.

To begin with, let us assume the following situation. Suppose we have a spelling error-free corpus. Further suppose it undergoes a certain filter (or noise), which replaces a certain amount of words with misspellings (just as in the noisy channel model). The filter could be the learners' language device in their brain. Hereafter, we will refer to the error-free corpus and the erroneous corpus as *original corpus* and *error corpus*, respectively.

Now let us introduce some more symbols in addition to those defined in Sect. 3 to discuss TTR and K in more detail. Let $\mathbb{W}$ be the set of words appearing in the original corpus, $f(w)$ be the frequency of the word $w \in \mathbb{W}$, and n be the number of new spellings (words) occurring from the spelling errors in the error corpus. Here, it should be emphasized that the total number of words N is the same for the original and error corpora[5].

With these symbols, we can denote the number of distinct words (or spellings) in the error corpus as $V + n$. Strictly, words that occur only once in the corpus in question (i.e., hapax legomena) do not increase the number of distinct words or in other words do not contribute to $V + n$. Excluding spelling errors in these hapax legomena, it follows that the number of distinct spellings newly occurring from spelling errors directly affects TTR. For example, if the number of distinct spelling doubles, the increase in the number of distinct words also doubles. Also, $V + n$ shows that the frequencies of each spelling error do not affect TTR at all.

The discussion so far can be extended to other lexical richness measures that are based on the number

[5]This is because we assume that correctly spelt words in the original corpus are replaced with spelling errors.

of distinct words (i.e., V). For instance, one can apply the exact same discussion as above to Guiraud's R, which is defined as $\frac{V}{\sqrt{N}}$. The difference becomes relatively small in the measures that take the logarithm of V, but it is still relatively large compared to K (as we will show in the next paragraphs). For instance, Herdan's C, which is defined as $\frac{\log V}{\log N}$, suffers from the influence of n in the logarithm.

Now let us move on to K. The definition of K given by Eq. (2) can be rewritten as

$$K = c[-\frac{1}{N} + \sum_{w \in \mathbb{W}} (\frac{f(w)}{N})^2]. \tag{3}$$

Here, the summation is taken over the word set $\mathbb{W}$ in Eq. (3) whereas it is over the frequency of m in Eq. (2).

From Eq. (3), we can see that K is based on $f(w)^2$, i.e., the second power of each word frequency. This implies that even if n doubles in the original corpus because of spelling errors, that does not necessarily mean that their influence will double. Also, the influence from highly frequent words is dominant in the difference in K because of the second power.

We can further discuss the influence of each word. Suppose that a spelling error was created from $w \in \mathbb{W}$ and that $100r\%$ of all occurrences of w underwent the noise and were replaced with it. Then, the contribution of w to the entire value of K decreases by:

$$\frac{1}{N^2}\{(1-r)f(w)\}^2. \tag{4}$$

On the other hand, the newly created spelling increases the value of K by:

$$\frac{1}{N^2}\{rf(w)\}^2. \tag{5}$$

In total, the difference caused by a spelling error can generally be written as:

$$\frac{1}{N^2}[\{(1-r)f(w)\}^2 + \{rf(w)\}^2] = \frac{1}{N^2}\{(1-r)^2 + r^2\}f(w)^2. \tag{6}$$

Accordingly, it follows that the influence is only dependent on r. The difference becomes a maximum when $r = \frac{1}{2}$. At the same time, the values of r are expected to be small for most words. In other words, it is expected that a word is spelt correctly most of the time and only a few are misspelled[6]. If this is true, the following approximation holds:

$$\frac{1}{N^2}\{(1-r)^2 + r^2\}f(w)^2 = \frac{1}{N^2}(1 - 2r + 2r^2)f(w)^2 \tag{7}$$

$$\approx \frac{1}{N^2}(1-2r)f(w)^2. \tag{8}$$

This expression immediately shows that the difference caused by one type of spelling error is negligible when r is small. Even if r is relatively large, its influence becomes relatively small with respect to the whole value of K considering the term has the coefficient $\frac{1}{N^2}$. The discussion can be extended to the general situation where t spellings are created from $w \in \mathbb{W}$. The influence becomes maximum when $r = \frac{1}{2}$ (or generally, $r = \frac{1}{t+1}$). However, one can safely expect that it will rarely occur in frequent words in learner corpora (or corpora in general). For example, it would be rare to encounter a situation where half of the occurrences of a frequent word (e.g., *the*) are spelt correctly and the rest mistakenly (e.g., *hte*). It may happen to infrequent words, but again they scarcely affect the whole value of K because the influence of highly frequent words is dominant in K as we have just discussed at the beginning of this section.

We actually estimated r from the three corpora. It turned out that its mean and standard deviation were 0.06 and 0.10 for words where $10 \leq f(w) < 100$; similarly, 0.01 and 0.024 for words where

[6]Strictly, it can be restated that every word has, correctly or incorrectly, its representative spelling. Namely, it is assumed that $1 - r \ll 1$ or $r \ll 1$ holds.

$f(w) \geq 100$. These observations agree with our expectation and empirically explain why K is stable with respect to spelling errors.

The discussion above reconfirms the empirical findings that the difference caused by spelling errors is large in TTR and is negligible in K. Whether or not the difference in TTR can be problematic depends on the purpose and/or the way it is used. However, one should always keep in mind the fact that its difference is (at least superficially) large when one uses it. For example, the difference might cause a problem to a machine learning-based classifier when it is used as a feature; actually, some researchers (Pilán et al., 2016; Tack et al., 2017) are aware of this and thus they correct spelling errors as a preprocessing in their applications. In contrast, there is much less concern about the use of K. Besides, it has a nice property that it is also stable with respect to text length as Kimura and Tanaka-Ishii (2011) show. Consequently, it follows that it would be more accurate to use K instead of TTR when one analyzes learner English.

6 Conclusions

In this paper, we have addressed the influence of spelling errors on lexical variation measures. Specifically we have explored the following hypothesis:

> **Hypothesis**: Lexical variation measures become unstable in learner English because of spelling errors.

to augment the findings Granger and Wynne (1999) showed. We have tested it for TTR and Yule's K using three groups of learner English.

As a result, we have found that the hypothesis holds for TTR. To be precise, we have revealed that the difference in its value caused by spelling errors is relatively high throughout the tree groups, observing not less than 16% difference.

In contrast, this is not the case with K, which shows no more than 1% difference throughout the three groups. In other words, it is highly stable with respect to spelling errors.

We have investigated the results in detail to reveal why such a counterintuitive phenomenon occurs. We have shown theoretical and empirical reasons why new spellings derived from correct word forms by spelling errors directly affect the value of TTR, but not the value of K. Based on the results and the discussion, we have concluded that it would be more accurate to use K instead of TTR when one measures the lexical variation of learner English.

It will be interesting to test the present hypothesis on English texts written by learners other than Japanese. Also, it will be interesting to do the same for other languages than English. While our findings suggest that it will likely hold for other learner Englishes and also for other languages, mother tongue interference or the nature of other languages might affect the results. In particular, in certain languages (e.g., Japanese), it becomes much harder to identify spelling errors. Accordingly, the future work should include how to identify spelling errors in such languages. We will investigate these research questions in our future work.

Abstract

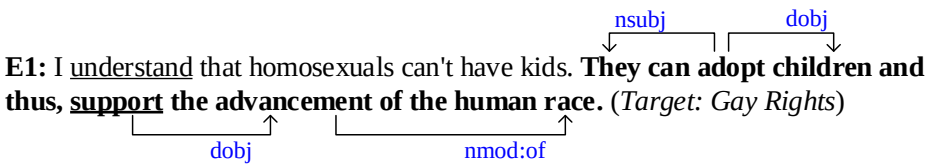
Stance detection aims to assign a stance label (*for* or *against*) to a post toward a specific target. Recently, there is a growing interest in using neural models to detect stance of documents. Most of these works model the sequence of words to learn document representation. However, much linguistic information, such as polarity and arguments of the document, is correlated with the stance of the document, and can inspire us to explore the stance. Hence, we present a neural model to fully employ various linguistic information to construct the document representation. In addition, since the influences of different linguistic information are different, we propose a hierarchical attention network to weigh the importance of various linguistic information, and learn the mutual attention between the document and the linguistic information. The experimental results on two datasets demonstrate the effectiveness of the proposed hierarchical attention neural model.

1 Introduction

While a lot of works on document-level opinion mining have involved determining the polarity expressed in a customer review (Pang et al., 2008; Liu, 2012), researchers have begun exploring new opinion mining tasks in recent years. One such task is stance detection: given a post written for a two-sided topic discussed in an online debate forum, determine which of the two sides (i.e., *for* and *against*) its author is taking. Stance detection system can potentially have a positive social impact and are of practical interest to non-profits, governmental organizations, and companies.

Previously, some of the related researches used feature engineering to extract either linguistic (Somasundaran and Wiebe, 2010) or structure (Sridhar et al., 2015) features manually. Recently, neural models have achieved high success and obtained the best results on stance detection (Zarrella and Marsh, 2016; Du et al., 2017).

A key issue of the neural model is document representation, and most of previous works learn document representation from word sequence using Convolutional Neural Networks (CNNs) (Chen and Ku, 2016; Vijayaraghavan et al., 2016) or Recurrent Neural Networks (RNNs) (Augenstein et al., 2016; Du et al., 2017).



However, besides the word sequence, stance is correlated with some explicit and implicit linguistic factors. Take E1 for example, both sentimental words (i.e., understand, support) and argument sentence (i.e., They can adopt ...) support the *favor* stance toward the target "Gay Rights". In addition, the dependency pair, $(adopt, children)$ and $(advancement, race)$, also express a positive stance. Hence,

Proceedings of the 27th International Conference on Computational Linguistics, pages 2399–2409
Santa Fe, New Mexico, USA, August 20-26, 2018.

we should learn the document representation by fully employing these linguistic factors (i.e., sentiment, argument, dependency) into neural model.

Moreover, the influence of different linguistic factors of each document is different. For example, the argument sentence in E1 is more important than sentiment and dependency information, and indicates the stance toward the target directly. Hence, we should measure the importance of different linguistic factors for each document through the neural model.

To address the above challenges, we propose a hierarchical attention model, which stands for the mutual attention between the document and the linguistic factors. The model contains two parts: linguistic attention part and hyper attention part. The former helps learn flexible and adequate document representation with different linguistic feature set, and the latter helps adjust the weight of different feature sets. In summary, the contributions are as follows.

- We present a novel hierarchical attention based neural model tailored to stance detection task, which considers the mutual influence between the representation of documents and the corresponding feature sets.
- We make a systematic comparison of LSTM with different linguistic features using the same benchmarks, and we explore influence of different linguistic features on neural models for stance detection.
- Experimental results on two open datasets demonstrate the effectiveness of the proposed approach.

2 Related Works

Previous works on stance detection have focused on congressional debates (Thomas et al., 2006; Burfoot et al., 2011), company-internal discussions (Agrawal et al., 2003), and debates in online forums (Somasundaran and Wiebe, 2010; Anand et al., 2011). Recently, there is a growing interest in performing stance detection on microblogs (Mohammad et al., 2016; Du et al., 2017). Most of existing works on stance detection can be separated into three categories: using linguistic features, using structure features, and using neural models. In the following subsections, we discuss the works on these three categories one by one.

2.1 Linguistic Features

Mosts of previous works employed various kinds of linguistic features for stance detection. For example, Somasundaran and Wiebe (2010) developed a baseline for stance detection by modeling verbs and sentiments. Anand et al. (2011) augmented the n-gram features with lexicon-based and dependency-based features. Except the above transitional linguistic factors, Hasan and Ng (2014) considered the importance of argument for stance detection, and explored the relations between stance and argument, and proposed a pipeline system to predict the stance and extract argument sentence from documents jointly.

2.2 Structure Features

Although linguistic features show effectiveness for stance detection in many works, stance detection has been newly posed as collective classification task with extra structure information. For example, citation structure (Burfoot et al., 2011) or rebuttal links (Walker et al., 2012), was used as extra information to model agreements or disagreements in debate posts and to infer their labels. Moreover, since similar users should express a similar opinion toward the same topic, user information is always used in stance detection. For example, Murakami and Raymond (2010) proposed a maximum cut method to aggregate stances in multiple posts to infer a user's stance on the target. Rajadesingan and Liu (2014) used a retweet-based label propagation method, which started from a set of opinionated users and labeled tweets by the people who are in the retweet network. Sridhar et al. (2015) utilized Probabilistic Soft Logic (PSL) to collectively classify the stance of users and stance in posts.

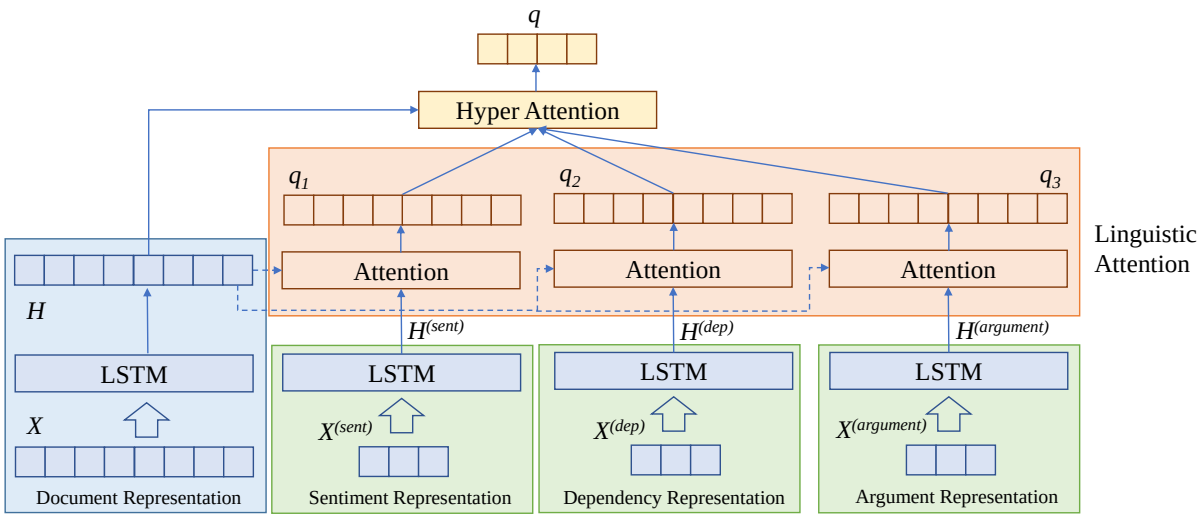


Figure 1: Overview of proposed model.

2.3 Neural Network Models

Since the deep neural network approaches can automatically extract features, there are many works using neural models to detect the stance recently, instead of using various kinds of linguistic features. For example, Augenstein et al. (2016) used two bidirectional RNN to model both target and text for stance detection, and Vijayaraghavan et al. (2016) proposed a combination of classifiers using word-level or character-level CNN models for stance detection. In addition, extra-information, especially user information, is incorporated into neural models for stance detection. For example, Chen and Ku (2016) proposed a user-based neural model to classify stance by using user tastes, topic tastes, and user comments on posts. Du et al. (2017) proposed a neural network-based model, which incorporated target-specific information into stance detection by following a novel attention mechanism.

Different from previous works, which either consider linguistic features individually, or learn the document representation on the word sequence, we propose a neural model to learn mutual attention between the document and the linguistic factors, and achieve best results.

3 Hierarchical Attention Neural Model

Formally, given a natural language document X, the stance detection system returns a binary label Y to denote the stance of the document, where $Y = 1$ denotes *favor* and $Y = 0$ denote *against* toward a special target. The architecture of our proposed hierarchical attention based stance detection system is shown in Figure 1, which illustrates the basic flow of our approach. First, we learn the representation of each document and linguistic features. Then, a hierarchical attention neural network is employed to represent the document under the influence of the different linguistic features: linguistic attention is used to learn the correlations between document representation and different linguistic feature set, and the hyper attention is employed to adjust the weight of different feature sets.

In the following subsections, we firstly show the representation of a document, and then show the representation of different linguistic features. Finally, we illustrate hierarchical attention model, and training process.

3.1 Document Representation

We use a standard Long Short-Term Memory (LSTM) model (Hochreiter and Schmidhuber, 1997) to learn the document representation. LSTM has been proven to be effective in many natural language processing (NLP) tasks such as machine translation (Sutskever et al., 2014) and dependency parsing (Dyer et al., 2015), and it is adept in harnessing long sentences. Let $X = (w_1, w_2, ..., w_n)$ be a document, where n is the document length and w_i is the i-th token. We transform each token w_i into a real-valued vector x_i using the word embedding vector of w_i, obtained by looking up a pre-trained word embedding

table D. We use the skip-gram algorithm to train embeddings (Mikolov et al., 2013).

The LSTM is used over X to generate a hidden vector sequence $(h_1, h_2, ..., h_n)$. At each step t, the hidden vector h_t of LSTM model is computed based on the current vector x_t and the previous vector h_{t-1}, and $h_t = LSTM(x_t, h_{t-1})$. The initial state and all stand LSTM parameters are randomly initialized and tuned during training. We use $H = h_n$ as the representation for X.

3.2 Representation of Linguistic Information

After obtaining the document representation, we learn the representation of different linguistic information.

Sentiment Representation

In principle, sentiment information of a post highly influences the stance. For example, the author is in favor of the target in E2, since he expresses the positive opinion toward the target. In addition, the stance toward the target and the sentiment of the post may be opposite in some posts. As in E3, the author is in favor of the given target although the post expresses the negative opinion.

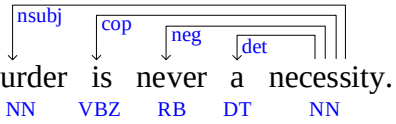
> **E2:** Hillary is our best choice if we truly want to continue being a progressive nation. (*Target: Hillary Clinton*)
>
> **E3:** When the last tree is cut down, the last fish eaten & the last stream poisoned, you will realize that you cannot eat money. (*Target: Climate Change is a Real Concern*)

Hence, it is a challenge task to employ sentiment information for stance detection, since the polarity of a post could be either the same or opposite toward the stance. In this study, we do not integrate sentiment information into document representation directly, but use attention mechanism to measure the correlation between document representation and sentiment information.

Particularly, we simply extract the sentimental word sequence $X^{(sent)} = \{x_1^s, x_2^s, ..., x_m^s\}$ of each document from sentiment lexicon, where x_i^s means sentiment word. We then learn the representation of sentiment information through this sentimental word sequence using LSTM model, and use $H^{(sent)} = LSTM(x_m^s, h_{m-1})$ as sentiment representation.

Dependency Representation

The dependency-based features can be utilized to capture the inter-word relationships (Anand et al., 2011; Persing and Ng, 2016). The dependency structure involves some stance-taking text related to the given target. As in E4, we notice that the important words that express a stance in the sentence are "murder", "never" and "necessity". By analyzing the dependency structure in this and other prompt parts, we can extract the stance-taking dependency information we identify as "murder-never-necessity".



Hence, we extract the pair of arguments sequence $X^{(dep)} = \{x_1^d, x_2^d, ..., x_m^d\} = \{x_1 \oplus x_3, ..., x_i \oplus x_j\}$ involved in each dependency relation from a dependency parser as a feature, where $x_i^d = x_j \oplus x_k$ is arguments pair from dependency relation.

We then learn the representation of dependency information through the dependency sequence $X^{(dep)}$ using LSTM model, and we use $H^{(dep)} = LSTM(x_m^d, h_{m-1})$ as dependency representation.

Argument Representation

In general, there are not only the stance of the author toward the target in a post, but also personal beliefs about what is true or what action should be taken. This personal belief is called argument (Wilson and Wiebe, 2005). There exist some arguments behind the stance people express on a specified target. If we can extract the argument sentence from the post, then it will be beneficial to detect the author's stance.

As in E5, with the help of argument sentence with bold, it will be easy to detect that the author support the legalization of marijuana.

> **E5: Most issues like this, such as sex between minors and alcohol, come down to one thing: it's your choice.** If you want to ruin your life, be my guest. It isn't the government's job to control that. (*Target: Legalization of marijuana*)

In order to utilize argument information for stance detection, we extract the argument sentence from each document, and treat argument sentence detection as a binary classification task (Hasan and Ng, 2014). After we get the argument sequence $X^{(argument)} = \{x_1^a, x_2^a, ..., x_m^a\}$ from argument sentences, where x_i^a is the i-th word in the argument sentences. We then learn the representation of argument information through the argument sequence $X^{(argument)}$ using LSTM model, and we use $H^{(argument)} = LSTM(x_m^a, h_{m-1})$ as argument representation.

3.3 Linguistic Attention

Based on our assumption, each linguistic resource should focus on different words of the same document. The extent of attention can be measured by the relatedness between each word representation $h_j \in H$ and a linguistic representation $l_i \in \{H^{(sent)}, H^{(dep)}, H^{(argument)}\}$. We propose the following formulas to calculate the weights.

$$\alpha_{ij} = \frac{\exp(w_{ij})}{\sum_{j=1}^{n} \exp(w_{ij})} \tag{1}$$

$$w_{ij} = \tanh(W^T[h_j : l_i] + b) \tag{2}$$

Here, α_{ij} denotes the weight of attention from a feature set l_i to the jth word in the document. $\tanh$ is a non-linear activation function. W is an intermediate matrix, and b is the offset. Both of them are randomly initialized and updated during training. Subsequently, according to the specific linguistic feature l_i, the attention weights are employed to calculate a weighted sum of the hidden representations, resulting in a semantic vector q_i that represents the document with the corresponding feature set.

$$q_i = \sum_{j=1}^{n} \alpha_{ij} h_j \tag{3}$$

3.4 Hyper Attention

Intuitively, different documents should value the three linguistic feature set differently. We thus define the final representation by weighting document representation and different linguistic representations $\{H, q_1, q_2, q_3\}$, as follows.

$$q = \sum_{j=1}^{4} \beta_j k_j, \quad k_j \in \{H, q_1, q_2, q_3\} \tag{4}$$

$$\beta_j = \frac{\exp(w_j)}{\sum_{j=1}^{4} \exp(w_j)} \tag{5}$$

$$w_j = \tanh(W^T V_j + b) \tag{6}$$

Here β_j denotes the attention of different document representation, indicating which document representation should be more focused. W is also an intermediate matrix, V is the weight matrix of different document representation and b is an offset value. Both of them are randomly initialized and updated during training. We use q as the final representation to learn and predict the model.

Stance	Abortion	GayRights	Obama	Marijuana
Favor (%)	54.9	63.4	53.9	69.5
Against (%)	45.1	36.6	46.1	30.5
Total	1741	1376	985	626

Table 1: Distribution of H&N14 dataset.

Stance	Atheism	Climate	Feminism	Hillary	Abortion
Favor (%)	16.9	59.4	28.2	16.6	17.9
Against (%)	63.3	4.6	53.9	57.4	58.3
None (%)	19.8	36.0	17.9	26.0	23.8
Total	733	564	949	984	933

Table 2: Distribution of SemEval16 dataset.

3.5 Training

We employ cross-entropy loss function to train the model. Specially, the loss function is defined as follows:

$$L(\Theta) = -\frac{1}{n}\sum_{i=1}^{n}\sum_{j=1}^{m} y_{ij}\log p_{ij} + \frac{\lambda}{2}||\Theta||^2 \quad (7)$$

where n is the total number of items of training data; m is the number of category; y_{ij} indicates whether the i-th sample belongs to the j-th category, which is the ground-truth label; and p_{ij} represents the predicted probability. Θ is the set of model parameters and λ is a parameter for L2 regularization.

Standard back propagation is performed to optimize parameters. We employ Adam (Kingma and Ba, 2014) for parameter optimization and Word embeddings are trained using the *Skip-gram* algorithm (Mikolov et al., 2013)[1].

4 Experiments

4.1 Datasets and Preprocessing

We use two datasets to evaluate the performance of the proposed system. **H&N14** is collected by Hasan and Ng (2014), and **SemEval16** is from SemEval-2016 Share Task 6.A (Mohammad et al., 2016).

H&N14 is collected from an English online debate forum with four targets: "Abortion" , "Gay Rights", "Obama", and "Marijuana". The distribution of the dataset is shown in Table 1. In Hasan and Ng (2014)'s setting, the dataset is split into five folds, and they conduct five-fold cross-validation on the division. For fair comparison, we follow their setting in all experiments.

SemEval16 is the dataset for stance detection from English tweets, and each tweet corresponds to a special target: "Atheism", "Climate Change is a Real Concern"("Climate"), "Feminist Movement"("Feminist"), "Hillary Clinton"("Hillary"), and "Legalization of Abortion"("Abortion"). The distribution of the dataset is shown in Table 2. The dataset has already been separated into training and testing set (Mohammad et al., 2016).

The average length of documents in H&N14 and SemEval16 is 114 and 18, respectively. The length of document in SemEval16 is much shorter than H&N14, since SemEval16 is collected from tweets. Based on such difference of source and document length, we can evaluate the performance of the proposed model on a different setting.

Some preprocessing approaches are employed to extract sentiment, dependency, and argument information from the two datasets:

- The sentiment word sequence of each document is extracted from MPQA subjective lexicon[2].

[1] https://code.google.com/p/word2vec/

[2] http://mpqa.cs.pitt.edu/lexicons/subj_lexicon/

- The dependency sequence is extracted from each sentence by using Stanford Parser[3]. We select the relations which include noun, verb, adjective, adverb or negation words such as "nsubj", "acl", "dobj" etc. and get the argument pairs in these relations.

- The argument sentence is extracted from each document. We firstly separate the document into a sentence set based on punctuation and connective, and then we use a SVM classifier to predict the argument label of each sentence. We employ the annotated training set in (Hasan and Ng, 2014) and simplify the argument sentence detection as a binary classification task which means that sentence is just identified whether or not an argument of the related stance specifically.

Hyper-parameters

We train 300 dimensional word embedding using Word2Vec (Mikolov et al., 2013) on all the training data, and fine-turning during the training process. The dimension of LSTM layers and the output of attention mechanism is set to 300. The dropout rate is set to 0.25. The other hyper-parameters and learning rate are tuned on the development data. The development data are extracted from 10% of training data.

4.2 Evaluation Metrics

Both micro and macro average of F1-score across topics are adopted as the metrics (Mohammad et al., 2016). F1-score for Favor and Against categories of all instances is calculated as:

$$F_{favor} = \frac{2 \times P_{favor} \times R_{favor}}{P_{favor} + R_{favor}} \tag{8}$$

$$F_{against} = \frac{2 \times P_{against} \times R_{against}}{P_{against} + R_{against}} \tag{9}$$

where P and R is precision and recall. Then the average of F_{Favor} and $F_{Against}$ is calculated as the final metrics:

$$F_{avg} = \frac{F_{favor} + F_{against}}{2} \tag{10}$$

We average the F_{avg} on each topic to calculate macro-average F score($MacF_{avg}$). Besides, we calculate F_{avg} score across all targets to get micro-average F score ($MicF_{avg}$).

Note that, different from H&N14, which only contains *favor* and *against* posts, SemEval16 dataset contains *none* posts, which do not express any stance. However, the final metrics disregard the None class. Following Mohammad et al. (2016) and Du et al. (2017), we take the average F-score for Favor and Against classes, and treat None as a class that is not of interest.

4.3 Experiment Results

Comparison with Baselines

We compare our proposed model with the following state-of-the-art baseline systems:

- *SVM* is a baseline model in many previous works (Hasan and Ng, 2014; Mohammad et al., 2016). We use libSVM[4] to train the SVM model with bag-of-words features.

- *LSTM* employs word embedding, and learn the document representation through LSTM model.

- *TAN* is proposed by Du et al. (2017), it uses an attention mechanism to learn the correlation between topic and document representation. It reports the best results on SemEval16 dataset.

- *HAN* is our proposed model, which uses Hierarchical Attention Neural (HAN) model to learn the mutual attention between document and linguistic information.

Model	Abortion	GayRights	Obama	Marijuana	$MacF_{avg}$	$MicF_{avg}$
SVM	59.48	**59.52**	63.02	55.02	59.26	60.52
LSTM	60.72	56.07	60.14	55.58	58.13	59.45
TAN	**63.96**	58.13	63.00	56.88	60.49	62.35
HAN	63.66	57.36	**65.67**	**62.03**	**62.18**	**63.25**

Table 3: Comparison with baselines on H&N14 dataset.

Model	Atheism	Climate	Feminism	Hillary	Abortion	$MacF_{avg}$	$MicF_{avg}$
SVM	62.16	42.91	56.43	55.68	60.38	55.51	67.01
LSTM	58.18	40.05	49.06	61.84	51.03	52.03	63.21
TAN	59.33	**53.59**	55.77	**65.38**	63.72	59.56	68.79
HAN	**70.53**	49.56	**57.50**	61.23	**66.16**	**61.00**	**69.79**

Table 4: Comparison with baselines on SemEval16 dataset.

Model	Abortion	GayRights	Obama	Marijuana	$MacF_{avg}$	$MicF_{avg}$
SVM	59.48	59.52	63.02	55.02	59.26	60.52
SVM+Ling	62.17	58.69	65.14	56.56	60.64	62.25
LSTM	60.72	56.07	60.14	55.58	58.13	59.45
LSTM+Att+Sentiment	63.88	58.69	63.76	57.08	60.85	62.45
LSTM+Att+Dependency	63.15	59.48	64.69	59.21	61.63	62.67
LSTM+Att+Argument	62.82	58.31	64.50	61.91	61.89	63.14
HAN	63.66	57.36	65.67	62.03	62.18	63.25

Table 5: Influence of linguistic feature.

We compare the proposed HAN model with baseline systems on H&N14 and SemEval16 datasets, and the results are given in Table 3 and Table 4. From the results, we can find that SVM outperforms LSTM in these two datasets. It indicates that, simply document representation on word sequence cannot capture useful information for stance detection. TAN outperforms both SVM and LSTM, and it indicates that target information is helpful for stance detection. Moreover, our proposed model outperforms all the discrete and neural models. It shows the effectiveness of linguistic features and proposed hierarchical attention model.

4.4 Influence of Linguistic Features

We then analyze the influence of proposed different linguistic features on H&N14 dataset. The results are shown in Table 5, where *SVM+Ling* is SVM classification with all the linguistic features employed in our paper, and *LSTM+Att+** employs attention mechanism to consider the correlations between document representation and each linguistic representation individually. For example, *LSTM+Att+Sentiment* means the model just employs linguistic attention of sentiment information in Section 3.3.

From the results, we can find that SVM+Ling outperforms SVM, it proves the effectiveness of linguistic information directly. Moreover, we find that every linguistic information with attention mechanism is effective for stance detection. Especially, the argument information outperforms other features, it may be due to that argument information is highly related with stance than other linguistic information. In addition, the proposed model with all kinds of linguistic information outperforms all other models which consider each linguistic information individually.

[4]https://www.csie.ntu.edu.tw/ cjlin/libsvm/

Model	Abortion	GayRights	Obama	Marijuana	$MacF_{avg}$	$MicF_{avg}$
HAN	63.66	57.36	65.67	62.03	62.18	63.25
-Hyper	62.84	57.63	64.71	58.61	60.95	62.45
-Hyper,-Ling	62.33	56.96	63.26	57.60	60.04	61.50
LSTM	60.72	56.07	60.14	55.58	58.13	59.45

Table 6: Influence of network configuration.

4.5 Influence of Network Configurations

We study the influence of various network configurations by performing ablation experiments on H&N14 dataset, as shown in Table 6. *-Hyper* denotes ablation of the hyper attention layer, and concatenate $\{H, q_1, q_2, q_3\}$ directly and put them into a fully-connected layer. *-Hyper,-Ling* denotes ablation both of the hyper attention and linguistic attention layer, and concatenates $\{H, H^{(sent)}, H^{(dep)}, H^{(argument)}\}$ together into a fully-connected layer.

By comparing between HAN and "-Hyper", we can find that hyper attention over all the linguistic representation does have significant influence on the results. Comparison between "-Hyper" and "-Hyper, -Ling", we can find that linguistic attentions with each linguistic features does have significant improvement. On the other hand, using LSTM to detect stance (LSTM) does not obtain a better performance compared to concatenating linguistic information directly ("-Hyper, -Ling"). This confirms our intuition that stance of document is influenced by various linguistic information.

5 Conclusion

In this paper, we focus on stance detection task. We consider the impacts of different linguistic features when representing the document, and propose a novel hierarchical attention model for stance detection. Specifically, we employ a neural model to represent the documents and their linguistic features with attention mechanism. In addition, on the top of different document representation, we use an attention model to measure the importance of different linguistic features, and learn the mutual attention between the document and the linguistic information. The extensive experiments demonstrate that the proposed model achieves better performance compared with the state-of-the-art models on two datasets.

Abstract

With more and more people around the world learning Chinese as a second language, the need of Chinese error correction tools is increasing. In the HSK dynamic composition corpus, word usage error (WUE) is the most common error type. In this paper, we build a neural network model that considers both target erroneous token and context to generate a correction vector and compare it against a candidate vocabulary to propose suitable corrections. To deal with potential alternative corrections, the top five proposed candidates are judged by native Chinese speakers. For more than 91% of the cases, our system can propose at least one acceptable correction within a list of five candidates. To the best of our knowledge, this is the first research addressing general-type Chinese WUE correction. Our system can help non-native Chinese learners revise their sentences by themselves.

Title and Abstract in Chinese

非中文母語學習者中文寫作用詞錯誤之更正

以中文爲第二語言的學習者與日俱增，遍及全球，對於中文更正工具的需求也相應而生。在HSK動態作文語料庫中，用詞錯誤（WUE）是中文學習者最常犯的錯誤類型。在這篇論文中，針對中文用詞的更正，我們建立了專屬的神經網路模型，同時參酌目標錯誤詞彙及其前後文資訊，以產生推薦的更正方式。經過中文母語人士的評估，在91%的測試案例中，系統所推薦的前五名候選詞彙，至少有一個是適當的更正方式。據我們所知，這是目前第一個全面性的中文用詞錯誤更正之研究。我們的系統可以幫助非中文母語人士自主修正其所寫的中文句子，促進華語文教學之成效。

1 Introduction

Grammatical error correction (GEC) tools can help language learners revise their writing. Chinese GEC tools are in high demand since Chinese has become an increasingly popular second language worldwide. Despite the increasing need, most of the existing studies on GEC are based on English learner data. The method of correcting sentences in Chinese, a language which differs substantially from English in major aspects such as the morphological structure and the distribution of learner errors, has not yet been fully developed.

This paper focuses on the correction of Chinese word usage errors (WUEs). According to the definition of Shiue and Chen (2016), a WUE refers to an incorrect token that involves morphological, syntactical, or semantical problems. The token is either an incorrect word form, or a correct existent word that is improper for its context.

Given a token in a sentence segment that is known to be erroneous, we aim to generate a suitable correction for it. The criteria for a suitable correction are:

- **Correctness**: After substituting the erroneous token with the correction token, the result is a syntactically and semantically correct Chinese sentence segment.

Proceedings of the 27th International Conference on Computational Linguistics, pages 2410–2422
Santa Fe, New Mexico, USA, August 20-26, 2018.

• **Similarity**: The meaning of the correction is close to the writer's intended meaning.

We discuss the criteria with the following example sentence segments.

(E1-1) *生活方式已經**猛烈**地改變了 (The way of living has been **fiercely** changed.)

(E1-2) *生活方式已經**暴烈**地改變了 (... has been **overpoweringly** changed.)

(E1-3) 生活方式已經**緩慢**地改變了 (... has been **slowly** changed.)

(E1-4) 生活方式已經**劇烈**地改變了 (... has been **dramatically** changed.)

For wrong segment (E1-1), (E1-2) is not a correction since it is incorrect itself. The adverb "暴烈地" (overpoweringly) does not collocate with the verb "改變" (change). (E1-3) is grammatical, but its meaning differs from the original meaning of (E1-1), so neither is it suitable. (E1-4) is a good correction that meets both criteria.

Nevertheless, there are some cases in which the similarity criterion is hard to meet. For example, the intended meaning of (E2-1) is very difficult to recognize. (E2-2) is the ground-truth correction, but the association between the original erroneous token "情緒" (emotion) and the correction "因素" (factor) is unclear.

(E2-1) *發生這種情況的**情緒**很多 (Many **emotions** happen this situation.)

(E2-2) 發生這種情況的**因素**很多 (Many **factors** can lead to this situation.)

When two criteria cannot be met at the same time, the correctness criterion should have higher priority, since an incorrect sentence can confuse the language learner.

In this paper, *target* refers to the original erroneous token written by the language learner, and *context* refers to other words in the sentence segment. A pair consisting of the target and its corresponding correction is called a *correction pair*. In example (E1) and (E2), "猛烈" and "情緒" are targets, and (猛烈, 劇烈) and (情緒, 因素) are correction pairs. According to the previous discussions, the major challenge of the WUE correction task lies in the derivation of the intended semantics and the generation of valid sentence segments.

We treat WUE correction as a candidate selection problem and propose a neural network-based model considering both target and context to rank correction candidates. Our main contributions are: (1) Though the detection of Chinese WUE and correction of certain types have been studied, this is the first research dealing with the correction of all types of WUEs. (2) To consider alternative corrections, we perform human evaluation and show that our system can propose at least one acceptable correction within the top five candidates for more than 91% of the cases. (3) We release the HSK WUE dataset with additional human annotations.

2 Related Work

English GEC is a rather mature field of study in NLP. Several shared tasks have been conducted for English GEC (Dale and Kilgarriff, 2011; Dale et al., 2012; Ng et al., 2013; Ng et al., 2014). Language models, machine learning classifiers, rule-based classifiers, and machine translation models are used. The machine translation approach has the advantage that there is no need to explicitly formulate the types of the errors. A series of English GEC studies are based on the phrase-based statistical machine translation (SMT) framework (Dahlmeier and Ng, 2011; Chollampatt et al., 2016b; Chollampatt et al., 2016a; Chollampatt and Ng, 2017).

Nevertheless, the satisfactory performance of the SMT approach cannot be reached without sufficient training data. In fact, Chollampatt et al. (2016a) have shown that the model trained with smaller training data from writers with the same first language (L1) as writers of the test data performs even worse than the model trained with larger training data from writers whose L1 differs from that of the test data. The amount of available Chinese learner data are even less sufficient than that of English ones. Therefore, as a preliminary research in Chinese WUE correction, we impose restrictions on our setting that there is exactly one error in a sentence segment, the error position is known, and the error can be corrected by replacing the erroneous token with an appropriate word.

The distribution of errors of non-native Chinese differ a lot from that of non-native English. In the CoNLL 2013 shared task (Ng et al., 2013), the most frequent error types are article, preposition, noun number, verb form, and subject-verb agreement. These error types are mostly in violation of English

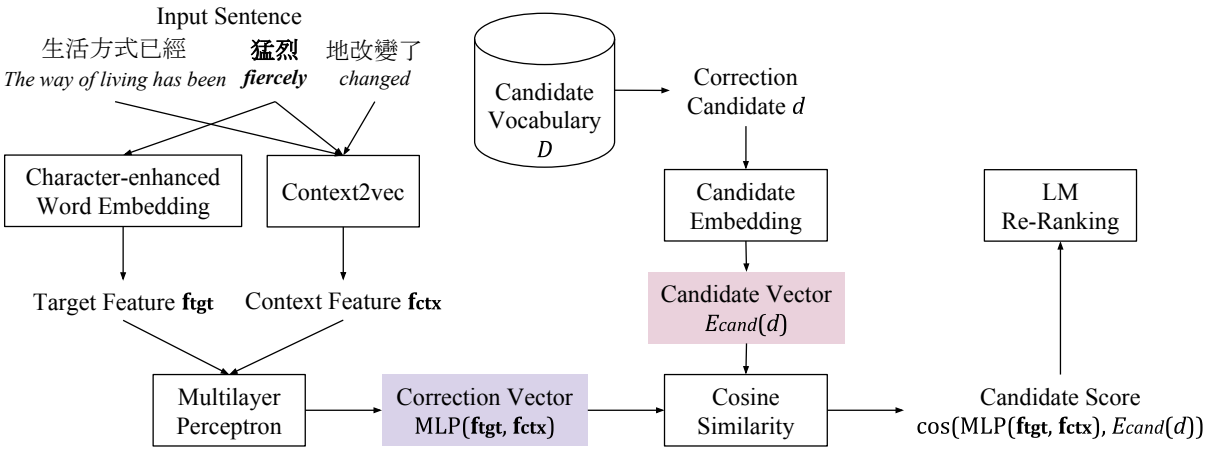

Figure 1: Overview of our correction generation model. The score of a correction candidate d is predicted for replacing the target erroneous word "猛烈" (fiercely) with the target and the context information.

grammar rules, so it is relatively easy to grasp some patterns of correction. In contrast, in the HSK dynamic composition corpus built by Beijing Language and Culture University, which is the largest available Chinese learner corpus at the time of this study, WUE is the most frequent lexical-level error. In most cases, a wrong usage of a word does not lead to violation of syntactic rules. Instead, its incorrectness cannot be determined without understanding the meaning of the whole sentence. As a result, besides directly adopting the techniques used for English GEC, many aspects of Chinese GEC are worth studying.

The Chinese spelling check task (Wu et al., 2013; Yu et al., 2014b; Tseng et al., 2015; Fung et al., 2017) evaluates the detection and correction of character errors. The Shared Task for Chinese Grammatical Error Diagnosis (Yu et al., 2014a; Lee et al., 2015; Lee et al., 2016; Rao et al., 2017) extends the above task to word errors, including redundant word, missing word, word disorder and word selection. Nevertheless, these tasks only deal with detection but not correction.

Some researchers focus on certain types of Chinese writing errors. For example, Yu and Chen (2012) identify word ordering errors (WOEs), and Cheng et al. (2014) further recommend word ordering correction candidates with the use of ranking support vector machine (RankSVM).

Previous researches on Chinese WUE include segment-level (Shiue and Chen, 2016) and token-level detection (Shiue et al., 2017). Huang et al. (2016) study the Chinese preposition selection problem, which is subsumed by WUE correction. Gated recurrent unit (GRU)-based models are trained to select the most suitable one from a closed set of 43 Chinese prepositions in a context.

Nevertheless, it is still worth investigating how to treat WUEs involving other types of words such as verbs and nouns. Correcting errors of such open-set types could be much more difficult since the set of candidates can be huge. To the best of our knowledge, this is the first research dealing with general-type Chinese WUE correction.

3 Neural Network-based Correction Generation Model

As shown in Figure 1, our correction generation model is a multilayer perceptron (MLP) neural network that takes target feature vector $\mathbf{f_{tgt}}$ and context feature vector $\mathbf{f_{ctx}}$ as input and outputs a *correction vector* MLP($\mathbf{f_{tgt}}, \mathbf{f_{ctx}}$). $\mathbf{f_{tgt}}$ and $\mathbf{f_{ctx}}$ are derived either from the segment itself or with the help of some external resources. Section 5 will give the details for several kinds of features we used.

Every candidate word d in a set D of all possible corrections is mapped to an embedding $E_{cand}(d)$. The details of candidate embedding model E_{cand} will be elaborated in Section 4. The training objective of our model is to make MLP($\mathbf{f_{tgt}}, \mathbf{f_{ctx}}$) as close to $E_{cand}(\hat{d})$ as possible, where $\hat{d}$ is the ground-truth correction. While MLP contains a bunch of trainable parameters, E_{cand} is fixed to preserve the ability to generalize the corrections that are unseen in the training data.

When testing, given the original erroneous sentence segment, our model selects the most probable correction $d*$:

$$d* = \underset{d \in D}{\operatorname{argmax}} \cos(\text{MLP}(\mathbf{f_{tgt}}, \mathbf{f_{ctx}}), E_{cand}(d)) \quad (1)$$

In fact, this model can propose several candidates, ranked by their cosine similarities to the correction vector. The goal is to rank the ground-truth correction toward the top of the list.

4 Candidate Embedding

For the candidate embedding model E_{cand}, we use the character-enhanced word embedding model (CWE), in which word vectors (hereafter WE) and character vectors (hereafter CE) are learned jointly (Chen et al., 2015). This model is developed based on one idiosyncratic characteristic of the Chinese writing system, that meanings of individual characters in a word usually contribute to the meaning of the word. Therefore, character-level information can help capture the meaning of Chinese words much better.

On the other hand, one common case of WUE is that the characters within a word is wrongly chosen or permuted. For instance, "決解" (jué jiě) is a misused form of "解決" (solve). Though the misused form is a non-existent word, its character components serve as an important clue for discovering what the writer originally means and help provide more suitable correction.

We adopt the position-based CWE (CWE+P), which keeps three embeddings for each character according to the character's position. This variant is designed to capture different morphological functions of a Chinese character when it is at different positions in a word. A character vector is denoted as $\text{CE}(c, p)$, where c is the character and $p = s, m, e$ depending on the position (start, middle or end, respectively) of c within a certain word. The word representation is the word vector plus the average of the component character vectors. For example, the representation of "農產品" (agricultural product) is $\text{CWE}_w(\text{農產品}) = \text{WE}(\text{農產品}) + \frac{1}{3}[\text{CE}(\text{農}, s) + \text{CE}(\text{產}, m) + \text{CE}(\text{品}, e)]$. If we ignore the internal structure of the word, a misused form "農作品" ('nóng zuò pǐn') is simply an out-of-vocabulary (OOV) word and has no association with the correction "農產品". With the use of CWE vectors, it is more possible for the model to learn a transformation from the incorrect token to its correction.

5 Input Features

To meet the two criteria for suitable WUE correction, we adopt several target and context features as input to the correction generation model. The division of $\mathbf{f_{tgt}}$ and $\mathbf{f_{ctx}}$ is just for indicating the source of information. These two feature vectors are concatenated and fed to the MLP model.

5.1 Target CWE+P Word Embedding

This set of features is derived from the same embedding model as we used for the candidate embedding. The way of composing a representation of an existent word is also the same. For OOV word, the representation is the average of the vectors of all characters. By doing so, among the three character vector terms in the representation of "農作品", $\text{CE}(\text{農}, s)$ and $\text{CE}(\text{品}, e)$ are shared with the correction vector $\text{CWE}_w(\text{農產品})$. The word and character vectors used to calculate this set of features are in the same space with the candidate embedding, enabling the model to directly learn a transformation between a correction pair. We use CWE_w to denote this set of features.

5.2 Target CWE Position-Insensitive Character Embedding

Although a character's position in a word could reflect its morphological function, non-native Chinese learners might not be so familiar with Chinese morphology. One common type of morphological WUE is incorrect ordering of characters within a word. For example, (*決解, 解決) is the tenth frequent correction pair in our dataset. With the use of CWE+P embeddings, the similarity between these two tokens might be underestimated since all the character vector terms are different.

To cope with this problem, we experimented with the CWE variant that only keeps one vector for each Chinese character regardless of its position, but the performance is not as good as the model with

CWE+P features. Alternatively, we design a separate set of character embedding features CWE_c which is the sum of the character embedding of all positions divided by the number of characters in the word. For instance, $\text{CWE}_c(\text{決解}) = \frac{1}{2}\sum_{p=s,m,e}[\text{CE}(\text{決}, p) + \text{CE}(\text{解}, p)]$. As can be seen, $\text{CWE}_c(\text{決解})$ will contain $\text{CE}(\text{解}, s)$ and $\text{CE}(\text{決}, e)$, which are the terms of $\text{CWE}_w(\text{解決})$.

5.3 Context2vec Features

Context2vec (Melamud et al., 2016) is a bidirectional LSTM-based model that can encode a "context" into a real-valued vector. A context is a sequence of words with a certain position blanked out. For instance, (E3-1) is a context:

(E3-1) 可是 每 個 人 的 [ ] 都 千差萬別 (but everyone's [ ] is different)

The representation of a context is a combination of the sequence of words before and after the blank:

$$\text{C2V}_{ctx}(w_1...w_{p-1}[\ ]w_{p+1}...w_L) = \text{LSTM}(w_1...w_{p-1}) \oplus \text{LSTM}(w_{p+1}...w_L) \quad (2)$$

where each w_i is a token, L is the number of tokens, p is the index of the blank, and $\oplus$ is the vector concatenation operation.

Context2vec also keeps the embeddings of individual words, which are called target embeddings[1] by Melamud et al. (2016). We use C2V_{tgt} to denote the vector of target word. Both target embeddings and the parameters in the LSTM layers are updated during training. The objective of the model is to predict the target word that actually occurs in the training sentence, given the encoded context vector.

The formulation of context makes Context2vec suitable for the sentence completion task. A candidate to fill the blank can be selected according to how similar its vector is to the context vector. That is, given a context where the p-th position is the blank, the best candidate $d*$ would be:

$$d* = \underset{d \in D}{\text{argmax}} \cos(\text{C2V}_{tgt}(d), \text{MLP}(\text{C2V}_{ctx}(w_1...w_{p-1}[\ ]w_{p+1}...w_L))) \quad (3)$$

where MLP is a non-linear projection that maps the context representation to a vector with dimensionality same as that of the target embeddings. Melamud et al. (2016) have shown the promising results of Context2vec in several sentence completion benchmarks. For the example context (E3-1), the best candidate selected in this way using our trained model is "境況", which can be put into the blank and the result is a correct sentence segment.

(E3-2) 可是 每 個 人 的 [境況] 都 千差萬別 (but everyone's [situation] is different)

In fact, (E3-1) is extracted from a wrong segment in our dataset. The original erroneous segment and the corresponding correction are shown in (E3-3).

(E3-3) 可是每個人的(*對應, 反應)都千差萬別

(but everyone's (correspondence, reaction) is different)

Given the original segment, one can conclude that the candidate "境況" (situation) selected by Context2vec is less suitable compared to the ground-truth "反應" (reaction), according to the similarity criterion. Therefore, WUE correction is different from sentence completion in that if the model ignores the word originally written by the language learner, it is likely to generate a correction that changes the meaning of the original sentence segment.

To take both context and target information into account, we include two feature vectors C2V_{tgt} and C2V_{ctx} , which belong to target and context features, respectively. C2V_{tgt} refers to the embedding of the original erroneous token, which can reveal important information about the writer's intended meaning as we discussed above.

5.4 Target POS Features

We analyze the part-of-speech (POS) tags before and after correction, and show the most frequent POS changes in the validation set in Table 1. The POS tagging is performed by using Stanford CoreNLP

[1]Note that the definition of "target" in the Context2vec paper is slightly different from ours. In our definition, target only refers to the original erroneous token, while for Context2vec, target can refer to any word to be put into the blank, regardless of whether the result is a correct sentence.

Original POS	Correction POS	# instances	Frequency
Unchanged		722	68.70%
VV	NN	27	2.57%
NN	VV	21	2.00%
P	VV	17	1.62%
DEC	DEV	15	1.43%
VV	P	13	1.24%
AD	VV	10	0.95%
VV	VA	10	0.95%

Table 1: Part-of-speech changes occurring at least 10 times.

(Manning et al., 2014). As can be seen, the POS tag does not change after the correction in nearly 70% of the cases. Besides, there are some systematic changes. For example, non-native Chinese learners seem to confuse some nouns with some verbs, so we can observe the interchanging phenomenon of the VV and NN tags. The case of VV and P is similar. These systematic changes indicate that it is possible to reduce the candidate vocabulary. We tried to limit the candidates to the POS transitions observed in the training and validation set. However, this results in slightly lower accuracy and MRR. Therefore, instead of modifying the candidate set directly, we encode the POS of the erroneous token in a one-hot vector and feed this feature to the correction generation model. This allows the model to learn different transformation function for different source POS, that is, the POS of the erroneous token.

6 Language Model Re-ranking

One drawback of our MLP correction generation model is that the correctness criterion does not explicitly take priority over the similarity criterion. In our experiments, we found that our model sometimes generates segments that seriously violate the correctness criterion, since it can bias toward the similarity criterion. (E4) is an example.

Wrong segment:

(E4-1) *到山頂**之間**路走得不容易 (The road **between** the hilltop was not easy to walk.)

Model prediction:

(E4-2) *到山頂**期間**路走得不容易 (The road **period** the hilltop ...)

Ground-truth correction:

(E4-3) 到山頂**的**路走得不容易 (The road **to** the hilltop ...)

The candidate "期間" (period) is selected since it is similar to the target "之間" (between), but the result sentence segment is incorrect. It is necessary to deal with this problem since the correctness criterion is more important, as we previously discussed in the introduction.

It is expected that this kind of unsuitable candidates can be eliminated by a language model (LM), if we assume that LM probability reflects the level of correctness of a sentence segment. Therefore, we emphasize the correctness criterion by incorporating LM scores of traditional n-gram LM or Recurrent Neural Network Language Model (RNNLM) (Mikolov et al., 2011) into the candidate selection process. One possible approach is to apply a probability cut-off and discard candidates that result in segments with low probability. Nevertheless, the "acceptable" LM probability varies from sentence to sentence since it can be affected by, for instance, length and lexical complexity of the sentence. Though we can let the cutoff be a function of various factors, it is difficult to design such a function explicitly.

Therefore, instead of performing combination of scores, we combine the rank proposed by the LM with the rank based on our correction generation model. One advantage of this approach is that the range of ranks is the same for all instances given fixed candidate vocabulary size, so the ranks can be evaluated with the same standard across different instances. For a candidate correction, let r_{LM} be its rank based on the LM probability, and r_{MLP} be the rank based on its cosine similarity to the correction vector generated by our MLP model. We adopt the following weighted harmonic mean to obtain a new "rank" for the candidate.

$$r_{com} = \frac{1}{\frac{\alpha}{r_{LM}} + \frac{1-\alpha}{r_{MLP}}} \tag{4}$$

where α is a parameter that can be tuned with the validation set (actual values will be given in Section 8.2). Preliminary experiments show that harmonic mean performs better than arithmetic and geometric mean. Though r_{com} may not be an integer, it can be interpreted as a rank. The correction with smaller r_{com} is considered better.

7 Experimental Settings

We adopt the HSK WUE dataset released by Shiue et al. (2017)[2] and follow their train/validation/test split. We use Stanford CoreNLP (Manning et al., 2014) for Chinese word segmentation and POS tagging. For each split, we filter the instances where the correction is not within the top 50,000 frequent words in the Chinese part of the ClueWeb corpus[3] (Yu et al., 2012). This decision is made based on the fact that the vocabulary used by non-native language learners is limited. After filtering, the number of instances in the train, validation, and test sets are 8,205, 1,026, and 1,025, respectively. With punctuation marks and English words eliminated, the candidate vocabulary size $|D|$ is 48,394.

Our MLP model has two hidden layers of size 1,024. The activation function is Rectified Linear Unit (ReLU) and the dropout rate is set to 0.2. The parameters are optimized with Adagrad (Duchi et al., 2011) under a cosine proximity objective function. CWE (embedding size 400), Context2vec (300 units), 5-gram LM and RNNLM (size-128 GRU) are all trained on Chinese ClueWeb. Please refer to Appendix A for detailed parameter settings.

8 Automatic Evaluation

8.1 Result before LM Re-ranking

We first evaluate our correction generation model with the single ground-truth correction per segment. The results are shown in Table 2. The baselines include the two LMs and the Context2vec sentence completion method, which selects a candidate most similar to the context but ignores the original erroneous token. The 5-gram LM is the strongest baseline for the WUE correction task.

The second part of Table 2 shows the result of a set of experiments with Context2vec features. The MLP model with only C2V$_{ctx}$ features differs from the Context2vec baseline in that it is trained with the WUE dataset. Learning a transformation from the erroneous token to the correction seems to be easier than guessing a correction only from context, probably because some common correction pairs can be learned. The model using only C2V$_{tgt}$ achieves performance substantially better than that using only C2V$_{ctx}$. Note that the Context2vec vectors does not lay in the same space with the CWE+P vectors we used for E_{cand}. This indicates that our model is indeed capable of learning a transformation, not just copying the vector terms from the input features. Combining C2V$_{tgt}$ and C2V$_{ctx}$ can further enhance the performance.

The third part of Table 2 shows another set of experiments, in which different kinds of features are included incrementally starting from the CWE+P target features. The last row indicates the performance when all features are used. The model with CWE$_w$ features performs better than that with C2V$_{tgt}$, since CWE+P composes a vector representation for OOV targets such as "農作品", giving the model more clues for generating the correction. The position-insensitive character feature CWE$_c$ slightly improves the performance over CWE$_w$. After including Context2vec context and target features, the model can consider the context and reaches accuracy 0.3512. Finally, incorporating POS information further enhances the accuracy to 0.3717 ($p < 0.05$ significance) and MRR to 0.4378.

8.2 Effect of LM Re-ranking

We apply LM re-ranking to the candidate ranks generated by the best correction generation model. The results of two alternative LMs are shown in Table 3. Although there is only slight improvement on the accuracy, the MRR and hit rates increase substantially after LM re-ranking is applied. The 5-gram LM

[2]http://anthology.aclweb.org/attachments/P/P17/P17-2064.Datasets.zip ; corresponding ground-truth corrections retrieved from: http://202.112.195.192:8060/hsk/login.asp

	+ CWE_c		0.2946	0.3570	0.4234	0.4722	0.6078
	+ $C2V_{tgt}$	+ $C2V_{ctx}$	0.3512	0.4250	0.5024	0.5571	0.6800
	+ POS		0.3717	0.4378	0.5063	0.5688	0.6956

Table 2: Performance of the correction generation model with various target and context features.

Model	Accuracy	MRR	Hit@5	Hit@10	Hit@50	Hit@100
Best MLP	0.3717	0.4378	0.5063	0.5688	0.6956	0.7415
+ 5-gram LM	**0.3727**	**0.4605**	**0.5561**	**0.6439**	**0.8039**	0.8488
+ RNNLM	**0.3727**	0.4527	0.5278	0.6205	0.7808	0.8302

Table 3: Performance with LM re-ranking.

gives slightly better MRR than RNNLM. The optimal α for 5-gram LM and RNNLM are 0.355 and 0.255, respectively.

(E5) is an example in which LM re-ranking helps promote the rank of the answer. Though sharing a common Chinese character, the meaning of "一起" (together) and "一直" (always, all the time) are not quite similar. Thus, the MLP rank is very low. In contrast, the LM rank is high, since "就...都不..." (have always not...) is a suitable context for "一直". The higher combined rank leads to enhanced MRR.

(E5) 我從上小學起成績就(*一起, 一直)都不理想

(Since I began elementary school, my grade has (together, always) been unsatisfactory.)

$r_{LM} = 7, r_{MLP} = 1284 \rightarrow$ Combined rank: 19

9 Human Evaluation

In the automatic evaluation, there is only one answer for each test instance. However, correction can be highly subjective and alternatives may exist. Moreover, since the HSK WUE dataset is composed of sentence segments, the model has no access to the context outside of the segment. This results in difficulties in making the choice among several candidate corrections that are different in meaning but all seem to be acceptable. Table 4 shows an example. The erroneous token "定心" ('dìng xīn') is not a valid noun in Chinese. The meaning of character "定" is related to "stable, fixed", and the meaning of "心" is related to "mind". The top five candidates proposed by our system are all differ from the ground-truth correction. However, except for the rank 3 candidate, all other four candidates are acceptable corrections. This example shows that the single-answer automatic evaluation can underestimate the performance of our system. Therefore, we perform human evaluation, in which the top candidates proposed by our model are judged by annotators.

Wrong segment	不過我們要以堅定的**定心**與病對抗 (but we should fight against the disease with strong **'dìng xīn'**.)
System 1st	不過我們要以堅定的**自信**與病對抗 (... with strong **self-confidence**.)
System 2nd	不過我們要以堅定的**信念**與病對抗 (... with strong **faith**.)
System 3rd	不過我們要以堅定的**理智**與病對抗 (... with strong **rationality**.)
System 4th	不過我們要以堅定的**自信心**與病對抗 (... with strong **sense of self-confidence**.)
System 5th	不過我們要以堅定的**毅力**與病對抗 (... with strong **persistence**.)
Ground-truth	不過我們要以堅定的**決心**與病對抗 (... with strong **determination**.)

Table 4: An example of alternative corrections.

9.1 Annotation Guideline

Each instance of annotation consists of two sentence segments:

(S0): the original wrong segment

(S1): a correction segment, which is either the ground-truth or one of the top k proposed candidates

We set $k = 5$; however, only the candidates ranked before the ground-truth need annotation. For example, if our system gives rank 3 to the ground-truth correction, only the ground-truth, the first candidate and the second candidate need to be judged by human. For the 1,025 test segments, a total of 3,692 annotation instances are generated.

An annotator is asked to answer (at most) two questions for each annotation instance. The questions and the instructions given to the annotators are shown in Table 5. The answers to both questions are either Yes (1) or No (0). If the answer to Q1 is No, the answer to Q2 must be No, since (S1) violates the correctness criterion; we will skip Q2 in such cases. As long as the meaning of (S1) is similar to that of (S0), the annotator should answer Yes, regardless of whether (S0) is incorrect. In case the meaning of (S0) is not understandable, as illustrated by (E2-1), the annotator should answer Yes. This corresponds to our previous claim that the correctness criterion is more important.

Q1 (*is_g*): Is (S1) a correct sentence segment?
1. If (S1) is ungrammatical, please answer No. 2. If (S1) is grammatical but its semantics is not logical, or violates some common-sense knowledge, please also answer No. 3. Since we split sentences into segments by punctuation marks, if you encounter an "incomplete" sentence, please answer Yes to it, if it is itself correct and can be completed in some reasonable way.
Q2 (*is_c*): Is (S1) a correction of (S0)?
1. This question will be presented only if you answered Yes to Q1, which means the grammaticality of candidate correction (S1) has been confirmed. 2. If the meaning of (S1) is the intended meaning of (S0), please answer Yes; otherwise please answer No.

Table 5: WUE correction annotation instructions.

There are 10 annotators who are native speakers of Chinese. They are properly trained by giving examples selected from the validation set for every case in the instructions. Each annotation instance is assigned to two annotators randomly, so we can assume that the difficulty of the data assigned to each annotator is the same. Therefore, we calculate the average inter-annotator agreement of all pairs of annotators. The average Cohen's Kappa for Q1 and Q2 are 0.4205 and 0.4070 respectively, showing moderate level of agreement. If the two annotators disagree on either question, a third annotator is introduced to break the tie. We use majority voting to determine the final answer.

9.2 Evaluation with Human Annotation

Total 95.60% of the ground-truth corrections and 82.73% of the system top candidates are judged as correct by the annotators. This indicates that the grammaticality of the system output is acceptable. We use the updated rank of the test instances, which is the rank of the highest ranked candidate that meets both correctness and similarity criteria according to annotation results, to re-evaluate our best model. The performance before and after applying annotation results are shown in Table 6.

As can be seen, there is large performance increase in all metrics, verifying the existence of alternative corrections. Both accuracy and MRR increase by more than 30%. Moreover, the hit@5 rate is above 91%, which means that for most of the test data, at least one of the top five candidates is an acceptable correction. A language learner can choose the one that is close to his or her intended meaning from the list of candidates. In fact, only the writer knows the exact "intended meaning", so it is nearly impossible for a system to guess the right meaning all the time. We argue that a fairly short list of candidates can be helpful for learning to write in foreign languages.

Evaluation	Accuracy	MRR	Hit@5	Hit@10	Hit@50	Hit@100
Ground-truth	0.3727	0.4605	0.5561	0.6439	0.8039	0.8488
+ Annotation	0.6829	0.7784	0.9122	0.9171	0.9502	0.9600

Table 6: Human evaluation results.

10 Error Analysis

We analyze the human evaluation result according to different POS tags of the erroneous token. The results of POS tags that occur more than 20 times are shown in Table 7. The most frequent POS tags, VV, NN and AD, which are open-set word types, contribute the most difficult cases. The accuracy is less than 70% and MRR is less than 80%. On the other hand, for closed-set word types such as prepositions (P), our system performs very well, reaching accuracy 0.81 and MRR 0.88. DEV is the POS tag of Chinese adverb marker "地". The marker inherits very regular usage, and regular pattern of learner errors, so the system can achieve perfect performance. This also indicates that our system is capable of handling various kind of errors, and there is no need to include a separate rule-based module for a specific error type.

POS	# Tests	Accuracy	MRR	Hit@5	Hit@10	Mean rank	Std.
VV	316	0.67	0.77	0.91	0.92	26.12	6.75
NN	277	0.64	0.73	0.88	0.88	73.97	11.50
AD	130	0.65	0.75	0.88	0.89	96.16	13.41
P	62	0.81	0.88	0.95	0.95	3.10	1.92
VA	45	0.60	0.76	0.98	0.98	1.98	1.08
DEV	23	1.00	1.00	1.00	1.00	1.00	0.00
PN	21	0.71	0.80	0.95	0.95	2.33	1.40

Table 7: Performance on most frequent POS tags.

11 Conclusion

In this paper, given a Chinese sentence segment with a known error position, we aim to generate correction candidates that not only result in a correct segment, but also preserve the original meaning of the writer. Our MLP correction generation model takes target and context features as input and outputs a correction vector, which can be compared against the vectors of the candidate vocabulary. We apply LM re-ranking to put emphasis on correctness, avoiding misleading corrections.

In the single-ground-truth automatic evaluation, we achieve accuracy 0.3727 and MRR 0.4605. With human evaluation, in which the top five proposed candidates are judged by native Chinese speakers to include some alternative acceptable corrections, the accuracy increases to 0.6829 and MRR to 0.7784. Moreover, the hit@5 rate reaches 0.9122. Since a list of five candidates is rather short, a language learner can choose a suitable one from the candidate list and revise his or her sentences even without the help of a language teacher.

To enable future investigations, the dataset we used is attached. We have dealt with semantic similarity and similarity in overlapping Chinese characters in this paper. Nevertheless, we have not handled phonetical similarity. For example, in the correction pair (影響, 印象), the source of confusion is that the pronunciation of "影響" (influence 'yǐng xiǎng') and "印象" (impression 'yìn xiàng') are very similar. Pronunciation information can serve as clues for selecting the suitable correction.

A Detailed Model Settings

A.1 MLP Model Parameters

We implement our MLP correction generation model with Keras (Chollet, 2015). Table 8 shows the parameters. Models with this setting generally perform the best on the validation set across different combinations of features. The activation function is not applied at the output layer, so that the model output can fit better to the candidate embedding of the ground-truth correction.

When the validation accuracy does not increase for two consecutive epochs, the training process is terminated. In most cases, our model converges in 5 to 9 epochs. We choose the model with the highest validation accuracy for each feature combination to evaluate on the test set.

Parameter	Value
Hidden layer size	4096
Number of hidden layers	2
Activation function	ReLU
Dropout rate	0.2
Cost function	cosine proximity
Optimizer	Adagrad
Initial learning rate	0.01
Batch size	32

Table 8: Parameter settings of our MLP model.

A.2 CWE Parameters

We use the publicly released implementation of CWE[4] to train the CWE+P model on the Chinese ClueWeb corpus. We set the embedding size to 400 and train for 20 iterations. All other hyperparameters are left default.

A.3 Context2vec Parameters

We use the publicly available toolkit[5] to obtain the Context2vec context and target representation model. The training is also performed on the Chinese ClueWeb corpus. We set the number of units to 300 and train for 5 epochs.

A.4 N-gram LM Settings

We fit a 5-gram language model with KenLM[6] on Chinese ClueWeb. The modified Kneser-Ney smoothing (Heafield et al., 2013) is applied to handle unseen n-grams.

A.5 RNNLM Parameters

We use the Faster RNNLM toolkit[7], which speeds up the training process of the original RNNLM by using the Hierarchical Softmax (HS) or Noise Contrastive Estimation (NCE). We choose NCE because it gives better performance on our WUE validation set.

We process the ClueWeb corpus before training. The words whose frequency is less than 10 are replaced with a "<unk>" token. When testing, an OOV word is treated as "<unk>". We split 10% of the corpus for validation. The toolkit automatically adjusts the learning rate and early-stops the training process based on validation entropy. The hyperparameter settings are shown in Table 9.

Hyperparameter	Value
Layer type	GRU
Layer size	128
Number of negative samples	20

Table 9: Hyperparameter settings of our RNNLM.

Abstract

Knowledge graphs are a versatile framework to encode richly structured data relationships, but it can be challenging to combine these graphs with unstructured data. Methods for retrofitting pre-trained entity representations to the structure of a knowledge graph typically assume that entities are embedded in a connected space and that relations imply similarity. However, useful knowledge graphs often contain diverse entities and relations (with potentially disjoint underlying corpora) which do not accord with these assumptions. To overcome these limitations, we present *Functional Retrofitting*, a framework that generalizes current retrofitting methods by explicitly modeling pairwise relations. Our framework can directly incorporate a variety of pairwise penalty functions previously developed for knowledge graph completion. Further, it allows users to encode, learn, and extract information about relation semantics. We present both linear and neural instantiations of the framework. Functional Retrofitting significantly outperforms existing retrofitting methods on complex knowledge graphs and loses no accuracy on simpler graphs (in which relations do imply similarity). Finally, we demonstrate the utility of the framework by predicting new drug–disease treatment pairs in a large, complex health knowledge graph.

1 Introduction

Distributional representations of concepts are often easy to obtain from unstructured data sets, but they tend to provide only a blurry picture of the relationships that exist between concepts. In contrast, knowledge graphs directly encode this relational information, but it can be difficult to summarize the graph structure in a single representation for each entity.

To combine the advantages of distributional and relational data, Faruqui et al. (2015) propose to *retrofit* embeddings learned from distributional data to the structure of a knowledge graph. Their method first learns entity representations based solely on distributional data and then applies a retrofitting step to update the representations based on the structure of a knowledge graph. This modular approach conveniently separates the distributional data and entity representation learning from the knowledge graph and retrofitting model, allowing one to flexibly combine, reuse, and adapt existing representations to new tasks.

However, a core assumption of Faruqui et al. (2015)'s retrofitting model is that connected entities should have similar embeddings. This assumption often fails to hold in large, complex knowledge graphs, for a variety of reasons. First, subgraphs of a knowledge graph often contain distinct classes of entities that are most naturally embedded in disconnected vector spaces. In the extreme case, the representations for these entities might derive from very different underlying data sets. For example, in a health knowledge graph, the subgraphs containing diseases and drugs should be allowed to form disjoint vector spaces, and we might want to derive the initial representations from radically different data sets. Second, many knowledge graphs contain diverse relationships whose semantics are different from – perhaps even in conflict with – similarity. For instance, in the knowledge graph in Figure 1, the model

Proceedings of the 27th International Conference on Computational Linguistics, pages 2423–2436
Santa Fe, New Mexico, USA, August 20-26, 2018.

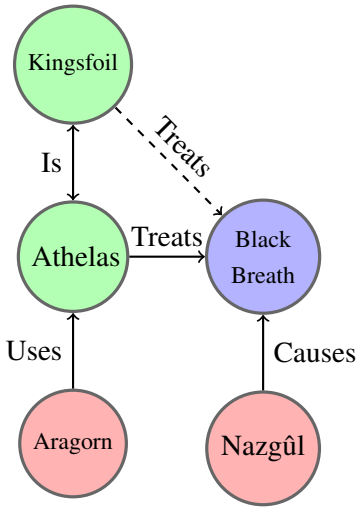

Figure 1: Toy knowledge graph with diverse relation types that connect treatments (green), diseases (blue), and persons (red) by known (solid) and unknown (dashed) relations. Traditional methods, which assume that all relations imply similarity, would retrofit Aragorn and Nazgûl toward similar embeddings.

of Faruqui et al. (2015) would model embeddings $\boldsymbol{q_{Aragorn}} \approx \boldsymbol{q_{Athelas}} \approx \boldsymbol{q_{BlackBreath}} \approx \boldsymbol{q_{Nazgûl}}$, which is problematic as Aragorn is not semantically similar to a Nazgûl (they are enemies).

To address these limitations, we present *Functional Retrofitting*, a retrofitting framework that explicitly models pairwise relations as functions. The framework supports a wide range of different instantiations, from simple linear relational functions to complex multilayer neural ones. Here, we evaluate both linear and neural instantiations of Functional Retrofitting on a variety of diverse knowledge graphs. For benchmarking against existing approaches, we use FrameNet and WordNet. We then move into the medical domain, where knowledge graphs play an important role in knowledge accumulation and discovery. These experiments show that even simple instantiations of Functional Retrofitting significantly outperform baselines on knowledge graphs with semantically complex relations and sacrifice no accuracy on graphs where Faruqui et al. (2015)'s assumptions about similarity do hold. Finally, we use the model to identify promising new disease targets for existing drugs.

Code which implements Functional Retrofitting is available at `https://github.com/roaminsight/roamresearch`.

2 Notation

A knowledge graph $\mathcal{G}$ is composed of a set of vertices $\mathcal{V}$, a set of relation types $\mathcal{R}$, and a set of edges $\mathcal{E}$ where each edge $e \in \mathcal{E}$ is a tuple (i, j, r) in which the relationship $r \in \mathcal{R}$ holds between vertices $i \in \mathcal{V}$ and $j \in \mathcal{V}$. Our goal is to learn a set of representations $\mathcal{Q} = \{\boldsymbol{q_i} : i \in \mathcal{V}\}$ which contain the information encoded in both the distributional data and the knowledge graph structure, and can be used for downstream analysis. Throughout this paper, we use a to refer to a scalar, $\boldsymbol{a}$ to refer to a vector, and $\boldsymbol{A}$ to refer to a matrix or tensor.

3 Related Work

Here we are interested in *post-hoc* retrofitting methods, which adjust entity embeddings to fit the structure of a previously unseen knowledge graph.

3.1 Retrofitting Models

The primary introduction of retrofitting was Faruqui et al. (2015), in which the authors showed the value of retrofitting semantic embeddings according to minimization of the weighted least squares problem

$$\Psi_{\mathcal{G}}(\mathcal{Q}) = \sum_{i \in \mathcal{V}} \alpha_i \left\| \boldsymbol{q_i} - \hat{\boldsymbol{q}}_{\boldsymbol{i}} \right\|^2 + \sum_{(i,j,r) \in \mathcal{E}} \beta_{ij} \left\| \boldsymbol{q_i} - \boldsymbol{q_j} \right\|^2 \tag{1}$$

where $\hat{\mathcal{Q}} = \{\hat{\boldsymbol{q}}_{\boldsymbol{i}} : i \in \mathcal{V}\}$ is the embedding learned from the distributional data and α_i, β_{ij} set the relative weighting of each type of data. When $\alpha_i = 1$ and $\beta_{ij} = \frac{1}{degree(i)}$, this model assigns equal weight to the distributional data and the structure of the knowledge graph.

More recently, Hamilton et al. (2017) presented GraphSAGE, a two-step method which learns both an aggregation function $f : \mathbb{R}^{d \times n} \rightarrow \mathbb{R}^k$, to condense the representations of neighbors into a single point, and an update function $g : \mathbb{R}^{k+d} \rightarrow \mathbb{R}^d$, to combine the aggregation with a central vertex. Here, d is the embedding dimensionality, k is the aggregation dimensionality, and $n > 0$ is the number of neighbors for each vertex. Note that $k > d$ is permitted, allowing for aggregation by concatenation. While this method is extremely effective for learning representations on simple knowledge graphs, it is not formulated for knowledge graphs with multiple types of relations. Furthermore, when the representation of a relation is known *a priori*, it can be useful to explicitly set the penalty function (e.g., Mrkšic et al. (2016) use hand-crafted functions to effectively model antonymy and synonymy). By aggregating neighbors into a point estimate before calculating relationship likelihoods, GraphSAGE makes it difficult to encode, learn, or extract the representation of a pairwise relation.

In a similar vein, Faruqui et al. (2016) developed a graph-based semi-supervised learning method to expand morpho-syntactic lexicons from seed sets. Though the task is different from the retrofitting task we consider here, the performance and scalability of their method demonstrate the utility of directly encoding pairwise relations as message-passing functions.

3.2 Relational Penalty Functions

Our new Functional Retrofitting framework models each relation via a penalty function $f_r : \mathbb{R}^{d_i+d_j} \rightarrow \mathbb{R}_{\geq 0}$ acting on a pair of entities (i, j) with embedding dimensionalities d_i and d_j, respectively. By explicitly modeling relations between pairs of entities, Functional Retrofitting supports the use of a wide array of scoring functions that have previously been developed for knowledge graph completion. Here, we present a brief review of such scoring functions; for an extensive review, see (Nickel et al., 2016).

TransE (Bordes et al., 2013) uses additive relations in which the penalty function $f_r(\boldsymbol{q_i}, \boldsymbol{q_j}) = \|\boldsymbol{q_i} + \boldsymbol{a_r} - \boldsymbol{q_j}\|_2^2$ is low iff $(i, j, r) \in \mathcal{E}$. The simple Unstructured Model (Bordes et al., 2012) was proposed as a naïve version of TransE that assigns all $\boldsymbol{a_r} = \mathbf{0}$, leading to the penalty function $f_r(\boldsymbol{q_i}, \boldsymbol{q_j}) = \|\boldsymbol{q_i} - \boldsymbol{q_j}\|_2^2$. This is the underlying penalty function of (Faruqui et al., 2015). It cannot consider multiple types of relations. In addition, while it models 1-to-1 relations well, it struggles to model multivalued relations.

TransH (Wang et al., 2014) was proposed to address this limitation by using multiple representations for a single entity via relation hyperplanes. For a relation r, TransH models the relation as a vector $\boldsymbol{a_r}$ on a hyperplane defined by normal vector $\boldsymbol{w_r}$. For a triple $(i, j, r) \in \mathcal{E}$, the entity embeddings $\boldsymbol{q_i}$ and $\boldsymbol{q_j}$ are first projected to the hyperplane of $\boldsymbol{w_r}$. By constraining $\|\boldsymbol{w_r}\|_2 = 1$, we have the penalty function $f_r(\boldsymbol{q_i}, \boldsymbol{q_j}) = \|g_r(\boldsymbol{q_i}) + \boldsymbol{a_r} - g_r(\boldsymbol{q_j})\|_2^2$ where $g_r(\boldsymbol{x}) = \boldsymbol{x} - \boldsymbol{w_r}^T \boldsymbol{x} \boldsymbol{w_r}$.

TransR (Lin et al., 2015) embeds relations in a separate space from entities by a relation-specific matrix $\boldsymbol{M_r} \in \mathbb{R}^{d \times k}$ that projects from entity space to relation space and a shared relation vector $\boldsymbol{a} \in \mathbb{R}^k$ that translates in relation space by $f_r(\boldsymbol{q_i}, \boldsymbol{q_j}) = \|\boldsymbol{q_i}\boldsymbol{M_r} + \boldsymbol{a} - \boldsymbol{q_j}\boldsymbol{M_r}\|_2^2$. We use this model as the inspiration for our linear penalty function.

The Neural Tensor Network (NTN; Socher et al. (2013)) defines a score function $f_r(\boldsymbol{q_i}, \boldsymbol{q_j}) = \boldsymbol{u_r}^T g(\boldsymbol{q_i}^T \boldsymbol{M_r} \boldsymbol{q_j} + \boldsymbol{M_{r,1}} \boldsymbol{q_i} + \boldsymbol{M_{r,2}} \boldsymbol{q_j} + \boldsymbol{b_r})$ where $\boldsymbol{u_r}$ is a relation-specific linear layer, $g : \mathbb{R}^k \rightarrow \mathbb{R}^k$ is the tanh operation applied element-wise, $\boldsymbol{M_r} \in \mathbb{R}^{d \times d \times k}$ is a 3-way tensor, and $\boldsymbol{M_{r,1}}, \boldsymbol{M_{r,2}} \in \mathbb{R}^{k \times d}$ are weight matrices. All of these models can be directly incorporated in our Functional Retrofitting framework.

4 Functional Retrofitting

We propose the framework of Functional Retrofitting (FR) to incorporate a set $\mathcal{F}$ of relation-specific penalty functions $f_r : \mathbb{R}^{d_i+d_j} \rightarrow \mathbb{R}_{\geq 0}$ which penalizes embeddings of entities i, j with dimensionalities

d_i, d_j, respectively. This gives the complete minimization:

$$\Psi_{\mathcal{G}}(\mathcal{Q};\mathcal{F}) = \sum_{i\in\mathcal{Q}} \alpha_i ||\boldsymbol{q_i} - \hat{\boldsymbol{q}}_{\boldsymbol{i}}||^2 + \sum_{(i,j,r)\in\mathcal{E}} \beta_{i,j,r} f_r(\boldsymbol{q_i}, \boldsymbol{q_j}) - \sum_{(i,j,r)\in\mathcal{E}^-} \beta_{i,j,r} f_r(\boldsymbol{q_i}, \boldsymbol{q_j}) + \sum_{r\in\mathcal{R}} \rho_\lambda(f_r) \tag{2}$$

where $\hat{\boldsymbol{q}}_{\boldsymbol{i}}$ is observed from distributional data, α_i and $\beta_{i,j,r}$ set the relative strengths of the distributional data and the knowledge graph structure, and ρ regularizes f_r with strength set by λ. $\mathcal{E}^-$ is the *negative space* of the knowledge graph, a set of edges that are not annotated in the knowledge graph. FR uses $\mathcal{E}^-$ to penalize relations that are implied by the representations but not annotated in the graph. To populate $\mathcal{E}^-$, we sample a single negative edge (i, j', r) with the same outgoing vertex for each true edge $(i, j, r) \in \mathcal{E}$. The user can calibrate trust in the completeness of the knowledge graph via the β hyperparameter.

In contrast to prior retrofitting work, FR explicitly encodes directed relations. This allows the model to fit graphs which contain diverse relation types and entities embedded in disconnected vector spaces. Here, we compare the performance of two instantiations of FR – one with all linear relations and one with all neural relations – and show that even these simple models provide significant performance improvements. In practice, we recommend that users select relation-specific functions in accordance with the semantics of their graph's relations.

4.1 Linear Relations

We implement a linear relational penalty function $f_r(\boldsymbol{q_i}, \boldsymbol{q_j}) = \|\boldsymbol{A_r q_j} + \boldsymbol{b_r} - \boldsymbol{q_i}\|^2$ with ℓ_2 regularization for minimization of:

$$\begin{aligned}\Psi_{\mathcal{G}}(\mathcal{Q};\mathcal{F}) = &\sum_{i=1}^{n} \alpha_i \left\|\boldsymbol{q_i} - \hat{\boldsymbol{q}}_{\boldsymbol{i}}\right\|^2 + \sum_{(i,j,r)\in\mathcal{E}} \beta_{i,j,r} \left\|\boldsymbol{A_r q_j} + \boldsymbol{b_r} - \boldsymbol{q_i}\right\|^2 \\ &- \sum_{(i,j,r)\in\mathcal{E}^-} \beta_{i,j,r} \left\|\boldsymbol{A_r q_j} + \boldsymbol{b_r} - \boldsymbol{q_i}\right\|^2 + \lambda \sum_{r\in\mathcal{R}} ||\boldsymbol{A_r}||^2 \end{aligned} \tag{3}$$

Identity Relations

Faruqui et al. (2015)'s model is a special case of this formulation in which

$$\boldsymbol{A_r} = \boldsymbol{I}, \quad \boldsymbol{b_r} = \boldsymbol{0} \quad \forall r, \qquad \beta_{i,j,r} = \begin{cases} \frac{1}{degree(i)} & (i,j,r) \in \mathcal{E} \\ 0 & (i,j,r) \in \mathcal{E}^- \end{cases}$$

Throughout the remainder of this paper, we refer to this baseline model as the "FR-Identity" retrofitting method.

Initialization

We initialize embeddings as those learned from distributional data and relations to imply similarity:

$$\boldsymbol{A_r} = \boldsymbol{I}, \quad \boldsymbol{b_r} = \boldsymbol{0} \quad , \quad \alpha_i = \begin{cases} 0 & \hat{\boldsymbol{q}}_{\boldsymbol{i}} = \boldsymbol{0} \\ \alpha & \hat{\boldsymbol{q}}_{\boldsymbol{i}} \neq \boldsymbol{0} \end{cases}, \quad \beta_{i,j,r} = \begin{cases} \frac{\beta^+}{d_r(i)} & (i,j,r) \in \mathcal{E} \\ \frac{\beta^-}{d_r(i)} & (i,j,r) \in \mathcal{E}^- \end{cases}$$

where $d_r(i)$ is the out-degree of vertex i for relation type r, α is a hyperparameter to trade off distributional data against structural data, and β sets the trust in completeness of the knowledge graph structure. In our experiments, we use $\beta^+ = 1,\ \beta^- = 0$ for straightforward comparison with the method of Faruqui et al. (2015) and optimize α by cross-validation. Given prior knowledge about the semantic meaning of relations, we could initialize relations to respect these meanings (e.g., antonymy could be represented by $\boldsymbol{A_r} = -\boldsymbol{I}$).

Learning Procedure

We optimize this model by block optimization. Conveniently, we have closed-form solutions where the partial derivatives of Eq. 3 equal 0:

$$\boldsymbol{b_r} = \frac{\sum_{(i,j)} (-1)^{I_{\{(i,j,r)\notin\mathcal{E}\}}} \beta_{i,j,r}(\boldsymbol{A_r q_j} - \boldsymbol{q_i})}{\sum_{(i,j)} (-1)^{I_{\{(i,j,r)\notin\mathcal{E}\}}} \beta_{i,j,r}} \tag{4}$$

$$\tilde{\boldsymbol{A}}_{\boldsymbol{r}} = \boldsymbol{U}\boldsymbol{V}^{-1} \tag{5}$$

$$\boldsymbol{U} = \sum_{(i,j):(i,j,r)\in\mathcal{E}} \beta_{i,j,r}(\boldsymbol{q_i} - \boldsymbol{b_r})\boldsymbol{q_j}^T - \sum_{(i,j):(i,j,r)\in\mathcal{E}^-} \beta_{i,j,r}(\boldsymbol{q_i} - \boldsymbol{b_r})\boldsymbol{q_j}^T \tag{6}$$

$$\boldsymbol{V} = \sum_{(i,j):(i,j,r)\in\mathcal{E}} \beta_{i,j,r}\boldsymbol{q_j}\boldsymbol{q_j}^T - \sum_{(i,j):(i,j,r)\in\mathcal{E}^-} \beta_{i,j,r}\boldsymbol{q_j}\boldsymbol{q_j}^T + \lambda\boldsymbol{I} \tag{7}$$

Constraining $\boldsymbol{A_r}$ to be orthogonal by $\boldsymbol{A_r} = \tilde{\boldsymbol{A}}_{\boldsymbol{r}}(\tilde{\boldsymbol{A}}_{\boldsymbol{r}}^T\tilde{\boldsymbol{A}}_{\boldsymbol{r}})^{-1/2}$, we have $\boldsymbol{q_i} = \frac{\boldsymbol{a_i}}{b_i}$ where

$$\begin{aligned}\boldsymbol{a_i} = \alpha_i\hat{\boldsymbol{q}}_{\boldsymbol{i}} &+ \sum_{(j,r):(i,j,r)\in\mathcal{E}} \beta_{i,j,r}(\boldsymbol{A_r q_j} + \boldsymbol{b_r}) + \sum_{(j,r):(j,i,r)\in\mathcal{E}} \beta_{j,i,r}\boldsymbol{A_r}^T(\boldsymbol{q_j} - \boldsymbol{b_r}) \\ &- \sum_{(j,r):(i,j,r)\in\mathcal{E}^-} \beta_{i,j,r}(\boldsymbol{A_r q_j} + \boldsymbol{b_r}) - \sum_{(j,r):(j,i,r)\in\mathcal{E}^-} \beta_{j,i,r}\boldsymbol{A_r}^T(\boldsymbol{q_j} - \boldsymbol{b_r})\end{aligned} \tag{8}$$

$$b_i = \alpha_i + \sum_{(j,r):(i,j,r)\in\mathcal{E}} \beta_{i,j,r} + \sum_{(j,r):(j,i,r)\in\mathcal{E}} \beta_{j,i,r} - \sum_{(j,r):(i,j,r)\in\mathcal{E}^-} \beta_{i,j,r} - \sum_{(j,r):(j,i,r)\in\mathcal{E}^-} \beta_{j,i,r} \tag{9}$$

4.2 Neural Relations

We also instantiate FR with a neural penalty function $f_r(\boldsymbol{q_i}, \boldsymbol{q_j}) = \sigma(\boldsymbol{q_i}^T\boldsymbol{A_r q_j})$ where σ is the element-wise tanh operation, $\boldsymbol{A_r} \in \mathbb{R}^{d_i \times d_j}$, again with ℓ_2 regularization.We initialize weights in a similar manner as for the linear relations and update via stochastic gradient descent. In our experiments, we use $\beta^+ = \beta^- = 1$, and sample the same number of non-neighbors as true neighbors.

5 Experiments

We test FR on four knowledge graphs. The first two are standard lexical knowledge graphs (FrameNet, WordNet) in which FR significantly improves retrofitting quality on complex graphs and loses no accuracy on simple graphs. The final two graphs are large healthcare ontologies (SNOMED-CT, Roam Health Knowledge Graph), which demonstrate the scalability of the framework and the utility of the new embeddings.

For each graph, we successively evaluate link prediction accuracy after retrofitting to links of other relation types. Specifically, for each relation type $r \in \mathcal{R}$, we retrofit to $\mathcal{G}_{\setminus r} = (\mathcal{V}, \mathcal{E}_{\setminus r})$ where $\mathcal{E}_{\setminus r} = \{(i,j,r') : (i,j,r') \in \mathcal{E}, r' \neq r\}$ is the set of edges with all relations of type r removed. After retrofitting, we train a Random Forest classifier to predict the presence of relation r between entities i and j (with 70% of vertices selected as training examples and the remainder reserved for testing). To have balanced class labels, we sample an equivalent number of non-edges, $\mathcal{E}_r^- = \{(i,j,r) : (i,j,r) \notin \mathcal{E}\}$ with $|\mathcal{E}_r^-| = |\mathcal{E}|$ and $|\{j : (i,j,r) \in \mathcal{E}_r^-\}| = |\{j : (i,j,r) \in \mathcal{E}\}| \; \forall \; i$. Thus, the random baseline classification rate is set to 50%. Other baselines are the embeddings built from distributional data and the retrofitting method of Faruqui et al. (2015), denoted as "None" and "FR-Identity", respectively.

5.1 FrameNet

FrameNet (Baker et al., 1998; Fillmore et al., 2003) is a linguistic knowledge graph containing information about lexical and predicate argument semantics of the English language. FrameNet contains two distinct entity classes: *frames* and *lexical units*, where a *frame* is a meaning and a *lexical unit* is a single meaning for a word. To create a graph from FrameNet, we connect lexical unit i to frame j if i occurs

in j. We denote this relation as "Frame", and its inverse "Lexical unit". Finally, we connect frames by the structure of FrameNet (Table 6). Distributional embeddings are from the Google News pre-trained Word2Vec model (Mikolov et al., 2013a); the counts of each entity type that were also found in the distributional corpus are shown in Table 6.

Results

As seen in Table 1, the representations learned by FR-Linear and FR-Neural are significantly more useful for link prediction than those of the baseline methods.

Retrofitting Model	**'Inheritance'** (2132/992)	**'Using'** (1552/668)	**'Reframing Mapping'** (544/312)	**'Subframe'** (356/168)	**'Perspective On'** (336/148)

Table 1: Retrofitting to FrameNet. Reported values are mean and standard deviation of the link prediction accuracies over three experiments. The number of edges used for (training/testing) is shown below each edge type.

5.2 WordNet

WordNet (Miller, 1995; Fellbaum, 2005) is a lexical database consisting of words (lemmas) which are grouped into unordered sets of synonyms (synsets). To examine the performance of FR on knowledge graphs which predominately satisfy the assumptions of Faruqui et al. (2015), we extract a simple knowledge graph of lemmas and the connections between these lemmas that are annotated in WordNet. These connections are dominated by hypernymy and hyponymy (Table 7), which correlate with similarity, so we expect the baseline retrofitting method to perform well.

Results

As seen in Table 2, the increased flexibility of the FR framework does not degrade embedding quality even when this extra flexibility is not intuitively necessary. Here, we evaluate standard lexical metrics for word embeddings: word similarity and syntatic relations. For word similiarity tasks, the evaluation metric is the Spearman correlation between predicted and annotated similarities; for syntatic relation, the evaluation metric is the mean cosine similarity between the learned representation of the correct answer and the prediction by the vector offset method (Mikolov et al., 2013b). In contrast to our other experiments, here the only stochastic behavior is due to stochastic gradient descent training, not sampling of evaluation samples. Even though the WordNet knowledge graph largely satisfies the assumptions of the naïve retrofitting model, the flexible FR framework achieves sustained improvements for both word similarity datasets (WordSim-353; Finkelstein et al. (2001), Mturk-771[1], and MTurk-287and syntatic relations (Google Analogy Test Set[2]).

[2] `http://download.tensorflow.org/data/questions-words.txt`

Retrofitting Model	Word Similarity			Syntactic Relation
	WordSim-353	MTurk-771	MTurk-287	Google Analogy
None	0.512	0.538	0.671	0.772
FR-Identity	0.512	0.532	0.664	0.774
FR-Linear	**0.542**	**0.562**	**0.679**	**0.793**
FR-Neural	$\underline{0.516 \pm 0.001}$	$\underline{0.543 \pm 0.001}$	$\underline{0.676 \pm 0.001}$	$\underline{0.784 \pm 0.000}$

Table 2: Retrofitting to WordNet. Reported values are Spearman correlations for the word similarity tasks and mean cosine similarity for the syntatic relation task. These are deterministic evaluations, so the only source of stochasticity is the optimization of the FR-Neural model.

5.3 SNOMED-CT

SNOMED-CT is an ontology of clinical healthcare terms and concepts including diseases, treatments, anatomical terms, and many other types of entities. From the publicly available SNOMED-CT knowledge graph,[3] we extracted 327,001 entities and 3,809,639 edges of 169 different types (Table 8). To create distributional embeddings, we first link each SNOMED-CT concept to a set of Wikipedia articles by indexing the associated search terms in WikiData.[4] We aggregate each article set by the method of Arora et al. (2016), which performs TF-IDF weighted aggregation of pre-trained term embeddings to create sophisticated distributional embeddings of SNOMED-CT concepts. This creates a single 300-dimensional vector for each entity.

Results

As the SNOMED-CT ontology is dominated by synonymy-like relations, we expect the simple retrofitting methods to perform well. Nevertheless, we see minimal loss in link prediction performance by using the more flexible FR framework (Table 3). Our implementation supports the use of different function classes to represent different relation types; in practice, we recommend that users select function classes in accordance with relation semantics.

Retrofitting Model	'Has Finding Site' (113748/49070)	'Has Pathological Process' (19318/8124)	'Due to' (5042/2042)	'Cause of' (1166/376)

FR-Linear	$\mathbf{95.35 \pm 0.01}$	$\mathbf{99.35 \pm 0.01}$	$\underline{93.50 \pm 0.46}$	$\underline{80.82 \pm 0.49}$
FR-Neural	95.22 ± 0.00	98.97 ± 0.22	91.70 ± 0.15	80.29 ± 0.80

Table 3: Retrofitting to SNOMED-CT. Reported values are mean and standard deviation of the link prediction accuracies over three experiments. The number of edges used for (training/testing) is shown below each edge type.

5.4 Roam Health Knowledge Graph

Finally, we investigate the utility of FR in the Roam Health Knowledge Graph (RHKG). The RHKG is a rich picture of the world of healthcare, with connections into numerous data sources: diverse medical ontologies, provider profiles and networks, product approvals and recalls, population health statistics, academic publications, financial data, clinical trial summaries and statistics, and many others. As of June 2, 2017 the RHKG contains 209,053,294 vertices, 1,021,163,726 edges, and 6,231,287,999 attributes. Here, we build an instance of the RHKG using only public data sources involving drugs and diseases.

[3] https://www.nlm.nih.gov/healthit/snomedct/index.html

[4] https://dumps.wikimedia.org/wikidatawiki/entities/

The structure of this knowledge graph is summarized in Table 9. In total, we select 48,649 disease–disease relations, 227,051 drug–drug relations, and 13,667 drug–disease relations used for retrofitting. A disjoint set of 11,306 drug–disease relations is reserved for evaluation.

In the RHKG, as in many industrial knowledge graphs, different distributional corpora are available for each type of entity. First, we mine 2.9M clinical texts for co-occurrence counts in physician notes. After counting co-occurrences, we perform a pointwise mutual information transform and ℓ_2 row normalization to generate embeddings for each entity. For drug embeddings, we supplement these embeddings with physician prescription habits. We extract prescription counts for each of 808,020 providers in the 2013 Centers for Medicare & Medicaid (CMS) dataset[5] and 837,629 providers in the 2014 CMS dataset. By aggregating prescriptions counts across provider specialty, we produce 201-dimensional distributional embeddings for each drug. Finally, we retrofit these distributional embeddings to the structure of the knowledge graph (excluding 'Treats' edges reserved for evaluation).

