In our case, the words in the modern languages are the sequences, and their characters are the tokens. Our purpose is to obtain, for each input word, a sequence of characters that compose its proto-word. To this end, we use conditional random fields (CRFs) (Lafferty et al., 2001). As features for the CRF system, we use character n-grams from the input words, extracted from a fixed window w around the current token.

2.2 Pairwise Sequence Alignment

To align pairs of words, we experimented with two alignment methods that have been proven useful in natural language processing and computational biology: the alignment method based on profile hidden Markov models proposed by Bhargava and Kondrak (2009) and the Needleman-Wunsch global alignment algorithm (Needleman and Wunsch, 1970).

Since the alignment is only a pre-processing step for our task, we evaluate the alignment methods by the downstream results, i.e., the accuracy obtained by the CRF system when using one or the other alignment method. We observed that the results obtained with the two alignment methods were very similar, slightly better for the latter. Thus, we report the results obtained with the Needleman Wunsch alignment algorithm.

The alignment algorithm uses, in our case, words as input sequences and a basic substitution matrix, which gives equal scores to all substitutions, disregarding diacritics (e.g., we ensure that *e* and *è* are matched). For example, for the Romanian word *frumos* (meaning *beautiful*) and its Latin ancestor *formosus*, the alignment is as follows:

```
f - r u m o s - -
f o r - m o s u s
```

For each character in the modern word (after the alignment), the associated label is the character which occurs on the same position in its proto-word. In the case of insertions, we add the new character to the previous label, because there is no input character in the source language to which we could associate the inserted character as label. We account for affixes separately: for each input word, we add two more characters B and E, marking the beginning and the end of the word. The characters that are inserted in the target word at the beginning or at the end of the word are associated to these special characters. In order to reduce the number of labels, we replace the label with $\star$ for input tokens that are identical to their labels. Thus, for the previous example, the labels are as follows:

```
B  f  r  u  m  o  s  E
↓  ↓  ↓  ↓  ↓  ↓  ↓  ↓
*  fo *  -  *  *  *  usE
```

2.3 Ensembles

Ensembles of classifiers combine the results of multiple classifiers, in order to improve performance. In our case, the classifiers use different input data: we train a classifier for each modern language and

combine their results, in order to obtain Latin proto-words with higher accuracy. Our goal is to improve the performance of the system by taking advantage of the information provided by all languages.

Each classifier produces, for each input word, an n-best list of possible proto-words. To combine the outputs of the classifiers, we propose four fusion methods based on the ranks in the n-best lists and the probability estimates provided by the individual classifiers for each possible production.

Given a cognate set, we combine the n-best lists previously obtained to compute a joint n-best list that leverages information from all modern languages.

Fusion by rank. We compute an average rank for each production from the n-best lists, as the average rank from all modern languages. We favor words that occur on the first position in multiple n-best lists. In other words, for a given n-best list, we associate weights in a Borda sense (Borda, 1781) to all the words from the list: we give weight *n* to the word produced with the highest confidence, *n - 1* to the second one, and so on, until weight *1* to the *n*-th produced word. For an n-best list L_i and a word u, we denote by $w(u_i)$ the weight of word *u* in L_i; if *u* is not a word from list L_i, then $w(u_i) = 0$. Given *k* n-best lists (one for each modern language) and a produced word u, we define the rank weight of u over the *k* n-best lists as:

$$w_r(u) = (1/k) * \sum_{i=1}^{k} w(u_i). \tag{1}$$

Fusion by rank and accuracy. Starting from the previous fusion method, we also take into account the training accuracy for each language. We give more importance to the *vote* of the languages that obtained a better performance, multiplying the weight by the training accuracy. In other words, for each n-best list L_i, let $\pi(i)$ be the training accuracy for language i (COV_{10}). Given *k* n-best lists (one for each modern language) and a produced word u, we define the rank-accuracy weight of u over the *k* n-best lists as:

$$w_{ra}(u) = (1/k) * \sum_{i=1}^{k} w(u_i)\pi(i). \tag{2}$$

Fusion by weight. We compute an average confidence score for each production from the n-best lists, using the confidence score reported by the sequence labeling system. We rerank the productions based on the average confidence score. Given *k* n-best lists (one for each modern language), a produced word u, and $w(u_i)$ the confidence score of the sequence labeling system in list L_i, we define the confidence weight of u over the *k* n-best lists as:

$$w_c(u) = (1/k) * \sum_{i=1}^{k} w(u_i). \tag{3}$$

This is similar to the first fusion method, but uses the sequence labeling system's weights instead of the weights obtained from the ranking in the n-best lists.

Fusion by weight and accuracy. Starting from the previous fusion method, we also take into account the training accuracy for each language. We give more importance to the *vote* of the languages that obtained a better performance, multiplying the score by the training accuracy. Given *k* n-best lists (one for each modern language), a produced word u, and $w(u_i)$ the confidence score of the sequence labeling system in list L_i, we define the confidence-accuracy weight of u over the *k* n-best lists as:

$$w_{ca}(u) = (1/k) * \sum_{i=1}^{k} w(u_i)\pi(i). \tag{4}$$

This is similar to the second fusion method, but uses the sequence labeling system's weights instead of the weights obtained from the ranking in the n-best lists.

The output of each ensemble is a new n-best list in which the words are sorted in descending order of their computed weights, as described in Equations 1-4.

Oracle. An oracle classifier is an ensemble method that produces the correct result if any of the comprising classifiers produces the correct result. The purpose of an oracle is to determine the upper limit of an ensemble. The probability of obtaining correct results from an oracle is the following (Kuncheva et al., 2003):

$$P(oracle) = 1 - P(all\_wrong) \tag{5}$$

3 Experimental Setup

In this section we describe the experimental setup that we employed to assess the performance and to analyze the proposed method for proto-word reconstruction.

3.1 Datasets

We use datasets of Romance languages with Latin ancestors:

Dataset 1. The dataset proposed by Bouchard-Côté et al. (2007). It contains 585 complete cognate sets in three Romance languages (Spanish, Portuguese, Italian) and their common Latin ancestors. It is provided in two versions: orthographic and phonetic (IPA transcriptions). This dataset allows us to compare our results with a previous state-of-the-art method for proto-word reconstruction.

Dataset 2. The dataset proposed by Reinheimer Ripeanu (2001). It consists of 1,102 cognate sets in five Romance languages (Spanish, Italian, Portuguese, French, Romanian) and their common Latin ancestors. Note that not all of these cognate sets are complete (that is, for some of them there are not cognates provided in all five modern languages).

Dataset 3. The dataset proposed by Ciobanu and Dinu (2014b) and previously used for cognate detection (Ciobanu and Dinu, 2014a). It contains 3,218 complete cognate sets in five Romance languages (Spanish, Italian, Portuguese, French, Romanian) and their common Latin ancestors. Below we provide an example of a cognate set from this dataset:

vehicul (**Ro**) | véhicule (**Fr**) | veicolo (**It**) | vehículo (**Es**) | veículo (**Pt**) | vehiculum (**Lat**)

3.2 Task Setup

We split each dataset in subsets for train, dev and test (3:1:1 ratio). For inferring the form of the proto-words, we use the CRF implementation provided by the Mallet toolkit (McCallum, 2002). For parameter tuning, we perform a grid search for the number of iterations in $\{1, 5, 10, 25, 50, 100\}$ and for the size of the window w in $\{1, 2, 3, 4, 5\}$.

3.3 Evaluation Measures

Following previous work in this area (Bouchard-Côté et al., 2007; Beinborn et al., 2013), we use the evaluation measures listed below to assess the performance of our method:

Average edit distance. To assess how close the productions are to the correct form of the proto-words, we report the edit distance between the produced words and the gold standard. We report both the unnormalized and the normalized edit distance. For normalization in the [0,1] interval, we divide the edit distance by the length of the longest string.

Coverage. Also known as *top n accuracy*, the coverage is a relaxed metric which computes the percentage of input words for which the n-best output list contains the correct proto-word (the gold standard). We use n $\in \{1, 5, 10\}$. The practical importance of analyzing the top n results is that we offer a filter to narrow down the possible forms of the output words to a low-dimensional list, that linguists can analyze, aiming to identify the correct form of the proto-word. Note that the coverage for n = 1 is the well-known measure accuracy.

Mean reciprocal rank. The mean reciprocal rank is an evaluation measure which applies to systems that produce an ordered output list for each input instance. Given an input word, the higher the position of its correct proto-word in the output list, the higher the mean reciprocal rank value:

$$MRR(w_i) = \frac{1}{m}\sum_{i=1}^{m}\frac{1}{rank_i}, \tag{6}$$

where m is the number of input instances, and $rank_i$ is the position of w_i's proto-word in the output list. If w_i's correct proto-word is not in the output list, we consider the reciprocal rank 0.

4 Results

In this section we analyze and compare the performance of our systems in different scenarios. We also compare our results with previous work.

4.1 Results Analysis

In Table 1 we report the results of our individual systems (one for each modern language) and the ensemble results. For individual experiments, Italian obtains the lowest average edit distance on all datasets.
For ensembles, we experimented with the four fusion methods described in the previous section, but report only the best performing one. Out of the four proposed fusion methods, the first two lead to similar results, that are superior to the other two. The best-performing ensemble uses the second fusion method, which assigns scores based on the rank in the n-best lists and the training accuracy for each individual system. We also tried applying the ensembles on language subsets (that is, not to take all modern languages into account at once). We investigated all combinations, and in the majority of cases using all modern languages lead to the highest performance among all ensembles.
In Table 2 we show an example of our systems' output n-best lists. This example illustrates how the ensemble can improve over the individual classifiers, by ranking the correct production higher than all the other systems. For all datasets we obtained performance improvements for proto-word reconstruction when we combined individual results using ensembles. As expected, the highest performance was obtained by the oracle classifiers. The results show the high potential of the ensemble methods for proto-word reconstruction.
The average edit distance of our best-performing ensemble, on Dataset 3, is 1.07, meaning that, on average, the proto-word reconstructions obtained by the system are a little more than one character different from the correct proto-words. Furthermore, the correct proto-word is listed among the 5-best list productions of our system in 70% of the cases (increasing to 74% for 10-best lists). These results are encouraging, having in mind the purpose of our system: to be a tool to be used by linguists (not to substitute the work of the experts).
Overall, we notice that the results are significantly better for Datasets 2 and 3 than for Dataset 1. One possible explanation is the nature of the dataset: while Datasets 2 and 3 are built based on the etymologies of the words (that is, the genetic relationships are taken into account), for Dataset 1 the cognacy decisions have been made based on an edit distance threshold between the words (Bouchard-Côté et al., 2007). To test this assumption, we ran an additional experiment, training the system on a subset of Dataset 3, having the same size as Dataset 1. The performance was close to that reported for Dataset 3 in Table 1, confirming that it is the nature of the dataset rather than its size that influences the results.

4.2 Additional Experiments: Neural Word Production

We performed additional experiments using a recurrent neural network (RNN) system with an encoder-decoder architecture instead of a CRF. RNNs have been proven useful in many applications, and are suitable for sequence labeling problems. However, they require large amounts of training data. In historical linguistics in general, and in the problem of proto-word reconstruction in particular, the resources are often scarce. Thus, we were interested to find out if RNNs can outperform the CRF system. We experimented with an encoder-decoder system with two long short-term memory (LSTM) layers, with stochastic gradient descent (SGD) optimization and a global attention mechanism (Luong et al.,

0.10 for Dataset 1, while the CRF system obtains about 0.15 on the same dataset). The results are not included here, since they do not provide better performance. We leave for future work experimenting with additional features and setups, in order to compensate for the lack of training data.

4.3 Error Analysis

In this subsection we perform a brief analysis of the errors of our ensemble systems. The purpose of this step is to understand where the systems are not able to learn the correct production rules, in order to improve them in the future.

Looking at the incorrect productions that have one character different from the correct proto-word, we notice that sometimes the final vowel is mistaken. Most commonly, *um* instead of *us*: *serenum* instead of *serenus*, *cantum* instead of *cantus*, *novum* instead of *novus*. Another one-character mistake is, sometimes, failing to double a consonant. For example, *ll* or *ss*: *colapsus* instead of *collapsus*, *intervalum* instead of *intervallum*, *disociatio* instead of *dissociatio*, *esentia* instead of *essentia*.

For productions that have two characters different from the correct proto-word , we notice the following patterns in the incorrect productions: sometimes the character *f* is mistakenly obtained instead of *ph*: *asfaltus* instead of *asphaltus*, *eufonia* instead of *euphonia*, *diafragma* instead of *diaphragma*. Another interesting pattern is obtaining the suffix *a* instead of *us*: *citrina* instead of *citrinus*, *alba* instead of *albus*. When this occurs for adjectives, the productions are not incorrect words in Latin; we obtain the feminine form instead of the masculine.

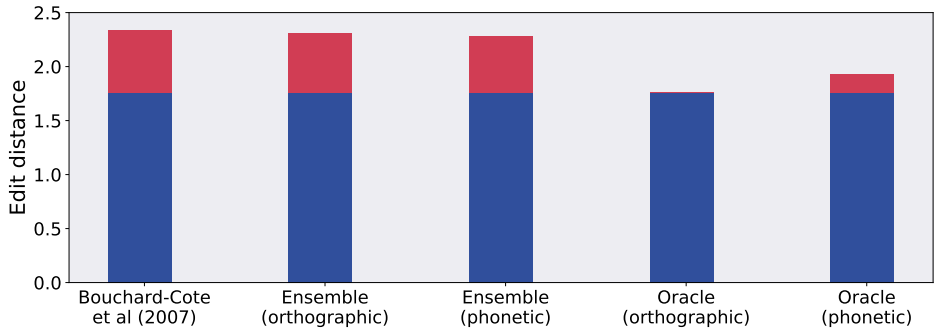

Figure 2: Comparison between previous work (Bouchard-Côté et al., 2007) and our ensembles and oracles on Dataset 1.

4.4 Comparison with Previous Work

Dataset 1 allows us a fair comparison with the state-of-the-art method proposed by Bouchard-Côté et al. (2007), as illustrated in Figure 2. On the same dataset, the authors report 2.34 average edit distance

between the produced words and the gold standard, when recreating Latin proto-words using the phonetic transcriptions. On the same dataset, we obtain better results on both the orthographic and the phonetic version of the dataset. The best of our systems (ensemble with fusion method based on the rank in the n-best lists and the training accuracy) obtains 2.28 average edit distance on the phonetic version of the dataset and 2.31 average edit distance on the orthographic version. The oracle obtains 1.76 average edit distance on the orthographic version of the dataset and 1.93 on the phonetic version.
The improvement of our systems is significant because we are able to obtain these results with less data than in previous experiments – which in historical linguistics is essential, as resources are most of the time scarce: the system is able to perform well even when not having the phonetic transcripts of the words.

5 Related Work

Researchers have been continuously interested in language derivation (Pagel et al., 2013). One of the main concerns in historical linguistics is language change across space and time (Rama and Borin, 2014). The first attempts to address this problem focused on regular sound correspondences to construct modern forms of the words, given a proto-language, or vice-versa. Traditionally, proto-language reconstruction has been investigated with comparative linguistics instruments (Campbell, 1998) and required a manual process and intensive work from linguistics and domain experts. Modern approaches impose the use and development of quantitative and computational methods in this field (McMahon et al., 2005; Heggarty, 2012; Atkinson, 2013), or even cross-disciplinary methods (such as those borrowed from biology).
Some of the early studies on partially automating proto-language reconstruction belong to Covington (1998) – investigating multiple alignment for historical comparison, and Kondrak (2002) – proposing, among others, methods for cognate alignment and identification.
More recent approaches addressed the complete automation of the reconstruction process. Oakes (2000) proposed two systems, Jakarta and Prague, that combined cover the steps of the comparative method for proto-language reconstruction. Another probabilistic approach belongs to Hall and Klein (2010), who obtained an average edit distance of 3.8 on the dataset of Romance languages proposed by Bouchard-Côté et al. (2009). Bouchard-Côté et al. (2013) used probabilistic models to trace language change in the Austronesian languages, based on a given phylogenetic tree.

6 Conclusions

In this paper, we proposed an automatic method for proto-word reconstruction. We applied our method on multiple datasets of Romance languages, in order to reconstruct Latin proto-words.
We used an approach based on sequence labeling and sequence alignment, combining the results of individual systems using ensembles. We obtained fairly good results (our best performance is 70% top 5 accuracy), and improved over previous work in this area. Our method has the advantage of requiring less input data than previous methods, and also accepting incomplete data, which is essential in historical linguistics, where resources are scarce.
We conclude that leveraging information from multiple modern languages, in ensemble systems, improves the performance on this task, producing n-best list of proto-words to be further analyzed by linguists and to aid in the process of comparative reconstruction for endangered or extinct languages.
As future work, we intend to refine the fusion methods for the ensemble classifiers – as the oracle results showed the high potential of the approach – and to evaluate our method on other datasets that cover more languages (for example, the Swadesh lists or the Austronesian basic vocabulary database (Greenhill et al., 2008)). We also intend to study rhotacism (Campbell, 1998), to investigate further ways of improving the performance of our CRF systems, and to enhance the RNN system even with little data available.

A Computational Model for the Linguistic Notion of Morphological Paradigm

Miikka Silfverberg and **Ling Liu** and **Mans Hulden**
Department of Linguistics
University of Colorado
first.last@colorado.edu

Abstract

In supervised learning of morphological patterns, the strategy of generalizing inflectional tables into more abstract paradigms through alignment of the longest common subsequence found in an inflection table has been proposed as an efficient method to deduce the inflectional behavior of unseen word forms. In this paper, we extend this notion of morphological 'paradigm' from earlier work and provide a formalization that more accurately matches linguist intuitions about what an inflectional paradigm is. Additionally, we propose and evaluate a mechanism for learning full human-readable paradigm specifications from incomplete data—a scenario when we only have access to a few inflected forms for each lexeme, and want to reconstruct the missing inflections as well as generalize and group the witnessed patterns into a model of more abstract paradigmatic behavior of lexemes.

1 Introduction

Most work in phonology and morphology assumes that the ability to inflect previously unseen or unheard word forms is through a model of analogy (Blevins and Blevins, 2009) to known forms. In languages with poor inflectional morphology, this often manifests itself in the capacity to inflect previously unwitnessed lexemes, e.g. **wug** $\mapsto$ **wugs** by analogy to some other lexeme, perhaps a noun like **bug** $\mapsto$ **bugs**. A closely related problem, relevant for languages that have complex inflectional morphology and where a single part-of-speech can be inflected in perhaps thousands of ways, is the capacity to inflect a lexeme with a previously unheard combination of inflectional features. For example, Finnish nouns are inflected in 2,253 different ways,[1] and no speaker will have witnessed all variants for any given noun. This capacity to fill in missing forms has been dubbed the **paradigm cell filling problem** (PCFP) (Ackerman et al., 2009).

The frequency of references to the nebulous label 'analogy' and its responsibility for human performance in these tasks stands in contrast to the dearth of proposed exact formal or computational models of analogical word-formation in the literature. Even in second-language teaching material, speakers are assumed to possess the capacity to directly generalize a pattern from a collection of inflected forms. Table 1 shows a partial inflection table for the Spanish verb **tostar** ('to toast') given in the resource *501 Spanish Verbs* (Kendris and Kendris, 2007). By contrast, the verb entry for **colar** ('to strain') contains no table at all, but simply provides a pointer to the inflection table for **tostar**. In other words, it is presupposed that, for example, given the analogy **tostar:tuesto::colar:x**, the astute reader can solve for **x** without undue problems, though no explicit procedure for doing so is given.[2]

One formalization of this implicit procedure is offered in Ahlberg et al. (2014) and Hulden (2014). In those works, a collection of inflected forms is first subjected to identifying the *longest common subsequence* (LCS) among the given forms. For example, the set of words {**tostar, tuesto, ...**} would contain

[1] http://www.ling.helsinki.fi/~fkarlsso/genkau2.html

[2] Note that to perform this 'analogy', it is not sufficient to merely identify a monolithic stem and possible suffix in the pair **tostar/tuesto** and add the discovered suffix to the presupposed stem of **colar**. This strategy works for simple cases like **bug:bugs::wug:wugs**, but obviously cannot be the basis for general analogical modeling in morphology.

(b) Paradigms extracted by LCS do not correspond to linguistic generalizations because they do not factor out regular phonological alternations.

Figure 1: Illustration of the LCS method for paradigm extraction in 1a. In 1b, we show the inability of the LCS method to factor out vowel harmony.

the LCS **tst**, as that subsequence occurs in every form. After locating this, the generalization is set up so that the LCS part is defined as a discontinuous *stem* that recurs throughout the inflectional paradigm, while the remainder can vary. In the above example, this would yield the generalization in Figure 1a where the $\mathbf{x_i}$s represent (in this case) the discontinuous 'stem'. Fitting another word such as **colar** into the first form would implicitly yield that the stem of that word is $\mathbf{x_1} = \mathbf{c}$, $\mathbf{x_2} = \mathbf{l}$. Having identified the stem, we can now produce the form $\mathbf{x_1}$ + **ue** + $\mathbf{x_2}$ + **o** which becomes **cuelo**, concluding the analogy as **tostar:tuesto::colar:cuelo**.

This strategy works reasonably well for supervised learning of morphological paradigms and provides a human-readable generalization as a result (Ahlberg et al., 2014; Ahlberg et al., 2015; Forsberg and Hulden, 2016). However, we identify two weaknesses in the model. First, the approach undergeneralizes in that it produces separate generalizations of paradigms for what is arguably very similar inflectional behavior. Secondly, it does not offer a method to learn paradigms from partial data—it operates on full inflectional tables—something that would address the paradigm cell filling problem.

To illustrate the first point, consider the two Finnish inflection tables and resulting paradigms in Figure 1b. Here, the only difference between the two learned patterns is that whenever one (P1) has an **a**-segment in its slots, the other (P2) has **ä**. This difference prevents the two patterns from being deemed alike. Naturally, a more thorough linguistic analysis would uncover that this is an instance of back/front vowel harmony dictated by the vowels found in the stem, the sequences **lla/llä** and **sta/stä** in effect being allomorphs of the same morpheme.

In this paper we propose a method that will discover such allomorphy through a purely data-driven approach—i.e. it will not be necessary to postulate any phonological evidence or analysis to be able to discover that several paradigms learned through the LCS method are actually alike and to deduce all the allomorphs. This, as we will show, will substantially cut down on the number of different inflectional paradigms discovered by the algorithm to something very close to that postulated by linguists after thorough phonological and morphological analysis.

Further, we propose a method on top of the LCS-paradigm generalization to discover partial paradigms from partially given inflection tables and to collapse these into full-size paradigms that allow us to address the paradigm cell filling problem.

1.1 Terminology

To avoid terminological confusion, we will adhere to some conventions in this paper. First, we make a distinction between an **inflection table** and **paradigm**: an **inflection table** is a concrete manifestation of forms such as the two in the left hand box in Figure 1b. By contrast, a **paradigm** is the result of generalizing into stems (the $\mathbf{x_i}$s) and affixes (the remainder), such as the two paradigms in the right-hand box. This is in line with the idea that a mere collection of inflected forms is not a generalization per se, and we therefore reserve the term **paradigm** to the generalized version of an inflection table.[3] A single **slot** in an inflection table which contains a **form** (such as 'koiralla' in Figure 1b) will be generalized into

[3]Some authors call the generalization an **inflectional class** (Haspelmath and Sims, 2013).

a **form pattern**, such as $\mathbf{x_i}$**+lla**. The features corresponding to a form, such as NOM;SG will be referred to as the **morphosyntactic description** (MSD).

2 Related Work

As noted above, we build on the work of Ahlberg et al. (2014), Ahlberg et al. (2015), and Forsberg and Hulden (2016) which introduced the LCS as a core strategy in formal definitions of morphological paradigm and analogy. Further linguistic arguments favoring the LCS-model are given in Lee (2015).

Learning to generalize from inflection tables to unseen forms has attracted much recent interest in natural language processing (Dreyer and Eisner, 2011; Durrett and DeNero, 2013). In addition, two recent shared tasks hosted by SIGMORPHON and CoNLL have contributed to the research by producing comparable large multilingual data sets (Cotterell et al., 2016; Cotterell et al., 2017) consistently annotated with the Unimorph scheme (Sylak-Glassman et al., 2015; Kirov et al., 2018). Overwhelmingly, most recent work in inflection generation has employed neural sequence-to-sequence models with attention (Sutskever et al., 2014; Bahdanau et al., 2015) in supervised scenarios (Kann and Schütze, 2016; Faruqui et al., 2016; Östling, 2016; Makarov et al., 2017; Aharoni and Goldberg, 2017), often with data augmentation mechanisms in low-resource settings (Bergmanis et al., 2017; Silfverberg et al., 2017; Kann and Schütze, 2017). The PCFP has been explicitly addressed by recurrent neural generators as well (Malouf, 2016; Malouf, 2017). While neural models perform quite well on such tasks—even in low-resource settings—their parameter opacity makes it difficult to extract concise linguistic generalizations that can be interpreted and compared with linguist analyses.

Since morphological annotation is usually done at the word-level (**flowers** $\leftrightarrow$ ❀**+PL**),[4] recent work has also attempted to learn the latent segmentation and recover the different allomorphs for stems and affixes (**flower** = ❀, **s=PL**). This is arguably similar to what an L1-learner does, and the kind of evidence L1 learners have—words with semantic (❀) and grammatical (**+PL**) content deducible from context, but crucially missing information about how these correspond to some subsequence of phonemes in an inflected word form. Silfverberg and Hulden (2017a) and Silfverberg and Hulden (2017b) propose a data-driven method that searches the space of possible allomorph and grammatical tag associations, and favors a small model. Similar approaches are found in Hayes (2018) who similarly argues that allomorphs can be detected "even if we don't yet understand the phonology". Our work, apart from providing an explicit model for paradigms, also implicitly extracts the different allomorphs used, something that falls out as a byproduct of the paradigm generalizations in section 4 and inference from partial inflection tables in section 5.

3 Data

We use two different data sets for experiments. The first one is the training and development parts from the data set developed by Durrett and DeNero (2013) for inflection generation, including Finnish, German and Spanish.[5] The data set was scraped from the English Wiktionary. It is used both for experiments on paradigm generalization and learning of full paradigms from partial paradigms. We describe the data set in Table 2.

The second data set comes from the CoNLL-SIGMORPHON 2017 joint shared task on morphological reinflection (Cotterell et al., 2017). We use the paradigm completion subtask (subtask 2) data. We use this data exclusively for the paradigm generalization task.[6] The CoNLL-SIGMORPHON shared task data set contains full morphological inflection tables. We use the task's train-dev-test splits. Like the data set by Durrett and DeNero (2013), the CoNLL-SIGMORPHON data set is also scraped from Wiktionary. It contains data from 52 languages representing a wide variety of language families. However, we perform experiments on a selection of 33 languages out of these 52 languages because of the variance in inflection table size for some languages as explained below.[7]

[4] An illustration of a semantic representation.

[5] `http://www.cs.utexas.edu/~gdurrett/`

[6] We do not use CoNLL-SIGMORPHON data for paradigm learning because of the limited size of the data set.

[7] These 33 languages are Albanian, Bengali, Catalan, Danish, English, Estonian, Faroese, Finnish, French, Georgian, Ger-

The paradigm extraction method developed by Ahlberg et al. (2014), as well as the paradigm generalization method to be proposed in section 4, operates on full paradigms, requiring that all of the inflection tables for a given part-of-speech have the same number of MSDs. However, this is not the case in the CoNLL-SIGMORPHON shared task data: inflection tables of German nouns, for instance, encompass between four and eight forms. There are several reasons for this discrepancy. For example, some nouns may lack plural or singular forms altogether (as an example, consider the English *plurale tantum* noun **pants**). We, therefore, first determine the maximal number of MSDs for inflection tables of each part-of-speech in each language and perform experiments only on those inflection tables where all MSDs are present. This is not possible for all languages because many do not contain a single table which would give forms corresponding to the full set of MSDs. Consequently, we limit our experiments to those languages where we can successfully find lexemes with a maximal number of MSDs.

4 Generalized Paradigms

We now turn to the method for making further generalizations over the basic paradigm model given in Ahlberg et al. (2014). This method also extracts sets of allomorphs.

As mentioned in section 1, the paradigm extraction procedure presented in Ahlberg et al. (2014) cannot group inflection tables under the same paradigm unless the non-stem parts of corresponding forms in the tables are identical. For example, the two Finnish stems **lauk** and **hyp** in Figure 2 cannot belong to the same paradigm because back vowels (**a**) and front vowels (**ä**) vary across the two paradigms, though the form patterns are similar in other respects. This does not adhere to standard linguistic assumption whereby regular phonological alternations—such as vowel harmony in this case—should not affect paradigm membership.

Our method for paradigm generalization groups together paradigms which exhibit such regular alternations, under the same *generalized paradigm*. The method is based purely on a formal comparison of the paradigms, not linguistic considerations; it is in effect 'phonology-free'. We discover regular alternations using a variable substitution described below, and group multiple paradigms under the same *generalized paradigm* whenever they exhibit regular alternation without regard to the identity of the variants.

4.1 Method

The basis for paradigm generalization is identification of regular alternations between paradigms. Consider the example in Figure 2. Both of the nominal lexemes **laukku** ('bag') and **hyppy** ('jump') undergo consonant gradation. In what is called the 'strong grade', the last stem consonant is doubled both in the nominative (NOM) and partitive (PART) cases. The alternation between the paradigms is regular in the sense that whenever the form for **laukku** has an additional **k**, **hyppy** will have an additional **p**. We abstract out the differences between variants by replacing the varying parts in form patterns with consecutively numbered new variables $\mathbf{y_i}$, where multiple occurrences of the same varying part all get the same variable $\mathbf{y_i}$. For the current case, the **k** in the paradigm for **laukku** and the **p** in the paradigm extracted from **hyppy** in the strong grade are replaced by $\mathbf{y_1}$ both in the nominative and partitive forms, **lla** and **llä** are both replaced with $\mathbf{y_2}$, **sta** and **stä** are both replaced with $\mathbf{y_3}$, and **a** and **ä** are both replaced with $\mathbf{y_4}$. Applying this second-order generalization procedure on top of the LCS-generalization results in identical generalized paradigm structure for **laukku** and **hyppy**, seen on the right in Figure 2.

4.2 Experiments and Results

As mentioned in Section 3 we use two data sets for experiments: the data set from Durrett and DeNero (2013), and part of the data (33 languages) for the second subtask of the CoNLL-SIGMORPHON 2017 shared task on universal morphological reinflection. The number of paradigms and generalized paradigms in the Durrett and DeNero (2013) data set is shown in Table 2 in the last two columns. The number of generalized paradigms agrees much better with linguist analyses regarding the number of

man, Hebrew, Hindi, Hungarian, Icelandic, Irish, Italian, Latin, Latvian, Lithuanian, Lower Sorbian, Northern Sami, Persian, Portuguese, Romanian, Slovak, Slovene, Spanish, Swedish, Turkish, Urdu, and Welsh, which are from the 11 different language groups (based on the original data source grouping given by Cotterell et al. (2017)) including Romance, Germanic, Indo-Aryan, Uralic, Kartvelian, Semitic, Celtic, Baltic, Iranian, Slavic, and Turkic

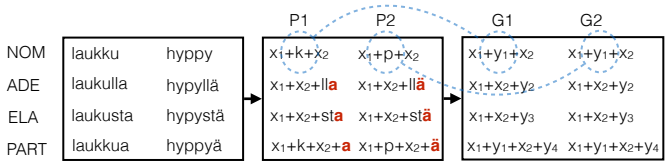

Figure 2: Forming a generalized paradigm (right) based on a paradigm discovered by the LCS method (Ahlberg et al., 2014) (middle) from raw inflection tables (left).

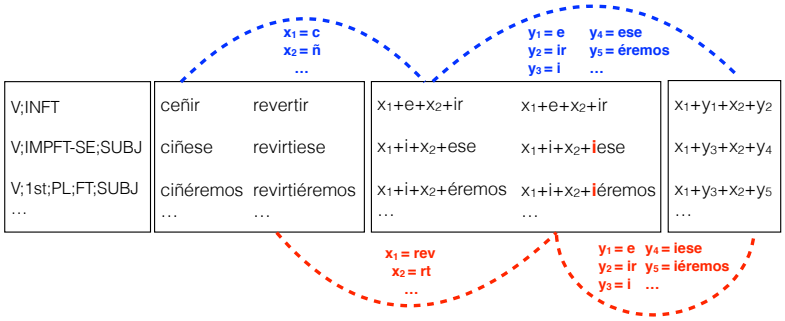

Figure 3: Illustration of a latent phonological generalization in Spanish.

types of inflection tables within languages. For example, Nykysuomen sanalista,[8] a lexical resource developed by the Institute for the Languages of Finland, recognizes 51 nominal inflection types and 27 verb inflection types for Finnish. The number of generalized paradigms for Finnish nouns and adjectives[9] produced by the current method is 40 for nouns and 30 for verbs. The average ratio between the number of generalized paradigms and the number of original LCS-paradigms across languages are 39.07% for verbs, 26.29% for nouns and adjectives, and 35.02% for all parts-of-speech together, showing a significant reduction in number of disctinct patterns identified.

In addition, generalized paradigms capture linguistically regular alternations. Figure 3 illustrates how the generalized paradigm captures a phenomenon surrounding the grapheme **ñ** in Spanish. Verbs that don't contain stem-final **ñ** [ɲ] insert an **i** in some forms, while verbs with **ñ** forgo the **i** as the **ñ** itself can be interpreted as a coalesced form that already contains an **i**, i.e. [ni] ↦ [ɲ]. Spanish verbs like **ceñir** ('to cling to') and verbs like **revertir** ('to revert to') would fall into two separate paradigms using the paradigm extraction method proposed in Ahlberg et al. (2014). These two LCS-paradigms are provided in the second box from the right in the figure. The dotted blue curve on top shows the first-order generalization provided by the LCS-strategy that assigns $\mathbf{x_i}$-variables, and our subsequent second-order abstraction that assigns $\mathbf{y_i}$-variables. After these two steps, the behavior of the the two verbs is seen to be identical in the new representation shown in the rightmost box. Other words which belong to the same LCS-paradigm as **ceñir** that all have **ñ** as their second variable include words like **reñir** ('to scold'), **constreñir** ('to restrict'), **teñir** ('to stain'). The second variable for words which get the same paradigm as **revertir** can be **rt**, **r**, **nt** etc. Words in this paradigm include **convertir** ('to convert'), **ingerir** ('to ingest'), **sentir** ('to feel') etc. The generalized paradigm groups the two paradigms together because the two paradigms become identical after $\mathbf{y_i}$-replacement following the method described in section 4.1. The $\mathbf{y_i}$s from the first paradigm are given along the blue dotted curve connecting the paradigm with the generalized paradigm, and the $\mathbf{y_i}$s from the second paradigm are added to the red dotted curve at the bottom combining the second paradigm with the generalized paradigm. By grouping the two paradigms together as one generalized paradigm, the alternation between **ñ** and any other consonants followed by **i** emerges.

With the second data set of 33 languages, we combine all the training, development and test sets together as the data set is small (less than 300 inflection tables altogether) for each language. For all the

[8] `http://kaino.kotus.fi/sanat/nykysuomi`

[9] Finnish nouns and adjectives are inflected in the same way in the data set.

languages we experiment with, the number of paradigms decreases consistently after generalization: the average ratio between the number of generalized paradigms and the number of LCS-paradigms across languages on this data set is 0.69 for verbs, 0.55 for nouns and adjectives, and 0.59 for all parts-of-speech together. The ratio is higher on this data set than on the Durrett and DeNero (2013) data set because the data size here is much smaller, and yields fewer paradigms in general.

LANGUAGE	POS	TABLE COUNT	TABLE SIZE	PARADIGM COUNT	GENERALIZED PARADIGM COUNT
FINNISH	NOUN & ADJ	6,400	28	259	40
FINNISH	VERB	7,249	53	276	30
GERMAN	NOUN	2,764	8	70	26
GERMAN	VERB	2,027	27	135	107
SPANISH	VERB	4,055	57	96	26

Table 2: Data sets by Durrett and DeNero (2013). We show counts of inflection tables and inflection table sizes for nouns, adjectives and verbs. Additionally, we show the number of paradigms found the LCS method (Ahlberg et al., 2014) and the resulting number of 'generalized paradigms' found by subsequently applying our method.

An example of how generalization over paradigms collapses them and catches regularities from the CoNLL-SIGMORPHON data set can be found by examining English verbal inflections. Different paradigms are extracted from verbs like **contest**, **establish**, **benefit**, **occur** and **bag**, though the paradigm for **establish** differs from that for **contest** only in the present tense for the third-person singular, with the last variable as **-es** for **establish**, but **-s** for **contest**; the paradigms for **benefit**, **occur** and **bag** differ from that of **contest** in the present participle, past participle and past tense, for which the last variables for **benefit**, **occur** and **bag** are **-ting**, **-ring** and **-ging** (for the present participle) and **-ted**, **-red** and **-ged** (for the past participle and past tense) respectively, but **-ing** and **-ed** for **contest**. The generalized paradigm approach groups all these patterns together, which completely agrees with the linguistic regularity.

5 Learning Full Paradigms from Partial Paradigms

In this section we present an algorithm for learning full morphological paradigms given partial inflection tables. Our algorithm takes as input a set of partial inflection tables, that is, inflection tables with a number of missing forms. It first derives a morphological LCS-paradigm for each partial inflection table and then imputes missing form patterns into the paradigm. At test time, form patterns are substituted by concrete word forms (see Figure 4a). A key component of the proposed algorithm is a stem sampling step which counteracts bad hypotheses about stems caused by missing information when performing paradigm extraction on only partial inflection tables.

V;INF	speak		V;INF	speak
V;PRES	?		V;PRES	speaks
V;PAST	?	$\Longrightarrow$	V;PAST	spoke
V;PAST;PCPLE	spoken		V;PAST;PCPLE	spoken
V;PRES;PCPLE	?		V;PRES;PCPLE	speaking

(a) Our inputs are partial inflection tables and the final outputs are completed inflection tables.

V;INF	-		V;INF	-
V;PRES	-		V;PRES	-
V;PAST	-	$\Longrightarrow$	V;PAST	-
V;PAST;PCPLE	eaten		V;PAST;PCPLE	$\mathbf{x_1{+}e{+}x_2}$
V;PRES;PCPLE	eating		V;PRES;PCPLE	$\mathbf{x_1{+}i{+}x_2{+}g}$

(b) Paradigm extraction is applied to a partial inflection table. The stem is incorrectly identified as **eatn**. This makes it impossible to correctly infer the infinitive **eat** and past tense **ate**.

Figure 4: We illustrate the paradigm cell filling task in 4a and show an example of over-generalization effects due to data sparsity in 4b.

We evaluate the presented algorithm with regard to its ability to reconstruct missing forms in partial paradigms and compare it against two baselines: majority voting and matrix completion. Our experiments demonstrate that the proposed algorithm delivers clear improvements over the baselines.

5.1 Methods

As mentioned above, our input consists of partial inflection tables. The first step is to apply the LCS procedure for paradigm extraction (Ahlberg et al., 2014) presented in Section 1. This results in a partial

paradigm as shown in Figure 4. We now present four different methods for imputing the missing forms into the resulting partial paradigm.

First Baseline using Majority Voting For each partial paradigm P, we apply a simple variant of majority voting in order to infer missing form patterns. We form the set of all partial paradigms which have a form pattern corresponding to a missing MSD, m, and perform a majority vote among the stem patterns. A slight variant of standard majority voting is, however, required because we do not want to infer a candidate with an incorrect number of stem variables. For example, if the PAST and PRES;PCPLE forms in P are $\mathbf{x_1}$**+ed** and $\mathbf{x_1}$**+ing** respectively, we do not want to infer a form $\mathbf{x_1}$**+**$\mathbf{x_2}$**+n** for PAST;PCPLE because the stem corresponding to P has only one variable $\mathbf{x_1}$. Therefore, we restrict the vote to paradigms which have the same number of variables ($\mathbf{x_i}$s) as P.

We want to further restrict the set of candidates, because whenever two paradigms P and P' disagree on a known form, it is likely that they will disagree on missing forms as well. For example, if the PAST form in P is $\mathbf{x_1}$**+ed** and the PAST form for P' is $\mathbf{x_1}$**+n**, that is, the paradigms disagree on the PAST MSD, then the PAST;PCPLE forms are unlikely to agree either. Therefore, we further restrict voting to those candidate paradigms P', where all the shared MSDs with P correspond to identical form patterns. For each MSD m, we now take a majority vote in the restricted set of candidate paradigms.

Priority Voting As a small additional restriction to the majority voting process, we consider restricting the set of candidates even further. Whereas we include candidates with no overlap, i.e. common forms, in majority voting, we now exclude such paradigms from voting. That is, only include candidates which have some common MSDs with the target paradigm P. These are, after all, more likely to agree other forms as well. This set may, however, be empty. We, therefore, resort to applying majority voting as fall-back.

Stem Sampling We apply the paradigm extraction procedure outlined in Section 1 to partial inflection tables. Unfortunately, this frequently leads to incorrectly identified stems as shown in Figure 4b. This happens when all of the given forms (for example, **eating** and **eaten**) share a substring (**n**) which, nevertheless, is a part of the inflectional affixes and not the actual word stem. The common substring then becomes incorrectly incorporated in the word stem (**eat**, **n**), because the stem is identified greedily as the longest common subsequence of all of the forms in the partial inflection table. This gives rise to implausible form patterns ($\mathbf{x_1}$**+i+**$\mathbf{x_2}$**+g** and $\mathbf{x_1}$**+e+**$\mathbf{x_2}$, from **eat**<u>**i**</u>**ng**, **eat**<u>**e**</u>**n**). To counteract this problem, we perform a sampling step before imputing missing forms.

By examining all partial paradigms extracted from partial inflection tables at once, we can make a better guess concerning the identity of the stems. It is a reasonable assumption that an MSD such as PAST;PCPLE have few distinct realizations. In English, most words take a past participle ending of either **-n** or **-ed**. Although there are examples of other PAST;PCPLE markers, the majority of words belong to one of these classes. Therefore, we would expect most form patterns in the past perfect slot to look similar to $\mathbf{x_1}$**+ed** or $\mathbf{x_1}$**+**$\mathbf{x_2}$**+n**. However, incorrectly identified stems will frequently result in implausible variants like $\mathbf{x_1}$**+**$\mathbf{x_2}$, $\mathbf{x_1}$**+d** or $\mathbf{x_1}$**+e+**$\mathbf{x_2}$. We can expect to find better stem candidates if we attempt to find a set of stems which minimize the number of realizations for each MSD over the whole data set, i.e. all partial paradigms.

The general plan of attack is to sample stems in a way that favors fewer realizations for each MSD. Let the partial inflection table be as in Figure 4b. The longest common subsequence between all of the given forms is **eatn**, which leads us to postulate it as the stem. We also get forms $\mathbf{x_1}$**+e+**$\mathbf{x_2}$ and $\mathbf{x_1}$**+i+**$\mathbf{x_2}$**+g**. We can consider additional stem candidates, for example, **ea** and **eat**, which are substrings of the original stem. Each stem candidate leads to different realizations for the inflections. For example, the candidate **eat** will give realizations $\mathbf{x_1}$**+en** and $\mathbf{x_1}$**+ing** for the PAST;PCPLE and PRES;PCPLE forms, respectively.

At the start of the sampling process, each paradigm P has a stem S_0, which is a collections of stem parts $S_0(1), ..., S_0(n)$ (for example $S_0(1) =$ **eat** and $S_0(2) =$ **n** in Figure 4b). Each stem part is a sequence of letters $S_0(i)^1, ..., S_0(i)^m$. Intuitively, we sample a new stem S_1 by replacing a random stem part $S_0(i)$ by a random continuous substring of $S_0(i)^k, ..., S_0(i)^{k+l}$. This gives us a new stem proposal

S_1, where each stem part $S_1(j) = S_0(j)$, except $S_1(i)$, which is a substring of $S_0(i)$. For example we could sample a new stem part $S_1(2) = \epsilon$ based on the existing stem part $S_0(2) = \mathbf{n}$. The new stem will now define new realizations for each of the MSDs in paradigm P (for example, $\mathbf{x_1}$**+en** and $\mathbf{x_1}$**+ing**) and we can use statistics about MSD realizations over the entire set of partial paradigms to determine whether to accept or discard the new stem.

Note that whenever we sample a new stem S_k, we sample a substring of the original stem part $S_0(i)$. This allows stem parts to both shrink and grow during the sampling process but they can never grow beyond the stem parts in the original stem S_0.

We set up stem sampling as a product of Chinese Restaurant Processes (CRP) and use Gibbs sampling to optimize the stem assignments for all inflection tables in the data set. This has the effect of preferring MSD realizations which are common. Therefore, sampling will indirectly minimize the number of distinct MSD realizations, which is our goal.

Let P be a randomly selected paradigm, S_i be a stem for P and S_{i+1} a sampled stem. Let $F_i = \{F_i(m_1), ..., F_i(m_k)\}$ and $F_{i+1} = \{F_{i+1}(m_1), ..., F_{i+1}(m_k)\}$ be the set of form patterns, determined by S_i and S_{i+1}, respectively, for each MSD m_1,...,m_k in paradigm P. Further, let $\#(f, m)$ be the count of form pattern f for MSD m over all paradigms $\neq P$. We now accept the new stem setting S_{i+1} with probability $p_a = \prod_j \frac{G_{i+1}(m_j)}{G_i(m_j)}$, where $G_k(m_j) = \alpha$, if $\#(F_k(m_j), m_j) = 0$, and $G_k(m_j) = \#(F_k(m_j), m_j)$, otherwise. Whenever, $p_a > 1$, we automatically accept the new setting S_{i+1}. If we reject the new setting, we set $S_{i+1} := S_i$. Based on preliminary experiments, we set α to 0.1.

We run the sampler for 100 steps over the entire training set. In order to ensure that each paradigm is sampled, we do not randomly select paradigms but instead loop through and sample all paradigms shuffling the data set after each epoch.

Second Baseline using Matrix Completion As an additional baseline, we frame the task of learning complete paradigms as a matrix completion task. We first infer the paradigm structure for each partial inflection table. We then encode each form pattern present in paradigm P into a one-hot representation $\mathbf{v_m} \in \mathbb{R}^N$, where N is the number of distinct realizations of MSD m as shown in Figure 5.[10]

Collecting the rows for each paradigm P, we then form a matrix M, whose rows $\mathbf{r_P} = [\mathbf{v_{m_1}}; ...; \mathbf{v_{m_n}}]$, where m_1, ..., m_n are all the distinct MSDs in the data set. Since the paradigms P are incomplete, M will have a number of missing entries. We complete these entries using the SOFT-IMPUTE algorithm introduced by Mazumder et al. (2010).[11]

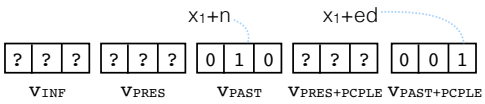

Figure 5: Form patterns are encoded into one-hot vectors and concatenated.

Completed entries $\mathbf{v_m}$ may not be one-hot vectors. Therefore, we transform them into one-hot vectors by applying the transformation $\mathbf{v_m}'[\arg\max_i \mathbf{v_m}[i]] = 1$ and $\mathbf{v_m}'[i] = 0$ otherwise. Finally, we decode the one-hot vectors defined by M into form patterns.

5.2 Experiments and Results

We start with complete inflection tables and uniformly sample a fixed number of forms n from each to form partial inflection tables (n=2,3,4,5 and 6). This gives us collections of partial inflection tables where each one has exactly n forms. We then extract paradigms from the partial inflection tables and use the different methods presented in Section 5.1 to impute the missing forms into the paradigms. More specifically, we apply the following methods (1) sampling of stems followed by priority voting, (2) Priority voting, (3) Majority voting (baseline I), and (4) matrix completion (baseline II).

To evaluate the method, we, after inferring the complete paradigms, substitute stem parts in to form patterns, for example $\mathbf{x_1}$**+ed** $\rightarrow$ **eased**. Thus, we end up with a complete inflection table. We evaluate

[10] In preliminary experiments, we encoded each form pattern as a distinct integer. This, however, delivered poorer performance.

[11] We use the implementation in the `fancyimpute` Python package `https://pypi.python.org/pypi/fancyimpute` by Alex Rubinsteyn and Sergey Feldman.

the result against the gold standard inflection tables. using two metrics: how many of the missing forms were correctly reconstructed and how many of the entire tables were correctly reconstructed.

We perform experiments separately on nouns (nouns and adjectives for Finnish) and verbs. We do this because (1) the performance varies quite a lot between nouns and verbs for the same language, and (2) we only have data for Spanish verbs but we have data both for nominals and verbs for Finnish and German.

Table 3 in Appendix A presents results of the experiment. Overall, we can see that the number of successfully reconstructed forms increases as the number of given forms in the paradigm increases. The best results are attained for German nouns where the number of MSDs in the paradigm is the smallest (8 MSDs per paradigm). Conversely, results are the poorest for Finnish verbs, which have a large number of MSDs per paradigm (54). However, all methods except matrix completion fare quite well on full paradigm learning for Spanish verbs which have even more MSDs per paradigm than Finnish verbs (57).

Matrix completion performs very poorly in comparison to the other methods on all data sets except German nouns. Even for German nouns it, however, performs worse than Baseline I, namely, majority voting. Priority voting consistently outperforms majority voting (by over 30%-points for Spanish verbs when three forms are given). We can also see that sampling gives a consistent improvement over other methods except for German nouns which have the smallest inflection tables (only nine forms per table).

6 Discussion and Conclusions

Our method for paradigm generalization results in a marked decrease in paradigm counts in both Durrett and DeNero (2013) and CoNLL-SIGMORPHON data sets. For Finnish, our paradigm counts for verbs and nouns very closely match the counts arrived at by linguists (40 vs. 51 and 30 vs. 27 for verbs and nouns+adjectives respectively). Qualitative analysis of generalized paradigms shows that the method is clearly capable of capturing regularities like the examples illustrated about Finnish, Spanish, and English.

On the full morphological paradigm learning task, the baseline voting methods (majority and priority voting) are surprisingly effective. Priority voting is able to reconstruct 84% of missing Spanish verb forms and 96% of missing German noun forms when six forms are given in the input inflection table. However, stem sampling on top of priority voting still results in sizable gains over the baseline methods especially in the presence of few given forms in the input table. It is to be expected that the effect diminishes when the number of input forms increases as this reduces the risk of mis-identifying stems. Nevertheless, even with six input forms, stem sampling still results in relatively large gains of around 4%-points for Finnish, German and Spanish verbs which have the largest table sizes in the data set.

Both methods proposed above can be useful for developers of linguistic resources. Paradigm generalization from partial paradigms can be valuable for development of morphological analyzers. Generalized paradigms can guide a linguist working on the phonological and morphological description of a language, and also extract all the allomorphs that are related to a grammatical category.

A clear future research direction for full paradigm learning is exploration of neural methods for the task. While it is to be expected that neural methods will reach high performance, it will be substantially more difficult to draw clear linguistic generalizations from the models they produce. As an added advantage of the current method, we automatically split word forms into stems and inflectional material. Such a split can be difficult to derive from a neural model which can reduce its usefulness as an aid in writing linguistic descriptions.

We have presented a model for automatically inducing generalized morphological paradigms which agrees well with the linguist intuitions concerning morphological pattern generalization since it factors out regular phonological alternations, without actually being 'phonology-aware'. Moreover, we have presented a method for learning full morphological paradigms given training data of partial inflection tables only, and have shown that the method is capable of inferring 90% of missing forms for paradigms as large as 57 forms from only six given forms.

Abstract

Given a set of instances of some relation, the relation induction task is to predict which other word pairs are likely to be related in the same way. While it is natural to use word embeddings for this task, standard approaches based on vector translations turn out to perform poorly. To address this issue, we propose two probabilistic relation induction models. The first model is based on translations, but uses Gaussians to explicitly model the variability of these translations and to encode soft constraints on the source and target words that may be chosen. In the second model, we use Bayesian linear regression to encode the assumption that there is a linear relationship between the vector representations of related words, which is considerably weaker than the assumption underlying translation based models.

1 Introduction

It has been observed that many lexical relationships can be modelled as vector translations in a word embedding space (Mikolov et al., 2013b; Pennington et al., 2014). Even though this remarkable property is now well-established, and is commonly used as a basis for evaluating word embedding models, its potential for knowledge base completion has only been explored in a preliminary way. In this paper, we are particularly interested in the following relation induction task, which was proposed in (Vylomova et al., 2016): given a set $\{(s_1, t_1), ..., (s_n, t_n)\}$ of word pairs that are related in a given way, identify new word pairs (s, t) that are likely to be related in the same way. We will refer to s and t as the source and target word respectively; we will write $\mathbf{w}$ for the vector representation of the word w.

One natural approach is to model the considered relation using the average translation vector $\mathbf{r} = \frac{1}{n}\sum_i(\mathbf{t_i} - \mathbf{s_i})$, and to accept (s, t) as a likely instance if $\cos(\mathbf{s} + \mathbf{r}, \mathbf{t})$ is sufficiently high. While this approach was found in (Drozd et al., 2016) to work well for analogy completion, for relation induction it typically leads to too many false positives. This is illustrated in Table 1 for the case where $\mathbf{r}$ is constructed from the instances of the *capital of* relation of the BATS dataset[1]. As can be seen in the table, most of the top-ranked pairs are actually incorrect. In practice, this problem is further exacerbated by the dramatic class imbalance: for typical vocabulary sizes there are tens (or hundreds) of billions of incorrect pairs, compared to only a few hundred correct instances. While correct instances may, on average, get a higher score than incorrect instances, as a result of this imbalance there will still be many incorrect instances that receive a very high score.

Another problem relates to the use of the cosine similarity, which treats each dimension in the same way when comparing the vectors $\mathbf{r}$ and $\mathbf{t} - \mathbf{s}$. In practice, however, some dimensions of the word embedding may correspond to features of meaning that are irrelevant for the considered relationship. When we are only given one example (s, t) of a correct instance, as in the most common version of the analogy completion task, the cosine similarity is a suitable choice as we cannot determine which dimensions are most relevant. For relation induction, however, we can use the empirical variance of the translation vectors $\mathbf{t_i} - \mathbf{s_i}$ to make a more informed choice.

[1] See section 4 for more details about the experimental set-up, including how negative test examples were chosen.

Table 1: Cosine scores for the average translation model applied to the *capital of* relation; correct instances are shown in italics.

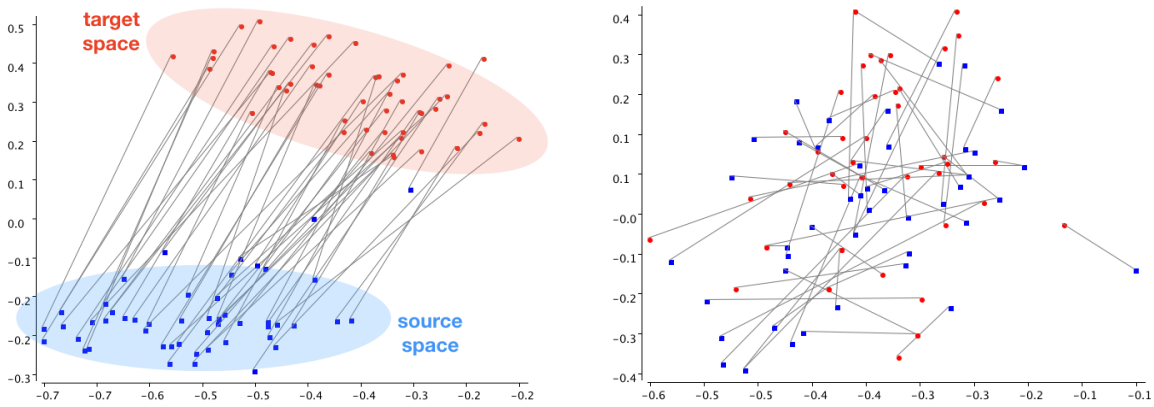
In this paper, we propose a probabilistic relation induction model that addresses both problems. First, to reduce the number of spurious instances that are detected, our model learns a soft constraint on which words are likely to occur as source and target words. Second, we use a (Bayesian estimation of a) Gaussian distribution over translation vectors to encode which features of word meaning are most important for the considered relation. We also consider a variant that is not based on translations and merely assumes that there is a linear mapping between source and target words, which we formalize using Bayesian linear regression. Being more general than the translation based approach, this model can potentially be more faithful, but it needs a larger number of training instances to be effective.

2 Related Work

Predicting Relations. At least three different types of approaches have been studied for predicting relations that are missing from a given knowledge base. First, there is a large body of work on relation extraction from text, for instance by using the known instances as a form of distant supervision (Mintz et al., 2009; Riedel et al., 2010; Surdeanu et al., 2012). The second type of approach relies on modeling statistical dependencies among the known instances of the considered relations, for instance by learning latent representations (Kok and Domingos, 2007; Speer et al., 2008; Nickel et al., 2012; Riedel et al., 2013; Bordes et al., 2013; Wang et al., 2014; Yang et al., 2015), or probabilistic rules (Schoenmackers et al., 2010; Lao et al., 2011; Wang et al., 2015). The third type of approach, which is the focus of this paper and is reviewed in more detail below, relies on vector space representations. A standard approach is to model relations as translations in the vector space (Mikolov et al., 2013b), although various other approaches have also been investigated (Weeds et al., 2014).

These three types of methods are highly complementary. While relation extraction methods can predict very fine-grained relations, they require that at least one sentence in the corpus states the relation explicitly. Statistical methods can predict relations even without access to a text corpus, but they are limited to predicting what can plausibly derived from what is already known. From a knowledge base completion point of view, the main appeal of word embeddings is that they may be able to reveal commonsense relationships which are rarely stated explicitly in text.

Modeling Relations in a Vector Space. It has been shown that word embeddings can be used to complete analogy questions of the form *a*:*b*::*c*:?, asking for a word that relates to c in the same way that b relates to a (e.g. *france*:*wine*::*germany*:?), by predicting the word w that maximizes $\cos(\mathbf{b} - \mathbf{a} + \mathbf{c}, \mathbf{w})$ (Mikolov et al., 2013b; Pennington et al., 2014). Similarly, several types of interpretable features can be modeled as directions in word embeddings. For example, in (Rothe and Schütze, 2016), it was shown that word embeddings can be decomposed in orthogonal subspaces that capture particular semantic properties, including a one-dimensional subspace (i.e. a direction) that encodes polarity. Along similar lines, in (Kim and de Marneffe, 2013) it was found that the direction defined by a word and its antonym (e.g. "good" and "bad") can be used to derive adjectival scales (e.g. bad $<$ okay $<$ good $<$ excellent). In (Gupta et al., 2015), it was shown that many types of numerical attributes can be predicted from word embeddings (e.g. GDP, fertility rate and CO_2 emissions of a country) using linear regression, again supporting the view that directions can model meaningful relations. Finally, in (Derrac and Schockaert, 2015) an unsupervised method was proposed to decompose domain-specific vector spaces into interpretable directions. For instance, in a space of movies, directions modeling terms such as "scary", "romantic" or "hilarious" were found.



(a) Superlative degree relation.

(b) Meronymy relation.

Figure 1: Superlative degree and Meronymy relations.

Several authors have focused on extracting hypernym relations from word embeddings. To decide whether a word h is a hypernym of w, in (Baroni et al., 2012) it is proposed to use an SVM with a polynomial kernel, using the concatenation of $\mathbf{h}$ and $\mathbf{w}$ as feature vector. In (Roller et al., 2014) it was shown that vector differences can lead to good results with a linear SVM, provided that the vectors are normalized, and that the squared differences of each coordinate are added as additional features. Intuitively, this allows the SVM classifier to express that h and w need to be different in particular aspects (using the vector differences) but similar in other aspects (using the squared differences). Some authors have also proposed to identify hypernyms by using word embedding models that represent words as regions or densities (Erk, 2009; Vilnis and McCallum, 2015; Jameel and Schockaert, 2017).

Beyond hypernyms, most work has focused on completing analogies. The problem of relation induction was studied in (Vylomova et al., 2016), where a linear SVM trained on vector differences was used. While strong results were obtained for several relations in a controlled setting (e.g. predicting which among a given set of relations a word pair belongs to), many false positives were obtained when random word pairs were added as negative examples. A variant of the relation induction problem was also studied in (Drozd et al., 2016), where the focus was on predicting the target word t given a valid source word s (as in analogy completion), given a set of training instances (as in relation induction). Two strong baselines were introduced in that paper, which will be explained in Section 4.1.

3 Modeling Relations

In this section, we propose two models for relation induction. We assume that we are given a set of pairs $\{(s_1, t_1), ..., (s_n, t_n)\}$ as training data, and we need to determine whether a given pair of words (s, t) are related in the same way.

3.1 Translation Model

Intuition. The source words $s_1, ..., s_n$ typically belong to some semantic or syntactic category, and their representations can often be expected to approximately belong to some relatively low-dimensional subspace of the word embedding. This is illustrated in Figure 1a for the 'superlative degree' relation from the BATS dataset[2] (see Section 4). Irrespective of the translation $\mathbf{t} - \mathbf{s}$, if (s, t) is a valid relation instance, we would expect $\mathbf{s}$ to be approximately in the same subspace as $\mathbf{s_1}, ..., \mathbf{s_n}$, and similar for the target words. Imposing this condition will intuitively allow us to ensure that only pairs where s and t are of the correct type are considered. As we will see, this will substantially reduce the number of false positives that are predicted by the model.

In Figure 1a we can see that there is no single translation vector that perfectly models the relation, although the translation vectors $\mathbf{t_i} - \mathbf{s_i}$ are all rather similar. This can be naturally modeled by considering

[2]In particular, the figure shows the two first principle components of the set $\{\mathbf{s_1}, ..., \mathbf{s_n}, \mathbf{t_1}, ..., \mathbf{t_n}\}$. As word vectors, we used the Skip-gram embedding that was learned from the Google news corpus.

a probability distribution over vector translations. In the example, this distribution would have a small variance along directions which are orthogonal to the average translation vector (as most vectors are almost parallel), but a larger variance along the direction of the average translation vector itself (as the translation vectors have varying lengths).

Putting everything together, we want to accept (s, t) as a valid instance if (i) $\mathbf{s}$ and $\mathbf{t}$ are sufficiently similar to the vector representations of the given source and target words, and (ii) the translation $\mathbf{t} - \mathbf{s}$ has a sufficiently high probability.

Model description. Let us write δ_s and δ_t be the event that the source word s and target word t are of the correct type, and let θ_{st} be the event that s and t are in the considered relation. Note that θ_{st} entails δ_s and δ_t, hence we have:

$$P(\theta_{st}|\mathbf{s}, \mathbf{t}) = P(\delta_s|\mathbf{s}) \cdot P(\delta_t|\mathbf{t}) \cdot P(\theta_{st}|\mathbf{s}, \mathbf{t}, \delta_s, \delta_t)$$

By making the core assumption that the relation can be modelled in terms of vector translations, together we Bayes' rule, we obtain:

$$P(\theta_{st}|\mathbf{s}, \mathbf{t}) \propto \frac{f(\mathbf{s}|\delta_s)}{f(\mathbf{s})} \cdot \frac{f(\mathbf{t}|\delta_t)}{f(\mathbf{t})} \cdot \frac{f(\mathbf{t} - \mathbf{s}|\theta_{st})}{f(\mathbf{t} - \mathbf{s}|\delta_s, \delta_t)}$$

We now discuss how the densities occurring in this latter expression can be estimated. First, $f(\mathbf{s}|\delta_s)$ models the density of words that can appear as source words in instances of the considered relation (i.e. the words which are intuitively of the correct type). We make the simplifying assumption that the vector representations of these words follow a Gaussian distribution. Note, however, that the number of available training instances n is typically small, and in particular smaller than the number of dimensions. In such cases, the covariance matrix cannot be reliably estimated, and we have to impose strong regularity assumptions. A common approach, which we will adopt, is to only allow diagonal covariance matrices. In this case, we have

$$f(\mathbf{s}|\delta_s) = \prod_{i=1}^{m} f(x_i^s|\delta_s)$$

where m is the number of dimensions in the word embedding, and we write x_i^s for the i^{th} coordinate of $\mathbf{s}$. The density $f(x_i^s|\delta_s)$ is then a univariate Gaussian distribution with an unknown mean and variance. Given the typically small number of training examples, a maximum likelihood estimation of the parameters would lead to a form of over-fitting. To address this, we use a Bayesian approach to estimate $f(x_i^s|\delta_s)$ as follows:

$$\int G(x_i^s; \mu, \sigma^2) NI\chi^2(\mu, \sigma^2|\mu_0, \kappa_0, \nu_0, \sigma_0^2) d\mu d\sigma$$

where G represents the Gaussian distribution and $NI\chi^2$ is the normal inverse χ^2 distribution. Note that in the standard relation induction setting, we have no prior information about μ and σ^2. The parameters $\mu_0, \kappa_0, \nu_0, \sigma_0^2$ can then be chosen such that they correspond to a flat prior; we refer to (Murphy, 2007) for details. For this choice, it can be shown that the integral evaluates to:

$$f(x_i^s|\delta_s) = t_{n-1}\Big(\overline{x_i}, \frac{(n+1)\sum_{j=1}^{n}(x_i^{s_j} - \overline{x_i})^2}{n(n-1)}\Big)$$

where $\overline{x_i} = \frac{1}{n}\sum_{j=1}^{n} x_i^{s_j}$ and t_{n-1} is the Student t-distribution with $n-1$ degrees of freedom. The density $f(\mathbf{t}|\delta_t)$ is evaluated in the same way. To evaluate $f(\mathbf{s})$ and $f(\mathbf{t})$, we make the simplifying assumption that the overall distribution of word vectors also follows a Gaussian distribution. Given the typical vocabulary sizes, we can reliably use the sample mean and covariance matrix as estimations of the parameters of this Gaussian.

The density $f(\mathbf{t}-\mathbf{s}|\theta_{st})$ is estimated similarly to $f(x_i^s|\delta_s)$, which corresponds to an assumption that the translations $\mathbf{t}-\mathbf{s}$ also follow a Gaussian distribution. In particular, we estimate $f(\mathbf{t}-\mathbf{s}|\theta_{st})$ as $\prod_{i=1}^{m} f(x_i^s - x_i^t|\theta_{st})$, where x_i^s is again the i^{th} coordinate of $\mathbf{s}$ and similar for x_i^t. Each univariate Gaussian $f(x_i^s -$

$x_i^t|\theta_{st})$ is then again estimated using the t-distribution, from the set of data points $\{x_i^{s_1} - x_i^{t_1}, ..., x_i^{s_n} - x_i^{t_n}\}$. We similarly estimate $f(\mathbf{t} - \mathbf{s}|\delta_s, \delta_t)$ as $\prod_{i=1}^m f(x_i^s - x_i^t|\delta_s, \delta_t)$. The mean of $f(x_i^s - x_i^t|\delta_s, \delta_t)$ is the same as the mean of $f(x_i^s - x_i^t|\theta_{st})$, but the variance is estimated from the differences $x_i^{s_l} - x_i^{t_k}$ corresponding to n randomly sampled pairs (s_l, t_k), where s_l and t_k are respectively sampled from the source and target words occurring in the training examples. Note that if the assumption that the considered relation corresponds to a translation is wrong, we can expect the variance of $f(x_i^s - x_i^t|\theta_{st})$ and $f(x_i^s - x_i^t|\delta_s, \delta_t)$ to be similar, in which case the last factor in the evaluation of $P(\theta_{st}|\mathbf{s}, \mathbf{t})$ will be approximately 1. In other words, the model implicitly takes into account how much the translation assumption appears to be satisfied.

3.2 Regression Model

Intuition. While there are several relations that can be approximately modelled as vector translations, there are many other relations for which this is not the case. To illustrate this, Figure 1b has been constructed in the same way as Figure 1a, but using the instances of the meronymy relation from the DiffVec dataset (Gladkova et al., 2016). This figure clearly suggests that we cannot expect an approach that models meronymy in terms of translations to perform well (for this word embedding). As an alternative, in this section we propose a model which weakens the translation assumption, and merely assumes that there is a linear mapping from source to target words. We can expect that the resulting model should perform well for a broader set of relations; for example, as we will see in Section 4, the meronymy relation can be modelled rather accurately in this way. The most important drawback of this approach is that we need more training examples to reliably estimate a linear mapping than to estimate a translation. In fact, while a translation can be estimated from a single example, we can only learn a linear mapping if the number of training examples is higher than the number of dimensions. We address this issue by reducing the number of dimensions of the source space, based on the available number of training examples.

Model description. We now estimate the probability that (s, t) is a valid instance of the considered relation as follows:

$$\begin{aligned} P(\theta_{st}|\mathbf{s}, \mathbf{t}) &\propto \frac{f(\mathbf{s}|\delta_s)}{f(\mathbf{s})} \cdot \frac{f(\mathbf{t}|\delta_t)}{f(\mathbf{t})} \cdot \frac{f(\mathbf{t}|\mathbf{s}, \theta_{st})}{f(\mathbf{t}|\mathbf{s}, \delta_s, \delta_t)} \\ &= \frac{f(\mathbf{s}|\delta_s)}{f(\mathbf{s})} \cdot \frac{f(\mathbf{t}|\delta_t)}{f(\mathbf{t})} \cdot \frac{f(\mathbf{t}|\mathbf{s}, \theta_{st})}{f(\mathbf{t}|\delta_t)} \\ &= \frac{f(\mathbf{s}|\delta_s)}{f(\mathbf{s})} \cdot \frac{f(\mathbf{t}|\mathbf{s}, \theta_{st})}{f(\mathbf{t})} \end{aligned}$$

The densities $f(\mathbf{s}|\delta_s)$, $f(\mathbf{s})$ and $f(\mathbf{t})$ are estimated as before. We estimate $f(\mathbf{t}|\mathbf{s}, \theta_{st})$ as $\prod_{i=1}^m f(x_i^t|\mathbf{s}, \theta_{st})$, where x_i^t is again the i^{th} coordinate of $\mathbf{t}$. Each univariate density $f(x_i^t|\mathbf{s}, \theta_{st})$ is estimated using a Bayesian linear regression model that predicts the possible representations of the target word from $\mathbf{s}$. However, this is only feasible if $\mathbf{s}$ has at most $n - 2$ coordinates. Therefore, we use a low-rank approximation of the source word representations, as follows.

Let A be a matrix whose rows are the vectors $\mathbf{s_1}, ..., \mathbf{s_n}$ and let $A = U\Sigma V^T$ be the SVD decomposition of A. Let $\mathbf{v_1}, ..., \mathbf{v_k}$ be the first k row vectors of V, for some $k < n - 1$. For a given vector $\mathbf{p}$, we can think of $\mathbf{p}^S = (\mathbf{p} \cdot \mathbf{v_1}, ..., \mathbf{p} \cdot \mathbf{v_k})$ as the representation of $\mathbf{p}$ in the source subspace. Given that we typically need far fewer dimensions to represent the source space than the total number of dimensions in the word embedding, we should be able to predict the target word from $\mathbf{s}^S$, even for relatively small values of k. In any case, the choice of k represents a trade-off: the lower the value of k, the better we can characterize the uncertainty underlying our predictions, but the less information we have for making predictions. In the experiments, we have used $k = \frac{n-1}{2}$. We estimate $f(x_i^t|\mathbf{s}, \theta_{st})$ as follows:

$$\begin{aligned} &\int G(x_i^t; \mathbf{s}^*\beta, \sigma^2) \cdot \\ &G(\beta; (X^TX)^{-1}X^T\mathbf{b^i}, (X^TX)^{-1}\sigma^2) \cdot \\ &NI\chi^2(\sigma^2|\nu_0, \sigma_0^2) d\beta d\sigma \end{aligned}$$

where $\mathbf{b^i} = (x_i^{t_1}, ..., x_i^{t_n})$, X is composed of the first k columns of $U\Sigma$ (with U and Σ the matrices from the SVD decomposition of A) with an additional 1 appended at the end of each row for the bias term, and $\mathbf{s}^*$ is the vector $\mathbf{s}^S$ with an additional 1 appended. Assuming a flat prior on the residual variance σ^2, the parameters ν_0 and σ_0^2 can be estimated from the training data as:

$$\nu_0 = n - k - 1$$
$$\sigma_0^2 = \frac{1}{n-k-1}(\mathbf{b^i} - X\hat{\beta})^T(\mathbf{b^i} - X\hat{\beta})$$

with $\hat{\beta}$ the least squares solution.

4 Evaluation

In this section, we experimentally compare the two proposed models with a number of baseline methods from the literature. The relations we consider are taken from three standard benchmark datasets, each containing a mixture of syntactic and semantic relationships: (i) the Google Analogy Test Set (Google), which contains 14 types of relations with a varying number of instances per relation (Mikolov et al., 2013a), (ii) the Bigger Analogy Test Set (BATS), which contains 40 relations with 50 instances per relation (Gladkova et al., 2016), and (iii) the DiffVec Test Set (DV), which contains 36 relations with a varying number of instances per relation (Vylomova et al., 2016). We report results for two embeddings that have been learned using Skip-gram, one from the Wikipedia dump of 2 November 2015 (SG-Wiki) and one from a 100B words Google News data set[3] (SG-GN). We also use two embeddings that have been learned with GloVe, one from the same english Wikipedia dump (GloVe-Wiki) and one from the 840B words Common Crawl data set[4] (GloVe-CC).

For relations with at least 10 instances, we use 10-fold cross validation, whereas for relations with less than 10 instances, we use a leave-one-out evaluation. Note that the considered datasets only contain positive examples. To generate negative test examples, we use four strategies. First, for each pair (s, t) in the test fold, we add (t, s) as a negative example. Second, for each source word s in the test fold, we randomly sample two target words from the test fold (provided that the test fold contains enough pairs), which do not occur together with s, and for each such target word t, we add (s, t) as a negative example. Third, for each positive example, we randomly select a pair from the other relations. Finally, for each positive example, we generate a random word pair from the words available in the dataset. This ensures that the evaluation involves negative examples that consist of related words, as well as negative examples that consist of unrelated words.

If we consider the task as a classification task, i.e. deciding for an unseen pair (s, t) whether it has the considered relation, we need to select a threshold, as the considered methods only produce a confidence score. To choose this threshold, we randomly select 10% of the 9 training folds as validation data. In the results below, we separately report precision, recall and F1. We can also evaluate this task as a ranking problem, where we merely evaluate to what extent each method assigns the highest score to the correct pairs. In that case, we use mean average precision (MAP).

4.1 Baselines

The first baseline we consider is the 3CosAvg (or 3CA) method proposed in (Drozd et al., 2016), which essentially treats the relation induction problem like an analogy completion problem, where we use the average translation vector across all pairs (s_i, t_i) from the training data. In particular, this method assigns the following score to the test pair (s, t):

$$\mathit{score}_{3CA}(t, s) = \cos\left(\mathbf{s} + \frac{\sum_i \mathbf{t_i} - \mathbf{s_i}}{n}, \mathbf{t}\right)$$

Another method proposed in (Drozd et al., 2016), called LRCos (or LRC), is based on the assumption that (s, t) is likely correct if $\cos(\mathbf{s}, \mathbf{t})$ is high and t is of the correct type, where a logistic regression

classifier was trained on the target words $\{t_1, ..., t_n\}$ to predict the probability that t is a valid 'target word'. To adapt this method to our setting, we also need to consider the probability that s is a valid 'source word' (which is not needed in the analogy completion setting considered in (Drozd et al., 2016), since s is always given as a valid source word). To allow for a more direct comparison with our methods, instead of using a logistic regression classifier, we will use our Bayesian estimation for the probability that s and t are of the correct type. In particular, we use the score $score_{LRC}(t, s)$ defined as follows:

$$\frac{P(\mathbf{s}|\delta_s)}{P(\mathbf{s})} \cdot \frac{P(\mathbf{t}|\delta_t)}{P(\mathbf{t})} \cdot \cos(\mathbf{s}, \mathbf{t})$$

As our final baseline, we train a linear SVM classifier using the training pairs $(s_1, t_1), ..., (s_n, t_n)$ as positive examples. Following (Vylomova et al., 2016), we use negative examples of the form (t_i, s_i), obtained by swapping the position of source and target word, as well as negative examples of the form (s_i, t_j), obtained by swapping t_i by the target word of another instance (while ensuring that (s_i, t_j) does not appear in the training data as well). Finally, we also add n random word pairs as negative examples. The C parameter (i.e. the cost parameter for mislabeled examples) of the SVM is tuned for each relation separately (choosing values from $\{0.01, 0.1, 1, 10, 100\}$), using the same validation data that is used for selecting the thresholds in the other models. To address class imbalance, negative examples were weighted by the ratio of positive to negative examples.

4.2 Results

The results are summarized in Table 2. As can be observed, our translation model consistently outperforms all other methods in both MAP and F1 score. Moreover, the regression model consistently outperforms the baselines in terms of MAP score, and outperforms the baselines for the Google and DV test sets in terms of F1 score (with the exception of the Glove-CC embedding, where 3CA has a better F1 score for the Google test set). The performance of the baselines varies, with 3CA generally performing best for the Google test set and LRC generally performing best for DiffVec.

To compare the performance of the methods across different types of relations, Table 3 contains the MAP scores for a number of selected relations from the DiffVec and BATS test sets, for the SG-GN word embedding. For the BATS dataset, the translation model consistently outperforms the baseline across all relations (including the relations that are not shown in the table). In the case of DiffVec there are a few exceptions, as can be seen in Table 3, but in such cases the differences with the translation model are small. The regression model also outperforms the baselines in most cases, but there are a few

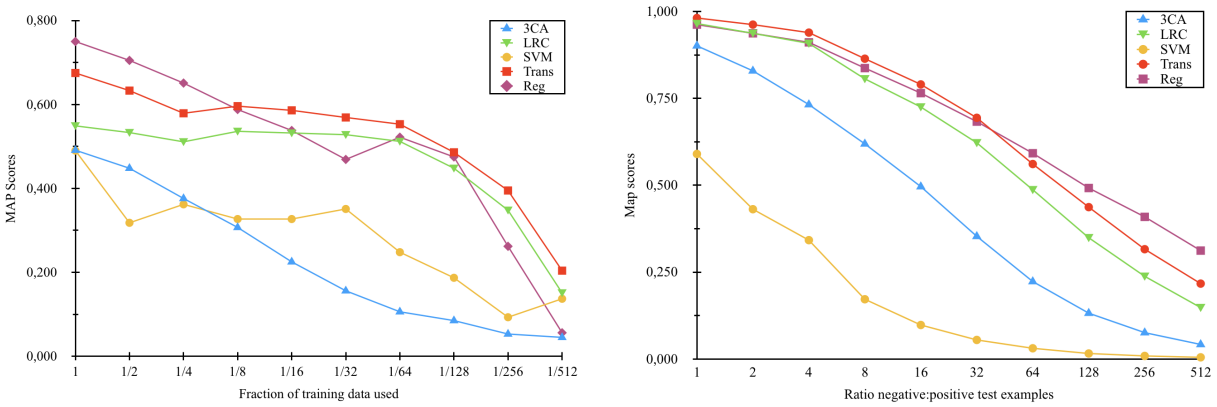
exceptions where it performs much worse (e.g. *Lvc* for DiffVec, and *Hypernyms-animals*, *Meronyms-substance*, *Synonyms-intensity* and *Antonyms-binary* in the case of BATS). While the regression model is outperformed by the translation model on average, there are several cases where it performs better. For relations such as *Event*, *Hyper* and *Mero* from DiffVec, where the number of examples is rather large (resp. 3583, 1173, 2825), we can see that the regression model actually substantially outperforms the translation model. The main weakness of the regression model is that it needs more training data: while a vector translation can be estimated from a single training example, learning an arbitrary linear mapping requires the number of training examples to be larger than the number of dimensions. While this can be addressed by using a low-dimensional approximation of the source word, information is lost in this way.

The impact of the amount of training data on the relative performance of the regression model is further analyzed in Figure 2a, taking the Mero relation from DiffVec as an example (for SG-GN). While the regression model performs best if all the training data is used, the translation model is less sensitive to the amount of training data, and starts outperforming the regression model if less than 1/8th of the training data is used.

We also noticed that the performance of the methods crucially depends on the number of negative test



(a) MAP scores for the Mero relation, in function of training data (as a fraction of the total amount).

(b) MAP scores for the Mero relation, in function of the ratio of negative to positive test examples.

Figure 2: MAP scores for the Mero relation, in function of training data/ratio of negative to positive test examples.

examples that are considered, even if these negative examples are randomly chosen word pairs. This is illustrated in Figure 2b, which shows the MAP scores for the Mero relation from DiffVec (for SG-GN), for different numbers of negative examples. For these experiments, as negative examples, we only considered random word pairs. The total number of such negative examples was varied from 1 times the number of positive examples, which is equal to the number of positive examples, to 512 times the number of positive examples. While the performance of each of the methods is affected by the number of such negative examples, the performance of the baseline models drops more quickly. Moreover, the regression model is more robust than the translation model, and starts outperforming it if the ratio of negative examples to positive examples is higher than 32:1.

5 Conclusions

We have proposed two probabilistic models for identifying word pairs that are in a given relation. The first model is based on the common assumption that lexical relations correspond to vector translations in a word embedding. The other model is based on linear regression, relying on the weaker assumption that there is a linear relationship between the source and target words of the considered relation. Both models implicitly factor in whether their underlying assumption is satisfied, and could thus easily be used in combination with each other, or with additional models. In our experimental evaluation, we have found both models to outperform existing approaches, with the translation model outperforming the regression model on average. However, in cases where sufficient training data is available, the regression model tends to perform better. We have also found some evidence that the regression model is better able to handle cases of extreme imbalance between positive and negative examples.

There are several interesting avenues for future work. First, a number of variants of the proposed models can be developed. For example, a model based on vector concatenations could intuitively model similar kinds of relationships as the regression model. However, in the case of vector concatenations, we can no longer use a diagonal covariance matrix, as that would mean that no interactions between source and target words are being captured. One solution could be to use a low-rank approximation of the vector concatenations and estimate full covariance matrices in a lower-dimensional space. Another interesting option to explore would be to estimate prior probabilities from coarser grained relations for which more training data is available. For example, we could learn a generic model for causal relations, and use that as a prior for the specific types of causal relationships that are considered in the DiffVec test set. It may even be useful to learn priors capturing e.g. syntactic relations, which would intuitively amount to finding a subspace of the embedding that relates to syntactic features.

Abstract

Recent advances in language modeling using recurrent neural networks have made it viable to model language as distributions over characters. By learning to predict the next character on the basis of previous characters, such models have been shown to automatically internalize linguistic concepts such as words, sentences, subclauses and even sentiment. In this paper, we propose to leverage the internal states of a trained character language model to produce a novel type of word embedding which we refer to as *contextual string embeddings*. Our proposed embeddings have the distinct properties that they (a) are trained without any explicit notion of words and thus fundamentally model words as sequences of characters, and (b) are *contextualized* by their surrounding text, meaning that the same word will have different embeddings depending on its contextual use. We conduct a comparative evaluation against previous embeddings and find that our embeddings are highly useful for downstream tasks: across four classic sequence labeling tasks we consistently outperform the previous state-of-the-art. In particular, we significantly outperform previous work on English and German named entity recognition (NER), allowing us to report new state-of-the-art F1-scores on the CoNLL03 shared task.

We release all code and pre-trained language models in a simple-to-use framework to the research community, to enable reproduction of these experiments and application of our proposed embeddings to other tasks: https://github.com/zalandoresearch/flair

1 Introduction

A large family of NLP tasks such as named entity recognition (NER) and part-of-speech (PoS) tagging may be formulated as *sequence labeling* problems; text is treated as a sequence of words to be labeled with linguistic tags. Current state-of-the-art approaches for sequence labeling typically use the LSTM variant of bidirectional recurrent neural networks (BiLSTMs), and a subsequent conditional random field (CRF) decoding layer (Huang et al., 2015; Ma and Hovy, 2016).

A crucial component in such approaches are *word embeddings*, typically trained over very large collections of unlabeled data to assist learning and generalization. Current state-of-the-art methods concatenate up to three distinct embedding types:

1. Classical word embeddings (Pennington et al., 2014; Mikolov et al., 2013), pre-trained over very large corpora and shown to capture latent syntactic and semantic similarities.

2. Character-level features (Ma and Hovy, 2016; Lample et al., 2016), which are not pre-trained, but trained on task data to capture task-specific subword features.

3. Contextualized word embeddings (Peters et al., 2017; Peters et al., 2018) that capture word semantics in context to address the polysemous and context-dependent nature of words.

Proceedings of the 27th International Conference on Computational Linguistics, pages 1638–1649
Santa Fe, New Mexico, USA, August 20-26, 2018.

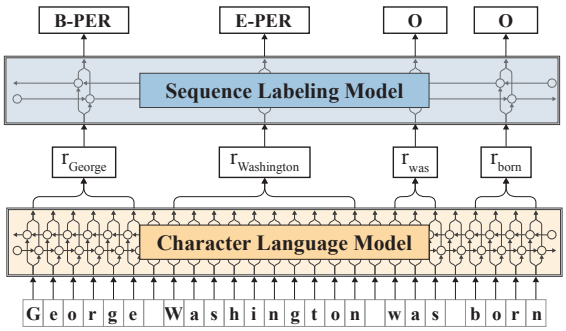

Figure 1: High level overview of proposed approach. A sentence is input as a character sequence into a pre-trained bidirectional character language model. From this LM, we retrieve for each word a contextual embedding that we pass into a vanilla BiLSTM-CRF sequence labeler, achieving robust state-of-the-art results on downstream tasks (NER in Figure).

Contextual string embeddings. In this paper, we propose a novel type of contextualized character-level word embedding which we hypothesize to combine the best attributes of the above-mentioned embeddings; namely, the ability to (1) pre-train on large unlabeled corpora, (2) capture word meaning in context and therefore produce different embeddings for polysemous words depending on their usage, and (3) model words and context fundamentally as sequences of characters, to both better handle rare and misspelled words as well as model subword structures such as prefixes and endings.

We present a method to generate such a contextualized embedding for any string of characters in a sentential context, and thus refer to the proposed representations as *contextual string embeddings*.

Neural character-level language modeling. We base our proposed embeddings on recent advances in neural language modeling (LM) that have allowed language to be modeled as distributions over sequences of characters instead of words (Sutskever et al., 2011; Graves, 2013; Kim et al., 2015). Recent work has shown that by learning to predict the next character on the basis of previous characters, such models learn internal representations that capture syntactic and semantic properties: even though trained without an explicit notion of word and sentence boundaries, they have been shown to generate grammatically correct text, including words, subclauses, quotes and sentences (Sutskever et al., 2014; Graves, 2013; Karpathy et al., 2015). More recently, Radford et al. (2017) showed that individual neurons in a large LSTM-LM can be attributed to specific semantic functions, such as predicting sentiment, without explicitly trained on a sentiment label set.

We show that an appropriate selection of hidden states from such a language model can be utilized to generate word-level embeddings that are highly effective in downstream sequence labeling tasks.

State-of-the-art sequence labeling. Based on this, we propose the sequence tagging architecture illustrated in Figure 1: each sentence is passed as a sequence of characters to a bidirectional character-level neural language model, from which we retrieve for each word the internal character states to create a contextual string embedding. This embedding is then utilized in the BiLSTM-CRF sequence tagging module to address a downstream NLP task (NER in the Figure).

We experimentally verify our approach in the classic sequence labeling tasks of named entity recognition for English and German, phrase chunking and part-of-speech tagging, and find that our approach reliably achieves state-of-the-art results. In particular, for both German and English NER, our approach significantly improves the state-of-the-art. But even for highly saturated tasks such as PoS tagging and chunking we find slight improvements over the already strong state-of-the-art (see Table 1).

We also find that our proposed embeddings on some tasks subsume previous embedding types, enabling simplified sequence labeling architectures. In addition to this, the character-level LM is compact and relatively efficient to train in comparison to word-level models. This allows us to easily train models for new languages or domains.

Contributions. To summarize, this paper proposes contextual string embeddings, a novel type of word embeddings based on character-level language modeling, and their use in a state-of-the-art sequence labeling architecture. Specifically, we

- illustrate how we extract such representations from a character-level neural language model, and

Task	PROPOSED	Previous best
NER English	**93.09**±0.12	*92.22*±0.1 (Peters et al., 2018)
NER German	**88.32**±0.2	*78.76* (Lample et al., 2016)
Chunking	**96.72**±0.05	*96.37*±0.05 (Peters et al., 2017)
PoS tagging	**97.85**±0.01	*97.64* (Choi, 2016)

Table 1: Summary of evaluation results for best configuration of proposed architecture, and current best published results. The proposed approach significantly outperforms previous work on the CONLL03 NER task for German and English and slightly outperforms previous works on CONLL2000 chunking and Penn treebank PoS tagging.

integrate them into a simplified sequence labeling architecture;

- present experiments in which we quantiatively evaluate the usefulness and inherent semantics of the proposed embeddings against previous embeddings and their stacked combinations in downstream tasks;

- report a new state-of-the-art on the CONLL03 NER task for English (**93.09** F1, ↑0.87 pp vs. previous best) and German (**88.33** F1, ↑9.56 pp vs. previous best), and state-of-the-art scores for chunking and PoS;

- release all code and pre-trained language models in a simple-to-use framework to the research community, to enable reproduction of these experiments and application of our proposed embeddings to other tasks.