Results

As shown in Table 5, the FR framework significantly improves prediction of 'Treats' relations. We hypothesize that this is due to the separable nature of the graph; as seen in Figure 2, the FR retrofitting framework can learn Disease and Drug subgraphs that are nearly separable. In contrast, Identity retrofitting generates a single connected space and distorts the embeddings.

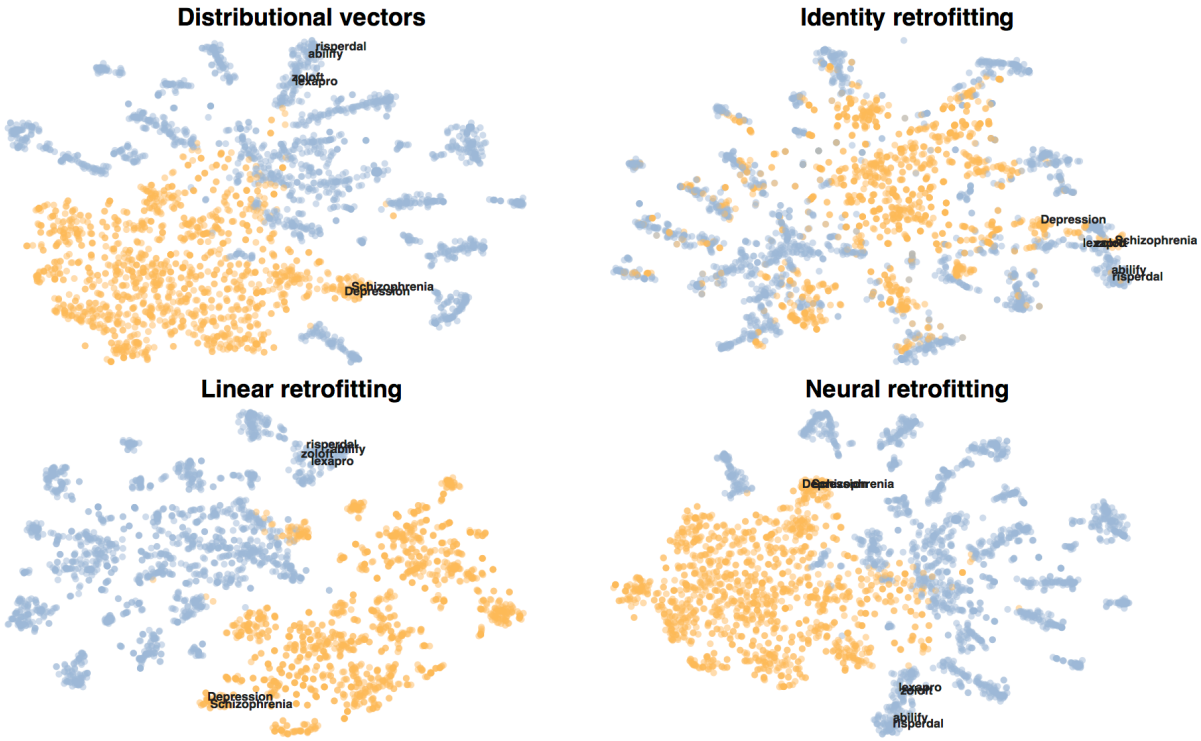

Figure 2: t-SNE Projections of the retrofitted embeddings of the drugs (blue) and diseases (orange) in the Roam Health Knowledge Graph, with selected annotations reflecting the 'Treats' relation. The distributional space strongly separates the two kinds of entity because their representations were learned in different ways. Identity retrofitting blurs this basic semantic distinction in order to make diseases and drugs in 'Treats' relations more similar. As Table 5 shows, the FR models achieve this same unification, but they need not distort the basic drug/disease distinction to do it.

We also investigate the predictions induced by the retrofitted representations. An interesting use of healthcare knowledge graphs is to predict drug *retargets*, that is, diseases for which there is no annotated treatment relationship with the drug but such a relationship may exist medically. As shown in Table 4,

None	72.02 ± 0.50
FR-Identity	72.93 ± 0.82
FR-Linear	$\mathbf{84.22 \pm 0.82}$
FR-Neural	$\underline{73.52 \pm 0.89}$

Table 5: Drug-Disease Link Prediction Accuracies.

the top retargets predicted by the linear retrofitting model are all medically plausible. In particular, the model confidently predicts that Kenalog would treat contact dermatitis, an effect also found in a clinical trial (Usatine and Riojas, 2010).The second most confident prediction of drug retargets was that Kenalog can treat pemphigus, which is indicated on Kenalog's drug label,[6] but was not previously included in the knowledge graph. The third prediction was that methyprednisolone acetate would treat nephrotic syndrome, which is reasonable as the drug is now labelled to treat idiopathic nephrotic syndrome.[7] Interestingly, several models predict that furosemide treats "aneurysm of unspecified site", a relationship not indicated on the drug label[8], though furosemide has been observed to reduce intracranial pressure (Samson and Beyer Jr, 1982), a key factor in brain aneurysms. Finally, both the distributional data and the embeddings produced by the baseline identity retrofitting model make the nonsensical prediction that Latanoprost, a medication used to treat intraocular pressure, would also treat superficial ankle and foot injuries.

The accuracy of the predictions from the more complex models underscores the utility of the new framework for retrofitting distributional embeddings to knowledge graphs with relations that do not imply similarity.

6 Conclusions and Future Work

We have presented *Functional Retrofitting*, a new framework for *post-hoc* retrofitting of entity embeddings to the structure of a knowledge graph. By explicitly modeling pairwise relations, this framework allows users to encode, learn, and extract information about relation semantics while simultaneously updating entity representations. This framework extends the popular concept of retrofitting to knowledge graphs with diverse entity and relation types. Functional Retrofitting is especially beneficial for graphs in which distinct distributional corpora are available for different entity classes, but it loses no accuracy when applied to simpler knowledge graphs. Finally, we are interested in the possibility of improvements to the optimization procedure outlined in this paper, including dynamic updates of the β and α parameters to increase trust in the graph structure while the relation functions are learned.

A Structure of Knowledge Graphs

A.1 FrameNet

The structure of the FrameNet (Baker et al., 1998; Fillmore et al., 2003) knowledge graph is shown in Table 6.

Entity Type	**Count**	**W2V Count**
Token	13572	12167
Frame	1221	464

Edge Type	**Connects**	**Count**
Frame	Token → Frame	13572
Lexical_Unit	Frame → Token	13572
Inheritance	Frame → Frame	1562
Using	Frame → Frame	1110
ReFraming_Mapping	Frame → Frame	428
Persepctive_on	Frame → Frame	242
Precedes	Frame → Frame	178
See_also	Frame → Frame	172
Causative_of	Frame → Frame	120
Inchoative_of	Frame → Frame	38
Metaphor	Frame → Frame	8

Table 6: Structure of the FrameNet knowledge graph.

A.2 WordNet

The structure of the WordNet knowledge graph (Miller, 1995) is shown in Table 7.

Entity Type	Count	W2V Count
Lemma	206978	115635

Edge Type	Count
Hypernym	136,235
Hyponym	136,235
Derivationally Related Form	60,250
Antonym	5,922
Pertainym	5,573
Usage Domain	69

Table 7: Structure of the WordNet knowledge graph.

A.3 SNOMED-CT

The structure of the knowledge graph extracted from the SNOMED-CT ontology is shown in Table 8.

A.4 Roam Health Knowledge Graph

The structure of the extracted subgraph of the RHKG is summarized in Table 9. A disjoint set of 11,306 drug–disease relations is reserved for evaluation.

Abstract

Despite the success of existing works on single-turn conversation generation, taking the coherence in consideration, human conversing is actually a context-sensitive process. Inspired by the existing studies, this paper proposed the static and dynamic attention based approaches for context-sensitive generation of open-domain conversational responses. Experimental results on two public datasets show that the proposed static attention based approach outperforms all the baselines on automatic and human evaluation.

1 Introduction

Until recently, training open-domain conversational systems that can imitate the way of human conversing is still not a well-solved problem and non-trivial task. Previous efforts focus on generating open-domain conversational responses as an unsupervised clustering process (Ritter et al., 2010), a phrase-based statistical machine translation task (Ritter et al., 2011) and a search problem based on the vector space model (Banchs and Li, 2012), etc. With the booming of deep learning, particularly the neural network based sequence-to-sequence models, generating open-domain conversational responses gradually turns into an end-to-end encoding and decoding process (Sutskever et al., 2014; Vinyals and Le, 2015; Shang et al., 2015; Serban et al., 2016b; Li et al., 2016a; Li et al., 2016b; Shao et al., 2017; Yao et al., 2017). Despite the success of the above research on single-turn conversational response generation, human conversations are usually coherent (Li et al., 2016c) and **context-sensitive** (Tian et al., 2017; Xing et al., 2017). Table 1 illustrates how contextual information in conversations impact on the response generation. For instance, given a message[1] "*How should I tell my mom?*", as input, to a single-turn

Conversation 1	Conversation 2
A: I got a high score on my exam.	A: I failed to pass the exam.
B: Oh! Great!	B: That's too bad.
A: *How should I tell my mom?*	A: *How should I tell my mom?*
B: ***Go and give her a big surprise!***	B: ***Just tell her the truth and do well next time.***

Table 1: An example of the impact of contextual information on human conversations. "A" and "B" denote two speakers in the conversations.

conversational response generation model, it should output a fixed response regardless of the content in previous utterances. However, as shown in Table 1, in the conversations[2], the responses to be generated (the last utterance in Table 1) should not only dependent on the last one message ("*How should I tell my mom?*"), but also need to consider the longer **historical utterances** in the conversations.

[1]Here, a "message" indicates an input of a response in single-turn conversational response generation.

[2]In this paper, a "conversation" equals to an "open-domain conversation"and a "conversational response" or "response" equals to an "open-domain conversational response".

Proceedings of the 27th International Conference on Computational Linguistics, pages 2437–2447
Santa Fe, New Mexico, USA, August 20-26, 2018.

Recent studies on generating open-domain conversational responses begin to explore the context information to generate more informative and coherent responses. Serban et al. (2016a) presented a hierarchical recurrent encoder-decoder (HRED) to recurrently model the dialogue context. Serban et al. (2017b) further introduced a stochastic latent variable at each dialogue turn to improve the diversity of the HRED model. Zhao et al. (2017) proposed a conditional variational autoencoder based approach to learning contextual diversity for neural response generation. Xing et al. (2017) proposed a hierarchical recurrent attention network (HRAN) to jointly model the importance of tokens and utterances. Tian et al. (2017) treated the hierarchical modeling of contextual information as a recurrent process in encoding. We could make two conclusions from these works.

- First, existing studies of utterance modeling mainly focus on representing utterances by using bidirectional GRU (Xing et al., 2017) or unidirectional GRU (Tian et al., 2017).
- Second, there are two types of approaches on context (inter-utterance) modeling. One is the attention-based approach (Xing et al., 2017), the other is the sequential integration approach (Tian et al., 2017).

Drawing the advantages of the existing approaches, in this paper, we proposed a novel context-sensitive generation approach, which obtains the context representation of a conversation by weighing the importance of each utterance using two attention mechanisms, namely dynamic and static attention, to generate open-domain conversational responses.

2 The Proposed Context-Sensitive Generation Approach

2.1 Preliminary

A typical neural network based sequence-to-sequence model for generating open-domain conversational responses usually includes an encoder and a decoder. The encoder expresses an input message as a dense vector which represents the semantics of the input message. The decoder then generates a conversational response according to the semantic representation of the input message. In context-sensitive generation of open-domain conversational responses, the input message to the encoder usually includes several historical utterances in a conversation. Therefore, one of the key problems in context-sensitive generation is how to encode historical utterances in a conversation. Figure 1 presents two state-of-the-art approaches to encoding contextual information for context-sensitive response generation. Here, u_i, u_{i+1} and u_j

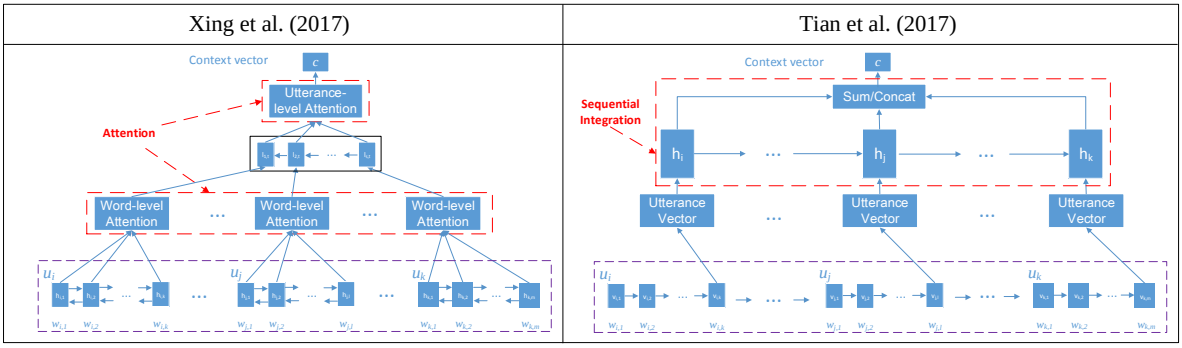

Figure 1: The encoders of two state-of-the-art approaches of open-domain conversational response generation using contextual information.

denote the i-th, i+1-th and j-th utterance, respectively, in a conversation. As the inputs of the two models, they are then represented to utterance-level vectors as shown in the second layer of the two models in Figure 1. The context vectors of the two models are obtained by hierarchically representing the utterances to a dense vector c for decoding. It is easy to recognize that the frameworks used to illustrate the encoders of two existing context-sensitive generation models look similar to each other. There are two different parts between the two frameworks:

- **Utterance Representations: Bidirectional GRU vs. Unidirectional GRU**

Xing et al. (2017) utilized a bidirectional GRU and a word-level attention mechanism to transfer word representations to utterance representations. Tian et al. (2017) represented the utterance in a simpler way, which is a unidirectional GRU.

- **Inter-utterance Representations: Attention vs. Sequential Integration**

Xing et al. (2017) proposed a hierarchical attention mechanism to feed the utterance representations to a backward RNN to obtain contextual representation. Tian et al. (2017) proposed a weighted sequential integration (WSI) approach to use an RNN model and a heuristic weighting mechanism to obtain inter-utterance representation.

2.2 The Proposed Model

The proposed context-sensitive generation model is under the framework of encoder-decoder. To obtain the contextual representations, the proposed model consists of a hierarchical representation mechanism for encoding. For utterance representation, we consider the advantages of the two state-of-the-art approaches to encoding contextual information for context-sensitive response generation (Xing et al., 2017; Tian et al., 2017). We utilize a GRU model to obtain utterance representation. For inter-utterance representation, inspired by the above approaches of modeling inter-utterance representations, we proposed two attention mechanisms, namely dynamic and static attention, to weigh the importance of each utterance in a conversation and obtain the contextual representation. Figure 2 shows the framework of the proposed context-sensitive generation model. Drawing the advantages of attention mechanism on

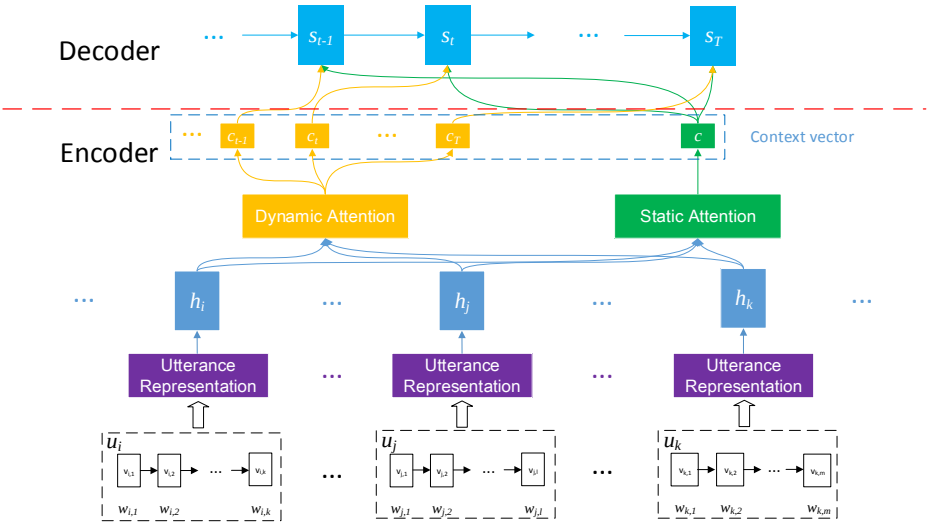

Figure 2: The proposed context-sensitive generation model for open-domain conversational response. Here, u_* denotes the $*$-th utterance in a conversation.

weighing the importance of utterances for generating open-domain conversational responses (Xing et al., 2017), we thus model the inter-utterance representation to obtain the context vector in two measures, namely static and dynamic attention, as shown in Figure 2. We then formally describe the static and dynamic attention for decoding process.

- **Static Attention based Decoding**

As shown in Figure 2, the static attention mechanism calculates the importance of each utterance as e_i or α_i ($i \in \{1, ..., s\}$).

$$e_i = V^T \tanh(Wh_i + Uh_s) \tag{1}$$

$$\alpha_i = \frac{\exp(e_i)}{\sum_i \exp(e_i)} \tag{2}$$

$$c = \sum_i \alpha_i h_i \tag{3}$$

Here, h_i and h_s denote the representations of hidden state of the i-th and the last utterance in a conversation, respectively. V, W and U are parameters. We can see that once the weights of each utterance α_i ($i \in \{1, ..., s\}$) are produced, they will be unchanged in the decoding process. In decoding, the t-th hidden state s_t can be calculated as follows:

$$s_t = f(y_{t-1}, s_{t-1}, c) \tag{4}$$

Here, y_{t-1} is the $t-1$-th output of the decoder and s_{t-1} is the hidden state of t-1-th time step in decoding. Notice that y_0 is set to be a special character and s_0 is initialized by h_s. The generated response is thus represented as a sequence of $y_1, y_2, ..., y_T$, where T denotes the last time step.

• **Dynamic Attention based Decoding**

Rather than the static attention mechanism fixes the weights of each utterance before decoding process, the dynamic attention mechanism maintains a weighting matrix and updates the weights of each utterance during decoding process as shown in Figure 2. The formal illustration of the dynamic attention mechanism for decoding is as follows:

$$e_{i,t} = V^T \tanh(W h_i + U s_{t-1}) \tag{5}$$

$$\alpha_{i,t} = \frac{\exp(e_{i,t})}{\sum_i \exp(e_i)} \tag{6}$$

$$c_t = \sum_i \alpha_{i,t} h_i \tag{7}$$

Here, V, W and U are also parameters that are independent to those in the static attention. T denotes the transposition operation of V. The $e_{i,t}$ and $\alpha_{i,t}$ are calculated in each time step t of decoding. The t-th hidden state s_t in dynamic attention-based decoder can be calculated as follows:

$$s_t = f(y_{t-1}, s_{t-1}, c_t) \tag{8}$$

The main difference between our proposed conversational response generation model and the above two state-of-the-art models is the two attention mechanisms for obtaining the contextual representation of a conversation. Rather than use a hierarchical attention neural network (Xing et al., 2017) to obtain the contextual representation of a conversation, we propose two utterance-level attentions for weighting the importance of each utterance in the context, which is more simple in structure and has less number of parameters than the hierarchical attention approach. Meanwhile, rather than use a heuristic approach to weigh the importance of each utterance in the context (Tian et al., 2017), in our proposed approach, the weights of utterance in the context are learned by two attention mechanisms from the data, which is more reasonable and flexible than the heuristic based approach.

3 Experimental Results

3.1 Experiment Settings

Dataset: Two datasets are selected for the experiment of generation of open-domain conversational responses. First is the Ubuntu dataset which is developed by Lowe et al. (2015). The dataset is extracted from the Ubuntu Internet Relayed Chat (IRC) channel and recently used for the generation of conversational responses in (Serban et al., 2016a; Serban et al., 2017b; Serban et al., 2017a). We follow the train-test split proposed by Serban et al. (2017a). It is worthy to note that there is no development set in Serban et al. (2017a). In this paper, we randomly select the same number of sessions to that in the test set from the training set. Second is the OpenSubtitles dataset which is proposed by Tiedemann (2009) and also used by Li et al. (2016a; Li et al. (2016c). The detailed statistics of the two datasets are shown in Table 2. It is worthy to note that the original released data of OpenSubtitles consists of about 40,000,000

utterances without partitions of conversational session, which is called "session" for short in the following of this paper. Therefore, we split each of 10 continuous utterances as a session. We then randomly sample 800,000 sessions for training (including 8,000 sessions for developing) and remove them from the complete dataset. In the rest of the complete dataset, we again randomly sample 8,000 sessions for testset. The vocabulary size equals to the number of unique tokens in both two datasets, respectively.

	Ubuntu	OpenSubtitles
Train size	429,915	792,000
Dev size	18,920	8,000
Test size	18,920	8,000
Vocabulary size	155,490	91,405
Avg # of u per session	7.5	10
Avg # of w per u	12.3	7.5

Table 2: The statistics of two experimental datasets. Avg is short for average. # represents number. u and w denote utterance and word respectively. The unit of training and test is a conversational session.

Hyper-Parameters: For the static attention model, the dimension of hidden layer in encoder and decoder is 512. The padding length is set to 15. The dimension of word embedding equals to 200. The word embedding is pre-trained using the skip-gram model in word2vec (Mikolov et al., 2013) and fine-tuned during the learning process. For the dynamic attention model, the dimension of hidden layer in encoder and decoder is 1024. The padding length and dimension of word embedding are same to the static attention model. Adam is used for optimization. The initial learning rate is 0.001 and the weight_decay is set to 10^{-5}. The dropout parameter equals to 0.5. Mini-batch is used and the batch size equals to 80. The number of iterations in training is 10.
Baselines: For the experimental comparisons, six baselines are chosen. Four out of them are state-of-the-art approaches. They are VHRED, CVAE, WSI, and HRAN.

- **LSTM:** Under the sequence-to-sequence framework for generation of conversational responses, the most simple but natural idea is to directly use the LSTM to encode all the utterances in a session word by word and then decode to generate a response.

- **HRED:** The first hierarchical recurrent encoder-decoder model, which is proposed by Serban et al. (2016a), for conversational response generation.

- **VHRED:** The augmented HRED model, which incorporates a stochastic latent variable at utterance level for encoding and decoding, is proposed by Serban et al. (2017b).

- **CVAE:** The conditional variational autoencoder based approach, which is proposed by Zhao et al. (2017), to learn context diversity for conversational responses generation.

- **WSI** and **HRAN** are proposed by Tian et al. (2017) and Xing et al. (2017) respectively. We detailed describe and compare the two models in Section 2.1 and 2.2 and their frameworks are shown in Figure 1.

3.2 Evaluation and Results

3.2.1 Automatic Evaluation

Until now, automatically evaluating the quality of open-domain conversational response is still an open problem. The BLEU score (Papineni et al., 2002), which is a widely used evaluation metric for machine translation, is not a suitable metric for conversation generation, as the appropriate responses to the same message may share less common words. Moreover, it is also impossible to construct a reference set, which includes all appropriate responses, of each message. The perplexity that is used to evaluate language model, is also not suitable to evaluate the relevance between messages and responses (Shang

Models	Ubuntu			OpenSubtitles

Static$_{\rightleftarrows}$	0.5998	0.4124	0.3886	0.5475	0.5147	0.3862
Static$_{\rightarrow}$	**0.6121**†	**0.4293**†	**0.3975**†	**0.5656**†	**0.5232**†	**0.3937**†

Table 3: The results of automatic evaluation on Ubuntu and OpenSubtitles datasets. Dynamic and Static are our proposed approaches whose framework is shown in Figure 2. The other models are baselines. $\rightarrow$ and $\rightleftarrows$ denote the use of unidirectional and bidirectional GRU in the proposed model to obtain utterance representations, respectively. † denotes the results pass the statistical significance test with $p < 0.05$.

et al., 2015; Li et al., 2016c). In this paper, we employ an evaluation metric that is proposed by Serban et al. (2016a) and also used in (Serban et al., 2017b). Rather than calculating the token-level or n-gram similarity as the perplexity and BLEU (Papineni et al., 2002), the metric measure the semantic similarity between a generated responses $\hat{r}$ and the ground-truth responses r by matching their semantic representations. The metric also has three aspects, namely $\mathbf{Average}$, $\mathbf{Greedy}$ and $\mathbf{Extrema}$. For the $\mathbf{Average}$, it first calculates the element-wise arithmetic average of embeddings of all words in $\hat{r}_a$ and r_a, respectively and produces two response representations $v_{\hat{r}_a}$ and v_{r_a}. The value of $\mathbf{Average}$ is then equals to the cosine similarity of $v_{\hat{r}_a}$ and v_{r_a}. For the $\mathbf{Greedy}$, every word in $\hat{r}$ will find a most similar word in r by calculating the cosine similarity of their word embeddings. After that, the element-wise arithmetic average of embeddings of all words in $\hat{r}_a$ and the corresponding words in r are calculated and two response representations $v_{\hat{r}_g}$ and v_{r_g} are produced. The value of $\mathbf{Greedy}$ is then equals to the cosine similarity of $v_{\hat{r}_g}$ and v_{r_g}. For the $\mathbf{Extrema}$, two embedding matrices $m_{\hat{r}}$ and m_r can be obtained by arranging the embeddings of all words in $\hat{r}_a$ and r_a, respectively. The i-th column of $m_{\hat{r}}$ is the embedding of the i-th word in $\hat{r}$ as well as that in m_r. Getting the maximum value of each row in $m_{\hat{r}}$ and m_r, respectively, we then obtain two response representations $v_{\hat{r}_e}$ and v_{r_e}. The value of $\mathbf{Extrema}$ is then equals to the cosine similarity of $v_{\hat{r}_e}$ and v_{r_e}.

Table 3 shows the experimental results on two datasets.

We can see that our proposed context-sensitive generation model with static attention outperforms all the baselines in the two datasets. It verifies the effectiveness of the proposed utterance-level attention mechanism on modeling context representations for generating conversational responses. To compare the dynamic and static attentions, we find that for the generation of conversational response, dynamically estimate the importance of each utterance in context performs worse than the static attention approach. The reason may be that the context vector in dynamic attention model is changed in every time step of decoding. The change of context vector may lead to decoding incoherent responses. Meanwhile, the unidirectional GRU based models outperform the bidirectional GRU based models. It doesn't illustrate the unidirectional GRU is better than the bidirectional GRU in utterance representation. It only indicates that in the current experimental settings, the unidirectional GRU based model outperforms the bidirectional one.

3.2.2 Human Evaluation

For human evaluation, we proposed 2 metrics, namely **Coherence** and **Naturalness**. As the example shown in Table 1, in context-sensitive generation of conversational responses, a generated response should not only dependent on the last one message but also need to consider the longer context in the

Models	Ubuntu			OpenSubtitles		
	Coherence	**Naturalness**	**Diversity**	**Coherence**	**Naturalness**	**Diversity**
LSTM	0.930	0.477	0.069	0.963	0.443	0.099
HRED	0.967	0.490	0.141	0.963	0.443	0.098
VHRED	1.010	0.507	0.140	0.986	0.473	0.093
CVAE	0.987	**0.513**	0.140	1.000	0.477	**0.114**
WSI	1.010	0.507	0.141	1.013	0.490	0.110
HRAN	1.027	0.510	0.147	**1.033**	0.477	0.109
Dynamic	0.987	0.507	**0.158**	1.013	0.477	0.109
Static	**1.070**	**0.513**	0.150	1.027	**0.497**	0.110

Table 4: The results of human evaluation on Ubuntu and OpenSubtitles datasets.

conversation. **Coherence** is thus used to evaluate the semantic consistency between a generated response and its context. The Coherence score is in the range of 0 to 2, where 0, 1, 2 denote *incoherent*, *neutral* and *coherent*, respectively. In some cases, a coherent response may not be a natural one. Given an example message, "*Can you tell me the way to the nearest bazaar?*", the response "*Yes, I can tell you the way to the nearest bazaar.*" is definitely a coherent but not a natural response. A more extreme example of a message-response pair is "*I don't know what you are talking about!*" and "*I don't know what you are talking about!*". Therefore, besides the Coherence, we proposed another metric, Naturalness, to evaluate the quality of generated responses. For human evaluation, given a context and a conversational response generated by a model, **Naturalness** denotes whether the response can be an alternative to a human response. The Naturalness value equals to 1 or 0, which represents the generated response can be an alternative to a human response or not, respectively. Besides the Coherence and Naturalness, we also want to compare the **Diversity** of the responses generated by all baselines and our proposed approach. Here, diversity score of a generated response equals to the number of distinct tokens in the response divided by the total number of distinct tokens in its context (including the number of distinct tokens in the response). The final Diversity score is the average diversity of all the generated responses in test set.

In the human evaluation, for each model, we randomly sample 500 test results from Ubuntu and OpenSubtitles datasets, respectively. Each of the three annotators, who are undergraduate students and not involved in other parts of the experiment, is asked to provide the evaluation scores for all the 8,000 test results. The final score of each model equals to the average score of the three annotators. Table 4 shows the human evaluation results on the two datasets. Generally speaking, we can see that the proposed static attention-based model outperforms the baselines in Coherence and Naturalness on Ubuntu dataset and obtains comparable performance with the HRAN model in Coherence on OpenSubtitles dataset. For the Diversity, we can see that the proposed dynamic attention-based model is better at generating diverse responses than other models on Ubuntu dataset. We also notice that the CVAE model obtains the best diversity performance on OpenSubtitles dataset and the best Naturalness performance on Ubuntu dataset.

3.2.3 Analysis of Context Length

To verify the impact of context length on the performance of the proposed model for the generation of conversational responses, we use different length of context to re-train the proposed models, which are called context varied models, on two datasets. Here, context length indicates the number of historical utterances that are used for encoding in a context. Figure 3 shows that the performance of the proposed static and dynamic attention models are varying with the change of context length. The values denote the difference between the results of Static$_{\rightarrow}$ and Dynamic$_{\rightarrow}$ in Table 3 and the results of the context varied models. It also verifies that the generation of conversational responses is a context-sensitive process, which relates to the numbers of utterance in context for encoding. Table 5 shows the conversational responses, which are sampled from the test result generated by the proposed static attention model. We can see that the attention values predicted by the static attention model can appropriately reveal the importance of the utterance in a context for generating conversational responses.

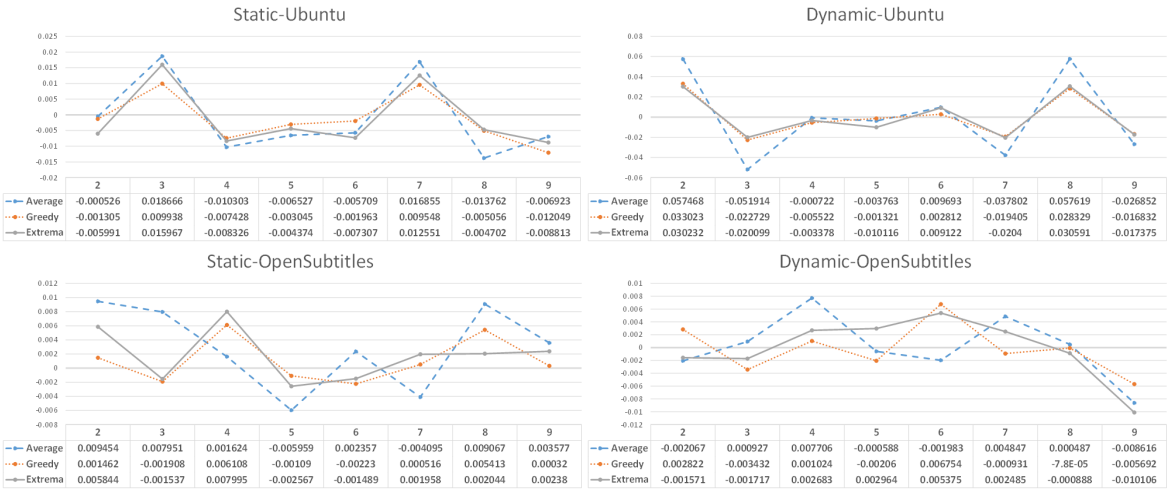

Figure 3: The impact of different number of utterances, used for encoding, in a context (context length) on the performance of the proposed static and dynamic attention based models on two experimental datasets. The range of context length is from 2 to 9.

Sample 1		α
Context	Bonhoeffer, what drives do you want to mount?	0.4872
	What?	0.1535
	I have an ext3 usb drive.	0.3593
Response	I have a usb drive, I want to use it for testing.	

Sample 2		α
Context	Are you using a 32bit version of firefox? why?	0.2284
	Need to use webex, doesn't support 64bit java.	0.4660
	Using 64bit firefox.	0.3056
Response	I have a 64-bit machine, and I want to use 64 bit.	

Table 5: Samples of the generated responses from the Ubuntu test result. α indicates the attention value of each utterance in context calculated by the proposed static attention mechanism.

4 Related Work

Ritter et al. (2010) proposed an unsupervised approach to model dialogue response by clustering the raw utterances. They then presented an end-to-end dialogue response generator by using a phrase-based statistical machine translation model (Ritter et al., 2011). Banchs and Li (2012) introduced a search-based system, named IRIS, to generate dialogues using vector space model and then released the experimental corpus for research and development (Banchs, 2012). Recently, benefit from the advantages of the **sequence-to-sequence learning** framework with neural networks, Sutskever et al. (2014) and Shang et al. (2015) had drawn inspiration from the neural machine translation (Bahdanau et al., 2014) and proposed an RNN encoder-decoder based approach to generate dialogue by considering the last one sentence and a larger range of context respectively. Serban et al. (2016b) proposed a parallel stochastic generation framework which first generates a coarse sequence and then generates an utterance conditioned on the coarse sequence. Shao et al. (2017) introduced the "glimpse-model" which adds self-attention to the decoder to maintain coherence for generating long, informative, coherent and diverse responses in single turn setting. Yao et al. (2017) first predicted cue words using point-wise mutual information (PMI) for short text conversation generation and then added them into the encoder-decoder framework. To consider the **context information** for improving the diversity of generated conversations, Serban et

al. (2016a) presented a hierarchical recurrent encoder-decoder (HRED) approach to encode each utterance and recurrently model the dialogue context to generate context-dependent responses. Serban et al. (2017b) further introduced a stochastic latent variable at each dialogue turn to improve the ambiguity and uncertainty of the HRED model for dialogue generation. Xing et al. (2017) proposed a hierarchical recurrent attention network (HRAN) to jointly model the importance of tokens in utterances and the utterances in context for context-aware response generation. Tian et al. (2017) presented a context-aware hierarchical model to generate conversations by jointly modeling the utterance and inter-utterance information for encoding process. As the advantages of **generative adversarial net (GAN)** and **variational autoencoder (VAE)**, Yu et al. (2017) proposed a sequence generative adversarial net model to assess a partially generated sequence with policy gradient and obtain the intermediate rewards by using Monte Carlo search. Zhao et al. (2017) modified the VAE model by conditioning the response into the VAE model in training step to optimize the similarity of prior network and recognition network for dialogue generation. Similarly, Shen et al. (2017) presented a conditional variational framework to generate specific responses based on the dialog context. Due to the recent advantages of **reinforcement learning** on modeling human-computer interactions, such as the AlphaGo (Silver et al., 2016), researchers begin to focus on modeling the success of a conversation by not only considering the quality of single turn response generation, but also considering long-term goal of the conversation. To address the problems of generating generic and repetitive response of the RNN encoder-decoder framework, Li et al. (2016c) proposed a deep reinforcement learning approach to either generate meaningful and diverse response or increase the length of the generated dialogues. Dhingra et al. (2017) presented an end-to-end dialogue system for information accquisition, which is called KB-InfoBot from knowledge base (KB) by using reinforcement learning. Asghar et al. (2017) proposed an active learning approach to learn user explicit feedback online and combine the offline supervised learning for response generation of conversational agents.

5 Conclusion and Future Work

This paper proposed a novel context-sensitive generation approach for open-domain conversational responses. The proposed model gained from the proposed static and dynamic attention for context or inter-utterance representation. Experimental results show that the proposed model generally outperforms all the baselines in automatic and human evaluations. It is also verified the impact of context length on the performance of the proposed generation models for conversational responses. In future work, the way to uniformly integrate the static and dynamic attention for decoding will be explored.

A LSTM Approach with Sub-word Embeddings for Mongolian Phrase Break Prediction

Abstract

In this paper, we first utilize the word embedding that focuses on sub-word units to the Mongolian Phrase Break (PB) prediction task by using Long Short-Term Memory (LSTM) model. Mongolian is an agglutinative language. Each root can be followed by several suffixes to form probably millions of words, but the existing Mongolian corpus is not enough to build a robust entire word embedding, thus it suffers a serious data sparse problem and brings a great difficulty for Mongolian PB prediction. To solve this problem, we look at sub-word units in Mongolian word, and encode their information to a meaningful representation, then fed it to LSTM to decode the best corresponding PB label. Experimental results show that the proposed model significantly outperforms traditional CRF model using manually features and obtains 7.49% F-Measure gain.

1 Introduction

A Text-to-Speech (TTS) system converts the input text into synthetic speech with high naturalness and intelligibility. Naturalness is mainly influenced by the prosody modeling, especially by the Phrase Break (PB) prediction. Because the PB prediction is the first step of TTS, any error in this step will propagate to downstream steps such as intonation prediction and duration modeling. Those errors will result in the synthetic speech which is unnatural and difficult to understand. So that many researchers devote themselves to improving the performance of the PB prediction.

Typically PB prediction methods usually use machine learning models like Hidden Markov Models (HMMs) or Conditional Random Fields (CRFs) which trained with large sets of labeled training data. In these PB prediction models, the Part-of-Speech (POS) tag have been shown to be an effective feature and usually been included in the input feature set. The POS estimation itself is also a challenging task, and relies on large labeled training corpus, too. Its accuracy is always lower than our expectation, especially for those low-resource languages like Mongolian where the required linguistic resources are not readily available, and manual annotation is expensive and time-consuming.

In recent years, there are many works applying the word embedding techniques to Natural Language Processing (NLP) tasks, such as question answering, machine translation and so on (Bordes, 2014; Xiong, 2017; Devlin, 2014). Previous work has shown that the POS prediction task can be solved with high accuracy only using the word embedding feature as the input (Wang, 2015). POS information is most likely to be included in the word embedding representations. Therefore, some PB prediction systems which don't rely on the POS feature are developed (Watts, 2011; Vadapalli, 2014; Vadapalli, 2016). In (Watts, 2011), the authors obtain continuous-valued word embedding features that summarize the distributional characteristics of word types as surrogates of POS features. In (Vadapalli, 2014), researchers propose a neural network dictionary learning architecture to induce task-specified word embedding representations and show that these features perform better at PB prediction task. (Vadapalli, 2016) presents their investigations of recurrent neural networks (RNNs) for the phrase break prediction task by using word embedding. The above efforts have also been directed toward unsupervised methods of inducing word representations, which can be used as surrogates for POS tags, in the PB prediction task.

Santa Fe, New Mexico, USA, August 20-26, 2018.

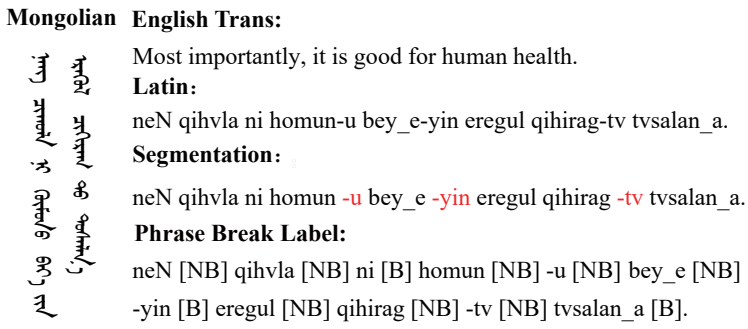

Figure 1: NNBS suffixes within a Mongolian sentences, the red part is the segmented NNBS suffixes from the word. There are three pauses in the sentence, one of which is located at the NNBS suffix: "-yin".

Although the word embedding training operates in an unsupervised way, this approach face an issue when applied to Mongolian languages, which are agglutinative in nature and the available Mongolian corpus is not large enough for the huge Mongolian vocabulary. Fortunately, Mongolian is a morphologically rich language. Its suffixes often act as a positive signal which implies the POS information of the word. It's like that the word implied by the suffix '-ly' is an adverb in English. Morphologically, unlike many other languages, a Mongolian word is not just a concatenation of characters. It is constructed by the special agglutinative property. Mongolian words can be decomposed into a set of morphemes: one root and several suffixes.

In this paper, we investigate Mongolian PB prediction models that operate on the level of sub-word units: stem and suffixes (the part without suffix). We hypothesize that stem and suffix serve to discriminate words based on syntactic meaning, and that these sub-word units can be used to model PB. We automatically segment every Mongolian word to a sequence of sub-word units, then map all sub-word units into a continuous vector representations by lookup table, which are then fed into a neural network. Instead of a feed-forward network, we use the Long Short-Term Memory (LSTM) network to predict the right PB label. The segmentation process reduces the vocabulary and alleviates the data sparse problem. Therefore, the learned word embedding for sub-word is more robust, then the performance of the PB prediction system can be improved.

Our experiments show the proposed model can achieve significant performance than the conventional CRF-based models, and the sub-word embedding based method outperforms the entire word embedding based method.

2 Mongolian characteristics

As an agglutinative language, like Turkish, Japanese and Korean, Mongolian has complex morphological structure. Most Mongolian words can be decomposed into root, derivational suffixes, and inflectional suffixes (Bao, 2013). The first two parts together are called a word-stem, it holds the major information in a word, and inflectional suffixes server to discriminate words based on lexical meaning. As for nouns, the inflectional suffixes contain case suffixes, reflexive suffixes, and plural suffixes. All above three suffixes are attached to stem through a Narrow Non-Break Space (NNBS) (U+202F, Latin: "-"). We call them NNBS suffixes. The NNBS suffixes used are very pervasive, in Fig.1, there are 3 NNBS suffixes in a sentence with only 8 words.

New words can be formed by connecting different suffixes to the end of a stem. A lot of new words can be induced from a single stem. For example:  ,  ,  ,  ,  . These words share the same word-stem "" (Latin: "sandali", means: "chair"). It makes Mongolian has a huge vocabulary, about one million, with only about 30 thousands stems (Bao, 2013). The large vocabulary leads to data sparse, and a serious dependence on a large corpus. However, the available Mongolian corpus is not enough for the word embedding training. The bad word embedding further reduces the accuracy of the PB prediction system. To get through the problem, we segment the NNBS suffixes from the Mongolian

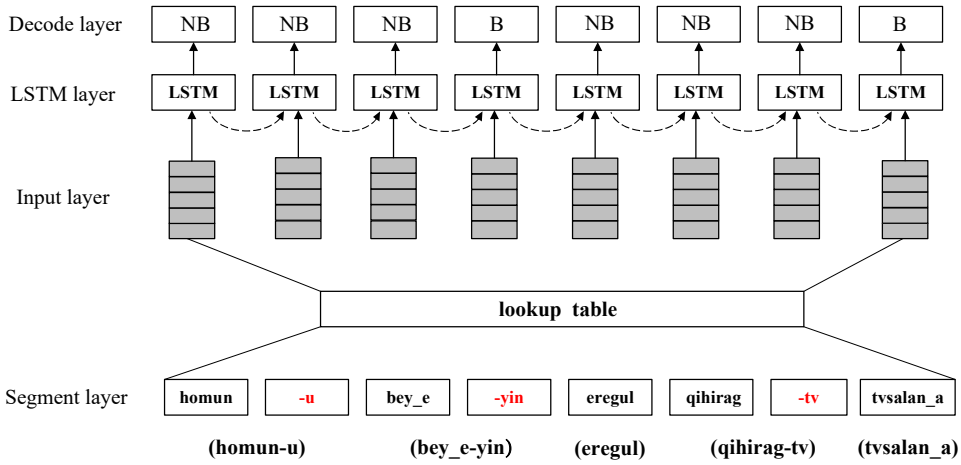

Figure 2: A framework for the proposed Mongolian PB prediction system based on sub-word embedding. The segment layer convert the Latin-cased Mongolian word to its sub-word form: stem (black part) and suffixes (red part); the sub-word embeddings are generated by a lookup table; the information is passed through a LSTM layer and the decode layer.

word and learn embedding representation on these individual suffixes and stems. After segmentating, the sentence will include more tokens, for example, in Fig.1, 3 words with NNBS will be turned into new units: "*homun-u*" turned into "*homun*" and "*-u*", "*bey_e-yin*" turned into "*bey_e*" and "*-yin*", "*qihirag-tv*" turned into "*qihirag*" and "*-tv*".

3 Proposed model

Our system framework is shown in Fig.2. This architecture consists of a segment layer, an input layer, a LSTM layer and a decode layer.

The system input is raw Mongolian sentence consisting of entire word. First, the segment layer converts every Mongolian word into stem and NNBS suffixes according to the location of NNBS inside of the word. Second, the input layer maps these processed Mongolian sub-word units into sub-word embeddings. The remaining layers are a LSTM network (Greff, 2017) used as a discriminative classifier and a decode layer to obtain the final PB label: "B" or "NB". "B" and "NB" are PB labels means *break after a word* and *non-break* respectively.

3.1 Sub-word embedding

In current work, we hypothesize that stem and suffix serve to discriminate words based on semantic meaning in Mongolian, and that these sub-word units can be used to model PB. We learn the embedding representation for sub-word units inspired the word embedding technique.

Word embedding represents words as continuous vectors in a low-dimensional space based on the distributional hypothesis that words in similar contexts have an analogous meaning. Based on this hypothesis, various word embedding models have been developed, including continuous bag-of-words model (CBOW), Skip-Gram model (Mikolov, 2013), and Global C&W(Glove) (Pennington, 2014). We use Skip-Gram model to train the sub-word embedding representation. Given a sequence of training unit $u_1, ..., u_T$, the Skip-Gram model try to maximize the average of log probability:

$$\frac{1}{T}\sum_{t=1}^{T}\sum_{-c\leq j\leq c}\log P\left(u_{t+c}|u_t\right) \tag{1}$$

where c is the training context around the center unit u_t. The prediction probability can be defined as:

$$P(o|i) = \frac{\exp(V_o^{\mathrm{T}}W_i)}{\sum_{u=1}^{U}\exp(V_u^{\mathrm{T}}W_i)} \tag{2}$$

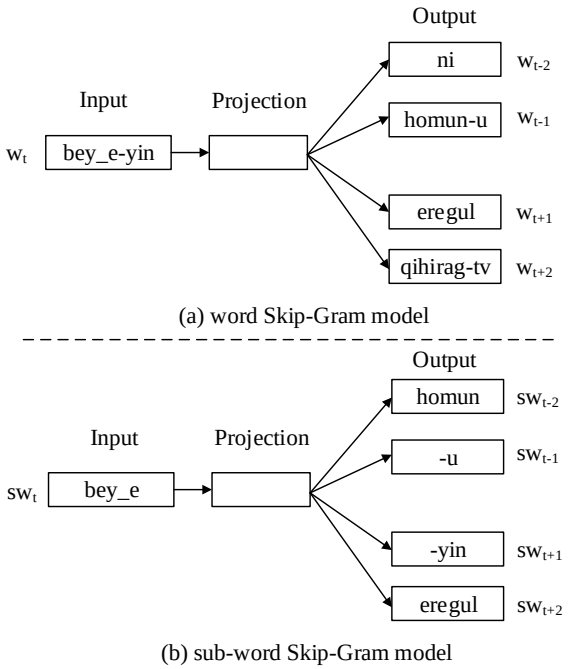

Figure 3: Comparision of the Mongolian Skip-Gram model representation of word unit (a) and sub-word unit (b). The sub-word Skip-Gram model regard stem and suffix as a basic unit, it allows the model to learn more information from suffixes with same context windows.

where W and V are the "input" and "output" unit vector representations of u, and U is the set of sub-word units. X^{T} is the transpose of matrix X.

The difference between word and sub-word Skip-Gram model is shown in in Fig.3 for the sentence: " *homun-u bey_e-yin eregul qihirag-tv tvsalan_a*". In the word Skip-Gram model, if the center word is "*bey_e-yin*", the nearby words are "*ni*", "*homun-u*", "*eregul*" and "*qihirag-tv*". While in sub-word Skip-Gram model, when the basic learning unit is changed to sub-word, the center word is turned to "*bey_e*", the nearby words to "*homun*", "*-u*", "*-yin*" and "*eregul*". The sub-word Skip-Gram model lies in dealing with sub-word units (stem and suffixes). It captures more information from the nearby suffixes under same context window size.

3.2 LSTM layer & Decode layer

PB prediction can be treated as a sequential labeling task that assigns boundary labels to words of an input sentence. Recurrent neural networks (RNNs) have recently produced outstanding performances on many tasks including sequential labelling (Vadapalli, 2016). In theory, RNN can learn from the entire historical inputs. But in practice, it can access only a limited range of context because of the vanishing gradient problem. LSTM uses purpose-built memory cells to store information, which is designed to overcome this problem. LSTM is composed of a set of recurrently connected memory blocks and each block consists of one or more self-connected memory cells and three multiplicative gates, i.e., input gate, forget gate and output gate. The three gates are designed to capture long-range contextual information by using nonlinear summation units.

Specifically, in this study, we follow the LSTM with forget gates and peephole connections to predict Mongolian phrase break. We use the following implementation:

$$i_t = \sigma(W_{xi}x_t) + W_{hi}h_{t-1} + W_{ci}c_{t-1} + b_i) \tag{3}$$

$$c_t = (1 - i_t) \odot c_{t-1} + i_t \odot \tanh(W_{xc}x_t + W_{hc}h_{t-1} + b_c) \tag{4}$$

$$o_t = \sigma(W_{xo}x_t + W_{ho}h_{t-1} + W_{co}c_t + b_o) \tag{5}$$

$$h_t = o_t \odot \tanh(c_t) \tag{6}$$

where $\odot$ indicates element-wise product and σ indicates element-wise sigmoid function. More detail description can be found in (Greff, 2017).

The LSTM is trained using standard backpropagation through time to maximize the data conditional likelihood:

$$\prod_t P(y_t|x_1 \cdots x_t) \tag{7}$$

where x_t, y_t are the input and output respectively at time t. As mentioned in Section 3.1, the input x_t to the LSTM at time t, is the sub-word embedding corresponding to the token at time t.

The probability distribution is strictly a function of the hidden layer activations, which in turn depend only on the inputs (and their own past values). Thus, the most likely sequence of phrase break labels can be computed as:

$$y_t^* = \arg\max P(y_t|x_1 \cdots x_t) \tag{8}$$

4 EXPERIMENTS AND RESULTS

4.1 Dataset

4.1.1 Embedding corpus

The embedding train data were crawled from mainstream websites in Mongolian. After cleaning web page tags and filtering longer sentences, its token size and vocabulary are about 200 million and 3 million respectively. After we split the suffixes into a new token, we find a dramatic decrease on vocabulary even with the token number growth. The segmented corpus' token size and vocabulary are about 300 million and 2.5 million respectively.

4.1.2 PB prediction corpus

To evaluate the proposed method, a Mongolian speech synthesis corpus is involved. This corpus is recorded by a native Mongolian female speaker, who is a television news announcer. This corpus contains 58,695 utterances, where there are about 449,000 Mongolian words and 22,050 vocabularies. This corpus is labeled with prosodic phrase boundary by hand according to its speech. The labels correspond to the actual stops in the utterance. Specifically, each word is labeled as "B" (means *break*) if there is a short break after the word. Otherwise, the word is labeled as "NB" (means *non-break*). We divide the corpus into suitable subsets for training, validation and test as 8:1:1.

4.2 Evaluation

We conduct three sessions of experimentation. The first session is designed to verify the effectiveness of sub-word method under the CRF model, which aims to investigate the performance of regard the stem and suffixes as individual tokens. The second session about CRF-based systems is built to evaluate the idea of replacing the POS with the embedding representation for word and sub-word. The third session aims to investigate whether utilizing the LSTM model with sub-word embedding can improve the performance of Mongolian PB prediction. All Mongolian words are Latin-cased before passing through the lookup table to convert to their corresponding embeddings.

We evaluate the systems with F-Measure of the PB prediction, which this the harmonic mean of the *Precision* and the *Recall*. F-Measure values range from 0 to 1. The higher F-Measure means better PB prediction performance.

4.2.1 CRF with subword

We use CRF++ toolkit[1] to build a CRF-based Mongolian phrase break prediction system as a baseline named "CPw". "CPw" system consider the nearby words and its POS feature within the fixed context window size. Another two CRF-based systems are built to analyze the effects of the sub-word named "CPs" and "CPB", which have the same configuration as the CRF baseline, except the word feature. The 'CPs' system removes the segmented suffixes from the input token. The 'CPB' system segments the

[1] *https://taku910.github.io/crfpp/*

word into stem and suffixes, and uses them both as individual input tokens. All the CRF models used in this paper is a linear-chain CRF, we carry on all experiments under two context windows type: Unigram (U: previous one word, current word and future one word) and Bigram (B: previous two words, current words and future two words).

As illustrated in Table 1. Compared with the 'CPw' baseline under all context windows type, we can see the performance of the 'CPs' drop down. It is because that the word stems have less discriminative information than the entire word, since its suffixes are removed. 'CPB' outperforms the baseline and achieves the peak performance (82.96%) under Bigram context window. It can learn all semantic information from the individual suffix and stem but also alleviate the data sparse problem in a limited corpus.

Model	**F-Measure (U)**	**F-Measure(B)**
CPw	82.23	82.40
CPs	82.12	82.34
CPB	82.52	**82.96**

Table 1: Performance of F-Measure for CRF-based model with different context window types. (U: Unigram, B: Bigram)

4.2.2 CRF with sub-word embedding

In these systems, the POS feature is replaced by the embedding, i.e. the systems input is the word or sub-word unit and its corresponding embedding. And follow the experimental setting of the Section 4.2.1, we index the three system as 'CEw', 'CEs' and 'CEB' respectively, which denotes CRF model using embedding feature on the entire word, word stem or both the suffix and stem. We test the performance of all systems with five embeddings dimension: 50, 100, 150, 200, 300. The evaluation results are listed in Table 2.

Comparing these three systems, we get the same conclusion as the previous experiment, sub-word based methods performance is better than the entire word setting. For Bigram context, 'CEB' achieves the highest F-Measure (83.79%) in all embedding dimensions. The performance of all systems is first

raised and then decreased with the embedding dimension range from 50 to 300, and reaches the best in 150. While a too long dimension will include other boring information that decoder cannot utilize, a too small dimension can not learn enough information from context. More informative, the performance of the Unigram context is worse than that of the Bigram context but shows the same trend.

The systems using sub-word embedding feature performs better than the systems utilizing POS feature (Section 4.2.1). As can be seen, the performances of 'CEw', 'CEs', 'CEB' are obviously higher than that of 'CPw', 'CPs', 'CPB'. This is mainly caused by the representation power of the word embedding technique. By using the sub-word embedding, we make a better use of the very limited training data in Mongolian. And again the proposed sub-word method alleviate the data sparse problem for both the word embedding training and the PB prediction models training.

4.2.3 LSTM with sub-word embedding

In this experiment, we replace the CRF model with the powerful LSTM model. All of the LSTM models used a single hidden layer of 512 units. All models are trained with a momentum of 0.3, an initial learning rate of 0.01. We select *tanh()* as our activation function, the minibatch size and forget gate bias is 1, weight and inner cells initialization are glorot uniform (Glorot, 2010) and orthogonal (Saxe, 2013) respectively. We train the LSTM model 50 epochs according to the development set. The evaluation results are listed in Table 3 under the name of 'LEw', 'LEs' and 'LEB', which means LSTM model using word embedding feature on the entire word (Vadapalli, 2016), sub-word embedding feature on word stem or both the suffix and stem.

Compared with CRF-based systems (Section 4.2.2) the LSTM-based systems show a clear advantage. 'LEw', 'LEs', 'LEB' systems respectively increased the performance by 2.91%, 2.18%, and 6.1% compared with 'CEw', 'CEs', 'CEB' under the optimum embedding dimension – 150. Our proposed method ('LEB') obtains 7.49% F-Measure gain compared with the baseline system - 'CPw' (Section 4.2.1) under 150 embedding dimensions. It is another evidence of the power of the LSTM model. LSTM model is more suitable than the CRF model in the PB prediction task. It shows that the LSTM model can fully absorb the nutrients of the embedding representation and get more benefits from the sub-word embedding.

5 CONCLUSIONS

In this paper, we look at sub-word units and explore the use of sub-word embedding on stem and suffixes to model Mongolian phrase break by using LSTM network. Embedding representation for the sub-word unit is learned in an unsupervised manner from an untagged Mongolian text corpus. These sub-word units can be directly identified from the text with a simple and effective approach. It provides more information for model Mongolian PB and eliminates the need for additional manually features like part-of-speech (POS) taggers. Experimental results demonstrate by means of the objective measure that LSTM model built using these sub-word embeddings perform significantly improvement than conventional CRF model built using POS sequence information. This work can also inspire other agglutinative language research.

Abstract

This paper describes CzEngClass, a bilingual lexical resource being built to investigate verbal synonymy in bilingual context and to relate semantic roles common to one synonym class to verb arguments (verb valency). In addition, the resource is linked to existing resources with the same or a similar aim: English and Czech WordNet, FrameNet, PropBank, VerbNet (SemLink), and valency lexicons for Czech and English (PDT-Vallex, Vallex and EngVallex). There are several goals of this work and resource: (a) to provide gold standard data for automatic experiments in the future (such as automatic discovery of synonym classes, word sense disambiguation, assignment of classes to occurrences of verbs in text, coreferential linking of verb and event arguments in text, etc.), (b) to build a core (bilingual) lexicon linked to existing resources, serving for comparative studies and possibly for training automatic tools, and (c) to enrich the annotation of a parallel treebank, the Prague Czech English Dependency Treebank, which so far contained valency annotation but has not linked synonymous senses of verbs together. The method used for extracting the synonym classes is a semi-automatic process with a substantial amount of manual work during filtering, role assignment to classes and individual class members' arguments, and linking to the external lexical resources. We present the first version with 200 classes (about 1800 verbs) and evaluate interannotator agreement using several metrics.

1 Introduction

Lexical resources, despite the fast progress in building end-to-end systems based on deep learning and artificial neural networks, are an important piece of the puzzle in Computational Linguistics and Natural Language Processing (NLP). They provide information that humans need to understand relations between words as well as the usage of these words in text. In addition, they can help various NLP tasks. This is why lexicons like WordNet (Miller, 1995; Fellbaum, 1998; Pala et al., 2011), FrameNet (Baker et al., 1998; Fillmore et al., 2003), VerbNet (Schuler, 2006), PropBank (Palmer et al., 2005) or EngVallex (Cinková, 2006; Cinková et al., 2014) have been created. They are for English, but there are also similar resources for other languages, often in a multilingual setting: WordNet is available in many languages (Vossen, 2004; Fellbaum and Vossen, 2012), Predicate Matrix (Lopez de Lacalle et al., 2016) extend coverage of several verbal resources and adds more romance languages, FrameNet has been extended to multiple languages (Boas, 2009), or there is the bilingual valency lexicon CzEngVallex for the case of Czech and English (Urešová et al., 2016).

One might thus question why it is necessary to develop another resource, and not just to connect some additional information to one or more of existing resources. After a thorough review (cf. also Sect. 2), it appears that for verbal synonymy, none of those resources fully corresponds to our goal of providing a lexicon of verbal synonyms based on at least semi-defined/semi-formal criteria, supported by real (parallel) texts usage. In addition, most of those resources have been first created for English and as some of the above publications acknowledge, there are then challenges to extend these resources to other languages (Fellbaum and Vossen, 2012).

Proceedings of the 27th International Conference on Computational Linguistics, pages 2456–2469
Santa Fe, New Mexico, USA, August 20-26, 2018.

In this paper, we describe CzEngClass, a lexical resource containing verbs in synonym groups ("classes") that is based on certain criteria that help to determine membership in such classes. These criteria use information from valency lexicons and semantic frames, and rely on actual examples of use in a bilingual context. The lexicon is thus built "bottom up", with emphasis on corpus evidence. In the resulting lexicon, links to existing lexical resources are added.Through these links, all entries also refer to examples from real bilingual texts with rich annotation, providing additional syntactic and morphological information for all CzEngClass entries.

The paper is structured as follows. In Sect. 2, related literature is discussed in more detail, while the resources actually used or referred to are described in Sect. 4. The criteria used for determining synonym class membership, specifically in bilingual context, are specified in Sect. 3. The resulting lexicon structure is presented in Sect. 5. Sect. 6 contains a description of the annotation process, while the interannotator agreement reached so far is analyzed in Sect. 7. We summarize some open questions and outline future work in Sect. 9.

2 Related work

Due to the needs of various NLP tasks, attention is paid to building interlinked resource(s) which integrates semantic information by mapping semantic knowledge from the individual lexical resources. One of the goals is to establish semantic interoperability between various semantic databases. As examples, we can name the SemLink (Palmer, 2009; Bonial et al., 2013) which provides manual mappings of four lexical resources (PropBank, VerbNet, FrameNet and WordNet), while the Predicate Matrix (Lopez de Lacalle et al., 2016) integrates and extends semantic information included in SemLink via automatic methods. BabelNet (Navigli and Ponzetto, 2012) integrates the largest multilingual Web encyclopedia(s), but mostly concetrates on "facts". Besides a whole range of monolingual synonym lexicons such as Roget's thesaurus (PSI and Associates, 1988) or WordNet (Miller, 1995; Fellbaum, 1998) for English, there are also cross-lingual synonym resources such as EuroWordNet, linking WordNet synsets across languages (Fellbaum and Vossen, 2012). WordNet contains a rich network or relations between its synsets (hyperonymy, hyponymy, ...), however, it does not contain information about syntactic and compositional semantic behavior, which is a drawback especially in case of verbs.

Our approach to verbal synonymy builds on previous research which also considered multilingual data (translations) in parallel corpora as an important resource. Translational context is regarded as a rich source of semantic information (de Jong and Appelo, 1987; Dyvik, 1998; Adamska-Sałaciak, 2013; Andrade et al., 2013). Parallel corpora have also been used (Resnik, 1997; Ide, 1999; Ide et al., 2002) for automatic methods for sense induction and disambiguation, for cross-lingual similarity detection and synonym extraction (Wu et al., 2010; Wu and Palmer, 2011). (Wang and Wu, 2012) studies various assumptions about synonyms in translation, for the purpose of trend detection from titles. While these works aim at automatic methods and applications, they share the idea that if two words are semantically similar in a language, their translations in another language would be also similar. Translations of a word from another language are often synonyms of one another (Lin et al., 2003; Wu and Zhou, 2003). A similar idea, i.e., that words sharing translational context are semantically related, can be found in (Plas and Tiedemann, 2006).

Interannotator agreement evaluation is regularly used in corpus annotation. However, it is much more scarcely used in lexicon entry creation and annotation, especially in a multilingual setting. For assignment of topics to words in Hindi and English, see (Kanojia et al., 2016). More detailed account on the influence of semantic lexical granularity within the Context Pattern Analysis paradigm on interannotator agreement can be found in (Cinková et al., 2012).

3 Synonymy in bilingual context

Synonymy in bilingual context is closely related to translational equivalence, sameness, similarity, meaning, word sense, etc. These terms - and the term synonymy itself - are not always used in an unambiguous way. We thus discuss the terminology first, and then specify how we define verbal synonymy in bilingual context in the work on building the CzEngClass lexicon.

3.1 Terminology

Although Cruse (1986) notes that "there is unfortunately no neat way of characterising synonyms", the notion of synonymy is mostly seen as "sameness or identity of meaning" (Palmer, 1976; Sparck Jones, 1986). Leech (2012) restricts synonymy to equivalence of conceptual meaning. *Synonym* is mostly defined as "a same-language equivalent" (Adamska-Sałaciak, 2010; Adamska-Sałaciak, 2013) and "does not exceed the limits of a single language" (Gouws, 2013), while for bilingual contexts the term *translational equivalent* is used. On the other hand, (Martin, 1960; Klégr, 2004; Hahn et al., 2005; Hayashi, 2012; Haiyan, 2015; Dinu et al., 2015) recognize interlingual synonymy and use either the term *foreign-language equivalent, cross-lingual synonym, synonymous translation equivalent* or *bilingual synonym*.

In building CzEngClass, we consider the relationship between the lexical unit of the source language (SL) and of the target language (TL) unit as a specific type of synonymy, an *interlingual* synonymy. For words from different languages which are interlingual synonyms, we prefer to use the term *bilingual synonyms*. We understand that the meaning correspondence does not mean absolute equivalence and automatic interchangeability. We agree with (Louw, 2012) that the translation equivalent might be a TL item that can only be a substitute for the SL item in one or in some of its uses and each equivalent has to be supported with additional contextual and co-textual restrictions that will allow the user to make an appropriate choice of an "equivalent" for a given usage situation. Accordingly, we believe that interlingual synonymy considerations are essential in the translation process because it is up to the translator to choose the most suitable expression among (intralingual) synonyms, based on context and the meaning of the SL text (Catford, 1965; Newmark, 1988).

Intralingual synonyms are often not interchangeable, i.e., not quite equivalent. Synonymy, as viewed by (Lyons, 1968; Cruse, 1986), has to be seen as a scale of similarity (absolute, near and partial synonymy) and it is generally acknowledged that absolute synonymy is rare in natural languages. Therefore, it is believed that context must be taken into account (Palmer, 1981). Such synonyms are then called contextual synonyms (Zeng, 2007) or contextual correlates of synonymy (Rubenstein and Goodenough, 1965) and described as words that are "synonymously" used in certain specific texts.

3.2 Definition of contextual synonymy in CzEngClass

Both types of synonymy (interlingual and intralingual) are captured in the CzEngClass lexicon, which aims to group verbs into synonym classes both monolingually and cross-lingually. Along with (Palmer, 1981), we believe that synonymy can only be considered in context. We define two (or more) verb senses to be *bilingual synonyms* if they both (or all) convey the same meaning in a given particular context. Similarly, for the intralignual case, we work with the "loose" interpretation of synonymy (Lyons, 1968; Palmer, 1981), and consider context as a key factor that helps to overcome the vagueness of such "looseness".

In CzEngClass, *context* is defined as the set of semantic roles (SRs) that the given verb, as a member of a bilingual synonym class, expresses by its arguments and/or adjuncts, or which are implicitly present, possibly with additional structural or semantic restrictions. Each class has an associated, single (common) set of SRs while such a set is shared by all its members, even if each SR can be expressed (*mapped* to) by a different argument (or by an adjunct, or implicitly or explicitly in the verb's dependent substructure) for different verbs as members of that class. Conversely, such mapping must exist at least for all obligatory valency slots as defined in the two corresponding valency lexicons. To keep each class focused, only a relatively small set of SRs is usually assigned to it (corresponding roughly to "core" Frame Elements in FrameNet, even though the labels might not match).[1]

Such focus then helps to answer the question of candidate verb membership in a particular synonym class. If a mapping of all arguments to the SRs associated with that class is found, as well as a mapping

[1] In fact, there is one substantial difference between the intended properties of CzEngClass's SRs and those found in FrameNet: while FrameNet explicitly states that SRs (FEs) from one Frame, even if under the same label, should not be construed as being the same as equally labeled SR (FE) in a different Frame, we would like to use such a set of SRs that *is* labeled consistently across CzEngClass classes. For the moment, however, we resort to VerbNet thematic roles for the most common SR "slots", such as Agent and to a certain extent also Theme, renaming them in the future consistently once we have a larger set of classes ready. For more details on the process, see Sect. 6.

of all SRs of that class to the candidate verb arguments, adjuncts (or implicit, or even more deeply embedded dependents), and it does not violate any of the associated restrictions, then the candidate verb is considered to be a valid member of such class. Since CzEngClass is built mainly manually,[2] it is important to establish such criteria in order to achieve higher interannotator agreement (IAA) as well as for guiding the adjudication process. Table 1 illustrates one possible class and the context (SR mappings) for each member.

4 Resources used

The resources used to create the CzEngClass lexicon are divided into two groups - primary and secondary.

Primary resources are those used for word sense disambiguation and valency information when creating the class member candidates. We use the parallel Prague Czech-English Dependency Treebank 2.0 (PCEDT 2.0) (Hajič et al., 2012) with its associated lexicons. This treebank contains over 1.2 million words in almost 50,000 sentences for each language. About 90,000 tokens are verbs on each side. The English part contains the entire Penn Treebank - Wall Street Journal Section (Marcus et al., 1993). The Czech part is a manual translation of all the Penn Treebank-WSJ texts to Czech. PCEDT is annotated using The Prague Dependency Treebank style (Hajič et al., 2006; Hajič et al., 2018) manual linguistic annotation based on the Functional Generative Description framework (Sgall et al., 1986). Our research benefits primarily from the deep syntactico-semantic (tectogrammatical) dependency trees, interlinked across the two languages on sentence and node (content word) levels. Each deep syntax verb occurrence in the PCEDT is linked to the corresponding valency frame (predicate-argument structure frame) in the associated valency lexicons, PDT-Vallex (Urešová et al., 2014; Urešová, 2011) and EngVallex (Cinková, 2006; Cinková et al., 2014), effectively providing also word sense labeling. The parallel bilingual valency lexicon CzEngVallex (Urešová et al., 2016; Urešová et al., 2015), built over the PCEDT, is also heavily used, both in the annotation process itself but also for automatic preannotation.

Secondary resources are the well-known English lexical resources: FrameNet (Baker et al., 1998; Ruppenhofer et al., 2006), FrameNet+ (Pavlick et al., 2015), VerbNet and OntoNotes (Schuler, 2006; Pradhan et al., 2007), SemLink (Palmer, 2009; Bonial et al., 2012), PropBank (Palmer et al., 2005), and English WordNet (Miller, 1995; Fellbaum, 1998). For Czech, we use Czech WordNet (Pala and Smrž, 2004) and VALLEX (Lopatková et al., 2016). These resources are used for the extraction of an initial set of SRs (taken from FrameNet and VerbNet), and most importantly, their entries (if possible to the level of

[2]With automatic preselection of candidate class members based on parallel corpora and the valency lexicons available for Czech and English, see Sect. 6.

exact lexical units / frames / synsets) are referred to (explicitly linked) from all the corresponding entries in the CzEngClass lexicon.

5 Lexicon Structure

The structure of CzEngClass is described in detail (Urešová et al., 2018a; Urešová et al., 2018d; Urešová et al., 2017a; Urešová et al., 2017b). Here we summarize only its main characteristics.

The CzEngClass lexicon is in principle a set of (bilingual synonym) classes. Each class contains both Czech and English verbs (class members), identified by their valency frame identifier (i.e., a link to the Czech and English valency lexicons that served as the initial sense inventory for each verb). For each class, the lexicon records also the set of semantic roles, which is common for the class. For each class member, its arguments (valency slots) are mapped to this set (not necessarily 1 : 1 - arbitrary $m : n$ mappings are allowed). For each member, additional restrictions (for the time being, in the form of a plain text description) are recorded as well. In addition, the lexicon also records, within each class, the original verb pairs as found aligned across the two languages in the PCEDT, and their argument alignment as coming from the CzEngVallex bilingual valency lexicon. All external links (to FrameNet frame(s), Ontonotes Sense Groupings, VerbNet type(s), WordNet synset(s)) are also recorded (see Sect. 4).

The lexicon, technically a single XML file with external references, also contains a header with all the SRs used and their description, annotator IDs, bookkeeping information about all the external resources in order to create a URL for each external link, and all entries also contain the usual annotation information (log with timestamps, etc.).[3]

6 The lexicon annotation process

First, we automatically aligned Czech verbs with their English verbal translations[4] as found in the PCEDT. There are two phases, each further broken down to several steps.

In Step 1 of the first phase, we have automatically extracted 200 Czech verbs[5] and their English translations. These 200 verbs have been selected to represent both high-, medium- and low-frequency verbs in the PCEDT. They have been found in 23,769 sentences, covering about half of the corpus.[6] Each Czech verb serves as a "seed" in the future bilingual synonym class. The English translations are the (first-phase, English-language) class member candidates. Using the principles of both intra-lingual and inter-lingual synonymy (Sect. 3), and with the help of comparing the valency frames of the Czech verb and the English verb and the English verbs among themselves, we then manually pruned these candidates, obtaining a list of (English) synonym class members.

In Step 2 of the first phase, we have used these English verbs and added, similarly to Step 1 but in an opposite direction and using the same corpus, additional Czech synonym class member candidates. These have been pruned manually again and a result of this pruning was a (first-phase) bilingual synonym class, built around the original Czech verb.

In the second phase, two tasks had to be carried out for all classes. First, to every class member the appropriate linking to English and Czech resources had to be provided. Using a dedicated class editor, we started with mapping every English verb sense in the class to Ontonotes Sense Grouping. Then, links to FrameNet, PropBank, WordNet and Czech VALLEX have been added.[7] Second, core SRs inventory (for each class) had to be created. We were mostly inspired by FrameNet's *frame elements* (FEs) resorting to more general VerbNet's *thematic roles* if FEs were deemed to be specific. For each class member, its valency arguments (taken from PDT-Vallex for Czech verbs and EngVallex for English ones) have been mapped to the appropriate SR from the set of SRs assigned to the whole class. So far, this second step has been performed for the first 60 classes only.

[3] Current version of CzEngClass: `http://hdl.handle.net/11234/1-2824`

[4] As already mentioned, we pay attention only to verbs.

[5] I.e., 200 verb senses represented by their valency frames as annotated in the data.

[6] Average number of sentences per Czech verb is 119, median is 26. These sentences may contain also other verbs.

[7] Links to Czech WordNet will be added later.

The process described above was first tested and fine-tuned by two annotators, and then a detailed testing (so far, of Step 1 of the first phase), as reported in Sect. 7 below, has been performed by eight annotators.

7 Evaluation: interannotator agreement

Using the first part of the annotation process (filtering of the precomputed list of English verbs for a given Czech verb, in a particular sense), an IAA evaluation scheme has been set up (Table 2).

	No. of classes (Czech verbs)	No. of English verbs (sum over all clases)
Part 1	15	131
Part 2	15	134
Part 3	17	127
Part 4	13	152
Total	60	544

Table 2: Interannotator agreement experiment setup

As described in Sect. 6, the 60 Czech verbs (senses) have been selected in the PCEDT such that they represented high-, medium- and low-frequency verbs in roughly the same proportion.[8] For those 60 verbs, all their English translational verbal counterparts[9] aligned with them have been extracted automatically from the corpus, with the help of the CzEngVallex lexicon which refers to particular verb senses.This alignment is however not perfect for our purposes. The task of the annotators was to prune, for each Czech verb sense (i.e., the potential/future synonym class), the automatically preselected list of its English verbal translational equivalents so that only synonym candidates corresponding to the meaning of the Czech verbs as it appears in the bilingual corpus are preserved. For this experiment, the annotators have not been given the full definition of the synonym as presented here in Sect. 3. They have been instructed, for each pair of the Czech verb and its English synonym candidate, to check the corpus examples through the CzEngVallex valency argument alignments, i.e., the usage in context as defined in Sect. 3, but not to validate (yet) against the set of SRs for the given class.[10]

There have been 8 annotators, each of them annotating 2 different parts. 1 of the annotators is a professional translator, 2 of them are researchers in the field of Computational linguistics with a Ph.D. degree, and the remaining 5 are undergraduate students of various language and linguistic programs, all with high-level fluency in English. All annotations have been treated as equal.

Each English synonym class member candidate verb was annotated by 4 annotators (Table 2). The annotators have been asked to assign, to each candidate English verb, one of the five labels summarized in Table 3, corresponding to a scaled decision of how strong the annotators feel about including (or not including) the English word in the resulting synonym group.

Only the labels have been presented to the annotators, which have been then converted to the scale used for some of the evaluation metrics, as described below. The data for the interannotator agreement as described in this paper are available with the previous version of CzEngClass (Urešová et al., 2018b).[11]

7.1 Interannotator agreement: Cohen's kappa

Cohen's kappa, used for comparing annotations pairwise, is defined as follows:

$$\kappa = (p_0 - p_e)/(1 - p_e) \quad (1)$$

[8]This selection is to gain insight to the issues with verbs of all frequencies; overall, of course, the verbs with low frequency will prevail, making the statistics more favorable since classes for these verbs tend to have less members and thus higher IAA.

[9]We are aware of the fact that many verbs are translated by nouns or other kinds of phrases. These translational counterparts are not yet part of the CzEngClass.

[10]We understand this as a first step. The class membership might be–and surely will be–changed in the second step, namely, when assigning the SR mappings to valency slots. This is the most important "context" criterion defining the class membership based on our principles of synonymy as defined in Sect. 3, and specifically in Sect. 3.2.

Label	Explanation	Inclusion weight
Y	Yes	4
R_Y	Rather Yes	3
R_N	Rather No	2
N	No	1
D	Delete (Alignment or other system error)	0

Table 3: Labels assigned to each English verb by the annotators

where p_0 is the observed agreement, and p_e the expected agreement based on the two annotations. Results are summarized in Table 4. For determining agreement, we have mapped the labels assigned by the annotators to two values only: Y (if they used labels Y and R_Y) and N (if they used labels N, R_N and D), since Cohen's kappa would be hard to interpret if scaled values are behind the labels used.

Annotator	A_1	A_2	A_3	A_4	A_5	A_6	A_7	A_8
A_1	-	0.46	0.19	0.42		0.43	0.43	0.33
A_2		-	0.57	0.55	0.46	0.68		0.31
A_3			-	0.42	0.37		0.26	
A_4				-	0.35		0.45	
A_5					-	0.48	0.56	0.41
A_6						-	0.48	0.51
A_7							-	0.48
A_8								-

Table 4: Interannotator agreement: Cohen's kappa, pairwise

Due to the distribution of Parts 1-4 to annotators, not all pairs of annotators could be compared (empty cells in Table 4). The parts in any row or column are different for different annotators.[12]

While averaging over the annotators is not well defined within such pairwise distribution of data, we can see quite clearly that A_3 has overall the lowest agreement with the others, but the differences are not that high. The values are low, but this is due to the fact that the label assignment has been biased to assigning Y (i.e., to keep the verb in) in about an 5:1 ratio.

7.2 Interannotator agreement: Fleiss' kappa

As opposed to Cohen's kappa, Fleiss' kappa can be used in a multiannotator setup with n annotators and N datapoints (total of English verbs in the 60 classes annotated, i.e., 544 in our case):

$$\kappa = (\bar{P} - \bar{P}_e)/(1 - \bar{P}_e) \tag{2}$$

where

$$\bar{P} = \frac{1}{N}\sum_{i=1}^{N}\frac{1}{n(n-1)}(n_{iYes}(n_{iYes}-1) + n_{iNo}(n_{iNo}-1)), \tag{3}$$

$\bar{P}_e = {p_Y}^2 + {p_N}^2$, $p_Y = \frac{1}{Nn}\sum_{i=1}^{N} n_{iYes}$ and $p_N = \frac{1}{Nn}\sum_{i=1}^{N} n_{iNo}$. The n_{iYes} (n_{iNo}) counts are defined as the number of times the i-th datapoint has been annotated Y and N, respectively (i.e., sum of n_{iYes} and n_{iNo} is n). The Ys and Ns have been obtained by the same mapping as in the Cohen's kappa case: Y and R_Y mapped to Y and N, R_N and D mapped to N. Table 5 shows the intermediate and final values of Fleiss' kappa. The 0.45 value characterizes the "global" difficulty of the task; again, we have to stress that the bias is high (about 5:1), so that any disagreement lowers the kappa value substantially.

[12] Given the amount of effort available for the annotation, the four parts have been distributed in such a way that at least those pairs listed in the table could be covered.

p_Y	p_N	$\bar{P}$	$\bar{P}_e$	κ
0.84	0.16	0.85	0.73	**0.45**

Table 5: Interannotator agreement: Fleiss' kappa, global

Given the low kappa values, we have been interested in numbers that could perhaps be easier to interpret from the point of view of adjudication, which will inevitably follow to ensure high quality of the resulting lexicon. In addition, we are not convinced that these widely used interannotator metrics are appropriate for highly biased lexical task (as opposed for running text annotation in a corpus). We have thus measured two more things: consensus and deviation from the assumed correct value, both described below.

7.3 Annotator consensus

As a first step, we have measured consensus. Of the 544 datapoints the annotators assigned the label (again mapped to Y and N only), in 488 cases a majority consensus could be reached (89.7%); i.e., only in slightly over 10% of the cases the result was 2:2 (with 4 annotators working on each datapoint). This number naturally varies with the number of annotators (it would be higher for 2 annotators, and always 100% for an odd number of annotators unless a higher threshold is set for determining consensus), but when combined with full agreement among the 4 annotators (358 cases out of the 544, or 65.8%), it gives a good idea of the adjudication effort needed (for 4 annotators, in our case).[13]

7.4 Comparison based on the annotated scale

Since the annotation of class membership for the candidate English synonym verbs has been in fact on a scale 0-4 (see Table 3), we tried to compute a global (averaged) score of deviation from a centerpoint, namely the assumed correct value, computed either as a majority or average value as assigned to every English verb by the four different annotators that had labelled it. We have used two methods.

In the **first method**, we have determined the "correct" value by taking the majority annotation, restricted again to two values: Y(es) and N(o) (with mapping from the five different (scaled) annotated labels as in the kappa computation, Sect. 7.1). For computing the deviation on a particular datapoint, we use the same mapping. In other words, the deviation can only be 0 (agreement with Y or N) or 3 (disagreement). The averaged (absolute) deviation $DevA2_j$ for an annotator j is then defined as

$$DevA2_j = \frac{\sum_{i=1}^{N} |B_i - S_{ij}|}{N} \tag{4}$$

where B_i is the correct value (4 for Y, 1 for N) for verb i (out of N verbs, where $N = 544$ in our dataset), and S_{ij} is the mapped value on that i-th verb for annotator j.

The deviation computed on this mapped (Y/N) values is summarized for all annotators in Table 6; the average over all annotators is 0.27 (within a span of maximum possible difference of 3 (4-1)). Since the bias towards the Y label in the consensus labeling is about 5:1, giving everything Y would result in approx. average deviation $1/6 \times 3 = 0.5$, so the annotation cut this deviation to half.

Annotator	A_1	A_2	A_3	A_4	A_5	A_6	A_7	A_8	**Data avg.**
Avg. deviation	0.21	0.20	0.23	0.26	0.41	0.21	0.31	0.31	**0.27**

Table 6: Deviation from consensus value, mapping to 2 values only (Y/N)

The **second method**, which is meant for evaluation purposes only, does not select one consensus value, but simply averages the scaled labels over all (four) labels assigned by the annotators to every datapoint (verb to annotate) i:

[13] The total agreement has been measured using all labels; i.e., if 3 annotators assigned N and 1 assigned R_N, it did not count as full agreement.

$$P_i = (\sum_{k=1}^{n} v_{ik})/n$$

where n is a number of annotations for a given datapoint (i.e., always four in our case, since each verb has been annotated by 4 annotators), k runs over all labels assigned to the i-th datapoint, and v_{ik} is the k-th value (0-4, mapped from (D, N, R_N, R_Y, Y; see Table 3) assigned to i-th datapoint.

The deviation for each annotator is then computed as

$$DevA5_j = \frac{\sum_{i=1}^{N} |P_i - A_{ij}|}{N} \quad (5)$$

where P_i is the averaged value as defined above for verb i (out of N verbs, where $N = 544$ in our dataset), and A_{ij} is value assigned to the i-th datapoint by annotator j.

The averaged values are shown in Table 7.

Annotator	A_1	A_2	A_3	A_4	A_5	A_6	A_7	A_8	**Data avg.**
Avg. deviation	0.32	0.32	0.32	0.32	0.45	0.36	0.37	0.41	**0.36**

Table 7: Deviation from average assigned value, all 5 values used (0-4)

These deviations are (somewhat surprisingly) larger than the deviations computed after mapping the labels to the binary (Y/N) values only. In other words, the deviation is *smaller* when the "unsure" labels (R_Y, R_N) are mapped to Y and N, and the D value also to N, disregarding the difference between these two.

Since the final lexicon will not contain any manually assigned weights, i.e., a given verb will be considered either in a class or not in a class. we believe that the relevant numbers are those in Table 6.

While the two methods of computing interannotator "deviation" compute absolute difference between the annotator-assigned value and the "truth", we have been interested yet in another value, namely whether a given annotator tends to keep the preselected verbs in the class or not. This number thus does not describe annotator's distance from the consensus value or the average, but rather his average positive attitude (prefers to keep many verbs in) or a negative one (prefers to mark verbs as not belonging to the synonym class in question).

We compute the "truth" as a simple average of the graded labels for every verb:

$$DevS5_j = \frac{\sum_{i=1}^{N} (P_i - A_{ij})}{N} \quad (6)$$

The resulting value can now be also negative, meaning that the annotator assigned lower values on the 0-4 scale than average, and by how much.

Annotator	A_1	A_2	A_3	A_4	A_5	A_6	A_7	A_8
Avg. (signed) deviation	0.09	0.05	0.13	0.08	-0.19	0.07	-0.02	0.11

Table 8: Signed deviation from average assigned value, all 5 values used (0-4)

Table 8 shows the results. The deviation for 2 annotators, A_5 and A_7 is in the negative territory. These annotators, and specifically A_5, are considered "conservative", since their annotation keeps the synonym classes small - they prefer only clear synonyms to become included in the class. Annotator A_3, on the other hand, is the most "liberal" of all and leans towards including more words in the class.

8 Extending CzEngClass to Other Languages

An interesting question is what is necessary in order to create a similar lexical resource–using the approach described here–for other languages or to extend our resource by another language. Based on our

experience so far, we believe this is the minimal set of necessities to start with: a valency or predicate-argument lexicon for that language (a corresponding parallel resource - with English, such as our CzEng-Vallex lexicon - might be helpful but it is not essential) and a word-aligned and (at least automatically) syntactically analyzed parallel corpus (pairing the language in question to English, or to any language that is already included in the Class lexicon being extended). In addition, some word-sense-distinguishing lexicon (e.g., WordNet in that language) is also nice to have to link the class members to. Moreover, having additional lexical resources in the given language (such as FrameNet) would be an advantage that will help the consistency of annotation and the usefulness of the final, externally linked synonym lexicon, but this is not strictly necessary.

9 Conclusions and future work

We have described the first version of a semi-manually built bilingual synonym lexicon of verbs, CzEng-Class, based on a parallel corpus and existing lexical resources. The process of building the lexicon is relatively complex, and we have presented results of the first step of "soft" (scaled) lexical unit annotation by several annotators. We have evaluated their agreement by several metrics, giving us some indication of how much future effort will be needed for adjudication in order to obtain a high-quality resource.

These first findings indicate that the traditional measures for IAA show low agreement, primarily due to high bias in the automatic preselection which favors the preselected verbs to be kept (in 5:1 ratio).[14] Using a different measure based on deviation from consensus, we found that a full consensus has been achieved among 4 annotators in almost 2/3rd of test cases, and if we lower the criterion of agreement to 3 of 4 annotators, in 9 of 10 cases (Sect. 7.3). This is only when considering the verb sense and valency; adding the semantic roles, which is the next step, would likely lower that agreement. For example, we will explore more the assumption (and try to explicitly define where and when it can be used) that the valency slots to semantic roles mapping might need to be *m:n*, which of course greatly influences the interannotator agreement as opposed to the case where only *1:1* mapping is allowed.

The first version (200 classes, i.e., approx. 1800 class members, Phase 1 annotation) has been released publicly (Urešová et al., 2018c).[15]

Phase 2 annotation is ongoing, with semantic role assignment to classes and the detailed mapping of valency to these roles. Eventually, we will extend CzEngClass to all verbs found in the PCEDT. This is expected to go smoothly, perhaps with the usual exception of the verbs *to be*, *to have*, *to become* and *to do*. Otherwise, since we have already (intentionally) dealt with verbs of various frequencies and degrees of homonymy, representing a wide range of possible valency-to-semantic-roles mappings, we believe no substantial issues in the specification nor the annotation process should arise.

For the more distant future, we plan to use the core PCEDT-derived CzEngClass lexicon to do experiments on automatic extraction of synonym classes from other (larger) data, while using CzEngClass as a gold standard. If successful, we plan to extend CzEngClass to other verbs similarly to what the Predicate Matrix project did, but with the arguably best system based on the above experiments; in all cases, we plan for manual pass to obtain consistent classes with those done fully manually.

Acknowledgements

This work has been supported by the grant No. GA17-07313S of the Grant Agency of the Czech Republic. Part of this work was conducted during a fellowship (of the 4th author) at the Oslo Center for Advanced Study at the Norwegian Academy of Science and Letters. The data used in this work have been created and are maintained in the LINDAT/CLARIN digital repository (http://lindat.cz), supported by the Ministry of Education, Youth and Sports of the Czech Republic as projects No. LM2015071 and CZ.02.1.01/0.0/0.0/16_013/0001781. The creation of part of the data used has been also supported by the European Commission under the T4ME (META-NET) project No. FP7-ICT-2009-4-249119.

[14] Which confirms, as a collateral result, that the data from which this preselection has been done are of quite high quality in terms of verb and argument alignment.

Abstract

This paper proposes a simple CNN model for creating general-purpose sentence embeddings that can transfer easily across domains and can also act as effective initialization for downstream tasks. Recently, averaging the embeddings of words in a sentence has proven to be a surprisingly successful and efficient way of obtaining sentence embeddings. However, these models represent a sentence, only in terms of features of words or uni-grams in it. In contrast, our model (CSE) utilizes both features of words and n-grams to encode sentences, which is actually a generalization of these bag-of-words models. The extensive experiments demonstrate that CSE performs better than average models in transfer learning setting and exceeds the state of the art in supervised learning setting by initializing the parameters with the pre-trained sentence embeddings.

1 Introduction

Representing word sequences such as phrases and sentences plays an important role in natural language understanding systems. In recent years, many composition functions have been applied to word embeddings to obtain vectors for longer phrases or sentences, ranging from simple operations like addition (Mitchell and Lapata, 2008) to richly-structured functions like recursive neural networks (Socher et al., 2011), convolutional neural networks (Kalchbrenner et al., 2014), and recurrent neural networks (Tai et al., 2015).

In this paper, based on convolutional neural networks (CNN), we introduce an architecture that can use both features of words and features of n-grams to encode sentences into real-valued vectors with the property that sentences with similar meaning have high cosine similarity in the embedding space. Our goal is to learn general-purpose sentence representations that can be transferred for measuring semantic textual similarity (STS) (Agirre et al., 2012) and can also act as effective initialization for downstream tasks.

Originally, the CNN model is invented to extract local features in computer vision (Lecun et al., 1998). But it has been shown to be effective for NLP and has achieved excellent results in sentence modeling (Kalchbrenner et al., 2014), and other traditional NLP tasks (Collobert et al., 2011). To encode the meaning of a sentence of varying length into a fix-length vector, our simple CNN model first utilizes multiple filters with different size to extract possible features of n-grams in it. Then we obtain one feature corresponding to one filter through pooling operation. The intuition is to capture one aspect of semantic features of n-grams for each filter. Inspired by the strong performance of simply averaging word embeddings (Wieting et al., 2016), we also set filter size to 1 to extract word semantic information.

To evaluate our model, we consider two types of learning settings: transfer learning evaluation and supervised learning evaluation. For the transfer leaning setting, we first train our model on noisy phrase pairs from the Paraphrase Database (PPDB) (Ganitkevitch et al., 2013), then evaluate it on every SemEval STS task from 2012 through 2015 and the 2014 SemEval SICK dataset (Marelli et al., 2014). Particularly, we follow the experiment setting of Wieting et al. (2016), in which they compared various types of neural network architectures except CNN, spanning the range of complexity from word averaging to LSTMs

Proceedings of the 27th International Conference on Computational Linguistics, pages 2470–2481
Santa Fe, New Mexico, USA, August 20-26, 2018.

and showed the impressive performance of Paragram-Phrase (PP), a simple word average model. So our work can also serve as complementary to theirs. As results, we found our model performs better than their PP model in most evaluation datasets. Moreover, researchers have recently found that since models are ultimately tested on sentences, sentence representations trained on noisy sentence pairs, obtained automatically by aligning Simple English to standard English Wikipedia (Coster and Kauchak, 2011), perform much better than those trained on noisy phrase pairs from PPDB dataset (Wieting and Gimpel, 2017). So we conduct the same transfer learning experiment on noisy sentence pairs with our model which is initialized with the parameters obtained from PPDB, and again find our model outperforms two state-of-the-art models: ATT-CCG (Shaonan Wang, 2017) and GRAN (Wieting and Gimpel, 2017). For the supervised learning setting, we use the model from transfer setting as a prior and fine-tune this model on the SICK dataset in a supervised style. With useful initialization, we achieve new state-of-the-art results on this task.

2 Related Work

Obtaining the most useful distributed representations of phrases or sentences could ultimately have a significant impact on language understanding systems since it is phrases and sentences, rather than individual words, that encode the human-like general world knowledge (or common sense) (Norman, 1972). According to their purposes, sentence embeddings generally fall into two categories: task-specific sentence embeddings and general-purpose sentence embeddings.

The first consists of sentence embeddings trained specifically for a certain task. They are usually combined with downstream applications and trained by supervised learning. Researchers have proposed many models along this line, and they typically use recursive neural networks (Socher et al., 2012; Socher et al., 2013), convolutional neural networks (Kalchbrenner et al., 2014; dos Santos and Gatti, 2014; Kim, 2014) or recurrent neural networks with long short-term memory (LSTM) (Hochreiter et al., 1997; Chung et al., 2014) as an intermediate step in creating sentence embeddings to solve a variety of NLP tasks including paraphrase identification and sentiment classification (Yin and Schütze, 2015; Tan et al., 2016; Lin et al., 2017).

The other category consists of universal sentence embeddings, which are usually trained by unsupervised or semi-supervised learning and can be served as features for many other NLP tasks such as text classification and semantic textual similarity. This include recursive auto-encoders (Socher et al., 2011), ParagraphVector (Le and Mikolov, 2014), SkipThought vectors (Kiros et al., 2015), Sequential Denoising Autoencoders (SDAE), FastSent (Hill et al., 2016), PP (Wieting et al., 2016), Sent2Vec (Pagliardini et al., 2017), GRAN (Wieting and Gimpel, 2017), etc.

In this paper, we also aim to learn general-purpose, paraphrastic sentence embeddings, the same purpose as Wieting et al. (2016). In their work, they demonstrate the strong performance of the PP model across a broad range of tasks and domains, but also show some limitations of this bag-of-words model. For future work, they leave a challenge: can we find a model that takes context into account while still generalizing as well as the PP model? Then in their following work (Wieting and Gimpel, 2017), they proposed a novel architecture, called GRAN that utilizes the context information to create gate for each word in a sentence. After obtaining gates which can be seen as a kind of attention mechanisms, they average the word embeddings, multiplied with their respective gates, to get the embedding of the sentence. Besides, there is another model, called ATT-CCG (Shaonan Wang, 2017), which also incorporates attention mechanism into PP model by using word attributes information (CCG supertag of words). Unlike GRAN and ATT-CCG, we propose a convolutional architecture, called Convolutional Sentence Encoder (CSE), which directly consider the semantics of n-grams by using convolving filters with different size. Further description of this model is included in Section 3.1.