This paper is structured as follows: we present our approach for extracting contextual string embeddings from character-level language models in Section 2. We evaluate our approach against prior work in Section 3. We then discuss the results and present an outlook into future work in Section 4.

2 Contextual String Embeddings

Our proposed approach passes sentences as sequences of characters into a character-level language model to form word-level embeddings. Refer to Figure 2 for an example illustration.

2.1 Recurrent Network States

Like recent work, we use the LSTM variant (Hochreiter and Schmidhuber, 1997; Graves, 2013; Zaremba et al., 2014) of recurrent neural networks (Sutskever et al., 2011) as language modeling architecture. These have been shown to far outperform earlier n-gram based models (Jozefowicz et al., 2016) due to the ability of LSTMs to flexibly encode long-term dependencies with their hidden state. We use characters as atomic units of language modeling (Graves, 2013), allowing text to be treated as a sequence of characters passed to an LSTM which at each point in the sequence is trained to predict the next character[1]. This means that the model possesses a hidden state for each character in the sequence.

Formally, the goal of a character-level language model is to estimate a good distribution $P(\mathbf{x}_{0:T})$ over sequences of charaters $(\mathbf{x}_0, \mathbf{x}_1, \ldots, \mathbf{x}_T) =: \mathbf{x}_{0:T}$ reflecting natural language production (Rosenfeld, 2000). By training a language model, we learn $P(\mathbf{x}_t|\mathbf{x}_0, \ldots, \mathbf{x}_{t-1})$, an estimate of the predictive distribution over the next character given past characters. The joint distribution over entire sentences can then be decomposed as a product of the predictive distribution over characters conditioned on the preceeding characters:

$$P(\mathbf{x}_{0:T}) = \prod_{t=0}^{T} P(\mathbf{x}_t|\mathbf{x}_{0:t-1}) \tag{1}$$

[1]Note that character-level LM is different from *character-aware* LM (Kim et al., 2015) which still operates on the word-level, but also takes into account character-level features through an additional CNN encoding step.

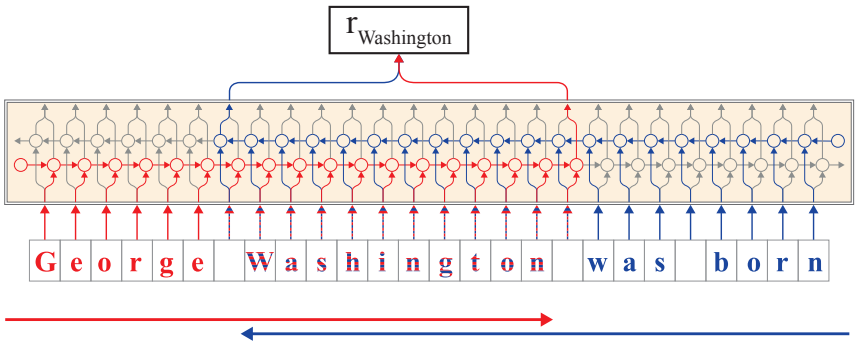

Figure 2: Extraction of a contextual string embedding for a word ("Washington") in a sentential context. From the forward language model (shown in red), we extract the output hidden state after the last character in the word. This hidden state thus contains information propagated from the beginning of the sentence up to this point. From the backward language model (shown in blue), we extract the output hidden state before the first character in the word. It thus contains information propagated from the end of the sentence to this point. Both output hidden states are concatenated to form the final embedding.

In the LSTM architecture, the conditional probability $P\left(\mathbf{x}_t|\mathbf{x}_{0:t-1}\right)$ is approximately a function of the network output $\mathbf{h}_t$.

$$P\left(\mathbf{x}_t|\mathbf{x}_{0:t-1}\right) \approx \prod_{t=0}^{T} P\left(\mathbf{x}_t|\mathbf{h}_t;\theta\right) \tag{2}$$

$\mathbf{h}_t$ represents the entire past of the character sequence. In an LSTM in particular, it is computed recursively, with the help of an additional recurrent quantity $\mathbf{c}_t$, the memory cell,

$$\begin{aligned}\mathbf{h}_t\left(\mathbf{x}_{0:t-1}\right) &= f_{\mathbf{h}}\left(\mathbf{x}_{t-1},\mathbf{h}_{t-1},\mathbf{c}_{t-1};\theta\right)\\ \mathbf{c}_t\left(\mathbf{x}_{0:t-1}\right) &= f_{\mathbf{c}}\left(\mathbf{x}_{t-1},\mathbf{h}_{t-1},\mathbf{c}_{t-1};\theta\right)\ ,\end{aligned}$$

where θ denotes all the parameters of the model. $\mathbf{h}_{-1}$ and $\mathbf{c}_{-1}$ can be initialized with zero or can be treated as part of the model parameters θ. In our model, a fully conected softmax layer (without bias) is placed ontop of $\mathbf{h}_t$, so the likelihood of every character is given by

$$P\left(\mathbf{x}_t|\mathbf{h}_t;\mathbf{V}\right) = \text{softmax}\left(\mathbf{V}\mathbf{h}_t+\mathbf{b}\right) \tag{3}$$

$$= \frac{\exp\left(\mathbf{V}\mathbf{h}_t+\mathbf{b}\right)}{\left\|\exp\left(\mathbf{V}\mathbf{h}_t+\mathbf{b}\right)\right\|_1} \tag{4}$$

where $\mathbf{V}$ and $\mathbf{b}$, weights and biases, are part of the model parameters θ (Graves, 2013; Jozefowicz et al., 2016).

2.2 Extracting Word Representations

We utilize the hidden states of a forward-backward recurrent neural network to create contextualized word embeddings. This means, alongside with the forward model (2), we also have a backward model, which works in the same way but in the reversed direction:

$$P^b\left(\mathbf{x}_t|\mathbf{x}_{t+1:T}\right) \approx \prod_{t=0}^{T} P^b\left(\mathbf{x}_t|\mathbf{h}_t^b,\theta\right) \tag{5}$$

$$\mathbf{h}_t^b = f_{\mathbf{h}}^b\left(\mathbf{x}_{t+1},\mathbf{h}_{t+1}^b,\mathbf{c}_{t+1}^b;\theta\right) \tag{6}$$

$$\mathbf{c}_t^b = f_{\mathbf{c}}^b\left(\mathbf{x}_{t+1},\mathbf{h}_{t+1}^b,\mathbf{c}_{t+1}^b;\theta\right) \tag{7}$$

Note that, in the following, we will use the superscript $\cdot^f$ to define $\mathbf{h}_t^f := \mathbf{h}_t$, $\mathbf{c}_t^f := \mathbf{c}_t$ for the forward model described in the previous section.

From this forward-backward LM, we concatenate the following hidden character states for each word: from the fLM, we extract the output hidden state after the last character in the word. Since the fLM

is trained to predict likely continuations of the sentence after this character, the hidden state encodes semantic-syntactic information of the sentence up to this point, including the word itself. Similarly, we extract the output hidden state before the word's first character from the bLM to capture semantic-syntactic information from the end of the sentence to this character. Both output hidden states are concatenated to form the final embedding and capture the semantic-syntactic information of the word itself as well as its surrounding context.

Formally, let the individual word-strings begin at character inputs with indices $t_0, t_1, \ldots, t_n$, then we define contextual string embeddings of these words as:

$$\mathbf{w}_i^{CharLM} := \begin{bmatrix} \mathbf{h}^f_{t_{i+1}-1} \\ \mathbf{h}^b_{t_i-1} \end{bmatrix} \tag{8}$$

We illustrate our approach in Figure 2 for a word in an example sentence, with the fLM in red and the bLM shown in blue.

Our approach thus produces embeddings from hidden states that are computed not only on the characters of a word, but also the characters of the surrounding context, since it influences the LM's ability to predict likely continuations of a sentence. As we later illustrate in Section 3.4, our proposed approach thus produces different embeddings for the same lexical word string in different contexts, and is able to accurately capture the semantics of contextual use together with word semantics itself.

2.3 Sequence Labeling Architecture

In the default configuration of our approach, the final word embeddings are passed into a BiLSTM-CRF sequence labeling module as proposed by Huang et al. (2015) to address downstream sequence labeling tasks. Then let us call the inputs to the BiLSTM g_l: $\mathbf{w}_0, \ldots, \mathbf{w}_n$. Then we have that:

$$\mathbf{r}_i := \begin{bmatrix} \mathbf{r}^f_i \\ \mathbf{r}^b_i \end{bmatrix} \tag{9}$$

Where $\mathbf{r}^f_i$ and $\mathbf{r}^f_i$ are the forward and backward output states of the BiLSTM g_l. The final sequence probability is then given by a CRF over the possible sequence labels y:

$$\widehat{P}(\mathbf{y}_{0:n}|\mathbf{r}_{0:n}) \propto \prod_{i=1}^{n} \psi_i(y_{i-1}, y_i, \mathbf{r}_i) \tag{10}$$

Where:

$$\psi_i(y', y, \mathbf{r}) = \exp(\mathbf{W}_{y',y}\mathbf{r} + \mathbf{b}_{y',y}) \tag{11}$$

Alternatively, we also experiment with directly applying a simple feedforward linear architecture (essentially multinomial logistic regression (Menard, 2018)). This configuration simply linearly projects the hidden states of the neural character LM to make predictions:

$$\mathbf{r}_i = \mathbf{W}_r\mathbf{w}_i + \mathbf{b}_r \tag{12}$$

Then the prediction of the label is given by:

$$P(\mathbf{y}_i = j|\mathbf{r}_i) = \text{softmax}(\mathbf{r}_i)[j] \tag{13}$$

Stacking Embeddings. Current sequence labeling models often combine different types of embeddings by concatenating each embedding vector to form the final word vectors. We similarly experiment with different stackings of embeddings; for instance in many configurations it may be benficial to add classic word embeddings to add potentially greater latent word-level semantics to our proposed embeddings. In this case, the final words representation is given by

$$\mathbf{w}_i = \begin{bmatrix} \mathbf{w}_i^{CharLM} \\ \mathbf{w}_i^{GloVe} \end{bmatrix} \tag{14}$$

Here $\mathbf{w}_i^{GloVe}$ is a precomputed GLOVE embedding (Pennington et al., 2014). We present different configurations of stacked embeddings in the next section for the purpose of evaluation.

3 Experiments

We conduct an experimental evaluation to assess in how far our proposed contextual string embeddings are useful for sequence labeling, and how they compare to existing embedding types. In addition, we aim to gain insights into the inherent semantics of the proposed embeddings.

Tasks. To this end, we evaluate our embeddings in four classic sequence labeling tasks in their default evaluation setups, namely named entity recognition in the CoNLL03 setup (Tjong Kim Sang and De Meulder, 2003), chunking in the CoNLL2000 setup (Tjong Kim Sang and Buchholz, 2000) and PoS tagging in the default Penn treebank setup described by Collins (2002). We evaluate NER to determine in how far our embeddings are helpful for shallow semantic tasks, while we use chunking and PoS to determine in how far they are helpful for shallow syntactic tasks. We also include the German NER task from the CoNLL03 setup to evaluate our embeddings in a language with richer morphology.

3.1 Experimental Setup

We utilize the BiLSTM-CRF sequence labeling architecture proposed by Huang et. al (2015) in all configurations of our comparative evaluation. In this architecture, we evaluate our proposed contextual string embeddings in stacked combinations with the three types of previous embeddings discussed in Section 1; namely (1) pre-trained static ("classic") word embeddings (Pennington et al., 2014), (2) task-trained (i.e. not pre-trained) static character features (Ma and Hovy, 2016; Lample et al., 2016), and (3) pre-trained contextual word embeddings (Peters et al., 2018).

Baselines. We also evaluate setups that involve only previous word embeddings. These are effectively reimplementations of state-of-the-art approaches within our sequence labeling architecture. We conduct these experiments to isolate the impact of our proposed embeddings vis-a-vis earlier approaches. The setups are as follows:

HUANG : A standard BiLSTM-CRF setup with pre-trained word embeddings, and thus a reimplementation of Huang et al. (2015).

LAMPLE : A hierarchical BiLSTM-CRF setup with pre-trained word embeddings, in which task-trained character features are additionally computed by a character-level BiLSTM for each word. It is thus a reimplementation of Lample et al. (2016).

PETERS : A BiLSTM-CRF setup that utilizes the release of Peters et al. (2018) in the ALLENNLP library to produce contextualized word embeddings, and thus is effectively a reimplementation of Peters et al. (2018) in our framework. Note that only English embeddings are provided, so we use this baseline only on the English tasks.

Proposed approach. We evaluate our proposed contextual string embeddings in the following configurations:

PROPOSED : The simplest setup of our proposed approach that relies solely on our proposed contextual string embeddings, passed to a standard BiLSTM-CRF architecture. This configuration thus matches the illustration in Figure 1.

PROPOSED$_{+\text{WORD}}$: An extension of PROPOSED in which we concatenate pre-trained static word embeddings with our contextual string embeddings as per Equation (14), to determine whether they complement or subsume our proposed embeddings.

PROPOSED$_{+\text{CHAR}}$:A similar extension in which we concatenate task-trained character features in a hierarchical BiLSTM-CRF architecture to our contextual string embeddings, to determine whether they complement or subsume our proposed embeddings.

PROPOSED$_{+\text{WORD+CHAR}}$: We also evaluate a setting in which we add both pre-trained word and task-trained character embeddings.

PROPOSED$_{+\text{ALL}}$: Finally, we evaluate a setup that uses all four embeddings. Since Peters et al. (2018) embeddings are only distributed for English, we use this setup only on the English tasks.

3.2 Model Training and Parameters

Character-level language models. We train our LMs using SGD to perform truncated backpropagation through time (BPTT) with a window length of 250, a non-annealed learning rate of 20.0, a batch size of 100, clipping gradients at 0.25 and dropout probabilities of 0.25. We prepare the data by unking-the rarest 0.0001 percent of characters. We set the number of hidden states of the (one-layered) LSTM to 2048. We halt training by tracking the performance on the validation set, stopping when negligible gains were observed, or after 1 week, whichever came first.

We train our English models on the 1-billion word corpus (Chelba et al., 2013) and our German models on a corpus of half a billion words aggregated from various open source corpora in the OPUS project[2]. After training, we find the models trained for the full week achieve character level perplexity on the supplied test-set of 2.42 for English and 2.38 for German. Resources did not allow us to train for longer or on larger language model variants. We hypothesize that more resources and time would permit learning an even better model.

Sequence tagging model. We train the sequence tagging model using vanilla SGD with no momentum, clipping gradients at 5, for 150 epochs. We employ a simple learning rate annealing method in which we halve the learning rate if training loss does not fall for 5 consecutive epochs. Following recommendations of Reimers et al. (2017)'s in-depth analysis of hyperparameters in sequence labeling, we utilize variational dropout, set the number of hidden states per-layer of the LSTM to 256, set the number of LSTM layers to 1, and perform model selection over the learning rate $\in \{0.01, 0.05, 0.1\}$ and mini-batch size $\in \{8, 16, 32\}$, choosing the model with the best F-measure (for NER and chunking) or accuracy (for PoS) in the best epoch as judged by performance on the validation set. Following Peters et al. (2017), we then repeat the experiment for the model chosen 5 times with different random seeds, and train using both train and development set, reporting both average performance and standard deviation over these runs on the test set as final performance.

Classic word embeddings. Following Reimers et al. (2017), we use GLOVE embeddings for English NER and KOMNIOS embeddings (Komninos and Manandhar, 2016) for PoS tagging and chunking. For German, we use the German FASTTEXT embeddings (Grave et al., 2018). In configurations that train character features, we apply a BiLSTM with 25 hidden states to each word separately and extract the final hidden output states (see Lample et al. (2016)).

[2]We aggregate over the PARACRAWL, EUROPARL, OPENSUBTITLES2018, and WIKIPEDIA releases in OPUS for versatile text and to allow reproduction of our results.

Table 3: Additional ablation experiment in which we evaluate our approach without BiLSTM and CRF. Here, we instead use a simple linear map over the embeddings to determine their direct information content.

3.3 Results

Our experimental results are summarized in Table 2 for each of the four tasks. We find that our approach either slightly or strongly surpasses all previously published results. This shows that our proposed contextual string embeddings are indeed highly useful for sequence labeling. In more detail, we make the following observations:

New state-of-the-art for NER. We find that our approach performs particularly well on the task of named entity recognition. For English, we surpass the previous state-of-the-art approach by a significant margin (**93.09** F1, ↑0.87 pp vs. Peters et al. (2018)). For German in particular, we significantly raise the state-of-the-art (**88.33** F1, ↑9.56 pp vs. Lample et al. (2016)). We hypothesize that pre-trained contextual character-level features are particularly helpful for this task, since entities are an open vocabulary of names that are often indicated by character features (such as capitalization or endings), as well as their contextual use. In addition, the CONLL03 shared task data set contains many sentences (such as article titles) that are in all-caps; since most traditional embeddings perform lower casing to manage vocabulary size, we assume that our character model can better capture the features of such sentences.

Good performance on syntactic tasks. We also find that our approach slightly outperforms the latest state-of-the-art approaches for chunking and PoS tagging. We do not however see the same improvements as for NER, which we mainly attribute to the fact that syntactic tasks are already solved by current approaches to very high accuracy, making it difficult to record further strong improvements (see Manning et al. (2014) for a discussion of this issue).

Traditional word embeddings helpful. Additionally, we observe that the added use of classic word embeddings in setup PROPOSED$_{+\text{WORD}}$ often produces the best results. Especially for NER, the use of classic word embeddings increases average F1 score by 1.1 pp to 93.07, compared with 91.97 for PROPOSED. We hypothesize that classic word embeddings capture word-level semantics that complement the strong character-level features of our proposed embeddings. We therefore recommend the setup PROPOSED$_{+\text{WORD}}$ as default setup for sequence labeling tasks.

Task-specific character features unnecessary. Another observation is that setups with task-specific character features (PROPOSED$_{+\text{CHAR}}$ and PROPOSED$_{+\text{WORD+CHAR}}$) do not perform better than those without. This indicates that they are largely subsumed by our proposed embeddings, and are thus no longer required. A positive side-effect of this is that this simplifies training of the sequence labeler (see Section 3.5).

3.4 Inherent Semantics

Quantiative investigation (Table 3). To gain additional insight into the content of the contextual string embeddings relative to the task, we replace the standard BiLSTM-CRF in the sequence labeling architecture with a direct feedforward map as per Equation (12), with and without a CRF decoder. This simplified approach makes predictions directly on the basis of the proposed embeddings without additional learning of the BiLSTM recurrence. The results for this simplified architecture are displayed in Table 3 for the

word	context	selected nearest neighbors
Washington	(a) ***Washington*** *to curb support for [..]*	(1) ***Washington*** *would also take [..] action [..]* (2) ***Russia*** *to clamp down on barter deals [..]* (3) ***Brazil*** *to use hovercrafts for [..]*

Table 4: Examples of the word "Washington" in different contexts in the CoNLL03 data set, and nearest neighbors using cosine distance over our proposed embeddings. Since our approach produces different embeddings based on context, we retrieve different nearest neighbors for each mention of the same word.

setups PROPOSED and PROPOSED$_{+\text{WORD}}$, as well as for a setup that involves only traditional word embeddings (GLOVE for English NER, KOMNIOS for English PoS and chunking, FASTTEXT for German NER).

We find that the effect of removing the BiLSTM layer on downstream task accuracy is far lower for the proposed embeddings than for classic embeddings. For the setups PROPOSED and PROPOSED$_{+\text{WORD}}$, we record only an average drop of 3% in F-score/accuracy between the BiLSTM-CRF and Map-CRF architectures. This stands in contrast to classic embeddings in which we find an average drop of 20% from BiLSTM-CRF to Map-CRF. This indicates that the inherent semantics of the proposed embeddings are meaningful enough as to require much less powerful learning architectures on top to perform downstream sequence labeling tasks. In particular, for PoS tagging, the simple feedforward map is competitive to BiLSTM and much more effective to train.

Qualitative inspection (Table 4). To illustrate the contextualized nature of our proposed embeddings, we present example embeddings of the polysemous word "Washington" in different contexts. We compute contextual string embeddings for all words in the English CoNLL03 corpus and compute nearest neighbors in the embedding space using the cosine distance. We then look up nearest neighbors for different mentions of the word "Washington".

As Table 4 shows, the embeddings successfully pry apart person, place, legislative entity and team (a-d). For instance, "Washington" used as last name in context (b) is closest to other last names, many of which are also place names ("Carla Sacramento"); "Washington" used as a sport team name in context (d) is closest to other place names used in sports team contexts. We include a negative example (e) in Table 4 in which the context is not sufficient to determine the type of mention. We hypothesize that modeling semantics in context is a key feature that allows our proposed embeddings to better address downstream sequence labeling task.

3.5 Discussion

Our proposed approach is one of the first to leverage hidden states from a language model to improve sequence labeling performance. Two prior works have suggested related approaches: The first is Liu et al. (2017) that jointly train a character-level language model together with the sequence labeling BiLSTM. In effect, this means that the language model is trained only on labeled task data and therefore has orders of magnitude fewer data available than our proposed approach (which we can pre-train on basically unlimited amounts of unlabled data). We hypothesize that this is the main reason for why our approach outperforms Liu et al. (2017) across all tasks.

A second approach is the method by Peters et. al (2017) which proposed to extract hidden states from pre-trained word-level language models as features for downstream NLP tasks. They report new state-

of-the-art results for NER (Peters et al., 2018) and chunking (Peters et al., 2017), but require the training of massive word-level language models: their best configuration uses a language model that was trained for 5 weeks on 32 GPUs (Jozefowicz et al., 2016), and still requires lower casing of all words to deal with the large vocabulary size. Their approach is the strongest baseline against which we compared.

We similarly propose to utilize trained LMs to generate embeddings, but consider LM at the character level. This has a number of advantages: First, character-level LM is independent of tokenization and a fixed vocabulary. Second, they produce stronger character-level features, which is particularly useful for downstream tasks such as NER. Finally, such models have a much smaller vocabulary size (distinct characters vs. distinct words) and are thus significantly easier to train and deploy in applications: the LM parameter-count scales according to $n_{layers}\, n^2_{hidden}$ (not true for word-level LM since these contain many inputs) and may be trained in 1 week on 1 GPU (e.g. significantly less than the 5 weeks on 32 GPUs used by Peters et al. (2017)). This allowed us to train models for other languages such as German with moderate resources, and thus allows our method to more effectively scale to new languages or domains.

4 Conclusion

We have proposed novel *contextual string embeddings* and a method for producing them using neural character LM. We find that they capture syntactic-semantic word features and disambiguate words in context, resulting in state-of-the-art performance in classic NLP sequence labeling tasks. To facilitate reproduction of our experiments, and enable application of our proposed embeddings to other tasks, we release all code and pre-trained language models in a simple-to-use framework to the research community[3]. Future work will focus on applying these embeddings to additional sentence level tasks such as image-retrieval and neural translation.

Learning Word Meta-Embeddings by Autoencoding

danushka@liverpool.ac.uk

Abstract

Distributed word embeddings have shown superior performances in numerous Natural Language Processing (NLP) tasks. However, their performances vary significantly across different tasks, implying that the word embeddings learnt by those methods capture complementary aspects of lexical semantics. Therefore, we believe that it is important to combine the existing word embeddings to produce more accurate and complete *meta-embeddings* of words. We model the meta-embedding learning problem as an autoencoding problem, where we would like to learn a meta-embedding space that can accurately reconstruct *all* source embeddings simultaneously. Thereby, the meta-embedding space is enforced to capture complementary information in different source embeddings via a coherent common embedding space. We propose three flavours of autoencoded meta-embeddings motivated by different requirements that must be satisfied by a meta-embedding. Our experimental results on a series of benchmark evaluations show that the proposed autoencoded meta-embeddings outperform the existing state-of-the-art meta-embeddings in multiple tasks.

1 Introduction

Representing the meanings of words is a fundamental task in Natural Language Processing (NLP). A popular approach to represent the meaning of a word is to *embed* it in some fixed-dimensional vector space (Turney and Pantel, 2010). In contrast to sparse and high-dimensional counting-based distributional word representation methods that use co-occurring contexts of a word as its representation, dense and low-dimensional prediction-based distributed word representations (Pennington et al., 2014; Mikolov et al., 2013a; Huang et al., 2012; Collobert and Weston, 2008; Mnih and Hinton, 2009) have obtained impressive performances in numerous NLP tasks such as sentiment classification (Socher et al., 2013), and machine translation (Zou et al., 2013).

Previous works studying the differences in word embedding learning methods (Chen et al., 2013; Yin and Schütze, 2016) have shown that word embeddings learnt using different methods and from different resources have significant variation in quality and characteristics of the semantics captured. For example, Hill et al. (2014; 2015) showed that the word embeddings trained from monolingual vs. bilingual corpora capture different local neighbourhoods. Bansal et al. (2014) showed that an ensemble of different word representations improves the accuracy of dependency parsing, implying the complementarity of the different word embeddings. This suggests the importance of *meta-embedding* – creating a new embedding by combining different existing embeddings. We refer to the input word embeddings to the meta-embedding process as the *source embeddings*. Yin and Schütze (2016) showed that by meta-embedding five different pre-trained word embeddings, we can overcome the out-of-vocabulary problem, and improve the accuracy of cross-domain part-of-speech (POS) tagging. Encouraged by the above-mentioned prior results, we expect an ensemble containing multiple word embeddings to produce better performances than the constituent individual embeddings in NLP tasks.

Proceedings of the 27th International Conference on Computational Linguistics, pages 1650–1661
Santa Fe, New Mexico, USA, August 20-26, 2018.

Despite the above-mentioned benefits, learning a single meta-embedding from multiple source embeddings remains a challenging task due to several reasons. First, the algorithms used for learning the source word embeddings often differ significantly and it is non-obvious how to reconcile their differences. Second, the resources used for training source embeddings such as text corpora or knowledge bases are different, resulting in source embeddings that cover different types of information about the words they embed. Third, the resources used to train a particular source embedding might not be publicly available for us to train all source embeddings in a consistent manner. For example, the Google news corpus containing 100 billion tokens on which the skip-gram embeddings are trained and released originally by Mikolov et al. (2013b) is not publicly available for us to train other source embedding learning methods on the same resource. Therefore, a meta-embedding learning method must be able to learn meta-embeddings from the given set of source embeddings without assuming the availability of the training resources.

Autoencoders (Kingma and Welling, 2014; Vincent et al., 2008) have gained popularity as a method for learning feature representations from unlabelled data that can then be used for supervised learning tasks. Autoencoders have been successfully applied in various NLP tasks such as domain adaptation (Chen et al., 2012; Ziser and Reichart, 2016), similarity measurement (Li et al., 2015; Amiri et al., 2016), machine translation (P et al., 2014; Li et al., 2013) and sentiment analysis (Socher et al., 2011). Autoencoder attempts to reconstruct an input from a possibly noisy version of the input via a non-linear transformation. The intermediate representation used by the autoencoder captures the essential information about the input such that it can be accurately reconstructed. This setting is closely related to the meta-embedding learning where we must reconstruct the information contained in individual source embeddings using a single meta-embedding. However, unlike typical autoencoder learning where we have a single input, in meta-embedding learning we must reconstruct multiple source embeddings.

We propose three types of autoencoders for the purpose of learning meta-embeddings. The three types consider different levels of integrations among the source embeddings. To the best of our knowledge, autoencoders have not been used for meta-embedding learning in prior work. We compare the proposed autoencoded meta-embeddings (AEME) against previously proposed meta-embedding learning methods and competitive baselines using five benchmark tasks. Our experimental results show that AEME outperforms the current state-of-the-art meta-embeddings in multiple tasks.

2 Related Work

Yin and Schütze (2016) proposed a meta-embedding learning method (1TON) that projects a meta-embedding of a word into the source embeddings using separate projection matrices. The projection matrices are learnt by minimising the sum of squared Euclidean distance between the projected source embeddings and the corresponding original source embeddings for all the words in the vocabulary. They propose an extension (1TON+) to their meta-embedding learning method that first predicts the source word embeddings for out-of-vocabulary words in a particular source embedding, using the known word embeddings. Next, 1TON method is applied to learn the meta-embeddings for the union of the vocabularies covered by all of the source embeddings. Experimental results in semantic similarity prediction, word analogy detection, and cross-domain POS tagging tasks show the effectiveness of both 1TON and 1TON+.

Although not learning any meta-embedding, several prior works have shown that incorporating multiple word embeddings learnt using different methods improve performance in various NLP tasks. For example, Tsuboi (2014) showed that by using both word2vec and GloVe embeddings together in a POS tagging task, it is possible to improve the tagging accuracy, if we had used only one of those embeddings. Similarly, Turian et al. (2010) collectively used Brown clusters, CW and HLBL embeddings, to improve the performance of named entity recognition and chucking tasks.

Luo et al. (2014) proposed a multi-view word embedding learning method that uses a two-sided neural network. They adapt pre-trained CBOW (Mikolov et al., 2013b) embeddings from Wikipedia and click-through data from a search engine. Their problem setting is different from ours because their source embeddings are trained using the same word embedding learning method but on different resources

whereas, we consider source embeddings trained using different word embedding learning methods and resources. Although their method could be potentially extended to meta-embed different source embeddings, the unavailability of their implementation prevented us from exploring this possibility.

Goikoetxea et al. (2016) showed that concatenation of word embeddings learnt separately from a corpus and the WordNet to produce superior word embeddings. Moreover, performing Principal Component Analysis (PCA) on the concatenated embeddings slightly improved the performance on word similarity tasks.

Chandar et al. (2015) proposed a correlation neural network that reconstruct an input using two views such that their correlation in a hidden layer os maximised. The setting of this work, using multiple views for reconstructing, is similar to our multiple source embeddings. However, we do not optimise simply for correlation, but require reconstructing the sources from meta-embeddings. Moreover, Chandar et al. (2015) did not consider meta-embedding learning, which is the focus of this paper.

3 Autoencoded Meta-Embeddings

To simplify the disposition of the proposed method, we focus on the problem of learning a single meta-embedding from two given source embeddings. The autoencoding methods we propose in this paper can be easily generalised to more than two source embeddings. Let us denote the two source embeddings by $\mathcal{S}_1$ and $\mathcal{S}_2$. Moreover, the dimensionalities of two source embeddings $\mathcal{S}_1$ and $\mathcal{S}_2$ are given respectively d_1 and d_2. Note that we do not assume d_1 and d_2 to be equal. The two word embeddings of a word $w \in \mathcal{V}$ is given respectively by $\boldsymbol{s}_1(w) \in \mathbb{R}^{d_1}$ and $\boldsymbol{s}_2(w) \in \mathbb{R}^{d_2}$. Here, the vocabulary $\mathcal{V}$ is the intersection set of two vocabularies $\mathcal{V}_1$ and $\mathcal{V}_2$ of source embeddings $\mathcal{S}_1$ and $\mathcal{S}_2$, i.e. $\mathcal{V} = \mathcal{V}_1 \cap \mathcal{V}_2$. For out of vocabulary words, we can first train a regression model using source embeddings for the common vocabulary as done by Yin and Schütze (2016) and then use it to predict the source embeddings for the words that do not occur in the intersection of the vocabularies.

Next, let us consider two encoders E_1 and E_2, which encode the two source embeddings to a common meta-embedding space $\mathcal{M}$ with dimensionality d_m for each word $w \in \mathcal{V}$. Dimensionalities of the encoded source embeddings are denoted respectively by d'_1 and d'_2. We denote the meta-embedding of a word $w \in \mathcal{V}$ as $\boldsymbol{m}(w) \in \mathbb{R}^{d_m}$. Correspondingly, we have two decoders D_1 and D_2, which will decode each word $w \in \mathcal{V}$ in the meta-embedding space $\mathcal{M}$ back to the two original source embeddings $\mathcal{S}_1$ and $\mathcal{S}_2$. Both encoders and decoders can be single or multi-layer neural networks.

We consider the problem of learning E_1, E_2, D_1 and D_2 such that we can learn a meta-embedding $\boldsymbol{m}(w)$ for a word w considering the complementary information from its source embeddings $\boldsymbol{s}_1(w)$ and $\boldsymbol{s}_2(w)$. We propose three different autoencoding methods for this purpose. The architectures of the three autoencodes are visualised in Figure 1.

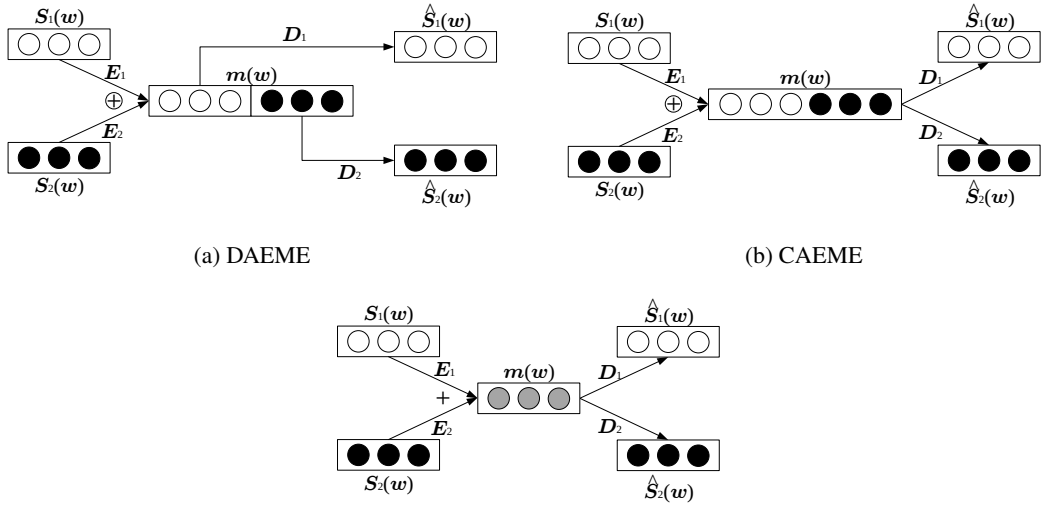
3.1 Decoupled Autoencoded Meta-Embedding (DAEME)

In DAEME, the meta-embedding $\boldsymbol{m}(w)$ is represented as the concatenation of two encoded source embeddings $E_1(\boldsymbol{s}_1(w))$ and $E_2(\boldsymbol{s}_2(w))$ for each word $w \in \mathcal{V}$, as given by (1).

$$\boldsymbol{m}(w) = E_1(\boldsymbol{s}_1(w)) \oplus E_2(\boldsymbol{s}_2(w)) \tag{1}$$

Concatenation has been found to be a simple yet effective baseline for creating meta-embeddings from multiple source embeddings. DAEME can be seen as an extension of concatenation that has non-linear neural networks applied on the raw model. Here, each encoder can be seen as independently performing a transformation to the respective source embedding so that it can learn to retain essential information rather than simply concatenate features.

The dimensionality of meta-embedding space $\mathcal{M}$ is therefore computed as the sum of dimensionalities of source embeddings $\mathcal{S}_1$ and $\mathcal{S}_2$ after encoding, i.e. $d_m = d'_1 + d'_2$. We then decode the meta-embedding to reconstruct the original source embeddings as $\hat{\boldsymbol{s}}_1(w)$ and $\hat{\boldsymbol{s}}_2(w)$ using two decoders. Specifically, we reconstruct the two components of the meta-embedding $\boldsymbol{m}(w)$ in (1) independently to the corresponding source embeddings. Because of this behaviour we call this approach *decoupled* autoencoded meta-embedding.



(a) DAEME

(b) CAEME

(c) AAEME

Figure 1: The architectures of proposed AEMEs. Rectangles represent word vectors, circles represent a single dimension of a word vector, and filled circles represent source of word embeddings. In (c), greyed circles in $\boldsymbol{m}(w)$ indicates mixing of vectors from the two source embeddings.

The reconstructed versions of the two source embeddings are given by (2) and (3).

$$\hat{\boldsymbol{s}}_1(w) = D_1(E_1(\boldsymbol{s}_1(w))) \tag{2}$$

$$\hat{\boldsymbol{s}}_2(w) = D_2(E_2(\boldsymbol{s}_2(w))) \tag{3}$$

To encourage encoded embeddings share common information from the two sources, while retaining complementary information, we propose the loss given by (4).

$$\mathcal{L}(E_1, E_2, D_1, D_2) = \sum_{w \in \mathcal{V}} \Big(\lambda_1 \left|\left| E_1(s_1(w)) - E_2(s_2(w)) \right|\right|^2 + \lambda_2 \left|\left| \hat{\boldsymbol{s}}_1(w) - \boldsymbol{s}_1(w) \right|\right|^2 + \lambda_3 \left|\left| \hat{\boldsymbol{s}}_2(w) - \boldsymbol{s}_2(w) \right|\right|^2 \Big) \tag{4}$$

The first term in the RHS of (4) emphasises the common information to the two source, whereas the second and third terms force the meta-embedding to retain sufficient information to reconstruct the two source embeddings. The coefficients λ_1, λ_2, and λ_3 in (4) can be used to control the effect of the three errors on the overall objective. Later in our experiments, we set these coefficients using validation data. We jointly learn E_1, E_2, D_1 and D_2 such that the total reconstruction error given by (4) is minimised. To prevent the weight matrices of the autoencoders degrading to the identity matrix $\mathbf{I}$ during training, we use a non-linear activation function (ReLU in our experiments) in encoders.

3.2 Concatenated Autoencoded Meta-Embedding (CAEME)

Similar to DAEME, the meta-embedding in CAEME is also constructed as the concatenation of two encoded source embeddings as described in (1). However, instead of treating the meta-embedding as two individual components, CAEME reconstructs the source embeddings from the *same* meta-embedding, thereby implicitly using both common and complementary information in the source embeddings. The reconstructed source embeddings for CAEME are given by (5) and (6).

$$\hat{\boldsymbol{s}}_1(w) = D_1(\boldsymbol{m}(w)) \tag{5}$$

$$\hat{\boldsymbol{s}}_2(w) = D_2(\boldsymbol{m}(w)) \tag{6}$$

In CAEME, the dimensionality of the meta-embedding space $\mathcal{M}$ is identical to that of DAEME, which is $d_m = d'_1 + d'_2$. The overall objective of CAEME is given by (7). Similar to DAEME, the coefficients λ_1 and λ_2 can be used to give different emphasis to the reconstruction of the two sources. For example, if we would like to emphasis reconstructing $\mathcal{S}_2$ more than $\mathcal{S}_1$ in the meta-embedding process, we can set $\lambda_2 > \lambda_1$. The coefficients are also tuned experimentally using validation data.

$$\mathcal{L}(E_1, E_2, D_1, D_2) = \sum_{w \in \mathcal{V}} \left(\lambda_1 \left|\left| \hat{\boldsymbol{s}}_1(w) - \boldsymbol{s}_1(w) \right|\right|^2 + \lambda_2 \left|\left| \hat{\boldsymbol{s}}_2(w) - \boldsymbol{s}_2(w) \right|\right|^2 \right) \tag{7}$$

Compared to DAEME, CAEME imposes a tighter integration between the two sources in their meta-embedding. We jointly learn E_1, E_2, D_1 and D_2 that minimises the total reconstruction error given by (7).

3.3 Averaged Autoencoded Meta-Embedding (AAEME)

AAEME can be seen as a special case of CAEME, where we compute the meta-embedding by averaging the two encoded sources in (1) instead by their concatenation. A recent work (Coates and Bollegala, 2018) shows that for approximately orthogonal source embedding spaces, averaging performs comparably to concatenation, without increasing the dimensionality. However, our AAEME can be seen as a more general version of averaging in the sense that we first transform each source embedding independently using two encoders before we compute their average. This operation has the benefit that we can transform the sources such that they could be averaged in the same vector space, and also guarantees orthogonality between the encoded vectors. AAEME computes the meta-embedding of a word w from its two source embeddings $\boldsymbol{s}_1(w)$ and $\boldsymbol{s}_2(w)$ as the ℓ_2-normalised [1] sum of two encoded versions of the source embeddings $E_1(\boldsymbol{s}_1(w))$ and $E_2(\boldsymbol{s}_2(w))$, given by (8).

$$\boldsymbol{m}(w) = \frac{E_1(\boldsymbol{s}_1(w)) + E_2(\boldsymbol{s}_2(w))}{||E_1(\boldsymbol{s}_1(w)) + E_2(\boldsymbol{s}_2(w))||_2} \tag{8}$$

Note that unlike CAEME, where the outputs of the two encoders might be of different dimensionalities, in AAEME they should be equal in order to facilitate summation. One could set the output dimensionalities of the two encoders to be different and pad zeros to the shorter output vector. However, we did not find this trick to perform well empirically in our preliminary experiments and do not consider output encodings of different dimensionalities in AAEME. Similar to CAEME, the two source embeddings are reconstructed from the same meta-embedding using two separate decoders D_1 and D_2 as given by (5) and (6). The overall reconstruction error for AAEME is the same as in (7).

4 Experiments

4.1 Source Word Embeddings

We use the following two source embeddings in our experiments:

CBOW: The Continuous Bag-Of-Words (CBOW) embeddings proposed by Mikolov et al. (2013a). The released version we used contains 929,019 word embeddings (phrase embeddings are discarded) with dimensionality of 300, and is trained on Google News corpus (about 100 billion words).

GloVe: The Global Vectors for word representation proposed by Pennington et al. (2014). The released version we used contains 1,917,494 word embeddings with dimensionality of 300 that is trained on Common Crawl dataset.

The intersection of two vocabularies contains 154,076 words for which we create meta-embeddings. We choose CBOW and GloVe as the source embeddings because according to Yin and Schütze (2016), CBOW and GloVe outperform other previously proposed word embeddings such as HLBL (Mnih and Hinton, 2009) and Huang (Huang et al., 2012) in several benchmark tasks such as semantic similarity measurement and word analogy prediction. However, we emphasise that all three proposed methods can be trained with more than two source embeddings.

[1] In our preliminary experiments we found ℓ_2-normalisation to improve performance.

4.2 Training Details

In our experiments, each autoencoder is implemented as a neural network with a single hidden layer. The weights of the encoders and decoders are randomly initialised by sampling from a Gaussian with zero mean and 0.01 standard deviation. We use Adam (Kingma and Ba, 2014) with mini-batches of size 128 for minimising the reconstruction error in each variant of AEME. Masking noises (MN) (Vincent et al., 2010) is applied during training, which will randomly set a fraction of the elements in an input vector to zero. Table 1 summarises hyperparameters, overall trainable parameters, and the time consumed by each method. The optimal hyperparameters were found using the Miller-Charles dataset as a validation dataset. Code implementing AEMEs is publicly available [2].

Method	bs	lr	epoch	activation	noise	λ_1	λ_2	λ_3	hidden neurons	parameters	time used (on CPU)
DAEME	128	0.001	500	ReLU	5% MN	1.0	1.0	5.0	600	361,200	3h 57min
CAEME	128	0.001	500	Sigmoid / ReLU	5% MN	1.0	1.0	/	600	541,200	6h 53min
AAEME	128	0.001	500	Sigmoid / ReLU	5% MN	1.0	1.0	/	600	361,200	2h 10min

Table 1: Training details. bs: batch size. lr: learning rate. Both Sigmoid and ReLU activations performed comparably for CAEME and AAEME in our experiments.

4.3 Evaluation Tasks

Following the common practice for evaluating word embeddings, we use the meta-embeddings created by the proposed method in a set of NLP tasks and measure the increase/decrease of the performance of those tasks. If a meta-embedding can improve the performance of an NLP task, then it can be considered as an accurate semantic representation for the words. All meta-embeddings compared in our experiments cover the same subset of words that appear in the benchmark dataset. Therefore, there is no unfair advantage to a particular meta-embedding method due to its coverage of the vocabulary. We use the following five evaluation tasks:

Semantic Similarity: The semantic similarity between two words is measured as the cosine similarity between the corresponding word embeddings. The computed semantic similarity scores are compared against human-rated similarity scores using the Spearman correlation coefficient. A high degree of correlation with the human ratings is considered as an indication of the accuracy of the word embeddings. We use the following benchmark datasets for this evaluation: Word Similarity 353 dataset (**WS**, 2023 word pairs) (Finkelstein et al., 2002), Rubenstein-Goodenough dataset (**RG**, 65 word pairs) (Rubenstein and Goodenough, 1965), Miller-Charles dataset (**MC**, 30 word pairs) (Miller and Charles, 1998), and the **MEN** dataset (3000 word pairs) (Bruni et al., 2012).

Word Analogy: Word analogy task consists of questions like "a to b is c to what?". Different methods have been proposed in the literature for finding fourth word d that completes an analogy. In our experiments we use the CosAdd method, which finds d such that the cosine similarity between the vector $(\boldsymbol{b} - \boldsymbol{a} + \boldsymbol{c})$ and $\boldsymbol{d}$ is maximised. We use the following benchmark datasets for this task: Google dataset (**GL**) (Mikolov et al., 2013b), **MSR** dataset (Levy and Goldberg, 2014), SemEval 2012 Task 2 dataset (**SE**) (Jurgens et al., 2012), and the **SAT** (Slack, 1980) dataset. The evaluation measure is the ratio of the questions that were answered correctly in each dataset using a particular word embedding.

Relation Classification: The DiffVec dataset (**DV**) (Vylomova et al., 2016) contains 12,458 triples of the form (r, w_1, w_2), where the relation r exists between the two words w_1 and w_2. DiffVec dataset contains tuples covering 15 different relation types. The task is to predict the relation that exists between two words w_1 and w_2 from the 15 relation types in the dataset. The relation classification accuracy is computed as the ratio of the correctly predicted instances to the total instances in the

[2] https://github.com/CongBao/AutoencodedMetaEmbedding

DiffVec dataset. We represent the relation between two words as the vector offset, $\boldsymbol{w}_1 - \boldsymbol{w}_2$, between the corresponding word embeddings. Next, we measure cosine similarity between the target test word-pair and word-pairs in the training dataset and use a 1-nearest neighbour classifier to predict the relation for the test word-pair.

Short-text Classification: In the short-text classification task, a text is represented by the centroid of the embeddings of the words contained in that text. All datasets used in the short-text classification tasks contain binary target labels. We train a binary logistic regression classifier using the train part of each dataset and the classification accuracy is measured on the test part of the corresponding dataset. We use the following short-text classification datasets in our experiments: Stanford Sentiment Treebank (**TR**) (Socher et al., 2013), Movie Review dataset (**MR**) (Pang and Lee, 2005), Customer Review dataset (**CR**) (Hu and Liu, 2004), and Subjectivity dataset (**SUBJ**) (Pang and Lee, 2004).

Psycholinguistic Score Prediction: Word embeddings can be used as features for predicting psycholinguistic ratings of a word (Paetzold and Specia, 2016). We use the learnt meta-embeddings in a neural network (containing a single hidden layer of 100 neurones and ReLU as the activation function) to learn a regression model for predicting different psycholinguistic ratings. We use a randomly selected 80% of words from the MRC database [3] and the ANEW dataset (Beth Warriner et al., 2013) to train regression models for arousal (**AS**), valence (**VAL**), and dominance (**DOM**). Pearson correlation between the predicted ratings and human ratings is used as the evaluation measure.

4.4 Baselines

We compare the meta-embeddings produced by the proposed methods against the following baselines:

Concatenation (CONC): Concatenation of the source embeddings for a particular word has been found to be an effective method for creating meta-embeddings citeYin:ACL:2016. Despite being simple, meta-embeddings created via concatenation have shown good performance in benchmark tasks such as semantic similarity measurement and word analogy detection. We create meta-embeddings by first ℓ_2 normalising the CBOW and GloVe embeddings for a word, and then concatenating the normalised embeddings. The normalisation operation gives an equal importance to the source embeddings when we measure cosine similarity using the concatenated meta-embeddings.

Singular Value Decomposition (SVD): A disadvantage of concatenation as a method for creating meta-embeddings is that it increases the dimensionality of the meta-embedding space. For example, if we concatenated two source embeddings of dimensionalities d_1 and d_2, the resultant meta-embedding will have a dimensionality of $(d_1 + d_2)$. SVD has been used in various tasks in NLP such as latent semantic analysis (Deerwester et al., 1990) and latent relational analysis (Turney, 2005) as a technique to reduce the dimensionality of a feature space. Yin and Schütze (2016) proposed the use of SVD to reduce the dimensionality of the meta-embeddings created from concatenation. Specifically, let N represents the number of words common to the vocabularies of CBOW and GloVe embeddings. We first create an $N \times (d_1 + d_2)$ matrix $\mathbf{C}$ representing the concatenation meta-embedding of all words in $\mathcal{V}$. Next, we perform SVD decomposition on $\mathbf{C} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^\top$, where $\mathbf{U}$ and $\mathbf{V}$ are unitary matrices and $\mathbf{\Sigma}$ is a diagonal matrix containing the singular values of $\mathbf{C}$. We then select largest k singular values from $\mathbf{\Sigma}$ to construct a diagonal matrix $\mathbf{\Sigma}_k$, and the corresponding left singular vectors from $\mathbf{U}$ to construct a matrix $\mathbf{U}_k$. Finally, we obtain our k-dimensional meta-embeddings given by the rows of $\mathbf{C}_k = \mathbf{U}_k\mathbf{\Sigma}_k$. SVD is guaranteed to produce the best (in the sense of least square error) rank k approximation of a matrix. In our experiments, we use CBOW and GloVe source embeddings of 300 dimensions ($d_1 = d_2 = 300$) and created $k = 300$ dimensional SVD meta-embeddings.

[3] http://websites.psychology.uwa.edu.au/school/MRCDatabase/uwa_mrc.htm

Averaging (AVG): Coates and Bollegala (2018) proposed averaging the source embeddings for a word as a method for creating meta-embeddings. Source embeddings are often trained independently and their vector spaces as well as dimensionalities are different, which is problematic when computing averages. Although it is possible to pad a source embeddings that have fewer dimensions with zero such that all source embeddings have the equal dimensionality, it is still not mathematically valid to add vectors in different spaces. Surprisingly however, Coates and Bollegala (2018) show that averaging performs well in a series of benchmark tasks. Moreover, they prove that if word embeddings can be shown to be approximately orthogonal, then averaging will approximate the same information as concatenation, without increasing the dimensionality. Averaging can be seen as a special case of AAEME. Similar to concatenation, we first perform ℓ_2-normalisation on both CBOW and GloVe embeddings prior to averaging them to create meta-embeddings. Since averaging of embedding does not increase the dimensionality, the final dimension of averaged meta-embedding in our experiments is $d_m = 300$, the same as the dimensionalities of the CBOW and GloVe source embeddings.

4.5 Evaluation Results

The evaluation results of different embeddings on different tasks or datasets are summarised in Table 2. In Table 2, rows 1 and 2 show the performance of the source embeddings. Performance of baseline methods are shown in rows 3-5, and rows 8-10 are the results for the proposed method. We also include 1TON and 1TON+ proposed by Yin and Schütze (2016) in rows 6 and 7 as a comparison, which is the current state-of-the-art. To make a fair comparison, we use the publicly available meta-embeddings released by Yin and Schütze (2016) in our evaluation and do not retrain their method.

Table 2: Results on the benchmark tasks. Best results are in bold, whereas statistical significance over 1TON is indicated by an asterisk.

From Table 2, we see that the ensemble methods (3-10) outperform the individual source embeddings (1-2) in most tasks. Among the proposed methods, DAEME performs best in short-text classification tasks, while CAEME is competitive in semantic similarity measurement tasks. On the other hand, AAEME performs overall well and obtains the best performance in word analogy, relation classification, and psycholinguistic score prediction tasks. We evaluate statistical significance against both 1TON and 1TON+. For the semantic similarity and psycholinguistic score prediction benchmarks we use Fisher transformation to compute $p < 0.05$ confidence intervals for Spearman correlation coefficients. In all other datasets, we use Clopper-Pearson binomial exact confidence intervals at $p < 0.05$.

Comparing DAEME, CAEME, and CONC, we see that using auto-encoder with nonlinear neural network can achieve better performance in most tasks as they combine complementary information from sources and also reduce probability that features from two source embedding counteract with each other. If we compare AAEME with AVG, we see that AAEME improves the performance of most tasks, especially in psycholinguistic score prediction. This result shows that nonlinear transformation helps to

ensure orthogonality between feature vectors, which is the reason to outperform AVG.

Concerning dimensionality, we see that performing SVD on CONC does not reduce the performance of most tasks, and even outperforms other methods in tasks such as GL, DV, and MR. Among the three proposed methods, both DAEME and CAEME have dimensionality of 600, and AAEME has dimensionality of 300. Although AAEME has smaller dimensionality, it performs similarly to DAEME and CAEME and outperforms them in 6 tasks. Considering the smaller dimensionality and the robust performance, among the three variants of AEME proposed in the paper, AAEME is the recommended meta-embedding for practical applications.

Prior work on word embedding learning shows that the dimensionality of the embedding can affect the performance of a downstream NLP application that uses the word embeddings as features (Bollegala et al., 2015; Bollegala et al., 2016). In order to directly compare the proposed meta-embedding learning methods against the current state-of-the-art meta-embedding learning methods under the same dimensionality, we reduce the dimensionality of the meta-embeddings created by the proposed methods to 200 dimensions using SVD, which is the dimensionality of the publicly released 1TON and 1TON+ meta-embeddings. Table 3 shows the results for this evaluation.

From Table 3, we see that the proposed AEMEs still perform well in tasks of word analogy, relation classification, and short-text classification. Comparing with the results in Table 2, we see that the reduction of dimensionality has not significantly affected the performance on those benchmark datasets. On the other hand, there is a slight drop in performance for the semantic similarity and psycholinguistic score prediction tasks when the dimensionality is reduced. Nevertheless, the proposed methods still outperforms 1TON and 1TON+ in majority of the tasks, which shows that the nonlinear transformations learnt by autoencoders to be superior to the linear transformations learnt by 1TON and 1TON+.

Table 3: Results on the benchmark tasks for 200 dimensional meta-embeddings. Best results are in bold, whereas statistical significance over 1TON is indicated by an asterisk.

5 Conclusion

We proposed three autoencoder-based approaches DAEME, CAEME, and AAEME for learning meta-embeddings from multiple pre-trained source embeddings. The experimental results on a series of benchmark datasets show that AEME outperforms previously proposed meta-embeddings on multiple tasks. We plan to extend the proposed method to create meta-embeddings from multi-lingual word embeddings.

Abstract

With the aid of recently proposed word embedding algorithms, the study of semantic similarity has progressed and advanced rapidly. However, many natural language processing tasks need sense level representation. To address this issue, some researches propose sense embedding learning algorithms. In this paper, we present a generalized model from the existing sense retrofitting model. The generalization takes three major components: semantic relations between the senses, the relation strength and the semantic strength. In the experiments, we show that the generalized model outperforms the previous approaches in three aspects: semantic relatedness, contextual word similarity and semantic difference.

1 Introduction

The distributed representation of word model (word embedding) has drawn great interest in recent years due to its ability to acquire syntactic and semantic information from a large unannotated corpus (Mikolov et al., 2013; Pennington et al., 2014). With the pre-trained word embedding, some researches propose post-processing models that incorporate with the existing semantic knowledge into the word embedding model (Faruqui et al., 2015; Yu and Dredze, 2014). However, word embedding models use only one vector to represent a word, and are problematic in some natural language processing applications that require sense level representation (e.g., word sense disambiguation, semantic relation identification, etc.). As a result, some researches try to resolve the polysemy and homonymy issue and introduce sense level embedding, either act as pre-process (Iacobacci et al., 2015) or post-process (Jauhar et al., 2015) fashion.

In this research, we focus on the post-processing sense retrofitting approach and propose *GenSense*, a generalized sense embedding learning framework that retrofits a pre-trained word embedding via incorporating with the semantic relations between the senses, the relation strength and the semantic strength. Although some parts of the idea are not new, it is the first time of putting all the parts into a generalized framework. Our proposed *GenSense* for generating low-dimensional sense embedding is inspired from *sense retro* (Jauhar et al., 2015), but has three major differences. First, we generalize the semantic relations from positive relations (e.g., synonyms, hyponyms, paraphrase, etc.) to positive and negative relations (e.g., antonyms). Second, each relation incorporates with both the semantic strength and the relation strength. Within a semantic relation, there should be a weighting for each semantic strength. For example, although *jewel* has the synonyms *gem* and *rock*, it is clear that the similarity between (*jewel*, *gem*) is higher than (*jewel*, *rock*), and thus (*jewel*, *gem*) should have higher weight. Last, *GenSense* gives different relations with different relation strengths. For example, if the objective is to train a sense embedding that can distinguish between the positive and negative sense, then the weight for the negative relation (e.g., antonyms) should be higher, and vice versa. The experimental results suggest the relation strengths play a role in balancing the relations and are application dependent. With an objective that considers these three parts, the sense vectors can be learned and updated via running a belief propagation process on the relation constrained network.

Santa Fe, New Mexico, USA, August 20-26, 2018.

In the experiments, we show that our proposed *GenSense* model outperforms the previous approaches in three types of datasets: semantic relatedness, contextual word similarity and semantic difference. While the generalized model of considering all the relations performs well in the semantic and relatedness tasks, we also find that the antonym relation is in favor of the semantic difference experiment. The remainder of this paper is organized as follows. Section 2 gives a survey on the related works. Section 3 defines the generalized sense retrofitting model. The experimental setup is in Section 4. Section 5 shows and discusses the experimental results. Section 7 concludes the remarks.

2 Related Works

The study of the representation of words has a long history. Early approaches include utilizing the term-document occurrence matrix from a large corpus and then perform dimension reduction techniques such as singular value decomposition (latent semantic analysis) (Bullinaria and Levy, 2007; Deerwester et al., 1990). Beyond that, recent word embedding approaches are more focus on neural-style (Dragoni and Petrucci, 2017; Mikolov et al., 2013; Pennington et al., 2014) and performs well on syntactic and semantic tasks. Apart from the unsupervised word embedding learning models, there are plenty of ontologies that contain lexical knowledge, such as WordNet (Fellbaum, 1998), Roget's 21st Century Thesaurus (Kipfer and Institute, 1993) or the paraphrase database (Pavlick et al., 2015). As a result, many researches combine the word embedding with ontological resources, either in a joint training (Bian et al., 2014; Liu et al., 2016; Yu and Dredze, 2014) or a post-processing (Faruqui et al., 2015) fashion. When the need for sense embedding is getting higher, some researches are inspired from the word level embedding learning model and propose sense level embedding (Iacobacci et al., 2015; Jauhar et al., 2015; Lee and Chen, 2017). Although some evidence shows that the sense embedding cannot improve every natural language processing task (Li and Jurafsky, 2015), the benefit of having a sense embedding for improving tasks that need sense level representation is still in great need (Azzini et al., 2012; Ettinger et al., 2016; Qiu et al., 2016).

3 Generalized Sense Retrofitting Model

Let $V = \{w_1, \dots, w_n\}$ be a vocabulary of a trained word embedding and $|V|$ be its size. The matrix $\hat{Q}$ will be the pre-trained collection of vector representations $\hat{q}_i \in \mathbb{R}^d$, where d is the dimensionality of a word vector. Each $w_i \in V$ is learned using a standard word embedding technique (e.g., GloVe (Pennington et al., 2014) or Word2Vec (Mikolov et al., 2013)). Let $\Omega = (T, E)$ be an ontology that contains the semantic relationship, where $T = \{t_1, \dots, t_m\}$ is a set of senses and $|T|$ is total number of senses. The edge $(i, j) \in E$ indicates a semantic relationship of interest (e.g., synonym) between t_i and t_j. In our scenario, the edge set E consists of several disjoint subsets of interest (i.e., $E = E_{s_1} \cup E_{s_2} \cup \dots \cup E_{s_k}$). For example, $(i, j) \in E_{s_1}$ if and only if t_j is the synonym of t_i. We use $\hat{q}_{t_j}$ to denote the word form vector of t_j (one should notice that $\hat{q}_{t_j}$ and $\hat{q}_{t_k}$ may map to the same vector representation even if $j \neq k$). Then the goal is to learn a new matrix $S = (s_1, \dots, s_m)$ such that each new sense vector is close to its word form vertex and its synonym neighbors. The basic form that considers only synonym relation for the objective of the sense retrofitting model is:

$$\sum_{i=1}^{m} \left[\alpha_1 \beta_{ii} \left\| s_i - \hat{q}_{t_i} \right\|^2 + \alpha_2 \sum_{(i,k) \in E_{s_1}} \beta_{ij} \| s_i - s_k \|^2 \right] \quad (1)$$

where α balances the importance of the word form vertex and the synonym, and βs control the strength of the semantic relations. From equation 1, the learned new sense vectors will close to its synonyms, meanwhile constraining its distance with its original word form vector. In addition, this equation can be further generalized to consider all the relations:

$$\sum_{i=1}^{m} \left[\alpha_1 \beta_{ii} \left\| s_i - \hat{q}_{t_i} \right\|^2 + \alpha_2 \sum_{(i,k) \in E_{s_1}} \beta_{ij} \| s_i - s_k \|^2 + \cdots \right] \quad (2)$$

Apart from the positive sense relation, we now introduce three types of special relations. The first one is the positive contextual neighbor relation s_2. $(i, j) \in E_{s_2}$ if and only if t_j has only one sense. In our model, we use the word form vector to represent the neighbors of the t_is in E_{s_2}. Those neighbors

are viewed as positive contextual neighbors as they learned from the context of a corpus (e.g., word2vec trained with Google News corpus) with positive meaning. The second is the negative sense relation s_3 (e.g., antonym). The negative senses are used in a subtraction fashion for pushing the sense away from the positive meaning. The last is the negative contextual neighbors s_4. Just like the positive contextual neighbors, the negative contextual neighbors were learned from the context of a corpus, but with negative meaning.

Figure 1 illustrates an example of the relation network. In Figure 1, *gay* may have two meanings: (1) bright and pleasant; promoting a feeling of cheer and (2) someone who is sexually attracted to persons of the same sex. If we focus on the first sense, then our model can attract s_{gay_1} to its word form vector $\hat{q}_{gay_1}$, its synonym s_{glad_1} its positive contextual neighbor $\hat{q}_{jolly}$. But in the same time, it will push s_{gay_1} from its antonym s_{sad_1} and its negative contextual neighbor $\hat{q}_{dull}$.

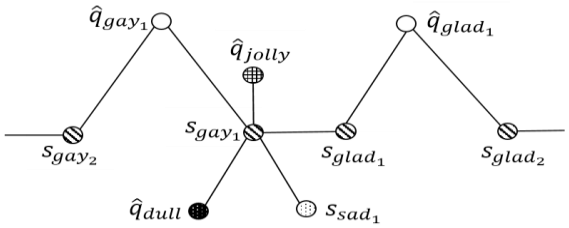

Figure 1. An illustration of the relation network. Different textures of the nodes represent different roles (e.g., synonym, antonym, etc.) in the GenSense model.

To formulize the above scenario and consider all the parts, the equation 2 would become:

$$\sum_{i=1}^{m}\left[\alpha_1\beta_{ii}\left\|s_i-\hat{q}_{t_i}\right\|^2+\alpha_2\sum_{(i,j)\in E_{s_1}}\beta_{ij}\left\|s_i-s_j\right\|^2+\alpha_3\sum_{(i,j)\in E_{s_2}}\beta_{ij}\left\|s_i-\hat{q}_j\right\|^2\right.$$
$$\left.-\alpha_4\sum_{(i,j)\in E_{s_3}}\beta_{ij}\left\|s_i-s_j\right\|^2-\alpha_5\sum_{(i,j)\in E_{s_4}}\beta_{ij}\left\|s_i-\hat{q}_j\right\|^2\right] \quad (3)$$

We therefore apply an iterative updating method to the solution of the above convex objective function (Bengio et al., 2006). Initially, the sense vectors are set to their corresponding word form vectors (i.e., $s_i \leftarrow \hat{q}_{t_i}\ \forall i$). Then in the following iterations, the updating formula for s_i would be:

$$s_i=\frac{-\alpha_5\sum_{j:(i,j)\in E_{s_4}}\beta_{ij}\hat{q}_j-\alpha_4\sum_{j:(i,j)\in E_{s_3}}\beta_{ij}s_j+\alpha_3\sum_{j:(i,j)\in E_{s_2}}\beta_{ij}\hat{q}_j+\alpha_2\sum_{j:(i,j)\in E_{s_1}}\beta_{ij}s_j+\alpha_1\beta_{ii}\hat{q}_{t_i}}{-\alpha_5\sum_{j:(i,j)\in E_{s_4}}\beta_{ij}-\alpha_4\sum_{j:(i,j)\in E_{s_3}}\beta_{ij}+\alpha_3\sum_{j:(i,j)\in E_{s_2}}\beta_{ij}+\alpha_2\sum_{j:(i,j)\in E_{s_1}}\beta_{ij}+\alpha_1\beta_{ii}} \quad (4)$$

A formal description of our proposed GenSense method is shown in Algorithm 1. In Algorithm 1, the β parameters are retrieved from the ontology. The ϵ is a threshold for deciding whether to update the sense vector or not, which is used as a stopping criteria when the difference between the new sense vector and the original sense vector is too small. Experimentally, 10 iterations are sufficient to minimize the objective function from a set of starting vectors to produce effective sense retrofitted vectors.

4 Experiments

We evaluate GenSense with three types of experiments: semantic relatedness, contextual word similarities, and semantic difference. In testing phase, if a test dataset has missing words, we use the average of all sense vectors to represent the missing word. Note that our reported results of vanilla sense embedding may be slightly different from the other researches due to the treatment of missing words and the similarity computation method. Some researches use zero vector to represent the missing words, whereas some remove those missing words from the dataset. However, within this research the reported performance can be compared due to the same missing word processing method and the same similarity computation method.

Algorithm 1 GenSense

Input: A pre-trained word embedding $\hat{Q}$, a relation ontology $\Omega = (T, E)$, hyper-parameters α and parameters β, number of iterations max_it, the convergence criteria for sense vectors ϵ.

Output: A trained sense embedding S

for $i = 1$ **to** m **do**
  $s_i^{(0)} \leftarrow \hat{q}_{t_i}$
end for
for $it = 1$ **to** $max\_it - 1$ **do**
  for $i = 1$ **to** m **do**
    Compute s_i^{tmp} using equation (4).
    if $\left\| s_i^{tmp} - s_i^{(it-1)} \right\| \geq \epsilon$ **then**
      $s_i^{(it)} \leftarrow s_i^{tmp}$
    else
      $s_i^{(it)} \leftarrow s_i^{(it-1)}$
    end if
  end for
end for
return S

4.1 Experimental Setup

We adopt the GloVe model in our experiment (Pennington et al., 2014). The pre-trained GloVe word embedding is trained on Wikipedia and Gigaword-5 (6B tokens, 400k vocab, uncased, 50d vectors). Roget's 21st Century Thesaurus (Kipfer and Institute, 1993) (Roget) is selected for building ontology in our experiments as it contains the strength information of the senses. As Roget does not provide the ontology directly, we manually built a synonym ontology and an antonym ontology from the resource. The vocabulary from GloVe pre-trained word embedding is used for fetching and building the ontology from Roget. In Roget, there are three levels of synonym relations, we set βs to 1.0, 0.6 and 0.3 for the nearest to the farthest synonyms. The antonym relation is built in the same way. For each sense, β_{ii} is set to the sum of all the relation specific weights. Unless specifically address, αs are set to 1 in the experiments. We set the convergence criteria for sense vectors to $\epsilon = 0.1$ with the number of iterations of 10. With the capability of generalization, we run three types of the model: GenSense-syn (only considers the synonyms and positive contextual neighbors), GenSense-ant (only considers the antonyms and negative contextual neighbors) and GenSense-all (considers everything).

4.2 Semantic Relatedness

We downloaded four semantic relatedness benchmark datasets from the web: MEN (Bruni et al., 2014), MTurk (Radinsky et al., 2011), Rare Words (RW) (Luong et al., 2013) and WordSim353 (WS353) (Finkelstein et al., 2001). In MEN dataset, there are two versions of the word pairs: lemma and natural form. We show the natural form in the experimental result, but the performances on two datasets are similar. In each dataset, there is a list of word pairs together with their corresponding human rated scores. A higher score value indicates higher semantic similarity. For example, the score of (*journey*, *voyage*) is 9.29 and the score of (*king*, *cabbage*) is 0.23 in WS353. For measuring the semantic similarity between a word pair (w, w') in the datasets, we adopt the sense evaluation metrics AvgSim and MaxSim (Reisinger and Mooney, 2010):

$$\text{AvgSim}(w, w') \stackrel{\text{def}}{=} \frac{1}{K_w K_{w'}} \sum_{j=1}^{K_w} \sum_{k=1}^{K_{w'}} \cos\left(v_{w_j}, v_{w'_k}\right) \tag{5}$$

$$\text{MaxSim}(w, w') \stackrel{\text{def}}{=} \max_{1 \le j \le K_w, 1 \le k \le K_{w'}} \cos\left(v_{w_j}, v_{w'_k}\right) \quad (6)$$

where K_w and $K_{w'}$ denote the number of senses of w and w', respectively. The AvgSim can be seen as a *soft* metric as it averages all the similarity scores. Whereas the MaxSim can be seen as a *hard* metric as it only selects the senses with maximum similarity score. For measuring the performance of the sense embedding, we compute the spearman correlation between the human rated scores and the AvgSim/MaxSim scores. Table 1 shows a summary of the benchmark datasets and their relationship with the ontologies. In Table 1, row 3 shows the number of words that are both listed in the datasets and the ontology. The word count in Roget is 63,942.

	MEN	**MTurk**	**RW**	**WS353**
Pair count	3,000	287	2,034	353
Word count	751	499	2,951	437
Roget	707	416	2,371	412

Table 1. A summary of the semantic relatedness benchmark datasets.

4.3 Contextual Word Similarity

Although the semantic relatedness datasets are used in many researches, one major disadvantage is that the words in those word pairs do not have contexts. Therefore, we also conduct experiments with the Stanford's Contextual Word Similarities (SCWS) dataset (Huang et al., 2012). SCWS consists of 2,003 word pairs together with human rated scores. A higher score value indicates higher semantic similarity. Different from the semantic relatedness datasets, the words in the SCWS have their contexts and part-of-speech tags. That is, the human subjects can know the usage of the word when they rate the similarity. For each word pair, we compute its AvgSimC/MaxSimC scores from the learned sense embedding (Reisinger and Mooney, 2010):

$$\text{AvgSimC}(w, w') \stackrel{\text{def}}{=} \frac{1}{K^2} \sum_{j=1}^{K} \sum_{k=1}^{\text{K}} d_{c,w,k} d_{c',w',j} d\left(\pi_k(w), \pi_j(w')\right) \quad (7)$$

$$\text{MaxSimC}(w, w') \stackrel{\text{def}}{=} d\left(\hat{\pi}(w), \hat{\pi}(w')\right) \quad (8)$$

where $d_{c,w,k} \stackrel{\text{def}}{=} d\left(v(c), \pi_k(w)\right)$ is the likelihood of context c belonging to cluster π_k, and $\hat{\pi}(w) \stackrel{\text{def}}{=} \pi_{\arg\max_{1 \le k \le K} d_{c,w,k}}(w)$, the maximum likelihood cluster for w in context c. We use a window size of 5 for the words in the word pairs (i.e., 5 words prior to w/w' and 5 words after w/w'). Stop words are removed from the context. For measuring the performance, we compute the spearman correlation between the human rated scores and the AvgSimC/MaxSimC scores.

4.4 Semantic Difference

This task is defined to answer if a word has a closer semantic feature to a concept than another word (Krebs and Paperno, 2016). In this dataset, there are 528 concepts, 24,963 word pairs, and 128,515 items. Each word pair comes with a feature. For example, in the test $(airplane, helicopter)$: $wings$, choosing the first word if and only if $\cos(airplane, wings) > cos(helicopter, wings)$, otherwise, choose the second word. As this dataset does not provide context for disambiguation, we use the similar strategies from the semantic relatedness task:

$$\text{AvgSimD}(w, w') \stackrel{\text{def}}{=} \frac{1}{K_w K_{w'}} \sum_{j=1}^{K_w} \sum_{k=1}^{K_{w'}} \cos\left(v_{w_j}, v_{w'_k}\right) \quad (9)$$

$$\text{MaxSimD}(w, w') \stackrel{\text{def}}{=} \max_{1 \le j \le K_w, 1 \le k \le K_{w'}} \cos\left(v_{w_j}, v_{w'_k}\right) \quad (10)$$

In AvgSimD, we choose the first word iff $\text{AvgSimD}(w_1, w') > \text{AvgSimD}(w_2, w')$. In MaxSimD, we choose the first word iff $\text{MaxSimD}(w_1, w') > \text{MaxSimD}(w_2, w')$. The performance is determined by computing the accuracy.

5 Results and Discussion

Table 2 shows the spearman correlation ($\rho \times 100$) of AvgSim and MaxSim between human scores and sense embedding's scores on each benchmark dataset. Row 2 shows the performance of vanilla GloVe word embedding. Note that the MaxSim and AvgSim scores will be the same when there is only one sense for each word (word embedding). Row 3 shows the performance of the retro model (Jauhar et al., 2015).

	MEN	**MTurk**	**RW**	**WS353**	Macro	Micro
GloVe	65.7	61.9	30.3	50.3	52.1	51.9
retro	62.4/67.7	57.4/60.1	15.1/26.9	43.9/51.1	44.7/51.5	44.0/51.6
GenSense-syn	67.6/67.9	64.1/64.0	**33.8/33.6**	50.5/52.8	54.0/54.6	54.3/54.5
GenSense-ant	65.1/65.0	62.1/63.1	31.0/30.9	48.4/47.1	51.6/51.5	51.7/51.6
GenSense-all	**68.8/68.6**	**65.1/64.8**	33.3/33.2	**53.2/54.0**	**55.1/55.2**	**54.9/54.8**

Table 2. $\rho \times 100$ of (MaxSim / AvgSim) on semantic relatedness benchmark datasets.

From Table 2, we find that our proposed model outperforms the comparison models *retro* and GloVe in all the datasets. When comparing our model with retro, the spearman correlation scores of MaxSim of each dataset grows at least 6.4. In RW, the spearman correlation score of GenSense exceed *retro* by 18.2. We also discover a significant growth of spearman correlation between GenSense-syn and GenSense-all. Surprisingly, the model that only adopts synonyms and positive contextual information can outperform *retro* and GloVe. After utilizing antonym knowledge from Roget, its performance can further be improved in all but RW dataset. This result supports an assumption that the antonyms in Roget are quite informative and useful. Moreover, GenSense can adapt information from synonyms and antonyms to boost its performance. Although our model can pull sense vectors away from its reverse sense with the help of antonym and negative contextual information. This shift cannot guarantee the new sense vectors will move to a better place with only negative relations. As a result, the GenSense-ant does not perform as well as GenSense-syn. Table 2 also shows the macro-averaged and micro-averaged results in the rightmost two columns. In both of the additional evaluation metrics, we find that the GenSense model outperforms *retro* with a large margin. These two metrics suggest the robustness of our proposed model when comparing to the *retro* model.

We also conduct an experiment to test how much benefit we can get from the relation strength. We run GenSense-syn over the Roget ontology with a grid of $(\alpha_1, \alpha_2, \alpha_3)$ parameters. Each parameter is tuned from 0.0 to 1.0 with a 0.1 step size. Table 3 shows the results with MaxSim metric and Table 4 shows the results with AvgSim metric. Note that the $\alpha_1/\alpha_2/\alpha_3$ parameter combinations of the worst or the best case may be more than one. In that case, we only report one $\alpha_1/\alpha_2/\alpha_3$ setting in Table 3 and Table 4 due to the space limitation. From Table 3, we find that the default setting can achieve relatively good results when comparing to the best case. Another point worth mentioning is that the worst performance happens under .1/1./.1 setting except the WS353 dataset. Similar results can be found in Table 4's AvgSim metric. The results demonstrate the importance of the original word vector and the synonyms sense vectors in the model.

	MEN	$\alpha_1/\alpha_2/\alpha_3$	**MTurk**	$\alpha_1/\alpha_2/\alpha_3$	**RW**	$\alpha_1/\alpha_2/\alpha_3$	**WS353**	$\alpha_1/\alpha_2/\alpha_3$
GenSense default	67.6	1./1./1.	64.1	1./1./1.	33.8	1./1./1.	50.5	1./1./1.
GenSense worst	52.4	.1/1./.1	50.3	.1/1./.1	25.1	.1/1./.1	34.8	.1/1./.8
GenSense best	68.1	.8/.5/.8	64.4	.4/.3 /.4	35.8	.1/.1/1.	52.0	1./.6/.3

Table 3. $\rho \times 100$ of MaxSim on semantic relatedness benchmark.

	MEN	$\alpha_1/\alpha_2/\alpha_3$	MTurk	$\alpha_1/\alpha_2/\alpha_3$	RW	$\alpha_1/\alpha_2/\alpha_3$	WS353	$\alpha_1/\alpha_2/\alpha_3$
GenSense default	67.9	1./1./1.	64.0	1./1./1.	33.6	1./1./1.	52.8	1./1./1.
GenSense worst	60.1	.1/1./.1	58.7	.1/1./.1	30.5	.1/1./.1	43.3	.1/1./1.
GenSense best	68.1	.5/.5/.8	64.2	.3/.5/.4	35.8	.1/.1/1.	53.1	.5/.5/.8

Table 4. ρ × 100 of AvgSim on semantic relatedness benchmark datasets.

Figure 2 shows the ρ × 100 of MaxSim on the semantic relatedness benchmark datasets as function of vector dimension. All GloVe pre-trained models are trained on the 6 billion tokens corpus of 50d, 100d, 200d and 300d. We use the GenSense-all model on the GloVe pre-trained models. Figure 2 shows the proposed GenSense-all outperforms GloVe in all the datasets of all the tested dimensions. In GloVe's original paper, they showed GloVe's performance (in terms of accuracy) is proportional to the dimension in the range within 50d and 300d. In this experiment, we show that both GloVe and GenSense-all's performance is proportional to the dimension in the range within 50d and 300d in terms of ρ × 100 of MaxSim. Similar results can be found in the AvgSim metric.

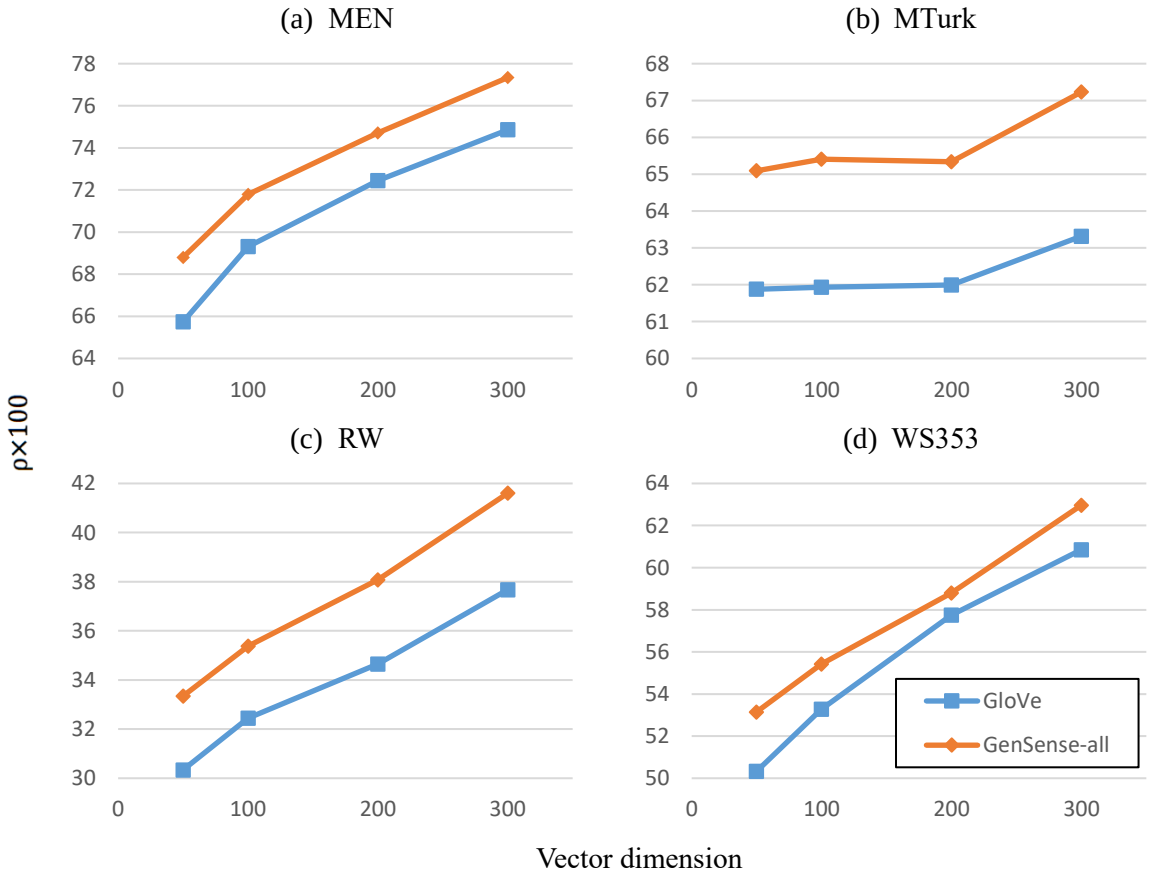

Figure 2. ρ × 100 of MaxSim on semantic relatedness benchmark datasets as function of vector dimension. GloVe model is compared.

Table 5 shows the selected MEN's word pairs and its corresponding GenSense-all, GloVe and retro scores for case study. For GenSense-all, GloVe and retro, we use the MaxSim scores and then sort and re-scale to MEN's score distribution. From Table 5, we find that Gensense-all can improve pre-trained word-embedding model (in terms of closeness to MEN's score, smaller is better) in the following situations: (1) both words have a few senses (*lizard*, *reptiles*), (2) both words have many senses (*stripes*, *train*) and (3) one word has many senses and one word has a few senses (*rail*, *railway*). Sometimes, the retro model increases the closeness to MEN's score. In other words, GenSense-all can handle all the possible situations well and outperform *retro*.

Word pair	#senses	GenSense-all	GloVe	retro
(*rail*, *railway*)	(15, 2)	1	3	36
(*stripes*, *train*)	(20, 17)	2	6	23
(*pregnant*, *women*)	(3, 4)	0	8	17
(*curve*, *dance*)	(10, 7)	2	6	25
(*blue*, *happy*)	(16, 4)	0	5	21
(*dripping*, *round*)	(5, 25)	0	4	24
(*nails*, *wolf*)	(10, 6)	2	6	26
(*action*, *truck*)	(12, 3)	0	9	19
(*lizard*, *reptiles*)	(2, 1)	7	13	28
(*amphibians*, *lizard*)	(3, 2)	9	16	34

Table 5. Selected MEN's word pairs and their scores difference with GenSense-all, GloVe and retro models. (the smaller the better).

Table 6 shows the spearman correlation ($\rho \times 100$) of Stanford's Contextual Word Similarity dataset. With the sense level information, both GenSense and retro can outperform the word embedding model GloVe. The GenSense model performs slightly better than *retro*. Again, we find that the retrofitting model cannot benefit with only negative relation information.

	SCWS
GloVe	52.9
retro	54.2/55.9
GenSense-syn	**54.8/56.0**
GenSense-ant	52.9/52.7
GenSense-all	54.2/55.3

Table 6. $\rho \times 100$ of (MaxSimC / AvgSimC) on SCWS dataset.

Table 7 shows the results of the semantic difference experiment. From Table 7, we find that GenSense outperforms *retro* and GloVe. The accuracy of *retro* declines in this experiment. This finding demonstrates the effectiveness and robustness of our proposed framework. Surprisingly, the antonym relation plays an important role when computing the semantic difference.

	Accuracy	Precision	Recall
GloVe	58.5	53.3	59.4
retro	57.5/57.3	52.2/51.9	58.0/52.0
GenSense-syn	57.8/57.6	52.5/52.3	61.2/59.8
GenSense-ant	58.0/**58.7**	52.7/**53.3**	59.7/**61.7**
GenSense-all	**58.7**/57.6	**53.3**/52.3	**62.4**/61.0

Table 7. $(\text{Accuracy}, \text{Precision}, \text{Recall}) \times 100$ of (MaxSimD / AvgSimD) on the semantic difference dataset.

6 Conclusion

In this paper we present *GenSense*, a generalized framework for learning sense embedding. The generalization takes in three parts: (1) we extend the synonym relation to positive contextual neighbor relation, antonym relation and negative contextual neighbor relation; (2) within each relation, we consider the semantic strength; and (3) we use relation strength between relations to balance different components. We then conduct experiments in three types of experiments: semantic relatedness, contextual word similarity, and semantic difference and show that the GenSense model outperforms the previous approaches. In the future, one of the possible applications is to apply the generalized sense

representation learnt by the proposed method in downstream natural language processing applications to conduct extrinsic evaluations. We release the source code and the pre-trained model as resource for the research community. [12] Other versions of the sense retrofitted embeddings can be found in the website.

Abstract

The variational encoder-decoder (VED) encodes source information as a set of random variables using a neural network, which in turn is decoded into target data using another neural network. In natural language processing, sequence-to-sequence (Seq2Seq) models typically serve as encoder-decoder networks. When combined with a traditional (deterministic) attention mechanism, the variational latent space may be bypassed by the attention model, and thus becomes ineffective. In this paper, we propose a variational attention mechanism for VED, where the attention vector is also modeled as Gaussian distributed random variables. Results on two experiments show that, without loss of quality, our proposed method alleviates the bypassing phenomenon as it increases the diversity of generated sentences.[1]

1 Introduction

The variational autoencoder (VAE), proposed by Kingma and Welling (2014), *encodes* data to latent (random) variables, and then *decodes* the latent variables to reconstruct the input data. Theoretically, it optimizes a variational lower bound of the log-likelihood of the data. Compared with traditional variational methods such as mean-field approximation (Wainwright et al., 2008), VAE leverages modern neural networks and hence is a more powerful density estimator. Compared with traditional autoencoders (Hinton and Salakhutdinov, 2006), which are *deterministic*, VAE populates hidden representations to a region (instead of a single point), making it possible to generate diversified data from the vector space (Bowman et al., 2016) or even control the generated samples (Hu et al., 2017).

In natural language processing (NLP), recurrent neural networks (RNNs) are typically used as both the encoder and decoder, known as a sequence-to-sequence (Seq2Seq) model. Although variational Seq2Seq models are much trickier to train in comparison to the image domain, Bowman et al. (2016) succeed in training a sequence-to-sequence VAE and generating sentences from a continuous latent space. Such an architecture can further be extended to a variational encoder-decoder (VED) to transform one sequence into another with the "variational" property (Serban et al., 2017; Zhou and Neubig, 2017).

When applying attention mechanisms (Bahdanau et al., 2015) to variational Seq2Seq models, however, we find the generated sentences are of less variety, implying that the variational latent space is ineffective. The attention mechanism summarizes source information as an *attention vector* by weighted sum, where the weights are a learned probabilistic distribution; then the attention vector is fed to the decoder. Evidence shows that attention significantly improves Seq2Seq performance in translation (Bahdanau et al., 2015), summarization (Rush et al., 2015), etc. In variational Seq2Seq, however, the attention mechanism unfortunately serves as a "bypassing" mechanism. In other words, the variational latent space does not need to learn much, as long as the attention mechanism itself is powerful enough to capture source information.

In this paper, we propose a variational attention mechanism to address this problem. We model the attention vector as random variables by imposing a probabilistic distribution. We follow traditional VAE

and model the prior of the attention vector by a Gaussian distribution, for which we further propose two plausible priors, whose mean is either a zero vector or an average of source hidden states.

We evaluate our approach on two experiments: question generation and dialog systems. Experiments show that the proposed variational attention yields a higher diversity than variational Seq2Seq with deterministic attention, while retaining high quality of generated sentences. In this way, we make VED work properly with the powerful attention mechanism.

In summary, the main contributions of this paper are two-fold: (1) We discover a "bypassing" phenomenon in VED, which could make the learning of variational space ineffective. (2) We propose a variational attention mechanism that models the attention vector as random variables to alleviate the above problem. To the best of our knowledge, we are the first to address the attention mechanism in variational encoder-decoder neural networks. Our model is a general framework, which can be applied for various text generation tasks.