3 Model and Training

3.1 Model

Figure 1 shows the architecture of the proposed model CSE. Our model encodes the meaning of a sentence of varying length into a fixed-length real-valued vector such that the semantic similarity between

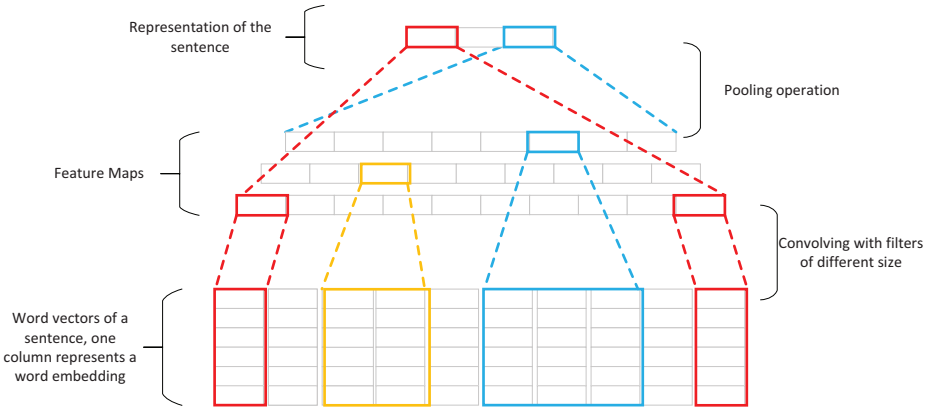

Figure 1: Model architecture

sentences can be measured by the cosine similarity of their corresponding vectors. We denote $\mathbf{x}_i \in \mathbb{R}^d$ as the d-dimensional word vector of the i-th word in a sentence. Then a sentence of length n (padded when necessary) is represented as

$$\mathbf{x}_{1:n} = \mathbf{x}_1 \oplus \mathbf{x}_2 \oplus \cdots \oplus \mathbf{x}_n, \tag{1}$$

Where $\oplus$ is the concatenation operator. In general, let $\mathbf{x}_{i:j}$ refers to the concatenation of words $\mathbf{x}_i, \mathbf{x}_{i+1}, \ldots, \mathbf{x}_j$. A convolution operation involves a filter $\mathbf{w} \in \mathbb{R}^{h*d}$, which is applied to a window of h words to produce a new feature. For example, a feature c_i is generated from a window of words $\mathbf{x}_{i:i+h-1}$ by

$$c_i = f(\mathbf{w} \cdot \mathbf{x}_{i:i+h-1} + b). \tag{2}$$

Here $b \in \mathbb{R}$ is a bias term and f is a activation function (either tanh or linear unit; linear unit is slightly better in our experiments, so we only report the linear unit results). This filter is applied to each possible window of words in the sentence $\{\mathbf{x}_{1:h}, \mathbf{x}_{2:h+1}, \ldots, \mathbf{x}_{n-h+1:n}\}$ to produce a feature map

$$\mathbf{c} = [c_1, c_2, \ldots, c_{n-h+1}] \tag{3}$$

with $\mathbf{c} \in \mathbb{R}^{n-h+1}$. Instead of using mean pooling, we then apply a sum pooling operation over the feature map for forcing our model to capture semantic similarity between words and phrases.[1] And we take the sum value $\hat{c} = sum(\mathbf{c})$ as the feature corresponding to this particular filter. The idea is to capture one aspect of n-gram semantic features for each feature map. This pooling scheme also naturally deals with variable sentence lengths.

We have described the process by which one feature is extracted from one filter. The model uses k filters (with varying window sizes) to obtain multiple features. These features form the representation of a sentence:

$$g(\mathbf{x}_{1:n}) = [\hat{c_1}, \hat{c_2}, \ldots, \hat{c_k}]. \tag{4}$$

For the learnable parameters in our model, we denote the word embeddings by W_w and all the other compositional parameters by W_c. In addition, We initialize W_w by some pretrained embeddings in all experiments.

3.2 Training

We follow the training procedure of Wieting et al. (2016), described below. The training data consists of a set S of phrase or sentence pairs $\langle s_1, s_2 \rangle$ from either PPDB (Ganitkevitch et al., 2013) or the aligned

[1] Suppose we have two sentences that are very different in length but have very close meanings. In order to get similar embeddings for them, our model must find a way to capture semantic similarity between words in the short sentence and n-grams in the long one.

Wikipedia sentences (Coster and Kauchak, 2011) where s_1 and s_2 are assumed to be paraphrases. We optimize a margin-based loss:

$$\min_{W_w, W_c} \frac{1}{|S|} \Bigg(\sum_{\langle s_1, s_2 \rangle \in S} \max(0, \delta - \cos(g(s_1), g(s_2)) + \cos(g(s_1), g(t_1))) + \max(0, \delta - \cos(g(s_1), g(s_2)) + \cos(g(s_2), g(t_2))) \Bigg) + \lambda_w \|W_{w_{initial}} - W_w\|^2 + \lambda_c \|W_c\|^2 \tag{5}$$

Where g is our sentence representation model, δ is the margin, λ_w and λ_c are the regularization parameters, $W_{w_{initial}}$ is the initial word embedding matrix, and t_1 and t_2 are carefully-selected negative examples taken from a nimi-batch during optimization. The intuition is that we want the two sentences to be more similar to each other $\cos(g(s_1), g(s_2))$ than either is to their respective negative examples t_1 and t_2, by a margin of at least δ.

Selecting Negative Examples: To select t_1 and t_2 in Eq. 5, we simply choose the most similar example in some set of phrases or sentences (other than those in the given pair). For simplicity, we use the mini-batch for this set, but it could be a different set. That is, we choose t_1 for a given $\langle s_1, s_2 \rangle$ as follows:

$$t_1 = \underset{t:\langle t, \cdot \rangle \in S_b \setminus \{\langle s_1, s_2 \rangle\}}{\arg\max} \cos(g(s_1), g(t))$$

where $S_b \in S$ is the current mini-batch. That is, we want to choose a negative example t_i that is similar to s_i according to the current model.

4 Experiments

In this part, we present the results of our experiments. We first use the semantic textual similarity (STS) tasks from 2012 to 2016 (Agirre et al., 2012; Agirre et al., 2013; Agirre et al., 2014; Agirre et al., 2015; Agirre et al., 2016) and the SemEval 2014 SICK (Marelli et al., 2014) test set to evaluate the performance of our model under the transfer learning setting. Then for supervised setting, we choose the SICK 2014 dataset with its standard train/dev/test split.

Given two sentences, the aim of the STS tasks is to predict their similarity on a 0-5 scale, where 0 indicates the sentences are on different topics and 5 indicates that they are completely equivalent. These STS datasets cover a broad range of domains, including news, image and video descriptions, glosses, web forum, twitter and so on. As for the supervised SICK task, it requires us to give a relatedness score for sentence pair on a 1-5 continuous scale similar as STS, but is an easier learning problem since the training and test examples are all drawn from the same distribution.

4.1 Transfer Learning

DataSets and Experimental Settings: As training data, we use noisy phrase pairs from Paraphrase Database (PPDB) (Ganitkevitch et al., 2013) which is automatically derived from naturally-occurring bilingual text. PPDB comes in different sizes (S, M, L, XL, XXL, and XXXL), where each larger size subsumes all smaller ones but contains noisier paraphrases. Considering precision and data size, we choose the XL section of PPDB which contains 3,033,753 unique phrase pairs. We use PARAGRAM-SL999 embeddings (Wieting et al., 2015) to initialize the word embedding matrix (W_w) for the model, and fix the learning procedure, using Adam (Kingma and Ba, 2015) optimizer with a learning rate of 0.001. Moreover, we use filter windows (h) of 1, 2, 3 with 100 feature maps each[2], since we want the dimension of sentence vectors of CSE to be same as the baseline models. The reason we use filter window of 1 is inspired by the strong performance of the bag-of-words PP model. For hyperparameter tuning, we search $\delta \in \{0.4, 0.6, 0.8\}$, $\lambda_w \in \{10^{-4}, 10^{-5}, 10^{-6}\}$, $\lambda_c \in \{10^{-5}, 10^{-6}, 10^{-7}, 0\}$, and batch

[2]We put filter window size selecting part in Section 5.2 for further analyzing the difference between CSE and PP.

size over {32, 64, 128, 256}. We train the model on PPDB for 10 epochs, using STS 2016 datasets for validation, then evaluate on STS 2012-2015 tasks and the SICK test set.

Wieting and Gimpel (2017) found the sentences in the STS test sets are quite different from the short training fragments in PPDB, which may affect performance of models that are more sensitive to overall characteristics of the word sequences. Therefore, after training on PPDB, we train the model for 10 more epochs on another source of data, called SimpWiki, which is a set of sentence pairs, automatically extracted from Simple English Wikipedia and English Wikipedia articles by Coster and Kauchak (2011). This dataset, consists of 167,689 sentence pairs, has been proved useful for semantic textual similarity task by Wieting and Gimpel (2017), although it was extracted for developing text simplification systems. When continuing to train on this dataset, we initialize the model with the parameters learned from PPDB, use the hyperparameters that maximize Pearson's r on the 2016 STS tasks and try dropout (Srivastava et al., 2014) on the word embeddings. Then, we again test CSE on all STS tasks and the SICK test set.

Results: In Table 1, we show the results of our model when trained on PPDB XL only. Particularly, this set of results is the median of five runs with random initialisations of the learnable parameters. As baseline, we compare to PP model (Wieting et al., 2016) since it is simple and proved to performs strongly in the STS and SICK tasks, and more importantly, it uses the same training dataset as CSE, which ensures a fair comparison. As we can see, CSE outperforms the baseline in the majority of datasets (14 out of 20) and in total average. We attribute the strong performance of CSE to the functional architecture which represents a sentence in terms of features that depend on words and n-grams. In contrast, PP model only extracts the features of words. But on very few datasets such as 2013 FNWN, our model performs poorly. Upon examination, two characteristics of this dataset may explain the poor performance: a).it

contains many sentence pairs of low similarity with low word overlap. But it is more likely for CSE to overestimate the similarity of sentences for capturing extra grammatical features of n-grams. b).most sentence pairs are very different in length. Since addition pooling differentiates more the length of sentences than mean pooling(or average), it is more difficult for CSE to determine the similarity of this kind of sentence pairs.

Table 2: Results on SemEval textual similarity datasets (Pearson's $r \times 100$) after CSE trained on SimpWiki. The highest score in each row is in boldface.

After CSE continues to be trained on SimpWiki, we compare it with two state-of-the-art models: ATT-CCG and GRAN. From Table 2, in the 19 datesets, tested by all three models, CSE outperforms the two other models on 10 datasets. In addition, on SICK 2014 test set, our model performs slightly better than GRAN, and on STS 2016 tasks, our average Pearson's r is 2.6 points higher than ATT-CCG. Our hypothesis explaining the strong performance is that when training our model on SimpWiki, we initialize it with the parameters learned from PPDB, which makes learning process easier.

4.2 Supervised Learning

To investigate whether CSE can also get strong performance in supervised setting, we evaluate it on the SICK 2014 dataset which contains 4,500 sentence pairs in the training set, 500 in the development

set, and 4,927 in the test set. We minimize the objective function[3] from Tai et al. (2015). Given a sentence pair $\langle s_1, s_2 \rangle$ with representations $\langle h_1, h_2 \rangle$ and a relatedness score y in the range $[1, K]$, they first compute:

$$\begin{aligned} h_* &= h_1 \oplus h_2, \\ h_+ &= |h_1 - h_2|, \\ h_s &= \sigma\left(W^{(*)} h_* + W^{(+)} h_+ + b^{(h)}\right), \\ \hat{p_\theta} &= softmax\left(W^{(p)} h_s + b^{(p)}\right), \\ \hat{y} &= r^T \hat{p_\theta}, \end{aligned}$$

Where $r^T = [1\ 2 \ldots K]$, θ represents model parameters. They then define a sparse target distribution p that satisfies $y = r^T p$:

$$p_i = \begin{cases} y - \lfloor y \rfloor, & \text{if } i = \lfloor y \rfloor + 1 \\ \lfloor y \rfloor - y + 1, & \text{if } i = \lfloor y \rfloor \\ 0, & \text{otherwise} \end{cases}$$

for $1 \leq i \leq K$. Finally, they use the regularized KL-divergence between p and $\hat{p_\theta}$ as cost function:

$$J(\theta) = \frac{1}{m} \sum_{k=1}^{m} KL\left(p^{(k)} \| \hat{p_\theta}^{(k)}\right) + \frac{\lambda}{2} \|\theta\|^2, \tag{6}$$

where m is the number of training pairs and the superscript k indicates the k-th sentence pair. For training, we initialize the supervised model with the parameters (including W_w and W_c) from Table 2, and regularize back to their initial values. Besides, we tune λ_w, λ_c and batch size same as in Section 4.1 and the extra hyperparameter $\lambda \in \{10^{-5}, 10^{-6}, 10^{-7}, 0\}$ in Eq. 6, referring to this setup as "universal". Again, we train the model for 10 epochs, using Adam optimizer with a learning rate of 0.001 and use Pearson's r index for validation. As a comparison, We also experiment with CSE with random initialization except initializing word embeddings W_w with PARAGRAM-SL999.

Table 3: Test results on the SICK dataset. Evaluation metrics are Pearson's r, Spearman's ρ, and mean squared error (*MSE*). The results of the first group are from SemEval 2014 systems. The best performance in each metric is in boldface.

The results are shown in Table 3. First, with random initialization, our model is not good enough, slightly better than models from SemEval 2014 systems and Constituency Tree-LSTM. But, initializing with universal parameters and regularizing back to them significantly improves the performance of our

[3]This objective function has been shown to perform very strongly on text similarity tasks, significantly better than squared or absolute error.

model, exceeding the state of the art on all of the three evaluation metrics. The results demonstrate that our universal sentence embeddings carry rich semantic information and therefore can be used as effective features for downstream tasks.

5 Analysis

5.1 Training Data Analysis

The quality of sentence embedding depends heavily on training data source, particularly when experimenting in transfer learning setting, since test examples are not drawn from the same distribution. Wieting and Gimpel (2017) found changing training data from PPDB to SimpWiki is an effective method for improving the performance of sentence model. But, in this paper, we also want to know if our model can get extra boost by cumulative learning, that is, learning on phrase pairs first, then on sentence pairs.

Dateset	CSE$_{phrase}$	CSE$_{sentence}$	CSE$_{cumulative}$
STS 2012 Average	**63.3**	62.0	63.0
STS 2013 Average	58.6	67.3	**68.8**
STS 2014 Average	72.1	75.0	**76.3**
STS 2015 Average	74.5	77.4	**78.6**

Table 4: Results on SemEval textual similarity datasets (Pearson's $r \times 100$). The highest score in each row is in boldface

To answer this question, we experiment with CSE, using phrase pairs dataset PPDB and sentence pairs dataset SimpWiki as training set. In Table 4, we show the results when CSE is trained on phrase or sentence pairs individually and a cumulative style of them two. First, we can see that it is better to use sentence pairs than phrase pairs for training since test sets are all sentences, which suggests CSE is sensitive to the overall characteristics of the word sequences, and the difference between train and test matters much. Otherwise, we find that CSE gains a large margin of performance improvement through the cumulative learning from phrase pairs to sentence pairs, justifying our claim that incremental learning is an important idea to gain extra improvements.

5.2 Filter Size Selecting

Dateset	1-gram	2-gram	3-gram	4-gram	combined
STS 2012 Average	*61.82*	61.53	61.44	60.73	**62.87**
STS 2013 Average	*63.06*	62.14	62.56	62.37	**64.26**
STS 2014 Average	***75.32***	73.61	73.52	73.39	74.26
STS 2015 Average	*76.45*	76.14	76.06	76.11	**76.99**
Total Average	*70.13*	69.29	69.28	69.04	**70.40**

Table 5: Results on SemEval textual similarity datasets (Pearson's $r \times 100$) where n-gram columns show the performance of CSE with filter windows of only size n. The highest score in each row is in boldface, and the highest score for the group of n-gram columns in each dateset is in italic

In this section, we explain how we choose the filter size of our model and analyze how big is the "n" on n-grams that it could be capturing. For comparison, we fix all the other hyperparameters except filter windows size.[4] Then we train the model with default Adam optimizer for 10 epochs, using SimpWiki as training data, STS 2016 for validation and STS 2012 to 2015 as test dataset. Results are shown in Table 5. From the first colunm group, we can see CSE with filter windows of size 1 performs much better than it with bigger window size, which indicates the meaning of words in a sentence plays a very important

[4]For qualitative explanation, we do not fine-tune the hyperparameters and simply fixed δ to 0.6, λ_w to 10^{-6}, λ_c to 0, and batch size to 100. Besides, we initialize the word embedding matrix (W_w) with PARAGRAM-SL999 embeddings and always keep the number of filters equal to 300.

role in composing the semantics of the sentence, which also proves why bag-of-words models like PP can have strong performance in STS tasks. In addition, with the window size increases, the performance of our model is getting poorer, and there is a significant drop in performance when n-gram comes to 4. Inspired by Kim (2014), we then try to combine filters with different window size for additional performance improvements. Simply choosing the three smallest filter windows size of 1, 2, 3 with 100 feature maps each leads us to better results, as shown in the *combined* column.

5.3 Error Analysis

#	Sentence A	Sentence B	CSE	PP	Gold
1	There are a lot of push up variations you can do and they all stress different muscle systems.	There are several different pushup variations out there and most of them provide a unique advantage.	**3.32**	3.14	4.2
2	the methodology takes much less time rather than naive methods.	this is a much quicker method than other more naive methods.	**4.88**	4.79	5.0
3	a boy plays with a noodle by the pool.	a boy plays with a foam noodle toy by a pool.	4.51	**4.61**	4.6
4	two hockey players fighting on the ice.	two hockey players in a struggle on the ice.	**4.78**	4.74	4.8
5	A group of sheep in a field.	A group of horses grazing in a field.	**3.86**	3.89	1.6
6	The lamb is looking at the camera.	A cat looking at the camera.	**3.89**	4.13	0.8
7	A person is riding their bike on a trail next to the woods.	A small child in a yellow shirt is holding their arms out to the sides.	2.63	**2.61**	0.4
8	A boy in a red sled is riding down the hill.	A multicolour dog in a red collar crouching on the grass.	3.29	**3.27**	0.0

Table 6: Illustrative sentence pairs from the STS datasets showing errors made by CSE and PP. The last three columns show the similarity score of CSE, the similarity score of PP, and the gold similarity score. Boldface indicates smaller error compared to gold standard scores.

In this section, we analyze the predictions of our model CSE and the average model PP on the STS datasets. After scaling the predicted cosine similarities into the range of [0, 5], We compare them to the gold standard scores. Examples are illustrated in Table 6. In the first group (examples 1 and 2), we found that when two sentences have a small amount of word overlap but similar meaning, CSE tends to make smaller error for taking the n-gram semantics into account. Then, just as we expected, when two sentences have a lot of word overlap, and have little differences in key semantic roles, PP performs better, as shown in example 3. But in example 4, we got the opposite result, our hypothesis explaining this result is that CNN architectures happen to be good at capturing semantic similarity between words and phrases (*fighting*, *in a struggle*). For the third group (examples 5 and 6), we inspect sentence pairs which have high word overlap rate but different meanings. Under this circumstance, the scores, predicted by CSE, are closer to the golds which suggests PP model is more easily fooled by the high amount of word overlap in such pairs and our model, CSE, is better able to recognize the semantic differences. But in last group (examples 7 and 8) where sentence pairs differ in meaning and have few words in common, CSE performs slightly worse than PP. We think this may due to its capability of capturing extra grammatical features, which leads it more likely to overestimate the similarity of sentences than bag-of-words models (or PP). In addition, from last two groups, both models tend to overestimate sentence pairs of low similarity which may be due to connections between words, whether grammatical or semantic.

6 Conclusion

We introduced a simple CNN architecture to create universal, paraphrastic sentence embeddings. Our model improves upon the state-of-the-art sentence representation models in transfer learning setting and exceeds the state of the art through initialization in the supervised setting. Furthermore, we analyzed the

advantages and disadvantages of our model, and found that it is better at capturing semantic similarity of two sentences than averaging models, especially when they have little word overlap but similar meanings. However, it tends to overestimate the low semantic similarity of a sentence pair. In addition, we released our trained model and codes to facilitate downstream tasks[5]. Future work could extend this model to related tasks including sentiment analysis, text classification and information retrieval.

Abstract

Due to the fact that Korean is a highly agglutinative, character-rich language, previous work on Korean morphological analysis typically employs the use of sub-character features known as graphemes or otherwise utilizes comprehensive prior linguistic knowledge (i.e., a dictionary of known morphological transformation forms, or actions). These models have been created with the assumption that character-level, dictionary-less morphological analysis was intractable due to the number of actions required. We present, in this study, a multi-stage action-based model that can perform morphological transformation and part-of-speech tagging using arbitrary units of input and apply it to the case of character-level Korean morphological analysis. Among models that do not employ prior linguistic knowledge, we achieve state-of-the-art word and sentence-level tagging accuracy with the Sejong Korean corpus using our proposed data-driven Bi-LSTM model.

Title and Abstract in Korean

한국어 형태소 분석 및 품사 부착에 효과적인 문자 단위 정보

한국어는 대표적인 교착어 중 하나이며, 문자 단위 정보의 중요도가 높다. 이에 따라 기존의 한국어 형태소 분석 연구는 자소 정보와 같은 문자 단위 자질을 사용하거나, 형태소 사전 및 변형 규칙과 같은 다량의 언어학적 지식을 활용하였다. 이러한 접근 방법은 사전을 사용하지 않은 문자 단위 형태소 분석은 변형 규칙의 복잡성으로 인해 불가능에 가깝다는 것을 전제로 하고 있다. 이러한 한계를 극복하고자, 본 연구에서는 어떠한 언어 단위도 입력으로 사용할 수 있으며 다단계 변형을 기반으로 형태소 분석 및 품사 부착을 수행하는 방법을 제안한다. 제안된 방법을 적용하여 구현된 데이터 기반 양방향 LSTM 모델의 성능을 세종 말뭉치를 이용하여 정량적으로 평가한 결과, 언어학적 지식을 활용하지 않은 접근 방법들 중 가장 높은 단어 및 문장 단위 부착 정확도를 보임을 확인하였다.

1 Introduction

Korean has traditionally posed a challenge for word segmentation and morphological analysis. In addition to virtually unbounded vocabulary sizes, out-of-vocabulary (OOV) rates for models can be high. Korean is an agglutinative, phonetic language with a SOV (Subject-Object-Verb) syntax and a flexible word order, although certain word orders are considered to be "canonical". Honorifics, conditionals, imperatives, and other forms are all signified using agglutinative endings which sometimes involve transformation of the stem to which they attach. Some endings can be further combined or fused to other endings in a defined order, and furthermore, morphological transformation rules also apply during this process. Transformation rules are mostly consistent at the grapheme level and can be represented by a handful of spelling rules, but many irregular forms do exist.

Table 2: Correct transformation and tag sequence for sample sentence containing ambiguous Eojeol "na-neun". # corresponds to correct parse sequence in Table 1, only labeled here for "na-neun".

In Unicode, Hangul (Korean alphabet) characters are allocated 11,140 codepoints. Each character contains an initial consonant, vowel, and final consonant represented in C+V+C, C+V, or V+C form. In Unicode, the form is always assumed to be C+V+C and the initial or final consonants are set to null according to the desired target form. Consonants and vowels are considered to be sub-character units called graphemes. Each character is represented using a combination of 19 initial consonants (including null), 21 vowels, and 27 final consonants (including null), and there is a mathematical formula that can be used to combine graphemes to generate the codepoint of a Hangul character. The character "김" (gim) can be represented in C+V+C form as follows.

Initial Consonant	Vowel	Final Consonant
ㄱ (g)	ㅣ (i)	ㅁ (m)

The Korean language has "fusion" spelling rules that apply across character boundaries (within an agglutinative unit), which implies that morphological transformation may occur among adjacent graphemes. When the final consonant of one character meets the initial consonant of the next character during verb inflection, there may be a change in the resulting combined character. This presents character-level embeddings with a unique challenge that is not present in most other languages.

In order to avoid confusion of terminology, we must define the precise meaning of morphological analysis in the context of Korean. For most languages, morphological analysis refers to a word-level tag that describes the aspect, tense, plurality, and other features of the word, whereas part-of-speech (POS) tagging serves to classify the word as a noun, verb, etc. The POS tag is sometimes concatenated to the morphological tag string as in the POSMORPH annotation employed by Heigold, et al (2016a).

In Korean, morphological analysis refers to the segmentation and restoration of morphemes within a "word" unit called an Eojeol and the POS tagging of each constituent morpheme. An Eojeol encodes not only lexical information but also grammatical information due to the agglutinative nature of the Korean language. The recovered morpheme segments often include a stem and other morphemes which indicate tense or other linguistic features. Traditional Korean morphological analysis algorithms operate at the Eojeol level and yield all ambiguous parses (Table 1) that lead to that particular Eojeol, including the morpheme transformations and tags. However, the model[1] proposed in this paper receives input at the sentence level and attempts to

[1]Model source code is made available at https://github.com/xtknight/rich-morphological-tagger

produce the one correct sequence of transformations and tags for all Eojeol within the sentence according to the context (Table 2).

2 Related Work

Morphological analysis of the Korean language has traditionally been performed in several ways, including separation of Korean characters into graphemes by using linguistic knowledge, lattice tree lookup (Park et al., 2010), application of regular and irregular inflection rules (Kang and Kim, 1992), morphosyntactic rule sets, and by using a pre-computed dictionary (Shim and Yang, 2004). However, we investigate whether morphological analysis of Korean is feasible without the use of any of these techniques and without a dictionary by making the assumption that common transformations and their underlying grapheme modifications can be easily recognized and learned with a Bi-LSTM model.

Bi-LSTM-CRFs have been used for sequential tagging with BIO annotation (Sang and Veenstra, 1999). Huang, et al (2015) show their effectiveness for POS tagging, chunking, named entity recognition (NER). These models show state-of-the-art accuracy at several tasks.

Similar models have also been proposed in universal morphological analysis. Heigold, et al (2016b) show how a nested LSTM architecture can be applied to word-level morphological tagging for a wide variety of languages. At the lower level, an LSTM network is used for character-level embedding to reduce OOV errors. However, this work does not investigate how such a model would operate for the most widely used Korean Sejong Corpus.

Sub-character tagging has also been attempted. Dong, et al (2016) demonstrate how radical-level features incorporated at the character-level for named entity recognition achieve state-of-the-art accuracy for Chinese. The most convincing attempt to tag Korean at the morpheme level is by Choi, et al (2016) who achieve state-of-the-art (dictionary-less) performance by using a multi-stage Bi-LSTM-CRF model that involves the splitting of Korean character input into constituent graphemes. However, the implicit assumption that Korean characters must first be split into graphemes to achieve optimal performance for morphological analysis is not well supported, and we should consider the splitting of characters into graphemes to be employing linguistic knowledge specific to Korean.

In our paper, we seek to answer the question of whether Korean morphemes can be tagged without grapheme-level splitting, rules specific to the language, or a dictionary. Although we initially considered Bi-LSTM-CRF for our model architecture, we show that the performance benefit by adding CRF is minimal and practically unnecessary compared to a standard Bi-LSTM model. Furthermore, CRF adds training and inference computational complexity due to the Viterbi algorithm.

3 Lemma and Form Alignment

고(go)	통(tong)	스(seu)	런(reon)
B-KEEP	I-KEEP	B-KEEP	I-MOD-렵, B-MOD-ㄴ
고통(go-tong)		스렵(seu-reob)	ㄴ(n)

Figure 1: Gold morphological transformation actions given by alignment oracle, including the resulting morphemes after running the BIO actions (Sejong corpus)

고통(go-tong)	스렵(seu-reob)	ㄴ(n)
NNG	XSA	ETM

Figure 2: Gold tagging actions (Sejong corpus)

In the Sejong corpus, Eojeol are annotated with their corresponding POS-tagged morpheme constituents, exactly as shown in Table 2. As mentioned earlier, morpheme spelling transformations may occur, and therefore the morpheme constituents may have slightly different graphemes than what is present in the original Eojeol form. To generate our training data, we must align the Eojeol form and its constituent morphemes at the character level, as we forbid using linguistic knowledge such as sub-character elements (graphemes) in our model. Like most agglutinative

languages, the Eojeol form and lemmas (morphemic elements in the Sejong corpus) often share overlapping characters at the beginning or end, and we utilize this assumption in our algorithm.

Gold Action	Count
B-KEEP	23,725,534
I-KEEP	8,650,166
B-MOD-하(ha), B-MOD-ㄴ(n)	153,130
NOOP	131,016
B-MOD:하(ha), B-MOD-았(ass)	61,592
B-MOD:이(i), B-MOD-ㄴ(n)	58,093
B-MOD:하(ha), B-MOD-아(a)	57,515
I-MOD:하(ha), B-MOD-아(a)	48,987
B-MOD:되(doe), B-MOD-ㄴ(n)	41,335
B-MOD:하(ha), B-MOD-ㄹ(l)	36,419

Table 3: Top 10 morphing actions

We present an action-based algorithm (called an "alignment oracle") to align two arbitrary strings. Our oracle attempts to generate a 1:1 character-level mapping between the morphological form and the lemmas of an Eojeol by searching for a prefix, suffix, and modified inner string portion. Three primary actions are defined: KEEP (no modification to character), NOOP (drop character), and MOD (modify character). In the case of Korean, morphological transformations happen at the end of a form, so there is rarely a common suffix unless no transformation occurs at all. These primary actions are then augmented with B- and I- actions to facilitate morpheme segmentation. It is important to note that our algorithm is not specific in any way to the Sejong corpus or Korean itself.

The full process is demonstrated in Figure 1 starting from the source form. The gold untagged segmented lemma form is shown in the bottom row, and the actions generated by the oracle to generate the lemma are given in the middle row. The first three characters (go-tong-seu) are preserved with KEEP actions and the last character is considered the "modified inner string". In this case, the number of actions (5) exceeds the number of full input characters (4), and therefore two actions are assigned to the last character which split the "reon" syllable into "reob" and "n". The output after morpheme segmentation can be seen in the bottom row. In Figure 2, these output morphemes are then placed through a standard sequential tagger to assign part-of-speech tags.

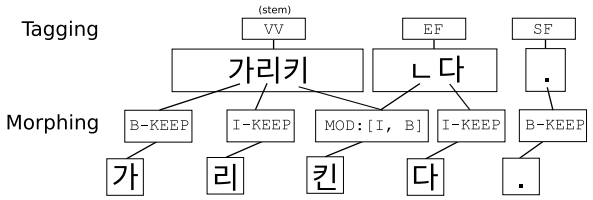

Figure 3: Actions for transformation with output segmentation

For Korean, the task is considerably more complicated. Rather than merely character-level transformation, new morpheme boundaries based on the results of those transformations are also required. A segmentation module adds B-/I- (beginning and inside) annotations to the KEEP and MOD actions. These actions allow morpheme segmentation to take place even amidst the modified character output sequence. This is detailed in Figure 1, where the final consonant sub-character unit ("n") of the last character of input ("reon") is transformed to "b" and the resulting fused full character is appended to the previous output morpheme, whereas the "n"

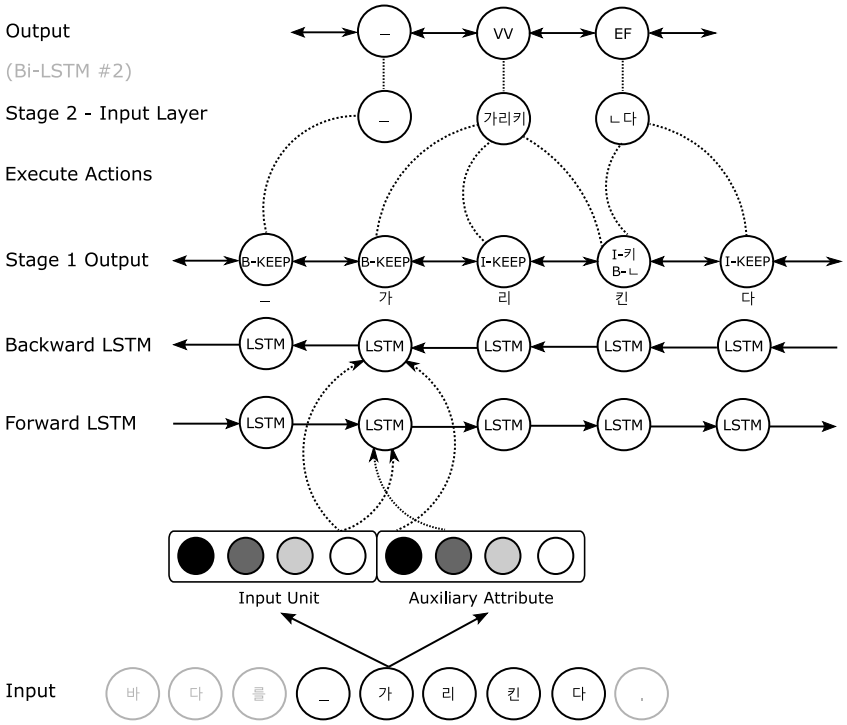

Figure 4: Partial example of two-stage tagging process for Korean phrase "to point out the sea"

sub-character unit becomes separated and represented as an entirely new morpheme itself. The top 10 resulting actions for the Sejong corpus on the form and lemma alignment stage are shown in Table 3.

4 The Model

Our model makes the assumption that in order to support morphological analysis for languages like Korean, two stages are required, which we call morphing and tagging. For tasks such as morphological transformation, word-level morphological analysis, or morpheme segmentation, only one stage is strictly necessary. To obtain tags for morphemes following morphological transformation, as in Korean, both stages are necessary, with tagging following morphing. The stages have no fundamental difference from each other: the second stage simply acts on the result of applying actions output by the first stage. Each stage outputs a single action for a single input unit. A single action could be as simple as a tag or as complicated as information resulting in advanced multi-character transformation along with the specification of the morphemic segments of those resulting characters. Model parameters are trained independently for each stage unless otherwise specified.

The model presented in this paper is inspired by word-level morphological analysis work by Heigold, et al (2016a) with the goal of allowing analysis at arbitrary units of input at each stage. Because we do not specify whether the input unit should be a word, morpheme, character, or even a unit at the sub-character level (such as graphemes in Korean or radicals in Chinese), we theoretically have the flexibility to tag a variety of languages at any level.

We employ a bidirectional Long Short-Term Memory (Hochreiter and Schmidhuber, 1997; Graves and Schmidhuber, 2005) network in our model and also experiment with optimization to a conditional random field (CRF) objective (Lafferty et al., 2001). In theory, CRF allows us to consider the likelihood of neighboring outputs and therefore jointly decode the highest probable chain of output labels for a given set of inputs. Although we posit that CRF is not strictly necessary, the overall architecture of our model is otherwise identical to a standard Bi-LSTM-CRF sequence tagging model (Huang et al., 2015) used for POS tagging and NER.

An overview of the architecture is shown in Figure 4. The input unit is embedded as a multi-dimensional vector. At the input level, an auxiliary attribute may be concatenated with the input unit to include auxiliary information for the unit, such as word break-level information, although empirical findings indicate our model performs best when using only the input unit. Nested embeddings as in (2016a) may also be appended at the input level.

All embeddings are concatenated to form a combined embedding which is then passed to the primary Bi-LSTM-CRF network and trained against a set of output actions. Whitespace delimiting Eojeols is represented as a reserved spacing token in the input unit.

Although each stage is independent and can accept an arbitrary unit of input suitable for any language, the following sections describe how this model pertains to our primary task of morpheme-level morphological analysis for the Korean language.

4.1 Morphing

The first stage of the model operates at the character level and is responsible for morphological transformation of the input form into the desired output lemma(s). During training, each input character is assigned one of three primary types by the alignment oracle as described in Section 3. Morpheme segmentation actions are also generated and augmented to the transformation actions at this stage for proper morpheme boundary identification. During inference, instead of using the alignment oracle, one action (including transformation and B-/I- tags) is predicted for each character based on trained parameters. At this point, tags are not yet assigned to each output morpheme.

4.2 Tagging

After the necessary morphological transformation and segmentation, tagging occurs at the morpheme level and acts on output produced by actions in the first stage of the model. An example of this is shown in Figure 2. In this stage, the action is simply to assign a POS tag to the morpheme, which is the input unit.

5 Experiments

5.1 Datasets

We conduct experiments using the full Sejong Korean Balanced Corpus dataset. The experiments are coded in Python using the TensorFlow library. The Sejong Corpus has been preprocessed to resolve punctuation inconsistencies and other surface-level errors. All datasets are converted at the sentence-level to a simple two-column format with each line containing an input unit and target action.

For all experiments, we follow an 85/10/5 cross-validation split for training, testing, and validation sets respectively. All data is randomly shuffled prior to splitting. Actions are inferred from the dataset by using lemma and form alignment. For evaluation, output from predicted actions in the first stage is used as input to the subsequent stage.

UniTagger represents the model proposed in this paper. The following number (for example, 500) represents the maximum action count for the morphing stage. The tagging stage only has as many actions as possible POS tags (45 in the Sejong corpus, including the reserved space token). Action pruning is performed at the training level, which removes from the training set the least common morphological transformation actions generated by the alignment oracle. For fair evaluation, actions are not removed from validation or test sets. All accuracy figures in this paper are reported based on a held-out test set.

5.2 Training

Optimization is performed using Adam (Kingma and Ba, 2014) with a learning rate of 0.001 and decay of 0.9. In the case of multi-stage models, model parameters are optimized independently for each stage. We use identical hyperparameters for all morphing and tagging models. Input

unit embedding size was set to 300 (for character and morpheme input). The final Bi-LSTM concatenating all embeddings before an optional CRF layer was used with an LSTM unit size of 300. Batch size was set to 64 for all experiments, except for the CRF experiment where it was set to 16. The maximum LSTM input length was set at a per-batch level which yielded optimal performance, and the maximum number of input units (whether characters or morphemes) was limited to 400 in both stages. A dropout of 10% was used for the reported model with best performance. Dropout is only applied at the unit embedding layer. Epoch count was set to 100 with early-stopping after 3 epochs with no improvement in validation set performance. Experiments were performed on GTX 1080 Ti 11GB GPUs. Average total training duration was around 5 hours for the entire Sejong dataset on a GTX 1080 Ti. In TensorFlow, the NVIDIA CuDNN-optimized LSTM was used (Appleyard et al., 2016).

5.3 Results

In Table 4, we show Eojeol-level morphological analysis accuracy for Korean. Note here that an Eojeol is considered correctly tagged only if all its constituent morphemes have been transformed, segmented, and tagged properly. Table 5 measures sentence-level tagging performance, which is the accuracy of all morphemes being transformed and tagged properly.

5.4 Analysis and Discussion

Our results show that our model can outperform previous state-of-the-art performance for Eojeol and sentence-level morphological analysis of Korean without linguistic knowledge.

When the dropout factor is adjusted, all metrics follow a similar trend as seen in Figure 5. Sentence accuracy is most sensitive to dropout factor adjustment. Best performance is achieved

with a dropout rate of 10%, and increasing the dropout rate further does not increase Eojeol-level OOV accuracy. This is a positive finding, as it indicates the model is not considerably overfitting to the training data beyond approximately the 10% level.

In Figure 6, a 300-dimensional unit embedding layer of the morphing stage is visualized using 2-component t-SNE. The corresponding gold actions are shown in Table 6, where all past tense morphemes end with final consonant "ㅆ" (ss). The model is able to infer that most of the forms shown in the graph represent the past tense and that they share a similar transformation pattern at the final consonant grapheme level. This shows that our model is able to correlate similar sub-character level morphological transformations even when operating at the character level. Furthermore, it is worth noting that Chinese characters still occur rarely in the Korean language in certain contexts. We can see Chinese characters grouped in a cluster, which shows that the model is able to distinguish one character-rich language (Korean) from another (Chinese). Other characters, such as punctuation, are also grouped by type in largely distinct clusters with occasional overlap.

Joint training of both stages was also attempted, though an initial investigation suggests that performance is not significantly different from training each stage's parameters independently.

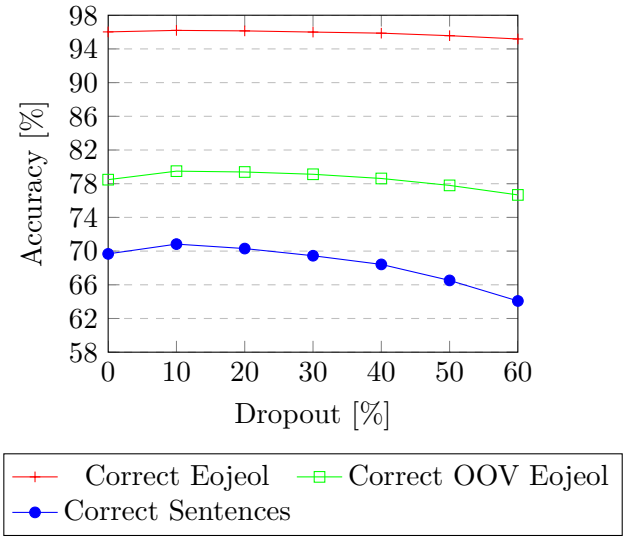

Figure 5: Impact of dropout on end-to-end tagging performance

The use of using an auxiliary binary break level attribute to represent whitespace was also investigated, but significantly higher accuracy was achieved by using a reserved spacing token instead. Despite the auxiliary break level attribute embedding, both stages of the model have a tendency to learn ambiguous morpheme transformations for adjacent Eojeol. In other words, even though the morpheme transformation and tags are correct, the Eojeol boundaries were incorrectly identified. With the reserved spacing token, this issue was extremely rare.

6 Conclusion and Future Work

In this work, we address the commonly held notion that Korean can not be tagged with competitive performance at the character level without prior linguistic knowledge. Our model architecture is not novel compared to previous work. The novelty of our morphological analyzer is its striking simplicity compared to previous approaches for character-rich languages such as Korean. The alignment oracle does not require any cost value for alignment operations such as in the Needleman–Wunsch algorithm (Needleman and Wunsch, 1970). The Bi-LSTM model is able to learn and utilize alignments that are purely arbitrary and apply them to unseen test data. Even when significantly limiting the number of actions in the training data, we show that by using the most common morphological transformation actions in an agglutinative language, we can

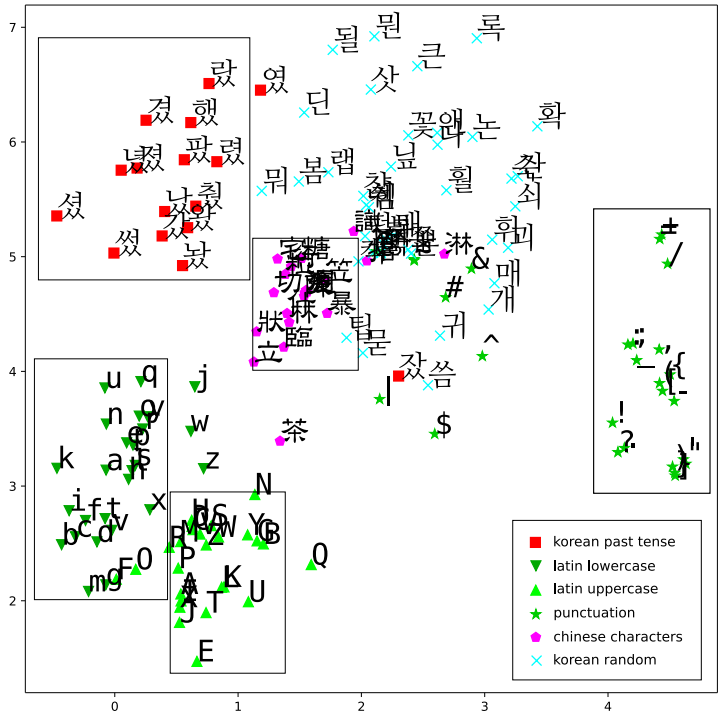

Figure 6: Deep embeddings of characters at the morphing stage (t-SNE)

exceed the performance of a model that uses linguistic knowledge such as sub-character features. We also show that the widely used CRF layer may in fact be unnecessary for high performance and add unnecessary computational complexity. This exceeded our own expectations and raises the possibility that a single architecture can handle tagging universally with only two simple Bi-LSTM stages. We contribute the necessary source code to replicate the experiments and to attempt alignment and training for any other language, assuming a corpus exists. Nevertheless, there are several points that future work should address.

Out-of-vocabulary morphemes generated by the morphing stage can also result in errors at the tagging stage, as the tagging stage was trained on the assumption of gold morphemes. We would like to experiment with including possible morpheme transformation errors at the tagging stage to determine if tagging performance can be improved.

We attempted joint training but found that end-to-end accuracy was marginally lower. We suspect this is because optimization of each individual stage is hindered by attempting to find optimal parameters for both stages. Future work should attempt joint training of an end-to-end model with the preinitialized parameters from optimizing each stage independently, which has been shown to be ideal in sequential models (Tang et al., 2016).

Lastly, although we are unaware of a language more character-rich and more morphologically complex than Korean, we would like to see our model applied to other morphologically complex languages to prove its universality. At the time of writing, we lacked sufficient baseline figures and methodology for generating training data for analyzing other languages at the morpheme level using the Universal Dependencies corpus, and the morphological tags were often conflated with part-of-speech tags. The baselines we found did not specify whether or not morpheme segmentation was taken into account. Without this information, it would be difficult to prove the performance of our model for other languages and we decided to leave training other languages as future work. That being said, our model does not employ any linguistic knowledge specific to Korean, and we therefore have no reason to believe it cannot be trained on any other arbitrary corpus with minor modifications at the preprocessing level.

Abstract

Representing the semantic relations that exist between two given words (or entities) is an important first step in a wide-range of NLP applications such as analogical reasoning, knowledge base completion and relational information retrieval. A simple, yet surprisingly accurate method for representing a relation between two words is to compute the vector offset (PairDiff) between their corresponding word embeddings. Despite the empirical success, it remains unclear as to whether PairDiff is the best operator for obtaining a relational representation from word embeddings. We conduct a theoretical analysis of generalised bilinear operators that can be used to measure the ℓ_2 relational distance between two word-pairs. We show that, if the word embeddings are standardised and uncorrelated, such an operator will be independent of bilinear terms, and can be simplified to a linear form, where PairDiff is a special case. For numerous word embedding types, we empirically verify the uncorrelation assumption, demonstrating the general applicability of our theoretical result. Moreover, we experimentally discover PairDiff from the bilinear relational compositional operator on several benchmark analogy datasets.

1 Introduction

Different types of semantic relations exist between words such as HYPERNYMY between *ostrich* and *bird*, or ANTONYMY between *hot* and *cold*. If we consider entities[1], we can observe even a richer diversity of relations such as FOUNDER-OF between *Bill Gates* and *Microsoft*, or CAPITAL-OF between *Tokyo* and *Japan*. Identifying the relations between words and entities is important for various Natural Language Processing (NLP) tasks such as automatic knowledge base completion (Socher et al., 2013), analogical reasoning (Turney and Littman, 2005; Bollegala et al., 2009) and relational information retrieval (Duc et al., 2010). For example, to solve a word analogy problem of the form "*a* is to *b* as *c* is to *?*", the relationship between the two words in the pair (a, b) must be correctly identified in order to find candidates d that have similar relations with c. For example, given the query "*Bill Gates* is to *Microsoft* as *Steve Jobs* is to *?*", a relational search engine must retrieve *Apple Inc.* because the FOUNDER-OF relation exists between the first and the second entity pairs.

Two main approaches for creating relation embeddings can be identified in the literature. In the first approach, from given corpora or knowledge bases, word and relation embeddings are *jointly* learnt such that some objective is optimised (Guo et al., 2016; Yang et al., 2015; Nickel et al., 2016; Bordes et al., 2013; Rocktäschel et al., 2016; Minervini et al., 2017; Trouillon et al., 2016). In this approach, word and relation embeddings are considered to be *independent* parameters that must be learnt by the embedding method. For example, TransE (Bordes et al., 2013) learns the word and relation embeddings such that we can accurately predict relations (links) in a given knowledge base using the learnt word and relation embeddings. Because relations are learnt independently from the words, we refer to methods that are based on this approach as *independent* relational embedding methods.

[1] We interchangeably use the terms *word* and *entity* to represent both unigrams as well as a multi-word expressions including named entities.

Proceedings of the 27th International Conference on Computational Linguistics, pages 2493–2504
Santa Fe, New Mexico, USA, August 20-26, 2018.

A second approach for creating relational embeddings is to apply some operator on two word embeddings to *compose* the embedding for the relation that exits between those two words, if any. In contrast to the first approach, we do not have to learn relational embeddings and hence this can be considered as an unsupervised setting, where the compositional operator is predefined. A popular operator for composing a relational embedding from two word embeddings is PairDiff, which is the vector difference (offset) of the word embeddings (Mikolov et al., 2013b; Levy and Goldberg, 2014; Vylomova et al., 2016; Bollegala et al., 2015b; Blacoe and Lapata, 2012). Specifically, given two words a and b represented by their word embeddings respectively $\boldsymbol{a}$ and $\boldsymbol{b}$, the relation between a and b is given by $\boldsymbol{a} - \boldsymbol{b}$ under the PairDiff operator. Mikolov et al. (2013b) showed that PairDiff can accurately solve analogy equations such as $\overrightarrow{\mathbf{king}} - \overrightarrow{\mathbf{man}} + \overrightarrow{\mathbf{woman}} = \overrightarrow{\mathbf{queen}}$, where we have used the top arrows to denote the embeddings of the corresponding words. Bollegala et al. (2015a) showed that PairDiff can be used as a proxy for learning better word embeddings and Vylomova et al. (2016) conducted an extensive empirical comparison of PairDiff using a dataset containing 16 different relation types. Besides PairDiff, concatenation (Hakami and Bollegala, 2017; Yin and Schütze, 2016), circular correlation and convolution (Nickel et al., 2016) have been used in prior work for representing the relations between words. Because the relation embedding is composed using word embeddings instead of learning as a separate parameter, we refer to methods that are based on this approach as *compositional* relational embedding methods. Note that in this approach it is implicitly assumed that there exist only a single relation between two words.

In this paper, we focus on the operators that are used in compositional relational embedding methods. If we assume that the words and relations are represented by vectors embedded in some common space, then the operator we are seeking must be able to produce a vector representing the relation between two words, given their word embeddings as the only input. Although there have been different proposals for computing relational embeddings from word embeddings, it remains unclear as to what is the best operator for this task. The space of operators that can be used to compose relational embeddings is open and vast. A space of particular interest from a computational point-of-view is the bilinear operators that can be parametrised using tensors and matrices. Specifically, we consider operators that consider pairwise interactions between two word embeddings (second-order terms) and contributions from individual word embeddings towards their relational embedding (first-order terms). The optimality of a relational compositional operator can be evaluated, for example, using the expected relational distance/similarity such as ℓ_2 between analogous (positive) vs. nonanalogous (negative) word-pairs.

If we assume that word embeddings are standardised, uncorrelated and word-pairs are i.i.d, then we prove in §3 that bilinear relational compositional operators are independent of bilinear pairwise interactions between the two input word embeddings. Moreover, under regularised settings (§3.1), the bilinear operator further simplifies to a linear combination of the input embeddings, and the expected loss over positive and negative instances becomes zero. In §4.1, we empirically validate the uncorrelation assumption for different pre-trained word embeddings such as the Continuous Bag-of-Words Model (CBOW) (Mikolov et al., 2013a), Skip-Gram with negative sampling (SG) (Mikolov et al., 2013a), Global Vectors (GloVe) (Pennington et al., 2014), word embeddings created using Latent Semantic Analysis (LSA) (Deerwester et al., 1990), Sparse Coding (HSC) (Faruqui et al., 2015; Yogatama et al., 2015), and Latent Dirichlet Allocation (LDA) (Blei et al., 2003). This empirical evidence implies that our theoretical analysis is applicable to relational representations composed from a wide-range of word embedding learning methods. Moreover, our experimental results show that a bilinear operator reaches its optimal performance in two different word-analogy benchmark datasets, when it satisfies the requirements of the PairDiff operator. We hope that our theoretical analysis will expand the understanding of relational embedding methods, and inspire future research on accurate relational embedding methods using word embeddings as the input.

2 Related Work

As already mentioned in §1, methods for representing a relation between two words can be broadly categorised into two groups depending on whether the relational embeddings are learnt *independently* of the word embeddings, or they are *composed* from the word embeddings, in which case the relational

embeddings fully depend on the input word embeddings. Next, we briefly overview the different methods that fall under each category. For a detailed survey of relation embedding methods see Nickel et al. (2015).

Given a knowledge base where an entity h is linked to an entity t by a relation r, the TransE model (Bordes et al., 2013) scores the tuple (h, t, r) by the ℓ_1 or ℓ_2 norm of the vector $(\boldsymbol{h} + \boldsymbol{r} - \boldsymbol{t})$. Nickel et al. (2011) proposed RESCAL, which uses $\boldsymbol{h}^\top \mathbf{M}_r \boldsymbol{t}$ as the scoring function, where $\mathbf{M}_r$ is a matrix embedding of the relation r. Similar to RESCAL, Neural Tensor Network (Socher et al., 2013) also models a relation by a matrix. However, compared to vector embeddings of relations, matrix embeddings increase the number of parameters to be estimated, resulting in an increase in computational time/space and likely to overfit. To overcome these limitations, DistMult (Yang et al., 2015) models relations by vectors and use elementwise multilinear dot product $\boldsymbol{r} \odot \boldsymbol{h} \odot \boldsymbol{t}$. Unfortunately, DistMult cannot capture directionality of a relation. Complex Embeddings (Trouillon et al., 2016) overcome this limitation of DistMult by using complex embeddings and defining the score to be the real part of $\boldsymbol{r} \odot \boldsymbol{h} \odot \bar{\boldsymbol{t}}$, where $\bar{\boldsymbol{t}}$ denotes the complex conjugate of $\boldsymbol{t}$.

The observation made by Mikolov et al. (2013b) that the relation between two words can be represented by the difference between their word embeddings sparked a renewed interest in methods that compose relational embeddings using word embeddings. Word analogy datasets such as Google dataset (Mikolov et al., 2013b), SemEval 2012 Task2 dataset (Jurgens et al., 2012), BATS (Drozd et al., 2016) etc. have established as benchmarks for evaluating word embedding learning methods.

Different methods have been proposed to measure the similarity between the relations that exist between two given word pairs such as CosMult, CosAdd and PairDiff (Levy and Goldberg, 2014; Bollegala et al., 2015a). Vylomova et al. (2016) studied as to what extent the vectors generated using simple PairDiff encode different relation types. Under supervised classification settings, they conclude that PairDiff can cover a wide range of semantic relation types. Holographic embeddings proposed by Nickel et al. (2016) use circular convolution to mix the embeddings of two words to create an embedding for the relation that exist between those words. It can be showed that circular correlation is indeed an elementwise product in the Fourier space and is mathematically equivalent to complex embeddings (Hayashi and Shinbo, 2017).

Although PairDiff operator has been widely used in prior work for computing relation embeddings from word embeddings, to the best of our knowledge, no theoretical analysis has been conducted so far explaining why and under what conditions PairDiff is optimal, which is the focus of this paper.

3 Bilinear Relation Representations

Let us consider the problem of representing the semantic relation $\boldsymbol{r}(\boldsymbol{h}, \boldsymbol{t})$ between two given words h and t. We assume that h and t are already represented in some d-dimensional space respectively by their word embeddings $\boldsymbol{h}, \boldsymbol{t} \in \mathbb{R}^d$. The relation between two words can be represented using different linear algebraic structures. Two popular alternatives are vectors (Nickel et al., 2016; Bordes et al., 2013; Minervini et al., 2017; Trouillon et al., 2016) and matrices (Socher et al., 2013; Bollegala et al., 2015b). Vector representations are preferred over matrix representations because of the smaller number of parameters to be learnt (Nickel et al., 2015).

Let us assume that the relation r is represented by a vector $\boldsymbol{r} \in \mathbb{R}^\delta$ in some δ-dimensional space. Therefore, we can write $\boldsymbol{r}(\boldsymbol{h}, \boldsymbol{t})$ as a function that takes two vectors (corresponding to the embeddings of the two words) as the input and returns a single vector (representing the relation between the two words) as given in (1).

$$\boldsymbol{r}: \mathbb{R}^d \times \mathbb{R}^d \rightarrow \mathbb{R}^\delta \tag{1}$$

Having both words and relations represented in the same $\delta = d$ dimensional space is useful for performing linear algebraic operations using those representations in that space. For example, in TransE (Bordes et al., 2013), the strength of a relation r that exists between two words h and t is computed as the $\ell_{1,2}$ norm of the vector $(\boldsymbol{h} + \boldsymbol{r} - \boldsymbol{t})$ using the word and relation embeddings. Such direct comparisons between word and relation embeddings would not be possible if words and relations were not embedded in the

same vector space. If $\delta < d$, we can first project word embeddings to a lower δ-dimensional space using some dimensionality reduction method such as SVD, whereas if $\delta > d$ we can learn higher δ-dimensional overcomplete word representations (Faruqui et al., 2015) from the original d-dimensional word embeddings. Therefore, we will limit our theoretical analysis to the $\delta = d$ case for ease of description.

Different functions can be used as $\boldsymbol{r}(\boldsymbol{h}, \boldsymbol{t})$ that satisfy the domain and range requirements specified by (1). If we limit ourselves to bilinear functions, the most general functional form is given by (2).

$$\boldsymbol{r}(\boldsymbol{h}, \boldsymbol{t}) = \boldsymbol{h}^\top \underline{\mathbf{A}} \boldsymbol{t} + \mathbf{P}\boldsymbol{h} + \mathbf{Q}\boldsymbol{t} \tag{2}$$

Here, $\underline{\mathbf{A}} \in \mathbb{R}^{d \times d \times d}$ is a 3-way tensor in which each slice is a $d \times d$ real matrix. Let us denote the k-th slice of $\underline{\mathbf{A}}$ by $\mathbf{A}^{(k)}$ and its (i, j) element by $A_{ij}^{(k)}$. The first term in (2) corresponds to the pairwise interactions between $\boldsymbol{h}$ and $\boldsymbol{t}$. $\mathbf{P}, \mathbf{Q} \in \mathbb{R}^{d \times d}$ are the nonsingular[2] projection matrices involving first-order contributions respectively of $\boldsymbol{h}$ and $\boldsymbol{t}$ towards $\boldsymbol{r}$.

Let us consider the problem of learning the simplest bilinear functional form according to (2) from a given dataset of analogous word-pairs $\mathcal{D}_+ = \{((h, t), (h', t'))\}$. Specifically, we would like to learn the parameters $\underline{\mathbf{A}}$, $\mathbf{P}$ and $\mathbf{Q}$ such that some distance (loss) between analogous word-pairs is minimised. As a concrete example of a distance function, let us consider the popularly used Euclidean distance[3] (ℓ_2 loss) for two word pairs given by (3).

$$J((h, t), (h', t')) = \left|\left|\boldsymbol{r}(\boldsymbol{h}, \boldsymbol{t}) - \boldsymbol{r}(\boldsymbol{h'}, \boldsymbol{t'})\right|\right|_2^2 \tag{3}$$

If we were provided only analogous word-pairs (i.e. positive examples), then this task could be trivially achieved by setting all parameters to zero. However, such a trivial solution would not generalise to unseen test data. Therefore, in addition to $\mathcal{D}_+$ we would require a set of non-analogous word-pairs $\mathcal{D}_-$ as negative examples. Such negative examples are often generated in prior work by randomly corrupting positive relational tuples (Nickel et al., 2016; Bordes et al., 2013; Trouillon et al., 2016) or by training an adversarial generator (Minervini et al., 2017).

The total loss J over both positive and negative training data can be written as follows:

$$J = \sum_{((h,t),(h',t')) \in \mathcal{D}_+} \left|\left|\boldsymbol{r}(\boldsymbol{h}, \boldsymbol{t}) - \boldsymbol{r}(\boldsymbol{h'}, \boldsymbol{t'})\right|\right|_2^2 - \sum_{((h,t),(h',t')) \in \mathcal{D}_-} \left|\left|\boldsymbol{r}(\boldsymbol{h}, \boldsymbol{t}) - \boldsymbol{r}(\boldsymbol{h'}, \boldsymbol{t'})\right|\right|_2^2 \tag{4}$$

Assuming that the training word-pairs are randomly sampled from $\mathcal{D}_+$ and $\mathcal{D}_-$ according to two distributions respectively p_+ and p_-, we can compute the total expected loss, $\mathbb{E}_p[J]$, as follows:

$$\mathbb{E}_p[J] = \mathbb{E}_{p_+}\left[\left|\left|\boldsymbol{r}(\boldsymbol{h}, \boldsymbol{t}) - \boldsymbol{r}(\boldsymbol{h'}, \boldsymbol{t'})\right|\right|_2^2\right] - \mathbb{E}_{p_-}\left[\left|\left|\boldsymbol{r}(\boldsymbol{h}, \boldsymbol{t}) - \boldsymbol{r}(\boldsymbol{h'}, \boldsymbol{t'})\right|\right|_2^2\right] \tag{5}$$

We make the following assumptions to further analyse the properties of relational embeddings.

Uncorrelation: The correlation between any two distinct dimensions of a word embedding is zero. One might think that the uncorrelation of word embedding dimensions to be a strong assumption, but we later show its validity empirically in §4.1 for a wide range of word embeddings.

Standardisation: Word embeddings are standardised to zero mean and unit variance. This is a linear transformation in the word embedding space and does not affect the topology of the embedding space. In particular, translating word embeddings such that they have a zero mean has shown to improve performance in similarity tasks Mu et al. (2018).

Relational Independence Word pairs in the training data are assumed to be i.i.d. For example, whether a particular semantic relation r exists between h and t, is assumed to be independent of any other relation r' that exists between h' and t' in a different pair. For example, (*ostrich*, is-a-large, *bird*) is independent from (*Trump*, president-of, *USA*).

[2] If the projection matrix is nonsingular, then the inverse projection exists, which preserves the dimensionality of the embedding space.

[3] For ℓ_2 normalised vectors, their Euclidean distance is a monotonously decreasing function of their cosine similarity.

For relation representations given by (2), 1 holds:

Theorem 1. *Consider the bilinear relational embedding defined by 2 computed using uncorrelated word embeddings. If the word embeddings are standardised, then the expected loss given by 5 over a relationally independent set of word pairs is independent of* $\underline{\mathbf{A}}$.

Proof. Let us consider the bilinear term in (2), because i and $j(\neq i)$ dimensions of word embeddings are uncorrelated by the assumption (i.e. $\text{corr}(u_i, u_j) = 0$), from the definition of correlation we have,

$$\text{corr}(u_i, u_j) = \mathbb{E}[u_i u_j] - \mathbb{E}[u_i]\mathbb{E}[u_j] = 0 \tag{6}$$

$$\mathbb{E}[u_i u_j] = \mathbb{E}[u_i]\mathbb{E}[u_j]. \tag{7}$$

Moreover, from the standardisation assumption we have, $\mathbb{E}[u_i] = 0, \ \ \forall_{i=1\ldots n}$. From (7) it follows that:

$$\mathbb{E}[u_i u_j] = 0 \tag{8}$$

for $i \neq j$ dimensions.

We will next show that (5) is independent of $\underline{\mathbf{A}}$. For this purpose, let us consider the $\mathbb{E}_{p_+}$ term first and write the k-th dimension of $\boldsymbol{r}(\boldsymbol{h}, \boldsymbol{t})$ using $\mathbf{A}^{(k)}$, $\mathbf{P}$ and $\mathbf{Q}$ as follows:

$$\sum_{i,j} \left(A^{(k)}_{ij} h_i t_j \right) + \sum_n P_{kn} h_n + \sum_n Q_{kn} t_n \tag{9}$$

Plugging (9) in (5) and computing the loss over all positive training instances we get,

$$\mathbb{E}_{p_+}[\sum_k (\sum_{i,j} \left(A^{(k)}_{ij} (h_i t_j - h'_i t'_j) \right) + \sum_n P_{kn}(h_n - h'_n) + \sum_n Q_{kn}(t_n - t'_n))^2] \tag{10}$$

Terms that involve only elements in $\mathbf{A}^{(k)}$ take the form:

$$\begin{aligned} &\sum_{i,j} \sum_{l,m} \mathbb{E}_{p_+} \left[A^{(k)}_{ij} A^{(k)}_{lm} (h_i t_j - h'_i t'_j)(h_l t_m - h'_l t'_m) \right] \\ &= \sum_{i,j} \sum_{l,m} A^{(k)}_{ij} A^{(k)}_{lm} (\mathbb{E}_{p_+}[h_i t_j h_l t_m] - \mathbb{E}_{p_+}[h_i t_j h'_l t'_m] - \mathbb{E}_{p_+}[h'_i t'_j h_l t_m] + \mathbb{E}_{p_+}[h'_i t'_j h'_l t'_m]) \end{aligned} \tag{11}$$

Lets first analyse the cases where $i \neq j$ and $l \neq m$. Because of the relational independence assumption, the second and the third expectations in (11) can be written as follows: $\mathbb{E}_{p_+}[h_i t_j]\mathbb{E}_{p_+}[h'_l t'_m]$ and $\mathbb{E}_{p_+}[h'_i t'_j]\mathbb{E}_{p_+}[h_l t_m]$, respectively. Each of the these expectations contains the product of different dimensionalities in two different words. Expected correlation of different dimensions in the same word is zero from (8). Therefore, such cross-correlations are likely to be small for different word pairs, which are nonsynomyous. On the other hand, first and fourth expectations in (11) involve the same pair of words. For example, we could write the first expectation as follows:

$$\mathbb{E}_{p_+}[h_i t_j h_l t_m] = \mathbb{E}_{p_+}[(h_i h_l)(t_j t_m) = \mathbb{E}_{p_+}[H_{il} T_{jm}]$$

where $H = h_i h_l$ and $T_{jm} = t_j t_m$. If we think of $\boldsymbol{H}$ and $\boldsymbol{T}$ as d^2-dimensional word embeddings, $\mathbb{E}_{p_+}[H_{il} T_{jm}]$ represents the expectation over two distinct dimensions of $\boldsymbol{H}$ and $\boldsymbol{T}$ for $il \neq jm$. Therefore, from the same logic as above, this expectation is approximately zero.[4]

For $i = j = l = m$ case we have,

$$A^{(k)2}_{ij} (\mathbb{E}_{p_+}[h_i^2 t_i^2] - 2\mathbb{E}_{p_+}[h_i t_i h'_i t'_i] + \mathbb{E}_{p_+}[h'^2_i t'^2_i]) \tag{12}$$

[4]Note that il could be equal to jm even when $i \neq j$ and $l \neq m$. However, such cases will be a rare minority. Nevertheless, it is an approximation and not an exact zero.

Because we are considering word-pairs (h, t) for which a relation r is known to hold, from the definition of the correlation between the same dimension in different words we have:

$$\text{corr}(h_i^2, t_i^2) = \mathbb{E}[h_i^2 t_i^2] - \mathbb{E}[h_i^2]\mathbb{E}[t_i^2] = 1$$
$$\mathbb{E}[h_i^2 t_i^2] = \mathbb{E}[h_i^2]\mathbb{E}[t_i^2] + 1$$

Because $\mathbb{E}[h_i^2] = \mathbb{E}[t_i^2] = 1$ from the standardisation, we get:

$$\mathbb{E}[h_i^2 t_i^2] = 2 \tag{13}$$

Lets analyse the second term in (12). From the relational independence and because the word embeddings are assumed to be standardised to unit variance, we obtain the follows:

$$2\mathbb{E}_{p_+}[h_i t_i h_i' t_i'] = 2\mathbb{E}_{p_+}[h_i t_i]\mathbb{E}_{p_+}[h_i' t_i'] = 2. \tag{14}$$

According to (13) and (14), (12) evaluates to $2{A_{ij}^{(k)}}^2$. We will then get the same term from the negative expectations and they would cancel out as $2{A_{ij}^{(k)}}^2$ is independent of the training dataset.

Next, lets consider the $A_{ij}^{(k)} P_{kn}$ terms in the expansion of (10) given by,

$$2\sum_{i,j}\sum_{n} A_{ij}^{(k)} P_{kn}(h_i t_j - h_i' t_j')(h_n - h_n'). \tag{15}$$

Taking the expectation of (15) w.r.t. p_+ we get,

$$2\sum_{i,j}\sum_{n} A_{ij}^{(k)} P_{kn}(\mathbb{E}_{p_+}[h_i t_j h_n] - \mathbb{E}_{p_+}[h_i t_j h_n'] - \mathbb{E}_{p_+}[h_i' t_j' h_n] + \mathbb{E}_{p_+}[h_i' t_j' h_n']). \tag{16}$$

Likewise, from the uncorrelation assumption and following the same logic as above it follows that all the expectations in (16) are approximately zero. A similar argument can be used to show that terms that involve $A_{ij}^{(k)} Q_{kn}$ disappear from (10). Therefore, $\underline{\mathbf{A}}$ does not play any part in the expected loss over positive examples. Similarly, we can show that $\underline{\mathbf{A}}$ is independent of the expected loss over negative examples. Therefore, from (5) we see that the expected loss over the entire training dataset is independent of $\underline{\mathbf{A}}$. □

3.1 Regularised ℓ_2 loss

As a special case, if we attempt to minimise the expected loss under some regularisation on $\underline{\mathbf{A}}$ such as the Frobenius norm regularisation, then this can be achieved by sending $\underline{\mathbf{A}}$ to zero tensor because according to 1 2 is independent from $\underline{\mathbf{A}}$.

With $\underline{\mathbf{A}} = \underline{\mathbf{0}}$, the relation between h and t can be simplified to:

$$\boldsymbol{r}(\boldsymbol{h}, \boldsymbol{t}) = \mathbf{P}\boldsymbol{h} + \mathbf{Q}\boldsymbol{t} \tag{17}$$

Then the expected loss over the positive instances is given by (18).

$$\begin{aligned}
&\mathbb{E}_{p_+}[\left|\left|\mathbf{P}(\boldsymbol{h} - \boldsymbol{h'}) + \mathbf{Q}(\boldsymbol{t} - \boldsymbol{t'})\right|\right|_2^2] \\
&= \mathbb{E}_{p_+}[(\boldsymbol{h} - \boldsymbol{h'})^\top \mathbf{P}^\top \mathbf{P}(\boldsymbol{h} - \boldsymbol{h'})] + \mathbb{E}_{p_+}[(\boldsymbol{h} - \boldsymbol{h'})^\top \mathbf{P}^\top \mathbf{Q}(\boldsymbol{t} - \boldsymbol{t'})] + \\
&\mathbb{E}_{p_+}[(\boldsymbol{t} - \boldsymbol{t'})^\top \mathbf{Q}^\top \mathbf{P}(\boldsymbol{h} - \boldsymbol{h'})] + \mathbb{E}_{p_+}[(\boldsymbol{t} - \boldsymbol{t'})^\top \mathbf{Q}^\top \mathbf{Q}(\boldsymbol{t} - \boldsymbol{t'})]
\end{aligned} \tag{18}$$

The second expectation term in the right hand side of (18) can be computed as follows:

$$\begin{aligned}
&\mathbb{E}_{p_+}[(\boldsymbol{h} - \boldsymbol{h'})^\top \mathbf{P}^\top \mathbf{Q}(\boldsymbol{t} - \boldsymbol{t'})] \\
&= \sum_{i,j} (\mathbf{P}^\top \mathbf{Q})_{ij} \mathbb{E}_{p_+}[(h_i - h_i')(t_j - t_j')] \\
&= \sum_{i,j} (\mathbf{P}^\top \mathbf{Q})_{ij} \left(\mathbb{E}_{p_+}[h_i t_j] - \mathbb{E}_{p_+}[h_i t_j'] - \mathbb{E}_{p_+}[h_i' t_j] + \mathbb{E}_{p_+}[h_i' t_j']\right)
\end{aligned} \tag{19}$$

When $i \neq j$, each of the four expectations in the RHS of (21) are zero from the uncorrelation assumption. When $i = j$, each term will be equal to one from the standardisation assumption (unit variance) and cancel each other out. A similar argument can be used to show that the third expectation term in the RHS of (18) vanishes.

Now lets consider the first expectation term in the RHS of (18), which can be computed as follows:

$$\begin{aligned}
&\mathbb{E}_{p_+}[(\boldsymbol{h}-\boldsymbol{h'})^\top \mathbf{P}^\top \mathbf{P}(\boldsymbol{h}-\boldsymbol{h'})] \\
&= \sum_{i,j} (\mathbf{P}^\top \mathbf{P})_{ij} \mathbb{E}_{p_+}[(h_i - h'_i)(h_j - h'_j)] \\
&= \sum_{i,j} (\mathbf{P}^\top \mathbf{P})_{ij} (\mathbb{E}_{p_+}[h_i h_j] - \mathbb{E}_{p_+}[h_i h'_j] - \mathbb{E}_{p_+}[h'_i h_j] + \mathbb{E}_{p_+}[h'_i h'_j])
\end{aligned} \tag{20}$$

When $i \neq j$, it follows from the uncorrelation assumption that each of the four expectation terms in the RHS of (20) will be zero. For $i = j$ case we have,

$$\begin{aligned}
&\sum_{i,j} (\mathbf{P}^\top \mathbf{P})_{ii} \left(\mathbb{E}_{p_+}[h_i^2] - 2\mathbb{E}_{p_+}[h_i h'_i] + \mathbb{E}_{p_+}[h_i'^2] \right) \\
&= 2 \sum_{i,j} (\mathbf{P}^\top \mathbf{P})_{ii}
\end{aligned} \tag{21}$$

Note that from the relational independence between h and h' we have $\mathbb{E}_{p_+}[h_i h'_i] = \mathbb{E}_{p_+}[h_i]\mathbb{E}_{p_+}[h'_i]$. From the standardisation (zero mean) assumption this term is zero. On the other hand $\mathbb{E}_{p_+}[h_i^2] = \mathbb{E}_{p_+}[h_i'^2] = 1$ from the standardisation (unit variance) assumption, which gives the result in (21).

Similarly, the fourth expectation term in the RHS of (18) evaluates to $2\sum_{i,j} (\mathbf{Q}^\top \mathbf{Q})_{ii}$, which shows that (18) evaluates to $2\sum_{i,j} \left((\mathbf{P}^\top \mathbf{P})_{ii} + (\mathbf{Q}^\top \mathbf{Q})_{ii} \right)$. Note that this is independent of the positive instances and will be equal to the expected loss over negative instances, which gives $\mathbb{E}_p[J] = 0$ for the relational embedding given by (17).

It is interesting to note that PairDiff is a special case of (17), where $\mathbf{P} = \mathbf{I}$ and $\mathbf{Q} = -\mathbf{I}$. In the general case where word embeddings are nonstandardised to unit variance, we can set $\mathbf{P}$ to be the diagonal matrix where $\mathbf{P}_{ii} = 1/\sigma_i$, where σ_i is the variance of the i-th dimension of the word embedding space, to enforce standardisation. Considering that $\mathbf{P}, \mathbf{Q}$ are parameters of the relational embedding, this is analogous to *batch normalisation* (Ioffe and Szegedy, 2015), where the appropriate parameters for the normalisation are learnt during training.

4 Experimental Results

4.1 Cross-dimensional Correlations

A key assumption in our theoretical analysis is the uncorrelations between different dimensions in word embeddings. Here, we empirically verify the uncorrelation assumption for different input word embeddings. For this purpose, we create SG, CBOW and GloVe embeddings from the ukWaC corpus[5]. We use a context window of 5 tokens and select words that occur at least 6 times in the corpus. We use the publicly available implementations for those methods by the original authors and set the parameters to the recommended values in (Levy et al., 2015) to create 50-dimensional word embeddings. As a representative of counting-based word embeddings, we create a word co-occurrence matrix weighted by the positive pointwise mutual information (PPMI) and apply singular value decomposition (SVD) to obtain 50-dimensional embeddings, which we refer to as the Latent Semantic Analysis (LSA) embeddings.

We use Latent Dirichlet Allocation (LDA) (Blei et al., 2003) to create a topic model, and represent each word by its distribution over the set of topics. Ideally, each topic will capture some semantic category and the topic distribution provides a semantic representation for a word. We use gensim[6] to extract 50 topics from a 2017 January dump of English Wikipedia. In contrast to the above-mentioned word embeddings,

[6] https://radimrehurek.com/gensim/wiki.html

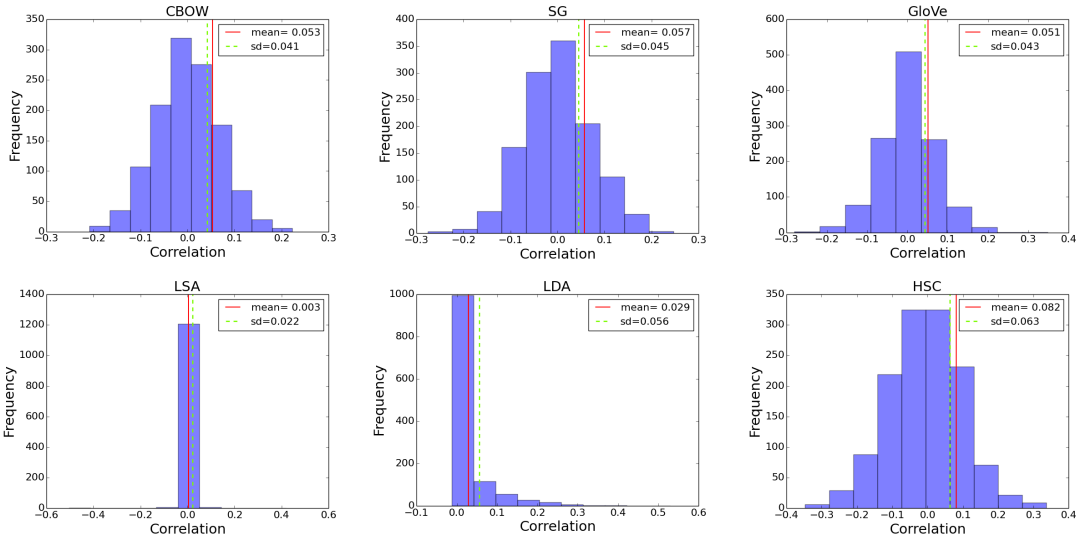

Figure 1: Cross-dimensional correlations for six word embeddings

which are dense and flat structured, we used Hierarchical Sparse Coding[7] (HSC) (Yogatama et al., 2015) to produce sparse and hierarchical word embeddings.

Given a word embedding matrix $\mathbf{W} \in \mathbb{R}^{m \times d}$, where each row correspond to the d-dimensional embedding of a word in a vocabulary containing m words, we compute a correlation matrix $\mathbf{C} \in \mathbb{R}^{d \times d}$, where the (i, j) element, C_{ij}, denotes the Pearson correlation coefficient between the i-th and j-th dimensions in the word embeddings over the m words. By construction $C_{ii} = 1$ and the histograms of the cross-dimensional correlations ($i \neq j$) are shown in Figure 1 for 50 dimensional word embeddings obtained from the six methods described above. The mean of the absolute pairwise correlations for each embedding type and the standard deviation (sd) are indicated in the figure.

From Figure 1, irrespective of the word embedding learning method used, we see that cross-dimensional correlations are distributed in a narrow range with an almost zero mean. This result empirically validates the uncorrelation assumption we used in our theoretical analysis. Moreover, this result indicates that Theorem 1 can be applied to a wide-range of existing word embeddings.

4.2 Learning Relation Representations

Our theoretical analysis in §3 claims that the performance of the bilinear relational embedding is independent of the tensor operator $\underline{\mathbf{A}}$. To empirically verify this claim, we conduct the following experiment. For this purpose, we use the BATS dataset (Gladkova et al., 2016) that contains of 40 semantic and syntactic relation types[8], and generate positive examples by pairing word-pairs that have the same relation types. Approximately each relation type has 1,225 word-pairs, which enables us to generate a total of 48k positive training instances (analogous word-pairs) of the form $((h, t), (h', t'))$. For each pair (h, t) related by a relation r, we randomly select pairs (h', t') with a different relation type r', according to the ℓ_2 distance between the two pairs to create negative (nonanalogous) instances.[9] We collectively refer both positive and negative training instances as the *training* dataset.

Using the $d = 50$ dimensional word embeddings from CBOW, SG, GloVe, LSA, LDA, and HSC methods created in §4.1, we learn relational embeddings according to (2) by minimising the ℓ_2 loss, (4). To avoid overfitting, we perform ℓ_2 regularisation on $\underline{\mathbf{A}}$, $\mathbf{P}$ and $\mathbf{Q}$ are regularised to diagonal matrices $p\mathbf{I}$ and $q\mathbf{I}$, for $p, q \in \mathbb{R}$. We initialise all parameters by uniformly sampling from $[-1, +1]$ and use AdaGrad (Duchi et al., 2011) with initial learning rate set to 0.01.

Figure 2 shows the Frobenius norm of the tensor $\underline{\mathbf{A}}$ (on the left vertical axis) and the values of p

[7] http://www.cs.cmu.edu/~ark/dyogatam/wordvecs/

[8] http://vsm.blackbird.pw/bats

[9] 10 negative instances are generated from each word-pair in our experiments.

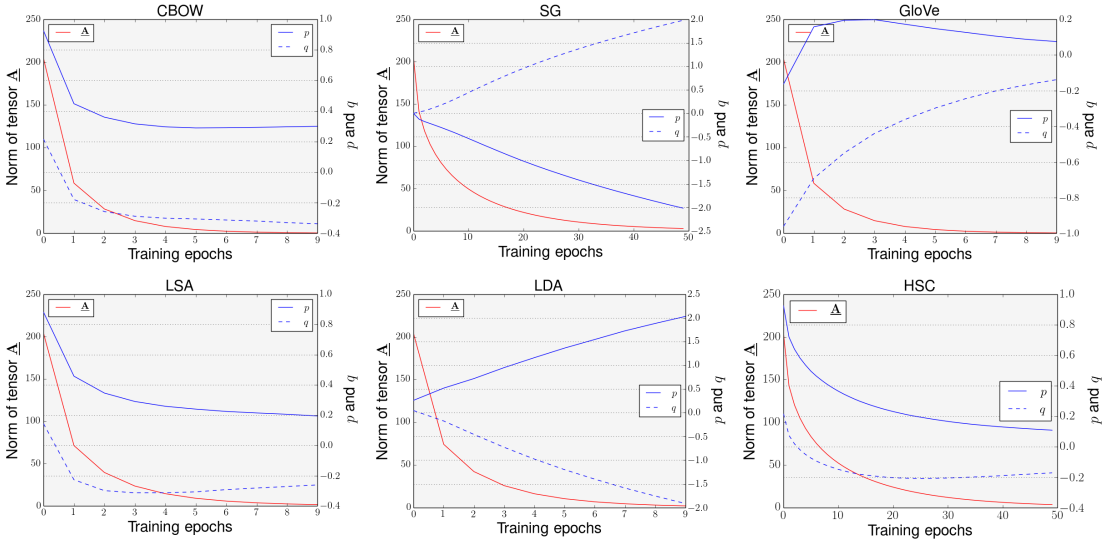

Figure 2: The learnt model parameters for different word embeddings of 50 dimensions.

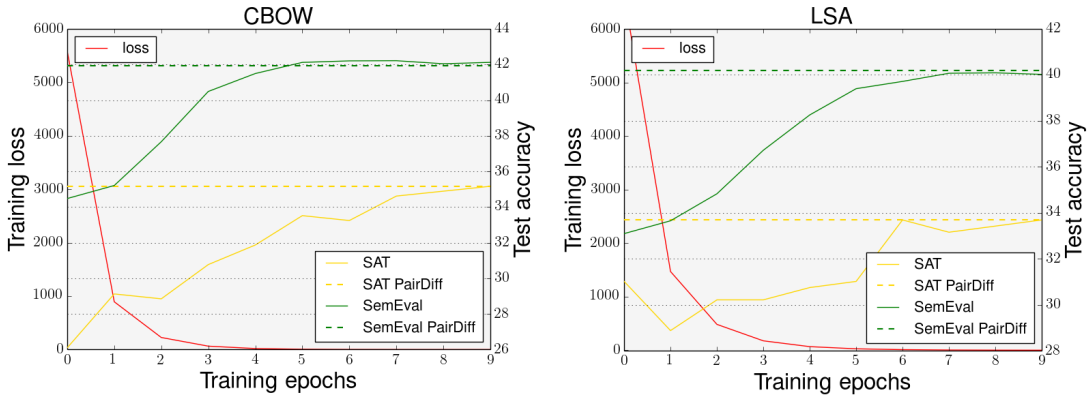

Figure 3: The training loss and test performance on SAT and SemEval benchmarks for relational embeddings.

and q (on the right vertical axis) for the six word embeddings. In all cases, we see that as the training progresses, $\underline{\mathbf{A}}$ goes to zero as predicted by Theorem 1 under regularisation. Moreover, we see that approximately $p \approx -q = c$ is reached for some $c \in \mathbb{R}$ in all cases, which implies that $\mathbf{P} \approx -\mathbf{Q} = c\mathbf{I}$, which is the PairDiff operator. Among the six input word embeddings compared in Figure 1, HSC has the highest mean correlation (0.082), which implies that its dimensions are correlated more than in the other word embeddings. This is to be expected by design because a hierarchical structure is imposed on the dimensions of the word embedding during training. However, HSC embeddings also satisfy the $\underline{\mathbf{A}} \approx \underline{\mathbf{0}}$ and $p \approx -q = c$ requirements, as expected by the PairDiff. This result shows that the claim of Theorem 1 is empirically true even when the uncorrelation assumption is mildly violated.

4.3 Generalisation Performance on Analogy Detection

So far we have seen that the bilinear relational representation given by (2) does indeed converge to the form predicted by our theoretical analysis for different types of word embeddings. However, it remains unclear whether the parameters learnt from the training instances generated from the BATS dataset accurately generalise to other benchmark datasets for analogy detection. To emphasize, our focus here is not to outperform relational representation methods proposed in previous works, but rather to empirically show that the learnt operator converges to the popular PairDiff for the analogy detection task.

To measure the generalisation capability of the learnt relational embeddings from BATS, we measure their performance on two other benchmark datasets: SAT Turney and Bigham (2003) and SemEval 2012-Task2[10]. Note that we *do not* retrain $\underline{\mathbf{A}}$, $\mathbf{P}$ and $\mathbf{Q}$ in (2) on SAT nor SemEval, but simply to use their values learnt from BATS because the purpose here to evaluate the generalisation of the learnt operator.

In SAT analogical questions, given a stem word-pair (a, b) with five candidate word-pairs (c, d), the task is to select the word-pair that is relationally similar to the the stem word-pair. The relational similarity between two word-pairs (a, b) and (c, d) is computed by the cosine similarity between the corresponding relational embeddings $\boldsymbol{r}(\boldsymbol{a}, \boldsymbol{b})$ and $\boldsymbol{r}(\boldsymbol{c}, \boldsymbol{d})$. The candidate word-pair that has the highest relational similarity with the stem word-pair is selected as the correct answer to a word analogy question. The reported accuracy is the ratio of the correctly answered questions to the total number of questions. On the other hand, SemEval dataset has 79 semantic relations, with each relation having ca. 41 word-pairs and four prototypical examples. The task is to assign a score for each word pair which is the average of the relational similarity between the given word-pair and prototypical word-pairs in a relation. Maximum difference scaling (MaxDiff) is used as the evaluation measure in this task.

Figure 3 shows the performance of the relational embeddings composed from 50-dimensional CBOW and LSA embeddings[11]. For CBOW, the level of performance reported by PairDiff on SAT and SemEval datasets are respectively 35.16% and 41.94%, and are shown by horizontal dashed lines. From Figure 3, we see that the training loss gradually decreases with the number of training epochs and the performance of the relational embeddings on SAT and SemEval datasets reach that of the PairDiff operator. This result indicates that the relational embeddings learnt not only converge to PairDiff operator on training data but also generalise to unseen relation types in SAT and SemEval test datasets.

5 Conclusion

This paper theoretically analyses the bilinear operator for representing relations between words using their embeddings. We showed that, if the word embeddings are standardised and uncorrelated, then the expected ℓ_2 distance between analogous and non-analogous word-pairs is independent of bilinear terms, and the relation embedding further simplifies to the popular PairDiff operator under regularised settings. Among diverse methods for calculating word embeddings, we empirically show the uncorrelation in word embedding dimensions, which is one of the prerequisites for simplifying the bilinear operator to a linear one. Empirically, we supports the theoretical analysis by showing that when optimising a general bilinear formulation on a labeled word pair relational dataset, the solution converges to the simple linear form, and more specifically to the simple PairDiff formulation.

In this work, we model relations as vectors and we measure relational strength using Euclidean distance. We are aware that there are many other relation representation methods and relational strength measurement methods besides what we have considered in the paper. Similar analysis can be conducted in follow-up work for different types of relation representations and strength measures. For instance, an interesting future research direction of this work is to extend the theoretical analysis to nonlinear relation composition operators, such as for nonlinear neural networks.

Abstract

Detecting changes within an unfolding event in real time from news articles or social media enables to react promptly to serious issues in public safety, public health or natural disasters. In this study, we use on-line Latent Dirichlet Allocation (LDA) to model shifts in topics, and apply on-line change point detection (CPD) algorithms to detect when significant changes happen. We describe an on-line Bayesian change point detection algorithm that we use to detect topic changes from on-line LDA output. Extensive experiments on social media data and news articles show the benefits of on-line LDA versus standard LDA, and of on-line change point detection compared to off-line algorithms. This yields F-scores up to 56% on the detection of significant real-life changes from these document streams.

1 Introduction

In recent years, the detection of emerging events from publicly available data streams such as twitter messages has received a lot of attention. The approaches used range from topic modeling, incremental clustering, the concept of interestingness, and others (Hasan et al., 2017). For example, methods relying on topic models detect latent topics from tweets and use that semantic structure to guide the event detection task. In particular, Latent Dirichlet Allocation, *aka* LDA (Blei et al., 2003), and extensions have been widely used to model topics from large corpora. It has been used for event detection (Pozdnoukhov and Kaiser, 2011; Ertl et al., 2012; Vavliakis et al., 2012; Lau et al., 2012; Zhou and Chen, 2014), summarization, or finding influential users in social media. However, only few studies used LDA to detect topic changes over time (Lau et al., 2012; Zhou and Chen, 2014).

Once a main event is identified, detecting key sub-events is an essential task. For example, during a public health epidemic crisis, detecting turning points in the spread of the disease is extremely important. Relatively little attention has been paid on detecting these change points during an event. For example, Bruggermann et al. (2016) used the dynamic topic model, *aka* DTM (Blei and Lafferty, 2006), to detect and track stories in news articles. In addition, although many studies use topic models for event detection, very few focus on real-time or sub-event detection.

In statistics, change point detection (CPD) is the task of finding locations where the underlying stochastic process governing time series changes. Change-point detection algorithms can be split into two categories: Real-time (or on-line) detection and retrospective (or off-line) detection, depending on how data is used. Most CPD algorithms are retrospective (Barry and Hartigan, 1993; James and Matteson, 2015): the main drawback is that they can't be run before all the data has been acquired, which is a significant operational constraint when monitoring unfolding safety or health crises. Few algorithms address real-time detection (Adams and MacKay, 2007).

Our study focuses on real-time change point detection in document streams by combining on-line LDA with on-line CPD. Most previous studies on event detection used off-line topic models (Ertl et al., 2012; Vavliakis et al., 2012), which is not appropriate for document streams. In addition, many studies using LDA or on-line LDA for event detection only tested on several case studies (Pozdnoukhov and

Proceedings of the 27th International Conference on Computational Linguistics, pages 2505–2515
Santa Fe, New Mexico, USA, August 20-26, 2018.

Kaiser, 2011; Ertl et al., 2012): there were no reference events to test against. By contrast, we collected document streams from social media and news articles, and gathered reference change points for each dataset, in order to evaluate the performance on these datasets.

In the following section, we review some related work in order to position ours. In Section 3 we describe the methods: topic modeling, CPD and their combination. Sections 4 and 5 report on our experiments and results, before we discuss our findings (Section 6).

2 Related Work

LDA is a three-level hierarchical Bayesian model (Blei et al., 2003) where each document is a multinomial distribution over topics, and each topic is a multinomial distribution over the vocabulary. The Dynamic Topic Model (Blei and Lafferty, 2006) is an extension of LDA that captures the evolution of topics in a sequentially organized corpus of documents. In order to process document streams, several on-line LDA (oLDA) methods have also been proposed (Hoffman et al., 2010; Lau et al., 2012; Zhai and Boyd-Graber, 2013).

These models have been used for event detection from social media data. Pozdnoukhov and Kaiser (2011) used LDA to identify topics and classified tweets according to the most probable topic. Ertl et al. (2012) combined LDA with Seasonal Trend Decomposition in order to detect and rank topics, remove daily chatter and detect abnormal topics. Vavliakis et al. (2012) used LDA for topic identification and event detection in the MediaEval-2012 Social Event Detection task. Zhou and Chen (2014) proposed a location-time constrained topic model to represent social data information over content, time, and location. By considering the time and location of messages as additional variables, it outperformed oLDA on the tested datasets. In addition to using spatial information on top of LDA, none of the previous studies consider real-time event detection.

Other recent work attempt to build storylines from either news articles or social media data. Bruggermann et al. (2016) use the word-topic distribution from the DTM model to represent the changes during events, but did not evaluate the performance of the DTM model on topic identification, or whether the turning points from the word-topic distribution discover actual sub-events. Wang and Goutte (2017) evaluated the performance of change point detection algorithms using the temporal profiles of hashtags and frequency of tweets on two twitter data sets. Their work is an early attempt to use CPD algorithms on the content of document streams. Previous studies (Guralnik and Srivastava, 1999; James et al., 2016) detected significant changes from sensor signals but do not use the textual content of message streams. Recently, Goutte et al. (2018) used a similar on-line CPD approach, but applied it on time series recording the sentiment polarity in streams of tweets.

3 Methods

In this section, we describe on-line topic modeling, several competing ways to produce time series from the topic models, and several change point detection algorithms.

3.1 On-line Topic Model

We use both standard LDA and an on-line version of LDA with infinite vocabulary, oLDA$^\infty$. The basic LDA generates documents from a distribution over topics, each topic having a distribution over words. For D documents over K topics, the generative process is as follows (Blei et al., 2003):

1. For each doc $d=1\ldots D$, pick $\theta_d \sim \mathsf{Dir}(\alpha)$,
2. For each topic $k=1\ldots K$, pick $\phi_k \sim \mathsf{Dir}(\beta)$,
3. For each word w_n, $n=1\ldots N_d$, in document d (of size N_d),
   (a) Pick topic $z \sim \mathsf{Mult}(\theta_d)$,
   (b) Pick word $w_n \sim \mathsf{Mult}(\phi_z)$.

$\mathsf{Dir}()$ and $\mathsf{Mult}()$ are the Dirichlet and Multinomial distributions, respectively; α and β are hyper-parameters, and the parameters are usually estimated using collapsed Gibbs sampling. LDA inference

yields document topic distributions θ_d and word-topic probabilities ϕ_k. Both can be used for further processing, in particular θ_d encodes the topics represented in d.

One limitation of LDA and early on-line variants is that words are sampled over a fixed vocabulary. This makes sense in a batch setting, where all words are known from the collection, but not in a streaming or on-line setting, where new words may appear as documents are acquired. The on-line LDA with infinite vocabulary (oLDA$^\infty$) introduced by Zhai and Boyd-Graber (2013) addresses this by 1) processing data and doing inference in minibatches, and 2) instead of a Dirichlet distribution over a fixed vocabulary, topic distributions ϕ_k are drawn from a Dirichlet Process with a base distribution over *all* words. Dirichlet processes are a common tool from non-parametric statistics, allowing sampling and inference in finite time over unbounded and possibly countably infinite support. Details of the sampling and inference are provided by Zhai and Boyd-Graber (2013).

The original implementation of oLDA$^\infty$ updates the model for each minibatch containing a fixed *number of documents*. This does not work well in our setting where news articles or social media messages do not arrive regularly, and we want to update the model for fixed *time* increments (e.g. a few minutes or a few days). We therefore adapted oLDA$^\infty$ to process the collection in fixed-time minibatches containing variable numbers of documents according to their time stamps. We denote this variant by oLDA$^\infty_t$. Documents within the same time interval are placed in the same mini batch, and the model is updated at each time slot $t_1, t_2, \ldots t_m$. Inference yields corresponding word-topic distributions $\phi(1), \phi(2), \ldots \phi(m)$.