2 Background and Motivation

In this section, we introduce the variational autoencoder and the attention mechanism. We also present a pilot experiment motivating our variational attention model.

2.1 Variational Autoencoder (VAE)

A VAE encodes data $\boldsymbol{Y}$ (e.g., a sentence) as hidden random variables $\boldsymbol{Z}$, based on which the decoder reconstructs $\boldsymbol{Y}$. Consider a generative model, parameterized by $\boldsymbol{\theta}$, as

$$p_{\boldsymbol{\theta}}(\boldsymbol{Z}, \boldsymbol{Y}) = p_{\boldsymbol{\theta}}(\boldsymbol{Z}) p_{\boldsymbol{\theta}}(\boldsymbol{Y}|\boldsymbol{Z}) \tag{1}$$

Given a dataset $\mathcal{D} = \{\boldsymbol{y}^{(n)}\}_{n=1}^{N}$, the likelihood of a data point is

$$\log p_{\boldsymbol{\theta}}(\boldsymbol{y}^{(n)}) \geq \mathbb{E}_{\boldsymbol{z}\sim q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{y}^{(n)})}\left[\log\left\{\frac{p_{\boldsymbol{\theta}}(\boldsymbol{y}^{(n)}, \boldsymbol{z})}{q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{y}^{(n)})}\right\}\right]$$

$$= \mathbb{E}_{\boldsymbol{z}\sim q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{y}^{(n)})}\Big[\log p_{\boldsymbol{\theta}}(\boldsymbol{y}^{(n)}|\boldsymbol{z})\Big] - \mathrm{KL}\Big(q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{y}^{(n)})\|p(\boldsymbol{z})\Big) \triangleq \mathcal{L}^{(n)}(\boldsymbol{\theta}, \boldsymbol{\phi}) \tag{2}$$

VAE models both $q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{y})$ and $p_{\boldsymbol{\theta}}(\boldsymbol{y}|\boldsymbol{z})$ with neural networks, parametrized by $\boldsymbol{\phi}$ and $\boldsymbol{\theta}$, respectively. Figure 1a shows the graphical model of this process. The training objective is to maximize the lower bound of the likelihood $\mathcal{L}(\boldsymbol{\theta}, \boldsymbol{\phi})$, which can be rewritten as minimizing

$$J^{(n)} = J_{\text{rec}}(\boldsymbol{\theta}, \boldsymbol{\phi}, \boldsymbol{y}^{(n)}) + \mathrm{KL}\Big(q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{y}^{(n)})\|p(\boldsymbol{z})\Big) \tag{3}$$

The first term, called *reconstruction loss*, is the (expected) negative log-likelihood of data, similar to traditional deterministic autoencoders. The expectation is obtained by Monte Carlo sampling. The second term is the KL-divergence between $\boldsymbol{z}$'s posterior and prior distributions. Typically the prior is set to standard normal $\mathcal{N}(\mathbf{0}, \mathbf{I})$.

2.2 Variational Encoder-Decoder (VED)

In some applications, we would like to transform source information to target information, e.g., machine translation, dialogue systems, and text summarization. In these tasks, "auto"-encoding is not sufficient, and an encoding-decoding framework is required. Different efforts have been made to extend VAE to variational encoder-decoder (VED) frameworks, which transform an input $\boldsymbol{X}$ to output $\boldsymbol{Y}$. One possible extension is to condition all probabilistic distributions further on $\boldsymbol{X}$ (Zhang et al., 2016; Cao and Clark, 2017; Serban et al., 2017). In this case, the posterior of $\boldsymbol{z}$ is given by $q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{X}, \boldsymbol{Y})$. This, however, introduces a discrepancy between training and prediction, since $\boldsymbol{Y}$ is not available during the prediction stage.

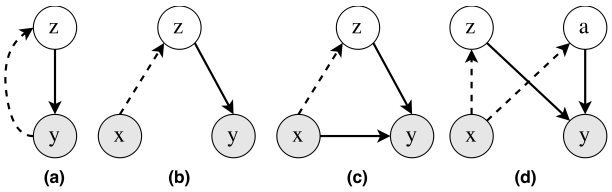

Figure 1: Graphical model representations. **(a)** Variational autoencoder (VAE). **(b)** Variational encoder-decoder (VED). **(c)** VED with deterministic attention (VED+DAttn). **(d)** VED with variational attention (VED+VAttn). **Dashed lines**: Encoding phase. **Solid lines**: Decoding phase.

the women are playing musical instruments	*the man is playing musical instruments*

Table 1: Sentences obtained by sampling from the VAE's latent space. (a) VAE without hidden state initialization. (b) VAE with hidden state initialization.

Another approach is to build a recognition model using only $\boldsymbol{X}$ (Zhou and Neubig, 2017). Making the assumption that $\boldsymbol{Y}$ is a function of $\boldsymbol{X}$, i.e., $\boldsymbol{Y} = \boldsymbol{Y}(\boldsymbol{X})$, we have $q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{y}) = q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{Y}(\boldsymbol{x})) \triangleq q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x})$. In this work, we follow Zhou and Neubig (2017) and adopt this extension. Figure 1b shows the graphical model of the VED used in our work.

2.3 Seq2Seq and Attention Mechanism

In NLP, sequence-to-sequence recurrent neural networks are typically used as the encoder and decoder, as they are suitable for modeling a sequence of words (i.e., sentence). Figure 2a shows a basic Seq2Seq model in the VAE/VED scenario (Bowman et al., 2016). The encoder has an input $\boldsymbol{x}$, and outputs $\boldsymbol{\mu}_z$ and $\boldsymbol{\sigma}_z$ as the parameters of $\boldsymbol{z}$'s posterior normal distribution. Then a decoder generates $\boldsymbol{y}$ based on a sample $\boldsymbol{z}$, drawn from its posterior distribution.

Attention mechanisms are proposed to dynamically align $\boldsymbol{y} = (y_1, \cdots, y_{|\boldsymbol{y}|})$ and $\boldsymbol{x} = (x_1, \cdots, x_{|\boldsymbol{x}|})$ during generation. At each time step j in the decoder, the attention mechanism computes a probabilistic distribution by

$$\alpha_{ji} = \frac{\exp\{\widetilde{\alpha}_{ji}\}}{\sum_{i'=1}^{|\boldsymbol{x}|} \exp\{\widetilde{\alpha}_{ji'}\}} \tag{4}$$

where $\widetilde{\alpha}_{ji}$ is a pre-normalized score, computed by $\widetilde{\alpha}_{ji} = \boldsymbol{h}_j^{(\text{tar})} W^T \boldsymbol{h}_i^{(\text{src})}$ in our model. Here, $\boldsymbol{h}_j^{(\text{tar})}$ and $\boldsymbol{h}_i^{(\text{src})}$ are the hidden representations of the jth step in target and ith in the source, and W is a learnable weight matrix.

Then the source information $\{\boldsymbol{h}_i^{(\text{src})}\}_{i=1}^{|\boldsymbol{x}|}$ is summed by weights α_{ji} to obtain the attention vector

$$\boldsymbol{a}_j = \sum_{i=1}^{|\boldsymbol{x}|} \alpha_{ji} \boldsymbol{h}_i^{(\text{src})} \tag{5}$$

which is fed to the decoder RNN at the jth step. Figure 2b shows the variational Seq2Seq model with such traditional attention.

2.4 "Bypassing" Phenomenon

In this part, we explain the "bypassing" phenomenon in VAE/VED, if the network is not designed properly; this motivates our variational attention described in Section 3.

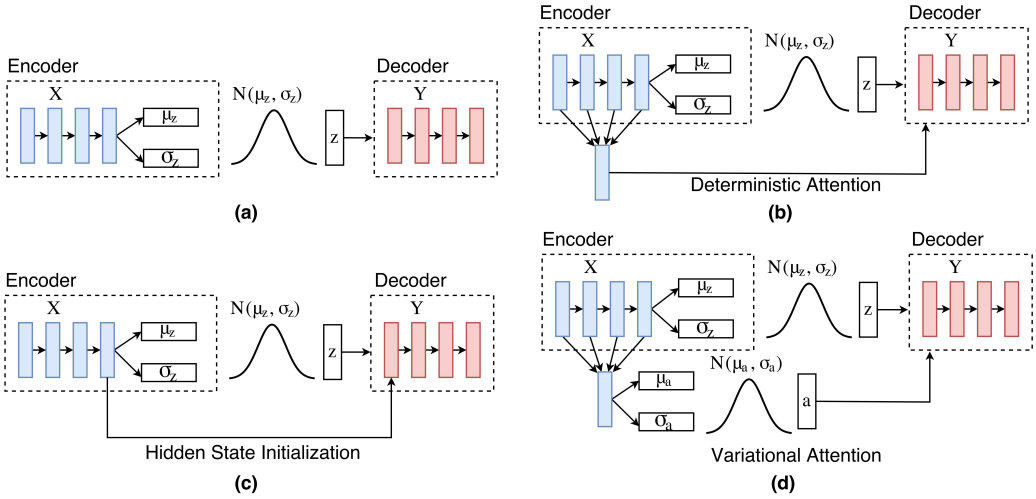

Figure 2: (a) Variational Seq2Seq model. (b) Variational Seq2Seq with deterministic attention. (c) Variational Seq2Seq with hidden state initialization. (d) Variational Seq2Seq with variational attention.

We observe that, if the decoder has a direct, deterministic access to the source, the latent variables $\boldsymbol{Z}$ might not capture much information so that the VAE or VED does not play a role in the process. We call this a *bypassing phenomenon*.

Theoretically, if $p_{\boldsymbol{\theta}}(\boldsymbol{Y}|\cdot)$ is aware of $\boldsymbol{X}$ by itself, i.e., $p_{\boldsymbol{\theta}}(\boldsymbol{Y}|\cdot)$ becomes $p_{\boldsymbol{\theta}}(\boldsymbol{Y}|\boldsymbol{X}, \boldsymbol{Z})$, it could be learned as $p_{\boldsymbol{\theta}}(\boldsymbol{Y}|\boldsymbol{X})$ without hurting the reconstruction loss J_{rec}, but the KL term in Eq. (3) can be minimized by fitting the posterior to its prior. This degrades a variational Seq2Seq model to a deterministic one.

The phenomenon can be best shown with a bypassing connection between the encoder and decoder for hidden state initialization. Some previous studies using VEDs set the decoder's initial state to be the encoder's final state (Cao and Clark, 2017), shown in Figure 2c. We conducted a pilot study with a Seq2Seq VAE with a subset (∼80k samples) of the massive dataset provided by Bowman et al. (2015), and show generated sentences and entropy in Table 1. We see that the variational Seq2Seq can only generate very similar sentences with such bypassing connections (Table 1b), as opposed to generating diversified samples from the latent space (Table 1a). We also computed the entropy for 10 randomly sampled outputs for a given input sentence. Quantitatively, the entropy decreases by 0.5 on average for 1k unseen input sentences. This shows a significant difference because entropy is a logarithmic metric. Our analysis sheds light on the design philosophy of neural architectures in VAE or VED.

Since attention largely improves model performance for deterministic Seq2Seq models, it is tempting to include attention in the variational Seq2Seq as well. However, our pilot experiment raises the doubt if a traditional attention mechanism, which is deterministic, may bypass the latent space in VED, as illustrated by a graphical model in Figure 1c. Also, evidence in Zheng et al. (2018) shows the attention mechanism is so powerful that removing other connections between the encoder and decoder has little effect on BLEU scores in machine translation. Therefore, a VED with deterministic attention might learn reconstruction mostly from attention, whereas the posterior of the latent space can fit to its prior in order to minimize the KL term.

To alleviate this problem, we propose a variational attention mechanism for variational Seq2Seq models, as is described in detail in the next section.

3 The Proposed Variational Attention

Let us consider the decoding process of an RNN. At each timestep j, it adjusts its hidden state $\boldsymbol{h}_j^{(\text{tar})}$ with an input of a word embedding $\boldsymbol{y}_{j-1}$ (typically the groundtruth during training and the prediction from the previous step during testing). This is given by $\boldsymbol{h}_j^{(\text{tar})} = \text{RNN}_{\boldsymbol{\theta}}(\boldsymbol{h}_{j-1}^{(\text{tar})}, \boldsymbol{y}_{j-1})$. In our experiments, we use long short-term memory units (Hochreiter and Schmidhuber, 1997) as RNN's transition. Enhanced

with attention, the RNN is computed by $\boldsymbol{h}_j^{(\text{tar})} = \text{RNN}_{\boldsymbol{\theta}}(\boldsymbol{h}_{j-1}^{(\text{tar})}, [\boldsymbol{y}_{j-1}; \boldsymbol{a}_j])$. The predicted word is given by a softmax layer $p(y_j) = \text{softmax}(W_{\text{out}}\boldsymbol{h}_j^{(\text{tar})})$, where W_{out} is a weight matrix. As discussed earlier, traditional attention computes $\boldsymbol{a}_j$ in a deterministic fashion by Eq. (5).

To build a variational attention, we treat both the traditional latent space $\boldsymbol{z}$ and the attention vector $\boldsymbol{a}_j$ as random variables. The recognition and reconstruction graphical models are shown in Figure 1d.

3.1 Lower Bound

Since the likelihood of the nth data point decomposes for different time steps, we consider the lower bound $\mathcal{L}_j^{(n)}(\boldsymbol{\theta}, \boldsymbol{\phi})$ at the jth step. The variational lower bound in Eq. (2) becomes

$$\mathcal{L}_j^{(n)}(\boldsymbol{\theta}, \boldsymbol{\phi}) = \mathbb{E}_{\boldsymbol{z},\boldsymbol{a}\sim q_{\boldsymbol{\phi}}(\boldsymbol{z},\boldsymbol{a}|\boldsymbol{x}^{(n)})}\Big[\log p_{\boldsymbol{\theta}}(\boldsymbol{y}^{(n)}|\boldsymbol{z},\boldsymbol{a})\Big] - \text{KL}\Big(q_{\boldsymbol{\phi}}(\boldsymbol{z},\boldsymbol{a}|\boldsymbol{x}^{(n)})\|p(\boldsymbol{z},\boldsymbol{a})\Big) \tag{6}$$

$$= \mathbb{E}_{\boldsymbol{z}\sim q_{\boldsymbol{\phi}}^{(z)}(\boldsymbol{z}|\boldsymbol{x}^{(n)}),\boldsymbol{a}\sim q_{\boldsymbol{\phi}}^{(a)}(\boldsymbol{a}|\boldsymbol{x}^{(n)})}\Big[\log p_{\boldsymbol{\theta}}(\boldsymbol{y}^{(n)}|\boldsymbol{z},\boldsymbol{a})\Big] \tag{7}$$
$$- \text{KL}\Big(q_{\boldsymbol{\phi}}^{(z)}(\boldsymbol{z}|\boldsymbol{x}^{(n)})\|p(\boldsymbol{z})\Big) - \text{KL}\Big(q_{\boldsymbol{\phi}}^{(a)}(\boldsymbol{a}|\boldsymbol{x}^{(n)})\|p(\boldsymbol{a})\Big)$$

Eq. (7) is due to the independence in both recognition and reconstruction phrases. The posterior factorizes as $q_\phi(\boldsymbol{z},\boldsymbol{a}|\cdot) = q_\phi^{(z)}(\boldsymbol{z}|\cdot)\, q_\phi^{(a)}(\boldsymbol{a}|\cdot)$ because $\boldsymbol{z}$ and $\boldsymbol{a}$ are conditionally independent given $\boldsymbol{x}$ (dashed lines in Figure 1d), whereas the prior factorizes because $\boldsymbol{z}$ and $\boldsymbol{a}$ are marginally independent (solid lines in Figure 1d). In this way, the sampling procedure can be done separately and the KL loss can also be computed independently.

3.2 Prior

We propose two plausible prior distributions for $\boldsymbol{a}_j$.

- The simplest prior, perhaps, is the standard normal, i.e., $p(\boldsymbol{a}_j) = \mathcal{N}(\mathbf{0}, \mathbf{I})$. This follows the prior of the latent space $\boldsymbol{z}$ as in a conventional autoencoder (Kingma and Welling, 2014; Bowman et al., 2016).
- We observe that the attention vector has to be inside the convex hull of hidden representations of the source sequence, i.e., $\boldsymbol{a}_j \in \text{conv}\{\boldsymbol{h}_i^{(\text{src})}\}$. We impose a normal prior whose mean is the average of $\boldsymbol{h}_i^{(\text{src})}$, i.e., $p(\boldsymbol{a}_j) = \mathcal{N}(\bar{\boldsymbol{h}}^{(\text{src})}, \mathbf{I})$, where $\bar{\boldsymbol{h}}^{(\text{src})} = \frac{1}{|\boldsymbol{x}|}\sum_{i=1}^{|\boldsymbol{x}|}\boldsymbol{h}_i^{(\text{src})}$, making the prior non-informative.

3.3 Posterior

We model the posterior of $q_{\boldsymbol{\phi}}^{(a)}(\boldsymbol{a}_j|\boldsymbol{x})$ as a normal distribution $\mathcal{N}(\boldsymbol{\mu}_{a_j}, \boldsymbol{\sigma}_{a_j})$, where the parameters $\boldsymbol{\mu}_{a_j}$ and $\boldsymbol{\sigma}_{a_j}$ are obtained by a recognition neural network. Similar to VAEs, we compute parameters as if in the deterministic attention in Eq. (5) (denoted by $\boldsymbol{a}_j^{\text{det}}$ in this part) and then transform them by another layer, shown in Figure 2d.

For the mean $\boldsymbol{\mu}_{a_j}$, we apply an identity transformation, i.e., $\boldsymbol{\mu}_{a_j} \equiv \boldsymbol{a}_j^{\text{det}}$. The identify transformation makes much sense as it preserves the spirit of "attention." To compute $\boldsymbol{\sigma}_{a_j}$, we first transform $\boldsymbol{a}_j^{\text{det}}$ by a neural layer with $\tanh$ activation. The resulting vector then undergoes a linear transformation followed by an $\exp$ activation function to ensure that the values are positive.

3.4 Training Objective

The overall training objective of Seq2Seq with both variational latent space $\boldsymbol{z}$ and variational attention $\boldsymbol{a}$ is to minimize

$$J^{(n)}(\boldsymbol{\theta}, \boldsymbol{\phi}) = J_{\text{rec}}(\boldsymbol{\theta}, \boldsymbol{\phi}, \boldsymbol{y}^{(n)}) + \lambda_{\text{KL}}\Big[\text{KL}\Big(q_\phi^{(z)}(\boldsymbol{z}|\boldsymbol{x}^{(n)})\|p(\boldsymbol{z})\Big) + \gamma_a \sum_{j=1}^{|\boldsymbol{y}|}\text{KL}\Big(q_\phi^{(a)}(\boldsymbol{a}_j|\boldsymbol{x}^{(n)})\|p(\boldsymbol{a}_j)\Big)\Big] \tag{8}$$

Here, we have a hyperparameter λ_{KL} to balance the reconstruction loss and KL losses. γ_a further balances the attention's KL loss and $\boldsymbol{z}$'s KL loss. Since VAE and VED are tricky with Seq2Seq models

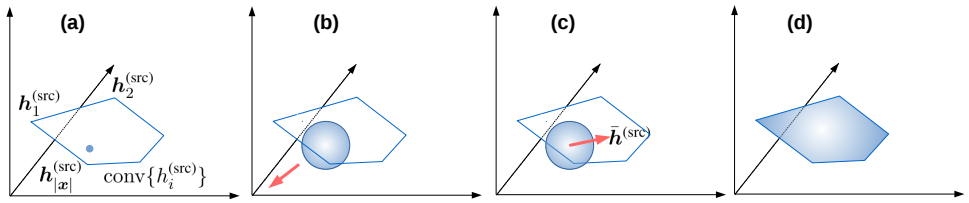

Figure 3: Geometric interpretation of attention mechanisms.

(e.g., requiring KL annealing), we tie the change of both KL terms and only anneal λ_{KL}. (Training details will be presented in Section 4.1.)

Notice that if $\boldsymbol{a}_j$ has a prior of $\mathcal{N}(\bar{\boldsymbol{h}}^{(\text{src})}, \mathbf{I})$, the derivative of the KL term also goes to $\bar{\boldsymbol{h}}^{(\text{src})}$. This can be computed straightforwardly or by auto-differentiation tools, e.g., TensorFlow.

3.5 Geometric Interpretation

We present a geometric interpretation of both deterministic and variational attention mechanisms in Figure 3.

Suppose the hidden representations $\boldsymbol{h}_i^{(\text{src})}$ is of k-dimensional space (represented as a 3-d space in Figure 3). In the deterministic mechanism, the attention model is a convex combination of $\{\boldsymbol{h}_i^{(\text{src})}\}_{i=1}^{|\boldsymbol{x}|}$, as the weights in Eq. (5) are a probabilistic distribution. The attention vector $\boldsymbol{a}_j$ is a point in the convex hull $\text{conv}\{\boldsymbol{h}_i^{(\text{src})}\}$, shown in Figure 3a.

For variational attention in Figures 3b and 3c, the mean of posterior is still in the convex hull, but the sample drawn from the posterior is populated over the entire space (although mostly around the mean, shown as a ball). The difference between the two variants is that the standard normal prior $\mathcal{N}(\mathbf{0}, \mathbf{I})$ pulls the posterior to the origin, whereas the prior $\mathcal{N}(\bar{\boldsymbol{h}}^{(\text{src})}, \mathbf{I})$ pulls the posterior to the mean of $\boldsymbol{h}_1^{(\text{src})}, \boldsymbol{h}_2^{(\text{src})}, \cdots, \boldsymbol{h}_{|\boldsymbol{x}|}^{(\text{src})}$ (indicated by red arrows).

Finally we would like to present a (potential) alternative of modeling variational attention. Instead of treating $\boldsymbol{a}_j$ as random variables, we might also treat $\boldsymbol{\alpha}_j$ as random variables. Since $\boldsymbol{\alpha}_j$ is the parameter of a categorical distribution, its conjugate prior is a Dirichlet distribution. In this case, the resulting attention vector populates the entire convex hull (Figure 3d). However, it relies on a reparametrization trick to propagate reconstruction error's gradient back to the recognition neural network (Kingma and Welling, 2014). In other words, the sampling of latent variables should be drawn from a fixed distribution (without parameters) and then transformed to a desired sample using the distribution's parameters. This is nontrivial for Dirichlet distributions and further research is needed to address this problem.

4 Experiments

We evaluated our model on two tasks: question generation (Section 4.1) and dialog systems (Section 4.2).

4.1 Experiment I: Question Generation

Task, Dataset, and Metrics. We first evaluated our approach on a question generation task. It uses the Stanford Question Answering Dataset (Rajpurkar et al., 2016, SQuAD), and aims to generate questions based on a sentence in a paragraph. We used the same train-validation-test split as in Du et al. (2017). According to Du et al. (2017), the attention mechanism is especially critical in this task in order to generate relevant questions. Also, generated questions do need some variety (e.g., in the creation of reading comprehension datasets), as opposed to machine translation, which is typically deterministic.

We followed Du et al. (2017) and used BLEU-1 to BLEU-4 scores (Papineni et al., 2002) to evaluate the quality (in the sense of accuracy) of generated sentences. Besides, we adopted entropy and *distinct* metrics to measure the diversity. Entropy is computed as $-\sum_w p(w) \log p(w)$, where $p(\cdot)$ is the unigram probability in generated sentences. *Distinct* metrics—used in previous works to measure diversity (Li et al., 2016)—computes the percentage of distinct unigrams or bigrams (denoted as *Dist-1* and *Dist-2*, respectively).

Model	Inference	BLEU-1	BLEU-2	BLEU-3	BLEU-4	Entropy	Dist-1	Dist-2
DED (w/o Attn) (Du et al., 2017)	MAP	31.34	13.79	7.36	4.26	-	-	-
DED (w/o Attn)	MAP	29.31	12.42	6.55	3.61	-	-	-
DED+DAttn	MAP	30.24	14.33	8.26	4.96	-	-	-
VED+DAttn	MAP	**31.02**	14.57	8.49	5.02	-	-	-
	Sampling	30.87	**14.71**	**8.61**	**5.08**	2.214	0.132	0.176
VED+DAttn (2-stage training)	MAP	28.88	13.02	7.33	4.16	-	-	-
	Sampling	29.25	13.21	7.45	4.25	2.241	0.140	0.188
VED+VAttn-0	MAP	29.70	14.17	8.21	4.92	-	-	-
	Sampling	30.22	14.22	8.28	4.87	**2.320**	**0.165**	**0.231**
VED+VAttn-$\bar{h}$	MAP	30.23	14.30	8.28	4.93	-	-	-
	Sampling	30.47	14.35	8.39	4.96	2.316	0.162	0.228

Table 2: BLEU, entropy, and distinct scores. We compare the deterministic encoder-decoder (DED) and variational encoder-decoders (VEDs). For VED, we have several variates: deterministic attention (DAttn) and the proposed variational attention (VAttn). Variational models are evaluated by both max *a posteriori* (MAP) inference and sampling.

Training Details. We used LSTM-RNNs with 100 hidden units for both the encoder and decoder; the dimension of the latent vector $\boldsymbol{z}$ was also 100d. We adopted 300d word embeddings (Mikolov et al., 2013), pretrained on the SQuAD dataset. For both the source and target sides, the vocabulary was limited to the most frequent 40k tokens. We used the Adam optimizer (Kingma and Ba, 2015) to train all models, with an initial learning rate of 0.005, a multiplicative decay of 0.95, and other default hyperparameters. The batch size was set to be 100.

As shown in Bowman et al. (2016), Seq2Seq VAE is hard to train because of the issues associated with the KL term vanishing to zero. Following Bowman et al. (2016), we adopted KL cost annealing and word dropout during training. The coefficient of the KL term λ_{KL} was gradually increased using a logistic annealing schedule, allowing the model to learn to reconstruct the input accurately during the early stages of training. A fixed word dropout rate of 25% was used.

All the hyperparameter tuning was based on validation performance on the motivating Seq2Seq VAE discussed in Section 2.4, and the same hyperparameters were used for all of the models described in Section 3.

Overall Performance. Table 2 represents the performance of various models. We first implemented a traditional vanilla Seq2Seq model, which we call a deterministic encoder-decoder (DED), and generally replicated the results on the question generation task as reported in Du et al. (2017), showing that our implementation is fair. Incorporating attention mechanism in this model (DED+DAttn) improves BLEU scores, as expected. In the variational encoder-decoder (VED) framework, we report results obtained by both max *a posterior* (MAP) inference as well as sampling. In the sampling setting, we draw 10 samples ($\boldsymbol{z}$ and/or $\boldsymbol{a}$) from the posterior given $\boldsymbol{x}$ for each data point, and report average BLEU scores.

The proposed variational attention model (VED+VAttn) largely outperforms deterministic attention (VED+DAttn) in terms of all diversity metrics. It should be noted that entropy is a logarithmic measure, and hence a difference of 0.1 in Table 2 is significant; VED+VAttn also generates more distinct unigrams and bigrams than VED+DAttn.

Regarding the prior of variational attention, we propose two variants: $\mathcal{N}(\mathbf{0}, \mathbf{I})$ and $\mathcal{N}(\bar{\boldsymbol{h}}^{(\mathrm{src})}, \mathbf{I})$, denoted as VED+VAttn-0 and VED+VAttn-$\bar{h}$, respectively. VED+VAttn-0 has slightly lower BLEU but higher diversity. The results are generally comparable, showing both priors are reasonable.

We also tried a heuristic of 2-stage training (VED+DAttn 2-stage), in which the VED is first trained without attention for 6 epochs, and then the attention mechanism is added to the model. This heuristic is proposed in hopes of better training the variational latent space at the beginning stages. However, experiments show that such simple heuristic does not help much, and is worse than the principled variational attention mechanism in terms of all BLEU and diversity metrics.

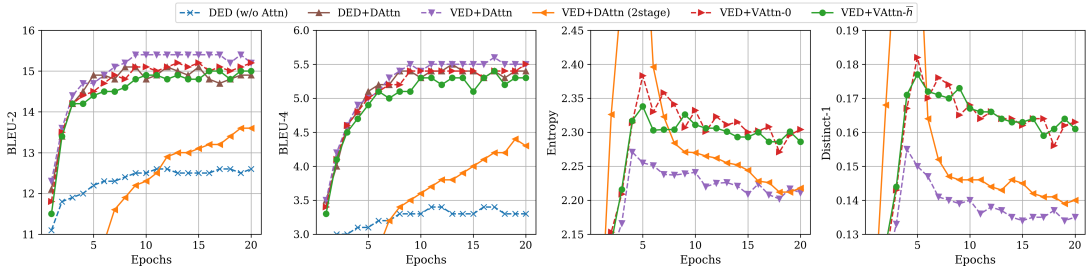

Figure 4: BLEU-2, BLEU-4, Entropy, and *Dist-1* calculated on the validation set as training progresses.

Table 3: Case study of question generation.

Human Evaluation. In order to assess the quality of the generated text in terms of language fluency, a human evaluation study was carried out. For each of the two models under comparison (VED+DAttn and VED+VAttn-$\bar{h}$), a randomly shuffled subset of 100 generated questions were selected. Six human evaluators were asked to rate the fluency of these 200 questions on a 5-point scale: 5-Flawless, 4-Good, 3-Adequate, 2-Poor, 1-Incomprehensible, following Stent et al. (2005). The average rating obtained for VED+DAttn was 3.99 and for VED+VAttn-$\bar{h}$ was 4.01, the difference between which is not statistically significant. The human annotations achieved 0.61 average Spearman correlation coefficient (measuring order correlation) between any two annotators. According to Swinscow (1976), this indicates moderate to strong correlation among different annotators. Hence, we conclude variational attention does not negatively affect the fluency of sentences.

Learning curves. Figure 4 shows the trends of sentence quality (BLEU-2 and BLEU-4) and diversity (entropy and *Dist-1*) of all models on the validation set, as training progresses.[2] We see that BLEU and diversity are conflicting objectives: a high BLEU score indicates resemblance to the groundtruth, resulting in low diversity. However, the variational attention mechanisms (red and green lines in Figure 4) remain high in both aspects, showing the effectiveness of our model.

Strength of Attention's KL Loss. We tuned the KL term's strength in variational attention, i.e., γ_a in Eq. (8), and plot the BLEU and diversity metrics in Figure 5. In this experiment, we used the VED+DAttn-$\bar{h}$ variant. As shown, a decrease in γ_a increases the quality of generated sentences at the cost of diversity. This is expected because a lower γ_a gives the model less incentive to optimize the attention's KL term, which then causes the model to behave more "deterministic." Based on this experi-

[2]Other metrics are omitted because the trend is the same.

Model	Inference	BLEU-2	Entropy	Dist-1	Dist-2
DED+DAttn	MAP	1.84	–	–	–
VED+DAttn	MAP	1.68	–	–	–
	Sampling	1.68	2.113	0.311	0.450
VED+VAttn-$\bar{h}$	MAP	1.78	–	–	–
	Sampling	1.79	**2.167**	**0.324**	**0.467**

Table 4: Performance on conversation systems.

ment, we chose a value of 0.1 for γ_a, as it yields a learning curve in the middle among those of different hyperparameters, being a good balance between quality and diversity.

It should be further mentioned that, with a milder γ_a (e.g., 0.01), VED+VAttn outperforms VED+DAttn in terms of both quality and diversity (on the validation set). This is consistent with the evidence that variational latent space may serve as a way of regularization and improves quality (Zhang et al., 2016). However, a small γ_a only slightly improves diversity, and hence we did not choose this hyperparameter in Table 2.

Case study. We show in Table 3 two examples of generated sentences by VED+DAttn and VED+VAttn-$\bar{h}$, each containing three random sentences drawn from the variational latent space(s) for a given input. In both examples, the variational attention generates more diversified sentences than deterministic attention. The quality of generated sentences is close in both models.

4.2 Experiment II: Dialog Systems

We present another experiment on generative conversation systems. The goal is to generate a reply based on a user-issued utterance. We used the Cornell Movie-Dialogs Corpus[3] (Danescu-Niculescu-Mizil and Lee, 2011) as our dataset, which contains more than 200k conversational exchanges. All the settings in this experiment were the same as in Subsection 4.1 except that we had 30k words as the vocabulary for both the encoder and decoder. We evaluated the quality of generated replies with BLEU-2, as it has been observed to be more or less correlated with human annotators among the BLEU metrics (Liu et al., 2016).

Table 4 shows the performance of our model (VED-VAttn-$\bar{h}$) compared with two main baselines. We see that VEDs are slightly worse than the deterministic encoder-decoder (DED) in this experiment. However, variational attention outperforms deterministic attention in terms of both quality and diversity, showing that our model is effective in different applications. However, we find the improvement is not so large as in the previous experiment. We conjecture that in conversational systems, there is a weaker alignment between the source and target information. Hence, the attention mechanism itself is less effective.

5 Related Work

The variational autoencoder (VAE) was proposed by Kingma and Welling (2014) for image generation. In NLP, it has been used to generate sentences (Bowman et al., 2016). Serban et al. (2017) propose a variational encoder-decoder (VED) model to generate better (more diverse and thus meaningful) replies in a dialog system. VED frameworks have also been applied to knowledge base reasoning (Zhang et al., 2018). Another thread of VAE/VED applications is to control some characteristics of generated data, such as the angle of a face image (Kumar et al., 2017), and the sentiment of a sentence (Hu et al., 2017).

In this paper, the focus is on the scenario where VED is combined with attention mechanism. We show that the variational attention space is effective, in terms of the diversity of sampled sentences (since VEDs are probabilistic models). Although previous studies have addressed diversity using diversified beam search (Vijayakumar et al., 2016) and determinantal point processes (Song et al., 2018), we would like to point out that our paper is "orthogonal" to those studies. The diversity in our approach arises

[3] https://www.cs.cornell.edu/~cristian/Cornell_Movie-Dialogs_Corpus.html

through probabilistic modeling, as opposed to a manually specified heuristic function of the diversity metric. It is to be noted that our approach can be naturally combined with the above methods.

6 Conclusion and Future Work

In this paper, we proposed a variational attention mechanism for variational encoder-decoder (VED) frameworks. We observe that, in VEDs, if the decoder has direct access to the encoder, the connection may bypass the variational space. Traditional attention mechanisms might serve as bypassing connection, making the output less diverse. Our variational attention mechanism imposes a probabilistic distribution on the attention vector. We also proposed different priors for the attention vector. The proposed model was evaluated on two tasks: question generation and dialog systems, showing that variational attention yields more diversified samples while retaining high quality.

In future work, it would be interesting to investigate VEDs that model the attention probability with Dirichlet distributions (see Figure 3d). Our framework also provides a principled methodology for designing variational encoding-decoding models without the bypassing phenomenon.

Acknowledgments

We thank Hao Zhou for helpful discussions. The Titan Xp GPU used for this research was donated by the NVIDIA Corporation to Olga Vechtomova.

Abstract

In this paper, a new deep reinforcement learning based augmented general sequence tagging system is proposed. The new system contains two parts: a deep neural network (DNN) based sequence tagging model and a deep reinforcement learning (DRL) based augmented tagger. The augmented tagger helps improve system performance by modeling the data with minority tags. The new system is evaluated on SLU and NLU sequence tagging tasks using ATIS and CoNLL-2003 benchmark datasets, to demonstrate the new system's outstanding performance on general tagging tasks. Evaluated by F1 scores, it shows that the new system outperforms the current state-of-the-art model on ATIS dataset by 1.9 % and that on CoNLL-2003 dataset by 1.4 %.

1 Introduction

Sequence tagging/labeling is one of the general techniques required for implementing different natural/spoken language understanding (NLU/SLU) tasks, such as: Named-entity recognition (NER), Part-of-speech (POS) Tagging in NLU, or Slot filling in SLU. Though the purpose of the tasks and their sequence labels are different, most of the state-of-the-art results for these tasks are generated using neural network based architectures. For example, Ma et al. demonstrates that their BLSTM-CNN-CRF model (Ma and Hovy, 2016) can achieve state-of-the-art performance for the NER task (without using extra features) on CoNLL-2003 dataset; Liu et al. gives an attention-based bi-directional LSTM model (Liu and Lane, 2016) for the slot-filling task, which also gives the best performance on the popular ATIS dataset (Hemphill et al., 1990) for SLU tasks (This result is obtained by intial paper submission, a better result is published later by Yu et al. (Wang et al., 2018)). The details of these related works will be given in next background section. The solution for general sequence tagging tasks (like NER/Slot filling) should mainly contain two properties: the first one is that the model can handle the language sequence in a word/token level manner, *i.e.*, it can read in the sequence word by word and outputs their corresponding labels; the second property is that the model should capture the contextual information/constraints which helps understand the word/token's tags, either as named-entity or simply slot tags. In(Lample et al., 2016; Ma and Hovy, 2016), the authors use a conditional random filed (CRF) to assist their basic bidirectional LSTM model to capture the contextual constraints in NER task. Similarly, Liu et al. uses an attention based mechanism to take advantages of the weighted collective information from the hidden states of all words in an utterance.

Due to the imbalance of data distribution under different labels, normally the evaluations for different models will be based on their precision and recall, or simply the F1 scores. It can be observed that, though the neural network based models are becoming more and more complicated, it becomes harder to make further improvement on these tagging tasks by using more advanced network structures. The main reasons are from two aspects:

1. Though the tagging models are designed to be more and more complicated, they also becomes more likely to be over-fitting by using more layers, hidden nodes or advance recurrent neural network structures

(like bidirectional LSTM). A model's performance may easily reach a bottom-neck by simply tuning hyper-parameters or changing network structures.
2. Considering the fact that the numbers of words/tokens under some wrongly labeled tags may be quite small, it may not give us more improvement if we still use the same group of training data by simply changing the model. Normally a model will focus on finding the pattern of the data under majority tags instead of minority. Sometimes, even a new model can improve the performance on minority tags' classes, at the cost of degrading the model's performance on the majority tags with more training data, which is a common issue resulting from the imbalanced data distribution under different tags (He and Garcia, 2009; Chawla et al., 2004).

Weighted sampling is one general solution to resolve the imbalanced data issue by giving more weights to minority tags and fewer to the majority ones (He and Garcia, 2009; Sun et al., 2009). The technique, however, gives the issue of distorting the original tagging distribution, which may adversely affect model's performance on majority tags. Similar approach, like adaptive synthetic sampling (He et al., 2008), also suffers from the same problem.

This gives us the dilemma on dealing with imbalanced tagged data (either for slot filling or NER task): On the one hand, it is a non-trivial task to re-organizing/sampling the data under different tags without any distortion of information; on the other hand, the improvement by changing models has an upper bound which is mainly decided by the data pattern itself instead of the model structure. Due to these two reasons, in this paper, a new concept of augmented tagging system based on deep reinforcement learning is proposed to furture improve the performances of sequence labeling tasks without sacrificing their original data distributions. This novel system will use a deep reinforcement learning based compensatory model to capture the wrong labeled tags and learn their correct labels, hence it can improve the whole model system performance without affecting the original correctly labeled tags. Detailed experiments will be further conducted on two sequence labeling tasks in the domain of SLU/NLU, as NER and slot filling, using public datasets.

The paper is organized as following: In section 2, a brief overview of two common NLP/SLU tagging tasks, *i.e.* NER and Slot filling, are given. Their current state-of-the-art models will also be explained briefly. Section 3 gives a background of deep reinforcement learning (DRL) first, then illustrates our DRL based augmented general tagging system (DAT) in detail. In section 4, two different tagging tasks on different datasets are given, One is a slot filling task performed on the ATIS benchmark dataset. The other is a named-entity recognition (NER) task, tested on the CoNLL-2003 benchmark dataset. Both experiments will compare our new algorithm with their current best-performed models with state-of-the-art results.

2 Background

In this section, a brief background overview on the models for two sequence labeling tasks will be given. Their state-of-the-art neural network structures will also be discussed for further comparison purpose.

2.1 Slot filling in SLU

Slot filling task is one of the fundamental tasks in spoken language understanding. It sequentially labels the words in an utterance using the pre-defined types of attributes or slot tags. The most straight-forward approach for this task is by using a single recurrent neural network (RNN) to generate sequential tags by reading an input sentence word by word. The current state-of-the-art result on ATIS is an attention based bidirectional LSTM model (Liu and Lane, 2016). A brief overview about this approach is given for a better illustration of our new algorithm. The model introduced in (Liu and Lane, 2016) covers both of the intent detection and slot filling tasks. Considering the focus of this paper, we will only discuss the slot filling part of the model. The structure of the attention based BLSTM model for slot filling task is as shown in Figure 1.

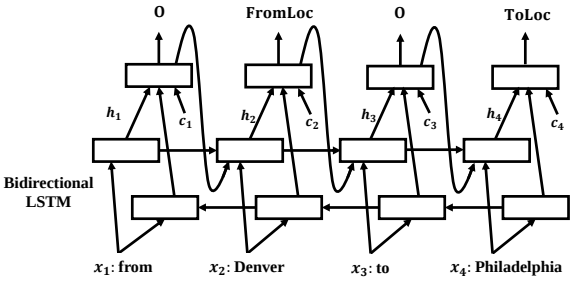

Figure 1: Attention based Bidirectional LSTM for Slot Filling

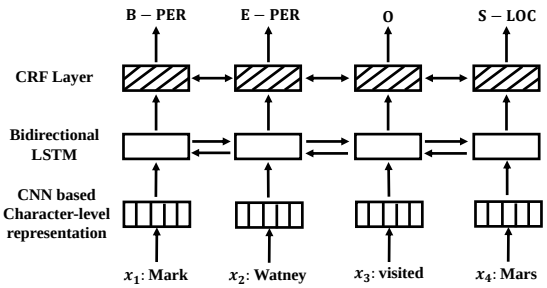

Figure 2: BLSTM-CNN-CRF Structure for Named-entity Recognition

As shown in the figure, a contextual vector $c_i(\cdot)$ is defined using the attention of hidden states h_j:

$$c_i = \sum_{j=1}^{L} \alpha_{i,j} h_j \tag{1}$$

where $\alpha_{i,j}$ is the attention coefficient defined as:

$$\begin{aligned} \alpha_{i,j} &= \frac{e^{e_{i,j}}}{\sum_{k=1}^{L} e^{e_{i,k}}} \\ e_{i,k} &= \phi(s_{i-1}, h_k) \end{aligned} \tag{2}$$

where $\phi(\cdot)$ is a feed-forward neural network and s_{i-1} is the decoder hidden state.
This model consists of tw0 main properties:
1. It uses the Bi-direction LSTM (BLSTM) structure to capture the long-term dependencies in both directions.
2. The attention vector c_i gives additional contextual information, for which cannot be captured by the hidden states in BLSTM.

The model gives the state-of-the-art slot filling performance on ATIS dataset. In this paper, we will also use this model as a baseline for comparison purpose. Also, this attention based model is chosen as the DNN part of our new system, *i.e.*f_{dnn}, to generate the filtered input data to the deep reinforcement learning based augmented tagger (DAT) sub-model of the system.

2.2 Named-entity recognition in NLU

Another very common NLU sequence labeling task is named-entity recognition (NER), which seeks to locate and classify entities into some pre-defined named labels. In this section, a brief overview about the neural network based NER model as in (Ma and Hovy, 2016) will be given. The model gives the state-of-the-art performance on CoNLL-2003 dataset (without lexicon features).

The structure contains a convolutional neural network for generating character-level representations, which is used as an input to a bidirectional LSTM network followed by a conditional random field layer. The conditional random field layer is designed to capture the strong dependency across the labels, which can be formulated as:

$$\begin{aligned} s(X, y) &= \sum_{i=0}^{n} A_{y_i, y_{i+1}} + \sum_{i=0}^{n} P_{i, y_i} \\ p(y|X) &= \frac{e^{s(X,y)}}{\sum_{\tilde{y} \in Y_x} e^{s(X,\tilde{y})}} \end{aligned} \tag{3}$$

where $s(X, y)$ is the score defined a predicted labeling sequence y given X. A_{y_i, y_j} represents transition score from the tag y_i to tag y_j, and P_{i,y_i} is the probability of the y_i output tag of the i^{th} input word

Table 1: Comparison between Minority Tags and Majority Tags on ATIS and CoNLL-2003

	ATIS			CoNLL-2003		
	Training Data		**Test Data**	**Training Data**		**Test Data**
	# of tag types	# of tokens	% of wrongly labeled data	# of tag types	# of tokens	% of wrongly labeled data
Minority Tags (<1% of total # of data)	119	6,323	92%	2	2,312	78%
Majority Tags (≥ 1% of total # of data)	8	38,707	8%	7	202,255	22%
Total	127	45,030	100%	9	204,567	100%

generated by the bidirectional LSTM. Y_X represents all possible tag sequences for an input sentence X, and $p(y|X)$ is the predicted output y's tagging probability giving an input words sequence $X = \{x_1, x_2, \cdots, x_n\}$.

The model shown above gives the state-of-the-art result on the English NER task with an F1 score of 91.2 on CoNLL-2003 dataset (without extra features).

Though decent experimental results are obtained by using deep learning models on the slot filling and NER tagging tasks, the potentials of these models are still limited by the imbalanced data distribution, since most of the tokens don't have any entity names (labeled as 'O'). The model can easily cover the majority tags but not the minority ones. Table 1 gives a summary of minority tags (each tag has less than 1% of entire data) and majority tags on ATIS and CoNLL-2003 datasets, and their corresponding occurrence ratio among the wrongly labeled data in test dataset.

In Table 1, it shows that about 92% of the wrongly labeled data are from minority tags in ATIS dataset and 78% in CoNLL03 dataset. This gives us an indication that, in order to further improve the model performance, the new model needs to figure out how to better label the minority tags and wrongly labeled tags without sacrificing the model performance on majority tags.

3 Deep Reinforcement Learning

In this section, a novel deep reinforcement learning (DRL) based augmented tagging system is proposed to address the issue as described earlier. The system contains two parts: one is the original deep neural network(NN) based tagger (f_{dnn}) as in section 2.1 for slot filling and section 2.2 for NER, the second part is a deep reinforcement learning (DRL) based augmented tagger (f_{dat}), which can be trained to learn the correct tags that are labeled wrongly by the deep learning based tagger, such that it can compensate the weakness of the original single tagger.

3.1 Reinforcement Learning and Deep Q Network (DQN)

Reinforcement learning (RL) is a bit different from the supervised learning and unsupervised learning algorithm. Formulated as a markov decision process (MDP) , an RL based model mainly contains several key elements: state (s_t), action (a_t), rewards (r_t) and policy (π). In a given a state of a stochastic environment, an agent is seeking its best action to perform in order to maximize its expected rewards to be obtained, by following some policy. The main target of a RL based model is to seek the best policy, hence the corresponding action, for an agent to perform. There are mainly three types of reinforcement learning algorithms: value-based, policy gradient and actor-critic. In our scenario, due to the necessity to define rewards at each state and small discrete action space, a value-based model design using Q-learning is proposed for our problem. Its optimal action-value function Q^π, which is also the maximum expected reward obtained by selecting the best policy π, is defined as:

$$Q^\pi(s_t, a_t) = \max_\pi \mathbb{E}[R_t \mid a_t, s_t, \pi] \tag{4}$$

One well-known issue of applying reinforcement learning in real problems is that, in order to compute this optimal action-value function Q^π, it is necessary to store all of the Q values for each state action pair (s_t, a_t) in a table, which is not very practical if the state or action space is large. This problem is described as "the curse of dimensionality" by Bellman (Powell, 2007). One approach to overcome it is

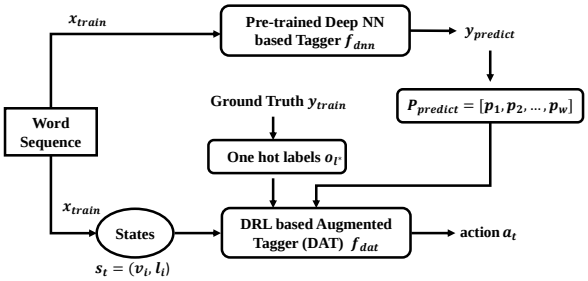

Figure 3: Training Model of DRL based Augmented Tagger

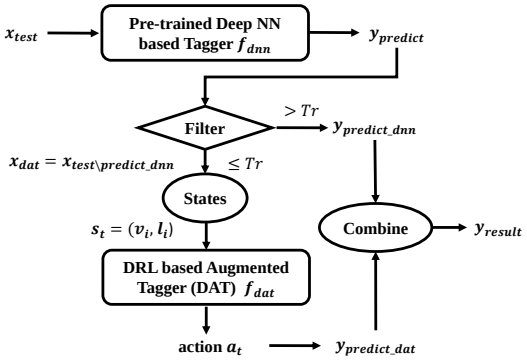

Figure 4: Inference Model of DRL based Augmented Tagger

by training a deep neural network based estimator $Q(s_t, a_t|\theta_t)$ to estimate $Q^\pi(s_t, a_t)$ at time t. However, these types of estimators tend to be unstable since the convergence cannot be fully guaranteed. Recently, the deep Q network (DQN) (Mnih et al., 2013; Mnih et al., 2015) demonstrates much better convergence performance on large state space, by taking advantage of a novel training technique called "experience replay". In this paper, we will use DQN as our selected deep reinforcement learning structure to satisfy the model requirement due to large state space.

In DQN structure, the optimal action-value function $Q^\pi(s_t, a_t)$ is estimated by a neural network based estimator $Q(s_t, a_t|\theta_t)$, *i.e.*

$$Q(s_t, a_t|\theta_t) \sim Q^\pi(s_t, a_t) \tag{5}$$

where θ_t is the neural network parameter, and the state s_t serves as the input of the network. In next section we will describe how to use the techniques in DQN to build our augmented tagger from a system perspective. Also, the states, actions and rewards of the DRL based tagger are also going to be carefully designed next.

3.2 DRL based Augmented Tagger (DAT) System

The design of DRL based augmented tagging (DAT) system is as given in Figure 3 and Figure 4. Due to the differences of using augmented tagger in training and inference, we discuss these two parts separately.

3.2.1 Training DAT System

In order to train the entire tagging system, one may need to first pre-train a deep NN based tagger f_{dnn}, this tagger will follow the design as discussed in section 2.1 for slot filling task or section 2.2 for the NER task. Once f_{dnn} is fully trained, the output labels of f_{dnn} using training input x_{train} are stored as $y_{predict}$ with a probability distribution $P_{y_{predict}} = [p_1, p_2, \cdots, p_w]$, where w is the total number of tags in the entire training dataset. Following is the DRL based design of our new DAT structure:

States (s_t): The DAT model's state s_t is shown in Figure 5. The state is defined by each word/token w_i in sentences, it mainly contains two parts: the first part contains the word level information represented by an n-gram (n is odd) averaged vector v_i, and the other part is a given label l_i of w_i. During the generation of training states, l_i uses all possible tags for the word/token w_i. v_i is defined as the average of the vector of word sequences from $w_{i-(n-1)/2}$ to $w_{i+(n-1)/2}$, where w_j is the center of this sequence:

$$v_i = \frac{1}{n} \sum_{j=i-(n-1)/2}^{j=i+(n-1)/2} w_j \tag{6}$$

Remarks: The reason to use an n-gram vector v_i to substitute w_i as a word level information in a state is due to that we want to better capture the contextual information compared to that using a single word vector. When $n = 1$, v_i is the same as word vector w_i. Also, the average of fewer words/tokens can be used if the index of word sequences is out of the boundary of an input sentence.

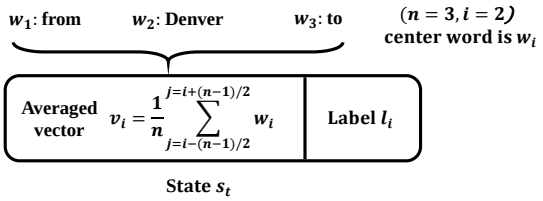

Figure 5: State of DAT

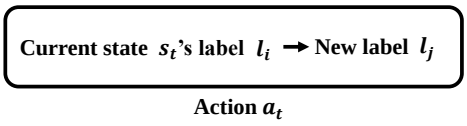

Figure 6: Action of DAT

Actions (a_t): The DAT model's action a_t at time step t is defined as in Figure 6. The action gives a transition signal such that the state will change from its current label l_i to its next label l_j by keep the same n-gram vector v_i. Simply speaking, the action set A contains all possible labels/tags for the word vector w_i or its correspond n-gram substitute v_i, *i.e.* $A = \{l_1, \cdots, l_k\}$. At each time step t, the action a_t with highest predicted action-reward value is chosen as:

$$a_t = \arg\max_a Q(s_t, a|a \in A, \theta_t) \tag{7}$$

Then the state will transit from its current label to the label directed by action a_t.

Rewards (r_t): The reward defined at a state s_t containing an n-gram vector v_i (with a center word/token w_i) will use the one-hot representation $o_{l_i^*}$ of w_i's true label l_i^*, the one hot vector o_{l_i} of the label l_i in current state s_t, and the predicted probability p_i for the word w_i using f_{dnn} as:

$$r_t = tanh(log(\frac{||o_{l_i^*} - p_i||_2}{||o_{l_i} - o_{l_i^*}||_2 + \epsilon})) \tag{8}$$

where $tanh(\cdot)$ is used to normalize the reward to be within -1 and 1, $||\cdot||_2$ is the $\mathcal{L}_2$ norm, and ϵ is a very small value added to avoid zero denominator.

The insight behind our reward design is using the ratio of the distance from f_{dnn} predicted label to $w_i's$ true label and that from current state's label to its true label. Based on our definition, a higher reward will be assigned to a state in which its label is more closer to the true label compared with the f_{dnn}'s predicted one. The reward function is one of the key factors for further improvement using our new augmented tagger.

Remarks: It is worth noticing that p_i should be generated by f_{dnn} using the same word sequence as preparing v_i. Similarly, l_i^* is the true label of w_i in the same sentence of preparing p_i and v_i.

Training: The training algorithm for DAT is as shown in Algorithm 1. The loss function is defined based on the difference of two estimated expected rewards at state s_t using an unsupervised approach as:

$$\begin{aligned} \mathcal{L}_{s_t} &= (\hat{Q}(s_t, a_t|\theta_t) - Q(s_t, a_t|\theta_t))^2 \\ &= (r_t + \gamma \max_{a_{t+1}} Q(s_{t+1}, a_{t+1}|\theta_t) - Q(s_t, a_t|\theta_t))^2 \end{aligned} \tag{9}$$

where $Q(s_t, a_t|\theta_t)$ is the predicted expected reward using (s_t, a_t) generated by the neural network-based estimator in DAT directly, and $\hat{Q}(s_t, a_t|\theta_t)$ is an estimation of $Q(s_t, a_t|\theta_t)$ using the current state reward r_t and its neighbors' estimations $Q(s_{t+1}, a_{t+1}|\theta_t)$ as in (9).

One training technique we borrowed from (Mnih et al., 2013) is the experience replay used in DQN. It improves the convergence issue in neural network-estimator based Q-learning by storing the state s_t visited before, action performed a_t, state's reward r_t and the next state s_{t+1} after performing the action a_t in an experience tuple (s_t,r_t, a_t, s_{t+1}). This tuple is then pushed into the experience replay memory queue M. The size of M is pre-defined based on experiment.

Whenever an action is performed then a new state is arrived, the past experience tuple will be pushed into the replay memory queue M if M is not full, otherwise M will pop out the first tuple and push in the latest one as First-in First-out (FIFO). At each training iteration, a random tuple is selected from M and the loss function value is calculated based on the s_t, r_t, a_t and s_{t+1} given by the tuple.

Algorithm 1 DAT Training using Experience Replay

Epochs: N
Batch Size: K
Initialize a replay memory M with size μ
for n=1 $\rightarrow$ N **do**
  Time step in state space: $t \leftarrow 0$
  Randomly select an initial state $s_t = (v_i, l_i)$, $l_i^* \leftarrow$ true label of v_i
  while l_i!=l_i^* **do**
    $Q(s_t, a_t|\theta_t) \leftarrow$ DAT(s_t)
    a_t=arg max$_a$ $Q(s_t, a|\theta_t)$
    Perform action a_t, generating next state s_{t+1}
    Push tuple (s_t, r_t, a_t, s_{t+1}) into replay memory M
    for b=1 $\rightarrow$ K **do**
      Randomly select a tuple m from M
      $s_t \leftarrow m(0)$, $r_t \leftarrow m(1)$, $s_{t+1} \leftarrow m(3)$
      $Q(s_t, a_t|\theta_t) \leftarrow$ DAT(s_t)
      $Q(s_{t+1}, a_{t+1}|\theta_t) \leftarrow$ DAT(s_{t+1})
      Obtain p_i from f_{dnn} and o_{l_i} in state s_t, $o_{l_i^*}$ from the ground truth in training data
      $r_t \leftarrow tanh(log(\frac{||o_{l_i^*} - p_i||_2}{||o_{l_i} - o_{l_i^*}||_2 + \epsilon}))$
      Update $\hat{Q}(s_t, a_t|\theta_t)$ in (9)
      Update the network by minimizing loss $\mathcal{L}_{s_t}$ in (9)
    end for
    $t \leftarrow t + 1$
  end while
end for

Remarks: 1. It is worth noticing that it is necessary to use reinforcement learning (RL) in our problem, since RL based model can learn the long-term dependency much better than the "conventional" deep learning approach. In our case, since we split a sentence into multiple word level vectors and select them randomly during training, not only we need to consider what the states current label is, but also how this state/word level vector is affected by its connected state in the network, such that it wont have any difficulty to find the correct label from its current wrong label.
2. In our model, we use a cascaded multiple model structure to boost the system performance. The concept of using information from multiple models (with the same or different structures) to achieve better performance has been widely used in deep learning ((Dean et al., 2012; Ngiam et al., 2011; Wang et al., 2018)), system identification ((Narendra et al., 2014; Narendra et al., 2015b; Murray-Smith and Johansen, 1997; Narendra et al., 2015c; Wang, 2017a; Wang, 2017b)) and also reinforcement learning field ((Narendra et al., 2015a; Wang and Jin, 2018; Narendra et al., 2016)) recently . Instead of using collective information, in this paper, we takes advantage of two models (DNN-based and DRL-based) to compensate each other, such that minor tags can be taken care of and learned.

3.2.2 Model Inference

As shown in Figure 4, the inference part of the DAT model is a bit different from training the DAT. Since during the training procedure, the entire training dataset (x_{train}, y_{train}) is used to train both DNN and DAT models. Comparatively, during inference, only partial of test data with "unsatisfied performance" will be collected and further evaluated by DAT. This is mainly because that we use DAT as an augmented tagger to compensate the minority cases when the original DNN based tagger f_{dnn} does not perform well. For the majority test data $x_{predict\_dnn}$, on which f_{dnn} can perform very well, we still use f_{dnn} to generate their tags $y_{predict\_dnn}$. In order to filter those data with "unsatisfied performance", a threshold value T_r is defined. All the tokens with their predicted tags' probabilities below T_r are filtered as the

minority cases and further used as the inference input of DAT, *i.e.* $x_{dat} = x_{test \backslash predict\_dnn}$. The outputs of DAT are the actions that will transfer the states from their current labels l_i to the target label l_i^*, which gives the output of minority cases, *i.e.* $y_{predict\_dat}$.

Remarks: The choice of T_r will slightly affect the performance of DAT as different percentage of data will be filtered. A general recommended T_r is to use a similar percentage of data under minority tags in training data as shown in section 2.2. For example, we use a T_r to filter around 14%(=6,323/45,030) percent of test data in ATIS for DAT since the training tokens under minority tags in ATIS are roughly around this ratio, as shown in Table 1.

4 Experiment

4.1 Data Sets

In our experiment, we will evaluate our deep reinforcement learning based augmented tagging system on two sequence labeling tasks: Slot filling task and NER task.

Slot Filling: For Slot filling task, we use the public ATIS dataset which follows the same format as in (Liu and Lane, 2015; Mesnil et al., 2015; Xu and Sarikaya, 2013; Liu and Lane, 2016). The training set contains 4,978 utterances/sequences, and the test dataset contains 893 utterances. There are totally 127 slot tags.

NER: For NER task, we use the public CoNLL-2003 dataset as in (Lample et al., 2016; Chiu and Nichols, 2016; Ma and Hovy, 2016; Xu et al., 2017; Huang et al., 2015). The training set contains 14,987 sentences, and the test dataset contains 3,684 sentences. The dataset contains four different types of named entities: *PERSON, LOCATION, ORGANIZATION, and MISC*. By using the BIO2 tagging scheme, the total number of different labels is 9. There are a total of 204,567 tokens in training set, and 46,666 tokens in test set.

4.2 Training Setup

Slot Filling: For slot filling task, the pre-trained DNN model f_{dnn} has the same set-up as in (Liu and Lane, 2016), by using an attention based bi-directional LSTM. The number of states in LSTM cell is 128. The randomly initialized word embedding size is also 128.The batch size is 16 and the dropout rate for non-recurrent connection is 0.5.

NER: For NER task, the pre-trained DNN model f_{dnn} follows the BLSTM-CNNS-CRF structure as in (Ma and Hovy, 2016), which gives the current state-of-the-art result on CoNLL-2003 dataset. The word embedding is chosen as the GloVe 100-dimensional embedding (Pennington et al., 2014). The CNN's window size is chosen as 3 and the number of filters is 30. The number of states in LSTM cell is 200. The batch size is 10 and the dropout rate is 0.5.

The DAT model f_{dat} used for Slot fill and NER tasks are almost the same except the batch size. The network structure chosen to estimate the action-value function Q is an LSTM structure with 100 states. The averaged word vector in a reinforcement learning state is chosen as a trigram, *i.e.* n=3. The discount factor γ in (9) is selected as 0.5, 0.7 and 0.9 for difference experiments. The minibatch size is $K = 16$ for slot filling task and $K = 10$ for NER in order to keep the same training batch size as f_{dnn} in different tasks, and the replay memory size is pre-defined as $\mu = 5,000$. The thresholds for both experiment are set as $T_r = 0.95$.

4.3 Performance on ATIS dataset

Our first experiment is performed on ATIS dataset and compared with other existing approaches, by evaluating their slot filling $F1$ scores. A detailed comparison is given in Table 2.

By using the same DNN based model for f_{dnn} as in (Liu and Lane, 2016), our new model surpassed the previous state-of-the-art result by 0.9%,1.2% and 1.9% for γ= 0.5, 0.7 and 0.9 separately. It is also worth noticing that, a larger discount factor γ gives a better performance as shown in Table. One empirical explanation is that when a larger discount factor is used, the model puts more weights on future states during training, hence it can search the correct label for the current word within a state in a faster manner.

Table 2: Performance of Different Models on ATIS Dataset

Model	F1 Score
Recursive NN (Guo et al., 2014)	93.96%
RNN with Label Sampling (Liu and Lane, 2015)	94.89%
Hybrid RNN (Mesnil et al., 2015)	95.06%
RNN-EM (Peng and Yao, 2015)	95.25%
CNN CRF (Xu and Sarikaya, 2013)	95.35%
Encoder-labeler Deep LSTM (Kurata et al., 2016)	95.66%
Attention Encoder-Decoder NN (Liu and Lane, 2016)	95.87%
Attention BiRNN (Liu and Lane, 2016)	95.98%
DRL based Augmented Tagging System ($\gamma = 0.5$)	**96.85%**
DRL based Augmented Tagging System ($\gamma = 0.7$)	**97.23%**
DRL based Augmented Tagging System ($\gamma = 0.9$)	**97.86%**

Table 3: Performance of Different Models on CoNLL-2003 Dataset

Model	F1 Score
NN+SLL+LM2(Collobert et al., 2011)	88.67%
NN+SLL+LM2+Gazetter* (Collobert et al., 2011)	89.59%
BI-LSTM-CRF* (Huang et al., 2015)	90.10%
ID-CNN-CRF (Strubell et al., 2017)	90.54%
FOFE (Xu et al., 2017)	90.71%
BLSTM-CNN+emb (Chiu and Nichols, 2016)	90.91%
BLSTM-CRF(Lample et al., 2016)	90.94%
BLSTM-CNN-CRFs (Ma and Hovy, 2016)	91.21%
BLSTM-CNN+emb+lex* (Chiu and Nichols, 2016)	91.62%
DRL based Augmented Tagging System ($\gamma = 0.5$)	**91.92%**
DRL based Augmented Tagging System ($\gamma = 0.7$)	**92.23%**
DRL based Augmented Tagging System ($\gamma = 0.9$)	**92.67%**

Table 4: Change on Tags' Distribution of Wrongly Labeled Data on ATIS and CoNLL-2003 Test Datasets

	ATIS Test Dataset		CoNLL-2003 Test Dataset	
	% of wrongly labeled data using f_{dnn}	% of wrongly labeled data using f_{dnn}+f_{dat}	% of wrongly labeled data using f_{dnn}	% of wrongly labeled data using f_{dnn}+f_{dat}
Minority Tags (<1% of total # of data)	92%	56%	78%	48%
Majority Tags ($\geq$ 1% of total # of data)	8%	44%	22%	52%
Total	100%	100%	100%	100%

4.4 Performance on CoNLL-2003 dataset

Our second experiment is conducted on the CoNLL-2003 dataset and compared with current existing neural network-based approaches for the NER tasks. The metric is also using their F1 scores, and the result is as shown in Table 3 (The results are collected before initial submission, some better results are released during final submission (Peters et al., 2018), despite our model's performance is still better).

The methods marked using $*$ are using extra features like lexicons and etc. It can be observed that our DAT system's result outperforms the state-of-the-art results in (Ma and Hovy, 2016) (without lexicon features) and (Chiu and Nichols, 2016) (lexicon features) by 1% and 1.4% using $\gamma = 0.9$ separately. Similar to the SLU task, a larger discount factor γ also boosts our system's performance.

4.5 Change on Result Distribution

Another observation from our experiment's result is that the tags' distribution of wrongly labeled data changed. Table 4 gives a summary about these changes on ATIS and CoNLL-2003 two test dataset.

It can be observed that the percentage of wrongly labeled data with minority tags decreases for both ATIS and CoNLL-2003 datasets by adding the DAT model f_{dat} to the DNN based model f_{dnn}. It indicates that the DAT model f_{dat} can help improve the performance of general sequence tagging model by correctly labeling data with minority tags, which is also the weakness of a single DNN based model f_{dnn}.

5 Conclusion

In this paper, a new DRL based augmented general tagging system is designed. The system use two sequence labeling models: one is a "conventional" DNN based tagger, and the other is a novel DRL based augmented tagger, *i.e.* DAT. By filtering DNN's output and picking out the "unsatisfied data", DAT can further improve sequence labeling tasks' performance by correctly relabeling the data below the threshold T_r, especially for those under minority tags. The experiment results on two sequence labeling tasks, *i.e.* Slot fillings and NER in SLU and NLU, both outperform the current state-of-the-art models. Besides the decent experimental performance obtained, more importantly, the new augmented approach can be generalized to more general sequence labeling models without changing their original model setups.

Abstract

Annotated corpora enable supervised machine learning and data analysis. To reduce the cost of manual annotation, tasks are often assigned to internet workers whose judgments are reconciled by crowdsourcing models. We approach the problem of crowdsourcing using a framework for learning from rich prior knowledge, and we identify a family of crowdsourcing models with the novel ability to combine annotations with differing structures: e.g., document labels and word labels. Annotator judgments are given in the form of the predicted expected value of measurement functions computed over annotations and the data, unifying annotation models. Our model, a specific instance of this framework, compares favorably with previous work. Furthermore, it enables active sample selection, jointly selecting annotator, data item, and annotation structure to reduce annotation effort.

Annotierte Korpora ermöglichen überwachtes maschinelles Lernen und Datenanalyse. Um die Kosten für manuelle Annotationen zu vermeiden, werden Aufgaben häufig Internetarbeitern zugewiesen, deren Urteile durch Crowdsourcing-Modelle abgeglichen werden. Wir nähern uns dem Problem des Crowdsourcings, indem wir einen Rahmen für das Lernen aus reichem Vorwissen vorschlagen, und wir bestimmen eine Familie von Crowdsourcing-Modellen mit der Fähigkeit, Annotationen mit unterschiedlichen Strukturen zu kombinieren: z.B., Dokumentbezeichnungen und Wortbezeichnungen. Bewertungen werden in Form des vorhergesagten erwarteten Werts von Messfunktionen (measurement functions) gegeben, die über Annotationen und die Daten berechnet werden. Darin werden die vorherige Annotationsmodelle vereinheitlicht. Unser Modell, eine spezifische Instanz dieses Rahmens, schneidet im Vergleich zu früheren Arbeiten positiv ab. Darüber hinaus ermöglicht es die aktive Stichprobenauswahl, indem Kommentator, Datenelement, und Annotationsstruktur gemeinsam ausgewählt werden, um den Annotationskosten zu reduzieren.

1 Introduction

Supervised machine learning is data hungry: new approaches require massive training sets. These training sets can come from inexpensive crowdsourcing platforms, but consistency is often sacrificed for speed and thrift. Sophisticated models (Surowiecki, 2005; Snow et al., 2008; Jurgens, 2013) can overcome the intrinsic annotation noise by reconciling redundant annotation and predicting true labels by modeling the error patterns associated with individual labels, documents, or annotators.

These models have typically assumed that we collect document-level *labels* and nothing else from annotators. But crowd workers could provide other valuable information. For example, if we wanted to predict the sentiment of documents about the weather (Figure 1), intuition says that words like "sunny",

- *. . . Sunshine: 60s and partly sunny? OK!*
- *. . . shopping, sunshine, margaritas, happiness!*
- *Going to the zoo . . . the weather is perfect.*
- *Another rainy day! Blah.*
- *Cold and rainy here in Boston, Wish I was in ATL*
- *Damn its hot out. Even when not working . . .*
- *Horrible wet morning . . . bring back the sunshine!*

Figure 1: Example tweets from the "Weather Sentiment" dataset available at `http://www.crowdflower.com/data-for-everyone`. Annotators can annotate both documents and *measurements* (e.g., whether a word appears in a document) to label sentiment.

"sunshine", and "perfect" will often appear in positive tweets, and words like "blah", "cold", and "hot" will tend to be more negative. This information is often complementary to labels attached to documents.

However, existing crowdsourcing models cannot simultaneously model multiple kinds of information. This paper introduces a framework and model to combine such diverse information from crowd workers, to measure and model individual annotator errors, and to form consensus final predictions.

We build on the measurements annotation framework (Section 2), which has previously only been applied to the scenario of a single, trusted annotator. Section 3 discusses the application of the framework to crowdsourcing scenarios with multiple untrusted annotators and show that our annotator-aware measurement framework subsumes existing crowdsourcing models. In Section 4 we develop inference for a crowdsourcing measurements model and show that it captures per-annotator variance on both simulated and crowdsourced data in Section 5. We then further extend the model for active query strategies, asking crowd workers for mixed annotations (Section 6).

2 Single-Annotator Measurements

Liang et al. (2009) introduce a supervised learning framework that uses more than the annotation of a document. This section reviews the intuition and notation of this framework that we extend to multiple annotators in the following sections.

The key intuition of the measurement framework is that annotators often have insights that generalize beyond a single document x and label y. For example, in a sentiment labeling task, an annotator could supply the clue that the word "lackluster" often appears in documents with negative sentiment.

These insights are encoded through functions called *measurement features*: $\sigma_k : \mathcal{X}, \mathcal{Y} \mapsto \mathcal{R}$. The measurement feature σ_k tests whether property k holds for the pair x, y, where x is a data item such as a sentence or document and y is its (possibly structured) label. The index k encodes everything needed by a measurement feature to fire only in an extremely specific situation. Measurement features are more specific and correspondingly more sparse than traditional NLP features.

Measurement features can encode traditional supervised labeling. For example, in sentiment classification some measurement feature $\sigma_{k'}$ might encode the fact that Document 343 has a positive label by being zero except when x exactly matches Document 343 and y is positive: $\sigma_{k'} = \mathbb{1}(x = x_{343}, y = Positive)$.

But introducing measurement functions also allows more flexibility. Returning to our "lackluster" example, we can include a function that is one if that word is in the example and the label is negative: $\sigma_{k''} = \mathbb{1}(\text{"lackluster"} \in x, y = Negative)$.

Thus measurement features map the data into an extremely sparse and high-dimensional (partially) observed space. Moreover, measurement features can span multiple documents, so each measurement feature is summed over the dataset $\sigma_k(x, y) = \sum_i \sigma_k(x_i, y_i)$. The learning from measurements framework defines K measurement features, one for every possible labeling. Table 1 provides examples of properties that measurements can encode.

The measurements framework treats observed measurement values τ as the result of measurement noise ϵ applied to the result of measurement features σ.

Measurement Type	Observed $\sigma_k(x, y)$	Partially Observed $\sum_i E_{q(y_i)}[\sigma_k(x, y)]$	Maximum $\max(\sigma_k)$
Document Label	$\mathbb{1}(x = x_m, y = c)$	$q(y_m = c)$	1
Word Label	$\mathbb{1}(f(x) = 1, y = c)$	$\sum_{i \in f(X)} q(y_i = c)$	$\sum_i \mathbb{1}(f(x_i) = 1)$
Label Proportion	$\mathbb{1}(y = c)$	$\sum_i q(y_i = c)$	N

Table 1: The measurement paradigm reformulates the direct labels of traditional supervised learning as indirect measurement features σ and their expected values. If we could directly observe class labels c then we would compute σ (*Observed* column). Since we only have indirect annotation evidence we must learn via the expected values in the *Partially Observed* column. $\mathbb{1}(\cdot)$ is an indicator function. Expected values are defined with respect to the approximate model q (defined in Section 4). All table values remain the same when dealing with annotator-indexed measurements σ_{jk}, although σ_{jk} additionally encodes annotator identity j as well as an implicit annotation value k.

Figure 2 illustrates the measurement framework's generative[1] story:

1. Draw parameter vector θ.
2. Draw measurement noise prior γ.
3. For $i \in N$ instances:
   (a) Draw label y_i from conditional exponential model family $p(y_i \mid x_i, \theta)$.
4. For $k \in K$ measurements:
   (a) Draw measurement noise ϵ_k from $p(\epsilon_k \mid \gamma)$.
   (b) Draw measurement τ_k from $p(\tau_k \mid \sum_i \sigma_k(x_i, y_i), \epsilon_k)$.

Although document labels y are part of the hypothetical generative story according to this model, at inference time y is always unobserved (Figure 2). Like many crowdsourcing models, while the true labels y cannot be observed directly, some byproduct τ of label y can provide evidence for inferring y.

While measurement noise ϵ_k is a part of the generative model, previous implementations of measurement models ignore this component, effectively assuming that all measurements have the same noise. Prior work ignored these considerations because traditional supervised learning training sets lack information about annotators to effectively model per-annotator or per-measurement noise.

In the next section, we correct this omission by extending the measurement model to specifically model not just the measurement noise model but to also estimate the *source* of these errors.

3 Connecting Measurements and Crowdsourcing

This section applies the measurements framework (Section 2) to crowdsourcing scenarios with multiple untrusted annotators and shows the connection to existing crowdsourcing frameworks. The adapted framework (Figure 2) requires two changes to the original measurements framework. First, each measurement k is replicated for each annotator j. This re-indexing of k accommodates annotator-specific parameters that can encode the expertise or focus of particular annotators in a crowdsourcing framework. The generative process is unchanged except for the final step:

4. For $j \in J$ annotators:
   (a) For $k \in K$ measurements:
      i. Draw measurement noise ϵ_{jk} from $p(\epsilon_{jk} \mid \gamma)$.
      ii. Draw measurement τ_{jk} from $p(\tau_{jk} \mid \sum_i \sigma_{jk}(x_i, y_i), \epsilon_{jk})$.

In addition to drawing per-annotator measurements, we also add a hierarchical prior γ over noise parameters (omitted here, as we consider multiple forms of the prior later): this induces parameter tying among measurement noise distributions. For example, this tied parameter can encode trust in annotator j by tying all ϵ_{jk} for annotator j and be left with a single noise parameter ϵ_j per annotator by imposing a prior where $\forall j \exists k, k'(\epsilon_{jk} \neq \epsilon_{jk'}) \implies p(\epsilon|\gamma) = 0$.

[1]The measurements framework omits the extra plate indexed by j. It will be addressed in the next section.

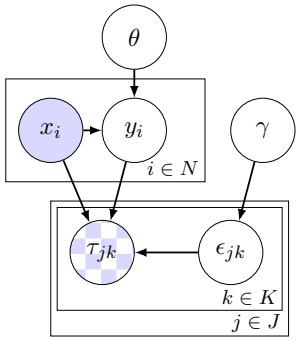

Figure 2: Plate diagram of the measurements framework (Liang et al., 2009) adapted for multiple untrusted annotators. Shaded nodes have observed values. Partially shaded nodes have some observed values. This model subsumes other crowdsourcing models with naïve measurements and extends them to varied annotation environments with richer measurement functions.

The measurements framework leaves the structure of y, the conditional exponential family used to model $p(y \mid x, \theta)$, and definitions of the distributions $p(\theta)$ and $p(\epsilon_{jk})$ unspecified. This paper situates the measurements framework into existing crowdsourcing models. To see the connection, let y_i take on discrete class values, let $p(y_i \mid x_i, \theta) = p(y_i \mid \theta)$ be a data-agnostic multinomial distribution, and let each observed annotation define a document label measurement σ_{jk} (Table 1) where k encodes a specific instance indexed by i, annotation value c', and label value c. Finally, let noise parameters ϵ_j for annotator j be tied to a confusion matrix with Dirichlet-distributed rows such that ϵ_{jk} selects the value at cell (c, c'), encoding how likely j is to produce annotation c' when shown a document whose true label is c. These settings recover the traditional item-response crowdsourcing model (Dawid and Skene, 1979). Using the same settings but defining $p(y \mid x, \theta) \propto exp[\theta^T f(x, y)]$, recovers a popular data-conditional crowdsourcing model (Raykar et al., 2010; Yan et al., 2014; Felt et al., 2015b). However, existing crowdsourcing models lack the representational richness of the measurements framework; we address this lacuna in the next section.

4 Per-annotator Normal Measurement Model for Classification

Having shown how the annotator measurements framework can capture existing crowdsourcing models, this section presents a novel crowdsourcing model that instantiates the richness of the measurements framework that we use in Sections 5–6. For brevity, we refer to this model as PAN (per-annotator normal) measurement model.[2] The generative story is:

1. Draw a stochastic vector θ over C classes from a symmetric Dirichlet Dir(δ)
2. For $i \in N$ documents, draw label y_i from categorical Mult(θ).
3. For $j \in J$ annotators:
   (a) draw measurement noise ϵ_j from inverse gamma IG(α, β).
   (b) For $k \in K$, draw measurement τ_{jk} from a normal Norm($\sum_i \sigma_{jk}(x_i, y_i), \epsilon_j$))

4.1 Learning by Variational Inference

The PAN model's conditional log joint distribution is

$$\log p(\theta, y, \tau \mid x) = \tag{1}$$
$$-\log \text{Beta}(\delta) + J\alpha \log \beta - J \log \Gamma(\alpha) - \sum_j \frac{K_j}{2} \log(2\pi) + \sum_c (\delta + n_c - 1) \log \theta_c$$
$$+ \sum_j (-(\alpha + \frac{K_j}{2}) - 1) \log \epsilon_j - \left(\frac{\beta + \frac{1}{2} \sum_k (\tau_{jk} - \sum_i \sigma_{jk}(x_i, y_i))^2}{\epsilon_j} \right)$$

[2]Data and code available at `https://github.com/BYU-NLP-Lab/Experiments`.

where $\beta\cdot$ is the multivariate beta function and K_j is the number of measurements values observed by annotator j. We use mean-field variational inference as an efficient approximation to full likelihood maximization by assuming a fully factorized approximate model:

$$q(\theta, y \mid \nu) = q(\theta \mid \nu^{(\delta)}) \prod_i q(y_i \mid \nu_i^{(y)}) \prod_j q(\epsilon_j \mid \nu_j^{(\alpha)}, \nu_j^{(\beta)})$$

and then minimizing Kullback-Leibler divergence $\mathrm{KL}(q \,\|\, p)$ via coordinate ascent by iteratively updating the variational parameters ν. That is, $q(\theta \mid \nu^{(\delta)}) \sim \mathrm{Dir}(\nu^{(\delta)})$ where

$$\nu_c^{(\delta)} = \delta + \sum_i \nu_{y_i,c}^{(\delta)} \ . \tag{2}$$

Similarly, $q(\epsilon_j | \nu_j^{(\alpha)}, \nu_j^{(\beta)}) \sim \mathrm{IG}(\nu^{(\alpha)}, \nu^{(\beta)})$ where

$$\nu_j^{(\alpha)} = \alpha + \frac{K_j}{2}, \quad \nu_j^{(\beta)} = \beta + \frac{1}{2} \sum_{k \in S(j)} \mathbb{E}_{q(y_i)} \left[\left(\sum_i \sigma_{jk}(x_i, y_i) \right)^2 \right] \tag{3}$$

where $S(j)$ is the set of measurements provided by annotator j. Although the term $\mathbb{E}_{q(y_i)} \left[(\sum_i \sigma_{jk}(x_i, y_i))^2 \right]$ appears intractable, we can simplify it by introducing terms to complete the square.

$$\mathbb{E}_{q(y_i)} \left[\left(\sum_i \sigma_{jk}(x_i, y_i) \right)^2 \right] = \tag{4}$$
$$\sum_i \left(\mathbb{E}_{q(y_i)} \left[\sigma_{jk}(x_i, y_i) \right] \right)^2 - \sum_i \mathbb{E}_{q(y_i)} \left[\sigma_{jk}(x_i, y_i) \right]^2 + \mathbb{E}_{q(y_i)} \left[\sigma_{jk}(x_i, y_i)^2 \right] .$$

Finally, $q(y_i \mid \nu_i^{(y)}) \sim \mathrm{Mult}(\nu_i^{(y)})$. We update $\nu_i^{(y)}$ by evaluating $\log \nu_i^{(y)} + const$ for each setting of y_i and then exponentiating and normalizing the resulting vector.

$$\log \nu_i^{(y)} = \psi(\nu_{y_i}^{(\delta)}) - \psi(\sum_{y_i} \nu_{y_i}^{(\delta)}) + const + \sum_j \frac{\nu_j^{(\alpha)}}{2\nu_j^{(\beta)}} \Bigg(\sum_{k \in S(i,j)} 2\tau_{jk}\sigma_{jk}(x_i, y_i) \tag{5}$$
$$- \sigma_{jk}(x_i, y_i)^2 - 2\sigma_{jk}(x_i, y_i) \sum_{i' \neq i} \mathbb{E}_{q(y_{i'})} \left[\sigma_{jk}(x_{i'}, y_{i'}) \right] \Bigg)$$

where $S(i, j)$ is the set of measurements provided by annotator j that relate to instance i. More formally, $S(i, j)$ is the set of measurements k where there is some setting of y_i that makes the measurement feature $\sigma_{jk}(x_i, y_i)$ evaluate to a non-zero value.

To get a taste of inference in PAN, consider a simple concrete scenario where four people are labeling the sentiment of a tweet: "Wishing good weather were here again". First Alice labels the tweet positive. Lacking any other information, PAN accepts that for now, calling $\nu_0^{(y)} = [0.75, 0.25]$ and assigning Alice moderate trust in the form of $\mathrm{IG}(\nu_{alice}^{(\alpha)} = 1.6, \nu_{alice}^{(\beta)} = 1.22)$ with a mean error rate of 2.03. Next Bob labels the tweet negative. Since it has no reason to trust Bob more than Alice, the model splits the class vote evenly $\nu_0^{(y)} = [0.5, 0.5]$ and downgrades its trust in both Alice and Bob because of the conflict, assigning them both error rate 2.25. Next Carol labels the word "good" as being positive. Since the word "good" is in our document this tips the balance in favor of positive: $\nu_0^{(y)} = [0.8, 0.2]$. Notice the positive balance is more than $2/3$ since Alice and Carol are now aligned with the model's belief about the true labels and their error rate is upgraded to 2.0, while dissenting Bob's error rate is downgraded to 2.5. Finally, Dave, who happens to be highly trusted *a priori* (perhaps because of admin status or previous good work) comes along and labels the word "wishing" as negative. Since Dave has clout the document swings negative $\nu_0^{(y)} = [0.2, 0.8]$, and Dave and Bob are now aligned with the truth, while Carol and Alice are not. Dave and Bob's error rates go to 0.56 and 2.0, respectively, while Alice and Carol's degrade to 2.5.

4.2 Implementation Considerations

The updates in the previous section contain terms like $\sum_j \sum_k \sum_i \mathbb{E}_{q(y_i)} [\sigma_{jk}(x_i, y_i)]$. Despite the apparent expense of these terms, many of these sums are very sparse and may be computed efficiently. In addition, these values may be cached and incrementally updated as necessary to reduce computational expense.

The scale of measurement features can confuse both users and the algorithm. In Equation 1, observed measurement values τ are compared with the value of measurement features summed over the dataset $\sum_i \sigma(x_i, y_i)$. This latter quantity is bounded by a different range for each measurement feature (see Table 1). However, humans may prefer to give measurement values between 0 and 1, where 1 means "this happens as often as possible." Such values must be scaled by $\max(\sigma_{jk})$.

A related point is that each measurement type is defined on a different scale, but the PAN model fits a common variance to all types. For this to make sense, it is necessary to re-scale each measurement to a common range before running inference. For all experiments reported in this paper, we choose the range $[0 \dots 1]$. Concretely, substitute $\frac{\sigma_{jk}(x_i,y_i)}{\max(\sigma_{jk})}$ for $\sigma_{jk}(x_i, y_i)$, $\frac{E_{q(y_i)}[\sigma_{jk}(x_i,y_i)]}{\max(\sigma_{jk})}$ for $E_{q(y_i)}[\sigma_{jk}(x_i, y_i)]$, and $\frac{\tau_{jk}}{\max(\sigma_{jk})}$ for τ_{jk}.

5 Experiments

This section explores the performance of PAN in rich annotation scenarios. Our goal here is not to establish the PAN model as the state of the art but rather to assess and validate the utility of incorporating diverse annotation types.

5.1 Baselines

We choose two common crowdsourcing baselines which are widely compared against. Despite their simplicity, previous work in establishing benchmark crowdsourcing tasks indicates that these baselines are surprisingly competitive with more sophisticated methods (Sheshadri and Lease, 2013).

Majority Vote (MV) chooses the label with the largest number of votes for each item, ignoring annotator identify. Ties are broken randomly. Although simple, majority vote is widely used and surprisingly successful across a variety of tasks.

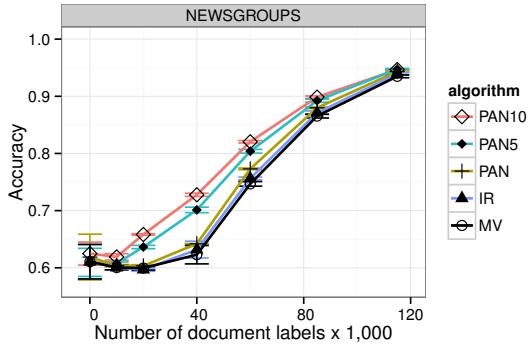
Dawid & Skene (IR). The *item response model* proposed by Dawid and Skene (1979) models annotator error over discrete responses via per-annotator confusion matrices. Much subsequent work uses the same basic structure, making it a good point of comparison. We use a Bayesian version of this model with variational inference adapted from Felt et al. (2015b). The general learning from measurements crowdsourcing framework generalizes this model and many of its extensions (Section 3).

5.2 Simulated Data

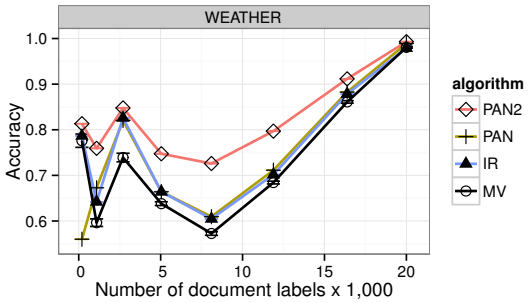
We first generate confidence in our implementation by running on the well-known *20 News Groups* dataset with simulated annotator measurements consistent with PAN's Gaussian noise assumptions. We simulate three different measurements: document labels, word labels, and estimated label proportions. Document label judgments are simulated by corrupting the known true document labels via confusion matrices for five annotators with 50%, 55%, 60%, 65%, and 70% accuracy rates, using the following process:

1. Choose a document randomly without replacement. If none are left, begin again.
2. Choose a simulated annotator randomly with replacement and annotate the document according to that annotator's accuracy.
3. Stop when each of the 20,000 documents has approximately six label annotations.

Word label judgments are simulated by choosing a word w and document label y uniformly at random, and then calculating the empirical rate of seeing documents with label y given that they contain word w. We add Gaussian noise proportional to the total number of documents containing word w and inversely proportional to the accuracy of the annotator. Finally, we manually specify twenty label proportion judgments to encode our *a priori* belief that classes appear roughly the same number of times in the data.