3.2 From Topic Models to Topic Change

The evolution of topics in on-line LDA models is usually shown using the most probable words from the word-topic distributions (Hoffman et al., 2010; Lau et al., 2012; Zhai and Boyd-Graber, 2013). However, the same top words can appear in different topics, making differences between topics hard to show. This is in particular the case when documents are related to a particular event, as words typical of that event are common in all topics. Other approaches rely on the top words in different ways: the cosine similarity of top words from the DTM Bruggermann et al. (2016), the Jensen-Shannon divergence (JSD) Lau et al. (2012), and the symmetrized Kullback-Leibler divergence of word distribution Zhou and Chen (2014) to represent topic change over time.

We propose to evaluate topic change by using the word-topic distribution $\phi(t)$ and the document-topic distribution θ_n at each time slot. Four methods were tested in our study to represent the topic change over time: cosine distance, Jensen-Shannon divergence, the word-topic distribution (WD), and the document-topic distribution (DD). For cosine distance, we used the cosine similarity between the top-word probabilities of all topics at the current time t and previous time $t-1$. From the word-topic distributions $\phi_k(t)$ and $\phi_k(t-1)$, we extract the top-word probabilities $P_W(t)$ and $P_W(t-1)$ and compute:

$$D_{\cos}(t) = 1 - \cos(P_W(t), P_W(t-1)), \tag{1}$$

$$\cos(P_W(t), P_W(t-1)) = \frac{\langle P_W(t), P_W(t-1)\rangle}{\|P_W(t)\|\|P_W(t-1)\|}$$

$D_{\cos}(t)$ is a univariate time series with $m-1$ points, which we use to detect significant changes using the CPD algorithms below.

The second method uses the sum of JSD between the top words in all topics between t and $t-1$. Normalizing the top-word distributions into $\overline{P}_W(t)$ and $\overline{P}_W(t-1)$:

$$D_{\text{JSD}}(t) = \text{JSD}(\overline{P}_W(t), \overline{P}_W(t-1)), \tag{2}$$

$$\text{JSD}(P,Q) = \frac{1}{2}\sum_i p_i \log\frac{2p_i}{p_i+q_i} + \frac{1}{2}\sum_i q_i \log\frac{2q_i}{p_i+q_i}$$

$D_{\text{JSD}}(t)$ again forms a univariate time series with $m-1$ data points.

The third method directly uses the word-topic distribution of top words. For each topic k, the probability of word w from the top L words is obtained from $\phi_k(t)$, $t = 1 \ldots m$. This produces a total of $K \times L$ time series representing evolutions in the word-topic distributions.

The last method uses the average document-topic distribution, for documents in each time interval. In the document-topic distribution matrix θ , each element θ_{kj} represents the probability of topic k in document j. Averaging over all documents from a minibatch t, we compute the average document-topic probability $\pi_k(t) = \frac{1}{|t|} \sum_{d_j \in t} \theta_{kj}$. This produces K times series, with m data points each, on which we run multivariate CPD.

3.3 Change Point Detection

In time series analysis, a change point is a location where the underlying stochastic process changes. Although it may seem superficially related, this is a different problem than anomaly detection, where the purpose is to identify observations that do not conform to an expected pattern or distribution in the data. In change point detection, we assume that data before the change point conforms to one distribution, while data after the change point comes from a second, different distribution. In our case, we are interested in identifying where the change has occurred, as soon as possible after it occurs.

Many algorithms have been proposed to detect change points. Most work on univariate time series, and use the entire time series to detect change points. We will focus on techniques that can be used with multivariate time series:

`bcp`

The Bayesian change point detection of Barry and Hartigan (1993) assumes that each block between two change points arises from a (multivariate) normal distribution. It outputs the posterior probability that a change occurred at each point in the time series. We use the implementation from the `R` package `bcp` (Erdman and Emerson, 2007), which runs in time linear in the length of the time series, and handles multivariate time series. The biggest limitations are that it is designed to detect changes in the mean of independent Gaussian observations, and that it works retrospectively, once the entire time series is available.

`ecp`

The nonparametric, hierarchical divisive algorithm of James and Matteson (2015) uses recursive bisections, identifying change points using a non-parametric divergence measure from Székely and Rizzo (2005). As the divergence measure is non-parametric, this makes `ecp` suitable to detect changes with minimal assumptions on the underlying distributions. The divisive approach by recursive bisections returns a number of consecutive *segments* between change points, without knowing the number of change points *a priori*. In addition, the implementation from the `R` package `ecp` handles multivariate time series. One remaining limitation is that it works only in retrospective mode, once the entire time series is available.

`ocp`

The Bayesian online change point detection algorithm of Adams and MacKay (2007) addresses that issue. It is designed to update the detection of change points sequentially, as new data points are acquired, rather than wait until the entire times series are available. It relies on two components: a probabilistic model $P(r_t|\mathbf{s}(1 \dots t))$ of the length of a *run* during which the underlying distribution is stable, given observations until time t; and an underlying predictive model (UPM) $P(\mathbf{s}(t+1)|\mathbf{s}(1 \dots t), r_t)$ governing the stochastic generation of new data in each run. Our basic implementation, available in the `R` package `onlineCPD`,[1] uses a multivariate Gaussian UPM.

`ocp+`

We extend the `ocp` algorithm beyond the Gaussian assumption by using a more flexible UPM, modeling linear trends within each run, using a multivariate linear regression with additive Gaussian noise. This allows modeling drifts in the time series without forcing multiple change points. Our implementation is also available in the `onlineCPD` `R` package available from github.

Table 1: Statistics on our two benchmark datasets.

Dataset	#Docs	#Ref timeline	Time interval	Time window
Olympics	30,115,218	89	1 hour	2 hours
Zika	31,356	31	1 day	2 days

4 Experiments

4.1 Datasets

To test the performance of our various combinations of online LDA and online CPD, we collected two datasets. One large collection of tweets related to the 2014 Sochi Winter Olympics, and a collection of public health news articles related to the 2015-2016 Zika epidemics. Statistics are shown in Table 1.

The 2014 Sochi Winter Olympics Twitter dataset was collected from the Twitter API during the whole olympic games period (Feb. 6-24th, 2014). Keywords such as "Sochi", "Olympics" were used to filter tweets. The dataset contains 3,115,218 tweets after removing re-tweets and non-English tweets. The reference events were collected from Wikipedia,[2] considering finals for most event, plus quarterfinals, semifinals, bronze and gold medal games for ice hockey, which adds up to 89 reference change points.

During the outbreak of Zika virus from 2015 to 2016, we collected news articles from November 3rd 2015 to December 31st 2016 on the GPHIN system.[3] News articles from a variety of sources were collected and translated into English, named entities and medical terms were identified, then keywords like "Zika" and "mysterious disease" were used to filter news articles (Carter, 2018). The final, filtered Zika dataset contains 31,356 news articles. The original reference events were collected from a web source.[4] Events on the same or subsequent days were combined into one, and the final gold standard contains 31 reference change points.

4.2 Evaluation

The performances of change point detection methods were measured by comparing detected change points with known reference events, using precision, recall and F-score. We count a detection as a true positive if it falls into the tolerance time window (Table 1, last column) of the reference change point, based on the order of references. The precision is computed by dividing true positives by all detections, while recall is computed by dividing true positives by total references, and the F-score is:

$$F = 2 \times \frac{\mathsf{Precision} \times \mathsf{Recall}}{\mathsf{Precision} + \mathsf{Recall}}$$

4.3 Experimental settings

In the experiments, we compare two types of LDA models, standard (LDA) and on-line (oLDA$_t^\infty$), and two categories of CPD algorithms, retrospective or off-line CPD (`bcp` and `ecp`) and real-time or on-line CPD (`ocp` and `ocp+`). We used the implementation of standard LDA from the `R` package `text2vec` (Selivanov, 2016) and adapted oLDA$_t^\infty$ from the code made available by Zhai and Boyd-Graber (2013).[5]

5 Results

We first examine whether the top words and top documents extracted from the topic models represent topic changes over time. We then compare four methods of generating time series for CPD from the on-line topic model. We also compare the performance of CPD using the on-line topic model versus the off-line topic model and a baseline using counts. Finally, we check how various CPD algorithms work in a simulated real-time experiment, and analyze the errors made by the different methods.

That awkward moment when snowflake doesn't work & turn into an Olympic ring. Whoops! #Sochi2014 #SochiProblems					

Figure 1: Top words (colored) and top documents for three topics from the Olympics opening ceremony: the beautiful Ballet, the strange US team uniform, and the malfunctioning 5th ring.

5.1 Validating topics from LDA and oLDA$_t^\infty$

We first run a sanity check on the topic models, with qualitative and quantitative evaluations of the resulting topics.

Figure 1 shows the top words and top documents from the LDA model of the Olympics opening ceremony, with $K = 20$ topics. Top words from topics 1, 13 and 17 are shown with colored backgrounds in the top 5 documents for each topic. Top documents (i.e. tweets, in that collection) provide more context than the top words, and clearly show that the topics are related to the ballet (topic 1), the US team uniform (topic 13) and the malfunctioning fifth ring (topic 17).

For a quantitative validation, we compare top documents extracted from the LDA and oLDA$_t^\infty$ models to the reference change points. The top documents for each topic were extracted from the portion of the document-topic distribution table corresponding to the time slot for a reference sub-event, and compared to its description. For example, at 19:00 on Feb. 22nd, the sub-event is the ice hockey bronze medal game between US and Finland. Top tweet "*Ice hockey USA vs Finland now #sochi*" in one topic is counted as a correct match, whereas "*Go Finland ice hockey team! #sochi*" is not, as it does not refer to a specific game. Whenever one top document from one topic matches with the reference, this is counted as the topic model (LDA or oLDA$_t^\infty$) correctly matching a sub-event. The rate of matching references for each model is reported in Table 2.

For the Zika dataset, we only use the titles of the five top documents from five topics. For example, on Aug. 27, 2016, a reference sub-event is Singapore's Ministry of Health confirming the first case of

Table 2: Percentage of reference sub-events matched by LDA and oLDA$_t^\infty$top documents.

Dataset	K	#Top docs	#Ref changes	LDA	oLDA$_t^\infty$

locally-transmitted Zika infections. A top document with title "*Singapore confirms the first case of Zika virus transmitted locally*" is counted as correct, whereas "*FDA: Screen all blood donations for Zika*" in another topic is not. Results in Table 2 show that top documents from LDA and oLDA$_t^\infty$ match the majority of reference change points in both datasets. Top documents from oLDA$_t^\infty$ clearly match better than standard LDA. As oLDA$_t^\infty$ updates the word-topic distribution on-line, adding new words as necessary, top documents can better reflect recent change.

5.2 Comparing Topic Change Time Series

We compare the different approaches to encode topic change into time series, as described in Section 3.2: cosine distance, JSD, word-topic (WD) and the document-topic (DD) distributions. We compare with a simple count-based baseline, where the time series is simply the number of document in each time slot. Table 3 (left) shows the performance obtained on the Olympics dataset. The word-topic distribution (WD) and document-topic distribution (DD) time series perform better than the cosine and JSD time series for ecp, ocp and ocp+. The reverse is true for bcp, although its best performance is lower than the other three CPD algorithms, and lower than using the count baseline. All topic change time series perform better than counts for ocp and ocp+. Overall best results are obtained by the DD time series and on-line change point detection.

Table 3 (right) shows the performance obtained on the Zika dataset. Results are not as consistent

as on the Olympics dataset, but time series derived from the on-line topic models outperform, in some configuration, the count baseline. The best performance is obtained by ocp on the JSD distance, followed by cosine distance on ecp, and the word-topic distribution on ocp and ocp+. ecp, ocp and ocp+ perform better than bcp again. Top performance (.429) is also lower than on the Olympics dataset (.523).

The Olympics and Zika datasets are quite different: the Olympics dataset has many documents in each time interval, whereas the Zika dataset is very sparse in the first several months. Documents from different topics in Zika are quite similar at first, and become much diverse later. The JSD and word-topic distribution can capture such changes of topics, but the changes in the document-topic distribution are subtle. Among these methods, only the document-topic distribution (DD) can be applied in both off-line and on-line topic models. The other three methods use the dynamic word-topic distribution at each time slot. Since the performance of the DD time series is best on the Olympic dataset and reasonable on the Zika dataset, we adopt that method in the following experiments.

5.3 Off-line vs. On-line Topic Models

We now focus on the difference between the off-line and on-line LDA. We use the document-topic distribution from LDA and oLDA$_t^\infty$ to produce time series on which we run the four CPD algorithms. Results are reported at the bottom of Table 3. On the Olympics dataset, the performance of CPD from LDA and oLDA$_t^\infty$ are much better than the baseline except on bcp. This confirms that the topic time series extracted from LDA and oLDA$_t^\infty$ help detect relevant changes. The off-line LDA degrades performance of ocp and ocp+ but improves that of ecp, which reaches the top performance on that dataset. On the Zika data set, the performance is better on the LDA time series than on oLDA$_t^\infty$. For bcp and ecp the performance stays below that of the baseline counts, suggesting that information from the topic model either does not help for these algorithms, or does not fit well with their underlying modeling assumptions. This may be due again to the smaller number of documents in the Zika dataset, and lower number of documents in the earlier time period. Note that although LDA yields better performance than oLDA$_t^\infty$ on the Zika dataset, the on-line topic model offers a key functionality: the topic model can be estimated in real-time as documents are acquired. The time series can then be build on-line and change detection can be applied on-line as well, in order to produce real-time change detection.

5.4 On-line Change Point Detection

The above change point detection experiments were performed in a off-line mode for bcp and ecp, and for all CPD algorithms using LDA: CPD algorithms read all data points at all time intervals at once. For real-time detection, however, it is necessary to test the performance in a real on-line fashion. In order to simulate that with bcp and ecp, we use a sliding window, feeding the algorithm overlapping slices of the data, step by step. Although ocp and ocp+ are built as on-line CPD algorithms, processing one new data point at a time, we used the same sliding window to get a fair comparison. On the Olympics and Zika datasets, we tested different sliding window sizes and steps to evaluate the impact of this size on performance. Table 4 shows the result obtained by the four CPD algorithms on either oLDA$_t^\infty$ topic scores or baseline message counts. On the Olympics data, oLDA$_t^\infty$ performs better than counts in all CPD algorithms except bcp. With smaller steps and window sizes, ecp performs the best. ocp performs best on the largest step and sliding window sizes (100 and 200 hours, respectively). The best performance for different settings (bold) are very close. On the Zika data, the performance of CPD algorithms on counts and oLDA$_t^\infty$ are not consistent. ocp+ reaches the best performance on counts using a 150 day window size in 75 day steps, and performs well on oLDA$_t^\infty$ in two other settings, while ecp performs well on counts in the remaining situation (100 day window, 50 day steps). Comparing the best performance obtained in off-line and on-line modes on these two datasets (Table 3 vs. Table 4), we see that the on-line CPD algorithms using sliding windows achieve better performance than using the entire data set off-line.

5.5 Error Analysis

As error analysis, we would like to understand whether all change point detection algorithms detected the same set of sub-events. We examined the sub-events detected by different change point detection

Table 4: F-score of oLDA$_t^\infty$ versus counts, using several sliding window and step sizes.

Olympics				
step (hour)	25	50	75	100
window (hour)	50	100	150	200

bcp count	0.254	0.251	0.250	0.250
bcp oLDA$_t^\infty$	0.169	0.229	0.216	0.213
ecp count	0.317	**0.427**	0.392	0.414
ecp oLDA$_t^\infty$	0.327	0.190	0.218	0.185
ocp count	0.366	0.395	0.324	0.351
ocp oLDA$_t^\infty$	0.326	0.321	0.341	0.361
ocp+ count	0.409	0.383	**0.482**	0.405
ocp+ oLDA$_t^\infty$	**0.447**	0.390	0.346	**0.424**

algorithms on the Olympics dataset in the sliding window setting of 100 hours steps and 200 hours window size (Figure 2). From the top true positives (top), we observe that on oLDA$_t^\infty$ topic scores, all change-point detection algorithms agree much more on the detected sub-events (57 out of 89) than using message counts. All reference sub-events are identified by at least two of four CPD methods. This demonstrates that the document distribution from oLDA$_t^\infty$tracks topic change much better than the raw volume of tweets. In addition, combining the results of four CPD methods might lead to better performance than using any of them alone. Also, looking at the performance of the two off-line and the two off-line methods, we observe that the detected sub-events are more consistent within these two sub-groups than between them, using either counts or oLDA$_t^\infty$.

False positives, shown at the bottom of Fig. 2 are much less consistent across CPD algorithms. Few false positives are detected by all four CPD algorithms. In addition, it is clear that using either counts or oLDA$_t^\infty$ topic scores, bcp generates many more false positives than the other three methods. In particular, on oLDA$_t^\infty$ none of the other three method generate a full positive that is not also produced by bcp. This is reflected in the high recall obtained by bcp (Table 3), at the expense of a very low precision. ocp also suffers from a large number of false positives on oLDA$_t^\infty$. On the contrary, ocp+ generates few false positives, yielding hogh precision but lower recall. Overall, the combination of oLDA$_t^\infty$ and ocp+ reaches the highest true positive rate and lowest false positive rate on the Olympics dataset.

6 Summary

Our study examined real-time detection of topic changes from document streams. The main outcome from the experiments is that real-time CPD based on the topic change detected by on-line topic models can reach good performance, identifying more than half the unknown reference changes from content alone. We also show that top documents extracted from oLDA$_t^\infty$ match reference change point descriptions better than from LDA. This shows that oLDA$_t^\infty$ captures the dynamic changes inside each topic.

We compared four methods of representing topic evolution as time series and evaluated them against reference change points. In the news article stream, the univariate time series based on the JSD distance performed well, while on the large tweet collection, tracking the multivariate document-topic distribution time series performed better. This suggests that selecting the best methods of representing topic evolution for detecting topic changes may depend on the type and genre of documents and remains a challenge.

Our experiments compared off-line with on-line topic models and also off-line CPD with on-line CPD in different settings. The on-line topic model oLDA$_t^\infty$ yields better performance than off-line LDA on the Olympics dataset, but worse performance on the Zika dataset. Also, on-line CPD algorithms ocp and ocp+ did better than off-line CPD algorithms bcp and ecp on both datasets. The combination of on-line topic modeling with the on-line change point detection reaches top performance in topic change detection in our simulated real-time conditions. This demonstrates that our method is promising for real document streaming applications.

7 Conclusion

We propose a method for real-time detection of topic changes in document streams, using a combination of on-line topic modeling and Bayesian on-line change point detection algorithms. Four approaches to

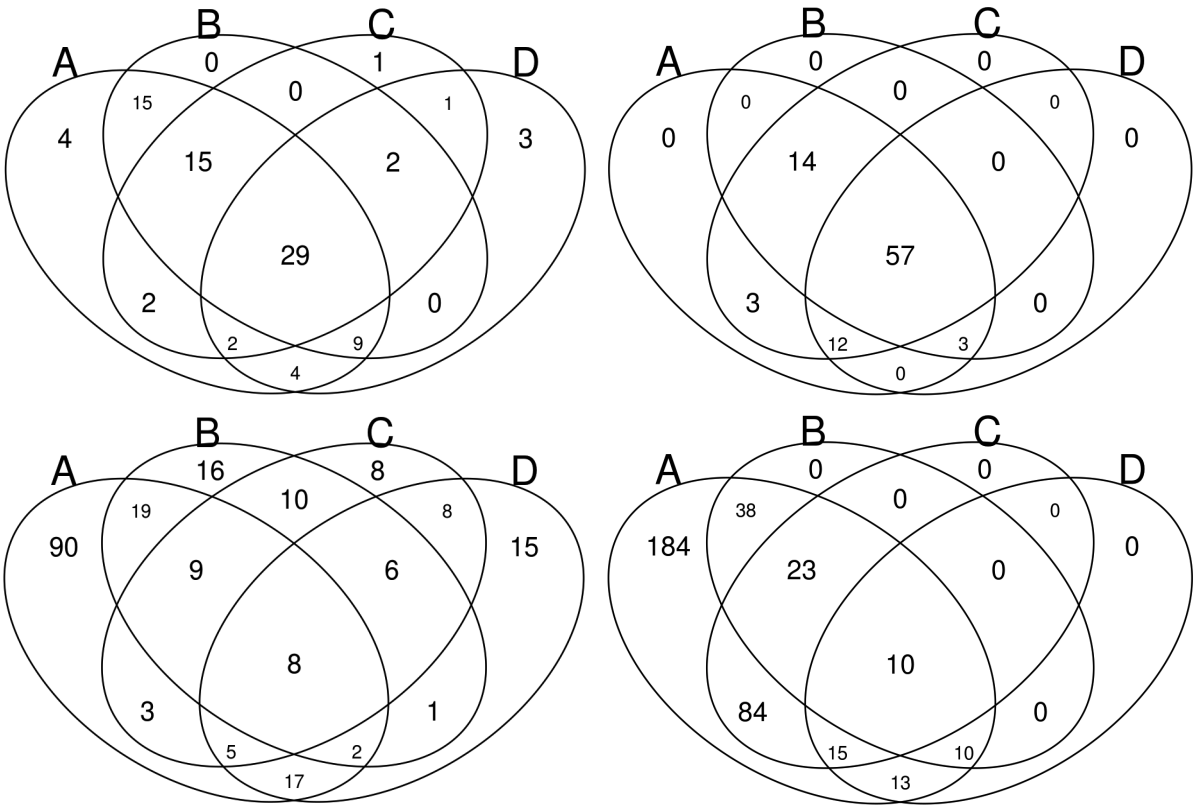

Figure 2: The number of true positives (Top) and false positives (Bottom) detected by A: `bcp`, B: `ecp`, C:`ocp`, D:`ocp+` on all sub-events of the Olympics data, using counts (Left) and oLDA$_t^\infty$(Right).

representing topic change time series were explored, and several off-line and on-line modes were explored. Extensive experiments with off-line and on-line topic models and with retrospective and on-line change point detection on one Twitter dataset and one news article dataset confirm that the combination of oLDA$_t^\infty$ and `ocp+` yield top performance, identifying up to 56% of reference changes in real-time mode on our large twitter collection. Although some off-line combinations yield similar, and sometimes slightly higher performance, the fully on-line combination is always competitive, while offering the benefit of true real-time detection. The CPD algorithms can also be applied to detect changes in other aspect of document streams such as sentiment or emotion.

Abstract

In this paper we use methods for creating a large lexicon of verbal polarity shifters and apply them to German. Polarity shifters are content words that can move the polarity of a phrase towards its opposite, such as the verb *"abandon"* in *"abandon all hope"*. This is similar to how negation words like *"not"* can influence polarity. Both shifters and negation are required for high precision sentiment analysis. Lists of negation words are available for many languages, but the only language for which a sizable lexicon of verbal polarity shifters exists is English. This lexicon was created by bootstrapping a sample of annotated verbs with a supervised classifier that uses a set of data- and resource-driven features. We reproduce and adapt this approach to create a German lexicon of verbal polarity shifters. Thereby, we confirm that the approach works for multiple languages. We further improve classification by leveraging cross-lingual information from the English shifter lexicon. Using this improved approach, we bootstrap a large number of German verbal polarity shifters, reducing the annotation effort drastically. The resulting German lexicon of verbal polarity shifters is made publicly available.

Title and Abstract in German

Die automatische Erstellung eines Lexikons polaritätsverschiebender Verben:
Einsprachige und sprachübergreifende Methoden für das Deutsche

In dieser Arbeit untersuchen wir Methoden zur Erstellung eines deutschsprachigen Lexikons polaritätsverschiebender Verben. Diese Verben, die vielfach auch Polaritätsshifter genannt werden, sind Inhaltswörter, die die Polarität einer Phrase zu ihrem entgegengesetzten Wert verschieben, wie z.B. das Verb *„aufgeben"* in der Verbalphrase *„alle Hoffnung aufgeben"*. Das Verhalten von Polaritätsshiftern ähnelt somit dem von Negationswörtern wie *„nicht"*. Für robuste Sentimentanalyse werden sowohl Negationswörter als auch Polaritätsshifter benötigt. Während Listen von Negationswörtern in vielen Sprachen verfügbar sind, existiert jedoch ein Polaritätsshifter-Lexikon hinreichender Größe nur für das Englische. Jene Ressource wurde mittels Bootstrapping erzeugt, indem ein überwachter Klassifikator auf einer kleinen Stichprobe von Verben trainiert wurde. Dieser Klassifikator nutzt Daten- und Ressourcen-getriebene Merkmale. Wir reproduzieren diesen Ansatz und passen ihn soweit notwendig für das Deutsche an. Somit weisen wir die Übertragbarkeit dieses Ansatzes auf andere Sprachen nach. Wir verbessern die Qualität der Klassifikation zudem weiterhin, indem wir Informationen aus dem existierenden englischen Polaritätsshifter-Lexikon nutzten. Mittels dieses verbesserten Ansatzes finden wir per Bootstrapping eine große Anzahl deutscher Polaritätsshifter und verringern somit deutlich den manuellen Annotationsaufwand. Das resultierende deutsche Lexikon polaritätsverschiebender Verben ist frei verfügbar.

Proceedings of the 27th International Conference on Computational Linguistics, pages 2516–2528
Santa Fe, New Mexico, USA, August 20-26, 2018.

1 Introduction

Polarity shifters are content words such as verbs, nouns or adjectives that influence the sentiment polarity of an expression in ways similar to negation words. For example, the negated statement in (1) that uses the negation word *nicht* in German and *not* in English can also be expressed using the verbal shifter *unterlassen* in German and *fail* in English, as seen in (2).

(1) Peter hat ihnen **nicht** geholfen.
Peter did **not** help them.
(2) Peter hat es **unterlassen**$_{shifter}$ ihnen zu helfen.
Peter **failed**$_{shifter}$ to help them.

Polarity shifters can affect both positive and negative expressions, moving their polarity towards the opposite polarity. In (3) the shifter *verweigern/deny* affects the positive polar expression *Stipendium/scholarship*, resulting in a negative polarity for the sentence. On the other hand, the shifter *lindern/alleviate* in (4) creates a positive sentence despite the negative polar expression *Schmerz/pain*.

(3) Ihr wurde das [[Stipendium]$^{+}$ **verweigert**$_{shifter}$]$^{-}$.
She was [**denied**$_{shifter}$ the [scholarship]$^{+}$]$^{-}$.
(4) Die neue Behandlung hat ihre [[Schmerzen]$^{-}$ **gelindert**$_{shifter}$]$^{+}$.
The new treatment has [**alleviated**$_{shifter}$ her [pain]$^{-}$]$^{+}$.

As can be seen for *verhindern/prevent* in (5) and (6), the same shifter can even affect both positive and negative expressions.

(5) Seine Prinzipien [**verhinderten**$_{shifter}$ eine [Einigung]$^{+}$]$^{-}$.
His principles [**prevented**$_{shifter}$ an [agreement]$^{+}$]$^{-}$.
(6) Ihre Maßnahmen [**verhinderten**$_{shifter}$ ein [Gemetzel]$^{-}$]$^{+}$.
Their measures [**prevented**$_{shifter}$ a [slaughter]$^{-}$]$^{+}$.

We present a **reproduction** and **extension** to the work of Schulder et al. (2017), which introduced a **lexicon of verbal polarity shifters**, as well as methods to increase the size of this lexicon through bootstrapping. The lexicon lists verb lemmas and assigns a binary label (*shifter* or *no shifter*) to each. The original approach was developed on English. We apply it to **German**, validating the generality of the approach and creating a new resource, a German lexicon of 677 verbal polarity shifters. We also improve the bootstrapping process by adding features that leverage polarity shifter resources across languages.

As is the case with negation, modeling polarity shifting is important for various tasks in NLP, such as relation extraction (Sanchez-Graillet and Poesio, 2007), recognition of textual entailment (Harabagiu et al., 2006) and especially sentiment analysis (Wiegand et al., 2010). However, while there has been significant research on negation in sentiment analysis (Wiegand et al., 2010), current classifiers fail to handle polarity shifters adequately (Schulder et al., 2017). This is in part due to the lack of lexical resources for polarity shifters. Unlike negation words (*no*, *not*, *never*, etc.), of which there are only a few dozen in a language, polarity shifters are far more numerous. Among verbs alone there are many hundreds (Schulder et al., 2017). Comprehensive shifter lexicons are, therefore, considerably more expensive to create. Once available, they can be used to improve the aforementioned tasks, as has already been shown for the case of English polarity classification (Schulder et al., 2017).

To reduce the cost of creating such polarity shifter lexicons, Schulder et al. (2017) introduced methods to automatically generate a labeled list of words using either a limited amount of labeled training data or no labeled data at all. Their approach includes both features that rely on semantic resources and data-driven ones. They limited their work to English verbs, but expressed the expectation that their methods should also work for other languages. To verify that expectation, we apply their approach to German, for which all resources required to reproduce their experiments are available. Keeping in mind that this is not the case for many other languages, we focus our evaluation on differentiating between features that rely on unstructured data and those requiring rare semantic resources.

While polarity shifters are not restricted to a particular part of speech – shifter nouns (e.g. *downfall*), adjectives (*devoid*) and adverbs (*barely*) also exist – we limit ourselves to verbs. Verbs and nouns are the most important minimal semantic units (Schneider et al., 2016) and verbs are usually the main syntactic

predicates of clauses, projecting far-reaching scopes. Focusing on verbs also allows us a closer comparison with Schulder et al. (2017) and to investigate cross-lingual similarities between verbal shifters.

The **contributions** of this paper are:

(i) we introduce a German lexicon of verbal polarity shifters;
(ii) we reproduce and adapt the approach of Schulder et al. (2017) to German to extend our lexicon;
(iii) we introduce additional methods that take advantage of the existence of the English verbal polarity shifter lexicon and improve upon the current state of the art.

The focus of our work is the binary classification of verbal polarity shifters in German. The resulting German lexicon of 677 verbal polarity shifters is made **publicly available**.[1]

2 Related Work

Existing work on negation modeling focuses almost exclusively on negation words (see the survey of Wiegand et al. (2010)). One reason for this is the lack of lexicons and corpora that cover other forms of polarity shifters. Even the most complex negation lexicon for English sentiment analysis (Wilson et al., 2005) includes a mere 12 verbal shifters. So far the only larger resources for polarity shifters are the English-language verbal shifter lexicons recently introduced by Schulder et al. (2017) and Schulder et al. (2018). Schulder et al. (2017) automatically bootstrap a lexicon which covers 980 verbal shifters at the lemma level, while Schulder et al. (2018) manually annotate word senses of verbs, creating a lexicon of 2131 shifter senses across 1220 verbs. As we reproduce and extend the work of Schulder et al. (2017), all further use of and comparison to an English shifter lexicon refers to their bootstrapped lexicon as well.

To create shifter lexicons at a large scale, automation and bootstrapping techniques are required. Danescu-Niculescu-Mizil et al. (2009) propose using *negative polarity items (NPIs)* to extract downward-entailing operators, which are closely related to polarity shifters. Schulder et al. (2017) also make use of NPIs in addition to a number of other features.

Rather than using lexicons, another approach would be to learn polarity shifters from labelled corpora. In the case of negation, this has already been examined for the biomedical domain (Huang and Lowe, 2007; Morante and Daelemans, 2009; Zou et al., 2013), the review domain (Ikeda et al., 2008; Kessler and Schütze, 2012; Socher et al., 2013; Yu et al., 2016) and across domains (Fancellu et al., 2016). Unfortunately, due to the considerably higher lexical diversity of polarity shifters, far larger corpora would be required for learning shifter than for learning negation.

Available corpora that are suitable for negation learning, such as the Sentiment Treebank (Socher et al., 2013) or the BioScope corpus (Szarvas et al., 2008), are fairly small in size. Most verbs occur in them in very few instances or not at all. In the BioScope corpus, for example, there are only 6 verbal shifters (Morante, 2010). Polarity classifiers trained on such corpora, such as the state-of-the-art Recursive Neural Tensor Network tagger (Socher et al., 2013), fail to detect many instances of polarity shifting. Schulder et al. (2017) show that the explicit knowledge provided by a shifter lexicon can improve polarity classification in such cases.

3 Data

We create a gold standard for German verbal shifters, following the approach Schulder et al. (2017) used for their English gold standard. An expert annotator, who is a native speaker of German, labeled 2000 verbs, randomly sampled from GermaNet (Hamp and Feldweg, 1997), a German wordnet resource. The remaining 7262 GermaNet verbs are used to bootstrap a larger lexicon in §5.3.

Each verb is assigned a binary label of being a shifter or not. To qualify as a shifter, a verb must permit polar expressions as its dependents and cause the polarity of the expression that embeds both verb and polar expression to move towards the opposite of the polar expression. For example, in (6) *verhindern* shifts the negative polarity of its dependent *ein Gemetzel*, resulting in a positive expression. Annotation is performed at the lemma level, as word-sense disambiguation tends to be insufficiently robust.

Resource Type	German Resource	English Resource
Wordnet	GermaNet (Hamp and Feldweg, 1997)	WordNet (Miller et al., 1990)
Text Corpus	DeWaC Web Corpus (Baroni et al., 2009)	Amazon Product Reviews (Jindal and Liu, 2008)
Polarity Lexicon	PolArt Sentiment Lexicon (Klenner et al., 2009)	Subjectivity Lexicon (Wilson et al., 2005)
Framenet	Salsa (Burchardt et al., 2006)	FrameNet (Baker et al., 1998)
Effects	EffektGermaNet (Ruppenhofer and Brandes, 2015)	EffectWordNet (Choi et al., 2014)

Table 1: Required German resources, compared with English resources used by Schulder et al. (2017).

	Frequency	Percentage
shifter	224	11.2
no shifter	1776	88.8

Table 2: Distribution of verbal shifters in annotated sample of 2000 verbs taken from GermaNet.

	Polar Verbs		Positive V.		Negative V.	
	Freq	%	Freq	%	Freq	%
shifter	81	23.1	12	11.7	69	27.9
no shifter	269	76.9	91	88.3	178	72.1

Table 3: Distribution of verbal shifters in the *PolArt Sentiment Lexicon* (Klenner et al., 2009).

Table 1 provides an overview of the German resources we use in our reproduction, compared to the resources used for the English shifter lexicon. More detailed descriptions of the resources are provided in sections discussing feature design (§4) and experiments (§5).

Table 2 shows that in our gold data 11.2% of verbs are shifters, which is a bit less than the 15.2% of the English gold standard. Table 3 shows the shifter distribution among verbs with sentiment polarity (determined using the *PolArt Sentiment Lexicon* (Klenner et al., 2009)). As was the case for the English gold data, it shows a tendency for shifter verbs to be negative rather than positive terms.

4 Feature Design

In this section we introduce the features that we will use to bootstrap our German verbal shifter lexicon in §5.3. We start by outlining the features proposed by Schulder et al. (2017) and how we adapt them for use with German (§4.1). We further separate them into data-driven features (§4.1.1) and resource-driven features (§4.1.2) to highlight their requirements when applied to a new language.

In §4.2 we introduce new methods that can either be used as stand-alone classifiers or as features for an SVM classifier. Both methods take advantage of existing knowledge about English verbal shifters. One method uses a bilingual dictionary (§4.2.1) and the other cross-lingual word embeddings (§4.2.2).

4.1 Feature Reproduction

In this section we briefly describe how we adapt the features of Schulder et al. (2017) to German language data. We distinguish between features that mainly rely on text data from a corpus (§4.1.1) and those that require complex semantic resources (§4.1.2). When working with languages with scarcer resources, it can be expected that the former will be more readily available than the latter.

4.1.1 Data-driven Features

The main requirement of the following features is a reasonably sized text corpus to detect syntactic patterns and word frequencies. The text corpus was lemmatized using the TreeTagger (Schmid, 1994) and parsed for syntactic dependency structures with ParZu (Sennrich et al., 2009).[2] For features requiring knowledge of polarities we use the *PolArt Sentiment Lexicon* (Klenner et al., 2009).[3]

[2]Lacking an appropriate parser, a part-of-speech tagger may approximate required syntactic structures (Riloff et al., 2013).

[3] We chose to consider features that use a polarity lexicon to still be data-driven features as there exist robust methods to generate them automatically from unlabeled corpora (Turney, 2002; Velikovich et al., 2010; Hamilton et al., 2016). The lexicon we use was created using bootstrapping (Clematide and Klenner, 2010).

Distributional Similarity (SIM): The distributional similarity feature assumes that words that are semantically similar to negation words are also likely to be polarity shifters. Semantic similarity is modeled as cosine similarity in a word embedding space. The word embeddings are created using Word2Vec (Mikolov et al., 2013) on the German web corpus DeWaC (Baroni et al., 2009), using the same hyperparameters as Schulder et al. (2017) and German translations of their negation seeds.

Polarity Clash (CLASH): The polarity clash feature assesses that shifting will often occur when a polar verb modifies an expression of the opposite polarity, such as in (7). The feature is further narrowed down to negative verbs that modify positive nouns, as polar verbal shifters are predominantly of negative polarity (Table 3).

(7) Er hat die [[Hoffnung]$^{+}$ [**verloren**]$^{-}$]$^{-}$.
He [[**lost**]$^{-}$ [hope]$^{+}$]$^{-}$.

Particle Verbs (PRT): Certain verb particles indicate a complete transition to an end state (Brinton, 1985). Schulder et al. (2017) hypothesize that this phenomenon correlates with shifting, which can be seen as producing a new (negative) end state. Therefore, they collect particle verbs containing relevant English particles, such as *away*, *down* and *out*. For our German data we chose the following particles associated with negative end states: *ab*, *aus*, *entgegen*, *fort*, *herunter*, *hinunter*, *weg* and *wider*.

Heuristic using 'jeglich' (ANY): *Negative polarity items (NPIs)* are known to occur in the context of negation (Giannakidou, 2008). Schulder et al. (2017) showed that the English NPI *any* co-occurs with shifters, so its presence in a verb phrase can indicate the presence of a verbal shifter. We expect the same for the German NPI *jeglich*, as seen in (8). We collect all verbs with a polar direct object that is modified by the lemma *jeglich*. The resulting pattern matches are sorted by their frequency, normalized over their respective verb frequency and then reranked using *Personalised PageRank* (Agirre and Soroa, 2009).

(8) Sie [**verwehrten**$_{shifter}$ uns jegliche [Hilfe$_{dobj}$]$^{+}$]$^{-}$.
They [**denied**$_{shifter}$ us any [help$_{dobj}$]$^{+}$]$^{-}$.

Anti-Shifter Feature (ANTI): This feature specifically targets anti-shifters, verbs that exhibit polar stability instead of causing polar shifting. These are commonly verbs indicating creation or continued existence, such as *live*, *introduce*, *construct* or *prepare*. Such verbs often co-occur with the adverbs *ausschließlich*, *zuerst*, *neu* and *extra*, as seen in (9)–(12). Accordingly, we can create a list of anti-shifters by selecting the verbs that most often co-occur with these adverbs.

(9) Im Winter **leben**$_{antiShifter}$ Schwarzbären ausschließlich von Fisch.
In winter, black bears exclusively **live**$_{antiShifter}$ on fish.
(10) Komplette Tastaturen auf Handys wurden zuerst in 1997 **eingeführt**$_{antiShifter}$.
Full keyboards on cellphones were first **introduced**$_{antiShifter}$ in 1997.
(11) Diese Gebäude wurden neu **gebaut**$_{antiShifter}$.
These buildings have been newly **constructed**$_{antiShifter}$.
(12) Sie haben extra für mich veganes Essen **zubereitet**$_{antiShifter}$.
They specially **prepared**$_{antiShifter}$ vegan dishes for me.

4.1.2 Resource-driven Features

The following features rely on advanced semantic resources which are available in only a few languages.

GermaNet: Wordnets are large lexical ontologies providing various kinds of semantic information and relations. Schulder et al. (2017) used glosses, hypernyms and supersenses taken from the English WordNet (Miller et al., 1990) as features in their work. We use GermaNet (Hamp and Feldweg, 1997), a German wordnet resource that provides all these features. In the case of glosses, called paraphrases in GermaNet, GermaNet offers two variations: the paraphrases originally written for GermaNet, and a more extensive set of paraphrases harvested from Wiktionary (Henrich et al., 2014). To improve coverage we use this paraphrase extension in our experiments.

Salsa FrameNet: Framenets provide semantic frames that group words with similar semantic behavior. Schulder et al. (2017) use the frame memberships of verbs as a feature, hypothesizing that verbal shifters will be found in the same frames. We reproduce this feature using frames from the German FrameNet project *Salsa* (Burchardt et al., 2006).

EffektGermaNet: Wiebe and colleagues (Deng et al., 2013; Choi et al., 2014) introduced the idea that events can have harmful or beneficial *effects* on their objects. These *effects* are related but not identical to polarity shifting. Choi et al. (2014) provide lexical information on *effects* in their English resource EffectWordNet. We use its German counterpart, EffektGermaNet (Ruppenhofer and Brandes, 2015), to model the *effect* feature in our data.

4.2 New Features

In §4.1 we described how we reproduce features already used for English shifter classification. Next we introduce new features that have not yet been used for the creation of a verbal shifter lexicon.

4.2.1 Bilingual Dictionary

The motivation behind the work of Schulder et al. (2017) was to introduce a large lexicon of verbal polarity shifters. Now that such a lexicon exists for English, it is an obvious resource to use when creating verbal shifter lexicons for other languages. We hypothesize that a verb with the same meaning as an English verbal shifter will also function as a shifter in its own language. All that is required is a mapping from English verbs to, in our case, German verbs. We choose to use the bootstrapped lexicon of Schulder et al. (2017), rather than the manually created one of Schulder et al. (2018), to show that bootstrapping is sufficient for all stages of the learning process.

One potential source for such a mapping is a bilingual dictionary. We use the English-German dataset by DictCC[4], as it is large (over one million translation pairs) and publicly available. It covers 76% of German verbs found in GermaNet and 77% of English verbs found in WordNet.

Mapping the shifter labels of the English verbs to German verbs is performed as follows: For each German verb, all possible English translations are looked up. Using the English verbal shifter lexicon, we confirm whether the English translations are shifters. If the majority of translations are shifters, the German word is also labeled as a shifter, otherwise as not a shifter. This approach provides explicit labels for 1368 of our 2000 gold standard verbs (68%). Less than 6% of these are tied between *shifter* and *no shifter* translations. Ties are resolved in favor of the *shifter* label. The remaining verbs are labeled with the majority label *no shifter*.

While this bilingual dictionary mapping approach makes for a promising feature, we refrain from considering it for generating a gold standard. Using a dictionary instead of annotating a random sample would introduce biases existing in the dictionary, e.g. more translation pairs being available for frequent words, which can in turn favor features that work better for frequent words. Schulder et al. (2017) also observe in their error analysis that some verbs act as shifters in only some of their word senses. As different word senses often do not translate into the same foreign word, indiscriminate translation may introduce non-shifting senses of English shifter words as false positives. Evaluating the dictionary mapping as a feature will allow us to judge its usefulness for high-precision lexicon induction in future works.

4.2.2 Cross-lingual Word Embeddings

As an alternative to using bilingual dictionaries we investigate transferring English shifter labels to German using cross-lingual word embeddings. These are word embeddings which provide a shared vector space for words from multiple languages. Similar to how the SIM feature (see §4.1.1) compares negation words to verbs in a mono-lingual word embedding, a cross-lingual word embedding allows us to compare English verbs to verbs of another language based on their distributional similarity without having labeled data for the other language. These comparisons can then be used to apply the labels of the English lexicon of verbal shifters to the other language.

Mapping shifter labels cross-lingually with a bilingual dictionary, as described in §4.2.1, requires a dictionary with good coverage for both languages. For many languages, publicly available dictionaries of adequate size are hard to come by. For instance, the second largest English dictionary on DictCC is only 40% the size of the English-German dataset and only a few others have more than 2% its size.

[4] `https://www.dict.cc`

In §5.2 we explore the effect of dictionary size on mapping performance and how cross-lingual word embeddings fare in comparison.

Methods for creating cross-lingual word embeddings can be grouped into *cross-lingual training* and *monolingual mappings*. *Cross-lingual training* learns joint embeddings from parallel corpora. However, such corpora are far smaller and rarer than monolingual corpora and, therefore, not ideal for us.[5]

Monolingual mappings take preexisting monolingual word embeddings and learn linear transformations to map both embeddings onto the same vector space. Commonly, these approaches use bilingual dictionaries to initialize this mapping, which would rather defeat our goal of using embeddings as a data-driven alternative to dictionaries. The *VecMap* framework (Artetxe et al., 2017) provides an initialization method that relies on numerals instead of a dictionary. The idea behind this is that Arabic numerals are used in most languages, even across different writing systems (e.g. Cyrillic, Chinese, etc.), and, therefore, can function as a dictionary without requiring actual bilingual knowledge.

For our experiments, we train Word2Vec word embeddings for English and German, using the Amazon Product Review (Jindal and Liu, 2008) and DeWaC (Baroni et al., 2009) corpora, respectively. Ideally, product review corpora would be used for both languages, but available German review corpora are considerably smaller than their English counterparts. For example, the German corpus Webis-CLS (Prettenhofer and Stein, 2010) contains only 33 million words, while the English-language Amazon Product Review Corpus consists of 1.2 billion words. When generating word embeddings, the size of the corpus is very important for the quality of the resulting embedding, so we choose instead to use DeWaC, a web corpus of 1.7 billion words.

Training is performed using the same hyperparameters as used by Artetxe et al. (2017).[6] We use VecMap to create a cross-lingual word embedding using the default configuration for numeral-based mappings. The resulting cross-lingual embedding covers 79% of German GermaNet verbs as well as 79% of English WordNet verbs. It covers 1598 of our 2000 gold data verbs (80%).

We use this new word embedding to apply English shifter labels to German. To achieve this, we go through our list of German verbs, look up the most similar English verb for each and apply its label. We also investigated majority voting using k-nearest neighbors, but this did not improve performance.

5 Experiments

5.1 Classifier Evaluation

We start our evaluation by reproducing the classifier evaluation of Schulder et al. (2017). The task is the classification of all verbs from the given gold standard in a 10-fold cross validation.

Analogous to Schulder et al. (2017) we evaluate a supervised SVM classifier as well as a graph-based label propagation (LP) classifier that requires no labeled training data. In addition, we evaluate our cross-lingual word embedding classifier (§4.2.2) and our dictionary classifier (§4.2.1), which both make use of the pre-existing English lexicon, but require no additional labeled German data. For an overview of the classifiers and their data requirements, see Table 4.

For the LP classifier we use the ANY features as seeds for the positive label (*shifter)* and the ANTI feature as negative label (*no shifter)* seeds. For SVM we group features into data-driven and resource-driven feature sets (see Table 6) as outlined in §4.1.1 and §4.1.2, as well as introducing the outputs of the cross-lingual word embedding and dictionary classifiers as additional separate features.

Table 5 shows the performance of our various classifiers. All classifiers clearly outperform the baseline[7] and resource-based features outperform data-based ones. This is similar to performance observed

[5] BilBOWA (Gouws et al., 2015) seeks to improve the coverage problem of parallel corpora by incorporating additional monolingual corpora into the training process. However, our experiments with it did not provide satisfactory results. This is in line with reports by Artetxe et al. (2017) and Upadhyay et al. (2016).

[6] Word2Vec configuration: CBOW, 300 dimensions, context window of 5 words, sub-sampling at $1e-05$, negative samples at 10 and vocabulary restricted to the 200,000 most frequent words. We also experimented with using the full vocabulary, but this resulted in lower quality embeddings.

[7] As in Schulder et al. (2017), accuracy proves to be a problematic measure, as it has a strong majority label bias. The *no shifter* label makes up 88.8% of our gold annotation (Table 2), which explains the strong performance of the majority baseline on this metric.

Classifier	Features	Shifter Lex	Text Corpus	Training Data
SIM	Data-driven	—	German	—
$LP_{ANY+ANTI}$	Data-driven	—	German	—
Cross-ling. Embedding	—	English	German, English	—
Dictionary	Bilingual Dictionary	English	—	—
$SVM_{data+resource}$	Data-driven, Resource-driven	—	German	German

Table 4: Classifiers used in Table 5 and their resource requirements.

Classifier	Acc	Prec	Rec	F1
$Baseline_{majority}$	88.1	44.4	50.0	47.0
SIM	70.7	58.0	67.6	62.4
$LP_{ANY+ANTI}$	87.1	67.2	65.0	66.1
Cross-lingual Embedding	85.1	67.6	74.6	$70.9^{*\dagger}$
Dictionary	86.5	69.2	77.3	$73.0^{*\dagger}$
SVM_{data}	74.6	60.8	72.6	66.2
$SVM_{resource}$	91.3	79.4	73.9	$76.4^{*\dagger}$
$SVM_{data+resource}$	91.4	79.0	76.7	$77.7^{*\circ\dagger}$
$SVM_{data+resource+embed}$	91.6	79.6	78.9	$79.2^{*\circ\dagger}$
$SVM_{data+resource+dict}$	91.3	78.0	80.9	$79.4^{*\circ\dagger}$
$SVM_{data+resource+dict+embed}$	**92.1**	**80.3**	**82.0**	$\mathbf{81.0}^{*\circ\dagger\ddagger}$

statistical significance (paired t-test with $p < 0.05$):
* better than LP; ° better than Dictionary; † better than SVM_{data}; ‡ better than $SVM_{data+resource}$

Table 5: Evaluation of classification (§5.1) on the 2000 verb gold standard (Table 2). Precision, recall and f-score are macro-averages.

Group	Features
data	$LP_{ANY+ANTI}$, SIM, CLASH, PRT
resource	GermaNet, Salsa, EffektGermaNet
embed	Cross-lingual Embedding
dict	Dictionary

Table 6: Features included in SVM feature groups in Table 5. All features in *data* and *resource* were also used in Schulder et al. (2017).

for English (Schulder et al., 2017). Cross-lingual embeddings and dictionaries as stand-alone classifiers both outperform the label propagation approach due to their better recall coverage of shifters.

Interestingly, the cross-lingual embedding classifier performs far better than SIM, despite both relying on word embeddings to judge distributional similarity. Comparing similarity among verbs, even cross-lingually, works better than across parts-of-speech, as required for negation-shifter comparisons.

Adding both cross-lingual features to the SVM classifier improves performance further. This shows that they are not only complementary to the existing features, but also to each other, as using only one cross-lingual feature does not improve performance as much. The most feature-rich SVM configuration, $SVM_{data+resource+dict+embed}$, provides a significant improvement over $SVM_{data+resource}$, the best classifier of Schulder et al. (2017). We conclude that cross-lingual shifter information is useful even when the same bootstrapping process and feature set is used in both the source and target language.

Figure 1 shows the learning curve of select SVM configurations, compared to the classifiers that work without labeled German data, i.e. LP, Embedding and Dictionary. Cross-lingual embedding and dictionary classifiers provide a stronger baseline than LP, outperforming $SVM_{data+resource}$ when training data is sparse. However, adding them as features to the SVM results in a classifier that consistently improves upon all other systems, even at small training sizes of only 20%. Combining all available sources of information as SVM features is therefore the preferred approach if any amount of training data is available.

5.2 Evaluation of Dictionary Size

The dictionary mapping approach (§4.2.1) has been shown to be a strong stand-alone classifier and SVM feature (Table 5), slightly outperforming the cross-lingual word embedding approach (§4.2.2). However, the underlying English-German dictionary by DictCC is of considerable size, consisting of over 1.1 million translation pairs. Even then, almost a quarter of WordNet and GermaNet verbs are not

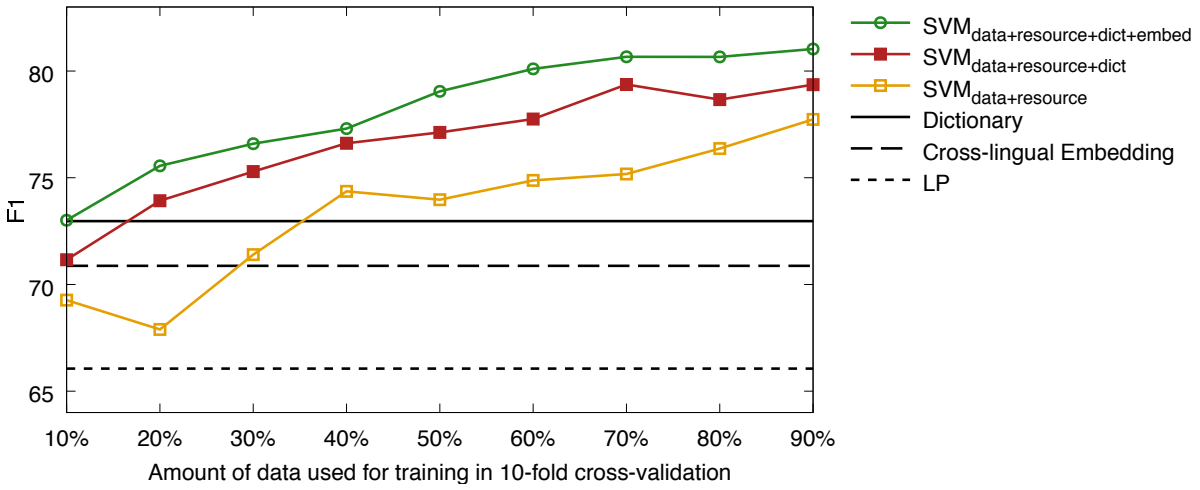

Figure 1: Learning curve on gold standard. $\text{SVM}_{\text{data+resource}}$ represents the previously best classifier (Schulder et al., 2017).

covered. For many other languages, finding a publicly available dictionary of comparable size may pose a challenge. Therefore, we investigate how smaller dictionaries may perform in our classifiers.

The English-German DictCC dictionary covers slightly over 8000 of the English verbs found in WordNet. Of the 2000 German verbs in our gold standard, DictCC covers 1368. To simulate bilingual dictionaries of smaller size, we create a version of the DictCC dictionary with half the English vocabulary by limiting it to the 4000 most frequent verbs from WordNet ($\text{Dict}_{\text{voc\_size=4k}}$). We also create even smaller versions with only the 1000 ($\text{Dict}_{\text{voc\_size=1k}}$) and 500 most frequent English verbs ($\text{Dict}_{\text{voc\_size=0.5k}}$).

As bilingual dictionaries provide a many-to-many mapping, having half the English vocabulary does not necessarily mean that we receive only half the German translations. Many German words receive multiple translations, all of which we then use to determine their shifter label via majority vote. Reducing the English vocabulary, therefore, first reduces the number of label votes for each German word, until, eventually, German words are removed as there are no more votes for them. Having fewer votes per German output label can, however, still affect the robustness of the labeling process. In our case, reducing the English vocabulary by half still provides translations for 1168 of German words in our gold data, i.e. 85% of the full dictionary. Reducing it further to 1000 English verbs drops the size of the German vocabulary to 52%. Using only the 500 most frequent English words leaves a German coverage of 33%.

Figure 2 shows the performance of the differently sized dictionaries as stand-alone classifiers, while Figure 3 shows how much they can improve the best classifier of Schulder et al. (2017), i.e. $\text{SVM}_{\text{data+resource}}$. In both cases we see that while even smaller dictionaries can still provide acceptable performance, using cross-lingual embeddings is preferable to using a dictionary of insufficient size.

5.3 Bootstrapping

In their intrinsic evaluation Schulder et al. (2017) showed that explicit knowledge of a large number of polarity shifters can improve sentiment analysis. To increase the size of our lexicon, we bootstrap additional shifters following their approach. We train our best classifier (Table 5) on the 2000 verbs from our gold standard (§3) and then use it to classify the remaining 7262 GermaNet verbs that had not been labeled so far. Of these, the classifier labels 595 verbs as shifters. A German native speaker manually checks these predicted shifters and confirms 453 to be true verbal shifters. Limiting our annotation effort to predicted shifters and discarding all others reduces the cost of annotation by 92%.

Table 7 shows the classifier precision at different confidence intervals. Like Schulder et al. (2017), we see very high performance for the first quartile, matching their observation that manual confirmation is not strictly necessary for high confidence labels. Combining the 453 bootstrapped shifters with the 224 shifters from the gold standard we produce a **novel list of 677 German verbal shifters** *(see footnote 1)*.

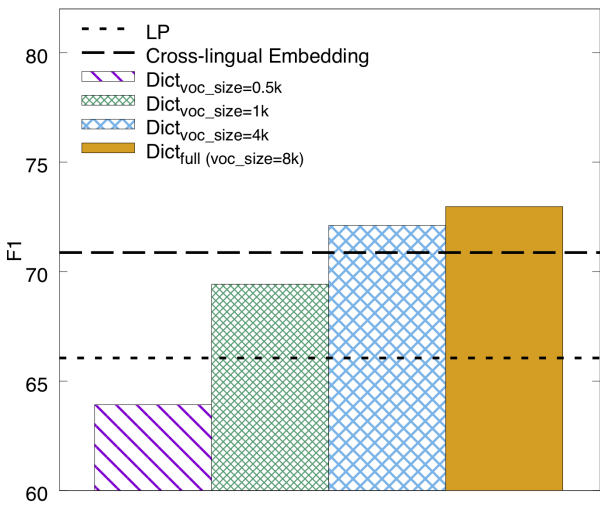

Figure 2: Comparison of dictionaries with different vocabulary sizes. Classifiers use *no labeled training data*. $\text{Dict}_{\text{full}}$ is equivalent to the dictionary shown in Table 5.

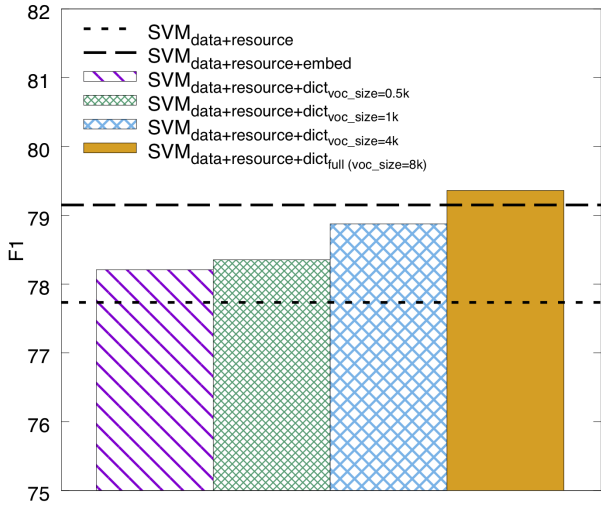

Figure 3: Comparison of SVM classifiers using dictionaries with different vocabulary sizes. $dict_{full}$ is equivalent to the SVM feature *dict* in Table 5.

Confidence Rank	1–150	151–300	301–450	451–595
Precision	97.3	83.3	70.0	53.1

Table 7: Classification of GermaNet verbs that were ***not*** part of gold standard (§3); verbs are ranked by confidence-score of classifier and evaluated at intervals by precision of *shifter* label.

6 Conclusion

We confirm that the bootstrapping process for creating a large lexicon of verbal polarity shifters can successfully be applied to German. Given appropriate resources, the effort for adjusting to a new language is minimal, mostly requiring translating seed words and adjusting syntactic patterns, while the underlying concepts of the features remain the same. Using a manually annotated sample of 2000 verbs taken from GermaNet, we train a supervised classifier with various data- and resource-driven features. Its performance is further improved by leveraging information from an existing English lexicon of verbal shifters using bilingual dictionaries and cross-lingual word embeddings. The resulting improved classifier allows us to triple the number of confirmed German shifters in our lexicon.

We differentiate features by whether they require only unlabeled data and basic linguistic tools or whether they depend on rare semantic resources that may not be available for many languages. In addition, we introduce the possibility of using cross-lingual resources to reduce the dependence on resources in the target language. This shows promise, improving performance for both unsupervised and supervised classification, especially for scenarios where only small amounts of training data are available. However, supervised learning that combines all features still provides the best results.

Our recommendation for creating shifter lexicons in new languages is to start out with cross-lingual label transfer, but to also invest in annotating a random sample of verbs if possible, especially if advanced semantic resources like a wordnet are available, as they require supervised learning to be leveraged.

In reproducing the work of Schulder et al. (2017), we limited ourselves to verbs. In the future, we would like to investigate methods to extend the shifter lexicon to also cover nouns and adjectives.

While we have shown that the same approach for classifying verbal shifters works for German and English, future work will expand the number of languages, especially to verify that these methods can also be applied to non-Indo-European languages, such as Chinese, Japanese or Arabic. In this context it will also be interesting to see whether using shifter lexicons from several languages can further improve the dictionary and cross-lingual word embedding classifiers.

Acknowledgements

The authors would like to thank Stephanie Köser for annotating the German gold standard lexicon presented in this paper. For proofreading the paper the authors would also like to thank Meaghan Fowlie and David M. Howcroft.

The authors were partially supported by the German Research Foundation (DFG) under grants RU 1873/2-1 and WI 4204/2-1.

Abstract

Most work on part-of-speech (POS) tagging is focused on high resource languages, or examines low-resource and active learning settings through simulated studies. We evaluate POS tagging techniques on an actual endangered language, Griko. We present a resource that contains 114 narratives in Griko, along with sentence-level translations in Italian, and provides gold annotations for the test set. Based on a previously collected small corpus, we investigate several traditional methods, as well as methods that take advantage of monolingual data or project cross-lingual POS tags. We show that the combination of a semi-supervised method with cross-lingual transfer is more appropriate for this extremely challenging setting, with the best tagger achieving an accuracy of 72.9%. With an applied active learning scheme, which we use to collect sentence-level annotations over the test set, we achieve improvements of more than 21 percentage points.

1 Introduction

Most natural language processing (NLP) applications have been developed for and tested on only a handful of languages. The majority of the world's languages are under-represented in the field, mostly due to the lack of proper resources. Endangered languages pose additional problems, as the lack of resources is further exacerbated by the lack of standard orthography. Therefore, there is an obvious need for both resources and technologies adapted to languages of under-represented communities. Especially in the case of endangered languages, computational approaches can be used to scale and accelerate documentation and revitalization efforts.

For the purposes of this study, we focus on Griko, a Greek dialect spoken in southern Italy, in the Grecìa Salentina area southeast of Lecce.[1] There is another endangered Italo-Greek variety in southern Italy spoken in the region of Calabria, known as Grecanico or Greco. Both languages, jointly referred to as *Italiot Greek*, were included as seriously endangered in the UNESCO *Red Book of Endangered Languages* in 1999. Griko is only partially intelligible with modern Greek, and unlike other Greek dialects, it uses the Latin alphabet. Less than 20,000 people (mostly people over 60 years old) are believed to be native speakers (Horrocks, 2009; Douri and De Santis, 2015), a number which is quite likely an overestimation (Chatzikyriakidis, 2010).

In general, the lack of annotated resources can be addressed through several directions. The obvious first one is the collection of human annotations, an expensive and time-consuming process. Another option is to collect additional monolingual data and use them in weakly-supervised approaches. Finally, one could use methods that transfer knowledge across languages, in which case they could focus on collecting translations or bilingual data. With this paper we attempt to quantify how effective each of these directions can be at the beginning of building applications for an endangered language.

We present a corpus of Griko narratives, first collected in the beginning of the 20th century, along with their Italian translations, suitable for computational research on the language.[2] We focus on the task

[1] A discussion on the possible origins of Griko can be found in the paper by Manolessou (2005).

of part-of-speech (POS) tagging, an important subcomponent of many downstream NLP applications, although our long-term goal is to annotate the whole corpus with morphosyntactic tags. Three linguists were tasked with creating gold-standard annotations for a portion of the resource, which we use as a test set in our experiments. Subsequently, our corpus includes human annotations as well as monolingual data and translations, allowing us to explore all approaches.

Based on another small Griko corpus with POS annotations, we explore computational methods for annotating our collected resource with POS tags. We evaluate several commonly used models for POS-tagging. We start with a traditional feature-based cross-entropy tagger, a Conditional Random Field (CRF) tagger, and a neural bi-LSTM tagger. We further experiment with methods that take advantage of additional monolingual data, and with methods that project cross-lingual tags through alignments. In addition, we are the first to combine the two latter approaches for POS-tagging in a low-resource setting, and we show that their combination achieves higher accuracy. Finally, we study how additional human annotations can be incorporated through an applied active learning scenario. In line with previous work, we show that this greatly improves the tagging accuracy.

Our contributions are three-fold: first, we aim to provide coarse insights into what type of annotations and resources are more effective at the early stages of developing a tagging tool for an endangered language. Second, we hope that the release of our resource will spark further interest in the computational community, so that previous, and future, methods are tested in actual endangered language settings. Finally, we benchmark the accuracy of several models on our dataset, and test them in a traditional setting and in a *transduction* setting where we also use the translations of the test set. We also evaluate all methods in an active learning scenario, showing that different approaches are suitable for different amounts of annotated data.

When only 360 annotated sentences are available, the best method is the one that combines them with both cross-lingual projections and monolingual data, achieving an accuracy of 72.9%. As the active learning scheme unfolds, however, we show that there is no need for either semi-supervised nor transfer learning approaches: a simpler feature-based CRF model achieves the highest scores, with more than 94% accuracy.

2 Resource

Resources in Griko are very scarce. The German scholar Gerhard Rohlfs pioneered research on Griko and composed the first grammar of the language (Rohlfs, 1977), also heavily influencing the subsequent grammar created by Karanastasis (1997). Although the language has been further studied, almost no corpora are available for linguistics research.

The only Griko corpus available online[3] (Lekakou et al., 2013) consists of about 20 minutes of speech in Griko, along with text translations into Italian. The corpus (henceforth `UoI` corpus, as it is hosted at the University of Ioannina, Greece) consists of 330 mostly elicited utterances by nine native speakers, annotated with transcriptions, morphosyntactic tags, and glossing in Italian.

The most noted Griko scholar is Vito Domenico Palumbo (1854–1928) who made the first serious attempts to create a literary Griko for the dialect of Calimera (the most populous of the nine remaining communities where Griko is still spoken), based on modified Italian orthography. Salvatore Tommasi and

Salvatore Sicuro then edited and published Palumbo's manuscripts (Palumbo, 1998; Palumbo, 1999), a part of which we now make available for computational and linguistic research.

After scraping from their website[4] 114 narratives that Palumbo had collected, along with their Italian translations, we removed all HTML markup and normalized the orthography: we substituted all curly quotes and apostrophes with simple ones, and substituted the vowels with circumflex (â, ô, û) that were used in a few contractions with the more common accented vowel–apostrophe combination (à', ò' ù'). Using the Moses tools (Koehn et al., 2007) with the Italian settings, we lowercased and tokenized our parallel dataset. For completeness purposes, we also make available the untokenized and proper-case versions of the corpus. The statistics of the resource are shown in Table 1.

We chose the first 10 narratives to be our test set, as they correspond to about 10% of all sentences. The rest of the narratives are treated as a monolingual or parallel resource to be leveraged. The test set was, in addition, hand-annotated by linguists: they corrected any tokenization errors that were introduced by the automatic process (for example, regarding the use of the apostrophe) and produced POS tags for every test sentence.

For every narrative, one of the linguists was presented with the produced output of the tagger, and proceeded to correct it. In order to ensure the quality of the annotations, a second linguist was then presented with the result of the work of the first linguist and tasked with correcting it, until all disagreements were resolved. Although it significantly slowed down the annotation process, we hope that this scheme ensured the quality of our annotations.

2.1 Differences from previous Griko resources

Orthography Griko has never had a consistent orthography. The transcriptions in the `UoI` corpus are based on orthographic conventions found in the few textual resources such as the local magazine *Spìtta*, that closely follow conventions adopted in Italian, aiming to be familiar to the speakers of the language. This non-standardization of the orthography leads to variations in the transcription of the same words.

In addition, we find that the word segmentation in our collected narratives follows more the concept of a phonological word. As a result, words that are segmented in the `UoI` corpus, in our narratives are often fused in a single token. The most common case that also appears in both Italian and Greek, is the contraction of prepositions and subsequent articles, such as the Italian *alla* or the Greek *στη (sti)* 'to the.Fem'. Other examples of word fusion that is not permitted in either Italian or Greek but appear in our narratives are nouns and possessive pronouns, or adverbs with other adverbs or prepositions. A direct result of this phenomenon is that annotating such tokens with single POS tags does not capture all of the necessary information.

Therefore, we chose to annotate such words with multiple POS-tags, effectively making our tag dictionary the superset of the universal tagset. The final tags that appear in practice in our corpus, and their respective frequencies, are listed in Table 2. Examples of fused words and their glosses and associated tags are shown in Table 3.

[4] `https://www.ciuricepedi.it`

word:	*stì*	*mànassu*	*cikau*	*ènna*	*vàleti*	*pànuti*
morphemes:	*s[e]-tì*	*màna-su*	*ci-kau*	*è-na*	*vàle-ti*	*pànu-ti*
POS tag:	P+D	N+Pr	Adv+Adv	V+C	V+Pr	Adv+Pr
gloss:	to-the.Fem.SG	mother-your.SG	there-down	have-COMP	put-her	on-her
translation:	'to the'	'your mother'	'down there'	'will'	'put her'	'on her'

Table 3: Examples of fused types that receive multiple tags in our annotation. The first example is a common preposition-determiner contraction, while the second and last example denote the common fusion of pronouns that follow nouns or adverbs. Notice the doubled consonants in the second and fourth instance, due to *raddoppiamento fonosintattico*.

Phonosyntactic Gemination One important difference is that the UoI corpus explicitly annotates the phenomenon of *raddoppiamento fonosintattico* (phonosyntactic gemination, or doubling of the initial consonant of the word in certain contexts) with a hyphen that separates the two words. The transcriptions that we collected do not mark for this phenomenon. The two words are often fused into a single token, and the doubling is not always present. For example, both following types appear in our corpus: *aderfòmmu* and *aderfòmu* 'my brother'.

Furthermore, the UoI corpus also uses apostrophes to mark word boundaries within which the *raddoppiamento fonosintattico* takes place. The use of apostrophes in our collected narratives is more loose. They are used both to mark elision/apocope, stress, as well as what it seems to be instances of raddoppiamento fonosintattico. This poses further issues that are discussed in the next paragraph.

Code Switching There are three languages present in the region of Salento: the regional variety of Italian, the Italo-Romance dialect of Salentino, and Griko.[5] In modern day all members of the Griko community are bilingual or trilingual. The generations before the Second World War are considered to have been predominantly monolingual, and our narratives were collected at that time, around the beginning of the 20th century. However, elements of Salentino do appear in the narratives, either as passing words, or as full sentences, mostly in dialogue turns. Note that resources on Salentino are also extremely scarce if not non-existent.

In order to deal with such examples, we decided to distinguish two scenarios. Tag switching or intra-sentential switching instances were fully annotated. So, any Salentino words or phrases that appear *within* a Griko sentence, are used for training and evaluation. However, in the few cases where we encounter full sentences in Salentino, we opt to not use them for training or evaluation. Such sentences are marked with distinctive tags in the released corpus. Note that the UoI corpus does not include any non-Griko words or phrases. An extensive study of the code-switching phenomena that occur in our corpus is left for future work.

The following is an example of usage of a Salentino phrase (italicized) within a Griko sentence, taken from story 4. Note that there exists a Griko word for 'olive oil', namely *alài* or *alàdi*, as well words for 'good', namely *kalòn* or *brao*. However, the Salentino phrase *oju finu* 'fine oil' is chosen:

leo	ti	vastò	*oju*	*finu*
say-1SG	COMP	hold-1SG	oil	fine
V	C	V	N	Adj

'I say that I have good olive oil'

Tokenization The UoI corpus has been carefully crafted to make sure that word boundaries are clearly denoted by spaces or hyphens. This unfortunately is not the case in our collected narratives. The "loose" use of apostrophes complicates the work of the tokenizer. We chose to tokenize all apostrophes as a single token, except for the cases of known elisions that were present in previous corpora, such as the case of the conjunction *c' (ce)* 'and'. In addition, in the manually annotated test set, the linguists corrected any clear tokenization issues regarding the apostrophe.

[5] See (Golovko and Panov, 2013) for a broader overview of the linguistic diversity in the Salento area.

Stress Marking In the UoI corpus, all words with two or more syllables have a diacritic mark to indicate the location of stress. However, the resources that we collected are not consistent in the use of such a diacritic. Its use is, besides, not standardized and not well studied. Although in most cases such a diacritic is used, there are several instances of polysyllabic words that have no stress marks.

2.2 Metadata

We further provide as much information as possible for each narrative, in the form of metadata. This includes the original url of the narrative, the title of the narrative in Griko and its translation in Italian. Whenever they were reported (more than 95% of the narratives) we include the location where the narrative was collected, and we anticipate that further analysis could possibly reveal any regional variations. The vast majority of the stories were naturally collected in Calimera, the largest village and the center of the Griko community, but the resource also includes 10 stories collected in Martano, as well as stories collected in Corigliano and Martignano, two smaller villages. We also include information about the date that a story was collected, as well as the narrator of the story. There are a total of 37 different narrators, while the 10 stories from Martano were retrieved from anonymous manuscripts. There are also 11 stories where the narrator is not known. Two thirds of the stories were narrated by women, while 15% of the narrators were male. The oldest manuscript dates back to 1883, while the most recent story was collected in 1998. We hope that this additional information will further allow us to investigate morphosyntactic phenomena in relation to their temporal or location context, but this is left as future work.

3 Related Work

POS tagging is a very well studied problem; probabilistic models like Hidden Markov Models and Conditional Random Fields (CRF) were initially proposed (Lafferty et al., 2001; Toutanova et al., 2003), with neural network approaches taking over in recent years (Mikolov et al., 2010; Huang et al., 2015).

The use of parallel data for projecting POS tag information across languages was introduced by Yarowsky and Ngai (2001), and further improved at a large scale by Das and Petrov (2011) who used graph-based label propagation to expand the coverage of labeled tokens. Täckström et al. (2013) used high-quality alignments to construct type and token level dictionaries. In the neural realm, Zhang et al. (2016) used only a few word translations in order to train cross-lingual word embeddings, using them in an unsupervised setting. Fang and Cohn (2017), on the other hand, used parallel dictionaries of 20k entries along with 20 annotated sentences.

Most of the previous approaches are rarely tested on under-represented languages, with research on POS tagging for endangered languages being sporadic. Ptaszynski and Momouchi (2012), for example, presented an HMM-based POS tagger for the extremely endangered Ainu language, based on dictionaries, 12 narratives (yukar), using one annotated story (200 words) for evaluation. To our knowledge, no other previous work has extensively tested several approaches on an actual endangered language.

The lack of high quality annotated data led to approaches that attempt to use monolingual resources in a semi-supervised setting. Notably, Garrette and Baldridge (2013) used about 200 annotated sentences along with monolingual corpora improving the accuracy of an HMM-based model. They tested their model on two low-resource African languages, Kinyarwanda and Malagasy and they found that in this time-constrained scenario type-level annotation leads to slightly higher improvements than token-level annotation, increasing the accuracy of their taggers to slightly less than 80%. Similar conclusions were reached in Garrette et al. (2013): 4 hours of annotation are more wisely spent if annotating at the type-level, provided there exist additional raw monolingual data. This line of work adequately addressed the question of what labeled data are preferable when there is (exceptionally) restricted access to annotators.

However, language documentation neither is nor needs to be restricted to such minimal amounts of annotation work. In addition, recently proposed endangered language documentation frameworks (Bird et al., 2014b) advocate the collection of translations (Bird et al., 2014a) which render the resource interpretable. In the case of our resource, we argue that the translations are enough for providing type-level supervision. Possibly, this is only feasible because the two languages belong in the same family *and* have been in contact for centuries, so care needs to be taken with the application of this claim.

Model	Data		
	no transduction		*transduction*
	UoI	+clp	+clp-all
stanford	62.90	67.10	67.11
crf	57.79	59.12	59.26
crf-mod	67.52	62.89	66.50
neural	45.27	53.24	58.50
	UoI+mono	+clp	+clp-all
G&B	71.67	**72.92**	72.07

Table 4: The best performing model is the one that combines semi-supervised learning with cross-lingual projected tags (G&B+clp). All models except for crf-mod benefit from transfer learning through alignments (+clp). Transduction does not significantly affect performance, except for the neural model.

4 Part-of-Speech Tagging

First, we construct a mapping of the tags of the UoI corpus to the Universal Part-of-Speech tagset (Petrov et al., 2012). This mapping is available as part of the complementary material of our resource.

Starting with the tagged UoI corpus, we can use several methods to train a tagger, which we use as baselines. We use the Stanford Log-linear POS-tagger (Toutanova et al., 2003) (henceforth stanford), trained and tested with the default settings. We also test a simple feature-based CRF tagger (henceforth crf), using the implementation of the nltk toolkit (Bird and Loper, 2004). We extended the implementation to also use prefix and suffix features of up to 4 characters, along with bigram and trigram features.[6] We will refer to this method as crf-mod.

Finally, we also investigate the use of a simple neural model. It uses a single bi-LSTM layer to encode the input sentence, and it outputs tags after a fully connected layer applied on the output of the recurrent encoder, as was described in Lample et al. (2016). The model is implemented in DyNet[7] (Neubig et al., 2017), with input embedding and hidden sizes of 128, and output (tag) embedding size of 32. It is trained with the Adam optimizer with an initial learning rate of 0.0002 and for a maximum of 50 epochs. We select the best model based on the performance on a small dev set of 40 sentences that we sampled randomly from the training set.

The tagging performance of all methods is shown in the first column of Table 4. We find that the crf-mod model is the best baseline model. With such few data to train on, both the crf and the neural model do not perform well. The bi- and tri-gram features that the crf-mod model uses are very sparse, while the neural model has to deal with a very large number of unknown words, as discussed below in the Analysis subsection.

In line with previous work, we find that semi-supervised training achieves better results in such low-resource settings. We exploit all the narratives that we collected by treating them as an additional monolingual corpus, used in the framework proposed by Garrette and Baldridge (2013). This approach (henceforth G&B) significantly improves upon all baselines, achieving an accuracy of 71.67% in the test set, an improvement of more than 4 percentage points.

Cross-lingual projected tags So far, our results have not used the Italian translations of our resource. We can follow a procedure similar to the one of Täckström et al. (2013), and extract word alignments from the Griko-Italian parallel data of the training set. We use a pre-trained Italian tagger[8] in order to tag the Italian side, and we map those tags to the universal tagset. We can then project the tags of the Italian tokens to the aligned Griko ones.[9] For the cross-lingual projected tags, we found that in practice

[6] Our extensions will be submitted to the nltk codebase.

[7] We will make the code available online.

[8] http://elearning.unistrapg.it/TreeTaggerWeb/TreeTagger.html

[9] The type-level projections are also provided with the Supplementary Material.

type-level predictions work better, and thus we only report results with such models. The tags of the Italian side of our resource, the Griko-Italian alignments, and the cross-lingual POS projections on Griko types are available through the complementary material of our resource.

Augmenting the training set with the type-level projected tags (`clp` in Table 4), we achieve improvements for all models, except `crf-mod`. The `crf-mod` method uses sparser features and is more prone to errors due to the noise of the projections. The best performance is achieved when we combine the projected tags, as type-level supervision, with the `G&B` method that leverages monolingual data. Their combination achieves the best overall performance, with an accuracy of 72.9%, a significant improvement over all other methods. As far as we know, this is the first time that cross-lingual projected tags are combined with the method of Garrette and Baldridge (2013).

Transduction An additional approach that needs to be studied is the transductive approach. Since we have translations both for the training and the test sets, we can extract word alignments and project POS tags also for the test set. The results of the transductive approach using cross-lingual projected tags from all the data that we have are shown in the third column of Table 4 (under `clp-all`).

We find that most methods benefit from the transductive approach, with the `stanford` and `crf` methods exhibiting minimal improvements, while the `neural` method improves significantly by about 5 percentage points as now there are even less out-of-vocabulary words in the input. The `crf-mod` method improves over the `UoI+clp` version, but still does not surpass the `UoI` only version. The only method that does not benefit from the transduction setting is the `G&B` method, where the performance drops.

An additional transductive step that can be taken with the `G&B` method is to also add the test set as part of the monolingual data that it uses. However, including the test set in the monolingual data also resulted in a drop in performance. Using all monolingual data along with the train-only cross-lingual types (`clp`) leads to accuracy around 69.9% (a drop of 3 points from the best model), while using all monolingual data with `clp-all` leads to a drop of another 1.4 points, to an accuracy of only 68.5%, which however is still better than all other taggers. These accuracy drops are probably justifiable, since `G&B` was not developed under a transductive assumption.

Analysis It is worth noting that our choice of using combined tags for fused/contracted words means that our training sets, under all settings, do not contain all tags that we encounter in the test set. The tagset of the `UoI` corpus only had 14 tags (the 12 universal ones plus `P+D` and `C+Pr`), indicative of its small size. As more narratives were annotated, the size of the necessary tagset increased to the final 29. However, the additional tags that we had to use are rather rare and do not severely affect the performance of our models. The tags that are present in the `UoI` corpus in fact account for 96.7% of all target tags in the test set, a value that could be considered as a skyline for all methods.

The explanation of our models' performance lies in vocabulary coverage. The `UoI` corpus only includes 46.6% of the test set tokens (8.9% of the test set types). The augmented training set with type-level projections increases those numbers to 48.7% of test tokens and 14.8% of test types. Even though we restrict ourselves to high quality alignments,[10] we are able to project tags to 3870 types (3911 in the transductive scenario), an amount higher than the amount of tags that a trained linguist can produce within four hours of annotation (Garrette et al., 2013).

The `G&B` method deals with the vocabulary coverage issue by introducing a tag dictionary expansion as a first step. They use a label propagation algorithm —Modified Adsorption (Talukdar and Crammer, 2009)— in order to spread labels between related items. In our framework, the cross-lingual projected tags provide labels for a subset of the types, in a way similar that an annotator would, partially alleviating the difficulty of the method's first step. This leads to less noise in the created tag dictionary, leading to increased accuracy. Note that, out of the cross-lingual projected tags that correspond to types that appear in the test set (about 10% of the test set types, in the *no transduction* setting), more than 65% were correctly projected.

[10] An alignment is used if either its probability is 1, or its probability is higher than 0.9 *and* the frequency of both tokens is higher than 5. Relaxing those conditions leads to worse performance due to noise.

Iteration	Narrative	Best accuracy without AL	Best accuracy with AL	Δ	Accuracy on story 9	Best method
1	story-1	77.89	—	0.0	78.13	G&B+clp
2	story-8	72.76	78.48	5.72	82.12

Table 5: Tagging accuracy for each test narrative with and without active learning. We obtain significant improvements (shown in the Δ column) by adding each annotated narrative to the training set before retraining and tagging the next narrative. The last two columns further outline the improvements from active learning, showing performance on the last and longest narrative of the test set (story-9) in each iteration, also showing the best method in each iteration. The impact of using monolingual data and type-level cross-lingual projections disappears when more training data are available.

5 Active learning

We further explored the use of active learning while tagging our test set. Our active learning scheme is as follows: We first sorted the test set narratives according to length, and starting only with the UoI corpus, we trained all taggers, producing annotations for the first story of the test set. After the corrections on the annotation of each narrative were completed, it was added as gold training data and the taggers were re-trained. For each subsequent story, the linguists were provided with the output of the tagger that achieved the highest accuracy in the previous iteration.

The main reason why we decided to follow this narrative-level active learning scheme instead of collecting type-level annotations is that a noisy corpus is not very helpful for linguistics research; at least some part of the resource should have to be checked for quality and accuracy by hand. In addition, the translations of the narratives can provide such information, as we already showed in the previous section. As we expand the coverage of our POS annotations over the whole corpus, we will explore other methods for selecting the types or sentences to be annotated through an active learning scheme.

The results, per narrative, with and without active learning, in the order that they were annotated by our linguists (from the shortest narrative to the longest) are outlined in Table 5. The results for each narrative in the active learning scenario ("with AL" column) report the best performing model that is trained on the concatenation of the UoI corpus and all the stories that were annotated in previous iterations. It is clear that the performance of the taggers improved continuously, as we added more training data. This is further outlined by each iteration's tagging accuracy on story 9, the last and longest narrative of the test set. Of course, when a narrative is added in the training set, it is then excluded from the test set, and the performance is reported on the rest of the narratives.

All methods display notable improvement as we added the annotated narratives to the training set. The performance trends are outlined in Figure 1. Firstly, it is notable that as the training set increases, the advantage of the model of Garrette and Baldridge (2013) that leverages monolingual data diminishes, compared to our simpler crf-mod tagger, both with or without cross-lingual projected tags. Before the first iteration, the accuracy gap is 6.4 percentage points in favor of G&B. However, after adding around 4-5 narratives so that there are around 500 training sentences, our crf-mod+clp method surpasses the G&B method and keeps improving. This is also outlined by the dashed line in Table 5. As we add more training instances, the accuracy of the G&B method plateaus around 85% and does not improve further.

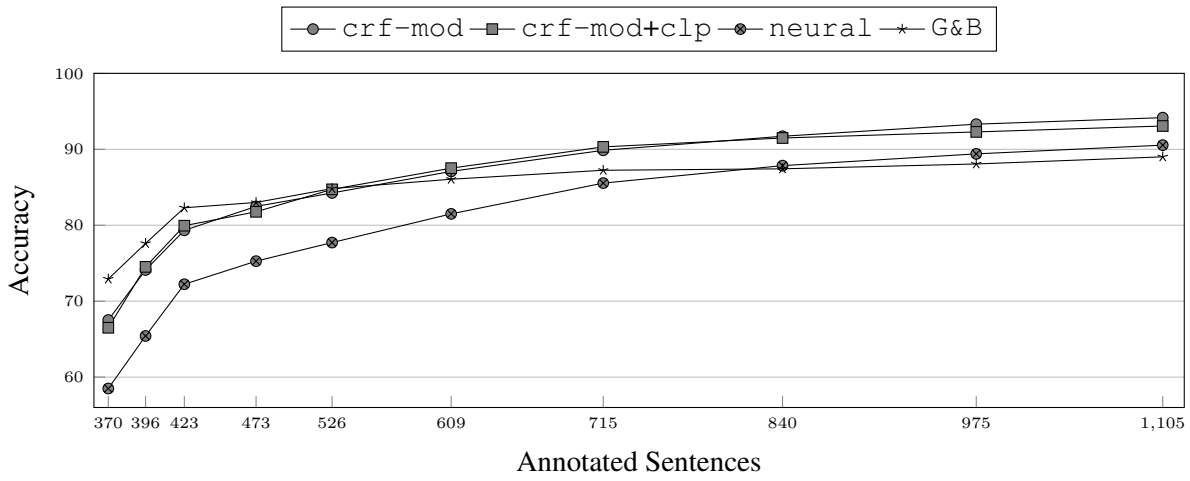

Figure 1: Accuracy on the (remaining) test set as we add annotated narratives to the training set. All methods benefit from the active learning approach, with G&B displaying better performance due to its use of monolingual data in the first iterations, but the crf-mod approach achieving the best results in the last iterations, eventually not even needing the cross-lingual type-level projections (+clp).

Furthermore, after a couple more iterations, when more than 800 annotated sentences are available for training, the crf-mod method without cross-lingual projected tags achieves higher accuracy than all others. We identify this point as the one where simple token-level supervision is efficient enough to outperform semi-supervised or transfer-learning approaches.

Finally, we observe that the accuracy of the neural bi-LSTM approach that only uses the tagged corpus without further use of monolingual data, improves significantly as the training set increases. With only 370 training sentences, the gap between the neural and the best method is more than 14 percentage points. With 1,100 training sentences, the accuracy gap diminishes to only 2 percentage points.

6 Cross-Validation

Our end goal is to annotate the whole corpus with POS tags, as well as richer annotations. Towards that direction, our gold annotated test data could be used to train a higher quality POS tagger, which we will use to annotate the rest of the corpus. In Section §5, we found that including all but one annotated narratives for training, and testing on the last one (story-9) we were able to obtain an accuracy of more than 94.17%. In order to get a better estimation of how well a tagger trained on our gold data would work, we perform a cross-validation experiment, using crf-mod, our best performing model.

For each cross-validation instance, one of the annotated narratives becomes the test set, and the rest will be included in the training set. This allows us to obtain an average performance over 10 instances. The average accuracy of the crf-mod model is about 91.9%, with a standard deviation of about 2 percentage points (minimum is 88.5% on story 5, and maximum is 94.9% on story 2).

The main obstacle to annotating the rest of the corpus with higher quality is out-of-vocabulary words. The combined vocabulary of the UoI corpus and our 10 annotated narratives covers 16% of the vocabulary of the 104 unannotated sentences (but 85% of the total tokens). As part of our future work, we plan to incorporate word-level active learning in our annotation/correction scheme, similar to the approaches proposed by Fang and Cohn (2017).

7 Conclusion

We presented a parallel corpus of 114 narratives on an endangered language, Griko, with translations in Italian. For now, a test set of 10 narratives is hand-annotated with Part-of-Speech tags, but in the future we will enrich the resource with annotations on the rest of the corpus, as well as with richer syntactic and morphological annotations. We also plan on contributing our corpus to the Universal Dependencies treebanks (Nivre et al., 2016) as Griko is absent from the supported languages.

We extensively evaluated several POS tagging approaches, and found that the method of Garrette and Baldridge (2013) can be combined with cross-lingual type-level projected tags, outperforming all other methods, with an accuracy of 72.9%, when less than 500 sentences are available. As data was added in the training set in an active learning scenario, a simple feature-based CRF approach outperforms all other models, with accuracy improvements of over 21 percentage points and over 94% accuracy on the last narrative. In fact, when more than 800 sentences are available for training, cross-lingual tag projections hurt performance.

The collected annotations from our test set could form the basis for training a high-accuracy POS tagger for Griko, so that we can expand the POS annotations to the rest of our corpus with only a small amount of noise. We aim to explore this direction in our future work, along with other active learning methods that require less human intervention. In addition, we plan to further enrich the annotations of our corpus with morphological tags similar to the `UoI` corpus, that will provide even more insight in Griko and its usage. When the full annotations of the corpus are completed, we plan to use statistical methods to study specific phenomena regarding the grammar and syntax of Griko.

Finally, and most importantly, we hope that the release of this corpus will spark further interest for computational approaches applied on endangered languages documentation and on under-represented languages in general.

Abstract

Question-Answer (QA) matching is a fundamental task in the Natural Language Processing community. In this paper, we first build a novel QA matching corpus with informal text which is collected from a product reviewing website. Then, we propose a novel QA matching approach, namely One vs. Many Matching, which aims to address the novel scenario where one question sentence often has an answer with multiple sentences. Furthermore, we improve our matching approach by employing both word-level and sentence-level attentions for solving the noisy problem in the informal text. Empirical studies demonstrate the effectiveness of the proposed approach to question-answer matching.

1 Introduction

Question answer (QA) matching is a task to determine whether an answer is answering a given question. For instance, in Figure 1, the question "*Where is dear john filmed at?*" in **E1** has two candidate answers "*The movie was filmed in 2009 in Charleston.*" and "*The file was released on May 25, 2010 on DVD.*" The first answer is determined with the "*Matching*" category since it answers the question while the second answer is "*Non-matching*" since it could not answer the question. The past five years have witnessed a huge exploding interest in the research on QA matching, due to its widely applications, such as question answering (Yang et al., 2015; Tan et al., 2016; Wang et al., 2017) and reading comprehension (Trischler et al., 2016; Dhingra et al., 2017).

However, all existing QA matching studies only focus on formal text. In real applications, there exists many scenarios where the QA text is informal. For instance, **E2** is a question-answer pair ext-

E1: Two QA pairs in formal text	
Q_1: *Where is dear john filmed at?* Label: *Matching*	A_1: *The movie was filmed in 2009 in Charleston.*
Q_2:*Where is dear john filmed at?* Label: *Non-matching*	A_2: *The film was released on May 25, 2010 on DVD.*
E2: Three QA pairs in informal text	
Q: *Will the response time slow after updating os? What about the battery? What about the screen?*	A: *The response time is not a spark of slow, it has 4G RAM. But you must use it carefully, my phone's secreen has broke down.*
Q_1: *Will the response time slow after updating os?* Label: *Matching*	A_1: *The response ..... broke down.*
Q_2: *What about the battery?* Label: *Non-matching*	A_2: *The response ..... broke down.*
Q3: *What about the screen?* Label: *Matching*	A_3: *The response ..... broke down.*

racted from the product reviewing platform "*Asking All*" in *Taobao*[1]. The QA text is informal where the question "*Will the response time slow after updating os? What about the battery? What about the screen?*" has more than one question and the answer contains multiple sentences which answer the first and the third sub-questions, leaving the second question un-solved. For simplicity, we split the question into three questions and generate three question-answer pairs, as shown in Figure1. In principle, for QA matching in the formal text, there are two main challenges:

First, for a particular sub-question, the answer contains multiple sentences, some of which do not answer this sub-question but other sub-questions. For instance, in **E2**, for the first question "*Will the response time slow after updating os?*", only the first sentence answers this question and the fourth sentence answers the third question "*What about the screen?*".

Second, the answer even might contain many uncorrelated sentences. For instance, in **E2**, the sentence "*It has 4G RAM*" and "*But you must use it carefully*" are uncorrelated with all three sub-questions. That is to say, there exits noisy information in some answers in informal text.

In this paper, we focus the research on QA matching with informal text. First of all, we build a novel QA matching corpus with informal text which contains many question-answer pairs from a product reviewing website. Then, we attempt to propose a novel QA matching approach for informal text. To deal with the first challenge above, we propose a novel matching approach, namely, One vs. Many Matching, to learn the matching measurement with one question sentence and multiple answer sentences. Specifically, we first adopt the BIMPM (Wang et al., 2017) to implement the matching measurement with one question sentence and one answer sentence, namely One vs. One Matching. Then, we learn the One vs. Many Matching representation by integrating all One vs. One Matching representations.

Furthermore, to deal with the second challenge, we introduce both the word-level and sentence-level attention mechanisms. Specifically, the word-level attention is applied in the One vs. One Matching learning process while the sentence-level attention is applied in the One vs. Many Matching learning process.

The remainder of this paper is organized as follows. Section 2 discusses the related work on QA matching. Section 3 presents data collection and annotation. Section 4 proposes our approach to QA matching. Section 5 reports the experimental results. Finally, section 6 gives the conclusion and our future work.

2 Related Work

2.1 Corpus construction

In previous studies for researching QA matching, there are mainly two corpora, namely TREC-QA and WikiQA. Specifically, TREC-QA is proposed by Wang et al. (2007) where the questions are a mixture of questions from both query logs and human editors, and the answers are selected from documents returned by past participating teams in TREC-QA tracks. Each question has at least one answer. WikiQA is proposed by Yang et al (2015). where the questions are sampled from real queries of *Bing* without editorial revision and the answers are from the summary section of a Wikipedia page of the topic. Different from TREC-QA, WikiQA has two-thirds questions with no matching answers.

Unlike these two corpora, this paper proposes a novel corpus for QA matching research where the question-answer pairs are real ones from "*Asking People*" in *Taobao*. Moreover, different from the above corpora, the question-answer pairs in our corpus are informal text.

2.2 Matching methods

Generally speaking, QA matching methods could be split into two categories: shallow learning methods and deep learning methods.

In shallow learning methods, some shallow learning algorithms, such as CRF, SVM and MaxEnt, are employed to train the learning models (Wang et al., 2010). Besides the learning algorithms, the related studies on shallow learning methods mainly focus on feature engineering, using linguistic tools and using external resources, such as lexical semantic resources (Yih et al., 2013), tree edit distance (Yao and Durme, 2013) and named entities (Severyn and Moschitti, 2013).

[1] https://www.taobao.com/

In deep learning methods, some neural network algorithms are employed to train learning models. Briefly, these methods could be categorized into three categories, i.e., siamense networks, attentive networks and compare-aggregate networks. In siamense networks, related studies use classic neural networks, such as LSTM and CNN, to get the representations separately and then concatenate them to classify. (Feng et al., 2015; Yang et al., 2015; Bowman et al., 2015). In attentive networks, instead of using the final time step of LSTM to represent a sentence, related studies use the attention strategy to get the weight of overall time steps and then use the weight to represent the sentence. (Tan et al., 2016; Hermann et al., 2015, Yin et al., 2015). In compare-aggregate networks, related studies use different matching strategy to get relationships within words. (He and Lin, 2016; Wang et al., 2017; Wang and Jiang, 2016; Trischler et al., 2016; Parikn et al., 2016.).

However, all above approaches are similar to our One vs. One Matching model which deals with the matching measurement between one sentence (or one piece of text) and another sentence (or another piece of text). In contrast, our approach is a One vs. Many Matching model which deals with the matching measurement between one sentence (or one piece of text) and multiple sentences (or multiple pieces of text).