(a) Simulated annotations over the 20 newsgroups corpus. The corpus is annotated until each document has approximately six document label annotations. Performance is competitive with methods with only document labels. However, as we add additional word labels—5,000 (*PAN5*), and 10,000 (*PAN10*)—via the measurements framework, performance increases further.



(b) Real annotations over the weather dataset. PAN is with (PAN2) and without (PAN) access to 2,266 labeled words from CrowdFlower. Labeled words substantially improve PAN's predictions.

Figure 3: Inferred labeled accuracy of Majority vote (MV), the item-response (IR) model, and the per-annotator normal (PAN) measurement model.

In practice, such prior knowledge about approximate label proportions may be available depending on how the data was gathered.

5.3 Inferred label accuracy curves

When the annotation process begins, few documents have annotations. Because crowdsourcing models require annotations to make a prediction, we can plot the accuracy of inferred labels only over those documents having at least one annotation. This means that until the dataset is annotated once, the denominator of the accuracy calculation is growing. Thus inferred label accuracy reflects the corpus accuracy over the subset of documents that have at least one label. This can make inferred label accuracy curves look unlike traditional learning curves, especially when annotation order is not controlled. In real annotation projects, some documents might be annotated multiple times before other documents receive any annotations, resulting in potential accuracy dips as the denominator changes.

PAN is competitive with baselines using only simulated document labels, and it benefits from additional simulated word labels (Figure 3a). Unsurprisingly, there are diminishing returns from additional labeled words: the difference between 0 and 5,000 labeled words is more dramatic than the difference between $5,000$ and $10,000$.

5.4 Sentiment Classification

The same trends hold with real annotator judgments using the "Weather Sentiment" dataset. In this dataset twenty annotators label 1,000 tweets as either `Positive`, `Negative`, `Neutral`, or `Not weather`. Majority vote labels are then evaluated in the related "Weather Sentiment Evaluated" task where a ten secondary annotators judge whether each consensus label is correct or not. For 724 of the tweets, at least nine secondary annotators agree that the consensus majority vote label is correct. We use these high confidence tweets as our gold standard.

Document label judgments are already available for this dataset, but no labeled words or label proportion judgments. We paid CrowdFlower workers to generate labeled words by showing them groups of then randomly selected weather tweets and asking them to list words that characterize each class of tweet. Although a more highly trained workforce could have generated and labeled more sophisticated measurements such as regular expressions, labeled words are a first test. Furthermore, we encode an *a priori* belief that each class occurs roughly the same number of times by manually adding four trusted label proportion measurements stating that each class occurs $N/C = 250$ times. Trusted measurements

are expressed in this framework by authoring measurements under the id of an artificial annotator who is assigned a strong prior distribution of low measurement noise.

From the workers we gather 864 word lists containing 2,482 individual words and covering a vocabulary of 995 unique words. Of the 2,482 word labels, 216 did not match any words in the corpus (we allowed users the freedom to draw on their own background knowledge as well as words of the corpus that they were shown). Interestingly, a brief manual examination of the word lists did not uncover any abusive behavior, although several annotators clearly wanted to match phrases rather than just words. Although the model would permit the use of labeled phrases, our Crowdflower task was not designed to distinguish the two cases, so for now we treat all words as individual judgments. We match word labels to document words after normalizing both by removing punctuation, converting to lower case, applying a Porter stemmer, and removing words from the MALLET stopword list (McCallum, 2002).

Labeled words improve PAN's accuracy. In Figure 3b, the PAN2 line uses $2k$ labeled words and beats vanilla PAN substantially. And while labeled words are not free, it took only 864 judgments to generate our labeled word set, which works out to about $9 at $0.01 per judgment; whereas the 20,000 judgments comprising the document labels would have cost $200 at $0.01 per judgment.

6 Active Measurement Selection

The learning curves in Section 5 assume that annotations were obtained in some arbitrary order, either randomly (Section 5.2) or else ordered by timestamp (Section 5.4). Active learning minimizes annotation costs by obtaining annotations in an order that maximizes their utility. Previous work in active learning either assumes a single, infallible annotator (Settles, 2010; Liang et al., 2009), or else allows multiple annotators but assumes a single kind of annotation (Donmez and Carbonell, 2008; Haertel, 2013; Yan et al., 2011; Nguyen et al., 2015). This paper presents the first active learning results in a setting with multiple annotators and diverse annotation types, jointly selecting annotator, document, and annotation type.

We adapt the active measurement selection algorithm of Liang et al. (2009) to fit the crowdsourcing scenario in Algorithm 1. At each step in the MEASUREMENTSELECTION subroutine, we have a set of observed measurement labels τ_0 and wish to observe a new measurement feature $\sigma_{j,k}$ encoding both the annotator j and the annotation type k (including the document to be annotated for document-centric measurement features).

The NEXTMEASUREMENT subroutine in Algorithm 1 contains our selection criteria, and can be understood as approximating expected net utility:

$$U(\sigma_{jk}) = \mathbb{E}_{p(\tau_{jk} \mid \tau_0, X)} \left[R(\sigma_{jk}, \tau_{jk}) - C(\sigma_{jk}) \right]$$

where $R(\sigma_{jk}, \tau_{jk})$ is the expected reward for obtaining judgment value τ_{jk} for measurement feature σ_{jk}, and $C(\sigma_{jk})$ is the expected cost of obtaining that judgment. To make this computation tractable, we introduce a number of approximations. Lines 11–15 of Algorithm 1 compute the expectation over τ_{jk} using stochastic integration. For PAN, we approximate sampling from the posterior $p(\tau_{jk} \mid \tau_0, X)$ by parameterizing the Normal distribution of the original PAN model with the mean value of our variational parameters: $p(\tau_{jk} \mid \tau_0, q_0) = \text{Norm}(\sum_i \sigma_{jk}(x_i, y_i), \frac{\nu^{(\beta)}}{\nu^{(\alpha)} - 1})$.

The expected reward function R should reflect our expected satisfaction at having observed τ_{jk}. Ideally, we would be able to compute model improvement directly by comparing true document labels y with our predicted labels $\hat{y}$ after adding the new observation: $\mathbb{E}_{p*(x)} \left[\max_{\hat{y}} r(y, \hat{y}) \right]$ where $r(y, \hat{y})$ is an internal reward function like label accuracy and $p^*(x)$ is the empirical distribution. In reality the true values y are unobservable, but we can expect over them using our posterior approximation $\tilde{q}$; thus $R_{\tilde{q}} = \mathbb{E}_{p*(x)} \left[\max_{\hat{y}} \mathbb{E}_{\tilde{q}(y)} \left[r(y, \hat{y}) \right] \right]$. With a label accuracy reward function the expected reward simplifies to $R_{\tilde{q}} = \sum_i \max_{\hat{y}} q(y_i = \hat{y}) = \sum_i \max_{\hat{y}} \nu_{i\hat{y}}^{(y)}$. For simplicity, we set the cost function $C_{\tilde{q}}$ to a constant, but leave it in the equations since future work should estimate and use annotation cost.

By default, Algorithm 1 jointly selects an annotator j and measurement k, but it could be used in other ways. Haertel et al. (2010) argue that in realistic scenarios the active learning algorithm typically cannot control when annotators are available but rather must respond to annotator requests for work. Algorithm 1

1: **function** MEASUREMENTSELECTION(τ_0)
2: $q_0 \leftarrow$ Inference(τ_0)
3: **while** more measurements are desired **do**
4: $j, k \leftarrow$ NextMeasurement(τ_0, q_0)
5: $\tau_0 \leftarrow \tau_0 \cup$ ObserveMeasurement(j, k)
6: $q_0 \leftarrow$ Inference(τ_0)
7: **return** q
8: **function** NEXTMEASUREMENT(τ_0, q_0)
9: **for** annotator j **do**
10: **for** measurement feature k **do**
11: draw t samples from $p(\tau_{jk}|\tau_0, q_0)$
12: **for** sampled τ_{jkt} **do**
13: $\tau_1 \leftarrow \tau_{jkt} \cup \tau_0$
14: $\tilde{q} \leftarrow$ Inference(τ_1)
15: $\mu_{\tau_{jkt}} \leftarrow R_{\tilde{q}}(\tau_1) - C_{\tilde{q}}(\tau_1)$
16: $\mu_{\tau_{jk}} \leftarrow \frac{1}{t} \sum_t \mu_{\tau_{jkt}}$
17: **return** $\operatorname{argmax}_{j,k} \mu_{\tau_{jk}}$

Algorithm 1: Active measurement selection algorithm for jointly selecting annotator j and annotation type k. The NEXTMEASUREMENT subroutine approximates expected utility.

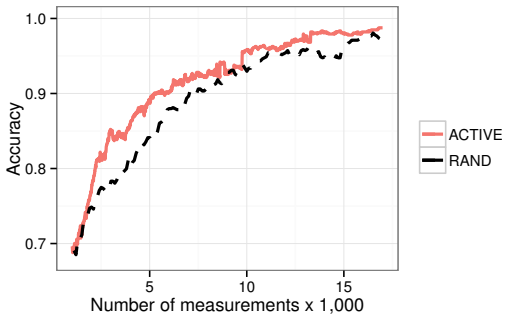


Figure 4: Inferred labeled accuracy of the PAN model selecting measurements randomly (*RAND*) compared with a strategy that selects measurements and annotators actively (*ACTIVE*).

can return the best measurement k given annotator $\hat{j}$ by computing $\operatorname{argmax}_k \mu_{\tau_{\hat{j}k}}$. Similarly, one can calculate the best annotator j for a desired measurement $\hat{k}$ as $\operatorname{argmax}_j \mu_{\tau_{j\hat{k}}}$.

Unfortunately, Algorithm 1 is computationally expensive. Prior to selection, each candidate measurement must be considered and a model retrained using t sampled candidate measurements. However, by applying a number of additional approximations we can run on the weather sentiment dataset from Section 5.4 with over 22,000 candidate measurements. We set the number of samples to three, and models trained in the inner loop (line 14 of Algorithm 1) are initialized using q_0 and then trained only one additional iteration. More importantly, we score only twenty-five randomly selected candidates at each round and select batches of the ten most promising measurements at each round.

We compare random and active selection of measurements (Algorithm 1) from the sentiment classification experiment in Section 5.4 in Figure 4. The active measurement selection improves over a random baseline.

7 Additional Related Work

Other supervised learning frameworks that incorporate rich prior knowledge include constraint-driven learning based on integer linear programming (Chang et al., 2008), generalized expectation criteria (Druck et al., 2008), and the posterior regularization (Ganchev et al., 2010). Ganchev et al. (2010) explain each of these three frameworks can be derived as a special case of the learning from measurements framework of Liang et al. (2009) by making particular approximations for the sake of tractability.

Traditional corpus construction assesses inferred label quality using annotator agreement heuristics such as Krippendorff's alpha (Krippendorff, 2012). Passonneau and Carpenter (2014) argue that inference in probabilistic models yields higher quality labels at lower cost, and should be preferred over agreement heuristics. Among crowdsourcing models, Hovy et al. (2013) include Bernoulli switching variables to identify and eliminate malicious contributors (spammers). Raykar and Yu (2012) iteratively

run inference and exclude problematic annotators in order to eliminate spammers. Raykar et al. (2010), Yan et al. (2014), and Felt et al. (2015a) model data jointly with labels, allowing patterns in the data to inform inferred labels. Simpson and Roberts (2015) model annotator dynamics, tracking the ways that annotator decision making changes over time in response to factors such as training and fatigue. Welinder et al. (2010) and Whitehill et al. (2009) both model item difficulty, reducing the effect of inherently ambiguous or difficult items on annotator reliability estimates.

Each of these crowdsourcing models focuses on incorporating one or more insights about the annotation process. We leave it to future work to incorporate these insights into crowdsourcing models that learn from measurements, either via measurement noise or via new measurement formulations. For example, item difficulty could be modeled by creating a measurement feature $\sigma_{jk}(x_i = x_{i'})$ for each $x_{i'}$ and assigning a separate measurement noise to each (perhaps with a shared hierarchical prior noise).

8 Conclusion and Future Work

The success of machine learning depends on data, and those data often come from human annotators. Asking the right questions of the right people is an often overlooked challenge of building an effective machine learning system. Extending the measurements framework allows modeling users' quirks and using their insights more effectively.

This paper makes a focused contribution by connecting the measurements framework with crowdsourcing models and using initial experiments to showcase the flexibility and promise of this connection. However, the measurements framework is far more general than this first round of experiments is able to show. One primary direction of follow-on work will be to extend crowdsourcing measurement models to more sophisticated structured prediction applications. Another will be to develop inference for a more robust noise model. For example, Gaussian Processes could be used as measurement noise priors to capture more complex interactions between measurement types and annotators.

As we move toward richer annotations, we also need to consider the implications for human interactions. Modeling the costs of annotations can prevent crowdsourcing from asking difficult, ambiguous, or annoying questions. Potentially interesting measurements may include allowing annotators to report their own reliability, to assess the reliability of other annotators, or to label locations in a semantically meaningful space rather than discrete words or documents.

Reproducing and Regularizing the SCRN Model

Olzhas Kabdolov, Zhenisbek Assylbekov, Rustem Takhanov
School of Science and Technology, Nazarbayev University
{olzhas.kabdolov, zhassylbekov, rustem.takhanov}@nu.edu.kz

Abstract

We reproduce the Structurally Constrained Recurrent Network (SCRN) model, and then regularize it using the existing widespread techniques, such as naïve dropout, variational dropout, and weight tying. We show that when regularized and optimized appropriately the SCRN model can achieve performance comparable with the ubiquitous LSTM model in language modeling task on English data, while outperforming it on non-English data.

Title and Abstract in Russian

Воспроизведение и регуляризация SCRN модели

Мы воспроизводим структурно ограниченную рекуррентную сеть (SCRN), а затем добавляем регуляризацию, используя существующие широко распространенные методы, такие как исключение (дропаут), вариационное исключение и связка параметров. Мы показываем, что при правильной регуляризации и оптимизации показатели SCRN сопоставимы с показателями вездесущей LSTM в задаче языкового моделирования на английских текстах, а также превосходят их на неанглийских данных.

1 Introduction

Recurrent neural networks (RNN) have demonstrated tremendous success in sequence modeling in general and in language modeling in particular. The most basic RNN (Elman, 1990) suffers from the problem of vanishing and exploding gradients (Bengio et al., 1994) and is hard to train efficiently. One of the most widespread and efficient alternatives to the basic RNN is the Long-Short Term Memory (LSTM) model (Hochreiter and Schmidhuber, 1997), which effectively addresses the problem of vanishing gradients. However, LSTM is a fairly complex model with excessive number of parameters and its inner functionality is not obvious. This complexity has motivated some of the researchers to find more apparent and less complex alternatives. One of such alternative models is a Structurally Constrained Recurrent Network (SCRN) proposed by Mikolov et al. (2015). They encouraged some of the hidden units to change their state slowly by making part of the recurrent weight matrix close to identity, thus forming a kind of longer term memory and showed that their SCRN model can outperform the simple RNN and achieve the performance comparable with the LSTM under no regularization and small parameter budget. It is natural to try to regularize the SCRN model under larger budgets: *Will it approach the performance of LSTM?* Our experiments show that (1) under naïve dropout the SCRN demonstrates performance close to that of the LSTM, but (2) under variational dropout and weight tying the LSTM demonstrates better performance.

2 Related Work

There has been several attempts on simplifying the ubiquitous LSTM model while not losing in performance. E.g., Ororbia II et al. (2017) introduced Delta-RNN architecture for which SCRN serves as a

Proceedings of the 27th International Conference on Computational Linguistics, pages 1705–1716
Santa Fe, New Mexico, USA, August 20-26, 2018.

predecessor. They showed that, when regularized using naïve dropout (Zaremba et al., 2014), Delta-RNN performs comparably to LSTM and GRU (Chung et al., 2014). However, they did not compare to regularized SCRN, and they did not consider more recent regularization techniques, such as variational dropout (Gal and Ghahramani, 2016) and weight tying (Inan et al., 2017; Press and Wolf, 2017).

Lei and Zhang (2017) proposed the Simple Recurrent Unit (SRU) architecture, a recurrent unit that simplifies the computation and exposes more parallelism. In SRU, the majority of computation for each step is independent of the recurrence and can be easily parallelized. SRU is as fast as a convolutional layer and 5–10x faster than an optimized LSTM implementation. The authors study SRUs on a wide range of applications, including classification, question answering, language modeling, translation and speech recognition. However, one important thing which needs to be mentioned is that this model also exploits the idea of highway connections (Zilly et al., 2017) letting the input directly flow into the hidden state. The use of highway connections could be the main reason why the model achieves high performance, especially in a multi-stacked setting.

Lee et al. (2017) introduced Recurrent Additive Network (RAN), a new gated RNN which is distinguished by the use of purely additive latent state updates. At every time step, the new state is computed as a gated component-wise sum of the input and the previous state, without any of the non-linearities commonly used in RNN transition dynamics. The authors show that the model performs on par with the LSTM, and claim that it has significantly less parameters. However, in their language modeling experiments the authors specify only the number of parameters in the recurrent units, and do not take into account parameters of the embedding and softmax layers, which actually make up most of the language model parameters.

3 Baseline SCRN Model

Let $\mathcal{W}$ be a finite vocabulary of words. We assume that words have already been converted into indices. Based on one-hot word embeddings $\mathbf{x_{1:k}} = \mathbf{x_1}, \ldots, \mathbf{x_k}$ for a sequence of words $w_{1:k}$, the baseline SCRN model (Mikolov et al., 2015) produces two sequences of states, $\mathbf{s_{1:k}}$ and $\mathbf{h_{1:k}}$, according to[1]

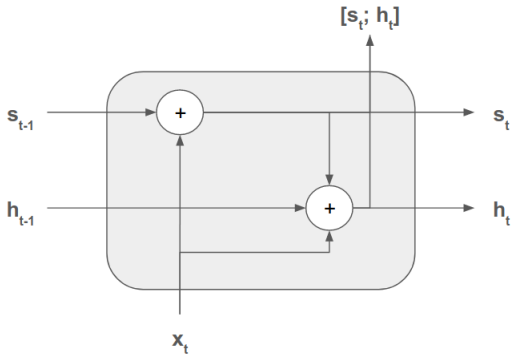

Figure 1: SCRN cell.

$$\mathbf{s_t} = (1-\alpha)\mathbf{x_t}\mathbf{B} + \alpha\mathbf{s_{t-1}}, \tag{1}$$

$$\mathbf{h_t} = \sigma(\mathbf{x_t}\mathbf{A} + \mathbf{s_t}\mathbf{P} + \mathbf{h_{t-1}}\mathbf{R}), \tag{2}$$

where $\mathbf{B} \in \mathbb{R}^{|\mathcal{W}| \times d_s}$, $\mathbf{A} \in \mathbb{R}^{|\mathcal{W}| \times d_h}$, $\mathbf{P} \in \mathbb{R}^{d_s \times d_h}$, $\mathbf{R} \in \mathbb{R}^{d_h \times d_h}$, d_s and d_h are dimensions of $\mathbf{s_t}$ and $\mathbf{h_t}$, $\sigma(\cdot)$ is the logistic sigmoid function. Mikolov et al. (2015) refer to $\mathbf{s_t}$ as a slowly changing *context state*, and to $\mathbf{h_t}$ as a quickly changing *hidden state*. The last couple of states $(\mathbf{s_k}, \mathbf{h_k})$ is assumed to contain information on the whole sequence $w_{1:k}$ and is further used for predicting the next word w_{k+1} of a sequence according to the probability distribution

$$\Pr(w_{k+1}|w_{1:k}) = \text{softmax}(\mathbf{s_k}\mathbf{U} + \mathbf{h_k}\mathbf{V}), \tag{3}$$

where $\mathbf{U} \in \mathbb{R}^{d_s \times |\mathcal{W}|}$ and $\mathbf{V} \in \mathbb{R}^{d_h \times |\mathcal{W}|}$ are output embedding matrices. For the sake of simplicity we omit bias terms in (2) and (3).

Training the model involves minimizing the negative log-likelihood over the corpus $w_{1:K}$:

$$-\sum_{k=1}^{K} \log \Pr(w_k|w_{1:k-1}) \longrightarrow \min_{\Theta}, \tag{4}$$

which is usually done by truncated backpropagation through time (Werbos, 1990). Here Θ denotes the set of all model parameters.

[1] Vectors are assumed to be row vectors, which are right multiplied by matrices ($\mathbf{xW} + \mathbf{b}$). This choice is somewhat non-standard but it maps better to the way networks are implemented in code using matrix libraries such as `TensorFlow`.

Notice that SCRN is a slight modification of the vanilla RNN model (Elman, 1990), and its simplicity (see Fig. 1) is in stark contrast with the complexity of the widespread LSTM model.

Dense embeddings: The original model spends

$$2 \cdot |\mathcal{W}| \cdot (d_s + d_h) \tag{5}$$

parameters to embed words into dense vectors at input and at output. We believe that it is more beneficial to first embed words w_t into dense vectors $\mathbf{w_t} = \mathbf{x_t}\mathbf{E} \in \mathbb{R}^{d_h}$ using only one embedding matrix $\mathbf{E} \in \mathbb{R}^{|\mathcal{W}| \times d_h}$ and then use $\mathbf{w_t}$ instead of $\mathbf{x_t}$ in (1) and (2) with the appropriate change of shapes for matrices: $\mathbf{B} \in \mathbb{R}^{d_h \times d_s}$ and $\mathbf{A} \in \mathbb{R}^{d_h \times d_h}$. In this case, the model spends $|\mathcal{W}| \cdot (2d_h + d_s)$ parameters on input/output embeddings, which is $d_s \cdot |\mathcal{W}|$ parameters less than (5). E.g., on the Penn Tree Bank (PTB) dataset (Marcus et al., 1993), where $|\mathcal{W}| = 10,000$, the reduction is 1M parameters for the SCRN model with $d_s = 100$.

4 Stacking and Regularizing the SCRN

4.1 Stacking recurrent cells

It is well known that stacking at least two layers in recurrent neural networks is beneficial, but between two and three layers the results are mixed (Karpathy et al., 2016; Laurent and von Brecht, 2017). To make our results comparable to the previous works on LSTM language modeling (Zaremba et al., 2014; Gal and Ghahramani, 2016; Inan et al., 2017), we experiment with two-layered architectures: the output of the first layer (1, 2) is concatenated $[\mathbf{s_t}; \mathbf{h_t}]$ and is fed as input into the second layer.

In what follows the superscript index in round brackets denotes the layer index, $\boldsymbol{\xi}(p) = [\xi_1, \ldots, \xi_d]$ is a random vector (dropout mask) with $\xi_i \sim \text{Bernoulli}(1-p)$, d is the dimensionality of the corresponding layer, p is a dropout rate, and $\odot$ is the element-wise (Hadamard) product. One time-step of a stacked SCRN model is fully specified by the following equations:

- Input embedding layer:

$$\mathbf{w_t} := \mathbf{y_t}^{(0)} = \mathbf{x_t}\mathbf{E}. \tag{6}$$

- Two SCRN layers: for $l = 1, 2$

$$\begin{aligned}
\mathbf{s_t}^{(l)} &= (1-\alpha)\mathbf{y_t}^{(l-1)}\mathbf{B}^{(l)} + \alpha\mathbf{s_{t-1}}^{(l)}, \\
\mathbf{h_t}^{(l)} &= \sigma\left(\mathbf{y_t}^{(l-1)}\mathbf{A}^{(l)} + \mathbf{s_t}^{(l)}\mathbf{P}^{(l)} + \mathbf{h_{t-1}}^{(l)}\mathbf{R}^{(l)}\right), \\
\mathbf{y_t}^{(l)} &= [\mathbf{s_t}^{(l)}; \mathbf{h_t}^{(l)}].
\end{aligned} \tag{7}$$

- Softmax prediction:

$$\Pr(w_{t+1}|w_{1:t}) = \text{softmax}\left(\mathbf{y_t}^{(2)}\begin{bmatrix}\mathbf{U} \\ \mathbf{V}\end{bmatrix}\right). \tag{8}$$

In the equations above, the matrices $\mathbf{U}$ and $\mathbf{V}$ are concatenated along the first dimension to produce a $(d_s + d_h) \times |\mathcal{W}|$ matrix.

4.2 Naïve dropout

Due to high complexity of deep neural networks the regularization techniques are crucial for good generalization performance. Zaremba et al. (2014) proposed one of the ways how dropout (Srivastava et al., 2014) can be used to regularize recurrent neural networks. They apply dropout only to non-recurrent connections, while keeping the recurrent connections without change. This method, usually referred to as *naïve dropout*, improves the baseline results of the LSTM model without any other modifications. Application of the same dropout technique to the SCRN model (6, 7, 8) is specified by

$$\begin{aligned}
\hat{\mathbf{y}}_\mathbf{t}^{(0)} &= \mathbf{y_t}^{(0)} \odot \boldsymbol{\xi_t}^{(0)}(p_i), \\
\hat{\mathbf{y}}_\mathbf{t}^{(l)} &= \mathbf{y_t}^{(l)} \odot \boldsymbol{\xi_t}^{(l)}(p_o), \quad l = 1, 2
\end{aligned}$$

correspondingly, where p_i and p_o are input and output dropout rates.

4.3 Variational dropout

The approach of Zaremba et al. (2014) have led many to believe that dropout cannot be extended to recurrent connections, leaving them with no regularization. However, Gal and Ghahramani (2016) showed that it is possible to derive a variant of dropout which successfully regularizes recurrent connections. In their dropout variant, which is usually referred to as *variational dropout*, they repeat the same dropout mask at each time step for inputs, recurrent layers, and outputs:

$$\begin{aligned}
\tilde{\mathbf{y}}_\mathbf{t}^{(0)} &= \mathbf{y}_\mathbf{t}^{(0)} \odot \boldsymbol{\xi}^{(0)}(p_i), \\
\hbar_\mathbf{t}^{(l)} &= \mathbf{h}_\mathbf{t}^{(l)} \odot \boldsymbol{\xi}^{(l)}(p_h), \quad l = 1, 2 \\
\tilde{\mathbf{y}}_\mathbf{t}^{(l)} &= \mathbf{y}_\mathbf{t}^{(l)} \odot \boldsymbol{\xi}^{(l)}(p_o), \quad l = 1, 2
\end{aligned} \tag{9}$$

where p_h is a recurrent dropout rate. This is in contrast to the naïve dropout where different masks are sampled at each time step for the inputs and outputs alone and no dropout is used with the recurrent connections. Notice that we do not regularize the context state $\mathbf{s_t}$ in horizontal (recurrent) direction.

4.4 Tying word embeddings

Tying input and output word embeddings in word-level RNNLM is a regularization technique, which was introduced earlier (Bengio et al., 2003; Mnih and Hinton, 2007) but has been widely used relatively recently, and there is empirical evidence (Press and Wolf, 2017) as well as theoretical justification (Inan et al., 2017) that such a simple trick improves language modeling quality while decreasing the total number of trainable parameters almost two-fold, since most of the parameters are due to embedding matrices. In case of the SCRN model, reusing input embeddings at output can be done by setting

$$\mathbf{V} = \mathbf{E}^\top$$

in the softmax layer (8).

5 Experimental setup

We use perplexity (PPL) to evaluate the performance of the language models. Perplexity of a model over a sequence $[w_1, \ldots, w_K]$ is given by

$$\text{PPL} = \exp\left(-\tfrac{1}{K}\sum_{k=1}^{K} \log \Pr(w_k | w_{1:k-1})\right).$$

Data sets: The baseline model is trained and evaluated on the PTB (Marcus et al., 1993), while all regularized and stacked configurations are trained and evaluated on the PTB and the WikiText-2 (Merity et al., 2017) data sets. For the PTB we utilize the standard training (0-20), validation (21-22), and test (23-24) splits along with pre-processing per Mikolov et al. (2010). WikiText-2 is an alternative to PTB, which is approximately two times as large in size and three times as large in vocabulary.

Baseline Model: To reproduce the results of the baseline (single-layer and non-regularized) SCRN model we use the original `Torch` implementation[2] released by Mikolov et al. (2015). We have spent fair amount of time and effort to make their script run, as several of its dependencies have not been updated for few years, and are not compatible with the up-to-date versions of the others. To simplify the path for other researchers we release a script[3], which installs necessary versions of the dependencies. We use exactly the same set of hyperparameters reported in the original paper (Table 1). We also implement the baseline SCRN model ourselves[4] using `TensorFlow` (Abadi et al., 2016) which, unlike `Torch`, uses static computational graphs, and thus has different style of truncated backpropagation through time[5] (BPTT). Because of this difference, we chose different set of hyperparameters for our implementation (Table 1),

[2] `https://github.com/facebookarchive/SCRNNs`

[3] `https://github.com/zh3nis/scrn/blob/master/scrnn_deps.sh`

[4] Our implementation is available at `https://github.com/zh3nis/scrn`

[5] `https://r2rt.com/styles-of-truncated-backpropagation.html`

Hyperparameter	Mikolov et al. (2015)	Our implementation
α in (1)	0.95	0.95
batch size	32	20
initial LR	0.05	0.8
LR decay	1/1.5	0.5
LR decayed if	valid PPL doesn't improve	valid PPL doesn't improve
BPTT steps	50	35
BPTT frequency	5	35
gradients	renormalized	norms clipped at 5
weights initialized over	$[-0.05, 0.05]$	$[-0.3, 0.3]$ ($[-0.2, 0.2]$)

Table 1: Hyperparameters of the baseline SCRN model. Abbreviations: LR — learning rate, BPTT — backpropagation through time. Values in brackets correspond to the $(d_h, d_s) = (300, 40)$ configuration when they differ from others.

and this choice is motivated by the previous work on word-level language modeling (Zaremba et al., 2014), which has an open-source implementation in `TensorFlow`[6].

Stacked and Regularized Models: In the previous works on regularizing the LSTM, small-sized models usually had $d_h = 200$ and medium-sized models had $d_h = 650$. The inner simplicity of the SCRN cell allows us slighlty larger hidden sizes: we use $d_h = 240$ for small models and $d_h = 750$ for medium models. Context state sizes d_s are chosen to be 40 (small) and 120 (medium), so that total number of parameters does not exceed the budget, which is 5M parameters for small models, and 20M parameters for medium models. We find empirically, that a good ratio between context size and hidden size in the SCRN model is around $1/6$. We optimize hyperparameters separately under naïve dropout and under variational dropout. Some of the hyperparameters are tuned using random search according to the marginal distributions:

- $p_i \sim U[0.01, 0.6]$,
- $p_h \sim U[0.01, 0.6]$,
- $p_o \sim U[0.01, 0.6]$,
- initial learning rate $\sim U[0.5, 0.99]$,
- learning rate decay $\sim U[0.5, 0.89]$,
- initialization scale $\sim U[0.05, 0.3]$.

where $U[a, b]$ means continuous uniform distribution over the interval $[a, b]$, and initialization scale is a number r such that all model weights are initialized uniformly over $[-r, r]$. Other hyperparameters are tuned manually through trial-and-error. When performing random search we first choose ranges mentioned above. After 100 runs the initial ranges are shrinked to the neighborhoods of the values that give best performances, and the random search is performed again. We repeat this procedure until hyperparameters converge to their (sub)optimal values. To prevent exploding gradients we clip the norm of the gradients (normalized by minibatch size) at 5. For training (4) we use stochastic gradient descent.

6 Results

Baseline: To assure that our implementation of the baseline SCRN is adequate, we evaluate it against the original SCRN code by Mikolov et al. (2015) (Table 2). As one can see, the original SCRN code does *not* fully reproduce the results reported in the original paper. Their hyperparameters (Table 1) work well for the case when $(d_s, d_h) \in \{(40, 10), (90, 10)\}$, but are not optimal for the other two configurations. Our implementation together with our set of hyperparameters (Table 1) brings the validation and test perplexities of *all* the configurations closer to those reported in the paper.

Stacked and Regularized Models: Tuning the stack of two SCRNs results in hyperparameters in Table 3. The results of evaluating these models against regularized and stacked LSTMs on PTB and WikiText-2 are provided in Table 4. Regularization *does* benefit the simple and intuitive SCRN model, which

initialization scale	0.3	0.3	0.3	0.3

Table 3: Tuned hyperparameters: ND – naïve dropout, VD – variational dropout. Values in brackets correspond to the WikiText-2 in cases when they differ from those used for the PTB.

demonstrates performance comparable to the sophisticated LSTM model under the naïve dropout, but lags behind the LSTM under the variational dropout regularization. This shows that at some point less complex models become less competitive, even when regularized and optimized appropriately. It is important to mention that no architectural modifications were applied to the original SCRN model except stacking.

Our feeling is that a little over-parameterization of the recurrent connections model *is* needed for the recent regularization techniques to work well. For example, consider the variational dropout of the recurrent connections (9) in the SCRN: dropping the coordinates $i_1, \ldots, i_l$ in the row $\mathbf{h_t}$ is equivalent to zeroing out the rows $i_1, \ldots, i_l$ in the matrices $\mathbf{A}$, $\mathbf{P}$, $\mathbf{R}$. Now consider one layer of the LSTM model:

$$\begin{aligned}
\mathbf{f_t} &= \sigma(\mathbf{x_t W_f} + \mathbf{h_{t-1} U_f} + \mathbf{b_f}) \\
\mathbf{i_t} &= \sigma(\mathbf{x_t W_i} + \mathbf{h_{t-1} U_i} + \mathbf{b_i}) \\
\mathbf{o_t} &= \sigma(\mathbf{x_t W_o} + \mathbf{h_{t-1} U_o} + \mathbf{b_o}) \\
\mathbf{c_t} &= \mathbf{f_t} \odot \mathbf{c_{t-1}} + \mathbf{i_t} \odot \tanh(\mathbf{x_t W_c} + \mathbf{h_{t-1} U_c} + \mathbf{b_c}) \\
\mathbf{h_t} &= \mathbf{o_t} \odot \tanh(\mathbf{c_t})
\end{aligned}$$

When one drops the coordinates $i_1, \ldots, i_l$ of $\mathbf{h_t}$ in LSTM, this can be understood as zeroing out the rows $i_1, \ldots, i_l$ in the matrices $\mathbf{W_f}$, $\mathbf{W_i}$, $\mathbf{W_o}$, $\mathbf{U_f}$, $\mathbf{U_i}$, $\mathbf{U_o}$, i.e. around 3 times more parameters are zeroed out given the same hidden state size d_h. In other words, the number of recurrent weights is 3 times larger in LSTM than in SCRN. We believe this is one of the reasons why the variational dropout works worse in SCRN. Roughly speaking, there is nothing much to regularize in the horizontal (recurrent) direction in SCRN, as most parameters are in the embedding and softmax layers.

6.1 Ablation analysis

We consider removal of some parts or forms of regularization from one of our well-performing configurations, SCRN + ND + WT, to see whether such removal degrades the performance. It also tells us which

Word-level model	PTB		WikiText-2	
	Small	Medium	Small	Medium

SCRN + VD	97.2	90.7	120.1	107.6
SCRN + VD + WT	96.8	90.7	112.2	106.0

Table 4: Evaluation of the SCRN against LSTM under different regularization techniques: ND – naïve dropout, VD – variational dropout, WT – weight tying. †We reproduced the LSTM-Word-Small model from Kim et al. (2016) on PTB and then evaluated it on WikiText-2. ‡We ran the open-source implementation from `https://github.com/tensorflow/models/tree/master/tutorials/rnn/ptb` at medium config on WikiText-2 data.

parts of the model are more important. The model and dropout variations are listed below.

Removing regularization: To understand how much improvement is gained by the use of regularization we completely remove dropout and weight tying:

$$p_i = p_o = 0, \qquad \mathbf{V} \neq \mathbf{E}^\top$$

Removing dropout of the context state: According to (1), context state $\mathbf{s_t}$ changes linearly and thus should not suffer from over-fitting. Thus it seems reasonable to try to not regularize it and apply dropout only to the hidden states, i.e. replacing the equation (7) by

$$\mathbf{y_t}^{(l)} = [\mathbf{s_t}^{(l)}; \mathbf{h_t}^{(l)} \odot \boldsymbol{\xi}_\mathbf{t}^{(l)}(p_o)], \qquad l = 1, 2.$$

Removing the context state from the softmax layer: As in the case of the SCRN, the inner state of the LSTM model also consists of two vectors $\mathbf{c_t}$ and $\mathbf{h_t}$, and usually the state $\mathbf{c_t}$ is not used at softmax. We do the same for the context state $\mathbf{s_t}$ in our model, i.e. the equation (8) is replaced by

$$\Pr(w_{t+1}|w_{1:t}) = \text{softmax}(\mathbf{h_t}^{(2)}\mathbf{V}).$$

The meaningfulness of removing the context state from the softmax is that, in our opinion, it plays the role of a long-term memory and thus should not be crucial for predicting the next word of a sequence. Moreover, such removal reduces the model size by at least $d_s \cdot |\mathcal{W}|$ parameters, which can be significant (see Section 3).

The results of the ablation analysis are provided in Table 5. As we can see, without regularization our SCRN + ND + WT model fails to generalize well on validation and test sets. Regularizing only the hidden state (and keeping the context state untouched) is less harmful but still degrades the performance of the model. Finally, not using the context state in the output only slightly worsens the performance but at the same time leads to a significant reduction in model size.

6.2 Hidden state changes

We performed an analysis of the SCRN's hidden state evolution as in the work of Ororbia II et al. (2017) on Delta-RNN (see their Figure 2). We found out that the hidden state changes in SCRN are similar to those in Delta-RNN: the L_1-norm of the state change is higher for informative words, such as "government", and the difference is in general more pronounced than in LSTM. See the Figure 2.

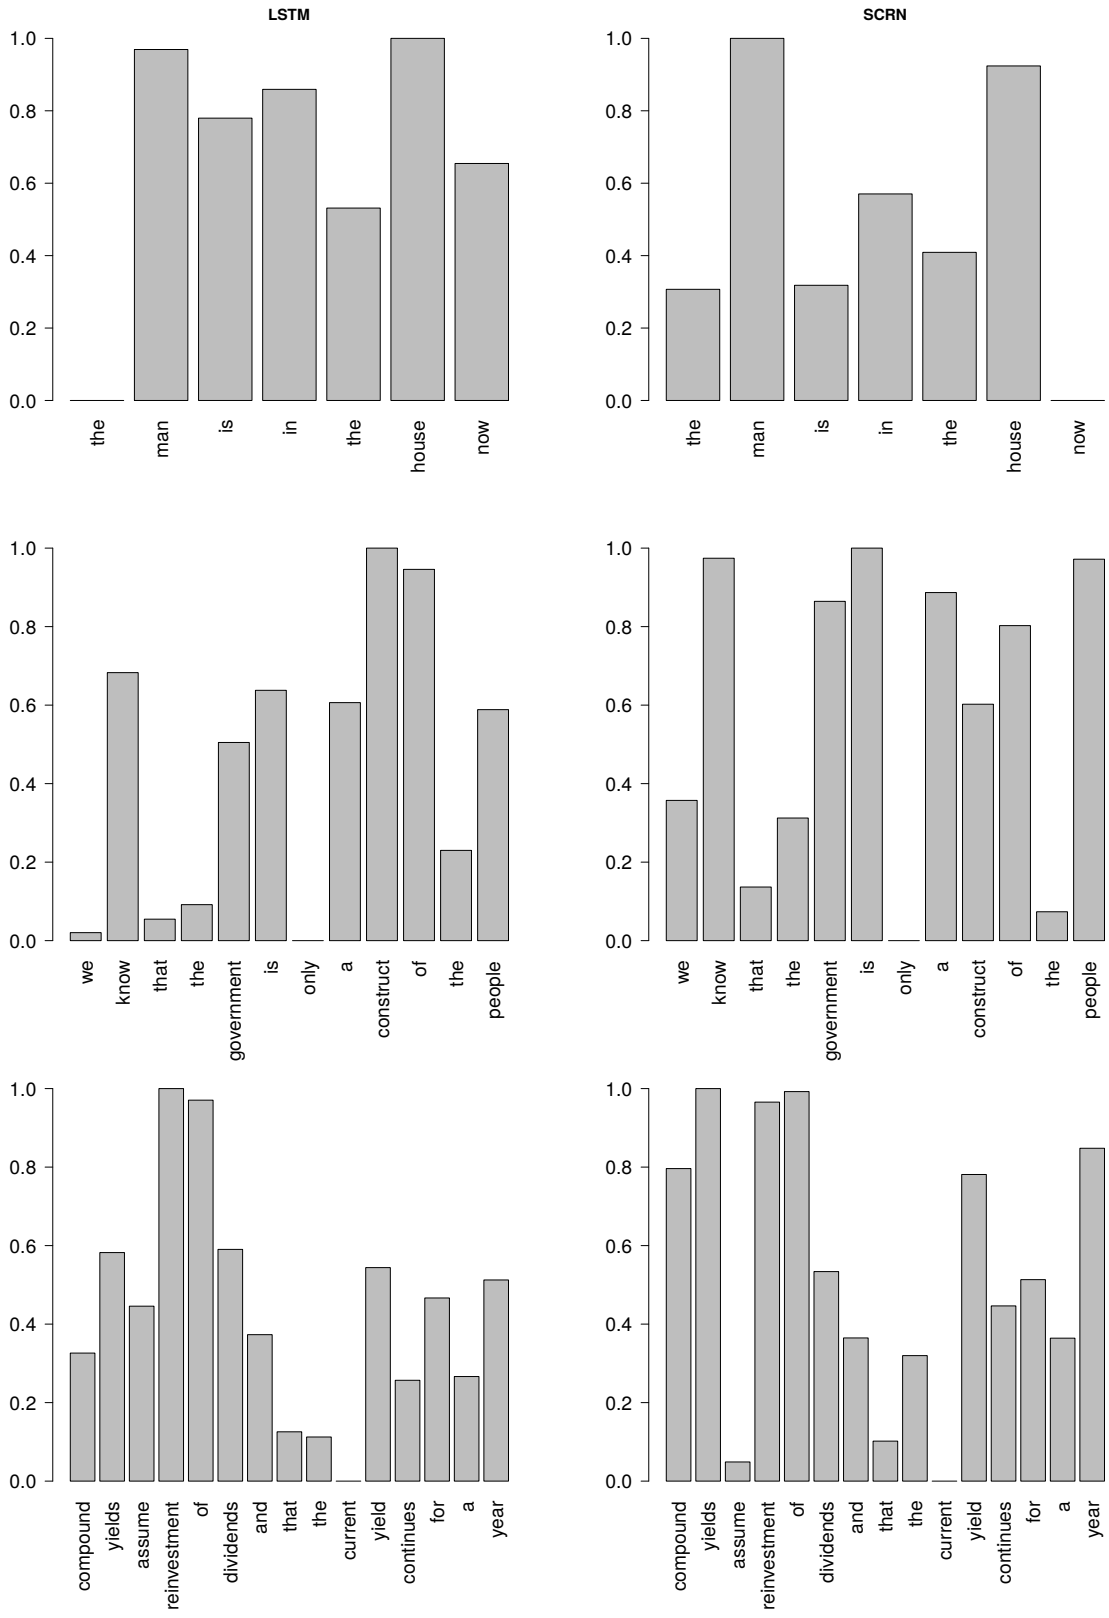

Figure 2: L_1 norm of deltas between consecutive states of LSTM (left) and SCRN (right) trained on Penn Treebank plotted over words of example sentences. The main observation is that the norm is in general lower for low-information content words, such as the article *the*, and higher for informative words, such as *government*, and this difference is more pronounced in SCRN.

Model	Small		Medium	
	Valid	Test	Valid	Test
SCRN + ND + WT	98.2	94.1	90.1	86.1
− regularization	123.3	117.6	146.1	140.2
− dropout of context	108.4	103.6	115.0	109.4
− context in softmax	100.8	96.4	91.7	87.6

Table 5: Model ablations for the small and medium SCRN + ND + WT models on PTB set.