3 Data Collection and Annotation

We collect 4,060 question-answer pairs from "*Asking All*" in *Taobao*, which is the most famous and biggest electronic business platform in China. The question-answer pairs are mainly from the *electronic* domain. Note that if a question contains multiple sub-questions, we split the question into several sub-questions and each sub-question and the whole answer is considered as a question-answer pair. For instance, as shown in Figure 1, the question in Example 2 contains three sub-questions, and we split it into three question-answer pairs.

To guarantee a high annotation agreement, we propose some annotation guidelines after several times of annotation processes on a limited size of data. Then, we ask more people to annotate the whole data set according to these annotation guidelines.

Generally, the two categories, "*Matching*" and "*Non-matching*" has following cases.

1) About the "*Matching*" category

(a) The answer directly answers the question. **E3** is an example of this case.
E3: Q: *Is the response time slow?*
A: *Slow.*

(b) The answer indirectly answers the question. **E4** is an example of this case.
E4: Q: *Is the response time slow?*
A: *Smooth.*

(c) The answer conditionally answers the question. **E5** is an example of this case.
E5: Q: *How long can the battery take?*
A: *If you don't play games, it can last two days.*

2) About the "*Non-matching*" category

(d) The answer is irrelevant with answer. **E6** is an example of this case.
E6: Q: *Is the microphone clear?*
A: *The battery life is decent. I like it.*

(e) The answer is about the product but doesn't talk about the aspect in the question. **E7** is an example of this case.
E7: Q: *Is the screen clear?*
A: *The quality of the screen is very good. It is a good cell phone.*

(f) The answer is an unknown response. **E8** is an example of this case.
E8: Q: *What about the performance of the phone?*
A: *I don't know, I bought it for my dad.*

For each question-answer pair, we assign two annotators to annotate the category, and the *Kappa* consistency check value of the annotation is 0.83. To deal with the question-answer pairs which are inconsistently annotated by two annotators, an expert is assigned to check them,

Category	Number
Matching	2505
Non-matching	1555

Table 1: Category distribution of the annotated data

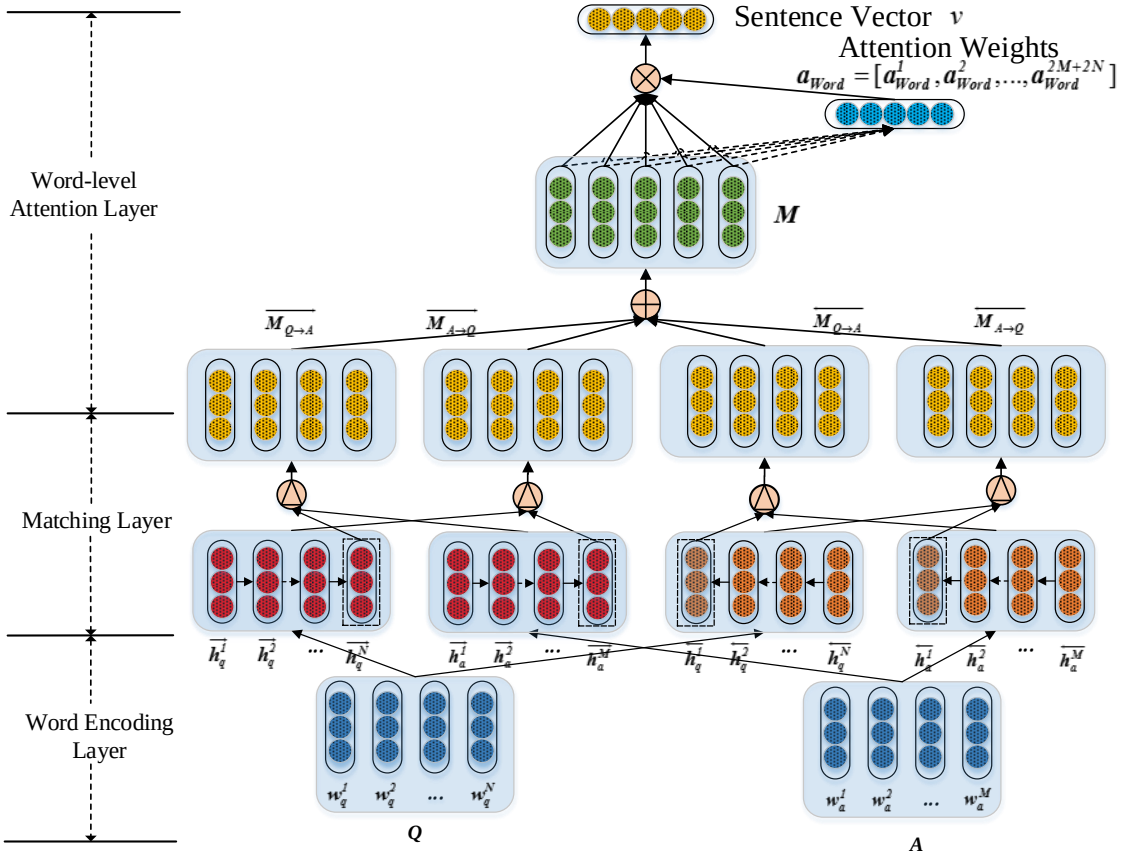

Figure 2: One vs. One Matching model with word-level attention

ensuring the quality of data annotation. Table 1 shows the category distribution of the corpus.

4 Our Approach

In this section, we propose our approach to QA matching in two steps. First, we propose the One vs. One Matching model which measures the matching between one sentence of the question text and one sentence in the answer text. Second, we propose the One vs. Many Matching model which measures the matching between one sentence of the question text and all sentences in the answer text.

4.1 One vs. One Matching Model

Figure 2 shows the overall architecture of our One vs. One Matching approach to QA matching. The involved layers are introduced in detail as following.

Word Encoding Layer. This layer has two inputs: the whole question sentence and one answer sentence. We represent the two sentences with *d*-dimensional vectors which is pre-trained with word2vec[2]. Then we utilize two bi-directional LSTM to encode the both of the sequences into contextual embeddings for each time step of the question and the sub answer sentence.

$$[\overrightarrow{h_q^1}, \overrightarrow{h_q^2}, ..., \overrightarrow{h_q^N}] = \overrightarrow{LSTM}([w_q^1, w_q^2, ..., w_q^N]) \quad (1)$$

$$[\overrightarrow{h_a^1}, \overrightarrow{h_a^2}, ..., \overrightarrow{h_a^M}] = \overrightarrow{LSTM}([w_a^1, w_a^2, ..., w_a^M]) \quad (2)$$

$$[\overleftarrow{h_q^1}, \overleftarrow{h_q^2}, ..., \overleftarrow{h_q^N}] = \overleftarrow{LSTM}([w_q^1, w_q^2, ..., w_q^N]) \quad (3)$$

$$[\overleftarrow{h_a^1}, \overleftarrow{h_a^2}, ..., \overleftarrow{h_a^M}] = \overleftarrow{LSTM}([w_a^1, w_a^2, ..., w_a^M]) \quad (4)$$

Matching Layer. This is the core layer in our One vs. One matching model. The goal of this layer is to compare the final contextual embedding (in the final time step of LSTM) of the sentence in the question against all contextual embeddings (in all time steps of LSTM) of one sentence in the answer. As

[2] https://code.google.com/archive/p/word2vec/

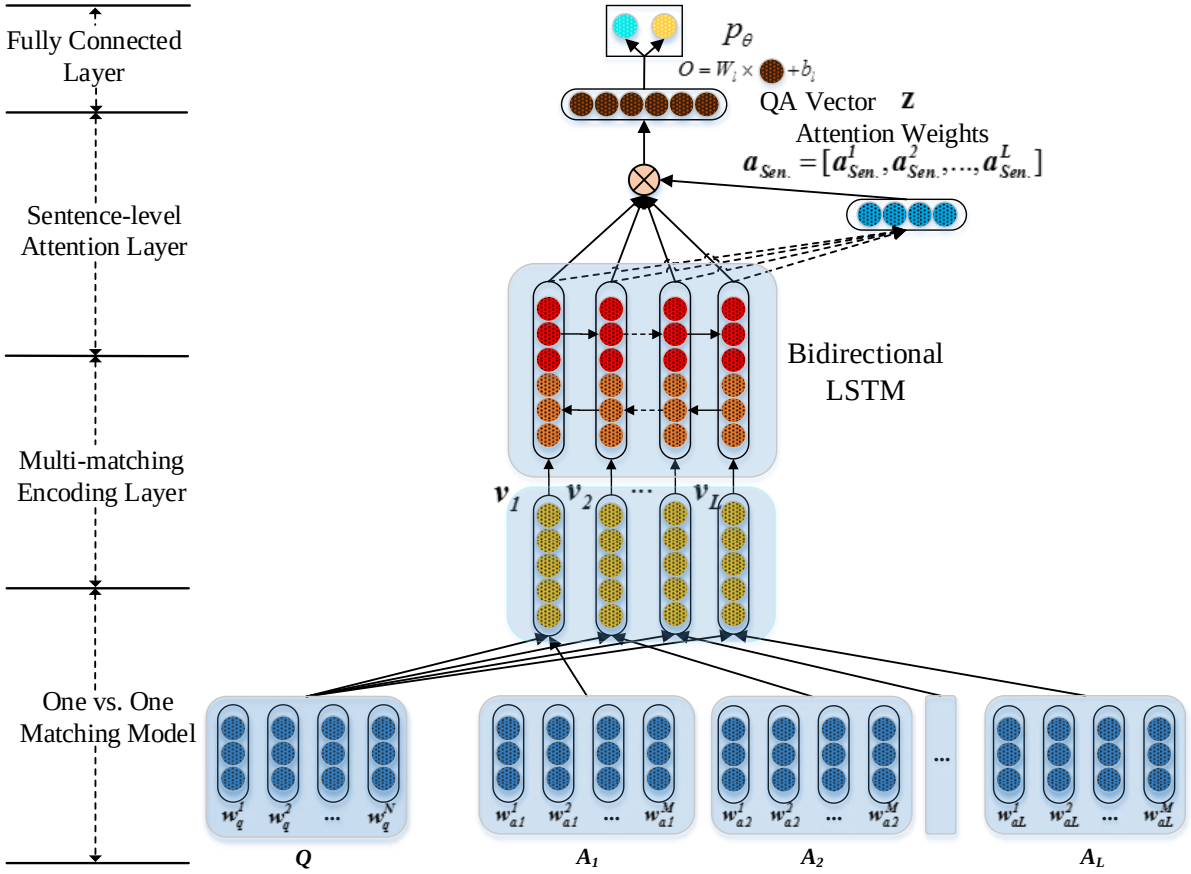

Figure 3: One vs. Many Matching model with sentence-level attention

shown in Figure 2, we match two sentences Q and A in two directions.

Formally, we use cosine function to calculate the similarity between two vectors, i.e.,

$$\overrightarrow{s_{q_N-a_i}} = cosine(\overrightarrow{h_q^N}, \overrightarrow{h_a^i}) \tag{5}$$

Inspired by Wang et al. (2017), we use the multi-perspective full matching strategy therein, i.e.,

$$\overrightarrow{s_{q_N-a_i}^k} = cosine(W^k \circ \overrightarrow{h_q^N}, W^k \circ \overrightarrow{h_a^i}) \tag{6}$$

where $\circ$ is the element-wise multiplication, and W^k is the k-th row of W, which controls the k-th perspective and assigns different weights to different dimensions of the dimension space.

Then, we obtain the similarity matrix $\overrightarrow{M_{Q\to A}} \in R^{P\times M}$, i.e.,

$$\overrightarrow{M_{Q\to A}} = \begin{bmatrix} \overrightarrow{s_{q_N-a_1}^1} & \cdots & \overrightarrow{s_{q_N-a_M}^1} \\ \vdots & \ddots & \vdots \\ \overrightarrow{s_{q_N-a_1}^P} & \cdots & \overrightarrow{s_{q_N-a_M}^P} \end{bmatrix} \tag{7}$$

where P means the number of perspectives.

Similarly, we get the matrices $\overleftarrow{M_{Q\to A}}$, $\overrightarrow{M_{A\to Q}}$ and $\overleftarrow{M_{A\to Q}}$.

Word-level Attention Layer. The goal of this layer is to assign weights to the similarity matrix and then get the most informative representation of the question sentence and one answer sentence.

First, we concatenate the $Q\to A$ and $A\to Q$ similarity matrix as the question-answer matrix.

$$M = \overrightarrow{M_{Q\to A}} \oplus \overleftarrow{M_{Q\to A}} \oplus \overrightarrow{M_{A\to Q}} \oplus \overleftarrow{M_{A\to Q}} \tag{8}$$

Second, we calculate the word attention weights a_{Word} with the following formula, i.e.,

$$a_{Word} = tanh(W_{Word} M + b_{Word}) \tag{9}$$

where W_{Word} is an intermediate matrix, b_{Word} is an offset value.

Third, we use a softmax function to normalize a_{Word}, i.e.,

$$a_{Word} = softmax(a_{Word}) \tag{10}$$

Finally, we multiply a_{Word} with M^T, and get the matching vector v, i.e.,

$$v = a_{Word} M^T \tag{11}$$

The matching vector v is the most informative representation of the question sentence and one answer sentence.

4.2 One vs. Many Matching Model

Figure 3 shows the overall architecture of our One vs. Many Matching approach to QA matching. The involved layers are introduced in detail as following.

One vs. One Matching Model. The purpose of this model is to use the question sentence and one answer sentence to calculate the most informative representation v_i. Suppose the answer contains L sentences, then we obtain the matching vectors between the question and answer, i.e., $V = [v_1, v_2, ..., v_L]$.

Multi-matching Encoding Layer. In this layer, we treat the above matching vectors as a sequence and employ a Bi-directional LSTM to learn a new representation, i.e.,

$$H = \overrightarrow{LSTM}(V) \oplus \overleftarrow{LSTM}(V) \tag{12}$$

Sentence-level Attention Layer. The goal of this layer is to get the most informative representation of the representation H.

First, we calculate the sentence attention weights $a_{Sen.}$, i.e.,

$$a_{Sen.} = tanh(W_{Sen.} H + b_{Sen.}) \tag{13}$$

where $W_{Sen.}$ is an intermediate matrix. $b_{Sen.}$ is an offset value.

Second, we use a softmax function to normalize $a_{Sen.}$, i.e.,

$$a_{Sen.} = softmax(a_{Sen.}) \tag{14}$$

Finally, we multiply $a_{Sen.}$ with H^T, and get the matching vector z, i.e.,

$$z = a_{Sen.} H^T \tag{15}$$

The matching vector z is the final representation for representing the matching measurement between the question and the whole answer.

Fully Connected Layer. The goal of this layer is to use the matching vector z to perform classification. Formally, we feed z to a softmax classifier, i.e.,

$$o = W_l z + b_l \tag{16}$$

where $o \in R^K$ is the output, W_l is the weight matrix and b_l is the bias. K is the number of categories. Then the probability of the category $k \in [1, K]$ is computed by:

$$p_\theta = \frac{exp(o_k)}{\sum_{t=1}^{K} exp(o_t)} \tag{17}$$

where θ denotes all parameters. Finally, the label with the highest probability stands for the predict label of the question-answer pair.

4.3 Model training

We use cross-entropy loss function to train our model end-to-end given a set of training data x_t, y_t, where x_t is the t-th question-answer pair to be predicted, and y_t is one-hot representation of the true category for x_t. We present this model as black-box function $\sigma(x)$ whose output is a vector representing the probability of categories. The goal of training is to minimize the loss function as following,

$$J(\theta) = -\sum_{t=1}^{N}\sum_{k=1}^{K} y_t^k \cdot \log\sigma(x_t) + \frac{l'}{2}\|\theta\|_2^2 \quad (18)$$

where N is the number of training samples and l' is a L_2 regularization to bias parameters.

We take Adam (Kingma and Ba, 2014) as the optimizing algorithm, and all the matrix and vector parameters are initialized with a uniform distribution in $\left[-\sqrt{6/(r+c)}, \sqrt{6/(r+c)}\right]$, where r and c are the rows and columns of the matrix (Glorot and Bengio, 2010).

5. Experiment

In this section, we systematically evaluate the performance of our approach to QA matching.

5.1 Experiment settings

Data Settings: As introduced in Section 3, the data contains 4,060 question-answer pairs and we randomly split the data into a training set (80% in each category), and a test set (the remaining 20% in each category). We also aside 10% data from training data as development data which is used to tune the parameters in each learning algorithm.

Word Segmentation and Embeddings: The Jieba[3] segmentation tool is employed to segment all Chinese text into words and word2vec[4] is employed to pretrain word embeddings using the data set that contains 200,000 question-answer pairs from the *electronic* domain. The dimensionality of the word vector is set to be 100 and the window size is set to be 1.

Sentence Split: We run sentence splitting with the CoreNLP[5] tool.

Hyper-parameters: The hyper-parameters values in the model are tuned according to performance in the development set. The size of units of the Bi-directional LSTM in the One vs. One Matching model is set to be 100, and the size of units of the Bi-directional LSTM in the One vs. Many Matching model is set to be 50. The default number of the sentences in an answer is set to be 5. The number of matching perspectives is set to be 20. The batch size is set to be 64.

Evaluation Measurement and Significance Test: The performance is evaluated using standard precision (*P*), recall (*R*), F-score (*F*) and *accuracy*. Furthermore, *t*-test is used to evaluate the significance of performance difference between two approaches.

5.2 Baselines

For comparison, we implement following approaches to QA matching:

- **LSTM:** A QA matching approach belonging to the siamense network, which is proposed by Bowman et al (2015). This approach employs a LSTM layer to encode the inputs.
- **Shallow Convolutional Neural Network (SCNN):** A state-of-the-art QA matching approach belonging to the siamense network, which is proposed by Zhang et al (2016). for the task of implicit discourse relation recognition.
- **Attentive LSTM:** A state-of-the-art QA matching approach belonging to an attentive network, which is proposed by Tan et al (2016).
- **MULT:** A state-of-the-art QA-matching approach belonging to the compare-aggregate network, which is proposed by Wang and Jiang (2017).
- **Bilateral Multi-Perspective Matching (BIMPM):** Another state-of-the-art QA matching approach belonging to the compare-aggregate network, which is proposed by Wang et al (2017). We use two implements where BIMPM (Full) employs the full matching strategy and BIMPM (Ensemble) employs all of the four matching strategies.

5.3 Our Approaches

Our approaches to QA matching are implemented with four different ways, i.e.,

[3] https://pypi.python.org/pypi/jieba/

Table 3: Performances of different approaches to QA matching in each category

- **One vs. Many Matching (OMM):** This is the implementation where neither word-level attention layer nor the sentence-level attention layer is employed.
- **OMM with Word-level Attention (OMM+WA):** This is the implementation where only the word-level attention layer is employed.
- **OMM with Sentence-level Attention (OMM+SA):** This is the implementation where only the sentence-level attention layer is employed.
- **OMM with both Word-level and Sentence-level Attention (OMM+WA+SA):** This is the implementation where both the word-level attention layer and the sentence-level attention layer are employed.

5.4 Results

Table 2 and Table 3 show the overall and detailed performances of all approaches to QA matching. From this table, we can see that all our four approaches perform better than all baseline approaches and the significance test with *t*-test shows that the improvements are statistically significant (*p*-value<0.05). From the result, we can see that our approach is extremely superior in the category of *Non-matching*. For instance, our approach OMM+WA+SA outperforms the baseline approach LSTM with an improvement of 0.129 in terms of F-score. Among all our four approaches, OMM+WA+SA performs best, which highlights the importance of employing attention strategy in QA matching.

5.5 Visualization of Attention

In order to get a better understanding of the attention model and validate whether this model can capture the key information of the answer sentences, we visualize the word-level attention layer and sentence-level attention layer according to the obtained attention weights a_{Word} and $a_{Sen.}$.

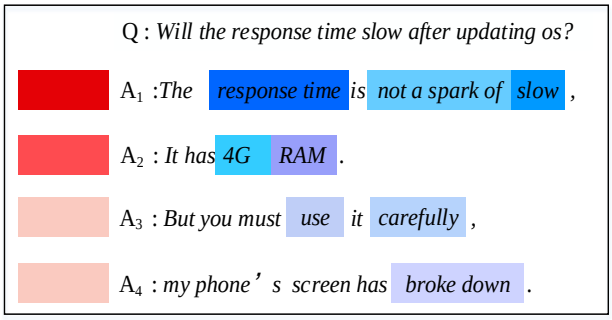

Figure 4: The attention visualization for a question answer pair

E9: Gold Label: *Non-matching*
Q: *屏幕清晰吗？*
（Is the screen clear?）
A: *屏幕质量很好。是个好手机。*
（The quality of the screen is good. It is a good phone.）
E10: Gold Label: *Matching*
Q: *有蓝牙吗？*
（Does it have bluetooth?）
A: *煤油，不要买。*
（Kerosene. Don't buy it.）
E11: Gold Label: *Matching*
Q: *系统是多少位的？*
（How many bits are there in the system?）
A: *64.*

Figure 5: Error Analysis

Figure 4 shows the attention visualizations for a question-answer pair. We normalize the word weight by the sentence weight to make sure that only informative words in informative sentences corresponding to the question are emphasized. In Figure 4, each line contains one sentence in an answer. Red denotes the sentence weight and blue denotes the word weight. The color depth indicates the importance degree of the attention weight for the question.

From the figure, we can see that the sentence-level attention function can select the informative sentences corresponding to the question, such as the first and the second sentences. In addition, the word-level attention function can select both the words and multi-word phrases carrying strong matching signals corresponding to the question, such as "*response time*", "*not a spark of*", and "*4G*".

5.6 Error Analysis

Through analyzing the classification results of our approach, we find that QA matching is still challenging and some kinds of errors are discussed as following.

First, the question and the answer share the same aspect of the product but the concerned contents of the aspect are different. For instance, in Figure 5 and **E9**, the question and the answer both have the word "*screen*". However, the question asks the clearness about the screen while the answer talks about the quality of the screen. Second, some words in the answer text have spelling mistakes. For instance, in Figure 5 and **E10**, the answer contains the word "*煤油* (*Kerosene*)" is a spelling mistake. It should actually be the word "*No*", although their pronunciations in Chinese are similar. Third, some question-answer pairs contain the answer sentence which is too short, like **E11** in Figure 5.

6. Conclusion

In this paper, we propose a new corpus for the research on QA matching in informal text. Moreover, we propose a novel approach to QA matching, namely One vs. Many Matching, to handle the difficulty in which the answer contains multiple sentences. Furthermore, we employ both the word-level and sentence-level attentions in our approach to further improve the matching performance. Empirical studies show that the proposed approach performs significantly better than several strong baseline approaches.

In our future work, we would like to enlarge the scale of the corpus by annotating some data in other domains. Furthermore, we would like to evaluate the effectiveness of our approach to QA matching in some other domains or some other languages.

Learning to Generate Word Representations using Subword Information

Yeachan Kim, Kang-Min Kim, Ji-Min Lee and SangKeun Lee
Korea University, Seoul, Republic of Korea
{yeachan,kangmin89,jm94318,yalphy}@korea.ac.kr

Abstract

Distributed representations of words play a major role in the field of natural language processing by encoding semantic and syntactic information of words. However, most existing works on learning word representations typically regard words as individual atomic units and thus are blind to subword information in words. This further gives rise to a difficulty in representing out-of-vocabulary (OOV) words. In this paper, we present a character-based word representation approach to deal with these limitations. The proposed model learns to generate word representations from characters. In our model, we employ a convolutional neural network and a highway network over characters to extract salient features effectively. Unlike previous models that learn word representations from a large corpus, we take a set of pre-trained word embeddings and generalize it to word entries, including OOV words. To demonstrate the efficacy of the proposed model, we perform both an intrinsic and an extrinsic task which are word similarity and language modeling, respectively. Experimental results show clearly that the proposed model significantly outperforms strong baseline models that regard words or their subwords as atomic units. For example, we achieve as much as 18.5% improvement on average in perplexity for morphologically rich languages compared to strong baselines in the language modeling task.

1 Introduction

Recently, distributed representations of words have become an inevitable component in systems of natural language processing (NLP), *e.g.,* chunking and named entity recognition (Turian et al., 2010), text classification (Kim, 2014), and question answering (Kumar et al., 2016). In such systems, word representations play a vital role by capturing useful information of words, leading to the improved performance of the systems. Most existing approaches to learning word representations are learned in an unsupervised learning manner from a large corpus and, for simplicity and effectiveness, they regard words as individual atomic units in a learning phase (Bengio et al., 2003; Collobert and Weston, 2008; Mikolov et al., 2013; Pennington et al., 2014).

However, word-based approaches typically ignore subword information in words. It prevents the approaches from taking into account the characteristic of words, *"words are lexically related when they share some morphemes or semantic elements"* (Williams, 1981). This constraint further makes representing out-of-vocabulary (OOV) words difficult. Even if lexically related words have been observed, word-based approaches fail to represent such words that are not included in a pre-defined vocabulary.

Perhaps the simplest way to sidestep this problem is to use one or more pseudo-words (*e.g.,* <unk>) to represent OOV words. However, this is not a fundamental remedy, as OOV words have their own meanings in many cases, such as variants, compounds, and misspellings. This problem is more evident when the domain of a text in which the word is learned differs from the domains to be applied to an NLP task. For example, the word *"talking"* and *"touchdown"* in the domain with generic text can be represented as *"tlking"* and *"touchdooown"* in the domain of social media. In this case, although these words share a similar sequence, representing words in other domain is difficult.

Proceedings of the 27th International Conference on Computational Linguistics, pages 2551–2561
Santa Fe, New Mexico, USA, August 20-26, 2018.

In this paper, we present a character-based approach to generate word representations. Unlike previous works that adopt unsupervised learning from a corpus, the proposed model learns to generate word representations based on the supervised learning of pre-trained word embeddings. We use a convolutional neural network (CNN) (LeCun et al., 1998) to extract subword features over characters and utilize a highway network (Srivastava et al., 2015) to relate salient subword features to pre-trained word embeddings.

The proposed model has several benefits. As we regard characters as our atomic units for learning word representations, we have an ability to generate representations for all kinds of words, including OOV words. Moreover, we take a set of pre-trained word embeddings and generalize it to represent all words. This enables the proposed model to learn word representations efficiently without having to train with a large corpus.

To evaluate the proposed model, we perform an intrinsic and an extrinsic task which are word similarity and language modeling, respectively. We specifically conduct these tasks in various languages, as subword information is a characteristic of many languages such as French and Spanish (which have more than 40 different inflected forms for verbs). Experimental results show that the proposed model outperforms strong baselines that regard words or their subwords as atomic units, while representing OOV words quite well. In summary, we make the following contributions:

- We propose a character-based approach to generate word representations utilizing a convolutional neural network and a highway network.
- We leverage a set of pre-trained word embeddings and generalize it to all word entries. It allows us to efficiently learn word representations in a learning phase without training in a large corpus.
- We verify the efficacy of the proposed model in both an intrinsic and an extrinsic task with various languages. Our experimental results reveal that the word representations derived from our model considerably improve the performance on both of tasks in most languages.

The remainder of this paper is organized as follows. In Section 2, we discuss related works. In Section 3, we describe the proposed model. We report our performance evaluation results and analyze our methodology in detail in Sections 4 and 5, respectively. Finally, we conclude this paper in Section 6.

2 Related Works

Recently, many works have been proposed to improve the quality of word representations using subword[1] information. Some works used word and subword representations concurrently to produce better word representations. For example, (Qiu et al., 2014) proposed a model that jointly learns word and subword representations for word embeddings. They found that this joint model is useful in producing better representations for rare words. Similarly, (Mousa et al., 2013) proposed a deep neural network for language modeling, where the inputs to the network are a mixture of words and morphemes as well as their respective features. This work showed that utilizing morphemes could enhance lexical coverage and mitigate the problem of data sparseness for a n-gram language model.

In a similar manner, many works have proposed utilizing only subword information to produce word representations. For example, (Wieting et al., 2016) proposed embedding models for words and sentences using character n-gram count vectors. Although they require specific paragraph pairs for training, these models showed promising results in representing words while considering subword information. Recently, (Bojanowski et al., 2017) proposed FastText, which is an extension of the continuous skip-gram model (Mikolov et al., 2013). In this model, a word representation is replaced with the sum of character n-gram representations. This work showed that utilizing subword information allows the model to be trained efficiently by sharing the n-gram parameters between words. (Luong et al., 2013) utilized recursive neural networks in which inputs are morphemes of words. The proposed model showed better estimations of rare and complex words.

[1] We use the term "subword" for representing units smaller than a word, such as morphemes or character n-grams.

Some of the above-mentioned works (Luong et al., 2013; Mousa et al., 2013; Qiu et al., 2014), which used morphemes and normalized words, require segmentation tools for morphological segmentation. By contrast, we do not have to use segmentation tools as we use only characters to produce word representations. In addition, most works learn word representations from a large corpus using an unsupervised learning manner. However, we do not require training from a large corpus because we employ a set of pre-trained word embeddings.

Some works employed subword information, especially by using characters, to represent words in NLP tasks. For example, (Santos and Zadrozny, 2014) and (Ling et al., 2015) used a CNN and a recurrent neural network (RNN), respectively, over character representations for part-of-speech tagging. For a language modeling, (Kim et al., 2016) used a CNN and a highway network which achieved better performance than word-based models. That network shares a similar architecture with ours. However, our architecture is different from the early network (Kim et al., 2016) in that ours is designed with a simpler network architecture and a different output layer based on the pre-trained word embeddings. For neural machine translation, (Ruiz Costa-Jussà and Rodríguez Fonollosa, 2016) and (Luong and Manning, 2016) incorporated character representations to produce OOV word representations and achieved improved performance over models that used unknown tokens to represent OOV words.

Most closely related to our work is Mimick (Pinter et al., 2017), which is a bidirectional long short-term memory (LSTM)-based word representation model. It learns a function from characters to word embeddings to represent OOV words. In terms of the quality of OOV word representations, Mimick has shown promising results in syntactical properties. By contrast, we explore a CNN-based architecture to learn features from pre-trained word embeddings. As words consist of locally salient features such as prefixes, roots, and suffixes, a CNN architecture is expected to be effective at extracting these features.

3 Proposed Model

Figure 1 provides an overview of the proposed model. Our learning strategy is to *reconstruct* pre-trained word embeddings from character representations. To this end, we first extract subword features using a character-based convolution module. We then utilize a highway network to adaptively combine the subword features derived from the convolution module. In the optimization step, we make this resultant representation similar to its pre-trained word embedding.

3.1 Character-based Convolution Module

A CNN is designed to capture the most informative local aspects of a particular task (LeCun et al., 1998). CNNs have been widely used in not only computer vision but also recently in NLP (Kim, 2014; Cao and Lu, 2017) because of its ability to extract local context features such as n-grams. Accordingly, we apply this network on a character sequence to extract its subword features.

We first use a one-hot encoding to quantize the character inputs, which has a value of 1 at the index of the corresponding character, otherwise it has a value of 0. We concatenate these character representations to constitute a word, which is represented as $r \in \mathbb{R}^{|V_c| \times n}$ where V_c is a vocabulary of characters and n is the length of a word. Thus, the input representation for convolution has the following shape:

$$r = c_1 \oplus c_2 \oplus \cdots \oplus c_n = \begin{bmatrix} | & | & \cdots & | \\ c_1 & c_2 & \cdots & c_n \\ | & | & \cdots & | \end{bmatrix}$$

where c_i is a one-hot encoding for representing the i-th character in a word and $\oplus$ is a concatenation operator. We then insert zero-paddings to the side of these character representations r in order to perform the same number of convolutions for all characters. The number of zero-paddings on each side is $\frac{h-1}{2}$, where h is the width of convolution filter F. We perform the convolution operation on the padded representation r using the following equation:

$$s_i = tanh(F \cdot r_{i:i+h-1} + b) \tag{1}$$

where filter F is represented as $F \in \mathbb{R}^{|V_c| \times h}$ and $r_{i:i+h-1}$ is a sequence representation between character representation c_i to c_{i+h-1}. Then, we apply $tanh$ as the non-linear function to the convolution results.

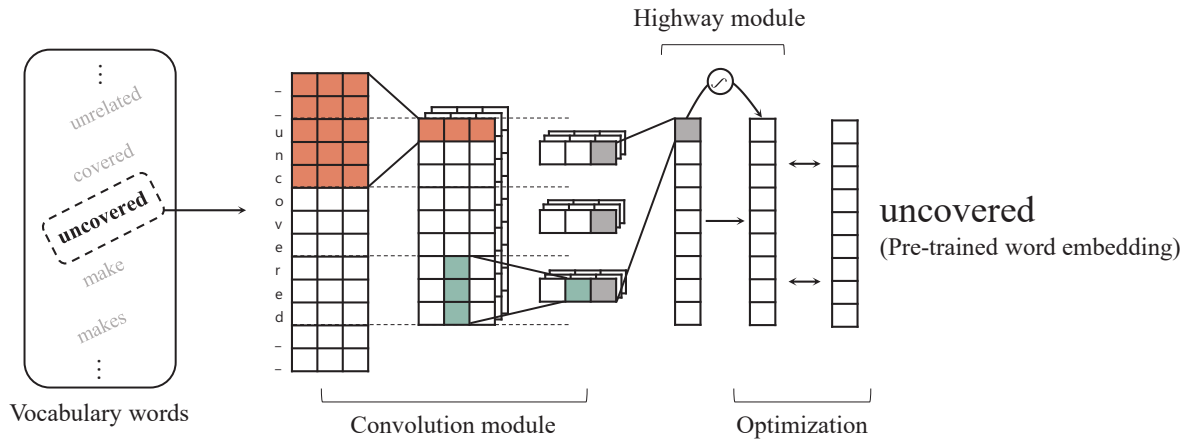

Figure 1: Overview of the learning phase in the proposed model. In this example, we process as input the word "*uncovered*" that is included in pre-trained word embeddings. In the convolution module, we use three filters with 5-width (thus, we add two zero-paddings) and other width filters, and we set the width of the stride to 3 for pooling. In the highway module, we use a single highway network. We then make this resultant representation similar to the pre-trained word embedding of "*uncovered*". After training converges, we can represent words that are lexically related to the input word but that are not included in pre-trained word embeddings, like "*uncovering*", as these words share similar character sequences.

The resultant vector s has the same length as the input word because of the zero-paddings. To extract salient features, we apply a max-pooling operation on the vector s. Specifically, we use max pooling with stride to derive locally salient features that can contain suffixes, roots, and prefixes. As a result, each feature derived from stride pooling has a summary of subword information in a character sequence. The equation for stride pooling is as follows:

$$e_i = \max\left[s_{k \cdot i : k \cdot (i+1)-1}\right] \tag{2}$$

where k is the length of a stride and $s_{k \cdot i : k \cdot (i+1)-1}$ is a sequence representation with one stride in s. As stride pooling results in features that vary in length according to the length of words, we therefore simply sum the elements of the vector e to produce fixed-sized features.

Thus far, we have described the procedure for a single filter. In our experiment, we use multiple filters with different widths to extract various subword features. We simply concatenate the results of each filter to merge the various features.

3.2 Highway Network Module

A highway network is an architecture that allows a model to train a very deep network efficiently (Srivastava et al., 2015). This network learns to route information using a gating mechanism. Recently, (Kim et al., 2016) utilized a highway network on a CNN for language modeling. It turned out that a highway network is helpful to a CNN, as it adaptively combines local features from individual filters. By following this line of work, we apply this network to adaptively combine subword features derived from a convolution module. It allows the proposed model to relate salient subword features with pre-trained word embeddings in a learning phase. The basic equation of a highway network is as follows:

$$y = T \odot H + C \odot e \tag{3}$$

where H is a non-linear transformation on its input e, T is the *transform gate* and C is the *carry gate*. In our work, we use C as a *(1-T)* for simplicity. For the function H and T, we use the following equations:

$$\begin{aligned} T &= \sigma(W_t \cdot e + b_t) \\ H &= \tanh(W_h \cdot e + b_h) \end{aligned} \tag{4}$$

where W_t, W_h and b_t, b_h are square matrices and biases[2], respectively. Finally, we set the size of resultant vector y as the pre-trained word embedding using a linear transformation for an optimization as follows:

$$w = W \cdot y + b \tag{5}$$

where w is a final word representation resulting from the proposed model, and W and b are parameters of linear transformation. Through the aforementioned procedures, we generate word representations while considering subword information.

3.3 Optimization with Pre-trained Word Embeddings

The proposed model reconstructs pre-trained word embeddings from characters. To make the word representation derived from our model learn the features of pre-trained word embeddings, we use the *squared Euclidean distance* as our objective function as follows:

$$E = \sum_{v \in V_w} \|w_v - \hat{w}_v\|^2 \tag{6}$$

where w_v is a word representation from our model and $\hat{w}_v$ is a pre-trained word embedding for a word v in the vocabulary. After training converges, we discard pre-trained word embeddings $\hat{w}$ and use w as our word representations for NLP tasks.

4 Experiments

To evaluate the proposed model, we perform both an intrinsic and an extrinsic task which are word similarity and language modeling, respectively. The word similarity evaluates the ability to capture the semantic similarity of words. The language modeling evaluates the usefulness of the proposed word representations in an NLP task. We specifically conduct both of tasks in various languages, as the subword information is a language-dependent feature.

4.1 Experimental Settings

We train the proposed model using pre-trained word embeddings. To simulate the settings having pre-trained word embeddings for various languages, we use word2vec (Mikolov et al., 2013), which is trained in Wikipedia[3] that was released on December 1, 2017 for seven languages: Arabic, Czech, German, English, Spanish, French, and Russian. The preprocessing for a corpus of each language is done using Natural Language Toolkit (NLTK) Tweet Tokenizer[4]. Based on (Lai et al., 2016), we assign to word vectors a 100 dimension, which has shown relatively better performance in both an intrinsic and an extrinsic task. In our experiments, we examine the following models:

- **word2vec** (Mikolov et al., 2013): This is a model that regards words as individual atomic units and adopts a window-based learning technique. Since this method is a word-based approach, it is incapable of representing OOV words. As a default for OOV words, we use null vectors for the word similarity task, and we randomly initialize and fine-tune them for the language modeling task. Of the two models of word2vec, CBOW and skip-gram, we use a skip-gram architecture for learning word representations, as it generally shows better performance than does CBOW (Lai et al., 2016).

- **FastText** (Bojanowski et al., 2017): This is an extension of word2vec and regards character n-grams as atomic units. The learning technique is similar to that of word2vec. We set the dimension of words to 100 that is same with other models and, for other settings, we follow the best settings described in the paper (Bojanowski et al., 2017).

[2]According to the suggestion of (Srivastava et al., 2015), we initialize b_t as -3 for making the networks initially biased towards *carry* behavior.

[3]https://www.wikipedia.org/

[4]https://www.nltk.org/

- **Mimick** (Pinter et al., 2017): This is a character-based model that learns a function from characters to word embeddings for representing words. For pre-trained word embeddings for this model, we use the previously mentioned skip-gram version of word2vec. In our experiments, we compare the best Mimick model, which uses pre-trained word embeddings for vocabulary words and generated embeddings for OOV words. We set the hidden dimension of an LSTM to 256 for better convergence, and other parameters are same as those of the paper (Pinter et al., 2017).

- **GWR** (proposed model): This is our proposed model, denoted as the generated word representation (GWR), and we use the word2vec for pre-trained word embeddings. We generate all words that are observed and use them for overall tasks.

We implemented the proposed architecture using TensorFlow frameworks (Abadi et al., 2016) and trained our model in a single machine equipped with Intel Core i5, 16GB of RAM, and an NVIDIA GeForce GTX 1080 with 8GB of RAM. The details of the training parameters are shown in Table 1. We chose these listed parameters by validating the word similarity task.

Type	value
optimizer	Adam (Kingma and Ba, 2014)
learning rate	0.001
batch size	50
the width of filter	[1,2,3,4,5,6,7]
the width of stride	3
# of filters	max(200, 50*width)
# of highway networks	2

Table 1: Experimental settings of the proposed model

4.2 Word Similarity

We first perform word similarity task to evaluate the ability of models to capture the semantic similarity among words. The performance of word similarity is measured by computing the Spearman's correlation coefficient between human judgment and the cosine similarity between word pairs.

4.2.1 Datasets

We collect word similarity datasets for six languages: Arabic (Ar), German (De), English (En), Spanish (Es), French (Fr), and Russian (Ru). For English, we compare the models on the WS353 (Finkelstein et al., 2001) and SL999 (Hill et al., 2014) datasets. For German, we conduct experiments on the GUR350 and ZG222 (Zesch and Gurevych, 2006) datasets, and we evaluate the models on the MC30 and WS353 datasets for Arabic and Spanish that are translated by (Hassan and Mihalcea, 2009). We evaluate French word vectors on the translated dataset RG65 (Joubarne and Inkpen, 2011), and for Russian, we evaluate the vectors on the HJ dataset introduced by (Panchenko et al., 2016).

4.2.2 Results

Table 2 shows the overall results. We first observe that subword-based learning methods (FastText, Mimick, GWR) show superior performance compared to that of the word-based method (word2vec) on most languages and datasets. This indicates that considering subword information is effective at representing words and useful with many languages. Among the subword-based methods, GWR outperforms Mimick in all languages except for English. We conjecture that this result can be explained by the fact that a CNN architecture is helpful in extracting local aspect features. In addition, GWR shows competitive performance with FastText that learns word representations from a large corpus (*i.e.,* GWR shows better performance in six out of nine datasets).

Language	Dataset	word2vec	FastText	Mimick	GWR$^-$	GWR
Ar	WS353	34.9	**52.1**	44.9	36.3	43.8
De	GUR350	34.6	48.7	47.6	35.4	**53.2**
	ZG222	16.2	35.4	36.5	16.4	**38.7**
En	SL999	29.5	27.7	**30.3**	28.6	29.8
	WS353	63.1	64.1	63.7	63.9	**64.6**
Es	MC30	40.6	**72.1**	66.8	41.4	69.8
	WS353	29.5	50.0	40.7	30.8	**50.2**
Fr	RG65	46.8	58.6	51.3	48.1	**60.5**
Ru	HJ	30.3	**60.1**	42.1	31.4	45.5

Table 2: Word similarity results on entire datasets (Spearman's $\rho \times 100$). GWR$^-$ implies a model using null vectors for OOV words. Best results are in bold.

To confirm that OOV word representations derived from GWR indeed improve the performance, we assess the performance of our model when used with null vectors for OOV words (GWR$^-$). The results show that the model generating OOV words (GWR) considerably outperforms the model that does not generate them (GWR$^-$). This improved performance indicates that the proposed model effectively expands the lexical coverage and generates representations of OOV words quite well. In addition, the GWR$^-$ model shows slightly better performance than that of the word2vec. It also shows its effectiveness at considering subword information in representing words. The differences between these two representations for vocabulary words are described in Section 5.2.

4.3 Language Modeling

As a second experiment, we perform language modeling as an extrinsic task to verify the usefulness of the proposed model when performing an NLP task. To evaluate the performance of word embeddings, we use an LSTM network with dropout regularization, which is used in (Bojanowski et al., 2017). Through the development set in (Botha and Blunsom, 2014), we set the hidden dimension of an LSTM to 256 and the probability of dropout to 0.5. In our experiments, we replace only the component of word embeddings to solely evaluate word embedding performance. The performance of language modeling is computed based on perplexity, which is a widely used metric in evaluating the usefulness of language modeling. Lower perplexity means a better model.

4.3.1 Datasets

We perform language modeling task using the datasets introduced by (Botha and Blunsom, 2014) on six languages: Czech (Cs), German (De), English (En), Spanish (Es), French (Fr), and Russian (Ru). Each dataset contains roughly one million tokens for training, and we follow the same pre-processing and data splits as reported in (Botha and Blunsom, 2014).

Language	$\lvert V_w \rvert$	word2vec	FastText	Mimick	GWR
Cs	46k	412.7	397.9	401.7	**352.1**
De	36k	263.8	248.2	258.6	**233.2**
En	17k	259.8	256.3	257.2	**240.7**
Es	27k	190.7	186.9	189.2	**174.7**
Fr	25k	205.2	207.7	202.4	**185.6**
Ru	62k	311.5	282.7	293.1	**243.1**

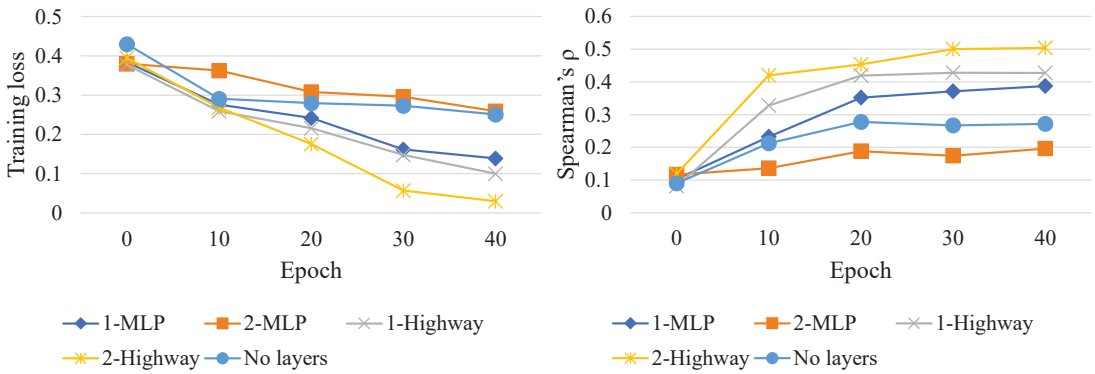
Table 3: Test perplexity on the language modeling for six languages. Best results are in bold.

4.3.2 Results

Table 3 shows the results. We observe a similar trend as with the performance of the word similarity task. The subword-based methods show better performance than the word-based method with most languages. Furthermore, the proposed GWR shows superior performances over these subword-based methods by a large margin. Based on the performance of the word2vec used in training GWR, we achieve notably improved performance in morphologically rich languages. For example, the performance on Slavic languages (Cs, Ru), which are morphologically rich, shows better perplexity reduction (15 and 22% for Czech and Russian, respectively) than other languages that are less significant languages in terms of morphology. This suggests that GWR is more useful and effective in morphologically rich languages.

5 Analysis

5.1 Effect of Highway Networks



(a) Training loss

(b) Word similarity performance (Spearman's ρ)

Figure 2: Training loss and word similarity performance with different architectures. The term of k-MLP indicates that k-layered MLP are stacked to the proposed model, and it is a same manner with a highway network.

As a component of the proposed model, we use a highway network rather than a multi-layer perceptron (MLP) that is widely used in CNNs (Kim, 2014; Cao and Lu, 2017). To show the effectiveness of a highway network in our architecture, we assess the training loss and performance of word similarity during training step when each network (highway network, MLP) is stacked to the proposed model. As a representative language in this analysis, we use the WS353 dataset in Spanish, which is a morphologically rich language. The results are shown in Figure 2.

In Figure 2a, we can observe that a highway network basically shows faster convergence than does MLP with respect to training loss. The interesting results occur when the model is deeper with each network (2-highway, 2-MLP). While 2-MLP shows slower convergence than 1-MLP, 2-Highway shows faster convergence than 1-Highway. These results are related to the property of a highway network, which allows the model to train more deeply.

Figure 2b shows the performance of word similarity task. We observe a similar trend with the results of the training loss. The highway network shows superior performance compared to MLP. Furthermore, when 2-Highway is stacked to the proposed model, it shows better performance than that of 1-Highway. In contrast, 2-MLP performs worse than 1-MLP, even when the proposed model does not have a layer (No layers).

Through this analysis, we observe that a highway network enhances the semantic similarity of words, and makes the training faster compared to a simple MLP. Furthermore, stacked highway networks enable us to train more deep model that leads the strong performance.

	In-Vocabulay				Out-of-Vocabulary

Table 4: Nearest neighbors of word representations for vocabulary and OOV words. Nearest words are sorted in descending order of similarity that computed by cosine similarity.

5.2 Nearest Neighbor of Words

To explore the quality of GWR, we perform a qualitative analysis by finding the nearest neighbors of word representations. Table 4 shows the nearest neighbors of word representations learned from the word2vec and GWR in English.

From nearest neighbors of OOV words, we discover the following: (i) GWR represents word-variants and compound words well (*computerization, bluejacket*); (ii) GWR captures different word styles (*globalise*) and syntactically related words (*global-globally-globalization*); (iii) GWR shows robustness on misspellings (*vehic**a**ls*); (iv) GWR captures semantically related words in most OOV words (*bluejacket-pants, vehicals-bicycles*).

We also derive some interesting results for nearest neighbors of vocabulary words. We observe that semantically or syntactically related words are located in nearest neighbors (*taxicab-minibus, teach-teaching*). Moreover, the proposed model renders lexically related word representation more similar. For example, the neighbors of "*connect*" show that the word-variants (*connects-connected-connecting*) are more closely located than are pre-trained word embeddings in vector space. This rendering satisfies the characteristic of words about *lexical relatedness* (Williams, 1981). Other words also show a similar trend (*teach-teaching*, *computes-compute-computable*). This is probably because the lexically related words share many parts of character sequences.

5.3 Training time

We measure the training time for GWR and corpus-based models. For a fair comparison, we use the same hardware resources, and record the training time when each model achieves the best performance on English data. Word2vec and FastText, which are corpus-based models, take approximately 10 and 14 hours, respectively. In contrast, GWR takes 52 minutes for learning 100,000 words in pre-trained word embeddings (*i.e.,* 16x faster than FastText). This result demonstrates that GWR produces word representations efficiently.

6 Conclusion

In this paper, we have proposed a character-based approach, denoted as GWR, to generate word representations. To this end, we have used a CNN and a highway network to extract salient subword features, and then learned features from pre-trained word embeddings. Notably, the proposed model allows us to produce high quality representations of OOV words by considering subword information. Experimental results demonstrate the efficacy of our methodology and clearly show that the proposed model works well for NLP tasks. We plan to apply the proposed model to different domains such as text classification and named entity recognition.

Abstract

State-of-the-art Natural Language Processing algorithms rely heavily on efficient word segmentation. Urdu is amongst languages for which word segmentation is a complex task as it exhibits space omission as well as space insertion issues. This is partly due to the Arabic script which although cursive in nature, consists of characters that have inherent joining and non-joining attributes regardless of word boundary. This paper presents a word segmentation system for Urdu which uses a Conditional Random Field sequence modeler with orthographic, linguistic and morphological features. Our proposed model automatically learns to predict white space as word boundary as well as Zero Width Non-Joiner (ZWNJ) as sub-word boundary. Using a manually annotated corpus, our model achieves F_1 score of 0.97 for word boundary identification and 0.85 for sub-word boundary identification tasks. We have made our code and corpus publicly available to make our results reproducible.

Title and Abstract in Urdu

اردو میں تقطیع الالفاظ بذریعہ کنڈیشنل رینڈم فیلڈز

جدید ترین نیچرل لینگویج پراسیسنگ کے الگورتھم رواں تحریر کی الفاظ میں تقسیم پر بہت انحصار کرتے ہیں۔ اردو ان زبانوں میں شامل ہے جن میں خودکار طریقے سے یہ تقطیع الالفاظ ایک پیچیدہ عمل ہے کیونکہ اردو لکھتے وقت الفاظ کے درمیان خالی جگہ اکثر حذف کر دی جاتی ہے اور کبھی غیرضروری طور پر داخل بھی کر دی جاتی ہے۔ یہ مسئلہ جزوی طور پر عربی رسم الخط کے استعمال کی وجہ سے ہے جس میں حدودِ الفاظ سے قطع نظر، حروف کی متصلہ اور غیر متصلہ، دونوں اشکال پائی جاتی ہیں ۔ اس مقالہ میں ہم اردو کے لیے ایک خود کار نظام پیش کر رہے ہیں جو کسی بھی اردو تحریر کی بآسانی تقطیع کر سکتا ہے۔ یہ نظام املائی، لسانی اور معنوی اوصاف کا استعمال کرنے والے ایک کنڈیشنل رینڈم فیلڈ ماڈل پر مبنی ہے۔ ہمارا مجوزہ ماڈل خود کار طریقے سے خالی جگہ کی لفظی حد کے طور پر پیشگوئی کرنا سیکھتا ہے اور اس کے ساتھ زیرو وڈتھ نان جائز (ZWNJ) کی ذیلی لفظ کی حد کے طور پر بھی پیشن گوئی کرتا ہے۔ ایک دستی نشان شدہ کارپس کا استعمال کرتے ہوئے، ہمارے ماڈل کو لفظی حد کی شناخت کے لیے 0.97 کا اور ذیلی لفظ کی حد کی شناخت کے لیے 0.85 کا F_1 سکور حاصل ہوتا ہے۔ اپنے نتائج کو قابل تکرار بنانے کے لیے ہم نے اپنے کوڈ اور کارپس کو عمومی طور پر دستیاب کر دیا ہے۔

1 Introduction

Word segmentation is an essential step for most Natural Language Processing (NLP) tasks. Most of the state-of-the-art NLP applications such as Machine Translation, Parts-of-Speech (POS) tagging etc. operate at word level. English and other languages that use Latin script usually rely on white spaces to mark word boundaries, with some exceptions like compound words, and exhibit less segmentation issues than Asian languages like Mandarin, Lao, and Urdu etc. that do not have consistent word boundary markings. In the absence of word boundary markers, tokenization of text for further processing is a non-trivial and challenging task.

Urdu, the official language of Pakistan, is an Indo-Aryan language with over 163 million speakers[1] worldwide. It uses Arabic script with segmental writing system. More specifically it uses an *abjad* system where consonants and (most) long vowels are necessarily written while short vowels (diacritics) are

[1] https://www.ethnologue.com/language/urd

Proceedings of the 27th International Conference on Computational Linguistics, pages 2562–2569
Santa Fe, New Mexico, USA, August 20-26, 2018.

optional. Urdu is bidirectional and characters are written from right-to-left while numerals are written from left-to-right. A sentence written in Urdu along with its English translation is given below:

اردو پاکستان کی قومی زبان ہے۔

Urdu is the national language of Pakistan.

When Urdu script is written in digital form, white space is not used for word boundary alone but also serves as a sub-word boundary marker as discussed in subsequent sections. Due to this absence of a clear word boundary marker, Urdu exhibits complex segmentation issues for natural language processing as well as information retrieval. In this paper, we present a system to solve this problem of word tokenization. **The major novel contributions of this paper are:**

1. A publicly available annotated corpus for Urdu word segmentation.
2. A Conditional Random Field (CRF) word segmentation utility for Urdu based on linguistic and orthographic features.

The remainder of this paper is structured as follows: Section 2 reviews segmentation techniques. We then present Urdu orthography and writing system in Section 3. Section 4 briefly discusses challenges in Urdu word segmentation. We present our corpus and model in section 5 and conclude in section 6.

2 Literature Review

Several techniques have been applied to solve segmentation issues for different world languages. Wong and Chan (1996) proposed a rule-based maximum-matching (max-match) dictionary look-up for Chinese word segmentation. This technique does not take into account the context of words and also never generates short valid words. Another rule-based variant of max-match exists that first generates all possible segmentations of character sequences and then selects the best one based on heuristics like minimum length words etc. (Sornlertlamvanich, 1993; Ping and Yu-Hang, 1994; Nie et al., 1994).

Statistical methods like n-grams have also been extensively used to segment character sequences into words and have proven very effective (Kawtrakul, 1997; Aroonmanakun, 2002). However, performance of statistical word segmentation methods relies heavily on the quality of training corpora and computationally expensive higher order n-grams to capture long distance dependencies. Charoenpornsawat et al. (1998) use context-based features like Winnow (Blum, 1997) for Thai word boundary identification.

Huihsin et al. (2005) proposed a conditional random field (CRF) sequence modeler for Chinese word segmentation. Their feature set consisted of simple n-gram features e.g. unigram and bigram features. Monroe et al. (2014) used the same CRF sequence modeler but with extended linguistic features for Arabic word boundary identification. They have reported F_1 score of 0.92 on Egyptian Arabic Treebank[2] and 0.98 on Arabic Treebank[3]. Our proposed model is similar to that of Monroe et al. (2014) but based on a different feature set.

More recently Cai and Zhao (2016) and Cai et al. (2017) investigated the use of neural language models with word and character-based embedding for efficient Chinese word segmentation and achieved better results than traditional segmentation algorithms. As with all deep-learning architectures, their model is data hungry and needs much training data, which is a barrier for low-resource languages.

There has been some research for Urdu word segmentation (Durrani and Hussain, 2010) using hybrid techniques such as rule-based methods relying on max-match, statistical methods such as n-grams together with the POS tags of words. Their best technique have achieved error detection rate of 85.8% for space insertion and space omission errors.

To our knowledge, there is no existing CRF based model for Urdu word segmentation along with a publicly available corpus and gold standard that can act as a reproducible reference for this task.

3 Urdu Writing System

Urdu is written using Arabic script in a cursive format (Nastaliq style) from right to left using an extended Arabic character set. The character set includes 37 basic and 4 secondary letters, seven diacritics, punctuation marks and special symbols (Hussain & Afzal, 2001; Afzal & Hussain, 2001; Hussain, 2004).

[2] LDC2012E{93,98,89,99,107,125}, LDC2013E{12,21}

[3] LDC2010T13, LDC2011T09, LDC2010T08

When characters in Urdu character-set join to form words, they can acquire different shapes. Based on context, a character may have up to four shape variants: 1) word initial 2) word medial 3) word final, and 4) isolated. Characters that can acquire all of the four shapes are known as *joiners* while one that only have two forms i.e. final and isolated are termed as *non-joiners*. Urdu joiners and non-joiners are shown in Table 1.

Joiners	ب پ ت ٹ ث ج چ ح خ س ش ص ض ط ظ ع غ ف ق ک گ ل م ن ہ ی
Non-joiners	ا د ڈ ذ ر ڑ ز ژ و ء ے

Table 1: Urdu joiners and non-joiners.

Inherently, Urdu does not have the concept of white space as a word boundary marker. During digital transcriptions, native Urdu typists use space to get accurate shape of characters instead of using it to mark word boundaries. For example, Urdu writers may insert a space within a word دولت·مند (rich) to make it visually correct, where the character · represents the ASCII space character. Omitting the space would lead to an incorrect visual form, دولتمند, for the same word. On the other hand, writers may omit a space between two separate words like اردوشاعر (Urdu poet) because the shape of characters with or without space remains identical. Due to ambiguous use of white-space in Urdu, it cannot be used as a reliable word boundary marker for NLP applications.

4 Challenges of Urdu Word Segmentation

Urdu word segmentation exhibits space omission as well as space insertion challenges. These challenges are discussed in detail by Durrani and Hussain (2010) and are summarized below:

4.1 Space Omission

Urdu words ending with non-joiner characters exhibit correct shape even without space and thus the writer may omit a space between words ending with non-joiner characters. Omission of space does not affect readability of words but raises a computation issue. An example is illustrated in Table 2.

a	اسد·قافلے·کے·صدر·کے·طور·پر·گیا۔
b	اسدقافلے کے صدر کے طورپرگیا۔
c	Asad went as the leader of caravan.

Table 2: Urdu sentence with all words ending in non-joiner characters (a) with space (shown by a ·) after each word (b) with no space after any word (c) English translation. Computationally, this sentence, which has eight tokens originally (with spaces), reduced to one token (without spaces).

4.2 Space Insertion

Another challenge of word segmentation in Urdu arises when two (or more) morphemes join to form a single word. If the first morpheme ends in a joiner character, writers may insert white space to prevent it joining with the next morpheme so that the word retains a valid visual form. If the first morpheme ends in a non-joiner, writers may (correctly) omit the space, as the shape of the word remains the same regardless. The error in this case can be avoided by using the Zero Width Non-Joiner (ZWNJ)[4] Unicode character but Urdu users are generally not aware of its existence and most Urdu keyboards also do not

[4] The standard ISO symbol for ZWNJ is ‌ which has been approximated by ‌ in this paper to avoid formatting issues

have a direct key mapping for this character. Thus an extra space within a word creates two (or more) separate tokens for a single word and creates a computational problem. The space insertion problem exists in the following cases:

- Affixation: to keep affixes separate from stem.
- Compounding: to keep words compounded together from visually merging.
- Reduplication: to keep reduplicated words from combining.
- Foreign word: to enhance readability of transliterated words.
- Abbreviation: to keep letters separate when foreign abbreviations are transliterated.

Case	a	b	c	Translation
Affixation	خوش·نصیب	خوشنصیب	خوش‌نصیب	Lucky
Compounding	نظم·و·ضبط	نظموضبط	نظم‌و‌ضبط	Discipline
Reduplication	دھوم·دھام	دھومدھام	دھوم‌دھام	Pomp & Show
Foreign word	فٹ·بال	فٹبال	فٹ‌بال	Football
Abbreviation	پی·ایچ·ڈی	پیایچڈی	پی‌ایچ‌ڈی	Ph.D.

Table 3: Example of space insertion (a) incorrect multiple tokens with space (·), correct shape (b) single token, incorrect shape (c) single token with ZWNJ (‌) as sub-word boundary, correct shape.

5 Urdu Word Segmentation Model

In order to accurately and efficiently solve space omission and insertion issues, we propose a Conditional Random Field (CRF) sequence model that uses linguistic and orthographic features to predict white space as word boundary and ZWNJ as sub-word boundary markers. Our model takes as input a concatenated sequence of characters and outputs sequence of words with space as word boundary and ZWNJ as sub-word boundary markers as shown in Figure 1. A description of our data annotation, experiments, and results is as follows.

5.1 Data Annotation

Unlike resource-rich languages such as English and Arabic that have abundant publicly accessible linguistic resources, Urdu is relatively under-resourced and does not have any segmentation benchmark corpus. To overcome this shortcoming, we manually annotated a corpus of approximately 111,000 tokens by using the Urdu-Nepali-English parallel corpus[5] as a starting point. This corpus is a parallel corpus to the common English source from PENN Treebank corpus where the source English sentences were news stories from Wall Street Journal (WSJ). We then used the CLE Urdu corpus cleaning application[6] to mark white space as word boundary and ZWNJ as sub-word boundary markers as per the rules proposed by Rehman et al. (2011). A summary of these rules is being reproduced here for the convenience of the reader:

- White space after each word ending.

[5] http://www.cle.org.pk/software/ling_resources/UrduNepaliEnglishParallelCorpus.htm
[6] http://www.cle.org.pk/software/langproc/corpuscleaningH.htm

- ZWNJ between two roots or stems of X-Y compounding e.g. انشاءاللہ
- ZWNJ between two roots or stems of X-e-Y compounding e.g. وزیراعظم
- ZWNJ before and after و in X-o-Y compounding e.g. نظم‌وضبط
- ZWNJ between reduplicated words e.g. روٹی‌ووٹی
- ZWNJ between prefix and root in case of prefixation e.g. خوش‌اخلاق
- ZWNJ between root and suffix in case of suffixation e.g. شادی‌شدہ
- ZWNJ between multiple morphemes of a single transliterated word e.g. فٹ‌بال
- ZWNJ between multiple morphemes of a transliterated abbreviation e.g. پی‌ایچ‌ڈی

The complete corpus was annotated by the first author. To calculate the inter-annotator agreement, 100 sentences (21,781 characters) were annotated by one of the co-authors and the inter-annotator agreement was found to be 0.98 as measured using Cohen's Kappa. Both annotators are native Urdu speakers with a background of computer science and NLP, and use Urdu scripts in both printed and digital form on a regular day-to-day basis.

Next, we applied Unicode text normalization to convert multiple equivalent representations of characters to their consistent underlying normal forms and removed all diacritics and multiple spaces from the text. Some of these characters, such as diacritics, are good indicators of word boundaries; however, it is a common practice of first language writers of Urdu to exclude diacritics in all informal and most formal forms of writing. The reader simply uses contextual information to interpret the correct word. Therefore, to model the real-life situation more closely we decided to omit all diacritics from our corpus. Omission of diacritics makes the segmentation task harder (as their removal loses a major word disambiguation and hence possibly word segmentation cue) but makes it unbiased at the same time. For the sake of comparison, we report results with diacritics present as well as removed in later sections.

The corpus consists of 4,325 sentences which cover most Urdu morphological and graphical constructs such as affixes, compounds, reduplicates, foreign words (transliterated from Latin to Arabic script) as well as abbreviations (transliterated from Latin to Arabic script) and words ending in both joiner and non-joiner characters. We have made this corpus publicly available on GitHub[7] along with our pipeline. For evaluation purposes, we have split the data in terms of sentences: 3,500 for training (90K tokens) and 825 for testing (21K tokens). The test set contains 20,264 word boundary spaces and 1,200 ZWNJ sub-word boundary markers.

5.2 Model

A CRF model, proposed by Lafferty et al. (2001), is defined as $P(\mathbf{Y}|\mathbf{X};\mathrm{w})$ where $\mathbf{X} = \{x_1,\ldots,x_n\}$ is a sequence of input and $\mathbf{Y} = \{y_1,\ldots,y_n\}$ is a predicted sequence of labels. We use a linear-chain model (Green and DeNero, 2012) with $\mathbf{X}$ as concatenated sequence of characters and $\hat{\mathbf{Y}}$ is chosen as per the following decision rule.

$$\hat{\mathbf{Y}} = \mathbf{argmax} \sum \mathrm{w}^{\mathrm{T}}\, \phi(\mathbf{X}, y_i);\ \mathrm{i} = 1,\ldots,\mathrm{n}$$

Where ϕ is a feature map defined in section 5.3. Our model classifies each y_i as one of the following:

- I: continuation of a word or sub-word.
- $\mathrm{B_W}$: beginning of a word.
- $\mathrm{B_S}$: beginning of a sub-word.

[7] https://github.com/harisbinzia/Urdu-Word-Segmentation

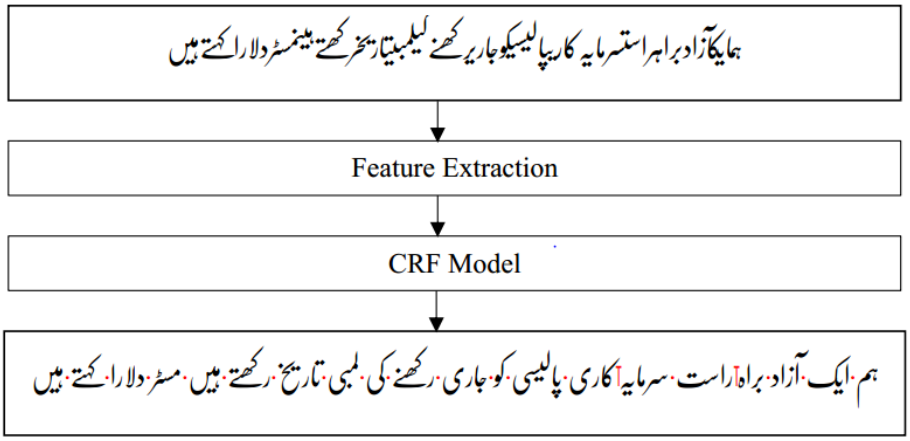

Figure 1: Urdu word segmentation pipeline. The input is a concatenated sequence of characters and the output is a sequence of words with white space (·) as word boundary marker and ZWNJ (‌) as sub-word boundary marker. In this example براہ‌راست (live) is a compound word that consists of two morphemes براہ and راست so our model predicted ZWNJ between them. Similarly, سرمایہ‌کاری (investment) is an example of affixation with ZWNJ between root سرمایہ and suffix کاری.

5.3 Feature Engineering

We experimented with different orthographic and linguistic features such as character windows of varying lengths, joining/ non-joining behavior etc. and selected the best ones for our model. Table 4 summarizes the effect of each feature on the performance of the model. Our final CRF model employs the following features:

- N-grams consisting of the current character and up to three preceding and three succeeding characters e.g. for each i^{th} character x_i, the character sequence $\{x_{i-3}, \ldots, x_i, \ldots, x_{i+3}\}$ is considered.
- Whether the current character is a digit.
- Whether the current character is a joiner.
- Unicode class of current character.
- Direction of current character. Urdu is bidirectional where basic/secondary characters and diacritics are written from right-to-left while numeric characters from left-to-right.

5.4 Results

We have used precision, recall, and F_1 measure as our evaluation metrics as they provides a more informative assessment of the performance than the word level and character level error rates. On an unseen undiacritized test set of 825 sentences (21K tokens) our model achieved F_1 score of 0.97 for word boundary and 0.85 for sub-word boundary identification. The detailed results are shown in Table 5 and 6.

Not surprisingly, the F_1 score for sub-word boundary identification is slightly higher for diacritized text as some diacritics are very indicative features of sub-word boundary e.g. ِ in compounding. Diacritized text also has high precision over undiacritized text for word boundary prediction as the diacritic ً is a clear indication of word boundary.

We also report the macro and micro F_1-measures. However the results do not show much improvement between diacritized and non diacritized corpora. One possible explanation is that the corpus is very sparsely diacritized with only 5,237 diacritics in 111K tokens. Solution to this problem via automatic diacritization is beyond the scope of the current paper.

Features	F_1 Word Boundary (Space)	F_1 Sub-word Boundary (ZWNJ)
Current character	0.59	0
+1 character window	0.77	0.07
+2 character window	0.85	0.46
+3 character window	0.92	0.72
+isDigit	0.95	0.79
+isJoiner	0.96	0.84
+Unicode class	0.97	0.85
+Direction	0.97	0.85

Table 4: Results with different feature set.

Gold \ Predicted	I	B_W	B_S
I	59,149	474	42
B_W	574	19,637	53
B_S	119	116	965

a) Undiacritized test set

Gold \ Predicted	I	B_W	B_S
I	60,254	405	44
B_W	560	19,660	44
B_S	115	88	997

b) Diacritized test set

Table 5: Confusion matrices for word and sub-word boundary identification.

	Boundary	Precision	Recall	F_1	
Without Diacritics	Word	0.97	0.97	0.97	macro-F_1= 0.91 micro-F_1= 0.96
	Sub-word	0.91	0.80	0.85	
With Diacritics	Word	0.98	0.97	0.97	macro-F_1= 0.92 micro-F_1= 0.96
	Sub-word	0.92	0.83	0.87	

Table 6: Test set results with and without diacritics.

6 Conclusion & Future work

We present a CRF sequence modeler for word and sub-word boundary identification in Urdu text using orthographic and linguistic features. Our best model achieves F_1 score of 0.97 and 0.85 for word and sub-word prediction tasks respectively. We also present handcrafted training and testing data that we have made publicly available to allow for reproducible research.

The presented system is trained using a manually crafted corpus of 4,325 sentences (111K tokens) which is relatively small compared to segmentation benchmark corpora of Arabic and Chinese. As a future direction we will extend our work to tag a much bigger corpus with space as word boundary markers and ZWNJ as sub-word boundary markers. We will explore more linguistic features for the CRF model to increase performance of sub-word boundary identification task. We also plan to explore neural models such as RNN and Bidirectional RNN for Urdu word and sub-word boundary prediction.

Abstract

In this article, we present ReSyf, a lexical resource of monolingual synonyms ranked according to their difficulty to be read and understood by native learners of French. The synonyms come from an existing lexical network and they have been semantically disambiguated and refined. A ranking algorithm, based on a wide range of linguistic features and validated through an evaluation campaign with human annotators, automatically sorts the synonyms corresponding to a given word sense by reading difficulty. ReSyf is freely available and will be integrated into a web platform for reading assistance. It can also be applied to perform lexical simplification of French texts.

1 Introduction

With the availability of very large corpora and the growing maturity of corpus linguistics and NLP techniques, quantitative descriptions of the lexicon have made noteworthy progress. The coverage of the resources has increased, tokenizing and part-of-speech tagging have enabled a better annotation of the lexical units and statistical models have yielded more accurate descriptions of the lexicon (in terms of frequencies, n-gram models, etc.). However, to the best of our knowledge, on-line lexical resources with a ranking of the lexical units as regards to their difficulty to be read and understood are scarse. Such information is highly relevant in communicative and educational contexts (e.g. clear and efficient writing, calibration of teaching materials, etc.) given that complex synonyms are identified and their simpler equivalents proposed.

In this paper, we present and describe such a resource for French. In ReSyf, synonyms are automatically disambiguated and ranked according to their complexity for L1 schoolchildren readers. The lexicon has been developed as part of the project ALECTOR[1] (Reading Aids to leverage Document Accessibility for Children with Dyslexia) that aims to support poor readers and dyslexic children to acquire French vocabulary and improve their reading skills in French through practise. More specifically, ALECTOR addresses the challenge of automatic text simplification for this population and illustrates one of the possible uses of ReSyf: it can be a knowledge database to carry out the substitution of complex words present in reading materials. The evaluation of the proposed ranking algorithm of the synonyms shows that, in 91% of the cases, the ranks in ReSyf correspond to the ranks given by human annotators. These results are encouraging taking into account the difficulty of the task (i.e. subjectivity, inter-annotator agreement). They are also important because the simplest synonym is always identified, which implies that ReSyf can indeed be used for reading assistance and can also be integrated into a model for automatic lexical simplification.

The paper is organized as follows. After reviewing related work at Section 2, we present the methodology applied to create ReSyf at Section 3. It includes three steps: (1) the choice of the synonym resource; (2) the disambiguation process, and (3) the ranking algorithm. Section 4 provides details on the resource itself, its availability and its evaluation by humans. Some concluding remarks and future work are discussed in Section 5.

2 Related work

Despite playing a crucial role in semantic applications, available machine-readable resources with synonyms are still scarce. In English, the Roget's 21st Century Thesaurus[2] (third edition) and WordNet (Miller et al., 1990) are notable examples. In French, the lexicon from CRISCO[3] (Morel and François, 2015) and the lexical network JeuxDeMots[4] (Lafourcade, 2007) are the most well-known and freely available on-line resources. Other semantic resources including synonymy relations are WOLF – the French WordNet – (Sagot and Fiser, 2008) or BabelNet (Navigli and Ponzetto, 2012). Yet, they have been automatically built from multilingual networks and therefore the granularity of their senses often lacks precision to be exploited for our purposes (not to mention wrong translations in the case of the French version of BabelNet).

With regards to graded lexicons, the idea of assessing a degree of 'difficulty' to words – although not recent – is not widespread. In the context of language learning and reading assistance (i.e. automatic lexical simplification in NLP), 'difficulty' can be understood as the level of proficieny required for a learner to read and understand a word. Beyond frequency counts, commonly used as proxys of the familiarity of a word[5], some initiatives have recently taken advantage of corpora with levels of difficulty. For French, Manulex (Lété et al., 2004) is a graded lexicon used by teachers and psycholinguists to identify the level of difficulty of words at school (in the context of learning French as mother tongue). This lexicon describes the frequency distributions of 23,812 French lemmas across three primary school levels: 1st grade, 2nd grade, and 3rd to 5th grades. The frequencies have been estimated on a corpus of pedagogical materials used at these three levels. FLELex (François et al., 2014) is a similar resource, aimed at learners of French as a foreign language. It is part of a larger project including graded resources for different European languages: the CEFRLex project[6]. All the resources in the CEFRLex project have been built based on corpora of pedagogical texts classified according to the six proficiency levels defined by the CECR (Conseil de l'Europe, 2001), ranging from A1 to C2.

The difficulty information in Manulex and FLELex can directly be used to assign difficulty levels to French words and synonyms (Gala et al., 2014). However, this approach presents some drawbacks. First, as they are both pedagogical resources, their coverage is limited. We thus have no level information for more complex synonyms if they are absent from these resources. Second, the pedagogical levels used in these resources may sometimes be too coarse-grained to make fine-grained distinctions as regards the complexity of synonyms. For instance, the word *minceur* ('thinness, slimness') is assigned the difficulty level 3 in Manulex, which is the highest difficulty level in this resource. However, in ReSyf, *minceur* is ranked at the 6th position in a list of 12 synonyms. Synonyms from position 7 to 12 are assumed to be more complex than *minceur*, but if we assign them the difficulty scores from Manulex, they would all be assigned to level 3. Such coarse-grained information does not allow to make any finer difficulty distinction between all these synonyms. We therefore believe that ranking synonyms is more efficient than assigning coarse-grained difficulty levels. Third, synonyms are extracted – and their difficulty is estimated – as word forms and not as word senses. For instance, *mince* is an adjective meaning 'thin, faint, slim'; it is given grade 1 in Manulex and A1 in FLELex, while in ReSyf it appears in 1st position with the meaning 'faint', in 3rd position with the meaning 'slim', and in 4th position with the meaning 'thin'.

As far as specific resources for automatic lexical simplification are concerned, to the best of our knowledge only the lexicon CASSAurus (Baeza-Yates et al., 2015) for Spanish is similar to ReSyf. However, the words in this lexicon are assigned only to two classes, simple and complex, which is a very coarse-grained view of lexical complexity.

3 Methodology to build the lexicon

To build ReSyf, we used the words in the lexical network JeuxDeMots (Lafourcade, 2007) linked by the synonymy relation (3.1). We then applied a disambiguation (3.2) and a ranking algorithm (3.3) to identify complexity within the word senses in a vector.

3.1 Nature of the lexical entries: synonyms

Synonymy is a lexico-semantic relation implying equivalence among two word senses. Absolute synonyms are very rare, synonyms are thus two lexical units having a semantic value close enough (by inclusion or intersection) to be replaced one by the other to convey the same meaning (Polguère, 2002). Word Sense Disambiguation (WSD) techniques are necessary to identify the meaning of the word forms to be able to identify the appropriate synonyms, i.e. the French word *grave* is synonym of *sérieux* when meaning 'serious' (i.e. a serious problem), but synonym of *profond* when meaning 'deep' (i.e. a deep voice).

3.2 Data acquisition: from word forms to word senses

3.2.1 Resources for bootstrapping

Similar to other resources where the complexity of the entries is given (see section 2), we first developped a version of ReSyf with word forms associated with grades (from 1 to 3) (Gala et al., 2013) and (Gala et al., 2015). This approach raised some important issues concerning the nature of the entries and Word Sense Disambiguation. These problems were very soon identified and we started to work in another version with refined senses[7] for each entry and with ranks dynamically assigned from 1 to n, depending of the number of synonyms in a vector, instead of static grades.

We created a second version using BabelNet (Navigli and Ponzetto, 2012), a lexical network automatically built from several resources (WordNet, Wikipedia, etc.). The problem with BabelNet is its excessive granularity of senses: for our purposes (for the targeted users of ReSyf), we needed a more accurate and simplified version. For instance, the word *toile* in French has fifteen senses in BabelNet. For schoolchildren, specially those with reading difficulties, four distinctions are enough ('computer network' , 'cloth' , 'painting' , 'spider web').

We finally decided to use the lexical network JeuxDeMots (Lafourcade, 2007) for the current version. The lexical database of this network, built by crowdsourcing, is very rich and constantly evolving. Each node in the lexical network represents a lexical unit describing a word (a simple word or a multiword expression, MWE). The relationships between the nodes are typed and weighted. Some of these relationships correspond to lexical functions related to the vocabulary itself (such as ASSOCIATED IDEA and SYNONYMY relationship) or to hierarchical semantic relations (such as HYPERNYMY and HYPONYMY). Senses are encoded with the SEMANTIC REFINEMENT relation. Each instance of this relation describes a specific sense for a given term.

JeuxDeMots is a human-based computation game, in other words, a game with a purpose (GWAP). The actors are simple players who play through an interface that has the form of an online game. The validation of the quality of the data collected for the construction of the lexical database, containing lexical items and relations between them, is provided by players. More specifically, relationships are proposed anonymously by a player and they are validated by other anonymous players. The relations between the lexical items are weighted. The weighting is carried out in the following way: the more an instance of a given relation is proposed, the more its weight increases, as long as the conditions of the game are respected.

At present, the JeuxDeMots lexical database contains:

a) 182 373 582 instances of all possible relations;

b) 3 081 091 terms having at least one outgoing relation ($term_A \rightarrow term_B$);

c) 2 497 238 terms having at least one incoming relation ($term_A \leftarrow term_B$).

[7] A refined sense $s_i(w)$ for the word w is a particular use of w that this word has no other similar refined sense to $s_i(w)$.

Synonyms are proposed for both words and word senses. However, it turns out that not all synonyms for a given word are grouped together in distinct senses. For example, *tissu* ('cloth') is a synonym for the lexical entry *toile* but it does not appear in the network as a disambiguated synonym. We thus need to include *tissu* as a disambiguated synonym aggregated to the word sense *toile* ('cloth'). To include all disambiguated synonyms into word senses, we use a disambiguation algorithm based on semantic representations for words and word senses (semantic signatures).

We previously proposed a methodology for the creation and validation of semantic signatures (Billami and Gala, 2017). In general terms, a semantic signature can be considered as a special representation form of Vector Space Model, VSM (Turney and Pantel, 2010). In the same way as VSM, the weight associated with a dimension in a semantic signature indicates relevance or importance of this dimension. The main difference is the way in which the weights are computed. VSM uses cooccurrence statistics in a given corpus whereas semantic signature uses structural properties of the used network (JeuxDeMots in our case).

The goal of our approach is to directly compare the semantic signature of each synonym with the semantic signature of each candidate word sense. The semantic similarity that we use is an activation function which takes into account the relation between two lexical units to compare (Billami and Gala, 2017). This relation checks whether the one (synonym or candidate word sense) represent a dimension in the semantic signature for the other. If it is true, the function returns a perfect similarity ($score\ of\ similarity\ =\ 1$) else the cosine similarity is estimated by using their semantic signatures.

We use the relation ASSOCIATED IDEA for creating the signatures. This relation contains the largest number of instances since it includes all terms that reflect a given lexical entry in JeuxDeMots (57% for ASSOCIATED IDEA instances). On the other hand, JeuxDeMots contains at least 100 lexico-semantic relations.

3.2.2 Word Sense Disambiguation method

The algorithm 1 described below allows to disambiguate a synonym by choosing the most suitable target word sense. For each pair of synonym syn_a and candidate word sense $Sense_i$ with $i \in 1 \ldots$ n (n : number of senses for the target word) the algorithm first checks whether the one represent a dimension in the semantic signature for the other. If it is true, the synonym is clustered directly to the $Sense_i$ else the cosine similarity is estimated by using their semantic signatures. In this case, the closest sense(s) with the best similarity are selected. We use a threshold $\varepsilon = 0.01$.

We have developed a variant of the algorithm 1 by comparing not directly a synonym with a candidate word sense, but each synonym sense (if this latter is polysemous) with each candidate word sense. This is the hypothesis that describes the similarity between two words as the similarity of their closest senses (Budanitsky and Hirst, 2006). On the other hand, if the synonym is monosemous, the algorithm 1 is applied (we note this variant algorithm 2).

In order to validate our algorithms, we used a list of manual disambiguated synonyms in JeuxDeMots as a test set (JeuxDeMots dump of December 2017, 33 039 pairs synonym – target word sense). The table 1 describes the precision results of our evaluation by applying the two clustering algorithms. In Word Sense Disambiguation, the precision is the ratio between the correct answers provided and the total answers provided, whereas recall is the ratio between the correct answers provided and the total answers to provide (Navigli, 2009).

Our semantic signatures based on associated ideas cover all synonyms and senses of the test set. Therefore, we have precision = recall = F-measure.

Not surprisingly, the results show that we have a better performance (higher precision) when we use the algorithm 1: the semantic signature of a synonym is most informative than a semantic signature for a specific synonym sense.

3.3 Data ranking method: from grades to ranks

Once all the senses were identified, we developed a ranking algorithm which is able to sort the synonyms according to their complexity (reading difficulty for target readers). For this task, we relied on an approach commonly used in the field of information retrieval to sort the results of a query by

Algorithm 1: Comparison of each candidate word sense with each synonym syn_a

Input:
$target\ word$: word to treat
$sem\_ref\ (target\ word)$: set of senses of the target word
syn_a: synonym of the target word
ε: validation threshold of the similarity
Result:
$\mathbf{\hat{Sense}_{target\ word}}$: senses of the target word with the highest score
Data:
$\mathrm{S_{a\_idea}}$: set of signatures whose dimensions are associated ideas

Initialization:
$Score_{refs\_C} = \emptyset$ // Score of the target word senses
for $Sense_i \in sem\_ref\ (target\ word)$ **do**
    $Score = \begin{cases} 1\ if\ (*) \\ Cosine\ (S_{a\_idea}(Sense_i), S_{a\_idea}(syn_a))\ otherwise \end{cases}$
    $(*) : Sense_i \in S_{a\_idea}(syn_a)\ \vee\ syn_a \in S_{a\_idea}(Sense_i)$;
    if $(Score\ \geqslant\ \varepsilon)$ **then**
        $Score_{refs\_C} \leftarrow Score_{refs\_C} \bigcup (Sense_i,\ Score)$;
$\mathbf{\hat{Sense}_{target\ word}} \leftarrow \mathbf{Best}\ (Score_{refs\_C})$

Clustering algorithms	Correct annotations	All annotations	%
Algorithm 1	32 802	33 039	**99.28**
Algorithm 2	25 307	33 039	76.6

Table 1: Evaluation results by applying the two clustering algorithms.

relevance: the pairwise approach, and more specifically the SVMRank algorithm (Herbrich et al., 2000). Such an approach requires a database of words already sorted by difficulty that will be used to create a training dataset composed of pairs of words with different levels of difficulty (section 3.3.1). We also computed, for each pair, a set of linguistic features (section 3.3.2) that can be used to predict which word of the pair is the most complex one. After model optimisation (section 3.3.3), we obtained a function that can predict, for a given input (word sense pair), which one is the more complex. This function may then be integrated into any sorting algorithm to rank a set of synonyms.

3.3.1 Training dataset

As ReSyf is mainly intended for schoolchildren, we used Manulex to obtain word difficulty annotations (see description at Section 2). As we only considered open class words (nouns, adjectives, adverbs, and verbs), we retained $19,038$ lemmas from Manulex for our training dataset.

Based on this resource, it is possible to create pairs of words in which one is more complex than the other. The pairs are then used to train the ranking model. However, this requires to transform the frequence distribution of each word into a single numerical value that can be used to compare the reading difficulty of two words. More formally, the distribution D for a word w takes the form of a vector (f_1, f_2, f_3) corresponding to the frequencies of the word at each of the three Manulex levels. Our goal is to define a function $\phi(D)$ that will output a single difficulty value l based on the values in D. Two approaches were tested. The first technique simply outputs a level value $L \in \{1, 2, 3\}$ that corresponds to the first level f_i for which $f_i > 0$. The training set based on this technique is called *Manulex-3N*. However, using only three values to represent difficulty creates a large amount of ties during the pair creation step. Therefore, we experimented a second technique to define $\phi(D)$ such as it outputs a

continuous value ranging from 1 to 3 using the formula below (Gala et al., 2013).

$$\phi(D) = L + \exp^{-r} \quad \text{where} \quad r = \frac{\sum_{i=1}^{L} f_i}{\sum_{i=L+1}^{3} f_i}$$

In this formula, L corresponds to the output of the first technique to which we add a continuous quantity that is function of the distribution D. This quantity is defined in terms of the ratio between the sum of the counts from levels 1 to L over the sum of the counts from $L + 1$ to 3. This way, we can distinguish two words such as *pomme* ('apple') et *cambrioleur* ('burglar') that both appear at level 1 ($L = 1$), but 724 times for 'apple' and only 2 times for 'burglar'. The training set based on this technique is called *Manulex-Cont*.

3.3.2 Word features

Each word sense from our dataset was first represented as a 69-feature vector capturing various linguistic and psycholinguistic properties that can be classified in the four following types:

- *Spelling features*: (1) number of letters, (2) number of phonemes, (3) number of syllables, (4) number of orthographical neighbors[8]; (5) cumulated frequencies of all orthographical neighbors; (6) number of neighbors that are more frequent as the target word; (7) transparency between the written and phonological forms; (8-13) six variables detecting specific complex graphems, namely oral vowels (e.g. *au* [o]), nasal vowels (e.g. *in* [ɛ̃]) , double consonnants (e.g. *pp*), double vowels (e.g. *ée*), other digrams (e.g. *ch* [ʃ]), or the sum of all five phenomenas; and (14-16) membership of the syllabic structure of the word to a class considered as either frequent, median, or rare.

- *Frequency features*: (17) the log-frequency of the word based on the Lexique3 (New et al., 2007) database and (18-26) the presence of the word in a list of simple words. We defined 9 lists of different sizes (1063, 2000, 3000, $\cdots$, 8000, and 8775 words), all based on the Gougenheim list (Gougenheim, 1958).

- *Semantic features*: (27) a binary variable coding whether the word is considered as polysemic in JeuxDeMots and (28) the number of synsets listed in BabelNet.

- *Morphological features*: the morphological analysis was automatically performed by systems developed by Bernhard (2006) and Bernhard (2010). The first of these systems splits words into tagged morphemes (root, prefixes, suffixes, etc.) and derives various frequency information about the identified morphemes, while the second system identifies the morphological families and can be used to extract information about a word family. The variables we used were : number of morphemes; presence of suffixes; presence of prefixes; presence of two bases or more (for compound words); the minimal frequency of the affixes of the word (i.e. number of different words in which appears the least frequent of the affix); the average frequency of all affixes in the word; the size of the morphological family; the frequency of the most frequent word in the morphological family; the mean frequency of all words in the family; and the cumulated frequency of all words in the family. The two systems include parameters that were manipulated, thus creating variants of the above variables. In total, we defined 41 morphological variables (29-69)[9].

3.3.3 Model definition and optimization

The definition of the ranking model was performed in three steps: (1) creating the training dataset (pairs of synonyms); (2) feature selecting; and (3) model training. To create the pair training dataset, we applied the following procedure: given two words w_i and w_j, each associated to a difficulty level (l_i and l_j) and to a feature vector ($\mathbf{v_i}$ and $\mathbf{v_j}$), we create a pair $< w_i, w_j >$ for which a new vector $\mathbf{v_{ij}}$ is obtained from the combination of the two vectors $\mathbf{v_i}$ and $\mathbf{v_j}$. Several arithmetic operations can be used to carry out

[8]The orthographic neighborhood of a word have been defined by Coltheart (1978) as all the words of same length and differing only by one letter (eg. FIST and GIST).

[9]For a detailed description of these parameters, see (Gala et al., 2014).

this combination, but we used substraction ($\mathbf{v_{ij}} = \mathbf{v_i} - \mathbf{v_j}$), as Tanaka-Ishii et al. (2010) showed that substraction was best for ranking texts by readability. Each pair $< w_i, w_j >$ was also assigned a new difficulty level (l_{ij}) obtained with the following rule: (1) if $l_i > l_j$, then $l_{ij} = 1$ and (2) if $l_i < l_j$, then $l_{ij} = -1$. As we had two original datasets, *Manulex-3N* and *Manulex-Cont*, we got two pair datasets.

Second, to select the best predictors of word difficulty, we computed the Spearman correlations between each of our 69 variables and the new binary difficulty variable (L_{ij}). We used only the *Manulex-3N* dataset for this aim. Table 2 displays the correlation for some of the best features in our set. At the end of this selection step, 21 variables were retained for the model.

Variable name	**Correlation (ρ)**
17 Freq. Lex3	-0.57
18 AbsGoug (6000)	-0.46
02 Nb. phon	0.35
15 Polysemy	-0.33
01 Nb. letters	0.32
03 Nb. syllables	0.32
4a Nb. neighbors	-0.23
15 Mean freq. of the morphological family	-0.27
15 Cum. freq. of the morphological family	-0.27
15 Max. freq. of the morphological family	-0.27
4b Cum. freq. of the neighbors	-0.23
16 Nb. of senses in BabelNet	-0.19

Table 2: Best variables based on Spearman correlation.

Third, we trained a SVM model with linear kernel on each pair dataset (*Manulex-3N* and *Manulex-Cont*). For each model, a grid-search was used to select the best value for the C meta-parameter. We then estimated the accuracy of pair classification by each model with a 10-fold cross-validation procedure. Table 3 summarizes the accuracy of both models and compares their scores with those of a full model (that uses all 69 features). The models including 21 variables reach similar or slighly better accuracy than the full model. More interestingly, the model trained on the *Manulex-3N* dataset (using the simple rule of first occurrence) clearly outperforms the model based on *Manulex-Cont*. As a result, we decided to retain the model based on the first way of defining $\phi(D)$ for the final version of ReSyf.

Dataset	**C**	**21 var.**	**C**	**69 var.**
Manulex-3N	0.01	77.4%	0.01	77.8%
Manulex-Cont	0.01	72.4%	0.01	71.4%

Table 3: Accuracy of the ranking models.

4 ReSyf: graded synonyms according to their difficulty

In this section we describe the data available in the lexicon (section 4.1) and an evaluation of the ranking algorithm (section 4.2).

4.1 Data available

ReSyf provides an inventory (a vector) of equivalent words ranked according to their difficulty to be read and understood[10]. For instance, *sec*(1), *léger*(2), *mince*(3), *allongé*(4) and *svelte*(5), corresponding to the meaning 'slim' . The first sense *mince (fin)* is the most general sense taking into account the weight of the relation between the word *mince* and the semantic refinement *mince (fin)* defined in JeuxDeMots. The weight of this type of relation allows to sort the senses from the most general to the most specific. Each weight is normalized by using the ratio between its value and the top level weight value.

[10]The resource is freely available for lookup and download (XML file) at http://cental.uclouvain.be/resyf

In order to distinguish words according to the four open classes (nouns, adjectives, adverbs, and verbs), we filtered all the single words with the French reference resource Lexique3 (New et al., 2007). For the multiword expressions (MWE), we used the parser Talismane[11] (Urieli, 2013) as a part-of-speech tagger. For MWE, we have considered that its POS is the POS assigned to its first open class item. Table 6 describes the distribution of entries in ReSyf (total number of entries: 57 589, 10 333 polysemic and 47 256 monosemic). The number of common nouns is greater than that of all the other parts-of-speech categories, either for the polysemic or the monosemic entries. Note that JeuxDeMots is constantly evolving and, as a result, more semantic refinements will be available in the future (more polysemic entries to be disambiguated).

The distribution of categories described in table 6 shows that the mean synonyms per polysemic entry sense is 4.95 (which is greater than what we can obtain when using other resources such as BabelNet).

	Nouns	**Verbs**	**Adjectives**	**Adverbs**	**Total**
#Polysemic entry (*Pe*)	**6 737**	1 779	1 691	126	**10 333**
#Monosemic entry (*Me*)	**30 869**	8 388	6 606	1 393	**47 256**
Single words	**21 495**	5 065	7 635	1 105	**35 300**
Multiword expressions	**16 111**	5 102	662	414	**22 289**
Mean synonyms per *Pe*	12.95	**17.97**	16.93	6.16	14.39
Mean synonyms per *Me*	4.19	6.86	**9.27**	4.71	5.39
Mean senses per *Pe*	2.95	**3.03**	2.65	2.25	2.9
Mean synonyms per *Pe* sense	4.39	5.92	**6.39**	2.73	4.95

Table 4: Distribution of ReSyf entries.

Table 5 describes the statistics as regards to the distribution of ReSyf synonym annotations (polysemic entries). As it is showed, JeuxDeMots currently proposes 27 466 associated synonyms to the semantic refinements for adjectives, adverbs, common nouns and verbs. By applying our first clustering algorithm (cf. algorithm 1), we are able to automatically disambiguate 121 182 synonyms. The automatic annotation represent a benefit of 4.4 more than what JeuxDeMots currently proposes.

	Nouns	**Verbs**	**Adjectives**	**Adverbs**	**Total**
#Automatic annotations	**69 323**	26 379	24 851	629	**121 182**
#Manual annotations	**17 954**	5 584	3 781	147	**27 466**

Table 5: Distribution of ReSyf synonym annotations (all polysemic entries).

The figure 1 shows a sample description of the Lexical Markup Framework (LMF) format used to encode the data in a XML file. Each lexical entry is encoded in the node 'LexicalEntry'. This latter contains different features such as the ambiguity (which takes 'one' if the lexical entry is polysemic or 'zero' otherwise), the lemma form to encode the lemma and the part of speech of the entry and sense nodes to encode all senses.

The figure 1 shows all the details for the second sense of *mince* ('faint, delicate'). The weight of this sense is 0.8511, which is lower than that of the first sense ('thin', 1.0). Each sense is available with its weight, its usage features and some examples which define the disambiguated synonym. Each sense example contains the annotation feature which takes a 'manually' value if the synonym is defined manually or 'automatically' value if the synonym is captured by the clustering algorithm 1. The feature 'word' encodes the lemma of the synonym. The features 'score_lemma' and 'score_sense' encode the maximal score obtained by our clustering algorithms. If these scores are greater or equal to 0.5 they are printed, else we print only '- -'.

[11] http://redac.univ-tlse2.fr/applications/talismane/talismane_en.html

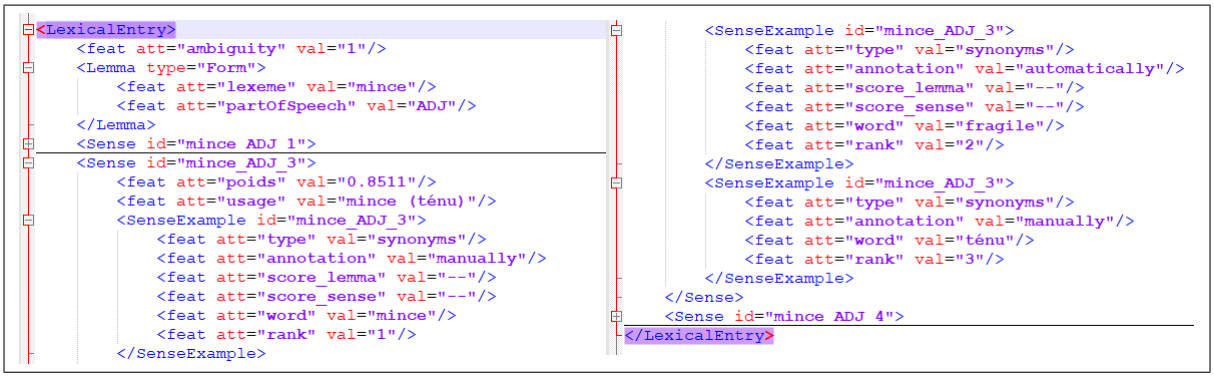

Figure 1: Lexical entry description of the word *mince* using the LMF format where the second sense is developed.

4.2 Comparison of automatic ranks with human judgments

We carried out an evaluation campaign with forty human annotators in order to obtain a gold-standard to evaluate our ranking algorithm. The annotators were asked to manually rank a list of forty senses (vectors) containing 2 to 6 synonyms (average of 3.5 synonyms/vector), with a total of 150 word forms (53 % nouns, 23 % verbs and adjectives, 1 % adverbs). The synonyms were proposed randomly (in terms of difficulty) and were not contextualized.

The ranks were manually annotated by 28 native speakers of French and 12 C1/C2 non-natives living in France for more than 5 years and having another Romance language as mother tongue. All of them were adults in the academic field: master or PhD students, assistant professors and researchers, with an average of 28,23 years old (standard deviation of 10.07).

The final reference list[12] obtained after the annotations contains 134 word forms and 36 meanings (4 senses corresponding to 16 synonyms were removed from the original list because (a) equality of the annotations or (b) presence of an unknown or irrelevant term in the vector, judged as so by most than one third of the annotators).

For each vector, the Krippendorff's alpha coefficient (α) was calculated. The global agreement obtained is 0.4, it slightly varies when it is calculated specifically for vectors with 3 or 5 synonyms. Unsurprisingly, the lesser the synonyms to rank, the higher the coefficient. These results can be compared with those obtained by Specia and collaborators at SemEval 2012 (Specia et al., 2012) (κ = 0.386 and 0.398) for a similar task.

The ranking algorithm we have developed achieves encouraging results: 83.33 % of the vectors are sorted exactly as the human annotators did, or with a slightly difference of one rank. Only 16.67 % of the vectors show a couple of synonyms ranked with more than two ranks of difference.

In terms of lexical units (synonyms), 91.04 % of them are correctly sorted or inversed with only one rank, 8.96 % have been automatically ranked with a difference of two ranks and 2.24 % (3 synonyms) have been sorted with a distance higher than two. This precise case is that of the adjectives *merveilleux, fantastique, fabuleux, formidable, splendide* ('marvellous, fantastic, fabulous, wonderful, splendid') were the annotators mostly proposed *fabuleux, formidable, fantastique, splendide, merveilleux*. This example shows the difficulty of the task for word forms with similar formal features (length, number of syllables, presence of digraphs) and corresponding to subjective senses with already very low human agreement (Krippendorff's α = 0.04).

5 Conclusion

In this paper, we have presented ReSyf, a resource for French with disambiguated synonyms that have been sorted according to readability features. The results of the ranking algorithm have been compared to human annotations and in 91% of the cases the synonyms are automatically ranked from the simplest

[12] Avalible at the end of the paper (Appendix A).

to the more complex. The lexicon can be used on-line, yet our aim is also to integrate ReSyf into a lexical simplification algorithm in order to reduce the lexical complexity of texts (lexical substitution task).

The perspectives of our work are twofold. First, we are working on the refinement of the lexicon in order to include multiword expressions (MWE). For now, the ranking of MWEs is based on an average of its content words (eg. for *faire faux bond* meaning 'to let down' , literally 'to make a false jump' , the ranking is based on feature vectors for *faux* and *bond*, which is an approximation of the reality). The issue of MWE handling is crucial for NLP applications, a more precise estimation of their complexity in reading comprehension is a real challenge.

A second perspective is that of tailoring the lexicon to the special needs of particular target audiences. By integrating ReSyf into an automatic text simplification system (lexical substitution), we aim at providing a tool to automatically adapt the words in a text to the specificities of a target reader. Roughly speaking, if avoiding long words is recommended for people with dyslexia, it might be interesting to favor them in texts tailored to adults with vision problems such as age-related macular degeneration (AMD). For instance, replace *cambrioleur* by *voleur* ('burglar' , 'thief') for dyslexic readers, but keep *cambrioleur* for AMD patients. Lexical simplification could find useful applications for different populations who struggle with reading. ReSyf could be a key component for such automatic simplification, but also for teachers, speech therapists and other professionals involved in vocabulary learning and reading assistance.

Acknowledgements

This work has been funded by the French Agence Nationale pour la Recherche, through the ALECTOR project (ANR-16-CE28-0005), and by the Belgian National Agency for Research (FNRS). The current version of the ReSyf website has been funded by Ortolang, we thank Dorian Ricci (UCL) and Brayan Delmée (UCL) for their work. We also thank Firas Hmida (LPL) and three anonymous reviewers for their comments on the previous versions of the paper.

Appendix A. List of synonyms evaluated (ranked) by human judges.

The following table shows the list of synonyms provided to the human judges for manual ranking. The words where presented decontextualized, randomly organized into a list correspondig to the same meaning. The judges had to rank them from 1 to n according to the difficulty they had to read and understand them. The table presents one line per vector of synonyms with an English translation at the end.

Abstract

Multiword expressions, especially verbal ones (VMWEs), show idiosyncratic variability, which is challenging for NLP applications, hence the need for VMWE identification. We focus on the task of variant identification, i.e. identifying variants of previously seen VMWEs, whatever their surface form. We model the problem as a classification task. Syntactic subtrees with previously seen combinations of lemmas are first extracted, and then classified on the basis of features relevant to morpho-syntactic variation of VMWEs. Feature values are both absolute, i.e. hold for a particular VMWE candidate, and relative, i.e. based on comparing a candidate with previously seen VMWEs. This approach outperforms a baseline by 4 percent points of F-measure on a French corpus.

Title and Abstract in French

Trait pour trait identiques ? Identification de variantes d'expressions polylexicales

Les expressions polylexicales (EP), et parmi elles plus particulièrement les EP verbales (EPV), se caractérisent par une grande variabilité idiosyncrasique de forme. La détection et l'identification de ces EPV variées pose ainsi un réel défi à la réalisation d'applications langagières robustes. Cet article met l'accent sur la tâche d'identification dans un corpus de variantes d'une EP verbale déjà rencontrées. Il propose une stratégie d'identification basée sur l'extraction de formes candidates à partir de patrons syntaxiques, suivie de leur classification basée sur des caractéristiques morphologiques et syntaxiques. Ces propriétés sont à la fois absolues (c.-à-d. concernent l'entité considérée) ou relatives (c.-à-d. issues de la comparaison avec des EPV déjà rencontrées). Les performances du système résultant ont été évaluées sur un corpus francophone. Elles montrent une amélioration de 4 points de F-mesure par rapport à une baseline bien établie.

1 Introduction

Multiword expressions (MWEs) such as ***red tape***, ***by and large***, *to* ***make*** *a* ***decision*** and *to* ***break*** *one's* ***heart*** are combinations of words exhibiting unexpected lexical, morphological, syntactic, semantic, pragmatic and/or statistical behavior (Baldwin and Kim, 2010). Most prominently, they are semantically non-compositional, that is, their meaning cannot be deduced from the meanings of their components and from their syntactic structure in a way deemed regular. For this reason, the presence of MWEs in texts calls for dedicated treatment, whose prerequisites include their automatic identification.

The goal of *MWE identification* is, given some input running text, to identify all MWEs' lexicalized components present in it (Schneider et al., 2016; Savary et al., 2017).[1] Such systems face three main

[1] A *lexicalized component* of a MWE, or *component* for short – marked in bold in examples – is one which is always realized by the same lexeme. For instance, the noun *decision* is lexicalized in *to* ***make*** *a* ***decision*** but the determiner *a* is not, because it can be replaced by other determiners (e.g. *to* ***make*** *this/any/the* ***decision***).

Proceedings of the 27th International Conference on Computational Linguistics, pages 2582–2594
Santa Fe, New Mexico, USA, August 20-26, 2018.

challenges: variability, ambiguity and discontinuity (Constant et al., 2017). Variability refers to the fact that the components of the same MWE can occur in different surface forms because of morphological and/or syntactic transformations, as in example (1) vs. (3) below. Variability is closely related to the issue of unseen data in machine learning – items whose surface forms differ between test and training data are usually harder to identify than those seen in identical forms (Augenstein et al., 2017). MWE ambiguity, conversely, makes the identification of seen MWEs harder, because a particular combination of words can be a MWE in some contexts, as in (1) and (2), but not necessarily all, because of *literal readings* (4) and *coincidental co-occurrence* of the MWE components (5) (Savary and Cordeiro, 2018).[2] Finally, external elements can occur in between MWEs' components, both seen and unseen (1)–(3). Discontinuity is known to be a challenge notably for methods based on sequence labeling.

(1) *He **broke** the **heart** of his class mate.*
(2) *He **broke** her young **heart** when he **let** her **down**.*
(3) *Just think of all the **hearts broken** by him.*
(4) *He broke her chocolate heart when he stepped on it.*
(5) *When her toy broke, her young heart was in sorrow.*

In this paper we address the three aforementioned challenges at a time by considering a sub-problem of MWE identification, namely *MWE variant identification*, that is, the identification of occurrences of known (seen) MWEs and their linguistic variants. For instance, suppose that we have seen the annotated MWE occurrence in (1) in some training data. We would like to correctly predict that the same MWE occurs also in (2) and (3) but not in (4) and (5). Notice that we do not aim at identifying the MWE ***let down*** in example (2) if it has not been previously seen. This focus on MWE variants has important theoretical and practical motivations discussed in Sec. 2.

MWEs are known to have specific variability profiles, e.g. the idiom in (1)–(3) admits passivization and noun inflection, while others do not, e.g. *he was **pulling** my **leg*** 'he was kidding me' vs. *he was pulling my legs*; *my leg was pulled*. Our research question is whether this MWE-specific variability profile may be captured automatically and leveraged for high-quality MWE variant identification. The idea is that defining a variability profile in terms of linguistically informed variation-oriented features should help, on the one hand, to bring different variants of the same MWE together and, on the other hand, to distinguish idiomatic occurrences of a MWE from its literal readings. We are specifically interested in morphological and syntactic variants of verbal MWEs (VMWEs). This phenomenon is particularly challenging in morphologically rich languages, notably due to the internal inflection of the VMWE components and to the relatively free word order. In this paper we are interested in VMWEs in French, which exhibits rich verbal inflection and moderate inflection of nouns and adjectives.

This paper is organized as follows. We discuss the state of the art in MWE variant modeling and identification (Sec. 2). We address aspects of VMWE variability in French (Sec. 3), and we describe the corpus used for our experiments (Sec. 4). Follows a presentation of our a baseline variant identification method (Sec. 5). We then propose linguistic features for classification and their extraction process, as well as the architecture of our VMWE variant identification system (Sec. 6). Finally, we present and analyze our results (Sec. 7), before we conclude and propose perspectives for future work (Sec. 10).

2 Related work

Variability, often referred to as flexibility, has been considered a key property of MWEs in various linguistic studies in the past. Gross (1988) analyzes French adjective-noun compounds and shows that their fixedness (the contrary of flexibility) is a matter of scale rather than a binary property. Tutin (2016) confirms this hypothesis with a corpus study of the 30 most frequent verb-noun expressions in French, and defines 6 variability levels. Nunberg et al. (1994) hypothesize a strong correlation between semantic decomposability and syntactic flexibility. They conjecture that MWEs such as *to **pull strings*** admit a large range of variants (e.g. *to **pull** political **strings**, the many **strings** he **pulled***) because their components *pull* and *strings* can be paraphrased by *use* and *influence*. This hypothesis has been criticized by Sheinfux et al. (2017), who stipulated that the degree of flexibility of Hebrew VMWEs depends on the links

[2] Literal readings and coincidental occurrences of MWEs are maked by wavy and dashed underlining, respectively.

between their literal and idiomatic readings rather than on their semantic decomposability. Inflectional and syntactic flexibility were also a major criterion for classifying MWEs into fixed, semi-fixed (subject to internal inflection only) and syntactically flexible expressions by Sag et al. (2002). This scale-wise variability challenges the traditional lexicon vs. grammar division of language modeling.

MWE variability has also been considered a major challenge in various NLP models and applications. Firstly, variants are pervasive. Jacquemin (2001) studies multiword nominal terms in French and English and shows that as many as 28% of their occurrences in texts correspond to variants of canonical forms listed in lexicons. Secondly, variants challenge automatic identification of MWEs, as discussed below. Finally, variant conflation is crucial for downstream applications such as information extraction (Savary and Jacquemin, 2003) and entity linking (Hachey et al., 2013).

Existing approaches to MWE identification partly model MWE variability to some extent. *Rule-based methods* often rely on MWE lexicons and a matching procedure. They sometimes extensively address MWE variation by morphological processors combined with rich finite-state patterns (Krstev et al., 2014) or unification meta-grammars (Jacquemin, 2001). Rule-based methods were often combined with statistical measures in the domain of multiword term extraction (Savary and Jacquemin, 2003), and explicitly addressed variation. But they can hardly distinguish literal from idiomatic readings, weakly cover discontinuous MWEs, and cannot generalize to MWEs absent from the lexicon and to new, initially uncovered, variation patterns. *Sense disambiguation methods* often focus on ambiguous known MWEs and neglect variant identification (Fazly et al., 2009). *Sequence taggers* learn identification models from annotated data based on regularities in sequences of tokens (Constant et al., 2013; Schneider et al., 2014). They are well suited for continuous seen MWEs and neutralize inflection when lemmas are available. They cope, however, badly with syntactic variation whenever it leads to discontinuities. *MWE-aware parsers* identify MWEs as a by-product of parsing a sentence (Green et al., 2013; Constant and Nivre, 2016). They often can deal with both morphological and syntactic variants, even though they are usually less accurate for highly discontinuous and variable MWEs, given that parsing is a hard problem by itself, and MWE-specific features increase data sparseness. *Parsing-based MWE identifiers* use generic parsers as providers of MWE candidates for classification (Vincze et al., 2013). They are less subject to data sparseness and can cope with discontinuities, provided that the underlying parser correctly handles long-distance dependencies. However, they may under- or overgenerate some syntactic transformations allowed by a MWE, e.g. indirect dependencies, as in Fig. 1.c and 1.f.

As a conclusion, it seems that MWE variant identification, although crucial both for corpus-based linguistic studies and for downstream NLP applications, has not yet received a satisfactory solution. Moreover, performances in solving this task are rarely explicitly reported on. Instead, the performances on seen vs. unseen data are addressed, and it is not always clear how these notions are understood. For instance, Constant et al. (2013) observe that 25% of the MWEs in their test corpus are unseen in the training data, and that at most 19% of them could be correctly identified by their system based on sequence labeling. However, the authors do not specify how unseen MWEs are defined, that is, if variants are counted as seen or unseen. The work by Maldonado et al. (2017) defines seen MWEs – similarly to our understanding – as MWEs present in the test set and sharing the same dependency structure, POS tags and lemmas with at least one annotated MWE in the training set. They find out that most systems perform better when the proportion of seen MWEs is high. This result suggests that MWE variant identification remains a hard problem and deserves being addressed explicitly by dedicated methods.

3 VMWE variation in French

VMWEs are known to have specific lexical and morpho-syntactic *variability profiles*: they are more or less variable, but usually not as variable as regular phrases with the same syntactic structure. Therefore, methods used for detecting paraphrases of regular phrases (Fujita and Isabelle, 2015) cannot be straightforwardly applied to VMWEs. Different aspects of variability may be considered.

Firstly, MWE-hood is, by nature, a lexical phenomenon, that is, a particular idiomatic reading is available only in presence of a combination of particular lexical units. Replacing one of them by a semantically close lexeme usually leads to the loss of idiomatic reading, e.g. (6) is an idiom but (7) can

only be understood literally. Lexical variability is admitted by some VMWEs, but usually with a very restricted list of equivalents only, as in (11) and (12). In this work, unlike Fazly et al. (2009), we exclude lexical variability from our scope. More precisely, two VMWE occurrences are considered *morpho-syntactic variants* of each other if they have the same (idiomatic) meaning and are *lexically identical*, that is, the multisets of the lemmas of their lexicalized components are identical. For instance, (12) is considered a separate VMWE rather than a variant of (11). Also, (16) is not a variant of (13) due to the determiner which is lexicalized in the latter but not in the former. Note that textually identical occurrences of a VMWE, like (13) vs. (15) are also considered variants.

(6) *Léa* ***tourne la page*** '*Léa turns the page*'⇒'Léa stops dealing with what occupied her'
(7) *Léa pivote la page* '*Léa rotates the page*'; *Léa tourne la feuille* '*Léa turns the sheet*'
(8) ***tournera****-t-elle* ***la page*** *de la politique?* '*turn-will-she the page of the politics?*'⇒'Will she stop dealing with politics?'
(9) ***la page*** *a été* ***tournée*** '*the page has been turned*'⇒'the subject is no longer dealt with'
(10) *elle tourne les pages de la politique* '*she turns the pages of politics*'
(11) *Ses plaintes me* ***cassent les oreilles*** '*his moans break my ears*'⇒'his moans annoy me'
(12) *Ses plaintes me* ***cassent les pieds*** '*his moans break my feet*'⇒'his moans annoy me'
(13) ***faire le tour*** *du sujet* '*make the tour of the topic*'⇒'consider all aspects of the topic'
(14) ***refaire le tour*** *du sujet* '*remake the tour of the topic*'⇒'reconsider all aspects of the topic'
(15) *on va en* ***faire le tour*** '*we will make the tour of it*'⇒'we will consider all aspects of it'
(16) ***faire*** *un* ***tour*** *en famille* '*make a tour in family*'⇒'go out with one's family'
(17) *le tour fait 3 kilomètres* '*the tour makes 3 kilometers*'⇒'the tour is 3 km long'
(18) ***filer le*** *parfait/grand.ADJ* ***amour*** '*spin the perfect/great love*'⇒'to live a perfect/great love'
(19) *Léa* ***prenait*** *souvent* ***la porte*** '*Léa took often the door*'⇒'Léa was often forced to go out'
(20) *la porte de la maison a été prise par Léa* '*the door of the house was taken by Léa*'

Another aspect of VMWE variability is morphological: some VMWE components do not admit inflection, as the noun *page* '*page*' in (8) vs. (10), while others do, as the verb *tourner* '*turn*' in (8). In rare cases, the head noun accepts derivation, often with prefixes like *re-*, to express repetition, as in (14).

Syntactic variability is also crucial for the VMWE variability profile. Firstly, idiomatic readings most often correspond to literal readings used metaphorically. Therefore, the VMWE components have to occur in a syntactic configuration which relates to the literal reading. For instance, (17) is not a variant of (13), since *tour* takes a different semantic role. Still, both the literal and the idiomatic meaning can sometimes be preserved under syntactic variation as in (6) vs. (9). Secondly, some types of syntactic variation (e.g. passivization) tend to be exhibited less frequently by VMWEs than by non-VMWEs of the same syntactic structures (Fazly et al., 2009). Thirdly, some types of syntactic dependencies can be specific to some VMWEs, e.g. (18) involves a compulsory though non-lexicalized adjectival modifier of the noun. This also means that this VMWE admits insertions of external elements between its lexicalized components. Finally, as previously shown (Pasquer et al., 2018), syntactic features are particularly strong indicators for linguistically motivated similarity and flexibility measures of (French) VWMEs.

The main challenge in modeling the variability profiles of VMWEs lies in the fact that VMWEs of the same syntactic structure may behave differently. For instance, the VMWEs in (6) and (19) both admit interrogation, insertions and inflection of the verb, and prohibit inflection of the noun. Still, modification of the noun and passivization is exhibited by the former (8)–(9) but not by the latter (20).

4 Corpus

We study VMWE variability on a corpus of French texts annotated with VMWEs for the PARSEME shared task.[3] In addition to VMWE annotation (based on universal guidelines), the corpus contains POS, lemmas, morphological features and dependency structures, which we use in our experiments. The original release of the VMWE-annotated corpus contained two sub-corpora: the French part of the Universal Dependencies v1.4 corpus (Nivre et al., 2016) and Sequoia (Candito and Seddah, 2012).

[3] `http://multiword.sf.net/sharedtask2017`, corpus at `http://hdl.handle.net/11372/LRT-2282`

Corpus	All POS patterns				All Verb-(Det-)Noun		Verb-(Det-)Noun variants	
	# Sentences	# Tokens	# VMWEs	# occ.	# VMWEs	# occ.	# VMWEs	# occ.
TrC	17,880	450,221	1,584	4,462	854	2098	n/a	n/a
TeC	1,667	35,784	291	500	177	283	86	132

Table 1: Number of different VMWE types (# VMWEs) and their token occurrences (# occ.) per POS and variability class in the training corpus (TrC) and in the test corpus (TeC).

The tagsets and dependency trees used in both sub-corpora were incompatible. We homogenized them by replacing the released annotations with their UDv2-compatible versions, while VMWE annotations remain unchanged.

The VMWEs annotated for French belong to three main categories: inherently reflexive verbs (***se plaindre*** '*pity oneself*'⇒'complain'), light-verb constructions (***prendre** une **décision*** '*take a decision*') and idioms (***tourner la page*** '*turn the page*'⇒'stop dealing with what one was occupied with'). In this study we focus only on verb-noun combinations, possibly involving a lexicalized determiner, hence only the last two VMWE categories are relevant.

Tab. 1 shows the VMWE statistics of the training corpus (TrC) and test corpus (TeC). Note that, with our focus on variants of seen VMWEs having the Verb-(Det-)Noun structure, only 86 VMWEs and their 132 occurrences from TeC are to be predicted. Among them, only 35 occurrences (26.5%) appear under identical surface forms in TeC as in TrC.

5 Baseline variant identification

The aim of our study is to automatically identify morpho-syntactic variants of VMWEs in a syntactically parsed French corpus. More precisely, given a set of VMWEs annotated in TrC, we wish to identify all their morpho-syntactic variants in TeC. Each of such variants to be predicted in TeC will be called a seen-in-train variant (STV). Note that, a given expression e in TeC can be an STV only if it has the same multiset of lemmas as a VMWE e' from TrC. But this condition is not sufficient due to the existence of literal readings and accidental co-occurrences (Sec. 1). We hypothesize that distinguishing such spurious candidates from STVs should be possible by relying on the morpho-syntactic variability profile. In other words, e has good chances to be a morpho-syntactic variant of e' if both are morpho-syntactically similar.

This idea suggests a relatively straightforward baseline STV identification approach, similar to the *BagOfDeps* strategy proposed by Savary and Cordeiro (2018). Given a dependency-parsed TeC, we extract each set of nodes e so that: (i) the multiset of lemmas in e is identical to some VMWE e' in TrC, (ii) e forms a connected dependency graph. Note that this approach neutralizes both morphological variation (via lemmatization) and syntactic variation (we disregard the labels and directions of the dependencies). As a result, the predicted STVs can be either true positives (Fig.1.a and 1.b) or false positives (Fig.1.d). False negatives include occurrences without direct connection like complex determiners (Fig.1.f). The baseline is also sensitive to syntactic annotation errors, as in Fig.1.e (*rôle* '*role*' rather than *clé* '*key*' should be the head of *rôle clé* 'key role'). Despite its simplicity, the baseline is already very strong, as shown in the first line of Tab. 2. It extracts 158 Verb-(Det-)Noun candidates, which – compared to the 132 STVs to be extracted – yield the F-score of 0.88. These results notably confirm previous observations that literal readings are rare (Waszczuk et al., 2016; Savary and Cordeiro, 2018).

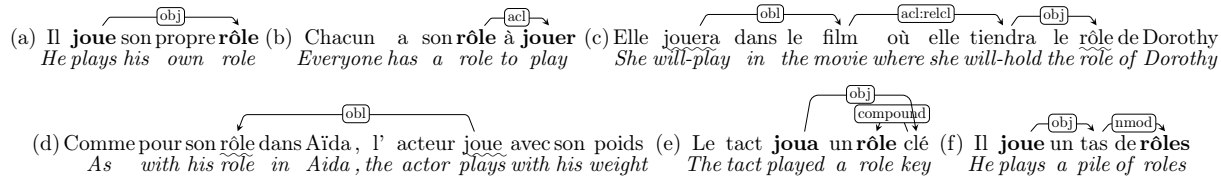

Figure 1: True positive (a,b) and true negative (c) STVs. False positive STV (d), inconsistent syntactic annotation (e), indirect dependencies (e,f)

6 Variant identification as a classification problem

We hypothesize that VMWE variability profiles can be exploited to achieve a better VMWE variant identification than the baseline. Variability profiles will be approximated by a set of morpho-syntactic features (Sec. 6.1). We will first use a more exhaustive candidate extraction method than the baseline, so as to avoid false negatives. Then, the features should help discriminate true STVs from spurious candidates (Sec. 6.2).

6.1 Variation-related features

We describe the profile of any given STV candidate expression e (hereafter called 'candidate' or e) by binary features characterized according to two dimensions:
Morphological, linear and syntactic features model characteristics discussed in Sec. 3, such as verbal/nominal inflection, linear insertions between components (e.g. adjectives, adverbs) or discrepancies between syntactic dependencies (e.g. subject vs. object).
Comparative and absolute features: Comparative features are based on the comparison of e with lexically identical VMWEs from TrC, e.g. if e's noun is found at least once with same inflection in a lexically identical VMWE in TrC, then the COMP_genderNumber(e) feature is True. Absolute features consist in contextual properties of e, e.g. if e's noun is in singular, the numberSing(e) feature is True.

6.1.1 Comparative features (COMP)

COMP features verify the correspondence of e's properties with those of VMWEs annotated in TrC. Henceforth, we say that a property of e matches if it is the same for e and for at least one lexically identical annotated VMWE in TrC. COMP features are binary (their value is False when no match is found and True otherwise) and belong to 3 types: morphological, linear and syntactic.
Morphological similarity is represented by a single feature, COMP_genderNumber, which focuses on the nominal inflection only, since previous experiments showed that it is more informative than verbal inflection (Pasquer et al., 2018). Thus, COMP_genderNumber(e) is True if e's inflection matches.
Linear similarity features account for different degrees of similarity:

- COMP_insertRaw: True if the POS sequence of insertions between lexicalized components of e matches. For instance, if e has an Adj-Adj-Det insertion, it can only match a VMWE having the identical sequence of insertions, Adj-Adj-Det.
- COMP_insertWithoutDuplicate: Same as above, ignoring duplicated POS, so Adj-Adj-Det can match both Adj-Adj-Det and Adj-Det. This feature neutralizes duplications, as we believe that MWEs have constraints on the POS of allowed insertions, but not on their number (e.g. it is rare that one adjective is tolerated but not two).
- COMP_insertPartial: True if a POS substring of more than 50% and less than 100% of insertions in e matches. This feature identifies the similarity between ***play*** *a*.DET *very*.ADV *important*.ADJ ***role*** and ***play*** *his*.DET *first*.ADJ *major* ***role***. However, linear similarity does not capture postnominal adjectives (e.g. ***jouer*** *un* ***rôle*** *important* 'play a role important'), hence the interest in syntactic similarity.

Syntactic similarity Like for morphological features, we noticed greater influence of the outgoing dependencies of the noun, as in Fig.1.b (contrary to incoming dependencies in Fig.1.a), hence the focus on the noun. These syntactic features include:

- COMP_depSynNounTotal, COMP_depSynNounPartial: True if 100%, or more than 50% and less than 100%, of the noun's outgoing dependencies match, respectively.
- COMP_distSyn : True if the syntactic distance between the verb and the noun matches. The *syntactic distance* between two components is defined as the number of elements in the syntactic dependency chain between these two components, regardless of the direction of the dependencies and excluding the components themselves. Inside known VMWEs, the syntactic distance never exceeds 2, so that the value is set to ">2" when this case occurs. In Fig. 1.c this chain is composed of *jouera-film-tiendra-rôle*. Supposing that all the VMWEs of the corpus are represented in Fig. 1, the syntactic distance is 2, hence COMP_distSyn = False since it differs from all the annotated VMWEs.

- COMP_typeDistSyn: True if the type of the syntactic distance matches. This type takes dependency directions into account, and can be serial (in Fig. 1.f, the noun *rôles* '*roles*' depends on *tas* '*pile*', which itself depends on the verb *jouer* '*play*'), parallel (in Fig. 1.e, both *jouer* '*play*' and *rôle* '*role*' depend on the non-lexicalized component *clé* '*key*') or "nonEvaluated" when the syntactic distance exceeds 2 elements.

We expect COMP features to be highly relevant. For instance, the noun in many VMWEs must remain in singular, as in (8) vs. (10), or in plural, as in (11). However, COMP features might fail in case of rare VMWEs, and cannot be calculated for hapaxes. Therefore, absolute features should also be useful.

6.1.2 Absolute features (ABS)

For each candidate, the set of absolute features includes the following.

Lemmas of the components can be considered individually or as a sequence. When considered individually, the VMWE in (6) has ABS_verbLemma = *tourner*, ABS_nounLemma = *page*, and ABS_detLemma = *le* (when there is no lexicalized determiner, ABS_detLemma = noDet). When considered as a sequence, we sort lemmas lexicographically to neutralize variable word order, as in (6) vs. (9), and obtain the *Normalized Form* (NF).[4] Thus, *le;page;tourner* 'the;page;turn' is the ABS_NF of the VMWEs in (6)–(10).

Morphological features for the noun are: ABS_numberSing, ABS_numberPlur, ABS_genderMasc, ABS_genderFem. Their value is True when the respective property is satisfied. For the verb, we only consider derivational inflection. Namely, the ABS_verbPrefix feature is True only if the verb starts with one of the most frequent repetition (*re/ré/r*) or negation prefixes (*de/dé*) and if the verb without this prefix matches the verb in any VMWE annotated in TrC, e.g. ABS_verbPrefix is True for the VMWE in (14).

Linear features correspond to insertions between lexicalized components. We add one insertion feature per possible POS, which is set to True if the e has an insertion with the given POS. For instance in ***effectuer*** *une*.DET *bonne*.ADJ *première*.ADJ ***saison*** 'make a good first season', we obtain ABS_insert_DET = True, ABS_insert_ADJ = True, ABS_insert_ADV = False, etc.

Syntactic features are defined similarly to the linear ones. We introduce one feature per possible dependency relation, and set it to True if the noun in e has at least one outgoing dependency arc with this relation (e.g. ABS_relDepNoun_amod = True for the previous example).

Syntactic distance between the verb and the noun is defined as before, i.e. as the number of elements in the syntactic dependency chain except for the components themselves.

Type of syntactic distance also follows the one in COMP features, and can be either serial or parallel. COMP features are far less numerous than ABS features (9 vs. 72 in the example detailed in App. A).

6.2 Overview of the method

Our goal is to extract STVs, i.e. variants of previously seen VMWEs. We wish to enhance over the baseline (Sec. 5), which is sensitive to indirect dependencies, to dependencies irrelevant to variation, and to annotation errors (which may cause a dramatic performance drop with automatically parsed data), as shown in Fig. 1.d–f. We thus propose an enhanced approach in two steps. First, a more relaxed variant candidate extraction is designed so as to achieve a better recall than the baseline (usually at the expense of a dramatic drop in precision), by extracting, for each annotated e' in TrC, its lexically identical candidates, disregarding syntax. Then, the extracted candidates are filtered by a binary classifier based on the features described above. Fig.2 illustrates the two most crucial phases of this process: the candidate extraction and the feature extraction. VMWE candidates from TrC are numbered (TrC1)–(TrC9), as shown in the first gray box. Those from TeC, (TeC1)–(TeC5), are shown in the first white box. Training of the classifier itself, and its application to prediction are standard and disregarded in Fig.2.

6.2.1 Variant candidate extraction

The easiest way to obtain a larger variant candidate extraction is to search, in each sentence, the simultaneous presence of all components of known VMWEs whatever their order, as described by (Savary

[4]The drawback of NF is that it ignores nominal inflection that could help distinguish between (very rare) VMWEs with different surface forms (e.g. ***fermer l'oeil*** '*close the eye*'⇒'sleep' vs. ***fermer les yeux*** '*close the eyes*'⇒'turn a blind eye').

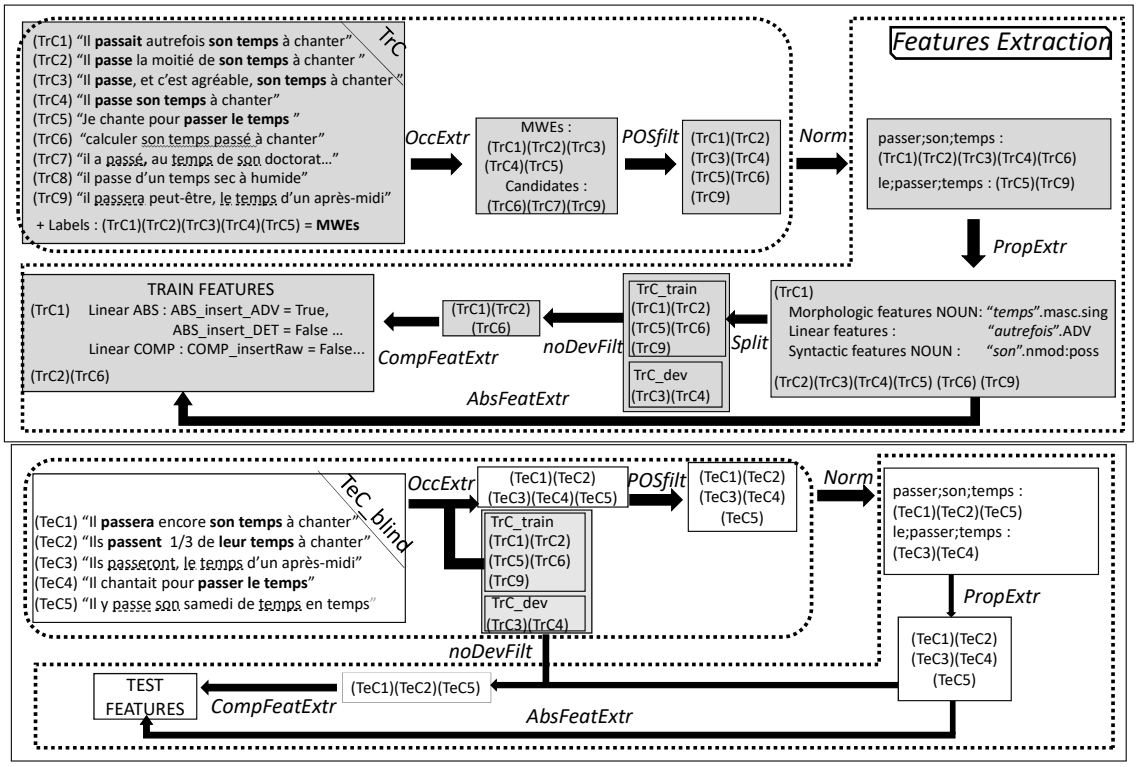

Figure 2: Candidate and feature extraction in training (above) and during prediction (below)

and Cordeiro, 2018). This phase is called *OccExtr*. Consider the first gray box in Fig.2, representing TrC, and several expressions related to two VMWEs ***passer son temps*** 'spend one's time' and ***passer le temps*** '*spend the time*'⇒'invent activities when one has nothing to do'. (TrC1)–(TrC5) are true VMWEs, (TrC6) is a literal reading, (TrC7) and (TrC9) are accidental co-occurrences, and (TrC8) is not lexically identical to any of the two VMWEs due to a missing determiner. Since *OccExtr* matches only occurrences lexically identical to known VMWE, it will extract, trivially, (TrC1)–(TrC5), and (TrC6)(TrC7)(TrC9), but not (TrC8).[5] *OccExtr* is expected to improve recall but precision should also significantly decrease. To limit possibly huge levels of noise, *OccExtr* extracts candidates in the shortest window. For instance, in (TeC5) only one candidate is extracted despite the repetition of the noun *temps* '*time*'.[6] *OccExtr* is enhanced by additional filtering (*POSfilt*) which eliminates irrelevant POS orders (i.e. incorrect in French), such as Verb-Noun-Det in (TrC7). Finally, the NFs for all candidates are produced (*Norm*).

6.2.2 *mweVIDE*: Binary classification of candidates

As a result of the previous phase, we obtain sets of candidates grouped by their NFs (cf. upper-right-hand box). Morpho-syntactic properties for these candidates are then extracted (*PropExtr*) and the whole set is randomly divided (*Split*) into two equal subsets TrC_train and TrC_dev, so as to be able to calculate COMP values. For a given candidate e from TrC_train, when no VMWE with the same NF is annotated in TrC_dev, e is deleted (*noDevFilt*), as is the case of (TrC6) and (TrC9). This may lead to a loss of almost 30% of TrC_train but is inevitable, since for each candidate we need at least one lexically identical VMWE in TrC_dev to calculate the values of the comparative features. The final set of positive and negative candidates is then represented by COMP and ABS features (*CompFeatExtr* and *AbsFeatExtr*), and fed into classifier training.

In the prediction phase (lower part of Fig. 2), the candidates are extracted from TeC on the basis of their

[5]Note that *OccExtr* in training (upper part of Fig.2) applies to TrC itself, since classification calls for both positive and negative examples. Conversely, in prediction, *OccExtr* is applied to the blind version of TeC.

[6]This may lead to both false negatives and false positives, as in *la* ***collaboration*** *que nous avons.[AUX=avoir 'have']* ***eue****.[VERB=avoir 'have']* 'the collaboration that we have had'.

lexical identity (i.e. NF-identity) with annotated VMWEs from TrC. They are *POSfilt*ered, *Norm*alized and subject to *Prop*erty *Extr*action, as in training. But no *Split* needs to be performed, since each TeC candidate can be compared to a VMWE in TrC_dev. The 3 candidates remained after *noDevFilt* are then represented as COMP and ABS features and classified into STVs or non-STVs.

We use the NLTK Naive Bayes classifier.[7] In the training phase it takes as input the set of positive and negative examples represented as feature-value pairs, together with their classes (STV/non-STV), and outputs a model. In the prediction phase, it takes as input the trained model and the candidates to classify, represented as feature-value pairs, and for each candidate outputs an STV or a non-STV label. Training and prediction are repeated 10 times with random TrC_train/TrC_dev split, corresponding to half of TrC each. The classification performance (recall, precision, F1-measure) is evaluated on the manually annotated version of TeC. For each of the 10 training and prediction turns, we also obtain the 100 most informative features associated to the (non-)STV label prediction.

7 Results

We firstly compare the performance of *OccExtr* with the baseline. Table 2 shows the performances of the systems on TrC (2098 occurrences) and TeC corpora (132 occurrences). As expected, the precision

	TrC #candidates	R	P	F1	TeC #candidates	R	P	F1
Baseline	2414	0.970	0.85	0.91	158	0.97	0.81	0.88
OccExtr	5364	0.999	0.39	0.56	484	1.00	0.27	0.43
mweVIDE	5364	n/a	n/a	n/a	484	0.97 (σ_R = 0.007)	0.87 (σ_P = 0.015)	0.92 (σ_{F1} = 0.010)

Table 2: Performance measure of the baseline, OccExtr and mweVIDE on TrC and TeC (average on 10 random TrC_train vs. TrC_dev splits)

of *OccExtr* is significantly lower than of the baseline. Conversely, both recall scores remain very close at a high level of performance. An almost perfect recall is reached by *OccExtr*, but its very low F-measure (0.56 and 0.43 on TrC and TeC, respectively) prevents its direct application to variant detection.

The classification of the candidates implemented in mweVIDE aims at improving the precision of *OccExtr* without impacting recall. As shown in Table 2, mweVIDE increases the F1-measure to 0.92 (vs. 0.88 for the baseline) with a better precision (0.87 vs. 0.81). Recall value is similar to the baseline. The low standard deviation of the F-score (0.01) we observed on the 10 experiments is a good indication of the statistical significance of this improvement. Note that, for this evaluation, we do not have access to data annotated directly with ground truth, i.e. describing which VMWEs are variants of each other. We rely instead on the comparison between the predicted and annotated VMWEs, hence a possible bias because of (i) distinct VMWEs with identical NFs, (ii) similar VMWEs with distinct NFs (due lemmatization errors).

8 Error analysis

In this section we perform a qualitative analysis of the errors performed by the baseline and mweVIDE, in order to investigate what kinds of situation are correctly handled by each system, and which leave room for improvement. The baseline cannot identify components without direct dependency (Fig.1.f) or with parallel dependencies (Fig.1.e). Other omitted cases include: (i) literal readings, (ii) overlap with another VMWE, (iii) coordination, (iv) enumeration, (v) co-reference : ***réunion*** *qui interviendra après celles* ***tenues*** 'meeting which will occur after those held' (where *those* = *meeting*), even though this specific case should not have been annotated according to the annotation guidelines.

As to mweVIDE, it may suffer from no similar VMWEs in TrC (e.g. neither similar syntactic distance, nor insertions or nominal inflection). After 10 evaluations on TeC, the predicted (non-)STV labels are

[7] NLTK (`http://www.nltk.org/`) is used with default parameter values, including ELEProbDist (Expected Likelihood Estimation based on Laplacian smoothing with alpha value = 0.5). Preliminary experiments with a linear SVM classifier (NLTK SklearnClassifier) yielded slightly lower performances than Naive Bayes. Given the low amount of the training data, Naive Bayes seems a satisfactory trade-off compared to other classification methods which require larger data (e.g. polynomial SVM).

STV label feature	$\overline{ratio}$	σ_{ratio}	non-STV label feature	$\overline{ratio}$	σ_{ratio}

Table 3: The most informative features (COMP in gray) according to the averaged likelihood ratio for (non-)STV prediction over 10 tests.

constant in 98.9% of the cases. Moreover, despite the *noDevFilt*, 99.2% of the candidates could be classified at least once. Among the 19 false positives, 5 should actually have been annotated as VMWEs. Cases of coordination, never identified by the baseline, are partially identified by mweVIDE, which seems to better handle the omission of a coordination conjunction than its addition. The better precision is due to our POS filtering which excludes irrelevant patterns and mainly to the typology of insertions in known VMWEs used by the classifier. For instance, subordinations between the components are less frequent in VMWEs than in coincidental co-occurrences as will be exposed in the next section.

9 Most informative features

Likelihood ratios associated with each feature allow us to determine which features are the most discriminative in distinguishing STV vs. non-STV candidates. For instance, if the ratio is equal to 2 for a given feature and label, this means that this feature is twice more frequently associated with this label than with the complementary label in the training set. By averaging these ratios on the 10 evaluations, we can extract the ten most informative ones for prediction (Tab. 3). The ranking presented in Tab. 3 is given with mean and standard deviation ratio values: the standard deviation is a good indication that, whatever the selected TrC_train corpus, the same features tend to favor STV (resp. non-STV) labels.

9.1 Features relevant for the STV label

As shown in Tab. 3, features which favor the STV label are both of COMP and ABS type.

COMP features The insertion-related features (COMP_insertRaw=True and COMP_insertWithoutDuplicate=True) are always ranked first. This is understandable, since with fewer insertions the number of potential inserted POS sequences is lower. In TrC, 97% of the VMWEs have less than 5 inserted elements vs. 30% of false STV candidates, which reflects how much non-STVs are susceptible to be more variable in terms of insertions. An identical syntactic distance (COMP_distSyn=True) often means that its value is 0 in a seen VMWE and its STV. False STVs tend to overpass this value because the syntactic connection between elements is often looser than inside a VMWE.

ABS features The relevance of ABS_distSyn=0 (which is the only criterion of the baseline) can be explained in the same way as COMP_distSyn=True above. The other most informative features are NFs (like *jouer;rôle* '*play role*') or isolated components (only the verb *jouer* '*play*'), which means that they are less frequently associated with coincidental co-occurrences or literal readings.

9.2 Features relevant for the non-STV label

Contrary to the prediction of the STV label, COMP features have negative values for non-STV labels, which highlights how much similarity (respectively dissimilarity) with known VMWEs is an important criterion for the STV (resp. non-STV) prediction.

COMP features The only discriminative COMP features are the syntactic distance and its type, when different from known VMWEs.

ABS features Insertions and syntactic distance are the most discriminating. All elements that tend to break the link between components are relevant. In descending order, it can be the insertion of a verb, a coordinating or subordinating conjunction, a punctuation or a proper noun. As for syntactic features, the most relevant here are the syntactic distance higher than zero or parallel syntactic distance.

10 Conclusions and future work

We developed a system for Verb-(Det-)Noun VMWE variant identification based on morphological and syntactic profiles of candidates which permit their classification as (non-)variant thanks to a set of absolute and comparative features (the latter relying on the comparison with known VMWEs). The system shows satisfactory performance (F1-measure = 0.92) and good reproducibility. This represents an improvement over the baseline based on the presence of a syntactic connection between components. Morphology does not appear as a discriminating feature to label a candidate as a STV, contrary to comparative linear features (i.e. similar POS insertions), which were rarely taken into account in previous works (Fazly et al., 2009). In general, comparative features appear to be more relevant for STV prediction. Conversely, absolute features predominate in non-STV variant prediction, since non-STVs often exhibit unreferenced variation profiles. Given the reduced size of our test corpus, we need further evaluations on larger corpora to improve our variant identification system, notably to handle cases of coordinations that are not systematically identified. We also project to include other comparative features such as orthographic similarity (***show one's true colours/colors***) or lexical similarity (***take a bath/shower***), which might help classify rare VMWEs that could not be evaluated here. A wider range of patterns than only Verb-(Det-)Noun should also be considered. Finally, future extension of our system to other languages available in the PARSEME corpus, whether Romance or not, could also be considered.

Abstract

Multilingual topic models enable crosslingual tasks by extracting consistent topics from multilingual corpora. Most models require parallel or comparable training corpora, which limits their ability to generalize. In this paper, we first demystify the knowledge transfer mechanism behind multilingual topic models by defining an alternative but equivalent formulation. Based on this analysis, we then relax the assumption of training data required by most existing models, creating a model that only requires a dictionary for training. Experiments show that our new method effectively learns coherent multilingual topics from partially and fully *incomparable* corpora with limited amounts of dictionary resources.

1 Introduction

Multilingual topic models provide an overview of document structures in multilingual corpora, by learning language-specific versions of each topic (Figure 1). Their simplicity, efficiency and interpretability make models from this family popular for various crosslingual tasks, *e.g.,* feature extraction (Liu et al., 2015), cultural difference discovery (Shutova et al., 2017; Gutiérrez et al., 2016), translation detection (Krstovski et al., 2016; Krstovski and Smith, 2016), and others (Barrett et al., 2016; Agić et al., 2016; Hintz and Biemann, 2016).

Typical probabilistic multilingual topic models are based on Latent Dirichlet Allocation (LDA, Blei et al. (2003)), adding supervision on connections between languages. Most models achieve this by making strong assumptions on the training data—they either require a *parallel corpus* that has sentence-aligned documents in different languages (*e.g.,* EuroParl, Koehn (2005)), or a *comparable corpus* that has documents of similar content (*e.g.,* Wikipedia articles paired across languages). These training requirements limit the usage of such models: an adequately large parallel corpus is difficult to obtain, particularly for low-resource languages. For example, only 300 languages are available on Wikipedia,[1] and only 250 languages have more than 1,000 articles. Another common choice for parallel corpus in multilingual research, the Bible, is available in 2,530 languages (Agić et al., 2015).[2] However, studies show that its archaic themes and small corpus size (1,189 chapters) can limit performance (Hao et al., 2018; Moritz and Büchler, 2017). Therefore, the requirement of parallel/comparable corpora for multilingual topic models limits their usage in many situations.

Another line of research focuses on using multilingual dictionaries as supervision (Ma and Nasukawa, 2017; Gutiérrez et al., 2016; Liu et al., 2015; Jagarlamudi and Daumé III, 2010; Boyd-Graber and Blei, 2009). In contrast to parallel corpora, dictionaries are widely available and often easy to obtain. PANLEX, a free online dictionary database, for example, covers 5,700 languages and more than one billion dictionary entries (Kamholz et al., 2014; Baldwin et al., 2010).[3] Thus, a multilingual topic model built on a dictionary rather than a parallel corpus is potentially applicable to more languages.

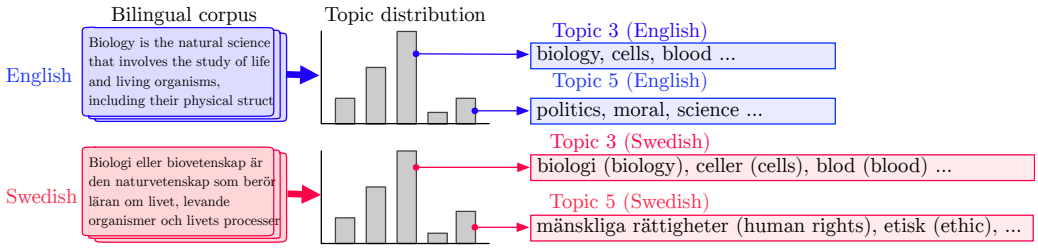

Figure 1: Multilingual topic models produce topics where each language has its own version.

A dictionary also allows for training on *incomparable* corpora—documents in different languages that are from different sources without direct connections—which have had less research on learning consistent topics. With a dictionary, a natural question is how to efficiently utilize the semantic information it carries so that a topic model can produce multilingually coherent topics. This work considers an alternative formulation of a dictionary-based topic model, one that borrows the structure of models used with comparable corpora, but uses a dictionary-based metric to learn connections between documents, instead of explicit connections from a comparable corpus. The main contributions of this work are:

- We summarize existing related work in Section 2 and propose a new formulation of multilingual topic models based on crosslingual transfer learning in Section 3. This new formulation explicitly shows the knowledge transfer mechanism during the generative process.
- Based on this new formulation, in Section 4 we generalize existing multilingual topic models and relax the assumptions of parallel/comparable datasets. Our approach requires only a dictionary, and is empirically shown to perform well even with only limited amounts of available entries.
- We evaluate our new model on five languages from different language families in Section 5. Our proposed model learns multilingually coherent topics and yields around a 25% relative improvement in crosslingual classification performance.

2 Multilingual Topic Models

Multilingual topic models generate K topics from a corpus consisting of multiple languages; each topic has a version specific to each language in the corpus (Figure 1). From a human's view, a coherent multilingual topic should talk about the same thing regardless of the language; from a machine's view, the success of multilingual topic models depends on the inferred topics being consistent across languages. For example, given an English-Swedish bilingual topic $\phi_k^{(\text{EN,SV})}$, the probability of an English word *island* and that of its translation in Swedish, *ö*, should be similar, *i.e.,* $\Pr\left(island_{\text{EN}}|\phi_k^{(\text{EN,SV})}\right) \approx \Pr\left(\ddot{o}_{\text{SV}}|\phi_k^{(\text{EN,SV})}\right)$. Most multilingual topic models extend LDA with one or both of two types of "link" information: document translations and word translations.

Document Links. The polylingual topic model (Mimno et al., 2009; Ni et al., 2009) assumes that during the generative process, a topic distribution $\theta_{\mathbf{d}}$ generates a tuple of comparable documents in different languages, *i.e.,* $\mathbf{d} = \left(d^{(\ell_1)}, \ldots, d^{(\ell_L)}\right)$ and each language ℓ has its own topic-word distributions, $\phi_k^{(\ell)}$. This model has been widely used (Vulić et al., 2013; Platt et al., 2010; Smet and Moens, 2009), but it requires a parallel/comparable corpus in order to link documents.

Vocabulary Links. Another type of model uses word translations (Jagarlamudi and Daumé III, 2010; Boyd-Graber and Blei, 2009) rather than linking documents. A multilingual dictionary is used to construct a tree structure where each internal node contains word translations, and applies hyper-Dirichlet type I distributions to generate words (Andrzejewski et al., 2009; Minka, 1999; Dennis III, 1991). For each topic k, a distribution from root r to all the internal nodes i is drawn by $\phi_{k,r} \sim \text{Dir}(\beta_r)$, and then a distribution from i to a leaf node is drawn by $\phi_{k,i}^{(\ell)} \sim \text{Dir}\left(\beta_i^{(\ell)}\right)$. A word $w^{(\ell)}$ in language ℓ is drawn from a product of the two multinomial distributions by $w^{(\ell)} \sim \text{Mult}\left(\phi_{k,r} \cdot \phi_{k,i}^{(\ell)}\right)$.

Variations. Many variations of these ideas have been proposed to deal with non-parallel corpus. Heyman et al. (2016) proposed C-BILDA, which distinguishes between shared and non-shared topics across languages, based on a document links model. The model, however, requires a comparable dataset that provides document links between languages. A variation proposed by Ma and Nasukawa (2017) deals with non-parallel corpora. This model is essentially a modified version of Jagarlamudi and Daumé III (2010) and Boyd-Graber and Blei (2009), so we consider this work to be another vocabulary links model. Other models have been proposed for very specific situations that needs additional supervision. For example, Krstovski et al. (2016) requires scientific article section alignments, and Gutiérrez et al. (2016) requires Part-of-Speech (POS) taggers, which are not always available for all languages. Without POS taggers, this model is equivalent to vocabulary links. In our work, we focus on the standard document links and vocabulary links models, which are the most generalizable models.

3 Document Links: A Crosslingual Transfer Perspective

Before we introduce our new approach, we first present an alternative understanding of the document links model from the perspective of crosslingual transfer learning. In multilingual topic models, "knowledge" refers to word distributions for a topic in a language ℓ, and we study how multilingual topic models transfer this knowledge from one language to another so that the model provides semantically coherent topics that are consistent across languages.

In the standard document links model, a "link" between a document d_{ℓ_1} in language ℓ_1 and d_{ℓ_2} in ℓ_2 indicates that they are translations or closely comparable. In this model, the topic assignments for both documents are independently generated from the same distribution, $\theta_{d_{\ell 1}, d_{\ell 2}}$. Thus, the joint likelihood of document links model is:

$$\Pr\left(\mathbf{w}_{d_{\ell 1}}, \mathbf{z}_{d_{\ell 1}}, \mathbf{w}_{d_{\ell 2}}, \mathbf{z}_{d_{\ell 2}} | \alpha, \beta\right), \tag{1}$$

where $\mathbf{w}_{d_\ell}$ and $\mathbf{z}_{d_\ell}$ are the word tokens and topic assignments of document d_ℓ. We refer this formulation as the **joint generative model**, since the topics and words of d_{ℓ_1} and d_{ℓ_2} are generated *simultaneously*.

The simultaneousness of this model formulation, in which both languages generate topics jointly, masks the knowledge transfer process. To highlight this process, and to help us generalize the model in the next section, we define an alternative formulation in which d_{ℓ_1} and d_{ℓ_2} are generated *sequentially*.

Assume the topics of d_{ℓ_1} have already been generated from $\theta_{d_{\ell 1}} \sim \mathrm{Dir}(\alpha)$, and $\mathbf{n}_{d_{\ell 1}} \in \mathbb{N}^K$ is a vector of topic counts in d_{ℓ_1}. In our alternative formulation, the generation of topics of d_{ℓ_2} depends on d_{ℓ_1} by $\theta_{d_{\ell 2}} \sim \mathrm{Dir}(\alpha + \mathbf{n}_{d_{\ell 1}})$, where the prior $\alpha + \mathbf{n}_{d_{\ell 1}}$ encourages the distribution $\theta_{d_{\ell 2}}$ to be similar to $\theta_{d_{\ell 1}}$. This formulation can go the other way, *i.e.,* generating d_{ℓ_2} first, and then d_{ℓ_1}. The combined likelihood of this formulation is:

$$\Pr\left(\mathbf{w}_{d_{\ell 1}}, \mathbf{z}_{d_{\ell 1}} | \mathbf{w}_{d_{\ell 2}}, \mathbf{z}_{d_{\ell 2}}, \alpha, \beta\right) \cdot \Pr\left(\mathbf{w}_{d_{\ell 2}}, \mathbf{z}_{d_{\ell 2}} | \mathbf{w}_{d_{\ell 1}}, \mathbf{z}_{d_{\ell 1}}, \alpha, \beta\right), \tag{2}$$

and we refer to this formulation as the **conditional generative model**.

This alternative formulation explicitly shows the knowledge transfer process across languages by shaping the topic parameters for ℓ_2 to be similar to that of the other language ℓ_1, and vice versa. In this formulation, the likelihood of the conditional generative model is different from the joint generative model. In fact, this is an instance of *pseudolikelihood* (Besag, 1975; Leppä-aho et al., 2017), where the joint likelihood of the two documents is approximated as the product of each document's conditional likelihood given the other, *i.e.,* $\Pr(d_{\ell_1}, d_{\ell_2}) \approx \Pr(d_{\ell_1} | d_{\ell_2}) \cdot \Pr(d_{\ell_2} | d_{\ell_1})$. As Leppä-aho et al. (2017) suggests, pseudolikelihood is not a numerically accurate approximation to the joint likelihood; Theorem 1 below, however, states that this formulation yields exactly the same posterior estimations of θ and ϕ.

Theorem 1. *The conditional generative model with document links yields the same posterior estimator to the joint generative model using collapsed Gibbs sampling.*

Proof. See Appendix. □

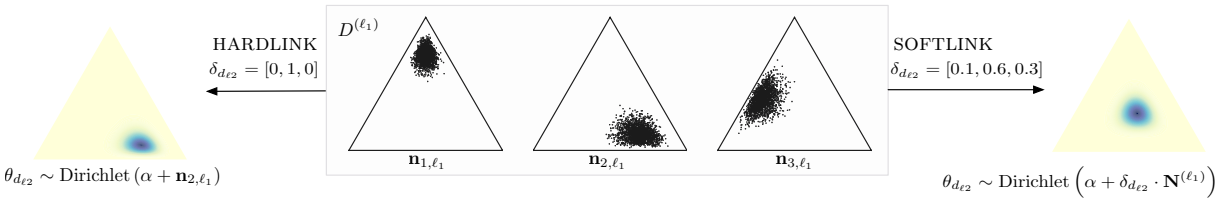

Figure 2: An illustration of how topic knowledge is transferred across languages through HARDLINK and SOFTLINK. To generate observations in d_{ℓ_2}, both models uses topics in ℓ_1 as prior knowledge to shape the Dirichlet prior for d_{ℓ_2}. This transfer happens in HARDLINK by aligned documents in a comparable corpus, while SOFTLINK uses a generalized transfer distribution δ.

4 Generalizing Document Links

Obtaining parallel corpora for training the document links model is very demanding, particularly for low-resource languages. Therefore, as the second major contribution in this paper, we generalize the document links model using the formulation described above to require only a bilingual dictionary.

4.1 From Hard Links to Soft Links

Following the above discussion, we introduce our method assuming the directionality from language ℓ_1 to ℓ_2. We generalize the model above by rewriting the generation of the distribution $\theta_{d_{\ell 2}}$:

$$\theta_{d_{\ell 2}} \quad \sim \quad \text{Dirichlet}\left(\alpha + \delta_{d_{\ell 2}} \cdot \mathbf{N}^{(\ell_1)}\right), \tag{3}$$

where $\mathbf{N}^{(\ell_1)} \in \mathbb{N}^{|D^{(\ell_1)}| \times K}$ is the matrix of topic counts per document with K topics in the corpus $D^{(\ell_1)}$ of language ℓ_1. This is equivalent to the above document links model when $\delta_{d_{\ell 2}} \in \mathbb{R}^{|D^{(\ell_1)}|}$ is an indicator vector that has value 1 for the corresponding parallel document $d_{\ell_1} \in D^{(\ell_1)}$ and 0 elsewhere. We refer this as **hard links** (HARDLINK), where each document $d_{\ell_2} \in D^{(\ell_2)}$ is informed by exactly one document d_{ℓ_1}, and this link is known *a priori* from a parallel corpus.

We create **soft links** (SOFTLINK) by relaxing the assumption that $\delta_{d_{\ell 2}}$ is an indicator vector, instead allowing $\delta_{d_{\ell 2}}$ to be any *distribution* over documents in $D^{(\ell_1)}$, a mixture of potentially multiple documents in language ℓ_1 to inform parameters for a document d_{ℓ_2} in language ℓ_2. We refer this distribution as the **transfer distribution**. The Dirichlet prior for document d_{ℓ_2} contains topic knowledge $\mathbf{N}^{(\ell_1)}$ transferred from corpus $D^{(\ell_1)}$, encouraging $\theta_{d_{\ell 2}}$ to be proportionally similar to documents in $D^{(\ell_1)}$. Figure 2 illustrates this process.

4.2 Defining the Transfer Distribution

The transfer distribution of document d_{ℓ_2} indicates how much knowledge should be transferred from every document $d_{\ell_1} \in D^{(\ell_1)}$. Intuitively, if d_{ℓ_1} and d_{ℓ_2} have a large amount of overlapping word translations, their topics should be similar as well. Therefore, we define the values of δ based on the similarity of document pairs using a bilingual dictionary. Specifically, for a document $d_{\ell_2} \in D^{(\ell_2)}$, the transfer distribution of d_{ℓ_2}, denoted as $\delta_{d_{\ell 2}}$, is a normalized vector of size $|D^{(\ell_1)}|$, *i.e.,* the size of corpus $D^{(\ell_1)}$. Each cell in $\delta_{d_{\ell 2}}$ corresponds to a document $d_{\ell_1} \in D^{(\ell_1)}$, defined as:

$$(\delta_{d_{\ell 2}})_{d_{\ell 1}} \quad \propto \quad \frac{|\,\{w_{\ell_1}\} \cap \{w_{\ell_2}\}\,|}{|\,\{w_{\ell_1}\} \cup \{w_{\ell_2}\}\,|}, \qquad \forall\, w_{\ell_1} \in d_{\ell_1} \text{ and } w_{\ell_2} \in d_{\ell_2}, \tag{4}$$

where $\{w_\ell\}$ contains all the word types that appear in document d_ℓ, and $\{w_{\ell_1}\} \cap \{w_{\ell_2}\}$ indicates all word pairs (w_{ℓ_1}, w_{ℓ_2}) that can be found in a dictionary as translations. In other words, $(\delta_{d_{\ell 2}})_{d_{\ell 1}}$ is the proportion of words in the document pair (d_{ℓ_1}, d_{ℓ_2}) that are translations of each other.

In practice, a dense transfer distribution is computationally inefficient and is less meaningful than a sparse distribution, as it becomes approximately uniform due to the large size of the corpus. The transfer

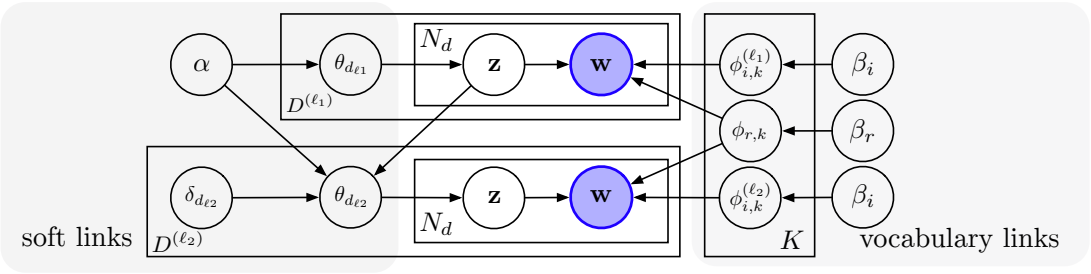

Figure 3: Plate notation of a multilingual topic model using soft links and vocabulary links.

distribution should be more heavily concentrated on documents with higher word-level translation probabilities, while reducing the noise negatively transferred from those with low probabilities. To this end, we propose two approaches to help transfer distributions more efficiently focus on specific documents.

4.2.1 Static Focusing: a Threshold Method

The first method is to focus the distribution on the highest values such that values below a threshold are set to 0, while the remaining values are renormalized to sum to 1. The modified distribution is thus:

$$\left(\widetilde{\delta}_{d_{\ell 2}}\right)_{d_{\ell 1}} \quad \propto \quad \mathbb{1}\left\{ \left(\delta_{d_{\ell 2}}\right)_{d_{\ell 1}} > \pi \cdot \max\left(\delta\right) \right\} \cdot \left(\delta_{d_{\ell 2}}\right)_{d_{\ell 1}} \tag{5}$$

where $\mathbb{1}$ is an indicator function, and $\pi \in [0, 1]$ is the **focal threshold**, a fixed parameter that adjusts the threshold. The threshold is defined with respect to the maximum value of δ. A *corpus-wise* threshold chooses $\max(\delta)$ from all the $\delta_{d_{\ell 2}}$ in $D^{(\ell_2)}$ globally, while we also consider a *document-wise* threshold for each document, $\pi \cdot \max\left(\delta_{d_{\ell 2}}\right)$. We refer these two manners as the **selection scope**.

4.2.2 Dynamic Focusing: an Annealing Method

Static focusing treats transfer distributions δ as fixed parameters during sampling, and it is difficult to decide how sparse a transfer distribution should be to achieve optimal performance. Therefore, we propose dynamic focusing, where we avoid choosing a specific focal threshold and selection scope. Specifically, we adjust the transfer distribution during inference dynamically, beginning with a dense transfer distribution and iteratively sharpening the distribution using deterministic annealing (Ueda and Nakano, 1994; Smith and Eisner, 2006; Paul and Dredze, 2015).

Assume at iteration t, the transfer distribution for a document d_{ℓ_2} is denoted as $\delta_{d_{\ell 2}}^{(t)}$. Then at iteration t', we anneal its transfer distribution by $\left(\delta_{d_{\ell 2}}^{(t')}\right)_{d_{\ell 1}} \propto \left(\delta_{d_{\ell 2}}^{(t)}\right)_{d_{\ell 1}}^{1/\tau}$ where τ is a fixed temperature, which we set to 0.9 in our experiments. We start with non-focused transfer distributions, and apply annealing at scheduling intervals during Gibbs sampling.

Designing an effective annealing schedule is critical. We propose two schedules below.

Fixed Schedule. The simplest schedule is to apply annealing for all transfer distributions every I iterations. In our experiments, we set $I = 10$ (*i.e.,* $t' = t + 10$) and stop annealing after 400 iterations. A potential problem with fixed schedule is that it can "over-anneal" the transfer distributions, *i.e.,* all the mass converges to only one document.

Adaptive Schedule. A robust multilingual topic model should produce similar distributions over topics for a pair of word translations $c = (w_{\ell_1}, w_{\ell_2})$, where we call c a concept. In other words, given a topic k, the probability of expressing a concept i in language ℓ_1 should be similar to language ℓ_2. Thus, during iteration t, we calculate $\varphi_c^{(\ell,t)}$, the distribution over K topics for each concept c for each language ℓ. Using $\varphi_c^{(\ell,t)}$ as features and its language ℓ as labels, we perform five-fold cross-validation by logistic regression for all concepts c. We define the average classification accuracy over the five folds as the **language identification score** (LIS). The lower the LIS, the better the model, since a high LIS means the

inferred distributions are inconsistent enough to discriminate between languages. This idea is related to adversarial training between languages (Chen et al., 2016).

During Gibbs sampling, we calculate LIS after each iteration, and average LIS every I iterations. We anneal all transfer distributions at iteration t only if $\overline{\text{LIS}}_{t-I:t} > \overline{\text{LIS}}_{t-2I:t-I}$. That is, if the average LIS score during iteration $t-I$ and t has been increasing since iteration $t-2I$ to $t-I$, we treat this as a warning sign of increased LIS and thus anneal the transfer distributions. As we sharpen δ by annealing, knowledge transfer between languages becomes more specific.

4.3 Modularity of Models

Multilingual topic models can include the different types of information we described in Section 2: document links, vocabulary links, or both (Hu et al., 2014), while a model with neither is equivalent to LDA. Document links can be either hard or soft, or a mix of both, as the only distinction is whether the transfer distribution is an indicator vector. A complete model with both soft document links and vocabulary links is shown in Figure 3. In Section 5, we experiment with a combination of SOFTLINK and VOCLINK.

5 Experiments

5.1 Data

We use five corpora in five languages from different language groups: Arabic (AR, Semitic), Spanish (ES, Romance), Farsi (FA, Indo-Iranian), Russian (RU, Slavic), and Chinese (ZH, Sinitic). Each language is paired with English (EN, Germanic), and we train multilingual topic models on these language pairs individually. All the corpora listed below are available at `http://opus.nlpl.eu/`. For preprocessing, we use stemmers to lemmatize and segment Chinese documents, and then remove stop words and the most frequent 100 word types for each language. Refer to the appendix for additional details.

Training corpora. As in many multilingual studies (Ruder et al., 2017), we use Wikipedia as our training corpus for multilingual topic models, and create two corpora, WIKI-INCO and WIKI-PACO for each language pair (EN, ℓ). For WIKI-INCO, we randomly select $2,000$ documents in each language without any connections, so that no documents are translations of each other (an *incomparable* corpus). We also create a *partially comparable* corpus, WIKI-PACO, which contains around 30% comparable document pairs for each language pair.

Test corpora. We create two test corpora for each language pair (EN, ℓ) from TED Talks 2013 (TED) and Global Voices (GV), which provide categories for each document that can be used as classification labels. The first one, TED+TED, contains documents from TED in both languages, while the second one, TED+GV contains English documents from TED and non-English documents from GV. After training a topic model, we use $\phi^{(\text{EN})}$ and $\phi^{(\ell)}$ to infer topics from both languages. For TED+TED, we choose the five most frequent labels in TED as the label set (*technology*, *culture*, *science*, *global issues*, and *design*); for TED+GV, we replace *global issues* and *design* with *business* and *politics*, since the label set from GV does not include *global issues* and *design*.

Dictionary. We use Wiktionary to extract word translations for VOCLINK and to calculate transfer distribution values δ for SOFTLINK. The dictionary is available at `https://dumps.wikimedia.org/enwiktionary/`.

5.2 Inference Settings

For each compared model, we set the number of topics $K = 25$. We run the Gibbs samplers for $1,000$ training iterations and 500 iterations to infer topic distributions on test corpora. We set Dirichlet priors $\alpha = 0.1$ and $\beta = 0.01$ for HARDLINK and SOFTLINK. For VOCLINK, we set $\beta_r = 0.01$ for priors from root to internal nodes, and $\beta_i = 100$ from internal nodes i to leaves, following Hu et al. (2014).

5.3 Evaluation Metrics

We evaluate each model in two ways. Experimental results below are averaged across all language pairs.

5.3.1 Intrinsic Evaluation: Multilingual Topic Coherence

Typical topic model evaluations include intrinsic and extrinsic measurements. Intrinsic evaluation focuses on topic quality or coherence of the trained topics. The most widely-used metric for measuring monolingual topic coherence is normalized pointwise mutual information (Lau et al., 2014; Newman et al., 2010). Hao et al. (2018) proposed crosslingual normalized pointwise mutual information (CNPMI) by extending this idea to multilingual settings, which correlates well with bilingual speakers' judgments on topic quality.

Given a bilingual topic k in languages ℓ_1 and ℓ_2, and a parallel reference corpus $\mathcal{R}^{(\ell_1,\ell_2)}$, the CNPMI of topic k is calculated as:

$$\text{CNPMI}(\ell_1, \ell_2, k) \quad = \quad \frac{1}{C^2} \sum_{i,j}^{C} \frac{1}{\log \Pr\left(w_i^{(\ell_1)}, w_j^{(\ell_2)}\right)} \cdot \log \frac{\Pr\left(w_i^{(\ell_1)}, w_j^{(\ell_2)}\right)}{\Pr\left(w_i^{(\ell_1)}\right) \Pr\left(w_j^{(\ell_2)}\right)} \tag{6}$$

where C is the cardinality of a topic, *i.e.,* the C most probable words in the topic-word distribution $\phi_k^{(\ell)}$. The co-occurrence probability of two words, $\Pr\left(w_i^{(\ell_1)}, w_j^{(\ell_2)}\right)$, is defined as the proportion of document pairs where both words appear. In the results below, we set $C = 20$, and average the CNPMI scores over $K = 25$ topics for each model output.

To calculate CNPMI scores, we use $10,000$ document pairs from a held-out portion of Wikipedia. CNPMI is an intrinsic evaluation, so it is only available for the training sets, WIKI-PACO and WIKI-INCO.

5.3.2 Extrinsic Evaluation: Crosslingual Classification

A successful multilingual topic model should provide informative features for crosslingual tasks. To show that our model is beneficial to downstream applications, we use crosslingual document classification to evaluate topic model performance. A high classification accuracy when testing on a different language from training indicates topic consistency across languages (Hermann and Blunsom, 2014; Klementiev et al., 2012; Smet et al., 2011).

As in other studies on multilingual topic models, we first train topic models on a bilingual corpus $D^{(\ell_1,\ell_2)}$, and then use topic-word distributions $\phi^{(\ell_1)}$ and $\phi^{(\ell_2)}$ to infer document-topic distributions on unseen documents $D'^{(\ell_1)}$ and $D'^{(\ell_2)}$. Thus, a classifier is trained on $\theta_{d_{\ell 1}}$ with corresponding labels where $d_{\ell 1} \in D'^{(\ell_1)}$, and tested on $\theta_{d_{\ell 2}}$ where $d_{\ell 2} \in D'^{(\ell_2)}$, and vice versa. In our experiments, we use WIKI-PACO and WIKI-INCO to train topic models first, and then perform inference on either TED+TED (both English and non-English documents from TED) or TED+GV (English documents from TED and non-English from GV). For each language pair, we train multi-label classifiers using support vector machines (SVM) with five-fold cross-validation on documents in one language and test on the other. The F-1 scores reported below are micro-averaged over all labels.

5.4 Baseline Comparison

We first compare SOFTLINK with other models: HARDLINK, which is expected to do well on the partially comparable corpus (WIKI-PACO) but poorly on the incomparable corpus (WIKI-INCO), and VOCLINK. We additionally combine SOFTLINK+VOCLINK.

Figure 4 shows the performance (both intrinsic and extrinsic) of all models. For the SOFTLINK models, we used the optimal hyperparameter settings, but we compare other settings in Section 5.5.

When the training corpus is partially comparable (WIKI-PACO), all models can learn comparably coherent topics based on CNPMI scores, though the CNPMI of HARDLINK is lower than all other models. When the data is completely incomparable (WIKI-INCO), HARDLINK loses all connections between languages, so as expected its topics are least coherent. Similarly, when measuring classification performance, HARDLINK is comparable to VOCLINK on WIKI-PACO, but much worse on WIKI-INCO, where it loses all information. When the test set contains mostly parallel documents (TED+TED), the F-1 scores are higher, but when the test domain changes across languages (TED+GV), the performance drops.

On the other hand, SOFTLINK consistently outperforms other models regardless of training and test sets. It seems that SOFTLINK benefits from learning new connections between documents, even when

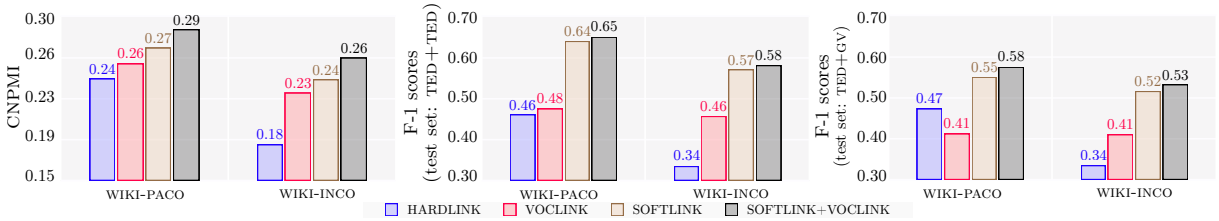

Figure 4: SOFTLINK consistently outperforms other models on both topic quality evaluation (CNPMI) and classification performance (F-1).

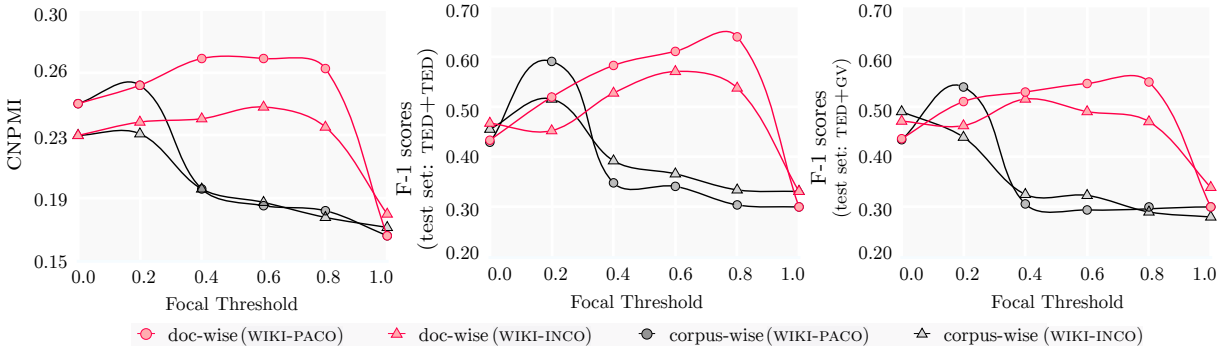
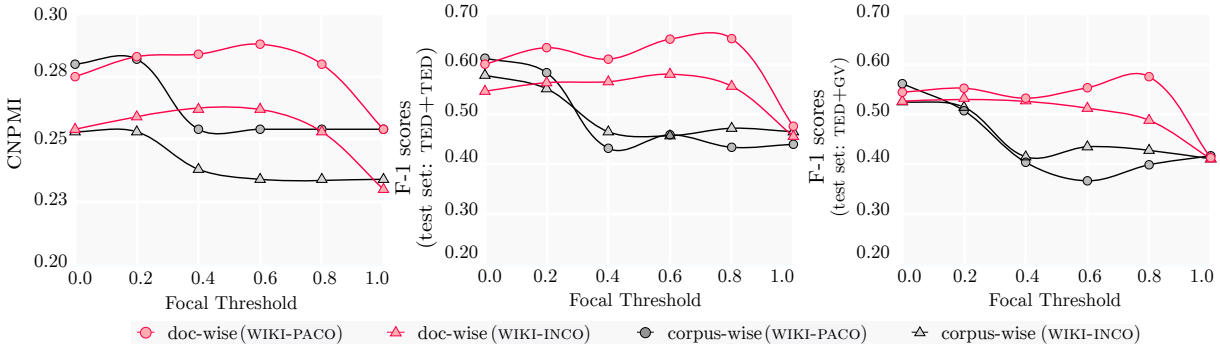


(a) Training SOFTLINK model.



(b) Training SOFTLINK with VOCLINK.

Figure 5: CNPMI scores and F-1 scores of crosslingual classification under different focal thresholds and selection scope of the transfer distribution for SOFTLINK and SOFTLINK+VOCLINK (Section 4.2).

part of the corpus contains direct links for training HARDLINK. It is also interesting that SOFTLINK uses the same dictionary resource as VOCLINK, but has a relative performance increase around 25%. It seems SOFTLINK can more efficiently utilize lexical information in a dictionary. We explore this relationship more in Section 5.6.

Finally, we observe that combining SOFTLINK+VOCLINK provides a performance boost over SOFTLINK in all cases, though the increase is small.

5.5 Comparison of Focusing Methods

We have shown that, when optimized, SOFTLINK can better utilize dictionary resources and outperform other models. We now focus on different training configurations for SOFTLINK, specifically, different methods of focusing the transfer distribution (Section 4.2).

Figure 5 shows how F-1 and CNPMI scores change with different static focusing methods. We vary the focal threshold and selection scope (*i.e.,* doc-wise or corpus-wise) for transfer distributions. As we increase the focal threshold π, more documents are zeroed out in the transfer distributions. When $\pi = 0.6$ or 0.8, the transfer distributions are very sparse, and we notice that document-wise selection

	F-1 scores (TED+TED)		F-1 scores (TED+GV)		CNPMI	
	LIS	Fixed	LIS	Fixed	LIS	Fixed
WIKI-PACO	0.627	0.638	0.551	0.534	0.256	0.258

(b) Training SOFTLINK with VOCLINK.

Table 1: Dynamically focusing transfer distributions in SOFTLINK yields competitive results on classification and topic quality evaluation. There is no significant difference between Fixed and LIS schedules.

achieves the best performance. In the extreme case that $\pi = 1$, the transfer distributions are all zero, so SOFTLINK loses its connections between ℓ_1 and ℓ_2, and thus degrades to monolingual LDA. When training SOFTLINK with VOCLINK, the change of CNPMI and F-1 scores are less obvious as we increase focal threshold, since increasing focal threshold only has an impact on the SOFTLINK component of the model. When the focal threshold is higher, fewer soft links are active, so the model is closer to a plain VOCLINK model.

Interestingly, when focal threshold π changes from 0.2 to 0.4, F-1 scores of corpus-wise selection scope trained on SOFTLINK drops drastically, in contrast to document-wise. This is because using corpus-wise selection could set a large portion of transfer distributions to zero, and only a small number of documents have non-zero transfer distributions. Since corpus-wise selection relies on the entire training corpus, it must be used with caution.

We find that using annealing to dynamically focus the distributions works well and is competitive with static focusing (Table 1). Annealing does better than the majority of settings of static focusing, though is worse than optimally-tuned focusing. We do not observe a significant difference between the two annealing schedules. When combining SOFTLINK and VOCLINK, the patterns are similar to that of SOFTLINK only.

5.6 Sensitivity to Dictionary Size

Both VOCLINK and SOFTLINK use the same dictionary resource, yet SOFTLINK produces better features for downstream tasks. To understand this behavior better, we experiment with different dictionary sizes to understand how well the models are utilizing the resource.

In Figure 6, we use different proportions (20%, 40%, ..., 80%) of the dictionary to train SOFTLINK and VOCLINK.[4] We observe that the performance of VOCLINK (both F-1 and CNPMI) increases almost linearly with the dictionary size. In contrast, SOFTLINK is already at its best performance with only 20% of the available dictionary entries. This is further confirmation that SOFTLINK is using this resource in a more efficient way.

In VOCLINK, knowledge transfer happens through internal nodes of the word distribution priors, *i.e.,* word translations pairs, and words without translations are directly connected to the Dirichlet tree's root. If the dictionary cannot cover all the word types appeared in the training set, VOCLINK will have a set of word types in ℓ_1 that cannot transfer enough topic knowledge to ℓ_2 and vice versa. The fewer entries the dictionary provides, the more VOCLINK degrades to monolingual LDA. In contrast, SOFTLINK can potentially transfer knowledge from the whole corpus. For SOFTLINK, the dictionary is not used directly for modeling, rather it is only used for linking documents. Thus, knowledge transfer does not heavily rely on the number of entries in the dictionary.

[4]We use document-wise selection scope and focal threshold $\pi = 0.6$ for training SOFTLINK; same as in Section 5.4.

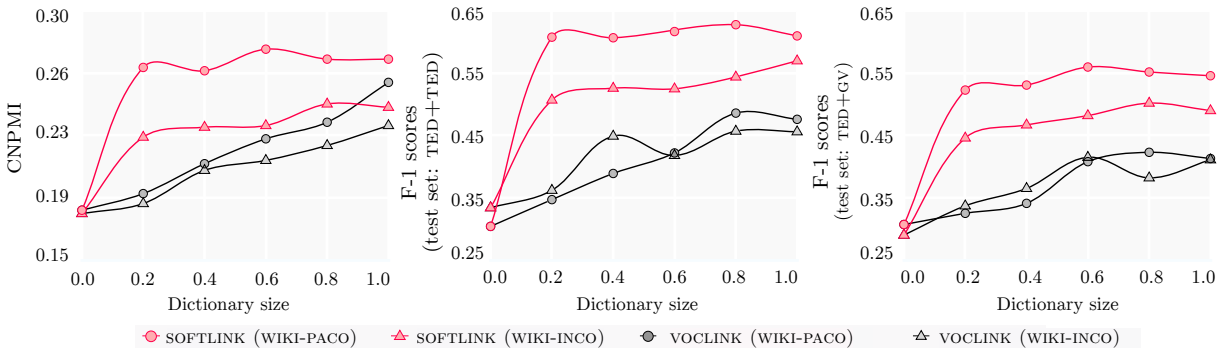

Figure 6: Performance of VOCLINK continues increasing when more dictionary entries are added, while SOFTLINK performance mostly stabilizes after using only 20% of available dictionary entries.

5.7 Discussion

The sensitivity to dictionary size is an important factor to be considered in practice. For low-resource languages, a dictionary is easier to obtain than a large parallel corpus (Section 1). Models that rely on dictionaries such as VOCLINK and SOFTLINK are therefore more applicable to low-resource languages than HARDLINK. However, there are also large variations in dictionary size among languages. For example, in Wiktionary, 57 languages have fewer than 1,000 entries, while 77 languages have more than 100,000 entries. For truly low-resource languages, dictionary size could be a limiting factor. Since SOFTLINK can outperform VOCLINK with only a limited amount of lexical information, it may be able to transfer knowledge to low-resource languages more effectively than other approaches.

In summary, SOFTLINK relaxes and generalizes HARDLINK to be adaptable to more situations, while using dictionary information more efficiently than VOCLINK.

6 Conclusions and Future Work

We have described a new formulation for multilingual topic models which explicitly shows the knowledge transfer process across languages. Based on this analysis, we proposed a new multilingual topic model that can learn multilingually coherent topics and provide consistent topic features for crosslingual tasks. Unlike existing models, our approach is flexible and adaptable to incomparable corpora with only a dictionary, which is beneficial in many situations, in particular low-resource settings.

There are many possible directions following this work. First, our formulation of the knowledge transfer process enables future work focusing on how to develop more efficient algorithms that transfer knowledge with minimal supervision. Second, for SOFTLINK we plan to explore more about characteristics of languages that can lead to better formulations and learning of the transfer distributions.

Appendix A Pseudolikelihood

Theorem 1. *The conditional generative model with document links yields the same posterior estimator to the joint generative model using collapsed Gibbs sampling.*

Proof. Suppose the document links model is sampling topic of the m-th token in document d_{ℓ_2}. The sampler calculates the conditional topic distribution, and then draw a topic assignment. Using collapsed Gibbs sampling, we calculate the conditional probability of a topic k:

$$\begin{aligned}
&\Pr\left(z_{d_{\ell 2},m}=k|\mathbf{z}_{d_{\ell 2},-},\mathbf{w}_{d_{\ell 2}};\mathbf{n}_{d_{\ell 1}},\alpha,\beta\right)=\frac{\Pr\left(z_{d_{\ell 2},m}=k,\mathbf{z}_{d_{\ell 2},-},\mathbf{w}_{d_{\ell 2}};\mathbf{n}_{d_{\ell 1}},\alpha,\beta\right)}{\Pr\left(\mathbf{z}_{d_{\ell 2},-},\mathbf{w}_{d_{\ell 2}};\mathbf{n}_{d_{\ell 1}},\alpha,\beta\right)}\\
=&\frac{\Pr\left(z_{d_{\ell 2},m}=k,\mathbf{z}_{d_{\ell 2},-},\mathbf{w}_{d_{\ell 2}};\mathbf{n}_{d_{\ell 1}},\alpha\right)}{\Pr\left(\mathbf{z}_{d_{\ell 2},-};\mathbf{n}_{d_{\ell 1}},\alpha\right)}\cdot\frac{\Pr\left(\mathbf{w}_{d_{\ell 2}}|z_{d_{\ell 2},n}=k,\mathbf{z}_{d_{\ell 2},-};\beta\right)}{\Pr\left(\mathbf{w}_{d_{\ell 2}}|\mathbf{z}_{d_{\ell 2},-},\beta\right)}\\
=&\frac{\frac{\prod_{k'\neq k}\Gamma\left(n_{k'|d_{\ell 2}}+\mathbf{n}_{d_{\ell 1},k'}+\alpha\right)\cdot\Gamma\left(n_{k|d_{\ell 2}}+\mathbf{n}_{d_{\ell 1},k}+\alpha+1\right)}{\Gamma\left(n_{\cdot|d}+\mathbf{n}_{d_{\ell 1}}+\alpha+1\right)}}{\frac{\prod_{k}\Gamma\left(n_{k|d_{\ell 2}}+\mathbf{n}_{d_{\ell 1},k}+\alpha\right)}{\Gamma\left(n_{\cdot|d_{\ell 2}}+\mathbf{n}_{d_{\ell 1}}+K\alpha\right)}}\cdot\frac{\frac{\prod_{w\neq w_{d_{\ell 2},m}}\Gamma\left(n_{w|k}+\beta\right)\cdot\Gamma\left(n_{w_{d_{\ell 2},m}|k}+\beta+1\right)}{\Gamma\left(n_{\cdot|k}+V^{(\ell_2)}\beta+1\right)}}{\frac{\prod_{w}\Gamma\left(n_{w|k}+\beta\right)}{\Gamma\left(n_{\cdot|k}+V^{(\ell_2)}\beta\right)}}\\
=&\frac{\Gamma\left(n_{k|d_{\ell 2}}+\mathbf{n}_{d_{\ell 1},k}+\alpha+1\right)}{\Gamma\left(n_{k|d_{\ell 2}}+\mathbf{n}_{d_{\ell 1},k}+\alpha\right)}\cdot\frac{\Gamma\left(n_{\cdot|d_{\ell 2}}+\mathbf{n}_{d_{\ell 1}}+K\alpha\right)}{\Gamma\left(n_{\cdot|d_{\ell 2}}+\mathbf{n}_{d_{\ell 1}}+\alpha+1\right)}\cdot\frac{\Gamma\left(n_{w_{d_{\ell 2},m}|k}+\beta\right)}{\Gamma\left(n_{w_{d_{\ell 2},m}|k}+\beta+1\right)}\cdot\frac{\Gamma\left(n_{\cdot|k}+V^{(\ell_2)}\beta\right)}{\Gamma\left(n_{\cdot|k}+V^{(\ell_2)}\beta+1\right)}\\
=&\frac{n_{k|d_{\ell 2}}+\mathbf{n}_{d_{\ell 1},k}+\alpha}{n_{\cdot|d_{\ell 2}}+\mathbf{n}_{d_{\ell 1}}+K\alpha}\cdot\frac{n_{w_{d_{\ell 2},m}|k}+\beta}{n_{\cdot|k}+V^{(\ell_2)}\beta},
\end{aligned}$$

where $\mathbf{z}_{d_{\ell 2},-}$ is all the topic assignments in d_{ℓ_2} except the current one, $n_{\cdot|d_{\ell 2}}$ the number of tokens in d_{ℓ_2}, $n_{k|d_{\ell 2}}$ the number of tokens assigned to topic k in d_{ℓ_2}, $n_{\cdot|k}$ the number of tokens assigned to topic k, $n_{w|k}$ the number of word type w assigned to topic k, and $V^{(\ell_2)}$ the vocabulary size of language ℓ_2. The roles of ℓ_1 and ℓ_2 are interchangeable, so both languages use the same conditional distributions. The last equation of the derivation above gives identical posterior estimation in the original model. Thus, the alternative formulation, despite not a numerically accurate likelihood approximation, does not make a difference for parameter estimation. □

Appendix B Dataset Processing Details

B.1 Pre-Processing

For all the languages, we use existing stemmers to stem words in the corpora and the entries in Wiktionary. Since Chinese does not have stemmers, we loosely use "stem" to refer to "segment" Chinese sentences into words. We also use fixed stopword lists to filter out stop words. Table 2 lists the source of the stemmers and stopwords.

B.2 Data Source

We list the statistics in Table 3.

Table 3: Statistics of corpora and dictionary in the five languages used in the experiments.

Wikipedia (WIKI-PACO, and WIKI-INCO). For training multilingual topic models, the dataset Wikipedia can be downloaded at `http://opus.nlpl.eu/TED2013.php`. For each language pair (EN, ℓ), we create WIKI-INCO, a completely incomparable corpus, where $2,000$ EN documents and $2,000$ non-English documents are randomly chosen but do not contain document-level translations to each other.

We also create WIKI-PACO, a partially comparable corpus. Each language has different proportions of comparable document pairs. See Table 4.

TED Talks 2013 (TED). TED Talks 2013 contains mostly parallel documents, and can be obtained from OPUS: `http://opus.nlpl.eu/TED2013.php`. Note that not all English documents have translations to another language, which is slightly different from the original assumptions in polylingual topic models.

The classification labels can be obtained from the documents. Each document has several "categories" that can be regarded as labels. Thus, we retrieve those labels, and choose the most frequent five labels for classification: *technology*, *culture*, *science*, *global issues*, and *design*.

Global Voices (GV). Global Voices can be obtained from OPUS as well: `http://opus.nlpl.eu/GlobalVoices.php`. Global Voices corpus has a large number of documents, so for efficiency, we randomly choose a sample of at most 2,000 documents for each language.

There's no label information from the corpus itself. However, the labels can be retrieved from the webpage of each document, at `https://globalvoices.org`. To make sure Global Voices have

Languages	AR	ES	FA	RU	ZH
Proportion	12.2%	9.35 %	50.85 %	50.20 %	17.90 %

Table 4: Proportions of linked document pairs in corpus WIKI-PACO.

the same label set to TED Talks, we changed the label set to: *technology*, *culture*, *science*, *business*, and *politics*.

Wiktionary. We use English Wiktionary to create bilingual dictionaries, which can be downloaded at `https://dumps.wikimedia.org/enwiktionary/`.

Abstract

Scientific papers from all disciplines contain many abbreviations and acronyms. In many cases these acronyms are ambiguous. We present a method to choose the contextual correct definition of an acronym that does not require training for each acronym and thus can be applied to a large number of different acronyms with only few instances. We constructed a set of 19,954 examples of 4,365 ambiguous acronyms from image captions in scientific papers along with their contextually correct definition from different domains. We learn word embeddings for all words in the corpus and compare the averaged context vector of the words in the expansion of an acronym with the weighted average vector of the words in the context of the acronym. We show that this method clearly outperforms (classical) cosine similarity. Furthermore, we show that word embeddings learned from a 1 billion word corpus of scientific texts outperform word embeddings learned from much larger general corpora.

1 Motivation

Scientific papers usually contain a high number abbreviations and acronyms that might be very general or very specific for a certain domain and that might be very common in that domain or that are constructed ad hoc. For various tasks, like retrieval or information extraction we need the expanded form of the acronyms.[1]

In most cases we can find the definition for an acronym in the paper. Finding this definition automatically is not as trivial as it might sound and there is a lot of literature on this topic. However, a lot of cases remain where we cannot find such a definition, because the extraction method fails or because there is no definition in the paper. In these cases we can use a definition found elsewhere. As already noted by Chang et al. (2002) in these cases acronyms often turn out to be ambiguous and the correct definition has to be chosen by considering the context of the acronym. Exactly this task is the topic of the present paper. Thus, although the goal of our work is acronym expansion, the work is more related to word sense disambiguation (WSD) than to typical work on acronym resolution. The main difference with WSD is that we do not have dictionaries with description of possible senses. Instead the possible expansions of the acronym directly represent the different senses.

In the Project NOA (Reuse of Open Access Images, http://noa.wp-hs-hannover.de) we analyze captions from images in scientific papers to collect appropriate metadata for those images (Charbonnier et al., 2018). In order to get maximal information from the usually short image captions we need to expand the acronyms. Moreover, the acronyms are often very specific technical terms that give a lot of information on the displayed image. Since the focus of the project is on image captions, in the present paper we consider only acronyms from image captions, but this is not relevant to our method that can be used to disambiguate any acronym in a scientific paper. Since the image captions in some cases are very short, we also use the text from the sentences referring to the image to disambiguate the acronyms in the caption.

Proceedings of the 27th International Conference on Computational Linguistics, pages 2610–2619
Santa Fe, New Mexico, USA, August 20-26, 2018.

2 Related Work

Typically definitions for acronyms are found using a number of patterns to find candidates in the context of the acronyms and a number of rules to select the most likely candidate. Patterns and rules are defined manually or learned in a supervised (Nadeau and Turney, 2005) or unsupervised (Kirchhoff and Turner, 2016) way. The work of Schwartz and Hearst (2011) focuses on finding and extracting abbreviations from medical publications by identifying <"short form", "long form"> pairs and was used in a majority of the work discussed here. They argue that many abbreviations in the biomedical domain follow a predictable pattern where the first letter of each word is a letter of its short form, but that there are cases where this is not true. Therefore they describe a simple and fast algorithm with a high recall and precision to find those pairs using string operations to verify that the acronym letters appear in the right order in the long form.

Much research on acronym resolution and disambiguation was done in the biomedical domain (Okazaki and Ananiadou, 2006; Finley et al., 2016; Vo et al., 2016; Wu et al., 2017). The most reliable approach for disambiguation is to train a classifier that chooses the right definition based on features representing the context of the acronym (Wu et al., 2015; Wang et al., 2016; Finley et al., 2016; Antunes and Matos, 2017). Typical features are the word frequencies but also morphemes and position features. Wu et al. (2015) and Antunes and Matos (2017) also include features from word embeddings. Kirchhoff and Turner (2016) learn the similarity between a possible expansion and the context in a neural network using word embedding features. Wu et al. (2015) use the sum of all pmi (pointwise mutual information) values between a definition and a context as a measure of their similarity. Thus they also use a more advanced similarity measure than just word overlap based on word co-occurrence in a large corpus.

Stevenson et al. (2009) created a biomedical evaluation corpus consisting of overall 55,655 documents using MEDLINE and MEDSTRACT. They counted the occurrence of 21 three letter abbreviations and of their expansions in the abstracts of those documents. The occurrence of these hand selected abbreviations range from $71 - 14,871$ times in the corpus. Jimeno-Yepes et al. (2011) created the widely used MSH-WSD dataset consisting of 203 ambiguous entities, where 106 are abbreviations. Each of those has a maximum of 100 instances from MEDLINE where they occur.

Disambiguation of acronyms is a special case of the more general problem of word sense disambiguation (Navigli, 2009; Yarowsky, 2010; Mihalcea, 2011). Word sense disambiguation is typically done by comparing the possible senses of an ambiguous word, expressed e.g. by their glosses in a dictionary, with the senses of the surrounding words (Lesk, 1986; Patwardhan et al., 2003). The gloss overlap can be improved, when the glosses are extended with related words (Banerjee and Pedersen, 2003). We will follow this idea below, but the extension of the glosses is done implicitly using distributional similarity, as also was done by Aga et al. (2016) and Oele and Noord (2017).

Henry et al. (2017) and Tulkens et al. (2016) specifically worked on disambiguation of acronyms. They used the MSH-WSD dataset and UMLS to disambiguate words/concepts in the domain of biomedicine. Tulkens et al. (2016) combined word representations and definitions from UMLS to create concept representations. Those concepts are then used to disambiguate terms using cosine similarity and the context of the unambiguous term. As features they used word embeddings as described by Mikolov et al. (2013) learned with MEDLINE abstracts and the MIMIC-III corpus. Henry et al. (2017) evaluate different feature extraction methods using 2-MRD (2nd Order Co-occurrence Machine Readable Dictionary) to disambiguate biomedical word senses. Among these were Singular Value Decomposition, Principal Component Analysis and Neural Word Embeddings trained with Bag of Words and Skip Gram. They used extended definitions like parent/children, narrow/broader relations and associated synonymous terms from UMLS to create those vectors. Pakhomov et al. (2016) evaluated the effect of domain specific corpora for disambiguating medical terms while using word embeddings. They showed that biomedical articles can be used to a degree to represent the semantics of clinical reports.

3 Data

Most available data sets with acronyms are quite small, or focus specifically on the biomedical domain, or do not contain ambiguous acronyms, or only ambiguous acronyms with a few very frequent resolutions. To develop a disambiguation method that is suited for our practical problem, we need a set of ambiguous

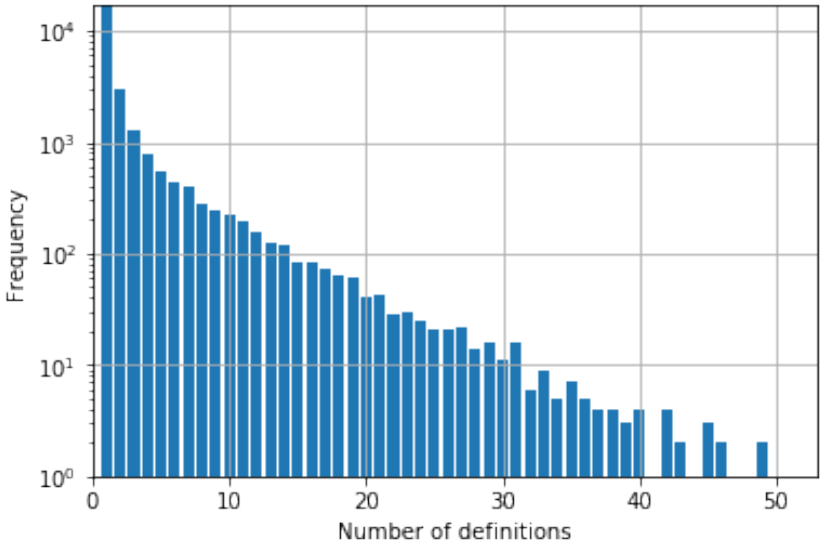

Figure 1: Number of definitions (after clustering) per acronym in the NOA corpus.

acronyms from different disciplines with possibly very infrequent and unusual definitions. In absence of such a test set, we created our own set of ambiguous acronyms.

3.1 Acronyms in the NOA Corpus

Our database contained 712,438 papers from open access journals by the end of 2017. The collection contains journals from almost all scientific disciplines with a focus on technical and biomedical research areas. We refer to Sohmen et al. (2018) for more details.

In this collection we found 2,838,713 occurrences of words written in all capitals of at least 3 letters that thus are likely to be acronyms. For 25,336 acronyms with a total of 628,470 occurrences we found a definition in the paper using a simple regular expression. For 379,509 additional acronyms we could find an unambiguous definition in another paper from the same journal. In total about 36% of all potential acronyms could be expanded. For 67 % of the remaining acronyms we have multiple possible expansions from other papers.

Since authors sometimes seem to be uncertain about the exact definition of acronyms we build clusters of definitions, such that for each pair (a, b) in a cluster either a is a permutation of b (like *annual average daily traffic* and *average annual daily traffic* for AADT) or if the Levenshtein Distance of a and b is smaller than 5 (like *anterior acetabular sector angle* and *Anterior acetabular section angle* for AASA.) Finally, we take the most frequent definition as the correct one. The average cluster size is 1.36. The average number of definitions was reduced from 3.6 to 2.7. Since we used simple heuristics for cluster building, we have a few cases in which two different definitions are put into one cluster and many cases of equivalent definitions that are still treated as different definitions: the overwhelming majority of the clusters only contain spelling variants, different capitalization and typos. The distribution of the number of definitions per acronym for all acronyms in image captions in the NOA corpus is given in Figure 1.

The acronym with the highest number of definitions is SSC with 52 definitions that is used for concepts like *Surgical Safety Checklist*, *symmetric similarity coefficients*, *secondary sclerosing cholangitis* and *Swedish Space Cooperation*.

3.2 Test Set

From our database we collected a set acronyms that have at least two and at most five definitions that are not too similar. As a criterion for similarity we used trigram overlap and we required that the Jaccard-Index of the sets of trigrams was smaller than 0.4. This gave us 4,365 acronyms. In this set we still have 140 acronyms with at least two definitions that only differ in one word, like *DNA Damage Induced Sumoylation*

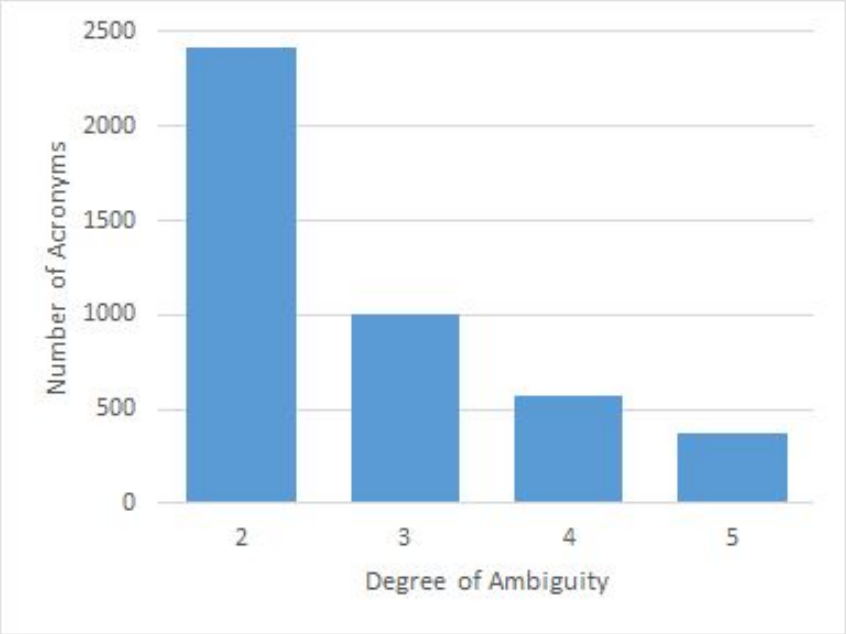

Figure 2: Number of acronyms for each degree of ambiguity in the test set. E.g. we see that there are 1000 acronyms with 3 possible expansions in the test set.

Table 1: Example of the data set. The contextual right definition is typeset in bold.

Acronym	Definitions	DOI of Source	Context/Caption
EBG	Electro-burnt Graphene **Electromagnetic Band Gap**	10.1155/2008/790358	*The EBG leaky wave antenna is fed with a patch array. It must radiate in the direction* $[\Theta = 30^o; \phi = 0^o]$.

and *DNA Damage Induced Senescence* or *very low calorie diet* and *very low carbohydrate diet*. The numbers of acronyms for each degree of ambiguity is given in Figure 2.

For each sense of an acronym we selected at least 1 and at most 5 image captions, in which that acronym was used, from papers in which it was unambiguously defined. This resulted in a set of 19,954 instances of acronyms in a specific context that have to be disambiguated. The data set is provided as supplementary material to this paper. A typical example of a such an instance is given in Table 1. The average length of the captions is 531.3 characters (105.7 tokens), the median is 385 characters (77 tokens). Figure 3 shows the number of expansions with one, two, etc. examples in the test set. Given the low number of examples, training a classifier for each ambiguous acronym is not possible.

3.3 Wordembeddings

We use the full text of all 672,157 papers in our database with a total of 1.662×10^9 tokens to compute word embeddings for all words in the definitions of the acronyms and in the image captions. For training of the word embeddings we only use the body texts and excluded the captions. The 12,002 definitions in our test set consist of 116,603 different tokens. For 92 of those tokens we do not have a word embedding. These are mainly stop words, typos and single letters (as in *Downstream of Kinases (DOK)* and *Vitamin K Antagonist (VKA)*, resp.). In the Google and GloVe dictionaries 821 and 189 tokens, respectively, are not captured. In theses dictionaries in addition many technical terms are missing.

The best results were achieved with a window size of 5 using CBOW, an embedding size of 300. We removed all tokens from our data that are in the NLTK stopword list, that have less than 2 characters or that occur less than 5 times in the corpus.

For comparison we also used two well known pre-trained general models: GoogleNews (Mikolov et al., 2013) and GloVe (Pennington et al., 2014).

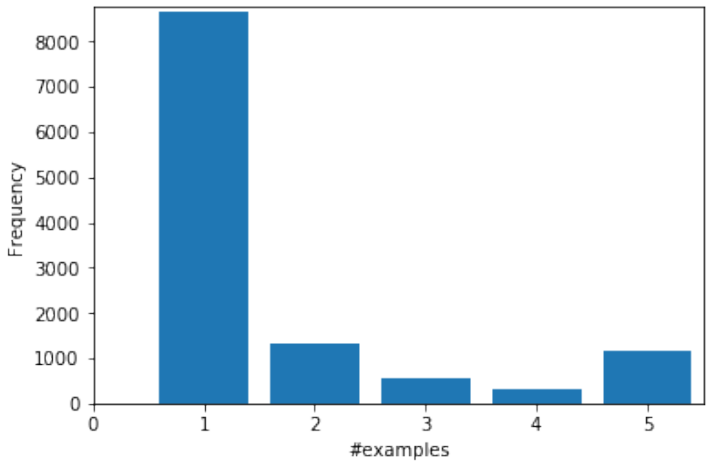

Figure 3: Frequency of each number of examples per definition: For the majority of the possible definitions of an acronym the test set only contains one example; there are about 1200 definitions for which there are 2 examples in the test set, etc.

4 Method

The general idea to decide which sense of an acronym is the contextual correct one, is to compare each definition of the acronym with its context. Now we can vary both the context and the method to compare the definition and context. As the context we take either the image caption from which the acronym was taken, or we expand the caption with sentences referring to the image.

4.1 Baselines

As a baseline we use an unsupervised classifier based on the cosine similarity between tf-idf-vectors of the definition and the context.

As a further baseline we use a majority classifier, that always assigns the definition that was found most frequently in the whole database.

4.2 Prediction

Since the simple cosine similarity used as a baseline captures only literal word overlap and not semantic similarities we also use word embeddings to represent the word in the texts and compare the average word embedding vector for both texts.

To decide which of the given candidates for a solution should be selected, we construct a representing vector for the example text. This vector is the weighted average of all word-embeddings found in the text. We simply discard any token that is not in our dictionary during the average vector calculation. We also calculate an average weighted vector representing the alternative definitions. In both cases we use idf-values as weights for the components. We calculate the cosine similarity and select the candidate with the higher similarity as the right solution.

Formally, let $t = s_0, s_1, \ldots, s_n$ be any sequence of tokens. Now we define the *context vector* of t as

$$cv(t) \quad = \quad \frac{1}{N} \sum_{i=0}^{n} idf(s_i) \cdot cv(s_i) \tag{1}$$

where $cv(s_i)$ is the word embedding or context vector of s_i. Now, for some acronym a let $\mathcal{D} = \{D^0, D^1, \ldots D^n\}$ be the set of definitions for a, with $D^i = d_0^i \ldots d_{k^i}^i$ the sequence of tokens from the definitions for each $0 \leq i \leq n$ and $C = c_0 \ldots c_l$ the tokens in the context. Now the predicted definition $\text{pred}(a, C)$ of a in context C is:

$$\text{pred}(a, C) \quad = \quad \max_{\forall D \in \mathcal{D}} \cos\left(cv(D), cv(C)\right) \tag{2}$$

Table 2: Accuracy of acronym disambiguation

Method	*small Context*	*larger Context*
Majority Classifier	0.44

Table 3: Acronyms incorrectly resolved by our method. The contextual right definition is typeset in bold.

Acronym	**Definitions**	**DOI of Source**	**Context/Caption**
DOW	Day of Week **Deep Ocean Water**	10.3390/md15060168	..... *DOW: TAA-induced mice fed with DOW (0.603 mL/kg/day), AS: TAA-induced mice fed with adenosine (0.329 mg/kg/day), CC: TAA-induced mice fed with cordycepin (0.615 mg/kg/day).*
AIHT	**Adaptive Inverse Hyperbolic Tangent** Analysis Iterative Hard Thresholding	10.1155/2014/825169	*AIHT function image enhancement algorithm procedures.*

4.3 Adding more Context

For very short captions we can extend the context of the acronym with text from paragraphs referring to the image. To be precise, if there are less then 15 tokens in the caption, we add the referring sentence to the context and keep adding left and right neighbor sentences until we have 35 tokens.

5 Results

The results are shown in Table 2. We see that all methods using the context of an acronym outperform the majority classifier. In all cases adding more context for short captions results in a small improvement. The results of the conditions using the pre-trained vectors are slightly worse than those obtained by simple word overlap. The similarity based classifier using the corpus specific word embeddings clearly outperforms all other variants.

6 Discussion

One would expect that using word embeddings to compare the acronym definition with the context of the abbreviation always has a big advantage over a simple word overlap measure, like cosine similarity. Surprisingly, this is not the case if we use pre-trained vectors. When we train a model on the same corpus from which we have collected our examples (excluding the parts, however, used for the examples), we get much better results indeed. This shows in the first place, that unsupervised disambiguation of acronyms is feasible, if we use word embeddings to represent the alternative definitions and the context. In the second place we have shown that training word embeddings on a specialized corpus with text comparable to those in the task to be carried out, has a big advantage over using available embeddings trained on a general corpus, even if the used corpus is much smaller than the general corpus.

6.1 Error analysis

Our data set is generated automatically and not manually corrected. Therefore, we have some errors in our data set that cause misclassifications. E.g., there are two definitions for DJF: *December January February* and *Dec Jan Feb*. Obviously, the first one is the correct one, but the classifier might find either. In some cases different but equivalent definitions are found for an acronym, like *Gap Junction Channel* and *Gap Junctional Communication* for GJC, or the same acronym is used for slightly different, but not

Table 4: Accuracy of acronym disambiguation using small context for complete models and models with restricted set of word embeddings.

Model	*all words*	*intersection*
Distr. Sim. – Google News	0.71	0.64
Distr. Sim. – Own vectors	0.84	0.83

identical concepts, like IPSO for *Improved Particle Swarm Optimization* and *Iteration Particle Swarm Optimization*.

Table 3 gives two typical examples of errors. The first example has a very misleading context. While words like *water* and *ocean* are not very typical for cell experiments, at the same time the word day, that is part of the alternative definition, occurs several times in the context. The second example is a typical case for acronyms from related disciplines and a context that is too short and general to find the correct definition.

Our impression is, that about 2% to 5% of the examples are erroneous, problematic or simply do not have enough information to disambiguate the acronym. Thus the upper bound for the accuracy would be around 0.95. Our result of 0.86 is already very close to this.

6.2 Quality of embeddings vs. number of embeddings

Finally we wanted to see whether we get better results because we have word embeddings for more (corpus specific) words, or because the word embeddings trained on the specialized corpus are better suited for our purpose. To get more insight in this question, we repeated the tests in Table 2 using only words that have an embedding in our model and in the Google News model. There are only 60,940 tokens that are shared among both models. The huge drop in the amount of words in our model (originally embeddings for 1,367,648 tokens) can be explained by the fact that we computed embeddings for many number, symbols, etc. The results for the repeated experiment using only words common to both models are given in Table 4. We see, that there is hardly any change in the results for our model. Surprisingly, the Google News Model seems to loose a number of important words. Thus we can conclude that the better results can be explained by the fact that the word embeddings in the specialized model better reflect the meaning of the words in our corpus of scientific papers.

6.3 Results with high confidence

Figure 4 suggests that we can achieve an accuracy of over 0.95 if we only consider cases in which the difference between the cosine similarities is at least 0.1. (Of course the exact value should be determined using an independent data set). This way we can still classify over 76% of all examples. Thus we can resolve a large number of acronyms in our database. However, we have to keep in mind that for most definitions just one example could be found. Thus, the most likely definition of any unresolved acronym is a definition that we have not seen up to now.

7 Conclusion and Future Work

We started our experiment with a very simple method to find definitions of acronyms in scientific papers. Using definitions from other papers we can resolve many unresolved definitions. Nevertheless, an obvious way to improve the overall results of acronym expansion would be to improve the methods to find definitions.

From our point of view the presented method has two aspects that should be improved in future work. While we use advanced methods to compute word representations, for a text we simply take the (weighted) average of the word representations. We will learn text representations with neural nets in future as well. A consequent next step then would be to learn text similarity as well.

The present result encourages us to follow this way, since we have shown (1) that training word embeddings on our own corpus gives much better results than using standard word vectors and that

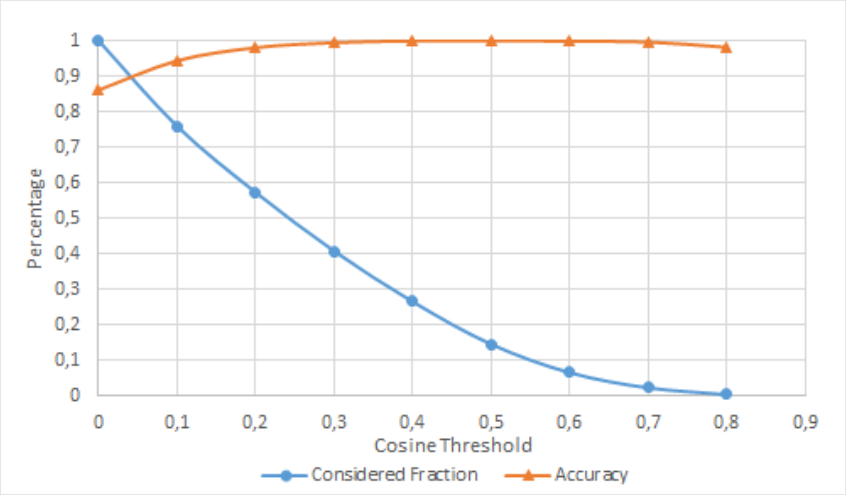

Figure 4: Fraction of classified pairs and accuracy when only examples with a difference between the cosine values above a given threshold are considered.

(2) we can obtain very good results for domain independent acronym disambiguation using these word embeddings.

Acknowledgments

The presented work was developed within the NOA Project - Automatic Harvesting, Indexing and Provision of Open Access Figures from the fields of Engineering and Technology Using the Infrastructure of Wikimedia Commons and Wikidata - funded by the DFG under grant number 315976924. NOA is a cooperative project of the Hochschule Hannover and the Technische Informationsbibliothek Hannover.

Abstract

In this article, we discuss which text, speech, and image technologies have been developed, and would be feasible to develop, for the approximately 60 Indigenous languages spoken in Canada. In particular, we concentrate on technologies that may be feasible to develop for most or all of these languages, not just those that may be feasible for the few most-resourced of these. We assess past achievements and consider future horizons for Indigenous language transliteration, text prediction, spell-checking, approximate search, machine translation, speech recognition, speaker diarization, speech synthesis, optical character recognition, and computer-aided language learning.

1 Introduction

There are approximately 60 Indigenous[1] languages from 10 distinct language families (Rice, 2008) currently spoken in Canada. Several of these languages have tens of thousands of speakers and are still acquired by most children, whereas others have a few tens or hundreds of mostly-elderly speakers; in all, 260,550 report speaking an Indigenous language at at least a conversational level (Statistics Canada, 2016). All of these languages are under significant pressure from English and French, but also have many young people interested in learning. The resurgent strength of community-driven Indigenous linguistic and cultural reclamation in Canada is at the heart of the growing demand for Indigenous language courses, materials and technology.

Indigenous languages are of paramount importance to the nations that speak them and the benefits associated with their use are wide-ranging (Whalen et al., 2016; Reyhner, 2010; Oster et al., 2014; Marmion et al., 2014). As a specific example, research in psychology has shown a compelling correlation

[1] In this document, "Indigenous languages" will specifically refer to Indigenous languages spoken in Canada.

Proceedings of the 27th International Conference on Computational Linguistics, pages 2620–2632
Santa Fe, New Mexico, USA, August 20-26, 2018.

between Indigenous language use and a decrease in youth suicide rates on reserves in British Columbia (Chandler, 1998; Hallett et al., 2007). With increased awareness of these benefits has come increased interest by both Indigenous communities and federal and provincial governments in language technology development, to promote the revitalization and documentation of these languages.

However, the development of Indigenous language technologies faces many challenges: most of these languages are highly morphologically complex, there is relatively little text and speech data available, and there can be significant differences in dialects and orthographies that make it difficult to develop applications that work for all users. Well-known "flagship" language technologies that require large amounts of training data, like machine translation and automatic speech recognition, are therefore probably only feasible to develop for a few of the better-resourced languages such as Inuktitut.

There are nonetheless many practical language technologies that would be feasible to develop for a large number of these languages, and in some cases already have been developed. In this document we assess the feasibility of text (§4), speech (§5), image (§6), and educational (§7) technologies for Indigenous languages, based on past efforts in developing them for these and other low-resource languages.[2]

Disclaimer This document represents the personal opinions of the authors regarding the feasibility of certain technologies, and is not a statement of Government of Canada policy or priorities.

2 Scope and organization

This document will primarily assess user-level applications like search and spell-checking, rather than software that primarily exists to enable linguistic research. This delineation is very approximate, however, as many such applications will have benefits for both kinds of users.

This document also will not be a general inventory of digital resources such as online corpora and lexica. The collection and dissemination of these resources is, of course, highly important and is often the foundational work that makes these technologies possible; it is just that such an inventory would be outside the scope of a document of this size.[3]

In terms of organization, technologies will be clustered from the point-of-view of the practical application of a technology (e.g., spell-checking or text prediction), rather than be organized by the computational model that makes the application possible (e.g., a finite-state transducer or statistical language model). A finite-state grammar of a language (e.g. Snoek et al. (2014), Dunham (2014), Arppe et al. (2017a), Bowers et al. (2017), Harrigan et al. (2017)) can power a number of practical applications from spell-checking, to morphologically-aware search and browsing of dictionaries and corpora, to computer-aided language learning (Arppe et al., 2016).

This document will categorize technologies into five groups, according to the feasibility of developing these for a wide range of Indigenous languages, ranging from "already available" to "infeasible for most languages" (§8). It should be emphasized that these are not ratings of desirability, impact, worthiness for funding, or the relative importance of these technologies to language communities. By contrast, Krauwer (2003) proposed BLARKs - Basic Languages Resource Kits that list basic language technologies and resources needed for successful support and further research of under-represented languages in the European context. Arppe et al. (2016) extend the model to define resource and application priorities for the endangered languages of Canada - EL-BLARK (BLARK for Endangered Languages). This survey finds many similarities with the applications proposed by Arppe et al. (2016).

3 General challenges

There are many challenges that are commonly encountered during the development of Indigenous language technologies, and are encountered in almost all Indigenous languages.

[2]The inventory of existing technologies presented here is likely incomplete, as many language technologies are not published academically or publicized outside of their communities.

[3]An extensive inventory of open-source resources, in both Indigenous and other languages, is available at `github.com/RichardLitt/endangered-languages`. There are also a number of Indigenous language education and reference apps on the iOS App Store and Google Play; Animikii (`www.animikii.com`) maintains a growing list of these at `www.animikii.com/blog/apps-for-learning-an-Indigenous-language`.

3.1 Morphological complexity

Indigenous languages are typically very morphologically complex, with most being polysynthetic or agglutinative. It is commonly the case that a single word carries the meaning of what would be an entire clause in English and French.

(1) *iah th-a-etsi-te-w-ate-wistohsera-'tarih-á:t-ha-k-e'*
no NOT-WOULD-AGAIN-WE-ALL-OWN-butter-HOT-CAUSE-HABIT-CONTIN-PERF.

'We will no longer keep heating up our butter.' Mohawk (Mithun, 1996, p. 170)

(2) *Qanniqlaunngikkalauqtuqlu,* *aninngittunga*
qanniq-lak-uq-nngit-galauq-tuq-lu, ani-nngit-junga
snow-a.little-frequently-NOT-although-3.IND.S-and go.out-NOT-1.IND.S

'And even though it's not snowing a great deal, I'm not going out.'
Inuktitut (Micher, 2017, p. 102)

This complexity presents a challenge for many applications and algorithms, especially those that encode assumptions about the atomic word being the basic unit of meaning/structure, or even the assumption that concatenative morphological analysis is sufficient for finding sub-word units (Arppe et al., 2017a).

3.2 Limited training data

For most languages, there is little to no digitized text or audio available for use as training data, at least not at the scale required for modern statistical or neural NLP. Existing technologies for Indigenous languages have therefore, with a few exceptions, been exclusively rule-based.

A further problem related to the lack of training data is that available training data often comes from only a single domain. For example, the bulk of Inuktitut parallel text comes from Nunavut Legislative Assembly transcripts, but this genre is highly self-similar, and the application of a machine translation system trained on this corpus will likely have difficulties translating other genres like conversation or literature.

A promising research frontier to address limited training data is multilingual modeling; many of the least-resourced Indigenous languages are reasonably closely related to a more-resourced language. For example, automatic speech recognition in Seneca could be trained in part on other Iroquoian languages like Mohawk and Oneida (Jimerson and Prud'hommeaux, 2018), since they have similar phonetic inventories but more available speech data.

3.3 Dialectal and orthographic variation

Most Indigenous languages have a variety of dialects, but often sources and research articles only represent one dialect, or the orthographic standards were developed for a particular dialect and it is unclear how they apply to related dialects. It is sometimes the case that the roadblock to providing technology more widely in a language community is that the dialectal situation is poorly understood, and more basic research on dialectal differences is needed.

Furthermore, even within a single dialect, published works can use a variety of orthographies, and even works using the same orthography often differ in the details such as the encoding of particular diacritics or which morphemes/enclitics are written as separate words or joined. This variety can even be seen in single works, such as those with multiple contributors or transcribers.

Dialectal and orthographic variation pose a particular problem to rule-based text processing systems, since these are usually based on one relatively-well-studied dialect and use particular writing conventions that user-contributed data do not always share. A promising frontier of research to address this, as seen in Micher (2017), is to begin with an existing rule-based system and use it to bootstrap a statistical or neural system (in this case a recurrent neural network) that is more robust when faced with noisy data and unknown morphemes.

4 Text technologies

4.1 Fonts and keyboard layouts

Given the widespread adoption of Unicode and a substantial expansion of character coverage in standard Windows and MacOS fonts like Times New Roman, font coverage of Indigenous languages is currently very good so far as desktop operating systems are concerned. Both Windows and MacOS ship with the Euphemia font for Canadian Aboriginal Syllabics (§6.2), although for some languages Euphemia can display incorrect character orientations[4].

Special Roman characters, diacritics, and Syllabics are not always supported by system-installed keyboard layouts, necessitating the development of custom keyboard layouts. Fortunately, keyboard layout coverage of Indigenous languages is extensive; LanguageGeek[5] provides Windows and MacOS keyboards in almost every Indigenous language, while Tavultesoft Keyman[6] and FirstVoices[7] have developed keyboards for iOS and Android that offer complete coverage of Indigenous languages as well as support for other non-Indigenous languages.

4.2 Predictive text

One common request concerning keyboards (particularly mobile keyboards) is "predictive text" or "autocomplete", in which the keyboard offers shortcut buttons that suggest probable next words to the user depending on what they have already typed. This technology is especially desirable because it appeals to young users as well as to advanced second language learners.

The Multiling O[8] keyboard app for Android offers dictionary-based predictive text in the SENĆOŦEN language.

Maheshwari et al. (2018) examine word and character-based language models for text prediction of Mi'kmaq, based on a small web corpus.

Given the relative paucity of digital text corpora for many languages, it is likely that most predictive text systems will not be able to rely entirely on statistical models, and will instead be built on rule-based (e.g. finite state) or hybrid statistical/rule-based systems.

4.3 Orthography conversion

Almost all Indigenous languages have been written in several different orthographies. While there is a general trend towards orthographic unification in most communities, it is still common to find geographical or generational differences in how languages are written.

Conversion between modern orthographies is generally straightforward, and there exist many applications that manage these conversions[9,10,11,12,13,14]. Conversion between historical and modern orthographies can be more difficult, as historical orthographies often made different assumptions about the vowel and consonant inventories of these languages. There exists a rule-based transliterator between historical and modern Kwak'wala text[15], but the correspondences are somewhat irregular and thus the results are not completely reliable.

4.4 Spell-checking

Although Indigenous languages of Canada have a relatively short tradition of writing, it is quickly gaining steam, especially among young users and learners. However, writing—especially writing "correctly"

[15] orth.nfshost.com/?lang=kwk&input=umista&output=boas

according to official community standards—can be particularly difficult for English- or French-dominant writers, since it requires making sound distinctions that English and French lack. Spell-checking is therefore a frequently-requested technology.

Since all Indigenous languages are morphologically complex, a purely word-list based spell-checking system is typically infeasible; a given stem can have hundreds or even millions of possible derivations/inflections. Corpus-based spell-checkers would have a similar problem; even when a digital corpus is available, only a small fraction of possible derivations/inflections will occur it. Therefore, efforts to develop spell-checkers in Indigenous languages typically concentrate on finite-state technology, since this allows the specification of very large lexicons in an efficient and succinct manner.

A Plains Cree spell-checker based on FST technology is available for system-wide use in recent versions of MacOS, and versions for Microsoft Office and Libre Office are in development (Arppe et al., 2016). The Giella infrastructure (Moshagen et al., 2013) offers an easy way to create FST-based spell-checkers that can be integrated into LibreOffice and, to a limited extent, into Microsoft Office. The spell-checkers use finite-state transducers as a backend, but it is possible to specify spelling relaxations as well as to include modules for likely or common errors. Theoretically the framework allows other types of language models as well, but they have been relatively untested.

An unexpected problem with integrating spell-checkers into mainstream office software is tokenization, since some Indigenous languages use commas, colons, and apostrophes to indicate phonetic differences, whereas many text processing systems assume internally that these are token boundaries. This points to a need for more flexible tokenization within mainstream office software to accommodate these languages.

4.5 Paradigm generation

It has generally been acknowledged that effectively teaching polysynthetic languages requires teaching morphology (Kell, 2014). Since all Indigenous languages have complex verb morphology, one frequent educational need is verb conjugators (Junker and MacKenzie, 2010; Junker and MacKenzie, 2011; Baraby and Junker, 2011; Arppe et al., 2017b), either stand-alone or integrated into an online dictionary.

For most Indigenous languages, learning morphology automatically from corpora is not a viable option. However, symbolic systems, especially those based on finite-state transducers (FSTs) have been successfully implemented for a number of languages. For example, Arppe et al. (2017b) developed an FST for East Cree by leveraging a lexical database. Arppe et al. (2016) and Arppe et al. (2017a) do not release stand-alone verb conjugators, but make verb conjugations available as a part of morphologically-aware online dictionaries for Plains Cree and Tsuut'ina languages respectively.

4.6 Approximate search

Approximate (or "fuzzy") search is a key language technology in situations where the language has not been widely written, or where a large proportion of technology users are learners. Moreover, whole-word search is problematic in highly polysynthetic/agglutinative languages, since the user's query may not use the inflectional form that appears in the dictionary or corpus. Both of these situations are common for Indigenous languages, and therefore the incorporation of approximate search is appropriate in nearly any text technology for these languages.

In general, approximate search can be done in a language-independent way—i.e., by simply counting the number of deletions, insertions, changes, and transpositions (Damerau, 1964; Levenshtein, 1966), without consideration of any language-specific properties—and can be done efficiently even on a large lexicon (Schulz and Mihov, 2002). There are three ways the user experience can be further improved for a particular language: by adapting to actual user queries, by building phonetic knowledge into the system, by making the search aware of morpheme breakdowns.

The East Cree[16] and Innu[17] dictionaries utilize relaxed search rules based on users' habits (Junker and Stewart, 2008).

[16] `dictionary.eastcree.org`
[17] `dictionnaire.innu-aimun.ca`

Mother Tongues Dictionaries[18] incorporates phonological background knowledge (e.g., that two sounds are similar and likely to be confused by users) in a finite-state approximate phonological search algorithm (Littell et al., 2017). It concentrates on Pacific Northwest languages where, due to the extensive consonant inventories and phonological complexity of these languages, approximate search is particularly important. This algorithm powers the search function in e-dictionaries for 17 Indigenous languages spoken in British Columbia, including FirstVoices'[19] mobile dictionary applications for iOS and Android, with dictionaries for 11 more languages currently in development.

Morphologically-aware search allows the user to find instances of their search query that may differ in one or more morphemes(Johnson et al., 2013). The Giella infrastructure offers morphology-aware search in dictionaries that are generated by linking a morphological model with lexical resources (and possibly with text corpora). A user can search with any inflected word form of a lemma (or root), possibly taking into account common spelling errors and spelling relaxations (Moshagen et al., 2013). Snoek et al. (2014) and Harrigan et al. (2017) use this technology to allow searching a dictionary of Plains Cree for specific lemmas. Similar capabilities exist for East Cree (Arppe et al., 2017b), Tsuut'ina (Arppe et al., 2017a), Northern Haida (Lachler et al., 2018) and Odawa (Bowers et al., 2017).[20]

4.7 Machine translation

Machine translation is one of the best-known language technologies, and receives significant attention from academia, industry, and the general public, so one of the more common queries from Indigenous groups is whether machine translation would be feasible for their languages.

The current state-of-the-art of machine translation is relatively language neutral, but requires very large amounts of parallel text, which is currently unavailable in most Indigenous languages save Inuktitut. Even then, given the complexity of Inuktitut morphology and the limited corpus available, it is probable that such systems will be, at best, aides to human translators working within that domain, rather than a general-purpose consumer technology like Google Translate.

Several prerequisite steps for Inuktitut machine translation have been achieved, including morphological segmentation (the Uqailaut analyzer[21] and its neural generalization (Micher, 2017)), and sentence and word-level alignment (Martin et al., 2003; Langlais et al., 2005). There are several Inuktitut-English machine translation systems currently under development.

The prerequisite steps can themselves power practical technology. For example, the WeBInuk translation memory system, an adaptation of the WeBiText system (Désilets et al., 2008) mines Inuktitut-English text and uses word alignments to suggest translations to Inuktitut translators.

5 Speech technologies

There has been little development of Indigenous language speech technology so far, but consultation with language communities has suggested that speech technologies are greatly desired, as these languages and cultures are traditionally oral. Text technologies typically expect the user to be able to write their language using the same conventions that the developer expects, which is a problematic expectation in languages without widespread agreement about written conventions. Speech technologies therefore offer an attractive proposition for users more accustomed to speaking and hearing their language than writing and reading it.

5.1 Automatic speech recognition

Full-vocabulary automatic speech recognition (ASR) currently requires large amounts of transcribed audio, and is therefore unlikely to be feasible in most Indigenous languages for the foreseeable future, at least not at a high degree of accuracy. However, even a low degree of accuracy can significantly assist human transcription; this technology, sometimes called Transcription Acceleration (TA), would probably be feasible for at least some languages now.

[18] mothertongues.org
[19] firstvoices.com
[20] altlab.artsrn.ualberta.ca/tools-applications/
[21] www.inuktitutcomputing.ca/Uqailaut/info.php

Jimerson and Prud'hommeaux (2018) has developed a preliminary ASR system for the Seneca language, and the Persephone ASR (Adams et al., 2018) system is being adapted to provide transcription acceleration within the Dative Online Linguistic Database interface (Dunham, 2014), which currently powers dozens of Indigenous language documentation efforts in Canada.

The frontier in speech recognition that is most promising for low-resource languages is multilingual recognition, in which a model trained on a large variety of languages can help compensate for a lack of transcribed speech data in the target language. A challenge for multilingual speech recognition is that some Indigenous languages, particularly in the Pacific Northwest, are global outliers in terms of phonological complexity, with large consonant inventories, rare consonants such as [t͡ɬ], and sometimes long sequences of consonants without the need for intervening vowels. At the very least, the development of practical multilingual recognition models would allow such languages to pool their resources, even if the difference between these and languages outside the region is too great to use a "universal" model.

5.2 Audio keyword search

The primary challenge of ASR in any language is the wide range of inputs the system might encounter—basically, anything that a person might talk about. On the other hand, ASR can also be used to find a *particular* word in an audio recording: the decision is not "what words are these?" but the simpler decision "is this part of the recording an instance of this word?".

This problem, of audio keyword search, is more tractable, but still potentially very useful for making un-transcribed speech recordings more accessible to the public, allowing users to search more quickly through long audio recordings in search of particular words or topics. The National Research Council of Canada (NRC), is collaborating with the Computer Research Institute of Montréal (CRIM) and the Pirurvik Centre on an audio keyword search project for Canadian Broadcasting Company (CBC) radio broadcasts in the Inuktitut and Cree languages.

5.3 Speech/text alignment

Even when resources are too limited to allow full, "open-vocabulary" ASR, prerequisite steps to ASR can be valuable in their own right. One of the prerequisite steps to both ASR and speech synthesis is speech/text alignment (sometimes called "forced alignment"), which involves taking a speech recording and a transcription of it and determining which segments of audio correspond to words and/or phonemes in the transcription.

This intermediate step can itself be of value for education, in creating time-aligned closed-captions from transcribed recordings, and read-along activities such as those available on the East Cree language portal[22] (Luchian and Junker, 2004; Junker et al., 2016) and in the Inuktitut-language Uqalimaarluk ("Read To Me") app for iPad[23].

5.4 Audio segmentation and speaker diarization

Even if automatic speech recognition ("what was said?") is beyond the means of current technology, speaker diarization ("who spoke when?") can be of great value, helping users to more quickly comb through large amounts of audio data in search of examples by a particular speaker or in a particular language.

The NRC-CRIM collaboration mentioned above (§5.2) will also be developing tools for automatic segmentation and speaker diarization. These are relatively language-neutral technologies that could be used in other languages as well.

5.5 Speech synthesis

The converse of automatic speech recognition, text-to-speech (TTS) is somewhat more feasible in low-resource situations. A limited-domain text-to-speech system (such as a talking clock or public transit announcement system) can be trained with just minutes or hours of total recordings, so long as the samples are adequately representative of the target domain.

[22] www.eastcree.org/cree/en/lessons/sing-along/

[23] itunes.apple.com/ca/app/uqalimaarluk/id1348117314

Interest in text-to-speech has come from communities where interested learners outnumber fluent speakers, such that the learner might want to know how a word is pronounced but does not currently have access to a speaker to model pronunciation for them. Interest has also come from communities working on projects such as talking online dictionaries, in which the inflectional complexity of the language (§3.1) has meant that it is not feasible to record every possible inflection of a word. In such projects, TTS could allow the user to hear the pronunciation of any inflected form of the word, rather than just uninflected stems.

To our knowledge there are not yet any complete speech-synthesis project in an Indigenous language spoken in Canada, but Synscenter Refsnæs and Oqaasileriffik (the Language Secretariat of Greenland) have developed a general-purpose text-to-speech system for Kalaallisut[24] (West Greenlandic), which is closely related to Inuktitut.

Figure 1: Example of a historical printed document in the Northern Haida language (Hubert et al., 2016), and Canadian Aboriginal Syllabics representing the Inuktitut language, courtesy of `tusaalanga.ca`.

6.1 Optical character recognition for Roman orthographies

Optical character recognition (OCR) has been successfully been applied to Indigenous language documents, including historical manuscripts printed using pre-digital presses (Fig. 1). Hubert et al. (2016) report a high degree of success on OCR with only a few pages of training data, suggesting that OCR would be feasible to implement for a wide range of Indigenous languages.

The challenge for OCR on many Roman orthographies for Indigenous languages is the proliferation of diacritics and superscript letters, particularly in languages with extensive consonant inventories. Diacritics and superscripts are difficult to differentiate from punctuation and from each other, and depending on the font resources, some letter-diacritic combinations may be very hard to distinguish. For example, British Columbian orthographies based on the Royal B.C. Museum recommendations often use underlined ⟨g⟩ for a uvular voiced plosive, and in some fonts (or in typewritten documents), this underline can overlap the descender on the ⟨g⟩.

6.2 Optical character recognition for Canadian Aboriginal Syllabics

While most Indigenous languages are written using a Roman orthography, several varieties of Inuktut, Cree, and Ojibwe[25] use a system called Canadian Aboriginal Syllabics (Fig. 1).

Canadian Aboriginal Syllabics (often simply called "Syllabics") is a "rotational syllabary" in which the shape of the glyph indicates the syllable's consonant and its rotational orientation to the vowel. There are also smaller, superscript characters that indicate consonants where no vowel follows (e.g. in a syllable

[24] `oqaasileriffik.gl/langtech/martha/`

[25] Syllabics have also historically been used for Blackfoot and some Athabascan languages such as Dakelh (Carrier), but have fallen out of use in favor of Roman orthographies.

coda). Like superscript characters in Roman orthographies, superscript characters in Syllabics can pose a problem for OCR, since due to their size and position they are easily confused for punctuation marks or with each other. Nonetheless, there have been several successful Syllabics OCR projects (e.g. Posgate and Leekam (2014)), and Inuktitut has since been included in the Tesseract OCR project[26] (Smith, 2007).

7 Computer-aided language learning

7.1 Course modules

Computer-aided language learning (CALL) course modules are widely available for Indigenous languages, particularly through the FirstVoices Language Tutor (FVLT) portal[27], which offers approximately 50 online courses covering many Indigenous languages, with exercises on listening, speaking, reading, and vocabulary development, as well as online language-learning games.

There are also language-specific CALL portals, including but not limited to:

- Tusaalanga[28] from the Pirurvik Centre, which offers exercises in five varieties of Inuktut.
- The Institut Tshakapesh learning portal[29], which offers educational games in the Innu language (Junker and Torkornoo, 2012; Junker et al., 2016). These were modeled after the eastcree.org lessons[30] for teaching syllabics, vocabulary and literacy.
- The *nêhiyawêtân* CALL portal for Plains Cree[31] fuses CALL and text technologies, in which students receive targeted feedback made possible by the integration of a finite-state morphology model (Arppe et al., 2016; Bontogon et al., 2018).
- The Yukon Native Language Centre[32] offers online audiovisual adaptations of language courses in eight Indigenous languages.

Several international CALL products have been adapted for Indigenous languages. 7000 Languages[33] adapts the Transparent Language software for low-resource and endangered languages, and offers courses on Denesuline, Dakota, and several varieties of Cree, Ojibwe, and Oji-Cree through partnerships with Grassroots Indigenous Multimedia[34] and the Manitoba First Nations Education Resource Centre[35]. Rosetta Stone[36] has also developed courses for Labrador Inuttitut and Kahnawá:ke Mohawk.

A forthcoming project headed by Dr. Marianne Ignace at Simon Fraser University presents an innovative "chat-based" UI (what is sometimes called "No-interface UI") for CALL apps, in which an AI tutor interacts with the student in a web-chat-like interface.

7.2 Phonetic tutorial

Some education applications focus more narrowly on the acquisition of speech sounds. Phonetic tutorials are particularly important in languages with rarer sounds, like lateral fricatives or ejective plosives.

The Yukon Native Language Centre[37] has developed a phonetic learning game in which players must count the number of instances of a particular sound (e.g., [t͡ɬ]) in a recording to mush a dog sled.

The Tiga Talk[38] app for iOS, originally a collection of speech-language pathology games for English, is currently being adapted to Cree to help support child acquisition.

[37] ynlc.ca
[38] tigatalk.com/app/

The UBC eNunciate[39] tools use ultrasound to illustrate to students the articulatory gestures of the tongue and vocal tract that cannot ordinarily be seen, in the Upriver Halqemeylem, SENĆOŦEN, Secwepemc, and Blackfoot languages (Bliss et al., 2016).

7.3 Augmented reality and virtual reality

Augmented and virtual reality technologies are not specifically language or learning technologies, but there is a growing amount of interest in their application to Indigenous language education primarily due to their ability to be naturally integrated into popular "place-based eduction" (Sobel, 2004) practices.

The feasibility of implementing augmented and virtual reality projects is aided by the widespread interest in the technology and 3D game engines like Unity and Unreal. However, there are still very few implementations for Indigenous languages in Canada. Some examples include *Tuwitames*, an augmented reality story-telling app narrated in Secwepemctsín (Lacho, 2018), an augmented reality companion app to a Blackfoot card game (Goff et al., 2017), and *Schoolû*, a virtual reality application for teaching Cree syllabics. Yet another augmented reality app, *Wikiup*[40], is designed to take users on tours throughout Canadian cities, transforming landmarks by telling AR-enhanced Indigenous stories and histories, but not necessarily involving Indigenous languages.

8 Summary

Widely available Successful technologies that are already available for many Indigenous languages *Keyboard layouts* (§4.1), *Approximate search* (§4.6), *Computer-aided language learning* (§7).

Ready for wider implementation Technologies that have been developed for some languages, and that could feasibly be developed for most or all Indigenous languages: *Orthography conversion* (§4.3), *Optical character recognition* (§6.1, §6.2).

Awaiting implementation Technologies for which there is already a technological basis in a few languages (e.g., a finite-state analyzer has been written), or for which there exists a language-neutral technological basis, but for which practical user interfaces or language-specific implementations are not yet developed or widely available: *Spell-checking* (§4.4), *Paradigm generation* (§4.5), *Speech/text alignment* (§5.3).

Experimental Technologies that have not yet proven to be successful on Indigenous languages, but show promise in other low-resource language situations: *Predictive text* (§4.2), *Transcription acceleration* (§5.1), *Audio keyword search* (§5.2), *Audio segmentation and speaker diarization* (§5.4), *Text-to-speech* (§5.5).

Restricted feasibility Technologies that will likely be feasible only in more-resourced languages (e.g. Inuktitut, Cree): *Machine translation* (§4.7), *Automatic speech recognition* (§5.1).

From the above, it is clear that there are a number of text, speech, image, and CALL technologies that are either already available, or could be made more widely available, in many cases with relatively reasonable further investment. The boundary between the first three categories at various stages of implementability and the two last experimental and restricted ones appears to determined by the existence of technological solutions that work with typically quite sparse data resources that can be reasonably expected for Indigenous languages. Meanwhile, new developments (particularly in multilingual and finite-state/neural hybrid modeling) may make technologies possible that until recently seemed infeasible for Indigenous languages.

Abstract

Text generation may require the pluralization of nouns, such as in context-sensitive user interfaces and in natural language generation more broadly. While this has been solved for the widely-used languages, this is still a challenge for the languages in the Bantu language family. Pluralization results obtained for isiZulu and Runyankore showed there were similarities in approach, including the need to combine morphology with syntax and semantics, despite belonging to different language zones. This suggests that bootstrapping and generalizability might be feasible. We investigated this systematically for seven languages across three different Guthrie language zones. The first outcome is that Meinhof's 1948 specification of the noun classes are indeed inadequate for computational purposes for all examined languages, due to non-determinism in prefixes, and we thus redefined the characteristic noun class tables of 29 noun classes into 53. The second main result is that the generic pluralizer achieved over 93% accuracy in coverage testing and over 94% on a random sample. This is comparable to the language-specific isiZulu and Runyankore pluralizers.

1 Introduction

The need for generating plurals to ease the use of software tools is well known in several areas. In Natural Language Understanding, plurals are used during parsing to distinguish between atomic elements (simple nouns) and collectives (Schubert, 2015), while in Natural Language Generation, pluralization is essential during quantification (Schubert, 2015) and number agreement. For instance, to inflect properly for the grammatical number in end-user tools, like a calendar properly stating to set off an alarm "1 hour" before and not "1 hours", but also for more advanced tools, such as automatically generating patient discharge notes instructing how many pills the patient has to take. Automated pluralization may use regular expressions of the ending of the nouns, alike for English (Conway, 1998), or extensive linguistic resources to devise pluralization, as for German (Nakisa and Hahn, 1996).

Pluralization for Runyankore and isiZulu, members of the Bantu language family, showed that neither of the above approaches were feasible. It required a combined morphology with syntactic and semantic approach, where the latter was covered by using a combination of the noun and noun class to pluralize, along with a few similar refinements of Meinhof's noun class definition (Byamugisha et al., 2016). A surprising observation was that a similar approach could be used despite the regions where these languages are spoken being thousands of kilometers apart (Uganda and South Africa) and they belong to different Guthrie zones (Guthrie, 1948; Maho, 2009). This suggests there may be sufficient similarities not only for closely related languages, but also for languages in other Guthrie zones.

We thus aim to investigate the generalizability of pluralization for Bantu languages, specifically those with an agglutinating morphology. The following questions guided this investigation:

Q1: Is a combined morphology with syntactic and semantic approach needed to pluralize nouns in other agglutinating Bantu languages as well?

Proceedings of the 27th International Conference on Computational Linguistics, pages 2633–2643
Santa Fe, New Mexico, USA, August 20-26, 2018.

Q2: Are the limitations identified in Meinhof's noun class system for automated pluralization in Runyankore and isiZulu (Byamugisha et al., 2016) present in other agglutinating Bantu languages? If so, how can Meinhof's noun class system be revised systematically?

Q3: Are the same 'exceptions' to pluralization found in other agglutinating Bantu languages, and if so, are the solutions used for isiZulu and Runyankore able to pluralize the same exceptions in these languages?

Q4: In attempting to develop a generic pluralizer, how can the language-specific pluralizers be generalized whilst maintaining roughly the same accuracy?

In order to answer these questions, we investigated the generalizability of the Runyankore and isiZulu approach to agglutinating Bantu languages, both within the same Guthrie zone and across zones. Five agglutinating Bantu languages were selected: two of these, Luganda and isiXhosa, belong to the same zone as Runyankore and isiZulu, respectively, and the rest belong to other zones, being Kinyarwanda (J.10), Kikuyu (E.10), and chiShona (S.10) (Maho, 2009).

We first examined their grammatical structures (Déchaine et al., 2013; Zentz, 2016; Mberi, 2002; Jeon et al., 2015; Baertlein and Ssekitto, 2014; Kimenyi, 2004; Taraldsen, 2010), which revealed that a combined morphology with syntactic and semantic approach, where the noun and its noun class are provided as input, is also required for pluralization. This is principally because there are nouns that have the same prefix but are pluralized differently, due to belonging to different classes. Further, Meinhof's 1948 noun class tables of singular/plural pairs is underspecified as to which option is used when. Therefore, we have revised the tables so as to achieve a deterministic selection during pluralization. Further, the same exceptions to pluralization identified for Runyankore and isiZulu (Byamugisha et al., 2016) were present in each of the five languages, and the same solutions were also applicable. Finally, we developed a pluralizer that can pluralize nouns in agglutinating Bantu languages, with generic pluralization rules but language-specific resources, which achieved similar accuracies as Byamugisha et al., (2016)'s language-specific pluralizers.

This paper is arranged as follows. We briefly introduce relevant aspects of Bantu languages in Section 2. Section 3 justifies why Meinhof's noun class system should be redefined, and describes the revised noun class tables. The generic pluralizer is presented in Section 4 and it is evaluated in Section 5. We discuss in Section 6 and conclude in Section 7.

2 Basics of Bantu Languages

Bantu languages are a group of languages indigenous to Africa, from the south of Nigeria, covering most of central, east, and southern Africa (Nurse and Philippson, 2003). There are Bantu language speaking communities in 27 of the continent's 54 countries, about 240 million speakers, and number of languages ranges from 300 to 680 (depending on the criteria used (Nurse and Philippson, 2003). They are agglutinating, have concordial agreement systems, and all nouns are assigned to a noun class (NC). There are over 20 noun classes, although most languages use fewer (Nurse and Philippson, 2003; Mohlala, 2003). A NC is characterized by a class prefix, a specific singular/plural pairing, and agreement with other constituents (Zentz, 2016; Nurse and Philippson, 2003). The semantic generalizations of the type of nouns in each NC are shown in Table 1 (Keet and Khumalo, 2014; Baertlein and Ssekitto, 2014; Kimenyi, 2004; Jeon et al., 2015; Zentz, 2016; Taraldsen, 2010; Mohlala, 2003).

Bantu languages are conventionally categorized into 16 zones, referred to as Guthrie zones, which are further subdivided into decades; for example, zone J.10 contains languages from J.11 to J.19 (Nurse and Philippson, 2003; Maho, 2009). We selected five languages from five different zones, and their grammars formed the basis of whether a generic pluralizer could be developed. These 5 languages were selected because: (1) they are widely used in their native countries; (2) their linguistics are taught at university level; and (3) they are actively researched, which provides current documentation. Table 2 summarizes the findings into the grammatical features of interest.

The NC classification for each of these languages is based on Meinhof's NC definition, which places the plural form of a noun in a different class from its singular (Nurse and Philippson, 2003; Mohlala, 2003). This is deemed as a standard for defining NCs among linguists, as it facilitates cross-language

Noun Class	Description of nouns typically found in those classes
1 and 2	People and kinship
3 and 4	Plants, nature, and some parts of the body
5 and 6	Fruits, liquids, some parts of the body, loan words, and paired things
7 and 8	Inanimate objects
9 and 10	Loan words, tools, and animals
11	Long thin stringy objects, languages, and inanimate objects
12 and 13	Diminutives
14	Abstract concepts
15	Infinitive nouns
16, 17, and 18	Locative classes
19	Diminutives
20, 21, and 22	Augmentative
23	Locative class

Table 1: Classification of nouns into noun classes.

Language	Guthrie Zone	Number of NCs	Phonological Conditioning
chiShona	S.10	20	Yes, with VC, VE, and VH
isiXhosa	S.40	15	Yes, with VC and VE
isiZulu	S.40	17	Yes, with VC and VE
Kikuyu	E.50	17	Yes
Kinyarwanda	J.60	16	Yes, with VC and VE
Luganda	J.10	21	Yes, with VC and VE
Runyankore	J.10	20	Yes, with VC, VE and VC for VH

Table 2: Relevant features of the selected languages; VC: vowel coalescence; VE: vowel elision; VH: vowel harmony.

comparisons and use (Chavula and Keet, 2014). Further, as noted, the NC determines the agreement markers on the associated lexical categories such as adjectives and verbs. Moreover, there are NCs with the same class prefix but belonging to different NCs (Déchaine et al., 2013; Zentz, 2016; Mberi, 2002; Jeon et al., 2015; Baertlein and Ssekitto, 2014; Kimenyi, 2004; Taraldsen, 2010), which are highlighted in Table 3.

We identified grammatical differences among these languages, which makes the use of the exact same pluralizer impossible: (1) each language has its own lexicon of prefixes, (2) they do not have the same number of NCs; and (3) the rules for phonological conditioning and verbal morphology are language-specific (Mberi, 2002; Jeon et al., 2015; Ferrari-Bridgers, 2009; Muhirwe, 2007; Kimenyi, 2004; Taraldsen, 2010). Regarding the latter, examples include: Runyankore uses vowel coalescence and elision next to a nasal compound (such as '*nk*'), while Luganda uses vowel elision; and in Runyankore, Luganda, and isiZulu, *-u-* + vowel may become *w* (such as *ulu-* + *-azi* = *ulwazi* 'knowledge' in isiZulu), which is not the case in Kikuyu and chiShona. Nonetheless, the noted grammatical similarities among these languages are expected to be sufficient for the generalizability of the pluralization approach.

However, Meinhof's NC definition (Table 3) has several limitations when applied to computational tasks, which impede pluralization and generalizability:

1. Meinhof's NC tables lack the specification for some rules and when to apply them, especially for lesser known cases. In isiZulu, for example, the standard NC1 and NC3 singular prefix is *um*, with its plural prefix *aba* in NC2 and *imi* for NC4 (Byamugisha et al., 2016), yet for NC1 nouns whose stem commences with *a, e, i*, or *o* the plural prefix *ab* is used instead (Byamugisha et al., 2016).
2. The rules for the pluralization of some nouns deviate from those according to Meinhof's NC definition, such as mass nouns (which are neither pluralized no singularized) and prefix exceptions

NC	chiShona	isiXhosa	isiZulu	Kikuyu	Kinyarwanda	Luganda	Runyankore
1	**mu-**	**u-m-**	**u-m-/u-mu-**	**mu-**	**u-mu-**	**o-mu-**	**o-mu-**

23	N/A	N/A	N/A	N/A	N/A	**e-**	N/A

Table 3: Standard NC classification by singular/plural pair (first line and the [2nd/3rd] line, respectively), highlighting the same prefixes across more than one NC for a language. The dashes between the letters in the prefix illustrate separation between the initial vowel (augment) and prefix; '-': empty prefix; 'N/A': the NC is not present in that language (none use NC19 or NC22).

(whose plural NC is different from the standard pairings). Byamugisha et al., (2016) handled this by placing an 'm' on the NC, while prefix exceptions were directly associated with their plurals.

Therefore, we investigated revising Meinhof's NC definition for other agglutinating Bantu languages within and across Guthrie zones.

3 Reclassification of Meinhof's 1948 Noun Class Specification

We investigated the presence of the limitations in Meinhof's NC definition by identifying whether a deterministic output could be achieved based on the standard NCs, and investigating whether the same limitations for mass nouns and prefix exceptions identified for Runyankore and isiZulu exist in the other five selected languages. We found that, there are also NCs that have more than one possible class prefix; e.g., NC7 has three prefixes in Kinyarwanda: *iki* pluralized with *ibi*, *icy* pluralized with *iby*, and *igi* pluralized with *ibi* and NC5 and NC9 both have *i* as a prefix. This makes the rules on pluralization non-deterministic. Additionally, each of these languages classified some mass nouns in singular NCs, which would result in them being incorrectly subjected to pluralization. We thus found it necessary to refine Meinhof's NC definition in order to ensure a deterministic output during pluralization.

There are several alternatives in which this revision can be done: (1) morphologically (and syntactically for compound nouns), where each different class prefix is reclassified as a subdivision of the general class, with the subdivision indicated with roman numerals, such as, NC5, NC5i, etc.; (2) semantically, which would account for special categories of nouns such as mass nouns, singular-only nouns, and prefix

Table 4: Reclassified noun classes. The first line in each pairing is the singular and the other line(s) its plural class (if more than one line is paired, the one with the prefix is applicable, or it is N/A); '-': empty prefix; 'N/A': NC is not present in that language.

exceptions; and (3) revising the entire NC classification to account for all fine-grained details on class prefixes, concords, and agreement.

Options (2) and (3) require extensive linguistic analysis of each language, such as that presented by Taraldsen (2010) for Nguni languages. Such analyses are beyond the scope of our work and left to linguists to complete. For immediate computational needs, we thus applied a morphological with syntactic approach to the reclassification. The details on concordial agreement (subject, object, adjective, and possessive concords) are still maintained in our reclassification, enabling its application in other generation processes (such as verb conjugation) beyond pluralization. Our reclassification ensures that there is always a one-to-one singular-plural mapping, hence, ensuring a deterministic outcome. Table 4 presents the reclassified NC definition; the new classes added are those with one or more 'i' after the number.

This resultant reclassified NC definition demonstrates the pluralization rules that Meinhof's NC definition does not. For example, in Luganda, NC 1ii contains nouns that denote kinship, such as mother (*maama*) and father (*taata*); they are pluralized in NC 2ii, ***ba****maama* and ***ba****taata* respectively.

More generally, this reclassification of the NC definition clarifies the rules for pluralization, resulting in a deterministic output. We used similar prefix features among languages to guide our reclassification, based on the following:

(1) Most NCs whose prefix ends in *u* (NCs 1, 3, 11, 13, 14, 17, and 20) have nouns that have *w* instead; this then becomes the new NC, as is the case with NCs 1i, 3i, 11i, 13i, 14i, 17i, and 20i;
(2) Some NCs whose prefix ends in *i* (NCs 7 and 8) also have nouns whose prefix ends in *y*, and this forms the new NC (7i and 8i);
(3) Nouns without prefixes in the singular and/or plural, which were previously not classified in Meinhof's NC definition, are placed in a new NC with '*ii*' such as NCs 1ii, 9ii, and 10ii; NC 2ii is the pairing for 1ii; and
(4) Languages with NCs with multiple prefixes but that do not fit the above criteria, use the standard prefix in the original class, but the alternative prefix in the new class; such as NCs 7 (*ki-*), 7i (*gi-*), 12 (*ka-*), 12i (*ga-*), 15 (*ku-*), and 15i (*gu-*) in Kikuyu.

4 Implementation of Generic Pluralizer

The decision of how to implement the generic pluralizer was based on research into three approaches for multilingual noun pluralization: Grammatical Framework (GF) (Ranta, 2011), SimpleNLG (Gatt and Reiter, 2009), and the pluralizer in Byamugisha et al., (2016). GF and SimpleNLG support multiple languages from different language families, while the pluralizers by Byamugisha et al., (2016) are very accurate for two agglutinating Bantu languages, isiZulu and Runyankore.

Grammatical Framework (GF) is based on type theory and functional programming; it uses distinct functions for singulars and plurals, and linearization rules to handle the language-specific inflectional forms of nouns during pluralization (Ranta, 2011; Ranta et al., 2015). It requires a large resource grammar. An attempt to develop such a resource grammar for Kiswahili (regarded as a Bantu language, with the same NC system that determines noun pluralization, and not as computationally under-resourced) only introduced some parameter types (Ngángá, 2011), but still has no resource grammar. There is thus no existing GF resource grammar for any Bantu language.

SimpleNLG is an NLG realizer with a Java API, where pluralization is achieved through the language-specific lexicon saved as an XML file (Gatt and Reiter, 2009). The lexicon contains 'words' in their base form, as well as attributes for their 'category' (such as noun, verb, adjective, etc.), 'id' for a unique identifier, and 'plural' (Mohamood, 2016). The plural is obtained by creating an inflected word element around the base form, adding appropriate features to it (such as 'plural' or 'past participle'), and then realizing it (Mahamood, 2015).

Byamugisha et al., (2016) developed two separate pluralizers, for isiZulu and Runyankore. They are based on a combined semantic and syntactic approach with morphology, where the semantics of the noun are determined by its NC, and the appropriate plural prefix replaces the singular prefix. This approach requires that the NC, together with the noun, is passed to the pluralizer in order to obtain the correct

plural. The importance of including the NC with the noun during pluralization can be seen in the increase in accuracy for especially the isiZulu nouns, which improved from about 50% correct pluralization for the noun-only pluralizer to about 85% by passing on the NC with the noun, while it increased it from 88% to 92% for Runyankore (Byamugisha et al., 2016). This effect is due to more or less NCs having the same prefix (recall Table 3).

The GF approach requires the definition of a large resource grammar for each language (Ranta, 2011). The attempt to develop one for Kiswahili showed the difficulties with adopting the GF parameter types to fit the grammar of Bantu languages; for example, the NC was represented as the Gender type (Ngángá, 2011). As no resource grammar was derived from these definitions, there is no way to know whether this is sufficient for pluralization and other generation tasks for Bantu languages. For SimpleNLG, the use of a lexicon for pluralization requires that both the singular and plural forms be stated for each word in the lexicon (Gatt and Reiter, 2009; Mohamood, 2016). We found this approach undesirable, as our aim is to generate the plurals, not manually declare them for each noun.

We therefore decided to develop the generic pluralizer based on the approach by Byamugisha et al., (2016), because the NC reclassification in Table 4 provides one singular prefix with one plural prefix for all these languages, and is thus generalizable to other agglutinating Bantu languages, and the need for the NC-based pluralization of compound nouns in (Byamugisha et al., 2016) also holds for other agglutinating Bantu languages.

Additionally, Byamugisha et al., (2016) identified several nouns that did not conform to the NC rules on pluralization, and referred to them as 'exceptions'. These exceptions were handled in three ways: (1) mass nouns (whose NC was marked with an '**m**'); (2) prefix exceptions, which were placed in a separate look-up file with their correct plural; and (3) singular-only nouns that were also placed in a separate look-up file. These same approaches were applied to the five selected languages, and were able to correctly handle these exceptions.

The design of the generic pluralizer thus comprised the following core rules:

(1) Providing a singular noun and its NC, so as to obtain its plural prefix based on its NC;
(2) Ensuring that mass nouns and singular-only nouns are not pluralized;
(3) Obtaining the plural of the main noun, and its plural agreement, during the pluralization of compound nouns (excluding those with adjectives); and
(4) Correctly pluralizing nouns whose pluralization deviates from the NC pairings.

The language-specific NC details are made available to the pluralizer through text files, one for each language, which are read into the program, and availed to the pluralizer as variables, as illustrated in the architecture in Figure 1. The selected language and noun(s) to be pluralized are entered through the **UI**. Through **Languages**, the text files that contain the reclassified NCs, the singular/plural pairings, as well as prefix exceptions are loaded into **Pluralizer** as variables. The following then takes place: 1) If the noun is a mass noun (with an '**m**' on the NC), then it is returned without pluralization; 2) If the noun is found in **Exceptions**, then it is pluralized according to the exceptions prefix instead of the standard one; and 3) If the noun's NC is the same as that in **NCS** (the noun class system), then it is pluralized accordingly.

The generic pluralizer was implemented as a Java application. It, as well as the datasets tested for all languages are available at `https://github.com/runyankorenlg/Generic-Pluralizer`.

5 Evaluation of Generic Pluralizer

We carried out two types of evaluation for the generic pluralizer: verification and validation. The aim of verification is to ensure that all NCs were accounted for correctly, based on what literature states should be in each NC. The validation was aimed at comparing the output of the generic pluralizer to the language-specific ones.

5.1 Materials and Methods

The evaluation was carried out in two phases that used two test-sets, SetI, for verification (internal) testing, and SetC, for coverage testing. SetI was an English wordlist compiled based on what should

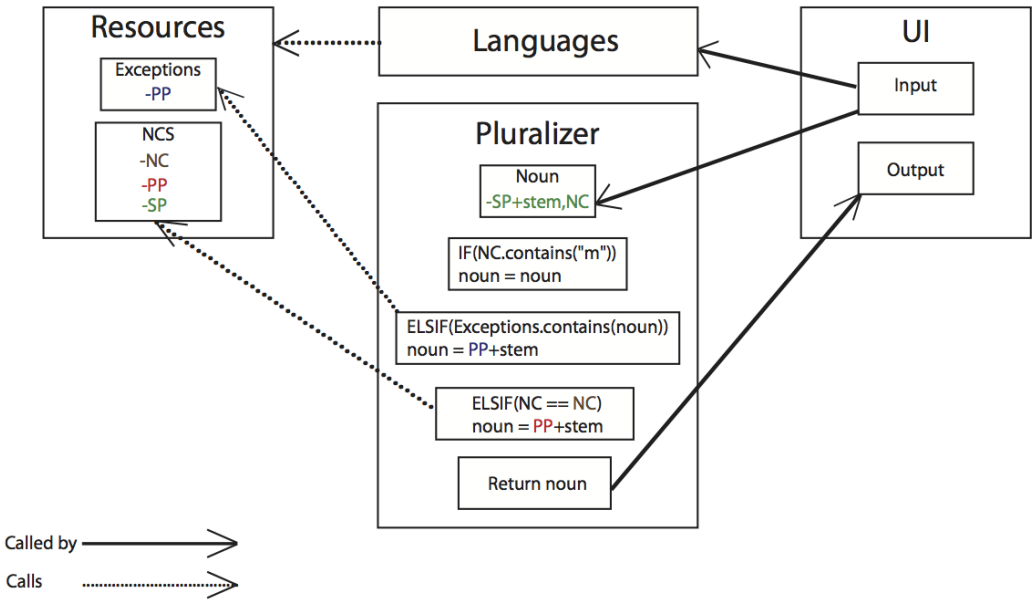

Figure 1: The architecture of the pluralizer; PP: plural prefix; SP': singular prefix; NC: noun class.

generally be in each NC (recall Table 1), and contained 81 nouns such that it includes mass nouns, abstract concepts, and compound nouns. This was done because, for several languages, no computational resources, such as dictionaries, were readily available, from which singular nouns otherwise could have been extracted randomly. The English wordlist was translated, and each noun had its NC; this formed SetI for each language. While not all nouns in the English wordlist were translatable in all languages, all NCs were accounted for in the resulting wordlists.

SetC was the same English wordlist used as Set1R in Byamugisha et al., (2016), and consists of 101 words informed by multiple ontologies. This was also translated by native speakers to chiShona, isiXhosa, Kikuyu, and Luganda, with each noun having its NC. The original Runyankore and isiZulu test-sets from (Byamugisha et al., 2016) were used, but their NCs were updated according to the new NC specification in Table 4.

The metric for evaluation is accuracy, determined as the percentage correct plurals over the test set.

5.2 Results and Analysis

Table 5 shows the accuracy of the generic pluralizer for each language, for SetI and SetC. The accuracy is based on the total number of translatable nouns. The reason for obtaining less than 100% is due to the absence of phonological conditioning. In chiShona for example, ***g**umbo* 'leg' is pluralized as *ma**k**umbo* instead of the generated *ma**g**umbo*. As explained in Section 2, the rules for phonological conditioning are language-specific, and as such could not be generalized. We propose that a separate language-specific phonological conditioning module be developed for each language, and added to that language's resources folder; we leave this for future work. Further, for isiZulu, the lower accuracy in the generic pluralizer is due to it only handling compound nouns with the possessive concord, while the isiZulu pluralizer in Byamugisha et al., (2016) additionally handles compound nouns with adjectives using the adjective concord.

Prefix Exceptions The true exceptions identified in Runyankore and isiZulu are those where pluralization does not correspond to the singular/plural pairings and there are no rules among them. They were thus placed in a separate look-up file with their corresponding plurals. In the generic pluralizer, a separate exceptions look-up file of the same structure was also created for each language (see Figure 1). Prefix exceptions were identified to be quite rare in each language; examples include: the plural of ***i**mbwa* (dog)

	SetI		SetC	
Language	**Translatable Nouns**	**Accuracy (%)**	**Translatable Nouns**	**Accuracy (%)**
chiShona	68	94.12%	74	94.59%
isiXhosa	74	97.30%	83	100%
isiZulu	71	100%	101	97.03%
Kikuyu	77	96.10%	76	94.74%
Kinyarwanda	70	97.14%	-	-
Luganda	75	93.33%	78	97.44%
Runyankore	81	93.83%	88	96.59%

Table 5: Accuracy of the generic pluralizer.

in chiShona as ***i****mbwa* instead of ***dzi****mbwa*; or *dagetari* (doctor) in Kikuyu, pluralized as ***ma****dagetari*, instead of *dagetari*; or ***i****nzu* (house) in Kinyarwanda, whose plural is ***ama****nzu* instead of ***i****nzu*.

Singular-only Nouns Singular-only nouns in isiZulu and Runyankore resulted from nouns for abstract concepts, such as 'greed' and 'thirst', found in several NCs, or infinitive nouns in NCs 15 and 15i. Abstract nouns belonging to plural NCs (for example, ***obu****rungi* 'beauty', Runyankore) were handled in the pluralization algorithm by returning them as they are. Those belonging to singular NCs were placed in a separate look-up file. Similarly, for the five selected languages, abstract concepts can either be found in singular or plural NCs; examples of the singular-only nouns identified in the wordlists are: *moto* 'fire' and *zuva* 'sun' (chiShona), *ubuhle* 'beauty' and *ubuhlobo* 'friendship' in isiXhosa, and *omululu* 'greed' and *enyoonta* 'thirst' in Luganda. The same algorithmic solution was used for those in plural NCs, while a look-up file was used for those in singular NCs. Both solutions were found to be sufficient to handle this class of exceptions.

Mass Nouns Mass nouns that belong to singular NCs are marked with an 'm', so that they can be identified and not be pluralized according to the singular/plural pairings (Byamugisha et al., 2016). This same rule was found to adequately cater for mass nouns that belonged to singular NCs; for example, *doro* (NC5, chiShona) and *umdiliya-omfaxangiweyo* (NC3, isiXhosa) 'wine', and *iria* 'milk' (NC5, Kikuyu). Mass nouns that belong to plural NCs, such as *mae* (NC6, Kikuyu), *mvura* (NC10ii, chiShona), and *amanzi* (NC6, isiXhosa) 'water' are handled algorithmically, as described in the previous section.

Compound Nouns From the translated wordlists, we identified that the main noun of a compound noun is placed before the modifier noun. When pluralizing compound nouns in isiZulu and Runyankore, the main noun was first pluralized, and the plural agreement for the modifier noun was obtained and used to associate with the modifier noun, as in (Byamugisha et al., 2016).

We further found that, similar to isiZulu and Runyankore, phonological conditioning was also required in chiShona, isiXhosa, Kinyarwanda, and Luganda; only Kikuyu does not require phonological conditioning. However, as explained in Section 2, the rules for phonological conditioning are language-specific. We omit its detail here due to space limitations.

6 Discussion

Our investigation into a generic pluralizer for agglutinating Bantu languages has shown that the approach taken by Byamugisha et al., (2016) was applicable to other Bantu languages not only within but also across Guthrie zones. For both the intra-zone and inter-zone investigations, the same approach was found to result in 100% accuracy in some datasets (recall Table 5). Moreover, the investigation into the generalizability offered a systematic way to revise the (outdated) Meinhof NC system into one that is more precise and usable for computational purposes. It clarifies the singular/plural pair rules for pluralization, resulting in a deterministic output with a higher accuracy.

Although the language-specific pluralizers achieved 100% on SetC in Byamugisha et al., (2016), the errors in the generic pluralizer were mainly found to originate from the lack of phonological conditioning. Generally, phonological conditioning is language-specific, but there may be some cases for

generalizability. For example, isiXhosa and isiZulu both have $a + i = e$ and Kinyarwanda, Luganda, and Runyankore, all have $a + vowel = ' '$. However, further research is required into under what circumstances such rules are true, in order to prevent overgeneralization. Further, we intend to extend the generic pluralizer to compound nouns with adjectives using the NC-based adjective concord, as was done in the isiZulu pluralizer (Byamugisha et al., 2016).

The processing of the resources required to add a new language to the pluralizer is quite considerable, with text files required for the noun class system (NC number, class prefixes, and genitive), NC pairings, as well as singular-only nouns and prefix exceptions if known. While the last two, singular-only nouns and prefix exceptions, can be added as errors are identified, the NC system and pairings are required for the pluralization to be done. It may be useful to use the revised NC table to speed up automated annotation of nouns, which then can facilitate resource development for pluralization. This amount of effort is still considerably less than that required by other multilingual noun pluralization implementations, notably, GF (Ranta et al., 2015) and SimpleNLG (Gatt and Reiter, 2009).

The criteria for the revised noun class table, as described in Section 3, can be used by other researchers in computational linguistics for other Bantu languages, who will undoubtably need to revise Meinhof's NC definition, especially when working with multiple languages.

7 Conclusion

We have presented a novel generic pluralizer to pluralize nouns of agglutinating Bantu languages. This pluralizer was based on a combined morphology with syntactic and semantic approach and handling of regular exceptions. The rules for pluralization are based on the classification of nouns into noun classes (NCs). To ensure deterministic outputs, i.e., one plural option for each singular noun, the standard noun class system of Meinhof (1948) had to be redefined from 29 noun classes into 53 noun classes. The generic pluralizer can pluralize simple nouns and exceptions resulting from mass nouns, singular-only nouns, prefix exceptions, and compound nouns. It achieved over 93% for all test-sets, with the remaining errors arising from the need for phonological conditioning and handling compound nouns with adjectives. Future work will center around adding support for adjectives and investigating how to implement phonological conditioning.

Acknowledgements We would like to thank Christine Wangiru Mburu, Goreth Byamugisha, Juliet Naggawa, Naissa Umutoni, Ngoni Choga, and Zola Mahlaza for providing the Kikuyu, Luganda, Kinyarwanda, chiShona, and isiXhosa translations.

This work is based on the research supported by the Hasso Plattner Institute (HPI) Research School in CS4A at UCT and the National Research Foundation of South Africa (Grant Number 93397).

Abstract

Commonsense, real-world knowledge about the events that entities or "things in the world" are typically involved in, as well as part-whole relationships, is valuable for allowing computational systems to draw everyday inferences about the world. Here, we focus on automatically extracting information about (1) the events that typically bring about certain entities (origins), (2) the events that are the typical functions of entities, and (3) part-whole relationships in entities. These correspond to the agentive, telic and constitutive qualia central to the Generative Lexicon. We describe our motivations and methods for extracting these qualia relations from the Suggested Upper Merged Ontology (SUMO) and show that human annotators overwhelmingly find the information extracted to be reasonable. Because ontologies provide a way of structuring this information and making it accessible to agents and computational systems generally, efforts are underway to incorporate the extracted information to an ontology hub of Natural Language Processing semantic role labeling resources, the Rich Event Ontology.

1 Introduction

Most adults could tell you that an umbrella is used to keep the rain off of you, that bread is baked, or that dandelions are made up of leaves, stems, and flowers. Commonsense, real-world knowledge about the events that entities or "things in the world" are typically involved in, as well as part-whole relationships, is valuable for allowing computational systems to draw everyday inferences about the world. Here, we describe our approach for automatically extracting this information from the Suggested Upper Merged Ontology (SUMO) (Niles and Pease, 2001a; Pease, 2011). We assume the theoretical framework of the Generative Lexicon (GL) (Pustejovsky, 1991), as we find GL qualia relations useful for considering the typical involvement of a particular entity in events. Thus, we focus on relationships between entities and events captured in a set of qualia associated with an entity. We find that human annotators asked to evaluate the quality and accuracy of the information extracted overwhelmingly find the origins, functions and part-whole relationships proposed to be reasonable.

One of our motivations is to add the extracted qualia relations to an ontology hub of Natural Language Processing (NLP) semantic role labeling (SRL) resources, the Rich Event Ontology (REO). We plan to exploit the qualia relations within REO to make generalizations across participant types for a given event type, thereby facilitating the addition of selectional restrictions, and to enable some shallow inferencing about how entities generally come into existence, how they are used, and what they are made up of. By structuring this information within REO we aim, for example, to allow an agent or computational system to infer that a room (whether detected visually or described in text) with a stove, pans, and a refrigerator is likely a kitchen where food preparation happens. Our approach first requires expansion of REO to include additional "things," or ENDURANTS as they are called in REO, since past efforts have focused on the inclusion of events or PERDURANTS. We again draw information from SUMO to quickly and efficiently add high-quality information on ENDURANTS to REO, and discuss the linking model we have developed to integrate the new classes from SUMO.

Proceedings of the 27th International Conference on Computational Linguistics, pages 2644–2652
Santa Fe, New Mexico, USA, August 20-26, 2018.

2 Theoretical Framework: Generative Lexicon

The theory of GL focuses on the distributed nature of compositionality in natural language (Pustejovsky, 1991), which attributes parts of the semantic load to non-verb constituents, as opposed to approaches where verbs are at the center of the notion of compositionality, (e.g. Levin (1993)). According to GL theory, every entity has a set of qualia that plays a role in what events that entity can be involved in, and that directly affects the compositional meaning that arises from the mention of a particular entity being involved in a particular event. The set of qualia GL proposes include formal, telic, agentive, and constitutive. The formal quale represents the IS-A relation for a given entity. For example, the formal quale for *dandelion* might be *plant*. The constitutive quale is the set of other entities that are typically considered to be parts of the given entity or the material of the entity. For example, the constitutive quale for *plant* could be *leaf*, *stem*, etc., and the constitutive quale for *pottery* could be *clay.* The telic quale represents the typical purpose or function of the given entity, if there is one (e.g., the telic quale of *umbrella* might be *protect from rain*). The agentive quale represents the factors involved in how the given entity came into being (e.g., the agentive quale of *bread* could be *baking*).

Note that there is no single set of defined quale for the entities of the world, hence there is indeterminacy in how these should be labeled and at what level of granularity (i.e., is the agentive quale of *bread* better captured as *baking* or as *applying heat*?). It is in part for this reason that situating qualia relations in an ontology, as was done with SIMPLE (Lenci et al., 2000), is so appealing. An ontology provides a common vocabulary for entities and events and structures them in a hierarchy from most general to most specific.

In an ontology with GL qualia, any node would inherit all the qualia from the set of its ancestors. The deeper we go into the lower levels of the hierarchy, the more specific the qualia get, and, in some cases, they may override parts of the qualia they have inherited. For instance, any physical object has a physical form (formal quale), so any `Artifact` inherits this property because it is a child to the physical object node in the ontology. In addition to this inherited quale, `Artifact` introduces to the ontology its own set of qualia: an agentive quale of *making* and a very general telic quale of *some event,* since every artifact is 'made' and typically has 'some purpose'.

3 Resource Background

3.1 SUMO (Suggested Upper Merged Ontology)

SUMO was originally an upper level ontology (Niles and Pease, 2001a), but now includes mid-level and domain ontologies as well (Pease, 2002). These domain-specific ontologies inherit the broad conceptual distinctions of SUMO, and specify the concepts and axiomatic content of a particular domain. Niles and Pease (2001b) explain SUMO's most general concepts and the relations between them, such as the distinction between `Object` and `Process`. Pease et al. (2002) illustrates the structure of SUMO and explains that the existence of SUMO-WordNet mapping serves as a gauge of the coverage of the ontology. Niles and Pease (2003) explain a SUMO-Wordnet mapping methodology and the specifics of the language used to show the synonymy, hypernymy, and instantiation relations.

In addition to the relations between entities that ontologies typically contain, SUMO provides relations between entities and processes, and statements in higher order logic (Benzmüller and Pease, 2012) that attempt to fully define each concept. For instance, the relation *result* is a binary relation with two arguments, a `Process` and an `Entity`, where the `Entity` is the output or product of the `Process`. So both temporally and causally, the `Process` is antecedent to the `Entity`. This relation is one of a few that help us find the agentive quale. Another relation between a `Process` and an `Entity` is *instrument*, where the `Entity` is used by an agent in bringing about a `Process`. So, in this case, the `Process` is consequent to the `Entity`. We use this relation to help find the telic quale for entities.

Relations are nodes under the `Abstract` hierarchy of SUMO, but many relations have sub-relations as well as instances. In general, since relations are like functions, each relation has a domain, and SUMO provides the set of arguments each relation can take. In some cases, the argument of a relation could be a whole formula by itself, so it does not point to a certain set. Rather, it is usually a complex axiom in

itself, containing at least one `Entity`, at least one relation, and possibly some `Processes`. One of the main pointers we use to find telic quale is *hasPurpose*, which usually has such complex arguments. These arguments are themselves logical formulae, supported in the higher order logic employed for SUMO. For instance, SUMO stipulates the purpose of a Microwave using the *hasPurpose* relation, with a formula that can translate to: there is an entity `PreparedFood` and a process `Heating`, and the `Microwave` is an instrument for `Heating`, through which the `PreparedFood` gets heated.

3.2 REO (Rich Event Ontology)

The Rich Event Ontology (REO) unifies existing SRL schemas by providing an independent conceptual backbone through which they can be associated, and it augments the schemas with event-to-event causal and temporal relations. The ontology was developed in response to unsuccessful efforts to map directly between FrameNet (Fillmore et al., 2002) and the small set of disparate event types in Rich Entities, Relations and Events (ERE) (Song et al., 2015) (originally based on Automatic Content Extraction (ACE) (Doddington et al., 2004)). The difficulty was mainly due to differences in the granularity of events described by the FrameNet frames and ERE event types and inconsistencies in how the resources divided the semantic space.

FrameNet, ERE, and VerbNet (Schuler, 2005) have wide-coverage lexicons having to do with events, and they contribute annotated corpora and additional semantic and syntactic information that can be crucial to identifying events and their participants. REO serves as a shared hub for the disparate annotation schemas and therefore enables the combination of SRL training data into a larger, more diverse corpus, as well as expanding the set of lexical items associated with each ERE event type. By adding temporal and causal relational information, the ontology also facilitates reasoning on and across documents, revealing relationships between events that come together in temporal and causal chains to build more complex scenarios.

The structure of REO, illustrated in Figure 1, consists of a main "reference" ontology of generic event types and individual OWL "resource" ontologies. The relationships between the generic event types in the reference ontology and the event designations made in a particular annotated data resource are spelled out in various "linking models" that import both the reference ontology and a resource ontology. In the example shown, REO `Discharge` events map to the Releasing frame in FrameNet and the Release-Parole event type in ERE. However, other mappings between ERE and FN are necessarily more indirect. With respect to the Communication node in REO, ERE/ACE only maps to instrument_communication and statement while FN has mappings to nearly all daughters, as does VN, and VN maps to the mother Communication node as well. Additional indirect mappings are detailed in Brown et al. (2017). Individual words within the resource classes can be detected in text to find a wide variety of each event type, or one can query to view its participants and its relations to other events that is independent of the various lexical resource schemas.

4 Related Work

In considering how to best capture the type of information desired for relating ENDURANTS to PERDURANTS, we have examined the approaches of other benchmark ontologies. We find that the Basic Formal Ontology (BFO) (Smith et al., 2014) and the Descriptive Ontology for Linguistic and Cognitive Engineering (DOLCE) (Masolo et al., 2003) largely focus on parthood relations, qualities, and general notions of participation of an ENDURANT (or "continuant" as labeled in BFO) in a PERDURANT (or "occurrent" in BFO). The parthood relations have some overlapping information with the GL constitutive quale. Also of relevance to our work, BFO includes a class of what it calls "specifically dependent continuants," which includes functions, such as the function of a hammer to drive in nails.

The Event and Implied Situation Ontology (ESO) focuses on pre and post situations with respect to some event type, making explicit how a participant's pre and post states change in an event. Although there may be some amount of overlap in what ESO includes and the information captured in the GL agentive quale (e.g., the agentive quale for bread is baking), ESO's information will likely be much broader than the GL agentive, which essentially is limited to creation events. Although we hope to

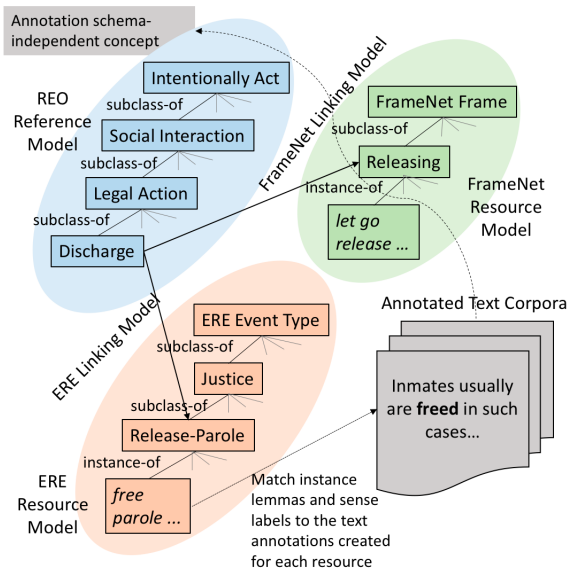

Figure 1: OWL resource models are linked to REO reference model in individual linking models (only ERE and FrameNet shown, but ACE and VerbNet linking models exist as well).

integrate or map the added and overlapping information from ESO, BFO and DOLCE in the future, here we focus on extracting information from SUMO.

5 Automatic Extraction of Qualia Relation Information

5.1 Methodology

In order to find qualia relations for entities in REO, we looked for ways to automatically extract them from SUMO. By examining around a hundred nodes in SUMO, a number of relations were found to be useful in extracting qualia. For instance, the relation *hasPurpose* in SUMO directly specifies the purpose (hence the telic quale) of a given entity. If a given entity is the second argument of the relation *instrument*, then it is a tool used to bring about an event which is the first argument of the relation *instrument* in the same axiom (e.g., (instrument ?TRANSFER ?ARTERY), where ARTERY is a tool enabling a TRANSFER event). Therefore, the first argument could be extracted as the telic quale of this entity. In the same way, a number of relations, including *part* and all its sub-relations, were found to lead us to the constitutive quale. For instance, we find that `Syllable` is a part of a `Word`, through an axiom roughly like (*part* `Syllable Word`). Though the sub-relations of *part* have fine-grained semantic differences, they all have the same weight here for our purposes. These include relations such as *initialPart, initiallyContainsPart, partTypes, typicalPart,* etc. The SUMO relation *result* leads us to the agentive quale, as its second argument is the output (or the product) of its first argument (e.g., (result ?WRITE ?TEXT) where TEXT is the output of WRITE event).

In addition to using SUMO relations, we used each node's documentation in SUMO to automatically extract telic quale using fairly straightforward regular expressions, since a number of entities were found in our initial examination to have their purpose described in their documentation, but not in their axioms. For instance, we extracted parts of the documentation that occur after terms such as 'purpose is,' 'intended to,' 'designed for,' etc. as potential candidates for the telic quale.

As the formal quale is basically an IS-A relationship, we extracted the parent of each node as its formal quale. Of course the inheritance is always at work for all the four types of qualia relations. For instance, an `Adverb` is a `Word` (parent), but is also a `LinguisticExpression` (grandparent).

The output of the function that automatically extracts qualia[1] currently can have two forms. If they are extracted from SUMO axioms, we have a set of functions to extract the actual SUMO node that

[1] `https://github.com/ghamzak/SUMOQualiaExtraction`

represents the desired quale. The second format of the output occurs when we extract qualia from the documentation. In this case, what we extract is actually plain English – a part of a sentence. In writing functions to extract sensible parts of sentences, we decided to sacrifice recall in favor of precision. At the end, we managed to extract 112 agentive, 762 telic, and 481 constitutive qualia relations. We also have a separate function that takes a SUMO entity as input and returns all possible qualia found in SUMO for that entity. For instance, `Building` has 13 total qualia found in SUMO, including 13 constitutive, 1 telic, and 1 agentive qualia relations. Table 1 illustrates the results of automatic extraction.

Agentive	112
Telic	762
Constitutive	481

Table 1: Number of Qualia found in SUMO using automatic extraction

5.2 Evaluation

In order to evaluate the automatically extracted qualia relations from SUMO, we designed an on-line annotation system, where we asked the annotators to decide whether the automatically extracted quale relation was reasonable or unreasonable, or indicate if they're not sure. We also had a comment box for each entry, and asked the annotators to provide comments. For instance, for the telic quale, our instruction for commenting was as follows:
If you feel the given function is reasonable but it's not at all how you would phrase or describe the function, then please provide your own description/phrasing of the function in the comment box.
You can also use to comment box to suggest a function for the unreasonable cases.
If you're unsure, comment on what makes you unsure.
In collecting such comments in addition to the reasonable judgments, we hope to gain insights into better alternatives for the quale relation.

We also provided SUMO documentation for the entity in question for cases where the annotator might not be familiar with the entity. The need for this was revealed in our pilot testing of the annotation system, where one of the annotators had not heard of some entities such as `Lanai`, which according to SUMO "refers to a roofed outdoor area Adjacent to a Building often furnished and used as a living room." So we decided to include SUMO documentation for each entity just in case the annotators are not familiar with it. Figure 2 shows a sample entry in our evaluation system.

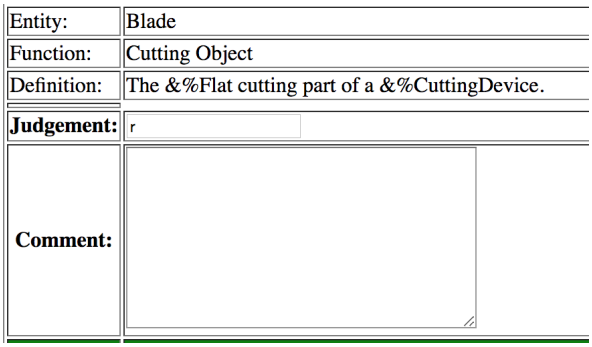

Figure 2: A sample entry in the evaluation system, asking about the telic quale.

To ensure that the annotators are not judging haphazardly and without thinking, we inserted 3 random attention tests in each page of annotation. The attention tests were completely unreasonable possibilities, in which the extracted function for one entity was paired with a totally different entity (e.g., Entity: AerobicExerciseDevice, Telic: to attach one thing to something else). So in each page, we had 25 real tasks and 3 attention tests. Examining the accuracy of each annotator, we had to throw out the data from

one of them with only 73% accuracy on the attention tasks; those tasks were re-annotated by another annotator.

It would be prohibitively difficult to have a measure of recall for this task of automatic extraction, so we limit our evaluation to the precision of the results, using human annotators' judgments as the gold standard. Table 2 shows the precision measures found. The average interannotator agreement was 84.13%.

	Agentive	Telic	Constitutive
Reasonable	93%	88.26	85.89%
Unreasonable	2%	7.87%	10.74%
Unsure	5%	3.87%	3.37%

Table 2: Precision of Qualia Relations Extracted from SUMO

5.3 Error Analysis

The 'unreasonable' judgment for the constitutive relation was mostly applied to the ones taken from SUMO axioms, where the constitutive relation was too general for our purposes. For instance, the extraction found `Object` as a component part of `WireCoil`, and `Physical` as what constitutes `Solenoid`. Despite being true, they're too general to be accepted by a human as a reasonable part-whole relation. Another reason for marking the extracted constitutive relation as unreasonable was the jargon used in particular professions with which an annotators was not familiar, such as biology or chemistry. For instance, an `AtomicGroup` is part of a `Molecule`, but it's been marked as unreasonable with the comment: "part whole switch." Some other errors were due to an ordering mistake in SUMO axioms, such as (part Penne Hole) (which means Penne is part of Hole), whereas the reverse is true. Still others were due to a bug in the extraction, which ignored negation in axioms when finding constitutive relations, such as `BloodTypeB` which does NOT contain `AntigenA` according to SUMO axioms. We extracted it as a part by ignoring the negation. Thus, the results of the annotation were illuminating: helping to pinpoint where SUMO is too general for our purposes, or where our extraction script needs refinement.

The unreasonable judgments for the telic quale were mostly due to not yet capturing and combining inherited relations from SUMO. At any particular node, SUMO underspecifies the definition because it assumes inheritance from ancestor nodes. Although we assume this as well, the qualia relations we have extracted are limited to the ones found with direct mentioning of that entity. For instance, for the entity `MilitaryVehicle`, the telic role extracted was "MilitaryOrganization uses it," which was marked as unreasonable with the suggested alternative "Provide transportation for any military organization." However, `MilitaryVehicle` has `Vehicle` as its parent and inherits from it. Therefore, the telic quale for `Vehicle`, which is extracted as "Translocation," would be inherited by `MilitaryVehicle`.

This sort of error confirms our plan to inherit qualia relations and add the quale for each entity to all its children. Not only will these types of errors be eliminated, the number of entities with qualia relations will increase significantly. Currently, many lower level entities have no specific qualia to be extracted at their SUMO node but have very informative quale that could be inherited from parent nodes. Thus, we would have a significant increase in coverage (recall), while precision is guaranteed to remain high.

Yet other instances of unreasonable telic quale were due to the wording used in SUMO. For instance, the following pairs have been judged as unreasonable.
Entity: HearingProtection – Function: protect Human from Injuring caused by RadiatingSound
Entity: PerformanceStage – Function: location of Demonstrating
Entity: Campground – Function: to have MobileResidences
These may not be how a human would describe the functions, but SUMO has tried to maximize the grounding of its definitions by using its other defined entities within them, leading to a more interconnected network of concepts. `Demonstrating`, for instance, is not the word people use to talk about the function of a performance stage, but according to the documentation of `Demonstrating` in SUMO, it would cover 'software demos, theatrical plays, lectures, dance and music recitals, museum exhibitions,

etc.' Given the connection of REO concepts to SUMO, we need not be overly concerned about these types of seemingly inaccurate results.

6 Incorporating Qualia Relations into REO

6.1 Expanding REO Endurants

As an ontology meant to provide a shared vocabulary of SRL annotation resources, the development of REO has focused on how to structure ontological relations between the events and states included in these resources (ACE, ERE, VerbNet, FrameNet). Although our intention has never been to create a detailed ontology of the entities that serve as the participants in these events/states, such information is needed to generalize and map this information across resources, as well as provide some insights into selectional restrictions generally and qualia relations specifically. Thus, we opted to integrate REO with an existing ontology containing the type of information on participants that we were interested in.

Given the detailed information on objects and accompanying information such as *hasPurpose* in SUMO, we decided that it was best suited to our needs. REO aligns with early distinctions made by DOLCE, distinguishing between ENDURANT Entities and PERDURANT Entities, where ENDURANTS are defined as "Those entities that can be observed/perceived as a complete concept, no matter which given snapshot of time," whereas PERDURANTS are defined as "Those entities for which only a part exists if we look at them at any given snapshot in time. Variously called events, processes, phenomena, or activities and states, PERDURANTS have temporal parts or spatial parts and participants." PERDURANTS largely map to what SUMO deems `Processes`, and although many ENDURANTS map to what SUMO deems `Objects`, there were also a variety of useful concepts in SUMO that seemed to fit the definition of an ENDURANT. These include: `ContentBearingPhysical`, `FinancialAsset`, `Graph`, `GraphElement`, `Model`, `PhysicalSystem`, `Quantity`, and `SetOrClass`. To flesh out the ENDURANT portion of REO, we opted to integrate all daughters of `Object` and the classes just mentioned as daughters of our ENDURANT class. Specifically, this was done in a linking model, similar to the linking models that serve to map the generic event concepts in REO's 'Reference Model' to particular groups of events in the SRL resource models (see Brown et al. (2017) for more details on the structure of REO). The linking model imports an abbreviated OWL version of SUMO (containing only the ENDURANT-compatible classes mentioned, their documentation that provides a description of what they are, and their associated WordNet sense keys), and the REO OWL reference model. The resulting model has all of the REO event ontology nested under PERDURANT, and the extracted SUMO content nested under ENDURANT (see Figure 3).

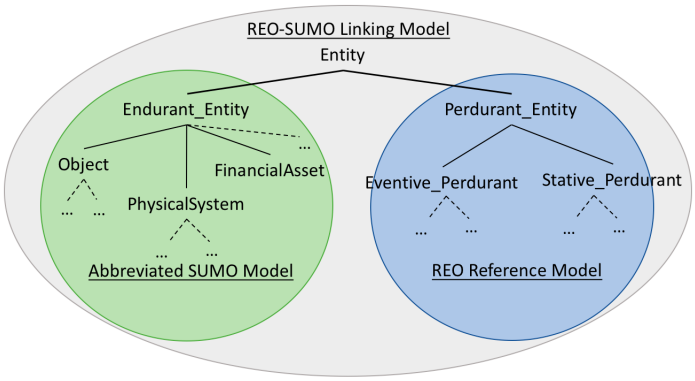

Figure 3: REO-SUMO Linking Model: This model imports the abbreviated SUMO model (containing ENDURANT-type classes only) and the REO reference model. Thus, REO specifies the PERDURANTS of the model, while SUMO specifies the ENDURANTS.

Admittedly, there are a variety of weaknesses to this model. A model that used all of SUMO would contain the many axioms found in the full version of SUMO, which OWL is not expressive enough

to handle (mathematically a description logic cannot state the content of first order logic, much less in this case, higher order logic). These axioms facilitate some of the rich reasoning potential of SUMO, which is lost in our more superficial model. We are therefore considering new ways in which to integrate the lexical resource information included in REO into the full SUMO model, enabling users to take advantage of SUMO with respect to reasoning about events included in the SRL annotations in the future.

6.2 Initial Integration of Qualia Relations

As a preliminary step in incorporating the extracted qualia relations into our ontology, we have simply added the information as annotations on the ENDURANTS drawn from the abbreviated SUMO model. We have introduced the following annotation properties: has_Quale_Agentive, has_Quale_Constitutive, and has_Quale_Telic. We do not include an explicit relation for the Formal quale, as we assume this information is encoded in the ontological structure itself. A variety of examples of these qualia incorporated are given in Table 1.

Endurant	**has_Quale**...	**Concept**
Brake	Telic	Decelerating
Building	Constitutive	Wall
Organization	Agentive	Founding

Table 3: Examples of has_Quale annotations of Endurant entities.

More general parent classes lack cohesive qualia. In fact, almost none of the nine direct daughters of ENDURANT (e.g., `Object, PhysicalSystem, Model,` etc.) have qualia annotations, but the daughters of these classes (and subclasses therein) are increasingly populated with qualia annotations, reflecting their increasing specificity.

In future work, we will incorporate the extracted qualia relation information (along with the comments acquired through annotators applied to them) into the REO/SUMO Linking Model using object properties (as opposed to the current annotation properties). These object properties will relate SUMO ENDURANTS to either REO PERDURANTS or other SUMO ENDURANTS, depending upon the relation, such that the ontology can be exploited for telic, agentive, formal, and constitutive qualia, as well as the events in which an endurant is typically involved. For example: `Meal` (ENDURANT extracted from SUMO) has_Quale_Telic CONSUMPTION (PERDURANT from REO). Unlike the annotation properties currently implemented, the object properties will better facilitate querying and reasoning using the ontology, and will effectively map the concepts extracted from SUMO (e.g., an extracted telic quale for `meal` is 'contains nutrients for humans') to the event classes in REO (labeled CONSUMPTION). We plan to do this mapping manually using a group of expert annotators who are familiar with the ontology and the linked lexical resources.

In addition, we plan to augment ongoing research evaluating the utility of REO in scene understanding in images and video (Tahmoush and Bonial, 2016). Specifically, we will be exploring how the information relating ENDURANTS and PERDURANTS for a given event type might be leveraged in putting together the pieces relating objects recognized in an image to higher-order scene understanding and perhaps even activity recognition. This is inspired in part by work on "visual semantic role labeling" using FrameNet for situation understanding (Yatskar et al., 2016), but we expect to exploit the more general qualia information to understand, for example, what type of room is encountered if a bed is recognized, versus a tooth brush, based on what we know about how those objects are typically used.

7 Conclusion

An understanding of events is not complete without understanding their participants. Similarly, an understanding of objects is incomplete without some knowledge of what events they are typically associated with. We have described efforts to extract GL qualia relations using a novel methodology exploiting particular information from SUMO relations and documentation. Our evaluation shows that the vast

majority of the automatically extracted relations are judged reasonable by human annotators. Our motivation has been to enrich REO with origin, function and part-whole information in the form of GL qualia relations. To lay the groundwork for this effort, we have first integrated REO with ENDURANTS drawn from carefully selected SUMO classes. We have completed an initial integration of the extracted qualia relation information as annotations in the updated REO. This version of the ontology will be made freely available, as will subsequent versions of the ontology that incorporate the qualia relations as object properties.

SeVeN: Augmenting Word Embeddings with Unsupervised Relation Vectors

Luis Espinosa-Anke and Steven Schockaert
School of Computer Science and Informatics, Cardiff University, UK
{EspinosaAnkeL,SchockaertS1}@cardiff.ac.uk

Abstract

We present SeVeN (Semantic Vector Networks), a hybrid resource that encodes relationships between words in the form of a graph. Different from traditional semantic networks, these relations are represented as vectors in a continuous vector space. We propose a simple pipeline for learning such relation vectors, which is based on word vector averaging in combination with an *ad hoc* autoencoder. We show that by explicitly encoding relational information in a dedicated vector space we can capture aspects of word meaning that are complementary to what is captured by word embeddings. For example, by examining clusters of relation vectors, we observe that relational similarities can be identified at a more abstract level than with traditional word vector differences. Finally, we test the effectiveness of semantic vector networks in two tasks: measuring word similarity and neural text categorization. SeVeN is available at bitbucket.org/luisespinosa/seven.

1 Introduction

Word embedding models such as Skip-gram (Mikolov et al., 2013a) and GloVe (Pennington et al., 2014) use fixed-dimensional vectors to represent the meaning of words. These word vectors essentially capture a kind of similarity structure, which has proven to be useful in a wide range of Natural Language Processing (NLP) tasks. Today, one of the major applications of word embeddings is their interaction with neural network architectures, enabling a kind of generalization beyond those words that were only observed during training. For example, if a classification model has learned that news stories containing words such as 'cinema', 'restaurant' and 'zoo' tend to be categorized as 'entertainment', it may predict this latter label also for stories about theme parks due to the shared semantic properties encoded in word vectors. Word embeddings thus endow neural models with some form of world knowledge, without which they would be far less effective. This has prompted a prolific line of research focused on improving word embeddings not only with algorithmic sophistication, but also via explicit incorporation of external knowledge sources such as WordNet (Faruqui et al., 2015), BabelNet (Camacho-Collados et al., 2016) or ConceptNet (Speer et al., 2016).

Regardless of how word vectors are learned, however, the use of fixed-dimensional representations constrains the kind of knowledge they can encode. Essentially, we can think of a word vector as a compact encoding of the salient attributes of the given word. For instance, the vector representation of *lion* might implicitly encode that this word is a noun, and that lions have attributes such as 'dangerous', 'predator' and 'carnivorous'. Beyond these properties, word embeddings can also encode *relational knowledge*. For instance, the embedding might tell us that the words 'lion' and 'zebra' are semantically related, which together with the attributional knowledge that lions are predators and zebras are prey may allow us to plausibly infer that 'lions eat zebras'. However, the way in which relational knowledge can be encoded in word embeddings is inherently limited. One issue is that only relationships which are sufficiently salient can affect the vector representations of their arguments; e.g. the fact that Trump has

Proceedings of the 27th International Conference on Computational Linguistics, pages 2653–2665
Santa Fe, New Mexico, USA, August 20-26, 2018.

visited France is perhaps not important enough to be encoded in the embeddings of the words 'Trump' and 'France' (i.e. there may be insufficient corpus-based evidence on this fact). Note that this is not a matter of how the embedding is learned; forcing the vector representations to encode this fact would distort the similarity structure of the embedding. From a formal point of view, there are also severe limitations to what can be encoded (Gutiérrez-Basulto and Schockaert, 2018). As a simple example, methods based on vector translations cannot model symmetric relations, and they are limited in the kind of many-to-many relations that can be encoded (Lin et al., 2015).

Like word embeddings, semantic networks such as WordNet (Miller, 1995), BabelNet (Navigli and Ponzetto, 2012) or ConceptNet (Speer et al., 2016) also encode lexical and world knowledge. They use a graph representation in which nodes correspond to words, phrases, entities or word senses. Edge labels are typically chosen from a small set of discrete and well-defined lexical and ontological relationships. Compared to word embeddings, the knowledge captured in such resources is more explicit, and more focused on relational knowledge (although attributional knowledge can be encoded as well, e.g., by using edge labels modeling the `has_property` relation). The use of discrete labels for encoding relation types, however, makes such representations too coarse-grained for many applications (e.g., a large proportion of the edges in ConceptNet are labelled with the generic 'related to' relationship). It also means that subjective knowledge cannot be modeled in an adequate way (e.g., forcing us to make a hard choice between which animals are considered to have the property 'dangerous' and which ones do not).

In this paper, we propose a hybrid representation, which we call SeVeN (Semantic Vector Networks). Similar to semantic networks, we use a graph based representation in which nodes are associated with words. In contrast to semantic networks, however, these edges are labelled with a vector, meaning that relation types are modeled in a continuous space.

To obtain a suitable *relation vector* for two given words a and b, we start by averaging the vector representations (from a pre-trained word embedding) of the words that appear in sentences that mention both a and b. The resulting vectors have two main disadvantages, however. First, they are high-dimensional, as they are constructed as the concatenation of several averaged word vectors. Second, the relation vectors are influenced by words that describe the relationship between a and b, but also by words that rather relate to the individual words a or b (as well as some non-informative words). Intuitively we want to obtain a vector representation which only reflects the words that relate to the relationship. For example, the relation vector for (paris,france) should ideally be the same as the vector for (rome,italy), but this will not be the case for the averaged word vectors, as the former relation vector will also reflect the fact that these words represent places and that they relate to France. To address both issues, we introduce an autoencoder architecture in which the input to the decoder comprises both the encoded relation vector and the word vectors for a and b. By explicitly feeding the word vectors for a and b into the decoder, we effectively encourage the encoder to focus on words that describe the relationship between a and b.

Once the semantic vector network has been learned, it can be used in various ways. For instance, the relation vectors could be used for measuring relational similarity (Jurgens et al., 2012), for identifying words that have a specific lexical relationship such as hypernyms (Vylomova et al., 2016), or complementing open information extraction systems (Delli Bovi et al., 2015). In this paper, however, we will assess the potential of SeVeN in terms of two tasks, namely using it for (1) unsupervised semantic similarity modeling, and for (2) enriching word vectors as the input to neural network architectures. The overarching idea in the latter case is that, instead of simply representing each word by its vector representation, the representation for each word position will be composed of (i) the vector representation of the word, (ii) the vector representations of the adjacent words in the semantic vector network, and (iii) the corresponding relation vectors (i.e. the edge labels).

2 Related Work

Related work broadly falls in two categories: methods which aim to improve word embeddings using relational knowledge, and methods which aim to learn relation vectors. To the best of our knowledge, there is no previous work which uses relation vectors with the aim of enriching word embeddings.

Improving Word Embeddings. One of the most notable features of word embedding models, such as

Skip-gram (Mikolov et al., 2013b) and GloVe (Pennington et al., 2014), is the fact that various syntactic and semantic relationships approximately correspond to vector translations. One limitation of vector translations is that they are not well-suited for modeling transitive relations, which is problematic among others for the is-a relationship. To this end, a number of alternative vector space representations have been proposed, which are specifically aimed at modeling taxonomic relationships (Vendrov et al., 2016; Yu et al., 2015; Nickel and Kiela, 2017). Note that while such alternative embedding spaces can solve some of the limitations of standard embeddings w.r.t. modeling taxonomic relationships, there are many other types of relations that cannot be faithfully modeled in these representations. Moreover, these alternative embeddings are not necessarily well-suited for modeling word similarity. More generally, various authors have explored the idea of adapting word embeddings to fit the needs of specific tasks, e.g. aiming to make embeddings better suited for capturing antonyms (Ono et al., 2015), hypernyms (Vulic and Mrksic, 2017) or sentiment (Tang et al., 2014).

As mentioned in the introduction, the use of semantic networks for improving word embeddings, based on the idea that words which are similar in the semantic network should have a similar embedding, has been explored by various authors (Faruqui et al., 2015; Camacho-Collados et al., 2016; Speer et al., 2016). Another possibility is to use a semantic network to decompose word embeddings into sense embeddings by imposing the constraint that the word vector is a convex combination of the corresponding sense vectors, as well as forcing similarity of the sense vector with the vector representations of its neighbors in the semantic network (Johansson and Piña, 2015). Finally, let us refer to work that learns additional embeddings that coexist in the same space as lexemes, e.g., WordNet synsets (Rothe and Schütze, 2015) or BabelNet synsets (Mancini et al., 2017).

Relation Vectors The idea of learning a relation vector for two words a and b, based on the words that appear in their context, goes back at least to the Latent Relational Analysis (LRA) method from (Turney, 2005). In that work, a matrix is constructed with one row for each considered word pair, where columns correspond to lexical patterns that have been extracted from sentences containing these words. The relation vectors are then obtained by applying Singular Value Decomposition (SVD) on that matrix. Along similar lines, in (Riedel et al., 2013) relation vectors are learned by factorizing a matrix whose rows correspond to entity pairs and whose columns correspond to properties (in this case comprising both lexical patterns from a corpus and triples from a knowledge graph). More recently, several methods have been proposed that learn a vector describing the relationship between two words by averaging the embeddings of the words that appear in between them in a given corpus (Weston et al., 2013; Hashimoto et al., 2015; Fan et al., 2015), or by learning a vector representation from PMI-like statistics on how strongly different words are associated with the considered word pair (Jameel et al., 2017). Beyond these unsupervised methods, a wide variety of supervised neural network based architectures have been proposed for learning relation vectors that are predictive of a given relation type (Zeng et al., 2014; dos Santos et al., 2015; Xu et al., 2015).

3 Constructing Semantic Vector Networks

Our aim is to construct a graph whose nodes correspond to words, whose edges indicate which words are related, and whose edge labels are vectors that encode the specific relationship between the corresponding words. We will refer to this representation as a semantic vector network. In this section, we describe our methodology for constructing such semantic vector networks. First, in Section 3.1, we provide details about the source corpus and explain how the structure of the network is chosen. In Section 3.2 we then discuss how suitable relation vectors can be constructed.

3.1 Defining the Network Structure

Our source corpus is a dump of the English Wikipedia from January 2018. We opted to keep preprocessing at a minimum to ensure that any emergent linguistic or relational regularity is captured during the network construction stages. Specifically, we applied sentence segmentation and word tokenization using *nltk*[1]. We also single-tokenized multiword expressions based on several lexicons (Schneider et al.,

[1] nltk.org

2014), and finally removed stopwords using the CoreNLP list[2]. After the above steps, we selected the 10^5 most frequent words as our vocabulary. To determine which words should be connected with an edge, we rely on Pointwise Mutual Information (PMI), which measures the strength of association between two random variables. It is commonly used in NLP as a method for identifying related words, e.g. in factorization based methods for learning word embeddings (Turney and Pantel, 2010). Specifically, we express the strength of association between words w_i and w_j as follows:

$$\textit{pmi}(w_i, w_j) = \log\left(\frac{x_{ij}x_*}{x_i x_j}\right)$$

In our case, x_{ij} is the number of times word w_i appears near word w_j, weighted by the nearness of their co-occurrences, and $x_i = \sum_j x_{ij} = \sum_j x_{ji}$ and $x_* = \sum_i \sum_j x_{ij}$. Specifically, let I_{w_i} be the word positions in the corpus at which w_i occurs, then we define:

$$x_{ij} = \sum_{p \in I_{w_i}} \sum_{q \in I_{w_j}} n(p, q)$$

where $n(p, q) = 0$ if the word positions p and q belong to a different sentence, or if $|p - q| > 10$, i.e. if there are at least 10 words in between them. Otherwise we define $n(p, q) = \frac{1}{|p-q|}$.

Table 1: Examples of the highest scoring (i.e. most strongly associated by pmi) words, as well as their nearest neighbors in the pretrained word2vec (w2v) Google news vector space.

To choose the edges of the semantic vector network, we only consider word pairs which co-occur at least 10 times in the corpus. Among such pairs, for each word w_i, we first select the 10 words w_j whose score $\textit{pmi}(w_i, w_j)$ is highest. This resulted in a total of about 900 000 pairs. Then, we added the overall highest scoring pairs (w_i, w_j) which had not yet been selected, until we ended up with a total of approximately 10^6 edges involving the initial vocabulary of 10^5 words. In the following we will write N_w for the neighbors of w, i.e. the set of words n such that $\{w, n\}$ was selected as an edge.

Note that by capturing pairs of words strongly connected by PMI, we encode a different type of relatedness than proximity in word embeddings. To illustrate this, in Table 1 we compare the most closely related words in our PMI graph, for some selected target words, with their nearest neighbors in the *word2vec* Google News word embedding space[3] (measured by cosine similarity). While the word2vec neighbors mostly consist of near-synonyms and other syntagmatic relationships, the chosen PMI pairs include a wide variety of topically related linguistic items. A semantic network based on such PMI pairs should thus capture information which is complementary to what is captured in word embeddings.

3.2 Learning relation vectors

Our general strategy for learning relation vectors is based on averaging word vectors. Specifically, for each sentence s in which w_i occurs before w_j (within a distance of at most 10), we construct three vectors, based on the words $a_1, ..., a_k$ which appear before w_i, the words $b_1, ..., b_l$ which appear in between w_i

[2] github.com/stanfordnlp/CoreNLP/blob/master/data/edu/stanford/nlp/patterns/surface/stopwords.txt

[3] https://code.google.com/archive/p/word2vec/

and w_j and the words $c_1, ..., c_q$ which appear after w_j:

$$pre^s_{w_iw_j} = \frac{1}{k}\sum_{r=1}^{k}\mathbf{v}_{a_r} \qquad mid^s_{w_iw_j} = \frac{1}{l}\sum_{r=1}^{l}\mathbf{v}_{b_r} \qquad post^s_{w_iw_j} = \frac{1}{q}\sum_{r=1}^{q}\mathbf{v}_{c_r}$$

where we write $\mathbf{v}_w$ for the vector representation of the word w. These vectors are then averaged over all sentences S_{ij} where w_i occurs before w_j:

$$pre_{w_iw_j} = \frac{1}{|S_{ij}|}\sum_{s\in S_{ij}} pre^s_{w_iw_j} \quad mid_{w_iw_j} = \frac{1}{|S_{ij}|}\sum_{s\in S_{ij}} mid^s_{w_iw_j} \quad post_{w_iw_j} = \frac{1}{|S_{ij}|}\sum_{s\in S_{ij}} post^s_{w_iw_j}$$

Since we can similarly obtain such vectors from sentences where w_j appears before w_i, we end up with a relation vector whose dimensionality is six times higher than the dimensionality of the word embedding, which would be impractical in the kind of applications we envisage (see Section 4). Another problem with these vectors is that they do not only reflect the relationship between w_i and w_j, but also the words w_i and w_j themselves. For instance, suppose we want to model the relationship between the words 'movie' and 'popcorn'. A sentence mentioning these two words could be:

Buttered popcorn is commonly eaten at movie theatres.

The most relevant words for describing the relationship are 'eaten at'. In contrast, however, 'buttered' is mostly related to the word 'popcorn' itself rather than describing its relationship with 'movie'. Similarly, 'theatres' is related to 'movie', but not relevant for characterizing the relationship.

To solve both issues, we propose to use an autoencoder architecture, in which the decoder has access to the word vectors $\mathbf{v}_{w_i}$ and $\mathbf{v}_{w_j}$, in addition to the encoded version of the relation vector. Let us write $\mathbf{z}_{w_iw_j}$ for the concatenation of $pre_{w_iw_j}$, $mid_{w_iw_j}$, $post_{w_iw_j}$, $pre_{w_jw_i}$, $mid_{w_jw_i}$, $post_{w_jw_i}$. Then the encoder is given by:

$$\mathbf{r}_{w_iw_j} = A\,\mathbf{z}_{w_iw_j} + \mathbf{b}$$

where $A \in \mathbb{R}^m \times \mathbb{R}^{6d}$ and $\mathbf{b} \in \mathbb{R}^m$, where d is the dimensionality of the word vectors, and m is the dimensionality of the encoded relation vectors m. In our experiments we experiment with different values for m. Empirically, we find that as the dimensionality of the compressed representations becomes smaller, the importance of word semantics gradually fades away in favor of their corresponding relational properties. Then, the decoder is then defined as:

$$\mathbf{z}^*_{w_iw_j} = B(\mathbf{v}_{w_i} \oplus \mathbf{r}_{w_iw_j} \oplus \mathbf{v}_{w_j}) + \mathbf{c}$$

where $\oplus$ denotes vector concatenation, $B \in \mathbb{R}^{6d} \times \mathbb{R}^{m+2d}$ and $\mathbf{c} \in \mathbb{R}^{6d}$. To train the autoencoder, we use the following L2-regularized reconstruction loss:

$$\mathcal{L} = \|\mathbf{z}_{w_iw_j} - \mathbf{z}^*_{w_iw_j}\|_2^2 + \lambda\|\mathbf{r}_{w_1n_1}\|_2^2$$

with $\lambda > 0$ a regularization parameter. This loss function balances two objectives: minimizing the reconstruction error and keeping the L2 norms of the encoded relation vectors as small as possible. Because of this latter part, we can think of the norm of the relation vectors $\mathbf{r}_{w_iw_j}$ as a measure of how strongly the words w_i and w_j are related. In particular, if sentences mentioning w_i and w_j contain few or no words that describe their relationship, we might expect $\mathbf{r}_{w_iw_j}$ to be close to the 0 vector.[4]

4 Evaluation

We propose to evaluate our semantic vector networks from three different standpoints. First, we provide a qualitative evaluation by exploring relation network spaces (both compressed and uncompressed) and discussing meaningful properties. Second, we perform experiments in word similarity where we compare

[4]We also conducted experiments without the regularization term, with slightly worse results across all evaluations.

against the standard approach of measuring the similarity of two words by means of the cosine distance between their corresponding word vectors. This evaluation serves as an illustration of how semantic vector networks could be used in an unsupervised application setting. Third, as a prototypical example of a supervised application setting, we analyze the impact of leveraging the enriched representation these networks provide in neural text classification, in particular topic categorization and sentiment analysis. In all experiments, the pretrained embeddings we use (both for baselines and for constructing the relation networks) are the *word2vec* Google News embeddings (Mikolov et al., 2013b).

4.1 Qualitative Evaluation

One of the strongest selling points of word embeddings is that they enable inference of relational properties, which can be obtained by simple vector arithmetic such as summation and subtraction (Levy et al., 2015). The basic idea is that the relationship between two words w_i and w_j is characterized by the vector difference $\mathbf{v}_{w_i} - \mathbf{v}_{w_j}$. Such vector differences, however, encode relations in a noisy way. For instance, while the differences $\mathbf{v}_{rome} - \mathbf{v}_{italy}$, $\mathbf{v}_{paris} - \mathbf{v}_{france}$ and $\mathbf{v}_{dublin} - \mathbf{v}_{ireland}$ are all rather similar, there are in fact many other word pairs (not in a capital-of relationship) whose difference is also similar to these differences (Bouraoui et al., 2018). Accordingly, it was found in (Vylomova et al., 2016) that a relation classifier which is trained on word vector differences is prone to predicting many false positives. In contrast, we can expect that our relation vectors are modeling relations in a far less ambiguous way. On the other hand, these relation vectors are limited to word pairs that co-occur sufficiently frequently. Apart from the associated sparsity issues, this also suggests that relation vectors are not suitable for characterizing syntagmatic relationships and several types of syntactic relationships. We thus view these relation vectors as complementary to word vector differences.

In this section we illustrate the semantic properties of different versions of SeVeN. To this end, we show the nearest neighbors of selected target relation vectors for a number of different representations: (1) the original 1800d SeVeN network (`original`), (2) an autoencoded 10-dimensional space (`compressed-10d`), (3) a slightly higher-dimensional version (`compressed-50d`), and finally (4) a baseline model according to which the relation between two words is modeled as the vector difference of the corresponding word vectors (`diffvec`). The five selected target relation vectors, along with their nearest neighbors, are shown in Table 2. These target relation vectors were chosen to capture a range of different types of relationships, including hypernymic ('nintendo - console' and 'gmail - email') and attributional ('roman - numerals') relations.

One immediate observation is that, in most cases, the `diffvec` neighbors remain very close to the given word pair, where each word from the given pair is either preserved or replaced by a closely related word. The `original` and `compressed-50d` relation vectors largely follow a similar trend, although a few more interesting analogies are also found in these cases (e.g. *arabic - alphabet* as a neighbor of *roman - numerals*). The results for the `compressed-10d` vectors, however, follow a markedly different pattern. For these low-dimensional vectors, our autoencoder forces the relation vectors to focus on modeling the relationship between the two words, while abstracting away from the initial domain. This leads to several interesting neighbors, although this seems to come at the cost of some added noise.

Let us now analyze more closely the results of the `compressed-10d` vectors. If we read the first example along the lines of "juice can be made from limes", similar relations are found close in the space, such as 'coconut - milk' and 'marzipan - paste'. Note that the relation 'noodles - egg' is also similar, although the two words appear in the incorrect order (i.e. noodles can be made from eggs rather than the other way around). As another example where the directionality of this pattern is not captured correctly, we also find the pair 'juice - lime'. It would be interesting to analyze in future work whether such issues can be avoided by using features from a dependency parser, e.g. following a similar strategy as in (Levy and Goldberg, 2014). Note that while all the `compressed-10d` neighbors are still related to food, these vectors have generalized beyond the domain of citrus fruits (see e.g., 'lime', 'tamarind' or 'lemon' in `diffvec`, or 'lemon' and 'orange' in `original`). A similar phenomenon occurs in some of the other examples. In the 'nintendo-console' case, after interpreting the relation as "major supplier of" or "entity which popularized", we find nearest neighbors in the `compressed-10d` space

Table 2: Nearest neighbors (by cosine) for selected relation vectors and the three models under consideration.

where the same relation holds, but which do not belong to the video games domain, such as 'itunes-download' or 'netflix-streaming'. Next, we find that the relation holding between 'gmail' and 'email' is similar to 'ie' and 'firefox' and 'browser', and even 'helvetica' and 'font'. The relation between 'google' and 'search', found for `compressed-50d`, is also of this kind. In contrast, the `diffvec` neighbors in this case all have *email* as the second word. In the 'roman-numerals' example, likewise, the `diffvec` neighbors similarly have 'numerals' as the second word, while for `compressed-10d` we see more interesting neighbors such as 'arabic-alphabet' and 'yemenite-pronunciation'. We also find the seemingly unrelated 'wii-remote' pair, although we may consider that the Nintendo Wii console introduced a fundamentally new type of remote, which at an abstract level is similar to the fact that the Romans introduced a fundamentally new way of writing numbers. This example also suggests, however,

that the way in which relations are modeled in the 10-dimensional space might be too abstract for some applications. Finally, the 'heavy-metal' case is a paramount example of how the the relation vectors may capture information which is fundamentally different than what is encoded by word vectors. In particular, the `diffvec` vectors all express relationships from the metalwork domain (e.g., 'heavy-metals' or 'annihilator-metal'), which reflects the fact that the music-related interpretation of the word 'metal' is not its dominant sense. In contrast, since our relation vectors are exclusively learned from sentences where both words co-occur ('heavy' and 'metal' in this example), the vector for 'heavy metal' clearly captures the musical sense (see e.g., 'thrash-metal' or 'glam-metal' in the `original` space).

4.2 Modeling Similarity

The capacity to capture and *embed* nuances of word meaning is one of the most celebrated features of word embeddings. The task of semantic similarity measurement, therefore, has been adopted as a *de-facto* testbed for measuring the quality of representations of linguistic items. The standard practice is to consider a distance (or similarity) metric such as cosine similarity and compare the similarity in a given vector space model with respect to human judgement. We note, however, that there exist other similarity metrics discussed in the literature, e.g., Weighted Overlap (Pilehvar et al., 2013) or Tanimoto Distance (Iacobacci et al., 2015). Our proposed similarity measurement parts ways from the idea of improving the representation of individual words, and rather seeks to refine their meaning by incorporating complementary cues via relation vectors, as well as the corresponding neighborhood structure. There are many possible ways in which this could be done, but we restrict ourselves here to a simple strategy, based on identifying the closest neighbors of the two words w_1 and w_2. The main intuition is that when w_1 and w_2 are similar, they should also be related to similar words. Specifically, we first determine the closest match between the neighbors of w_1 and the neighbors of w_2, as follows:

$$(n_1, n_2) = \underset{(n_1,n_2)\in N_{w_1}\times N_{w_2}}{\arg\max} \cos(\mathbf{v}_{n_1}, \mathbf{v}_{n_2}) + \cos(\mathbf{r}_{w_1n_1}, \mathbf{r}_{w_2n_2})$$

Note that to identify these neighbors, we compare both their word vectors $\mathbf{v}_{n_1}$ and $\mathbf{v}_{n_2}$, and their relationships to the target words, $\mathbf{r}_{w_1n_1}$ and $\mathbf{r}_{w_2n_2}$. Once these neighbors have been identified, we compute the similarity between w_1 and w_2 as follows:

$$\textit{sim}(w_1, w_2) = \cos(\mathbf{v}_{w_1} \oplus \mu\mathbf{v}_{n_1} \oplus \mathbf{r}_{w_1n_1}, \mathbf{v}_{w_2} \oplus \mu\mathbf{v}_{n_2} \oplus \mathbf{r}_{w_2n_2})$$

where $0 < \mu \leq 1$ is a scaling factor which is aimed at reducing the impact of the neighbors n_1 and n_2 on the overall similarity computation. The fact that $\mathbf{v}_{n_1}$ is similar to $\mathbf{v}_{n_2}$ is an important indicator for the similarity between w_1 and w_2, but it should not influence the resulting similarity score as much as the similarity of the word vectors of w_1 and w_2 themselves. Rather than tuning this value, in the experiments we have fixed it as $\mu = 0.5$, which was found to give better results than $\mu = 1$ (i.e. no scaling). Note that the proposed way of computing similarities favours words of the same type. For example, we may expect 'Spain' and 'France' to be more similar than 'Spain' and 'Barcelona', when this metric is used, since 'Spain' and 'France' are associated with the neighbors 'Madrid' and 'Paris' which are similar, and which are related in a similar way to the target words. In our experiments, we also consider a variant in which the relation vectors are only used for selecting the neighbors. The similarity itself is then calculated as:

$$\textit{sim}(w_1, w_2) = \cos(\mathbf{v}_{w_1} \oplus \mu\mathbf{v}_{n_1}, \mathbf{v}_{w_2} \oplus \mu\mathbf{v}_{n_2})$$

We evaluate the proposed similarity measure on four well-known benchmarking datasets for word representation learning. These are: (1) `rg65` (Rubenstein and Goodenough, 1965); (2) `wordsim` (Finkelstein et al., 2001); (3) `mc` (Miller and Charles, 1991); and (4) the English portion of `semeval17` (Camacho-Collados et al., 2017). We restrict our experiment to single words, and do not consider multiword expressions (e.g., named entities), as this would require a different approach for compositional meaning representation. We compare against a baseline model based on cosine similarity between the vectors of the target words (`cosine`). As for our proposed models, and observing the similarity measurement described above, we consider a 10-dimensional relation space, without (10rv$_w$) and with (10rv$_r$) the

relation vector as part of the similarity computation. We also provide results stemming from using the original 1800-dimensional relation vector model. As is customary in the literature, we use Pearson's (**p**) and Spearman's (**s**) correlation coefficients as evaluation metrics, as well as their average (**avg.**). Table 3 shows that the 10rv_w variant consistently outperforms the word-level baseline. Somewhat surprisingly, the variant 10rv_r (which uses the relation vector also in the similarity computation) performs consistently worse than the variant 10rv_w. When using the original 1800-dimensional vectors, however, the situation is reversed, with 1800rv_r outperforming 1800rv_w, and achieving the best results overall (with the exception of `mc`). These results clearly show that the relation vectors capture valuable information for measuring word similarity, although the information captured by the 10-dimensional vectors may in some cases be too abstract for this purpose.

4.3 Text Classification

Semantic Vector Networks may be thought of as a natural way of enriching word-level semantic representations, which may in turn be useful for informing a neural architecture with relational (e.g., commonsense or lexical) knowledge. We will focus on two well known tasks, namely text categorization and sentiment analysis. Our goal is to examine the extent to which the performance of a vanilla neural network increases by being injected vector graph information as a complement to the information encoded in each individual word embedding. The strength of our proposal lies in the fact that this information comes exclusively from corpora, and thus the need to rely on often incomplete, costly and language dependent ontological or lexical resources is avoided.

As evaluation benchmarks we use three text categorization datasets, namely `20news` (Lang, 1995), `bbc` (Greene and Cunningham, 2006) and `reuters` (Lewis et al., 2004). We also consider two polarity detection datasets (positive or negative), namely the Polarity04 (`pol.04`) (Pang and Lee, 2004) and Polarity05 (`pol.05`) (Pang and Lee, 2005) datasets, and finally a 10k document subset of the *apps for android* (`apps4and.`) corpus[5] (He and McAuley, 2016), which features reviews and associated ratings on a scale from 1 to 5. The neural network model we use for our experiments is a combination of a CNN (LeCun et al., 1998) and a bidirectional LSTM (Hochreiter and Schmidhuber, 1997). CNNs have been evaluated extensively in text classification (Johnson and Zhang, 2015; Tang et al., 2015; Xiao and Cho, 2016; Conneau et al., 2017) and sentiment analysis (Kalchbrenner et al., 2014; Kim, 2014; dos Santos and Gatti, 2014; Yin et al., 2017), and this specific model (CNN+BLSTM) has been explored in different NLP benchmarks (Kim, 2014). Finally, as evaluation metrics we use precision (**p**), recall (**r**) and f-score (**f**), as well as accuracty (**acc.**).

To use SeVeN for text classification, we keep the exact same neural network architecture, but use enriched vector representations for each word. As a proof-of-principle, in this paper, this enriched vector representation is simply obtained by concatenating the word vector of that word, with vector representations of its top-10 neighbors according to PMI (ordered by this PMI score), together with the corresponding relation vectors. For example, with word embeddings of 300 dimensions and relation vectors of 10 dimensions, the input for each word is given by a 3400-dimensional vector. We list experimental

Table 4: Experimental results on six benchmarking datasets for text classification.

results for several configurations, where the number of neighbors stays fixed, but the relation vector (rv) changes in dimensionality (10, 20 or 50). Experimental results are provided in Table 4. We can see that for the 20-dimensional vectors, the results are consistently better (or at least as good as) the baseline. The results for the 10-dimensional and 50-dimensional vectors are similar, although these configurations perform slightly worse than the baseline for pol.05.

Overall, these results show the usefulness of the relation vectors and neighborhood structure, despite the rather naive way in which this information is used. It seems plausible to assume that performance may be further improved by using network architectures which exploit the graph structure in a more direct way.

5 Conclusions and Future Work

In this paper we have presented SeVeN, a dedicated vector space model for relational knowledge. These relation vectors encode corpus-based evidence capturing the different contexts in which a pair of words may occur. An initially high-dimensional relation vector is is further "purified" thanks to a simple *ad-hoc* autoencoder architecture, designed to only retain relational knowledge. We have explored the characteristics of these vector networks qualitatively, by showing highly correlated word pairs, as opposed to, for example, difference vectors. While the latter are often assumed to capture relational properties, we found that the relational similarities they capture largely reflect the similarities of the individual words, with little relational generalization capability. In addition, we have evaluated our SeVeN vectors in terms of their usefulness in two standard NLP tasks: word similarity and text classification. In both cases we obtained better results than baselines that use standard word vectors alone.

There are several interesting avenues for future work. First, an obvious way to improve these unsupervised representations would be to leverage structured knowledge retrieved from knowledge graphs and/or Open Information Extraction systems. Such knowledge could easily be exploited by feeding any available structured knowledge as additional inputs to the autoencoder. Another way in which structured knowledge could be harnessed would simply be to label relation vectors, i.e. to identify regions in the relation vector space that correspond to particular relation types (e.g. hypernymy). Another possibility would be to improve SeVeN by aggregating relation vectors along paths in the graph. In this way, we may learn to predict missing edges (or to smooth relation vectors that were learned from too few or too uninformative sentences), similarly to the random walk based strategies that have been developed for completing traditional semantic networks and knowledge graphs (Gardner et al., 2014).

Abstract

We evaluated various compositional models, from bag-of-words representations to compositional RNN-based models, on several extrinsic supervised and unsupervised evaluation benchmarks. Our results confirm that weighted vector averaging can outperform context-sensitive models in most benchmarks, but structural features encoded in RNN models can also be useful in certain classification tasks. We analyzed some of the evaluation datasets to identify the aspects of meaning they measure and the characteristics of the various models that explain their performance variance.

1 Introduction

Distributed semantic models for words encode latent features that reflect semantic aspects and correlations among words. The goal of compositional semantic models is to induce latent semantic representations that encode the meaning of phrases, sentences, and paragraphs of variable lengths. Some neural architectures such as convolutional (Kim, 2014) and recursive networks (Socher et al., 2013) handle variable-length input by identifying shift-invariant features suitable for the classification problem at hand, which makes it possible to skip composition and work directly with the entire space of individual word embeddings. While such models can achieve excellent performance in supervised classification tasks such as sentiment analysis, we are interested in generic unsupervised fixed-length representations for variable-length text sequences so as to efficiently preserve essential semantic content for later use in various supervised and unsupervised settings.

Binary bag-of-words are simple and effective representations that serve as a strong baseline in several classification benchmarks (Wang and Manning, 2012). However, they do not exploit the distributional relationships among different words, which limits their applicability and generalization when training data are scarce. Additive compositional functions, such as word vector sum or average, are more effective in semantic similarity tasks even when compared with tensor-based compositional functions (Milajevs et al., 2014) and can outperform more complex and better tuned models based on recurrent neural architectures on out-of-domain data (Wieting et al., 2015a). Yet, averaging also has several drawbacks: unlike binary representations, the individual word identities are lost, and some words that do not carry semantic significance may end up being more prominently represented than essential words. Furthermore, additive compositional models disregard sentence structure and word order, which can lead to loss of semantic nuance. To alleviate the first issue, the weights of various words can be adjusted using word frequency statistics (Riedel et al., 2017) or by inducing context-sensitive weights using recurrent neural networks (Wieting and Gimpel, 2017), both of which have been shown to outperform vector averaging. Context-sensitive feed-forward neural models like the paragraph vector (Le and Mikolov, 2014) potentially incorporate word order, yet the training objective may not be sufficient to model deeper structure. Sequence encoder-decoder models, on the other hand, can be trained with various sentence-level objectives, such as neural machine translation (NMT) (Sutskever et al., 2014), predicting surrounding

Proceedings of the 27th International Conference on Computational Linguistics, pages 2666–2677
Santa Fe, New Mexico, USA, August 20-26, 2018.

sentences (i.e. skip-thought) (Kiros et al., 2015), or reconstruction of the input using denoising autoencoders (Hill et al., 2016). These sequential models have been evaluated and compared against other models and baselines on several supervised and unsupervised tasks in Hill et al. (2016). The denoising autoencoder model and skip-thought both performed well in supervised tasks, while the NMT model performed worse than the baselines. All three performed poorly in unsupervised settings.

To bridge some of the gaps in evaluation, we evaluated a subset of models with increasing complexity, from binary bag-of-words to RNNs, on various supervised and unupervised settings. Our objective is to evaluate compositional models against strong baselines and identify the elements that lead to performance gains. We evaluated binary vs. distributed features, weighted vs. unweighted averaging, three different word embedding models, and four context-sensitive models that optimize different objectives: the paragraph vector, the gated recurrent averaging network (Wieting and Gimpel, 2017), skip-thought, and an LSTM encoder trained on labeled natural language inference data (inferSent) (Conneau et al., 2017). We also analyzed the intrinsic structures of the various models by visual inspection and k-means clustering to gain insights into structural differences that may explain the variance in performance.

2 Background: Unsupervised Compositional Models

2.1 Baselines

The simplest way of representing a sentence is a binary bag-of-words representation, where each word is a feature in the vector space. This results in large and sparse representations that only account for the existence of individual words within a sentence, yet they have been shown to be effective in various supervised classification tasks, especially in combination with *n*-grams and Naive Bayes (NB) features (Wang and Manning, 2012). Let $\vec{x}_i$ be the binary representation of sentence i, and $y_i \in \{0, 1\}$ its label. The log-count ratio $\vec{r}$ is calculated as

$$\vec{r} = \log \frac{\vec{p}/\|\vec{p}\|}{\vec{q}/\|\vec{q}\|} \tag{1}$$

Where $\vec{p} = 1 + \sum_{i:y_i=1} \vec{x}_i$ and $\vec{q} = 1 + \sum_{i:y_i=0} \vec{x}_i$ are the smoothed count vectors for each class (i.e. the number of samples in the class that include each feature). The feature vectors are then modified using the element-wise product $\vec{x}_i \circ \vec{r}$. NB features identify the most discriminative words for each task, so using them results in task-specific rather than general representations. However, given the relative efficiency of this model, we include it as a baseline for comparison.

2.2 Word Embeddings and Composition Functions

Representations of variable-length sentences and paragraphs can be constructed by averaging the embeddings of all words within a sentence. However, simple averaging may not be the best approach since not all words within a sentence are semantically relevant. The following methods can be used to adjust the weights of words according to their frequency, assuming that frequent words have lower semantic content:

`tf-idf`-weighted Average The *term frequency-inverse document frequency* statistic measures the importance of a word to a document. We treat each sentence as a document and calculate the `idf` weight for term t as follows:

$$idf_t = \texttt{log}\frac{N}{1 + n_t} \tag{2}$$

where N is the total number of sentences and n_t the number of sentences in which the term appears. Terms that appear in more documents have lower `idf` weights.

`sif`-weighted Average The *smooth inverse frequency* (Riedel et al., 2017) is an alternative measure for discounting the weights of frequent words as follows:

$$sif_t = \frac{a}{a + p(t)} \tag{3}$$

where a is a smoothing parameter and $p(t)$ is the relative frequency of the term in the training corpus. In addition, as proposed in (Riedel et al., 2017), we subtract the projection of the vectors on the first principal component which corresponds to syntactic features associated with common words.

2.2.1 Word Embeddings

Random word projections: we generated a random vector drawn from the standard normal distribution for each word in the vocabulary. The vector sum of random word vectors is a low-dimensional projection of binary bag-of-words vectors. .

Continuous Bag of Words: `CBOW` is an efficient log-linear model for learning word embeddings using a feed-forward neural network classifier that predicts a word given the surrounding words within a fixed context window (Mikolov et al., 2013a). In Schnabel et al. (2015) word embedding evaluation, `CBOW` outperformed other word embeddings in word relatedness and analogy tasks.

Global Vectors: `GloVe` is a global log-bilinear regression model (Pennington et al., 2014) that produces word embeddings using weighted matrix factorization of word co-occurrence probabilities.

Subword Information Skip-gram `si-skip` learns representations for *n*-grams of various lengths, and words are represented as sums of *n*-gram representations (Bojanowski et al., 2017). The learning architecture is based on the continuous skip-gram model (Mikolov et al., 2013b), which is trained by maximizing the conditional probability of context words within a fixed window with negative sampling. The model exploits the morphological variations within a language to learn more reliable representations, particularly for rare morphological variants.

2.3 Neural Compositional Models

Several models have been proposed to overcome some of the weaknesses of bag-of-words and additive representations, such as lack of structure. We evaluated the following context-sensitive models:

The Paragraph Vector: `doc2vec` distributed memory model (Le and Mikolov, 2014) constructs representations for sentences and paragraphs using a neural feedforward network that maximizes the conditional probability of words within a paragraph given a context window and the paragraph embedding, which is shared for all contexts generated from the same paragraph. After learning word and paragraph embeddings for the training corpus, the model learns representations for new paragraphs by fixing the model parameters and updating the paragraph embeddings using backpropagation. This additional training at inference time considerably increases the time complexity of the model compared to all others in this study.

Gated Recurrent Averaging Network: `GRAN` has been recently introduced to combine the benefits of LSTM networks and averaging, where the weights are computed along with the word and sentence representations (Wieting and Gimpel, 2017). The model is trained using aligned sentences that are assumed to be paraphrases to maximize the similarity of their representations against negative examples. The intuition is to make the averaging operation context-sensitive, resulting in a more powerful construction than simple averaging where all words are equally important. The model was shown to outperform averaging and LSTM models in semantic relatedness tasks.

Skip-Thought: The `skip-th` model is a sequence encoder-decoder trained by projecting sentences into fixed-length vectors, which in turn are used as input to a decoder that is trained to reconstruct surrounding sentences (Kiros et al., 2015), where the encoder and decoder are RNNs with GRU activations (Chung et al., 2014). The model is trained with contiguous sentences extracted from a collection of novels. After training, the model's vocabulary is expanded by learning a linear mapping from pre-trained `CBOW` word embeddings to the vector space of the `skip-th` word embeddings.

Natural Language Inference Encoder: In `inferSent` (Conneau et al., 2017), a bidirectional LSTM encoder with max-pooling is trained jointly with an inference classifier trained on the Stanford Natural Language Inference (SNLI) dataset (Bowman et al., 2015), which is a large manually-annotated dataset of English sentence pairs and their inference labels: {entailment, contradition, neutral}.

Dataset	Pair-wise Similarity			Sentiment Analysis					Newsgroup				TREC
	STS	SICK	MSRP	CR	MPQA	RT-s	Subj	IMDB	REL	SPO	COM	POL

Table 1: Dataset statistics. **Train**: number of samples in the training set. **Test**: number of samples in the test set, if applicable (CV is applied otherwise). **pos ratio**: ratio of positive samples in the test set (or total for datasets with no splits). l: average length of all samples.

3 Evaluation Datasets

To evaluate the text representations, we used them as features in extrinsic supervised and unsupervised tasks that reflect various semantic aspects, which can be grouped in three categories: pairwise-similarity, sentiment analysis, and categorization. A summary of the dataset statistics is in Table 1.[1]

3.1 Pairwise Similarity

Semantic Textual Similarity: the STS benchmark dataset (Cer et al., 2017) includes a collection of English sentence pairs and human-annotated similarity scores that range from 0 (unrelated sentences) to 5 (paraphrases). The dataset includes training, development, and test sets. This task can be performed without supervision by calculating the cosine similarity between two sentence vectors. We also evaluated the models in a supervised settings using linear regression, where the input vector is a concatenation of the element-wise produce $u.v$ and absolute difference $|u - v|$ of each pair $\langle u, v \rangle$.

Sentences Involving Compositional Knowledge: SICK dataset is a benchmark for evaluating compositional models (Marelli et al., 2014). We evaluated the models on the relatedness subtask, which is constructed in a similar manner as STS benchmark.

Paraphrase Detection: This is a binary classification task that involves the identification of paraphrases in similar sentence pairs using the Microsoft Research Paraphrase Corpus, MSRP (Dolan et al., 2004). We evaluated the models in two ways: calculating the cosine similarity between the sentence pairs and classifying them as paraphrases if the similarity is larger than a threshold tuned from the training set. The second approach is to learn a logistic regression classifier using a concatenation of $u.v$ and $|u - v|$.

3.2 Sentiment Analysis and Text Categorization

Sentiment Analysis: We used the following binary classification tasks: **CR** customer product reviews (Hu and Liu, 2004), **MPQA** opinion polarity subtask (Wiebe et al., 2005), **RT-s** short movie reviews (Pang and Lee, 2005), **Subj** subjectivity/objectivity classification task (Pang and Lee, 2004), and **IMDB** full-length movie review dataset (Maas et al., 2011).

Newsgroups: Following the setup in (Wang and Manning, 2012) we used the 20-Newsgroup dataset [2] to extract several binary topic categorization tasks. We processed the datasets to remove headers, forwarded text, and signatures, which results in smaller sentences and paragraphs. We used the following newsgroups for binary classification: **religion** (atheism vs. religion), **sports** (baseball vs. hockey), **computer** (windows vs. graphics), and **politics** (middle east vs. guns). We also trained multi-class classifiers on the 8 newsgroups.

Question Classification: We used the TREC 10 coarse question categorization task [3] which categorizes questions into 6 classes: human (HUM), entity (ENTY), location (LOC), number (NUM), description (DESC), and abbreviation (ABBR).

4 Experimental Setup

4.1 Training Data

We trained the unsupervised word embedding models `CBOW`, `GloVe`, and `si-skip` on a set of ~ 7 million sentences extracted from the English Wikipedia and Amazon movie and product reviews (He and McAuley, 2016). We also trained the Paragraph Vector (`doc2vec`) model on this dataset, and initialized the word embeddings using the `si-skip` pre-trained word embeddings above. While better results overall could be obtained using pre-trained word embeddings trained with much larger text corpora, we used this medium-size corpus to evaluate the various models consistently and reduce model variability due to data and vocabulary coverage.

We used the publicly available pre-trained `GRAN`[4] and `skip-th`[5] models, which require training with special types of datasets: paraphrase collections, and contiguous text from books, respectively. To ensure a fair evaluation, we only compared these models against binary bag-of-words and equivalent word embeddings. The word embeddings within the `GRAN` model were initialized with `PARAGRAM-SL999` word vectors (Wieting et al., 2015b), so we used them as an evaluation baseline for `GRAN`. We compared `skip-th` against the `CBOW` embeddings that were used to expand the vocabulary, which account for most words in the final model's vocabulary. We used the pre-trained `inferSent` model [6] which uses pre-trained GloVe word embeddings [7]. We also experimented with the post-trained word embeddings for each model with similar results, so we omitted them for brevity.

4.2 Training Settings

We trained the unsupervised word embedding models using the optimal parameters recommended for each model. The hyper-parameters in `doc2vec` were set according to the recommendations in (Lau and Baldwin, 2016). For the supervised sentiment classification and text categorization tasks, we trained and tuned linear SVM models using grid search for datasets that include train/dev/test splits, and nested cross-validation otherwise. We also experimented with kernel SVMs but didn't observe notable differences in the results.

5 Evaluation Results

5.1 Pairwise Similarity Evaluation

Table 2: Pearson ρ for STS Benchmark and SICK relatedness, and Accuracy%/F1 for MSR Paraphrase detection. Results are shaded according to their statistical significance using the Williams test (Graham and Baldwin, 2014) with $\alpha = 0.05$. † pre-trained vectors used in the model above.

Table 2 shows the performance of the various models in the pair-wise similarity tasks. We highlight the best performance in each block; differences within the same shade are not statistically significant. Among the word embedding models, the subword skipgram `si-skip` achieved the best overall performance. For all models except `si-skip`, simple averaging performed poorly in semantic relatedness tasks, especially in the unsupervised setting, while `sif`-weighting generally outperformed `idf`-weighting (the improvement is most evident for `GloVe`). A similar trend is observed with random word vectors, which performed on par with `doc2vec`.

The binary bag-of-words model performed particularly well in the supervised SICK task. The performance of binary and random vectors can be explained by the high correlation between the percentage of overlapping words and the similarity scores as seen in Figure 1. We also highlighted the Pearson correlation coefficients for the following subsets of relatedness scores: $A = \{score \leq 2\}$, $B = \{score \in (2, 4)\}$, and $C = \{score \geq 4\}$. The overall Pearson correlation mostly reflects the performance on the most and least similar pairs, which tend to be the pairs with the highest and lowest word overlap, respectively; within the regions we highlighted, all correlations were relatively low. However, distributed models like `sif` and `inferSent` improved the correlation of A for SICK, and both A and C for STS Benchmark. Table 3 shows some examples of sentence pairs from A and C; while both `sif` and `doc2vec` vectors consistently identified similar concepts (namely food related and competition concepts) regardless of surface similarity, binary scores only reflected the lexical similarity, which resulted in inconsistent scores.

Sentence 1	Sentence 2	Score	Binary	si-sif†	doc2vec	skip-th	infer	gl-sif†
A person **is** frying some food.	There **is** no **person** peeling a potato.	0.25	0.41	0.49	0.41	0.51	0.67	0.71
A woman **is** cutting a fish.	The main **is** slicing potatos.	0.25	0.13	0.46	0.42	0.53	0.65	0.57
Two groups of people **are** playing **football**	**Two** team **are** competing in a **football** match.	0.93	0.52	0.74	0.72	0.60	0.79	0.71
Different **teams are playing** football on the field	Two **teams are playing** soccer	0.70	0.56	0.93	0.89	0.51	0.82	0.91

Table 3: Examples of sentence pairs in SICK and their relatedness scores vs. cosine similarity scores. All scores were normalized to be in [0,1]. Shared words are shown in bold and related words underlined. † sif-weighted average of `si-skipgram` and pre-trained `GloVe`

Sentence 1	Sentence 2	Label
Bashir felt he was being tried by opinion not on the **facts**, Mahendradatta told Reuters.	**Bashir** also **felt he was being tried by opinion** rather than **facts** of law, he added.	1
West Nile Virus-which **is spread** through infected **mosquitoes** -is potentially fatal.	**West Nile** is a bird **virus** that is **spread** to people by **mosquitoes**.	0
SCO says the **pricing** terms for a license **will** not be announced for week	Details on **pricing will** be announced within a few weeks , McBride said	1
Russ Britt **is** the Los Angeles **Bureau Chief** for **CBS.MarketWatch.com.**	Emily Church **is** London **bureau chief** of **CBS.MarketWatch.com.**	0

Table 4: Examples of sentence pairs in MSRP and their labels. Shared words are shown in bold and related words underlined.

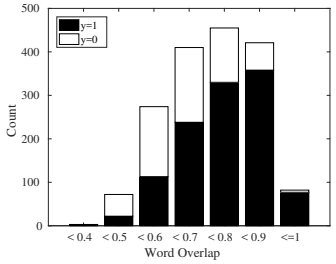

Figure 2: Ratio of paraphrases with increasing word overlap in MSRP.

GRAN outperformed simple averaging in both the STS and SICK tasks, which confirms the results in (Wieting and Gimpel, 2017), but compared with idf and sif averaging, there is no apparent improvement; it only outperformed weighted averaging in the unsupervised STS benchmark. skip-th vectors performed poorly in the unsupervised similarity tasks, but outperformed the pre-trained vectors in the supervised similarity tasks, particularly in SICK.

The low variance of the performance in the paraphrase detection task also reflects the overall correlation between word overlap and the likelihood of being a paraphrase as seen in Figure 2; for difficult cases, as in the examples in Table 4, the overall similarity is not a good indication of being a paraphrase. Significant improvements in this task may require more nuanced features as in (Ji and Eisenstein, 2013).

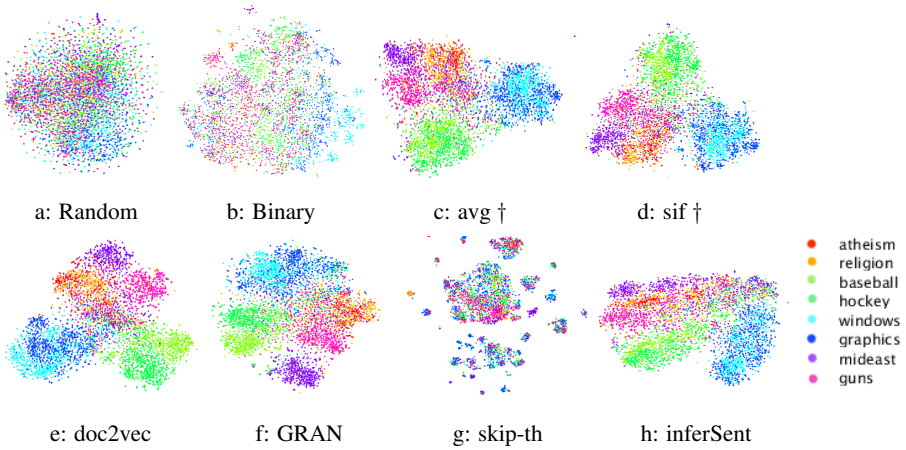

Figure 3: t-SNE visualizations of vectors on the 20-Newsgroup datasets. † `avg` and `sif` using `si-skip`.

Table 5 shows the performance in sentiment analysis and categorization tasks. Unlike in pair-wise similarity, random vectors underperformed the NBSVM and distributed models by a large margin. This underscores the importance of global and distributed features in these tasks. `si-skip` outperformed other word embedding models, but we observe no advantage for weighted vs. unweighted averaging. In TREC question classification and the subjectivity benchmarks, `avg` performed significantly better than both `idf` and `sif` weighted averaging. `skip-th` vectors also significantly outperformed the pre-trained vectors in these two tasks, and underperformed in all others. We surmise that the syntactic features conveyed in frequent function words and the overall structure encoded by the LSTM network in `skip-th` may provide useful clues for these two classification tasks. `inferSent` achieved the highest accuracy in CR sentiment task, and on par with `skip-th` and NBSVM in TREC, and it slightly underperformed the averaging models in Newsgroup categorization. In the next section, we analyze the Newsgroup and TREC datasets to shed light on intrinsic characteristics that may explain some of the performance variance.

6 Qualitative Analysis

Figure 3 shows t-SNE visualizations of the Newsgroup datasets using the various compositional models, including random and binary vectors. While random and binary vectors could identify shallow similarities between sentences as in STS tasks, they failed to do so in a globally cohesive manner. The random vectors also introduced noise in the representations, which resulted in a rather uniform vector space. All other models, except `skip-th`, clearly separated at least three regions that correspond to the categories **sport**, **computer**, and **religion/politics**. Smaller clusters with consistent labeling can also be identified with minimal separation between the clusters.

Table 6 shows examples of nearest neighbors using some of the models. `skip-th` vectors seem to be clustered more by structure than semantic content, unlike the `doc2vec` and `sif` models. To quantify these differences, we applied k-means clustering using $k = 3$ and $k = 8$, and calculated the clustering purity for each model as follows:

$$P(C, L) = \frac{1}{N} \sum_{k} \max_{\mathrm{J}} |c_k \cap \ell_j| \tag{4}$$

where $C = \{c_1, ..., c_K\}$ is the set of clusters, $L = \ell_1, ...\ell_K$ is the set of labels, and N the total number of samples. As shown in Table 7, using `doc2vec` and the averaging models, including `GRAN`, k-means successfully separated the 3 categories, with `doc2vec` and `sif` outperforming in both the fine-grained and coarse clustering. `skip-th` clusters, on the other hand, did not correspond with the correct labels, underperforming binary and random features, which explains its relatively low performance in text categorization tasks. `inferSent` achieved higher purity than binary, random and `skip-th` vectors but lower than the other models, particularly with $k = 3$.

sif †	And they work especially well when the **Feds** have **cut off your utilities.** The Dividians did not have that option after the **FBI cut off their electricity**. Did I **claim** that there was an absolute morality , or just an **objective** one? I have just spent two solid months **arguing** that no such thing as an **objective** moral system exists.
skip-th	**What** does this bill do ? **Where** do I get hold of these widgets ? **What** gives the United States the right to keep Washington D.C.? **What** makes you think Buck will still be in New York at year 's end with George back?	**I have just spent** two solid months arguing that no such thing as an objective moral system exists. The amount of energy being spent on one lousy syllogism says volumes for the true position of reason in this group. **I just heard** this week that he has started on compuserve flying models forum now.

Table 6: Examples of nearest neighbors in the 20-Newsgroup dataset. †`sif` using `si-skip`.

Model	Newsgroup		TREC
	k = 3, C=3	k = 8, C=8	k=6, C=6
Random	0.5563	0.2431	0.4424
Binary	0.6236	0.2963	0.444
avg †	0.8465	0.3969	0.4481
sif †	**0.8776**	0.4523	0.4037
doc2vec	**0.8625**	**0.4967**	0.3855
skip-th	0.4471	0.1854	0.3896
GRAN	0.8227	0.3553	0.3514
inferSent	0.6562	0.3801	0.4424

Table 7: Clustering purity measure with coarse categories (sports, computers, religion/politics) and the original 8 categories for the Newsgroup dataset, and 6 categories for TREC. †`avg` and `sif` using `si-skip`.

Figure 4 shows t-SNE visualizations of the questions in TREC training set. While all models identified some of the categories, like **HUM** and **LOC**, the `skip-th` and binary vectors appears to be more cohesively clustered by type than the other models. The question types are scattered in multiple smaller clusters, however, which explains why k-means clustering resulted in lower purity scores than `doc2vec` and `averaging` with $k = 6$. In Figure 5, purity results with various k are plotted. While purity is expected to increase with larger k, the rate of increase is much higher for `skip-th` than all other models, including binary features. This is consistent with the t-SNE visualization which shows several consistent clusters with `skip-th` that are larger than the binary clusters. `inferSent`'s performance was on par with `avg`, which is slightly lower than binary and `skip-th`, although the performance in the supervised setting was equivalent.

Table 8 shows nearest neighbors to the question "What country do the Galapagos Islands belong to?" using the various models. The averaging model clustered questions about islands; we observed similar behavior using weighted averaging, `doc2vec` and `GRAN`. On the other hand, `skip-th` clustered questions that start with "what country", which happens to be more suitable for identifying the **LOC** question type. Using binary vectors, questions that include the words "What" and "country" were clustered together, which do not necessarily correspond to the same question type. `inferSent` vectors seem to be clustered by a combination of semantic and syntactic features.

6.1 Discussion and Conclusions

In this study, we attempted to identify qualitative differences among the compositional models and general characteristics of their vector spaces that explain their performance in downstream tasks. Identifying the specific features that are most useful for each task may shed light on the type of information they encode and help optimize the representations for our needs. Word vector averaging performed reasonably well in most supervised benchmarks, and weighted averaging resulted in better performance in unsupervised similarity tasks outperforming all other models. Using the subword skipgram model for word embeddings resulted in better representations overall, particularly with `sif` weighting. The only model that performed on par with or slightly better than weighted averaging in unsupervised STS was

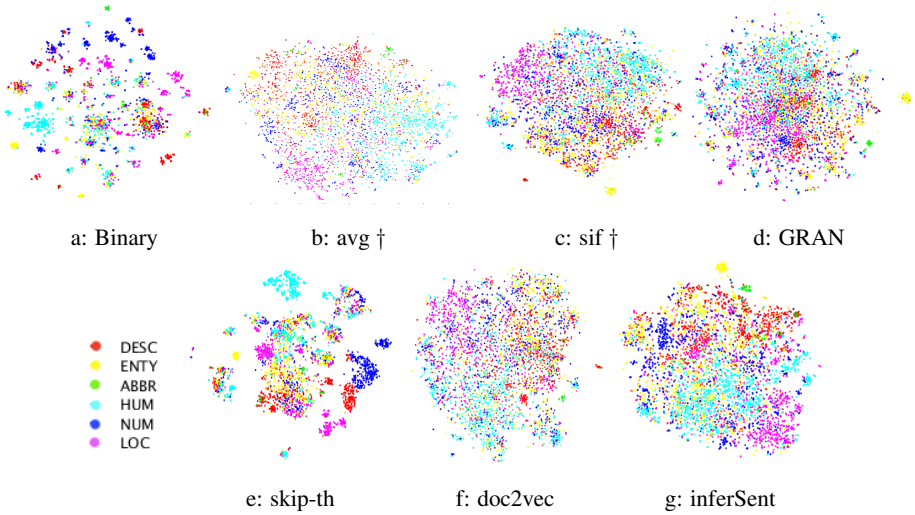

Figure 4: t-SNE visualizations of vectors on the TREC dataset. † `avg` and `sif` using `si-skip`.

avg†	What currents affect the area of the Shetland Islands and Orkney Islands in the North Sea?
	What two Caribbean countries share the island of Hispaniola?
Binary	What is a First World country?
	What is the best college in the country?
skip-th	What country is the worlds leading supplier of cannabis?
	What country did the Nile River originate in?
	What country boasts the most dams?
inferSent	What country did the ancient Romans refer to as Hibernia?
	How many islands does Fiji have?
	What country does Ileana Cotrubas come from ?

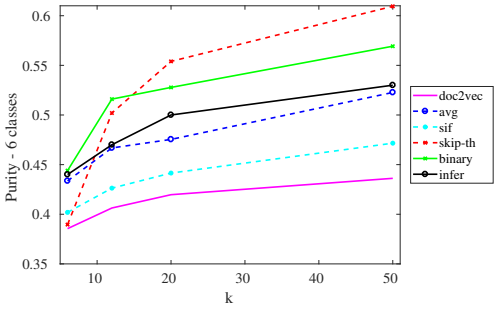

Figure 5: Clustering purity with increasing k on TREC. [`avg` and `sif` for `si-skip`]

`inferSent`. All models achieved higher correlation scores in the supervised STS evaluation, including `skip-th`, which performed poorly in the unsupervised setting. This suggests that at least some of the features in the vector space encode the semantic content and the remaining features are superfluous or encode structural information.

`doc2vec` and `GRAN` representations were qualitatively similar to `idf` and `sif` vectors where sentences/paragraphs were clustered by topic and semantic similarity. `skip-th` vectors, on the other hand, seemed to prominently represent structural rather than semantic features, which makes them more suitable for supervised tasks that rely on sentence structure rather than unsupervised similarity or topic categorization. `inferSent` vectors performed consistently well in all evaluation benchmarks, and a qualitative analysis of the vector space suggests that the vectors encode a balance of semantic and syntactic features. This makes `inferSent` suitable as a general-purpose model for sentence representation, particularly in supervised classification. For topic categorization, none of the compositional models outperformed the NBSVM baseline, which achieved significantly higher accuracies in all supervised topic categorization tasks. However, the distributional models, particularly weighted averaging, are more suitable in unsupervised or low-resource settings since sentences tend to be clustered cohesively by topic similarity and semantic relatedness.

Abstract

Formulaic expressions (FEs) used in scholarly papers, such as '*there has been little discussion about*', are helpful for non-native English speakers. However, it is time-consuming for users to manually search for an appropriate expression every time they want to consult FE dictionaries. For this reason, we tackle the task of semantic searches of FE dictionaries. At the start of our research, we identified two salient difficulties in this task. First, the paucity of example sentences in existing FE dictionaries results in a shortage of context information, which is necessary for acquiring semantic representation of FEs. Second, while a semantic category label is assigned to each FE in many FE dictionaries, it is difficult to predict the labels from user input, forcing users to manually designate the semantic category when searching. To address these difficulties, we propose a new framework for semantic searches of FEs and propose a new method to leverage both existing dictionaries and domain sentence corpora. Further, we expand an existing FE dictionary to consider building a more comprehensive and domain-specific FE dictionary and to verify the effectiveness of our method.

Title and Abstract in Japanese

執筆支援システムにおける定型表現の利用

論文中に用いられる定型表現（formulaic expressions）とは，例えば'there has been little discussion about'などであり，非英語母語話者の英語論文執筆に有益である。しかしながら，定型表現辞書をその都度参照して適切な表現を探すのは容易ではない。そこで本研究では，計算機による定型表現辞書の意味検索に取り組む。まず，本タスクにおける課題として以下の2つを挙げる。既存の定型表現辞書に収録されている例文が少なく意味表現の獲得に必要な文脈情報が不足していること，多くの定型表現辞書では意味カテゴリごとに定型表現が分類されているが，ユーザの入力から意味カテゴリを予測することが困難であり，ユーザに意味カテゴリを明示する手間が発生することである。 これらの課題を解決するため，本研究では定型表現の意味検索の新たな枠組みを提案し，既存の定型表現辞書を分野毎の英文コーパスと対応づけて利用するための手法を提案する。 さらに，既存の定型表現辞書を拡張し，より網羅性が高く，かつ分野特化型の定型表現辞書の構築を検討し，有効性を検証する。

1 Introduction

Non-native English speakers writing scholarly papers often use the same expressions repeatedly or are not confident in the correctness of their usage of certain wording. Existing computer-based writing assistance systems do not always help them find better expressions than those they already know because such systems search a corpus by using simple pattern-matching based on input keywords (Chang et al., 2015; Chang and Chang, 2015; Jeong et al., 2014; Liu et al., 2016; Mizumoto et al., 2017). For instance, when a user wants to write about previous work and find expressions other than '*little research was done*

Proceedings of the 27th International Conference on Computational Linguistics, pages 2678–2689
Santa Fe, New Mexico, USA, August 20-26, 2018.

on', the only one the user might know, a keyword-based search does not present expressions such as '*there has been little discussion about*' to the user.

A reasonable solution is using dictionaries of formulaic expressions (FEs) (Ellis et al., 2008; Conklin and Schmitt, 2008). FEs used in scholarly papers are helpful for non-native English speakers writing papers in English (Peters and Pauwels, 2015). FEs have a communicative function and thus in FE dictionaries, they are classified into categories on the basis of their functions. Consequently, if a user wants to write about the fact that there is little research on a topic, the user goes to the category '*to show lack of existing research*' and finds expressions such as '*there has been little discussion about*', even if the user has not ever encountered the entire expression.

Despite the usefulness of such FE dictionaries, it is time-consuming for users to choose a category and manually find candidate expressions every time they consult the dictionary. Therefore, the aim of our research is to enable semantic searches of FE dictionaries by computers with incomplete user input. In this paper, we formulate this problem as a prediction task for categories in FE dictionaries. Note that user input can be an incomplete sentence that does not contain a FE because we suppose users who do not think of FEs or who just input some words they have in mind.

We started by identifying two salient difficulties. The first is that very few example sentences are included in FE dictionaries, resulting in the lack of context information necessary for acquiring semantic representation of FEs. The second is that writing assistance systems must automatically predict a semantic category from user input so that users no longer need to designate the category.

In this paper, we propose a method to create a new writing assistance system and verify if it works. First, we extracted example sentences from corpora for a given FE. Second, we checked if having sufficient example sentences improved the prediction of a category from user input that would be an incomplete sentence or phrase. Finally, we classified FEs into categories using context information including full sentences and section labels in addition to the FEs themselves. In our experiment, we used two corpora from different disciplines, one from ACL Anthology (computational linguistics) and the other from PubMed (life science & medicine). For an existing FE dictionary, we used Academic Phrasebank (Morley, 2018).

FEs recorded in the dictionaries are not always suitable for writing assistance systems because many of the expressions do not occur in an actual corpus and differ depending on disciplines. Thus, we aim to build a more comprehensive and more domain-specific FE dictionary by expanding an existing FE dictionary. In this study, we formulate the extraction of FEs from corpora as a sequential labelling problem, which is solved by learning *formulaicity* with an existing dictionary.

The contributions of this paper are as follows. We present a new framework for semantic searches of FEs that can be used when writing scientific papers. We propose leveraging both existing dictionaries and domain-sentence corpora and show that using context information extracted from actual corpora improves the category-prediction accuracy, compared to using the context information originally recorded in the existing FE dictionary. We reformulate FE extraction as a sequential-labelling problem and show that the quality of the FEs extracted with our method is higher than that of those with previous methods.

2 Related Work

2.1 Writing Assistance Systems

Existing writing assistance systems are classified into three types. First, the most direct approach for computer-based writing assistance is that in which user-input sentences are used to retrieve example sentences. Search results are shown with concordances (Wu et al., 2006) or dependency structures (Kato et al., 2006).

Another approach is similar to an input method in which users can input non-alphabetical languages. FLOW (Chen et al., 2012) suggests an English translation from words written in another language. WINGS (Dai et al., 2014) suggests full Chinese sentences and words from pinyin. Full sentences are suggested on the basis of searches for sentences that contain words that are the same as or similar to the input.

The third approach is combined with an authoring system. With this approach, candidate English

expressions that follow user input are listed; then the users can choose one of them (Jeong et al., 2014; Chang et al., 2015; Yen et al., 2015; Chang and Chang, 2015; Liu et al., 2016; Mizumoto et al., 2017). Some systems allow users to specify the categories of FEs. Such categories include the Introduction, Method, Results and Discussion (IMRaD) structure (Jeong et al., 2014), argumentative zone (Teufel, 1999; Chang et al., 2015) and move-step structure (Swales, 1990; Mizumoto et al., 2017). Note that users must designate which category to use.

Overall, existing writing assistance systems adopt keyword-based searches, and thus the number of suggested expressions is limited to ones that contain user-input keywords.

2.2 Definitions of Formulaic Expressions

A survey of definitions of FEs shows that there are three ways of defining them (Durrant and Mathews-Aydınlı, 2011). The first is a 'phraseological' approach. Using this approach, *formulaicity* is definable by non-compositionality of word sequences. However, this definition is not for FEs but for idioms because the semantics of FEs are often compositional. For example, '*have been explored by many researchers*' has a compositional meaning but it is nonetheless a FE. The second is a 'frequency-based' approach. In this approach, frequently co-occurring word sequences are considered FEs. However, noise such as '*is one of the*' cannot be removed. Also, FEs do not always occur frequently. The third one is a 'psychological' approach, which defines FEs as word sequences that are processed and remembered as a whole in the human brain. This seems to be a successful definition of formulaicity, but computers cannot process word sequences using this approach.

Several analyses of FEs exist. Biber et al. (2004) analysed the usage of lexical bundles (continuous word sequences) in an academic context. They defined lexical bundles as 'the most frequent recurring lexical sequences in a register'. Their results showed that lexical bundles are not always syntactically structured. In fact, they often contain some fragments such as '*is based on the*', '*I don't know if*' and '*a little bit of*'.

Along with lexical bundles, Gray and Biber (2013) specifically examined phrase frames: discontinuous word sequences with a slot ' * 'that is filled by any word. The number of lexical bundles used in corpora is larger than that of phrase frames, but examining particularly those occurring in at least five texts, phrase frames are more numerous than lexical bundles. They classified phrase frames into three types: verb-based frames, frames with other content words and function word frames.

Although there are several definitions of FEs, many dictionaries of FEs has been published in which FEs are collected on the basis of intuitive definitions.

2.3 Extraction of Formulaic Expressions

Simpson-Vlach and Ellis (2010) extracted word sequences, three to five words in length, from corpora. Then, with frequency and mutual information, the extracted word sequences were ranked. Their results show that highly frequent word sequences alone cannot be regarded as FEs because they have no distinctive function or meaning. Further, useful expressions are not always highly frequent. In fact, word sequences with high mutual information are rare in corpora because many are subject-specific.

Vincent (2013) decomposed a candidate phrase into the phrasal core and its collocates. The phrasal core is a continuous or discontinuous word sequence occurring with high frequency. Candidate phrases including the core were first identified in a corpus. Then the collocates were sought.

Brooke et al. (2015) used the technique for multi-word expression extraction (Brooke et al., 2014) to find FEs. They split a sentence into parts with a lexical predictability ratio. They pointed out that evaluating newly acquired FEs is difficult because there is no answer dataset.

Aside from studies of FE extraction, several studies have addressed phrase extraction in particular for information extraction or text mining (Zhong et al., 2012; Zhang et al., 2013; Liu et al., 2015). However, these studies specifically addressed characteristic phrases that were informative. Therefore, FEs such as '*in this paper*' were not considered target expressions.

3 Semantic FE Search for Writing Assistance System

3.1 Proposed Searching System

Most existing writing assistance systems seek candidate expressions using keyword-based searches, which causes the problem wherein expressions very different from the input are not presented to users. Consequently, we first consider a semantic searching system that searches for FEs. Then, we propose a scheme for a dictionary of FEs.

The proposed searching system is based on the way people manually use FE dictionaries. Specifically, a user chooses a category that expresses the user's intent. Then, the user picks one of the FEs belonging to that category. Consequently, the proposed searching process consists of two steps. First, the system presumes a user's intention on the basis of written words, which may be an incomplete phrase or sentence. Second, the system searches a dictionary for candidate expressions in the category corresponding to the presumed intention. To choose the correct category, the system must use information related to context that is derived from what a user is writing. Therefore, a resource must include information related to context in which an expression is used. For example, the expression '*further research should be undertaken to investigate*' is not suggested by a keyword-based search with the keywords '*it is future work to investigate*' but by category-based search with the category '*about future work*'.

For this system, the proposed dictionary is formalised as follows. The dictionary consists of several categories, and each category has multiple FEs. Each FE has one or more example sentences. Figure 1 shows an image of the whole dictionary.

In the following subsections we discuss categories and FEs.

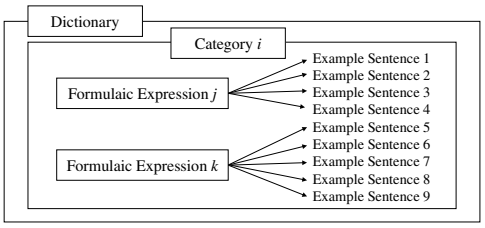

Figure 1: In the dictionary, categories have several FEs, each of which has corresponding example sentences.

3.2 Categorisation Systems

The question remains of what structures of categories are suitable for writing assistance. Presuming that FEs are classified according to their functions, writing assistance systems must anticipate what users want to write from the surrounding context. However, specifically examining scholarly papers shows that the structure of scientific documents is fixed to some degree. Consequently, as long as users write along this fixed structure, there is a good chance that the system can anticipate what the user wants to write if the categories correspond to the paper structure. Therefore, on the basis of the logical structure, categories correspond to both the functions of FEs and the user's intention.

A section-based structure is the simplest, with the Introduction, Method, Results and Discussion (IMRaD) structure adopted for many papers. However, the sections in a paper are so few that too many FEs belong to one category to choose an appropriate one easily. As described herein, we particularly examine move-step structures proposed by Swales (1990). According to Swales' analyses, a paper is composed of several sections, which include moves, each of which has steps (Table 1).

Several analyses have assessed move-step structures in scientific papers. In *Introduction* sections, the Create-A-Research-Space model was found to be adopted in many papers (Swales, 1990; Swales, 2004). Some research has specifically addressed move structures in all sections (Cotos et al., 2015) or *Abstracts* (Lorés, 2004). Other studies have emphasised examining the transition between moves (Ozturk, 2007) and differences in usage across disciplines (Peacock, 2002; Maswana et al., 2015).

Section: Introduction		
Move 1: Establishing a territory	Move 2: Establishing a niche	Move 3: Occupying the niche
Step 1: Claiming centrality	Step 1A: Counter-claiming	Step 1A: Outlining purposes
Step 2: Making topic generalization	Step 1B: Indicating a cap	Step 1B: Announcing present research
Step 3: Reviewing items of previous research	Step 1C: Question-raising	Step 2: Announcing principal findings
	Step 1D: Continuing a tradition	Step 3: Indicating RA structure

Table 1: A move-step structure for the introduction section of a research article (RA) called the Create-A-Research-Space model proposed by Swales (1990).

In our research, we use categories based on move-step structures for writing assistance systems. Specifically, we use the categorisation system that is adopted in Academic Phrasebank made by Morley (2018) because the categorisation of this resource is similar to move-step structures. In Academic Phrasebank there are six sections: Introducing Work, Referring to Sources, Describing Methods, Reporting Results, Discussing Findings and Writing Conclusions and 77 categories such as *Establishing the importance of the topic for the discipline* and *Giving reasons why a method was adopted or rejected*, which roughly correspond to steps. This is suitable for scholarly articles.

3.3 Formulaic Expressions

Considering previous work on the definitions of FEs and our semantic search model, we decide our target FEs as follows. FEs must be expressions that are helpful in writing a paper. Word sequences with an unclear function are excluded. For example, '*is the number of*' and '*the word in the*' do not have clear functions. Other expressions that should be excluded are classified into two types: overly general and overly specific expressions. The former type consists of phrases such as '*on the other hand*' and '*we would like to*'. These might appear to be useful, but they cannot be assigned one category label because '*on the other hand*' can be used in many sections of a paper. Therefore, we chose to exclude them from this research. '*Natural language processing*' or '*in the training dataset*' are examples of the latter type. Overall, in our research, we defined FEs as word sequences whose functions correspond to one category.

4 Methods

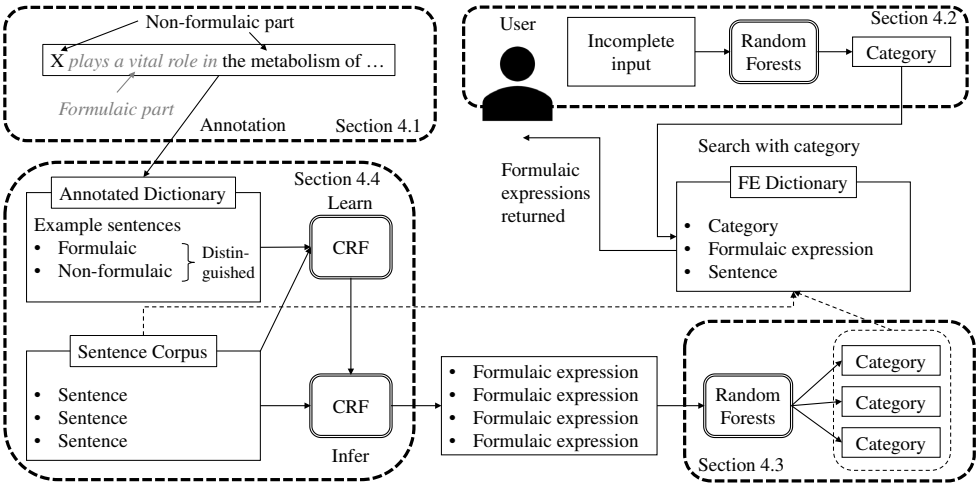

Figure 2: In Section 4.1, annotation is conducted to distinguish the formulaic from the non-formulaic part in each expression recorded in the existing dictionary to build the annotated dictionary. In Section 4.2, incomplete user input is assigned a category label. In Section 4.3, FEs and sentences are classified into categories. In section 4.4, FEs are extracted from a sentence corpus by learning formulaicity from the annotated dictionary.

4.1 Dictionary Annotation

We used two kinds of language resources: an existing dictionary of FEs and a sentence corpus extracted from a group of scientific papers. We first built an annotated dictionary from the existing dictionary.

Many expressions are recorded in the existing dictionary, but the formulaic and non-formulaic parts are not distinguished. For example, '*X plays a vital role in the metabolism of ...*' contains non-formulaic parts such as 'X', 'metabolism' and '...'. This is most problematic when using the existing dictionary because we cannot search corpora for sentences that contain FEs, using only formulaic parts. Therefore, for formulaicity to be learned from the dictionary, we first annotated the formulaic parts in the dictionary. Each word of an expression was manually labelled as either formulaic or non-formulaic (upper-left in Figure 2). Then, non-formulaic parts were removed. After annotation, we extracted sentences containing the annotated FEs from a corpus. Finally, in this annotated dictionary, each categorised FE has some example sentences derived from an actual corpus (Figure 3). All words are lemmatised to avoid inflections. Annotation guidelines are available on our GitHub repository[1].

Category: Stating the purpose of research
Formulaic expression: the objective of this research be to
Example sentences from ACL Anthology:
one of *the objectives of this research is to* make online documents more understandable by paraphrasing unknown …
Thus *the objective of this research is to* experiment with these techniques for Sinhala-Tamil, and identify the best …

Figure 3: In the annotated dictionary, each FE is classified into a category and has several example sentences extracted from a corpus[3].

As described in Section 3.2, we used Academic Phrasebank (Morley, 2018) as a dictionary because its categories are based on move-step structures.

4.2 Prediction of Categories from Incomplete Sentences

In the proposed searching system described in section 3.1, categories are automatically predicted from user input. This is formalised as a classification task from user input into categories.

The prediction is conducted with random forest[4](upper-right in Figure 2).

Each user-input is represented as a vector, which is an average of skip-gram vectors (Mikolov et al., 2013) of each word in the input. The vector representations are learned with a sentence corpus.

The annotated corpus is so divided into a training dataset and a test dataset that sentences in one category in one dataset are almost as many as those in the other dataset.

User input can be an incomplete sentence. Therefore, inputs of two types are prepared as presumed user inputs. One is a sentence not containing a FE, based on the idea that a user wants to find a FE with content words (WithoutFE). The other is a sentence with half or two thirds of the composing words removed. Specifically, we simply select words from every two or three words in a sentence. This simulates a situation where a user comes up with some words but does not compose a sentence (PickedWords). This vector can include part of a FE because users may know some of the words composing the FE.

4.3 Classification of FEs into Categories

In the proposed FE dictionary, FEs are classified into categories. In the previous section classified user input into categories; this section classifies FEs into categories. Therefore, the same methodology as the previous section can be applied to this task, but the input features are different.

We used random forests as a classifier and the input was a vector representation of a FE. The output was a category label (lower-right in Figure 2).

[1] `https://github.com/Alab-NII/FE/blob/master/annotation_guidelines.md`

[3] The example sentences were extracted from two papers: Higashinaka, R., & Nagao, K. 2002. Interactive paraphrasing based on linguistic annotation. In *COLING 2012*. and Hameed, R. A., et al. 2016. Automatic Creation of a Sentence Aligned Sinhala-Tamil Parallel Corpus. In *WSSANLP 2016*.

[4] we use an R package (`https://cran.r-project.org/web/packages/randomForest/randomForest.pdf`).

We used a sentence and a section label in which a FE is used as context information. We tested five kinds of vectors, as described below. Each vector is an average of the vectors of each composing word.

Sentence Vector (Sen) This vector is produced from every word of a sentence that includes the FE.

Sentence Vector without Functional Word Effects (Sen - FW) This vector was presented by Arora et al. (2017). To decrease the effect of functional words, each word embedding is weighed by the coefficient $\frac{a}{a+p}$ where a denotes a parameter set as 0.001 in our experiment and p is word frequency. Afterwards, singular value decomposition is applied.

Sentence Vector without Content Word Effects (Sen - CW) To decrease the content word effects, words with low frequency are removed. When calculating the average vector of each word embedding, words that occur in the sentence corpus less than once per million words are ignored.

Sentence Vector with Section Information (Sen + Sec) A simple one-hot vector which shows that the title of a section in which the FE is used contains *introduction* or *background*, *related work*, *method* or *approach*, *experiment* or *evaluation*, *result*, *discussion* or *conclusion* or *future*, is concatenated to the sentence vector. Some FEs appear in multiple sections, so we assigned the most popular section label in each FE to sentences.

Formulaic Expression Vector (FE) This vector is a baseline made solely from words that compose the FE in the annotated dictionary, which means that context information is excluded.

4.4 Acquisition of new FEs from Corpora

To exploit the intuitive definition of formulaicity in Academic Phrasebank, we implemented a supervised learning method to extract FEs. The FEs recorded in Academic Phrasebank and occurring in real corpora are few in number, so we first paraphrased all nouns, adjectives and adverbs in the annotated dictionary to expand the dataset, using PPDB2.0 (S size) (Pavlick et al., 2015). Subsequently, we attached BIO tags to each sentence in the annotated dictionary. Here, the first word of a FE is assigned a B label. Other words of a FE are tagged with an I label. The rest of the words in the sentence are labelled O. Formulaicity is learned using these sentences. We used conditional random fields (CRFs)[5] to learn and extract FEs. Features were words, part-of-speech tags and word frequency, which was discretised. Then, using the learned model, each word of every sentence in a sentence corpus was given a BIO tag (lower-left in Figure 2). This formulation facilitates the extraction of both continuous and discontinuous FEs.

5 Evaluation

5.1 Datasets

We built two kinds of datasets: an annotated dictionary and a sentence corpus. To build the annotated dictionary, we annotated Academic Phrasebank. Three annotators annotated FEs in five categories to check inter-annotator agreement. The value was 0.699 (Cohen's kappa coefficient). Then, the rest of the FEs were annotated by one annotator. Academic Phrasebank as an existing dictionary had 77 categories, but some categories in which there are fewer than two example sentences extracted from the sentence corpus or in which no FE was found after the annotation were removed. Consequently, 39 categories for ACL Anthology and 45 categories for PubMed were adopted.

We compiled a sentence corpus for which sentences were extracted from papers in ACL Anthology and PubMed. Our corpus consisted of 2,629,115 sentences from ACL Anthology and 2,894,721 sentences from PubMed. Table 2 shows the number of FEs and sentences after the paraphrasing. By paraphrasing FEs and sentences were increased. However, while the number of FEs in the annotated dictionary was originally 854, most of them did not occur in the corpora so that the number was reduced to 225 and 334, respectively.

[5]We use CRF++ (`https://taku910.github.io/crfpp/`).

ACL / PubMed	Before paraphrasing	After paraphrasing
Number of formulaic expressions	225 / 334	352 / 540
Number of example sentences	40,510 / 66,193	49,118 / 89,734

Table 2: Sentence corpora characteristics show that the number of FEs and sentences increased by paraphrasing.

5.2 Prediction of Categories from Incomplete Sentences

To show that sufficient example sentences are necessary for the writing assistance system to predict a category, we classified the presumed user input into a category with a comparison to the original Academic Phrasebank and the annotated dictionary.

Table 3 presents the accuracy, macro precision, macro recall and macro F-measure of the prediction. These results indicate that example sentences recorded in Academic Phrasebank are insufficient for the writing assistance system to predict a category from user input. Consequently, the dictionary requires example sentences extracted from an actual corpus depending on the writer domain.

Dataset	ACL Anthology				PubMed			
	Acc	P	R	F	Acc	P	R	F
WithoutFE w/AP	1.64%	3.52%	6.44%	0.64%	0.69%	2.61%	4.45%	0.52%
PickedWords w/AP	11.2%	6.04%	5.52%	3.14%	3.32%	4.91%	3.72%	2.21%
WithoutFE w/SC	55.9%	77.1%	20.6%	27.3%	47.8%	55.1%	17.8%	20.0%
PickedWords w/SC	81.7%	90.0%	43.2%	54.5%	72.1%	77.9%	37.6%	45.8%

Table 3: Accuracy (Acc), average precision (P), average recall (R) and average F-measure (F) of the classification are shown. The values in upper two rows are the results of the classification in which the training dataset was made from only example sentences in Academic Phrasebank (AP), while those in the lower two rows are the result of the proposed method trained with many more example sentences in a sentence corpus (SC).

5.3 Classification of FEs

The number of FEs was small, so we did a leave-one-out cross validation with FE vectors. The other types of vectors described in Section 4.3 were made from sentences. Eventually, the annotated corpus was divided into training and test datasets in the same way as described in Section 4.2. We also used Academic Phrasebank sentences as a training data for comparison.

The results are presented in Table 4. The results show that the classification of FEs is improved when context information such as example sentences and section information is used. Additionally, removing the effect of highly frequent word adversely affects the classification accuracy, probably because FEs usually consist of frequent words. The results demonstrate that sentences recorded in Academic Phrasebank are insufficient for the writing assistance system to classify FEs into categories.

5.4 Acquisition of new FEs

Using the learned model with CRFs, we extracted FEs from the corpora. After extraction, word sequences that occurred less than twice in the corpus, with a length of less than four words or in which the same words (excluding prepositions) were used twice or more were removed. From ACL Anthology we obtained 2,086 FEs (including 481 discontinuous FEs) with 117,889 example sentences. From PubMed we acquired 1,884 FEs (including 172 discontinuous FEs) with 184,311 example sentences. The extracted FEs are available on our GitHub repository[6].

We manually evaluated each extracted FE, checking if it met the definition we made. We picked FEs in the following way. First, we calculated the smallest edit distances between each FE and all expression

[6] https://github.com/Alab-NII/FE/

	ACL Anthology				PubMed			
Input vector	Acc	P	R	F	Acc	P	R	F
Sen	71.7%	79.0%	28.4%	35.7%	61.1%	51.1%	21.0%	23.3%
Sen - FW	65.1%	77.1%	25.3%	32.7%	54.2%	48.3%	18.6%	20.7%
Sen - CW	72.0%	78.3%	27.7%	35.0%	61.5%	51.7%	21.2%	23.4%