7 Sobolev Regularization

Together with dropout and weight tying techniques we conducted some experiments with a Sobolev-type regularization. By the Sobolev-type regularization we understand penalization of large gradients of certain parts of neural architecture treated as functions. The idea of penalizing norm of gradients can be traced back to the works on double backpropagation (Drucker and Le Cun, 1992). Zilly et al. (2017) demonstrated that an important property of the hidden vector's dynamics is its stability, which they decribe in terms of an upper bound on norm of Jacobian matrix $\frac{\partial \mathbf{h_t}}{\partial \mathbf{h_{t-1}}}$. Exploiting the latter intuition we suggest the following regularization term:

$$\mathcal{L}_{\text{Sobolev}} = \beta \sum_{t=1}^{K} \left\| \frac{\partial \mathbf{h_t}}{\partial \mathbf{h_{t-1}}} \right\|_F^2, \tag{10}$$

where $\|\mathbf{A}\|_F = \sqrt{\text{Tr}(\mathbf{A}^\top \mathbf{A})}$ is the Frobenius norm of a matrix $\mathbf{A}$. Note that we do not specify the layer, since our regularization can be applied to all layers, as well as to certain layers only. The strength of such penalty is controlled by the hyperparameter β.

Overall, our experimental results are consistent with conclusions to which we came for variational dropout, with a perplexity gain even smaller than in the latter case. A typical gain from the Sobolev-type regularization was up to 1 perplexity point when it was applied on top of naïve or variational dropout, and up to 7 perplexity points when it was the only regularization used. Based on those results, the conclusion from Section 6 can be reinforced: probably, the main weakness of SCRN model, in comparison with popular RNNs for which the regularization of recurrent connections is effective, is under-parameterization of those connections. The latter "does not give a space" for such regularization techniques. For completeness of narrative, let us give some details of implementing the Sobolev term in `TensorFlow`.

Since $\mathbf{h_t}$ is a row, then $\frac{\partial \mathbf{h_t}}{\partial \mathbf{h_{t-1}}}$ is understood as $\left[\frac{\partial h_t^j}{\partial h_{t-1}^i}\right]$ (i.e. transposed Jacobian $\frac{\partial \mathbf{h_t}^\top}{\partial \mathbf{h_{t-1}}^\top}$). According to (2), we have $\mathbf{h_t} = \sigma(\mathbf{x_t}\mathbf{A} + \mathbf{s_t}\mathbf{P} + \mathbf{h_{t-1}}\mathbf{R})$. After an application of the matrix chain rule, we obtain:

$$\frac{\partial \mathbf{h_t}}{\partial \mathbf{h_{t-1}}} = \mathbf{R} \cdot \text{diag}(\sigma'(\mathbf{a_t} + \mathbf{h_{t-1}}\mathbf{R})),$$

where $\mathbf{a_t} = \mathbf{x_t}\mathbf{A} + \mathbf{s_t}\mathbf{P}$ and $\text{diag}(\mathbf{v})$ is a diagonal matrix with its diagonal consisting of the components of a vector $\mathbf{v}$. Further, we have:

$$\left\| \frac{\partial \mathbf{h_t}}{\partial \mathbf{h_{t-1}}} \right\|_F^2 = \text{Tr}\left(\frac{\partial \mathbf{h_t}}{\partial \mathbf{h_{t-1}}}^\top \frac{\partial \mathbf{h_t}}{\partial \mathbf{h_{t-1}}} \right) = \text{Tr}\left(\text{diag}(\sigma'(\mathbf{a_t} + \mathbf{h_{t-1}}\mathbf{R})) \cdot \mathbf{R}^\top \mathbf{R} \cdot \text{diag}(\sigma'(\mathbf{a_t} + \mathbf{h_{t-1}}\mathbf{R})) \right).$$

Using the fact that trace is invariant w.r.t. to the transform $\mathbf{A} \to \mathbf{S}^{-1}\mathbf{A}\mathbf{S}$, we can set $\mathbf{S} = \text{diag}(\sigma'(\mathbf{a_t} + \mathbf{h_{t-1}}\mathbf{R}))$ and obtain the final formula:

$$\left\| \frac{\partial \mathbf{h}_t}{\partial \mathbf{h}_{t-1}} \right\|_F^2 = \text{Tr}(\mathbf{R}^\top \mathbf{R} \cdot \text{diag}(\sigma'(\mathbf{a_t} + \mathbf{h_{t-1}}\mathbf{R}))^2) = (\sigma')^2(\mathbf{a_t} + \mathbf{h_{t-1}}\mathbf{R})\mathbf{v}(\mathbf{R}),$$

where for $\mathbf{R} = [\mathbf{r_1}, \ldots, \mathbf{r_{d_h}}]$, $\mathbf{v}(\mathbf{R})$ is defined as the column $\left[\|\mathbf{r_1}\|^2, \ldots, \|\mathbf{r_{d_h}}\|^2\right]^\top$. Finally, the Sobolev term (10) can be given as

$$\mathcal{L}_{\text{Sobolev}} = \beta \left[\sum_{t=1}^{K} (\sigma')^2 (\mathbf{a_t} + \mathbf{h_{t-1}}\mathbf{R}) \right] \mathbf{v}(\mathbf{R}),$$

which is a form of a loss function that is suitable for an efficient implementation in `TensorFlow` (we also used the standard trick that $\sigma'(x) = \sigma(x)(1 - \sigma(x))$).

8 Performance on non-English data

It is interesting to see the performance of SCRN on texts written in non-English languages. For this purpose we conduct evaluation of the medium-sized versions of LSTM + VD + WT against SCRN + ND + WT on non-English data which comes from the 2013 ACL Workshop on Machine translation[7] with pre-processing per Botha and Blunsom (2014). Hyperparameters tuned on Wikitext-2 (Table 3) were used for all languages and we did not perform any language-specific tuning. Corpora statistics and the results of evaluation are provided in Table 6. Surprisingly, the SCRN model performs very well (compared to

	French	Spanish	German	Czech	Russian
Number of tokens	1M	1M	1M	1M	1M
Vocabulary size	25K	27K	37K	46K	62K
LSTM + ND (Kim et al., 2016)	222	200	286	493	357
LSTM + VD + WT	205	193	277	488	351
SCRN + ND + WT	**199**	**179**	**258**	**420**	**306**

Table 6: Evaluation of medium-sized models on non-English data.

LSTM) when it comes to modeling morphologically rich languages. Also, it is noteworthy that the higher the type-token ratio, the bigger the advantage of SCRN over LSTM. Our hypothesis for this phenomenon is as follows: in a morphologically rich language one needs less previous words (context) on average to predict the next word than in English, e.g.

German: Pr(lag | Der, einschlagspunkt)
English: Pr(was | The, location, of, the, impact)

The parameter α in the SCRN model (1) controls how much of the previous context is stored in the slowly changing state $\mathbf{s_t}$. Under the mentioned hypothesis, for the morphologically rich language an optimal value of α should be lower than for English. To verify this we train the medium-sized SCRN + ND + WT on all datasets for different values of α, and the results are provided in Table 7. Indeed, as we can see,

α	PTB	WikiText-2	FR	ES	DE	CS	RU
0.85	88.0	101.1	205	184	264	439	313
0.88	87.5	99.5	198	183	262	422	309
0.90	86.1	98.5	199	**179**	**258**	**420**	**306**
0.95	87.2	97.8	**197**	**179**	260	425	307
0.97	**86.0**	**96.5**	199	180	261	437	313
0.99	92.4	100.0	213	190	287	479	326

Table 7: Performance of SCRN + ND + WT for different values of α.

[7] `http://www.statmt.org/wmt13/translation-task.html`

$\alpha = 0.9$ is more beneficial for German, Czech and Russian (TTR > 0.03), but $\alpha = 0.97$ is better for English PTB and WikiText-2 (TTR < 0.03), while $\alpha = 0.95$ is optimal for French and Spanish (TTR ≈ 0.03). Also, notice that $\alpha = 0.99$ brings the SCRN's results closer to the LSTM's results on non-English data. Therefore, we think LSTM stores too much of the long-term memory via its trainable forget gate, while in SCRN we can directly control this through the α.

9 Conclusion

Being originally implemented in `Torch`, the SCRN model is fully reproducible in `Tensorflow` despite the difference in styles of truncated BPTT in these two libraries. Being conceptually much simpler, the SCRN architecture demonstrates performance comparable to the widely used LSTM model in language modeling task under naïve dropout, but it underperforms the LSTM under variational dropout regularization on English data. However, on texts written in morphologically rich languages, the SCRN with appropriately chosen hyperparameter α outperforms the LSTM.

Abstract

Seq2seq learning has produced promising results on summarization. However, in many cases, system summaries still struggle to keep the meaning of the original intact. They may miss out important words or relations that play critical roles in the syntactic structure of source sentences. In this paper, we present structure-infused copy mechanisms to facilitate copying important words and relations from the source sentence to summary sentence. The approach naturally combines source dependency structure with the copy mechanism of an abstractive sentence summarizer. Experimental results demonstrate the effectiveness of incorporating source-side syntactic information in the system, and our proposed approach compares favorably to state-of-the-art methods.

1 Introduction

Recent years have witnessed increasing interest in abstractive summarization. The systems seek to condense source texts to summaries that are concise, grammatical, and preserve the important meaning of the original texts (Nenkova and McKeown, 2011). The task encompasses a number of high-level text operations, e.g., paraphrasing, generalization, text reduction and reordering (Jing and McKeown, 1999), posing a considerable challenge to natural language understanding.

Table 1: Example source sentences, reference and system summaries produced by a neural attentive seq-to-seq model. System summaries fail to preserve summary-worthy content of the source (e.g., main verbs) despite their syntactic importance.

The sequence-to-sequence learning paradigm has achieved remarkable success on abstractive summarization (Rush et al., 2015; Nallapati et al., 2016; See et al., 2017; Paulus et al., 2017). While the results are impressive, individual system summaries can appear unreliable and fail to preserve the meaning of the source texts. Table 1 presents two examples. In these cases, the syntactic structure of source sentences is relatively *rare* but perfectly normal. The first sentence contains two appositional phrases ("suspect of murdering Jorge Microsse," "director of Maputo central prison") and the second sentence has a relative clause ("who was too drunk to drive"), both located between the subject and the main verb. The system, however, fails to identify the main verb in both cases; it instead chooses to focus on the first few words of the source sentences. We observe that *rare syntactic constructions* of the source can pose problems for neural summarization systems, possibly for two reasons. First, similar to *rare words*, certain syntactic constructions do not occur frequently enough in the training data to allow the system to learn the patterns. Second, neural summarization systems are not explicitly informed of the syntactic structure of the source sentences and they tend to bias towards sequential recency.

Proceedings of the 27th International Conference on Computational Linguistics, pages 1717–1729
Santa Fe, New Mexico, USA, August 20-26, 2018.

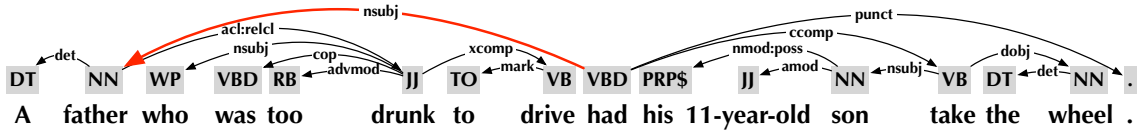

Figure 1: An example dependency parse tree created for the source sentence in Table 1. If important dependency edges such as "father ← had" can be preserved in the summary, the system summary is likely to preserve the meaning of the original.

In this paper we seek to address this problem by incorporating source syntactic structure in neural sentence summarization to help the system identify summary-worthy content and compose summaries that preserve the important meaning of the source texts. We present structure-infused copy mechanisms to facilitate copying source words and relations to the summary based on their semantic and structural importance in the source sentences. For example, if important parts of the source syntactic structure, such as a dependency edge from the main verb to the subject ("father" ← "had," shown in Figure 1), can be preserved in the summary, the "missing verb" issue in Table 1 can be effectively alleviated. Our model therefore learns to recognize important source words and source dependency relations and strives to preserve them in the summaries. Our research contributions include the following:

- we introduce novel neural architectures that encourage salient source words/relations to be preserved in summaries. The framework naturally combines the dependency parse tree structure with the copy mechanism of an abstractive summarization system. To the best of our knowledge, this is the first attempt at comparing various neural architectures for this purpose;
- we study the effectiveness of several important components, including the vocabulary size, a coverage-based regularizer (See et al., 2017), and a beam search with reference mechanism (Tan et al., 2017);
- through extensive experiments we demonstrate that incorporating syntactic information in neural sentence summarization is effective. Our approach surpasses state-of-the-art published systems on the benchmark dataset.[1]

2 Related Work

Prior to the deep learning era, sentence syntactic structure has been utilized to generate summaries with an "*extract-and-compress*" framework. Compressed summaries are generated using a joint model to extract sentences and drop non-important syntactic constituents (Daume III and Marcu, 2002; Berg-Kirkpatrick et al., 2011; Thadani and McKeown, 2013; Durrett et al., 2016), or a pipeline approach that combines generic sentence compression (McDonald, 2006; Clarke and Lapata, 2008; Filippova et al., 2015) with a sentence pre-selection or post-selection process (Zajic et al., 2007; Galanis and Androutsopoulos, 2010; Wang et al., 2013; Li et al., 2013; Li et al., 2014). Although syntactic information is helpful for summarization, there has been little prior work investigating how best to combine sentence syntactic structure with the neural abstractive summarization systems.

Existing neural summarization systems handle syntactic structure only implicitly (Kikuchi et al., 2016; Chen et al., 2016; Zhou et al., 2017; Tan et al., 2017; Paulus et al., 2017). Most systems adopt a "*cut-and-stitch*" scheme that picks words either from the vocabulary or the source text and stitch them together using a recurrent language model. However, there lacks a mechanism to ensure structurally salient words and relations in source sentences are preserved in the summaries. The resulting summary sentences can contain misleading information (e.g., "mozambican man arrested for murder" flips the meaning of the original) or grammatical errors (e.g., verbless, as in "alaska father who was too drunk to drive").

Natural language generation (NLG)-based abstractive summarization (Carenini and Cheung, 2008; Gerani et al., 2014; Fabbrizio et al., 2014; Liu et al., 2015; Takase et al., 2016) also makes extensive use of structural information, including syntactic/semantic parse trees, discourse structures, and domain-specific templates built using a text planner or an OpenIE system (Pighin et al., 2014). In particular, Cao et al. (2018) leverage OpenIE and dependency parsing to extract fact tuples from the source text and use those to improve the faithfulness of summaries.

[1]We made our system publicly available at: `https://github.com/KaiQiangSong/struct_infused_summ`

Different from the above approaches, this paper seeks to directly incorporate source-side syntactic structure in the copy mechanism of an abstractive sentence summarization system. It learns to recognize important source words and relations during training, while striving to preserve them in the summaries at test time to aid reproduction of factual details. Our intent of incorporating source syntax in summarization is different from that of neural machine translation (NMT) (Li et al., 2017a; Chen et al., 2017), in part because NMT does not handle the information loss from source to target. In contrast, a summarization system must selectively preserve source content to render concise and grammatical summaries. We specifically focus on sentence summarization, where the goal is to reduce the first sentence of an article to a title-like summary. We believe even for this reasonably simple task there remains issues unsolved.

3 Our Approach

We seek to transform a source sentence $\mathbf{x}$ to a summary sentence $\mathbf{y}$ that is concise, grammatical, and preserves the meaning of the source sentence. A source word is replaced by its Glove embedding (Pennington et al., 2014) before it is fed to the system; the vector is denoted by $\mathbf{x}_i$ ($i \in [S]$; 'S' for source). Similarly, a summary word is denoted by $\mathbf{y}_t$ ($t \in [T]$; 'T' for target). If a word does not appear in the input vocabulary, it is replaced by a special '$\langle \text{unk} \rangle$' token. We begin this section by describing the basic summarization framework, followed by our new copy mechanisms used to encourage source words and dependency relations to be preserved in the summary.

3.1 The Basic Framework

We build an encoder-decoder architecture for this work. An encoder condenses the entire source text to a continuous vector; it also learns a vector representation for each unit of the source text (e.g., words as units). In this work we use a two-layer stacked bi-directional Long Short-Term Memory (Hochreiter and Schmidhuber, 1997) networks as the encoder, where the input to the second layer is the concatenation of hidden states from the forward and backward passes of the first layer. We obtain the hidden states of the second layer; they are denoted by $\mathbf{h}_i^e$. The source text vector is constructed by averaging over all $\mathbf{h}_i^e$ and passing the vector through a feedforward layer with $\tanh$ activation to convert from the encoder hidden states to an initial decoder hidden state ($\mathbf{h}_0^d$). This process is illustrated in Eq. (2).

$$\mathbf{h}_i^e = f_e(\mathbf{h}_{i-1}^e, \mathbf{x}_i) \quad \mathbf{h}_t^d = f_d(\mathbf{h}_{t-1}^d, \mathbf{y}_{t-1}) \tag{1}$$

$$\mathbf{h}_0^d = \tanh(\mathbf{W}^{h_0} \frac{1}{S} \sum_{i=1}^{S} \mathbf{h}_i^e + \mathbf{b}^{h_0}) \tag{2}$$

A decoder unrolls the summary by predicting one word at a time. During training, the decoder takes as input the embeddings of ground truth summary words, denoted by $\mathbf{y}_t$, while at test time $\mathbf{y}_t$ are embeddings of system predicted summary words (i.e., teacher forcing). We implement an LSTM decoder with the attention mechanism. A context vector $\mathbf{c}_t$ is used to encode the source words that the system attends to for generating the next summary word. It is defined in Eqs (3-5), where $[\cdot||\cdot]$ denotes the concatenation of two vectors. The $\boldsymbol{\alpha}$ matrix measures the strength of interaction between the decoder hidden states $\{\mathbf{h}_t^d\}$ and encoder hidden states $\{\mathbf{h}_i^e\}$. To predict the next word, the context vector $\mathbf{c}_t$ and $\mathbf{h}_t^d$ are concatenated and used as input to build a new vector $\widetilde{\mathbf{h}}_t^d$ (Eq. (6)). $\widetilde{\mathbf{h}}_t^d$ is a surrogate for semantic meanings carried at time step t of the decoder. It is subsequently used to compute a probability distribution over the output vocabulary (Eq. (7)).

$$e_{t,i} = \mathbf{v}^\top \tanh(\mathbf{W}^e[\mathbf{h}_t^d||\mathbf{h}_i^e] + b^e) \tag{3}$$

$$\alpha_{t,i} = \frac{\exp(e_{t,i})}{\sum_{i'=1}^{S} \exp(e_{t,i'})} \tag{4}$$

$$\mathbf{c}_t = \textstyle\sum_{i=1}^{S} \alpha_{t,i} \mathbf{h}_i^e \tag{5}$$

$$\widetilde{\mathbf{h}}_t^d = \tanh(\mathbf{W}^h[\mathbf{h}_t^d||\mathbf{c}_t] + \mathbf{b}^h) \tag{6}$$

$$P_{vocab}(w) = \text{softmax}(\mathbf{W}^y \widetilde{\mathbf{h}}_t^d + \mathbf{b}^y) \tag{7}$$

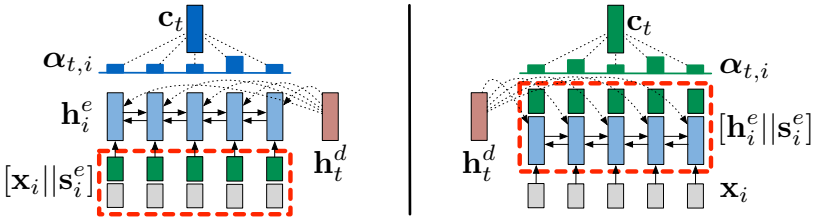

Figure 2: System architectures for 'Struct+Input' (left) and 'Struct+Hidden' (right). A critical question we seek to answer is whether the structural embeddings ($\mathbf{s}_i^e$) should be supplied as input to the encoder (left) or be exempted from encoding and directly concatenated with the encoder hidden states (right).

The copy mechanism (Gulcehre et al., 2016; See et al., 2017) allows words in the source sequence to be selectively copied to the target sequence. It expands the search space for summary words to include both the output vocabulary and the source text. The copy mechanism can effectively reduce out-of-vocabulary tokens in the generated text, potentially aiding a number of applications such as MT (Luong et al., 2015b) and text summarization (Gu et al., 2016; Cheng and Lapata, 2016; Zeng et al., 2017).

Our copy mechanism employs a 'switch' to estimate the likelihood of generating a word from the vocabulary (p_{gen}) vs. copying it from the source text ($1 - p_{gen}$). The basic model is similar to that of the pointer-generator networks (See et al., 2017). The switch is a feedforward layer with sigmoid activation (Eq. (8)). At time step t, its input is a concatenation of the decoder hidden state $\mathbf{h}_t^d$, context vector $\mathbf{c}_t$, and the embedding of the previously generated word $\mathbf{y}_{t-1}$. For predicting the next word, we combine the generation and copy probabilities, shown in Eq. (9). If a word w appears once or more in the input text, its copy probability ($\sum_{i:w_i=w} \alpha_{t,i}$) is the sum of the attention weights over all its occurrences. If w appears in both the vocabulary and source text, $P(w)$ is a weighted sum of the two probabilities.

$$p_{gen} = \sigma(\mathbf{W}^z[\mathbf{h}_t^d||\mathbf{c}_t||\mathbf{y}_{t-1}]) + b^z) \tag{8}$$

$$P(w) = p_{gen}P_{vocab}(w) + (1 - p_{gen}) \sum_{i:w_i=w} \alpha_{t,i} \tag{9}$$

3.2 Structure-Infused Copy Mechanisms

The aforementioned copy mechanism attends to source words based on their "semantic" importance encoded in $\{\alpha_{t,i}\}$, which measures the semantic relatedness of the encoder hidden state $\mathbf{h}_i^e$ and the decoder hidden state $\mathbf{h}_t^d$ (Eq. (4)). However, the source syntactic structure is ignored. This is problematic, because it hurts the system's ability to effectively identify summary-worthy source words that are syntactically important. We next propose three strategies to inject source syntactic structure to the copy mechanism.

3.2.1 Shallow Combination

Inspired by compressive summarization via structured prediction (Berg-Kirkpatrick et al., 2011; Almeida and Martins, 2013), we hypothesize that structural labels, such as the incoming dependency arc and the depth in a dependency parse tree, can be helpful to predict word importance. We consider six categories of structural labels in this work; they are presented in Table 2. Each structural label is mapped to a fixed-length, trainable structural embedding. However, a critical question remains as to where the structural embeddings should be injected in the existing neural architecture. This problem has not yet been systematically investigated. In this work, we compare two settings:

Structural info	Example
(1) depth in the dependency parse tree	0
(2) label of the incoming edge	'root'
(3) number of outgoing edges	3
(4) part-of-speech tag	'VBD'
(5) absolution position in the source text	9
(6) relative position in the source text	(0.5, 0.6]

Table 2: Six categories of structural labels. Example labels are generated for word 'had' in Figure 1. Relative word positions are discretized into ten buckets.

- **Struct+Input** concatenates structural embeddings of position i (flattened into one vector $\mathbf{s}_i^e$) with the source word embedding $\mathbf{x}_i$ and uses them as a new form of input to the encoder: $\mathbf{x}_i \Rightarrow [\mathbf{x}_i||\mathbf{s}_i^e]$;

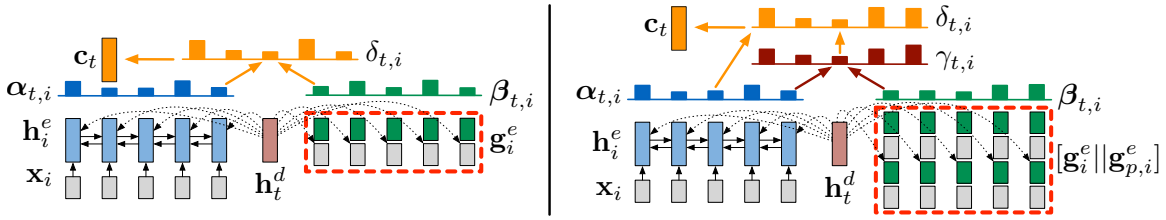

Figure 3: System architectures for 'Struct+2Way+Word' (left) and 'Struct+2Way+Relation' (right). $\beta_{t,i}$ (left) measures the structural importance of the i-th source word; $\beta_{t,i}$ (right) measures the saliency of the dependency edge pointing to the i-th source word. $\mathbf{g}_{p,i}^e$ is the structural embedding of the parent. In both cases $\delta_{t,i}$ replaces $\alpha_{t,i}$ to become the new attention value used to estimate the context vector $\mathbf{c}_t$.

- **Struct+Hidden** concatenates structural embeddings of position i (flattened) with the encoder hidden state $\mathbf{h}_i^e$ and uses them as a new form of hidden states: $\mathbf{h}_i^e \Rightarrow [\mathbf{h}_i^e||\mathbf{s}_i^e]$.

The architectural difference is illustrated in Figure 2. Structural embeddings are important complements to existing neural architectures. However, it is unclear whether they should be supplied as input to the encoder or be left out of the encoding process and directly concatenated with the encoder hidden states. This is a critical question we seek to answer by comparing the two settings. Note that an alternative setting is to separately encode words and structural labels using two RNN encoders, we consider this as a subproblem of the "Struct+Input" case.

The above models complement state-of-the-art by combining semantic and structural signals to determine summary-worthy content. Intuitively, a source word is copied to the summary for two reasons: it contains salient semantic content, or it serves a critical syntactic role in the source sentence. Without explicitly modeling the two factors, 'semantics' can outweigh 'structure,' resulting in summaries that fail to keep the original meaning intact. In the following we propose a two-way mechanism to separately model the "semantic" and "structural" importance of source words.

3.2.2 2-Way Combination (+Word)

Our new architecture involves two attention matrices that are parallel to each other, denoted by $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$. $\alpha_{t,i}$ is defined as previously in Eq. (3-4). It represents the "semantic" aspect, calculated as the strength of interaction between the encoder hidden state $\mathbf{h}_i^e$ and the decoder hidden state $\mathbf{h}_t^d$. In contrast, $\beta_{t,i}$ measures the "structural" importance of the i-th input word to generating the t-th output word, calculated by comparing the structure-enhanced embedding $\mathbf{g}_i^e$ with the decoder hidden state $\mathbf{h}_t^d$ (Eq. (10-11)). We use $\mathbf{g}_i^e = [\mathbf{s}_i^e||\mathbf{x}_i]$ as a primitive (unencoded) representation of the i-th source word.

We define $\delta_{t,i} \propto \alpha_{t,i} + \epsilon\beta_{t,i}$ as a weighted sum of $\alpha_{t,i}$ and $\beta_{t,i}$, where a trainable coefficient ϵ is introduced to balance the contribution from both sides (Eq. (12)). Merging semantic and structural salience at this stage allows us to acquire an accurate estimate of how important the i-th source word is to predicting the t-th output word. $\delta_{t,i}$ replaces $\alpha_{t,i}$ to become the new attention value. It is used to calculate the context vector $\mathbf{c}_t$ (Eq. (13)). A reliable estimate of $\mathbf{c}_t$ is crucial as it is used to estimate the generation probability over the vocabulary ($P_{vocab}(w)$, Eq. (6-7)), the switch value (p_{gen}, Eq. (8)), and ultimately used to predict the next word ($P(w)$, Eq. (9)).

$$f_{t,i} = \mathbf{u}^\top \tanh(\mathbf{W}^f[\mathbf{g}_i^e||\mathbf{h}_t^d] + \mathbf{b}^f) \tag{10}$$

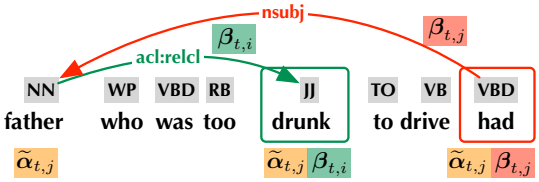
$$\beta_{t,i} = \frac{\exp(f_{t,i})}{\sum_{i'=1}^{S}\exp(f_{t,i'})} \tag{11}$$

$$\delta_{t,i} = \frac{\alpha_{t,i} + \epsilon\beta_{t,i}}{\sum_{i'=1}^{S}(\alpha_{t,i'} + \epsilon\beta_{t,i'})} \tag{12}$$

$$\mathbf{c}_t = \sum_{i=1}^{S}\delta_{t,i}\mathbf{h}_i^e \tag{13}$$

3.2.3 2-Way Combination (+Relation)

We observe that salient source relations also play a critical role in predicting the next word. For example, if a dependency edge ("father" $\xleftarrow{\text{nsubj}}$ "had") is salient and "father" is selected to be included in the summary, it is likely that "had" will be selected next such that a salient source relation ("nsubj") is preserved in the summary. Because summary words tend to follow the word order of the original, we assume selecting a source word and including it in the summary has an impact on its subsequent source words, but not the reverse.



In this formulation we use $\beta_{t,i}$ to capture the saliency of the dependency edge pointing to the i-th source word. Thus, an edge $w_j \leftarrow w_i$ has its salience score saved in $\beta_{t,j}$; and conversely, an edge $w_j \rightarrow w_i$ has its salience score in $\beta_{t,i}$. $\boldsymbol{\beta}$ is calculated in the same way as described in Eq. (10-11). However, we replace $\mathbf{g}_i^e$ with $[\mathbf{g}_i^e||\mathbf{g}_{p,i}^e]$ so that a dependency edge is characterized by the embeddings of its two endpoints ($\mathbf{g}_{p,i}^e$ is the parent embedding). The architectural difference between "Struct+2Way+Word" and "Struct+2Way+Relation" is illustrated in Figure 3.

To obtain the likelihood of w_j being selected to the summary prior to time step t, we define $\widetilde{\alpha}_{t,j} = \sum_{t'=0}^{t-1} \alpha_{t',j}$ that sums up the individual probabilities up to time step t-1. Assume there is a dependency edge $w_j \rightarrow w_i$ (j<i) whose salience score is denoted by $\beta_{t,i}$. At time step t, we calculate $\widetilde{\alpha}_{t,j}\beta_{t,i}$ (or $\widetilde{\alpha}_{t,j}\beta_{t,j}$ for edge $w_j \leftarrow w_i$) as the probability of w_i being selected to the summary, given that *one* of its prior words w_j (j<i) is included in the summary and there is a dependency edge connecting the two. By summing the impact over *all* its previous words, we obtain the likelihood of the i-th source word being included to the summary at time step t in order to preserve salient source relations; this is denoted by $\gamma_{t,i}$ (Eq. (15)). Next, we define $\delta_{t,i} \propto \alpha_{t,i} + \epsilon\gamma_{t,i}$ as a weighted combination of semantic and structural salience (Eq. (16)). $\delta_{t,i}$ replace $\alpha_{t,i}$ to become the new attention values used to estimate the context vector $\mathbf{c}_t$ (Eq. (13)). Finally, the calculation of generation probabilities $P_{vocab}(w)$, switch value p_{gen}, and probabilities for predicting the next word $P(w)$ remains the same as previously (Eq. (6-9)).

$$\widetilde{\alpha}_{t,j} = \sum_{t'=0}^{t-1} \alpha_{t',j} \tag{14}$$

$$\gamma_{t,i} = \sum_{j:j<i} \begin{cases} \widetilde{\alpha}_{t,j}\beta_{t,i} & \text{if } w_j \rightarrow w_i \\ \widetilde{\alpha}_{t,j}\beta_{t,j} & \text{if } w_j \leftarrow w_i \end{cases} \tag{15}$$

$$\delta_{t,i} = \frac{\alpha_{t,i} + \epsilon\gamma_{t,i}}{\sum_{i'=1}^{S}(\alpha_{t,i'} + \epsilon\gamma_{t,i'})} \tag{16}$$

3.3 Learning Objective and Beam Search

We next describe our learning objective, including a coverage-based regularizer (See et al., 2017), and a beam search with reference mechanism (Tan et al., 2017). We want to investigate the effectiveness of these techniques on sentence summarization, which has not been explored in previous work.

Learning objective. Our training proceeds by minimizing a per-target-word cross-entropy loss function. A regularization term is applied to the $\boldsymbol{\alpha}$ matrix. Recall that $\alpha_{t,i} \in [0, 1]$ measures the interaction strength between the t-th output word and the i-th input word. Naturally, we expect a 1-to-1 mapping between the two words. The coverage-based regularizer, proposed by See et al., (2017), encourages this behavior by tracking the historical attention values attributed to the i-th input word (up to time step t-1), denoted by $\widetilde{\alpha}_{t,i} = \sum_{t'=0}^{t-1} \alpha_{t',i}$. The approach then takes the minimum between $\widetilde{\alpha}_{t,i}$ and $\alpha_{t,i}$, which has the practical effect of forcing $\alpha_{t,i}$ ($\forall t$) to be close to either 0 or 1, otherwise a penalty will be applied. The regularizer Ω is defined in Eq. (17), where M is the size of the mini-batch, S and T are the lengths of the source

and target sequences. For two-way copy mechanisms, $\boldsymbol{\delta}$ replaces $\boldsymbol{\alpha}$ to become the new attention values, we therefore apply regularization to $\boldsymbol{\delta}$ instead of $\boldsymbol{\alpha}$. When the regularizer applies, the objective becomes minimizing $(\mathcal{L} + \Omega)$.

$$\Omega = \lambda \sum_{m=1}^{M} \frac{1}{T^{(m)} S^{(m)}} \sum_{t=1}^{T^{(m)}} \sum_{i=1}^{S^{(m)}} \Big(\min(\widetilde{\alpha}_{t,i}, \alpha_{t,i}) \Big) \tag{17}$$

Beam search with reference. During testing, we employ greedy search to generate system summary sequences. For the task of summarization, the ground truth summary sequences are usually close to the source texts. This property can be leveraged in beam search. Tan et al., (2017) describe a beam search with reference mechanism that rewards system summaries that have a high degree of bigram overlap with the source texts. We describe it in Eq. (18), where where $\mathcal{S}(w)$ denotes the score of word w. $\mathcal{B}(\mathbf{y}_{<t}, \mathbf{x})$ measures the number of bigrams shared by the system summary (up to time step t-1) and the source text; $\{\mathbf{y}_{<t}, w\}$ adds a word w to the end of the system summary. The shorter the source text (measured by length S), the more weight a shared bigram will add to the score of the current word w. A hyperparameter η controls the degree of closeness between the system summary and the source text.

$$\mathcal{S}(w) = \log P(w) + \eta \frac{\mathcal{B}(\{\mathbf{y}_{<t}, w\}, \mathbf{x}) - \mathcal{B}(\mathbf{y}_{<t}, \mathbf{x})}{S} \tag{18}$$

4 Experiments

We evaluate the proposed structure-infused copy mechanisms for summarization in this section. We describe the dataset, experimental settings, baselines, and finally, evaluation results and analysis.

4.1 Data Sets

We evaluate our proposed models on the Gigaword summarization dataset (Parker, 2011; Rush et al., 2015). The task is to reduce the first sentence of an article to a title-like summary. We obtain dependency parse trees for source sentences using the Stanford neural network parser (Chen and Manning, 2014). We also use the standard train/valid/test data splits. Following (Rush et al., 2015), the train and valid splits are pruned[2] to improve the data quality. Spurious pairs that are repetitive, overly long/short, and pairs whose source and summary sequences have little word overlap are removed. No pruning is performed for instances in the test set. The processed corpus contains 4,018K training instances. We construct two (non-overlapped) validation sets: "valid-4096" contains 4,096 randomly sampled instances from the valid split; it is used for hyperparameter tuning and early stopping. "valid-2000" is used for evaluation; it allows the models to be trained and evaluated on pruned instances. Finally, we report results on the standard Gigaword test set (Rush et al., 2015) containing 1,951 instances ("test-1951").

4.2 Experimental Setup

We use the Xavier scheme (Glorot and Bengio, 2010) for parameter initialization, where weights are initialized using a Gaussian distribution $\mathbf{W}_{i,j} \sim \mathcal{N}(0, \sigma)$, $\sigma = \sqrt{\frac{2}{n_{in}+n_{out}}}$; n_{in} and n_{out} are numbers of the input and output units of the network; biases are set to be 0. We further implement two techniques to accelerate mini-batch training. First, all training instances are sorted by the source sequence length and partitioned into mini-batches. The shorter sequences are padded to have the same length as the longest sequence in the batch. All batches are shuffled at the beginning of each epoch. Second, we introduce a variable-length batch vocabulary containing only source words of the current mini-batch and words of the output vocabulary. $P(w)$ in Eq. (9) only needs to be calculated for words in the batch vocabulary. It is magnitudes smaller than a direct combination of the input and output vocabularies. Finally, our input vocabulary contains the most frequent 70K words in the source texts and summaries. The output vocabulary contains 5K words by default. More network parameters are presented in Table 3.

[2] https://github.com/facebookarchive/NAMAS/blob/master/dataset/filter.py

Input vocabulary size	70K
Output vocabulary size	5K (default)
Dim. of word embeddings	100
Dim. of structural embeddings	16
Num. of encoder/decoder hidden units	256
Adam optimizer (Kingma and Ba, 2015)	lr = 1e-4
Coeff. for coverage-based regularizer	$\lambda = 1$
Coeff. for beam search with reference	$\eta \approx 13.5$
Beam size	$K = 5$
Minibatch size	$M = 64$
Early stopping criterion (max 20 epochs)	valid. loss
Gradient clipping (Pascanu et al., 2013)	g $\in$ [-5, 5]

Table 3: Parameter settings of our summarization system.

System	Gigaword Valid-2000 R-1	R-2	R-L
Baseline	42.48	21.34	40.18
Struct+Input	42.44	21.75	40.46
Struct+Hidden	42.88	21.81	40.63
Struct+2Way+Word	**43.21**	21.84	**40.86**
Struct+2Way+Relation	42.83	**21.85**	40.60

Table 4: Results on the Gigaword valid-2000 set (full-length F1). Models implementing the structure-infused copy mechanisms ("Struct+*") outperform the baseline.

S:	the government filed another round of criminal charges in a widening stock options scandal
T:	options scandal widens
B:	government files more charges in stock options scandal
I:	another round of criminal charges in stock options scandal
H:	charges filed in stock options scandal
W:	another round of criminal charges in stock options scandal
R:	government files another round of criminal charges in options scandal

Table 5: Example system summaries. 'S:' source; 'T:' target; 'B:' baseline; 'I:' Struct+Input; 'H:' Struct+Hidden; 'W:' 2Way+Word; "R:" 2Way+Relation. "2Way+Relation" is able to preserve important source relations in the summary, e.g., "government ~~‹nsubj~~ files," "files ~~dobj›~~ round," and "round ~~nmod›~~ charges."

S:	red cross negotiators from rivals north korea and south korea held talks wednesday on emergency food shipments to starving north koreans and agreed to meet again thursday
T:	koreas meet in beijing to discuss food aid from south eds
B:	north korea , south korea agree to meet again
I:	north korea , south korea meet again
H:	north korea , south korea meet on emergency food shipments
W:	north korea , south korea hold talks on food shipments
R:	north korea , south korea hold talks on emergency food shipments

Table 6: Example system summaries. "Struct+Hidden" and "2Way+Relation" successfully preserve salient source words ("emergency food shipments"), which are missed out by other systems. We observe that copying "hold talks" from the source also makes the resulting summaries more informative than using the word "meet."

4.3 Results

ROUGE results on valid set. We first report results on the Gigaword valid-2000 dataset in Table 4. We present R-1, R-2, and R-L scores (Lin, 2004) that respectively measures the overlapped unigrams, bigrams, and longest common subsequences between the system and reference summaries[3]. Our baseline system ("Baseline") implements the seq2seq architecture with the basic copy mechanism (Eq. (1-9)). It is a strong baseline that resembles the pointer-generator networks described in (See et al., 2017). The structural models ("Struct+*") differ from the baseline only on the structure-infused copy mechanisms. All models are evaluated without the coverage regularizer or beam search (§3.3) to ensure fair comparison. Overall, we observe that models equipped with the structure-infused copy mechanisms are superior to the baseline, suggesting that combining source syntactic structure with the copy mechanism is effective. We found that the "Struct+Hidden" architecture, which directly concatenates structural embeddings with the encoder hidden states, outperforms "Struct+Input" despite that the latter requires more parameters. "Struct+2Way+Word" also demonstrates strong performance, achieving 43.21%, 21.84%, and 40.86% F_1 scores, for R-1, R-2, and R-L respectively.

ROUGE results on test set. We compare our proposed approach with a range of state-of-the-art neural summarization systems. Results on the standard Gigaword test set ("test-1951") are presented in Table 7. Details about these systems are provided in Table 8. Overall, our proposed approach with structure-infused pointer networks perform strongly, yielding ROUGE scores that are on-par with or surpassing state-of-the-art published systems. Notice that the scores on the valid-2000 dataset are generally higher than those of test-1951. This is because the (source, summary) pairs in the Gigaword test set are not pruned (see §4.1). In some cases, none (or very few) of the summary words appear in the source. This may cause difficulties to the systems equipped with the copy mechanism. The "Struct+2Way+Word" architecture that respectively models the semantic and syntactic importance of source words achieves the highest scores. It outperforms its counterpart of "Struct+2Way+Relation," which seeks to preserve source dependency relations in summaries. We conjecture that the imperfect dependency parse trees generated

Table 7: Results on the Gigaword test-1951 set (full-length F1). Models with structure-infused copy mechanisms ("Struct+*") perform well. Their R-2 F-scores are on-par with or outperform state-of-the-art published systems.

ABS and **ABS+** (Rush et al., 2015) are the first work introducing an encoder-decoder architecture for summarization.

Luong-NMT (Chopra et al., 2016) is a re-implementation of the attentive stacked LSTM encoder-decoder of Luong et al. (2015a).

RAS-LSTM and **RAS-Elman** (Chopra et al., 2016) describe a convolutional attentive encoder that ensures the decoder focuses on appropriate words at each step of generation.

ASC+FSC1 (Miao and Blunsom, 2016) presents a generative auto-encoding sentence compression model jointly trained on labelled/unlabelled data.

lvt2k-1sent and **lvt5k-1sent** (Nallapati et al., 2016) address issues in the attentive encoder-decoder framework, including modeling keywords, capturing sentence-to-word structure, and handling rare words.

Multi-Task w/ Entailment (Pasunuru et al., 2017) combines entailment with summarization in a multi-task setting.

DRGD (Li et al., 2017b) describes a deep recurrent generative decoder learning latent structure of summary sequences via variational inference.

Table 8: Existing summarization methods.

by the parser may affect the "Struct+2Way+Relation" results. However, because the Gigaword dataset does not provide gold-standard annotations for parse trees, we could not easily verify this and will leave it for future work. In Table 5 and 6, we present system summaries produced by various models.

Linguistic quality. To further gauge the summary quality, we hire human workers from the Amazon Mechanical Turk platform to rate summaries on a Likert scale of 1 to 5 according to three criteria (Zhang and Lapata, 2017): *fluency* (is the summary grammatical and well-formed?), *informativeness* (to what extent is the meaning of the original sentence preserved in the summary?), and *faithfulness* (is the summary accurate and faithful to the original?). We sample 100 instances from the test set and employ 5 turkers to rate each summary; their averaged scores are presented in Table 9. We found that "Struct+2Way+Relation" outperforms "Struct+Input" on all three criteria. It also compares favorably to ground-truth summaries on "fluency" and "faithfulness." On the other hand, the ground-truth summaries, corresponding to article titles, are judged as less satisfying according to human raters.

System	Info.	Fluency	Faithful.
Struct+Input	2.9	3.3	3.0
Struct+2Way+Relation	3.0	3.4	3.1
Ground-truth Summ.	3.2	3.5	3.1

Table 9: Informativeness, fluency, and faithfulness scores of summaries. They are rated by Amazon turkers on a Likert scale of 1 (worst) to 5 (best). We choose to evaluate Struct+2Way+Relation (as oppose to 2Way+Word) because it focuses on preserving source relations in the summaries.

Dependency relations. We investigate the source dependency relations preserved in the summaries in Table 10. A source relation is considered preserved if both its words appear in the summary. We observe that the models implementing structure-infused copy mechanisms (e.g., "Struct+2Way+Word") are more likely to preserve important dependency relations in the summaries, including nsubj, dobj, amod, nmod, and nmod:poss. Dependency relations that are less important (mark, case, conj, cc, det) are less likely to be preserved. These results show that our structure-infused copy mechanisms can learn to recognize the importance of dependency relations and selectively preserve them in the summaries.

Coverage and reference beam. In Figure 11, we investigate the effect of applying the coverage regularizer ("coverage") and reference-based beam search ("ref_beam") (§3.3) to our models. The coverage regularizer is applied in a second training stage, where the system is trained for an extra 5 epochs with coverage and the model yielding the lowest validation loss is selected. Both coverage and ref_beam can improve the system performance. Our observation suggests that ref_beam is an effective addition to shorten the gap between different systems.

System	nsubj	dobj	amod	nmod	nmod:poss	mark	case	conj	cc	det
Baseline	7.23	12.07	20.45	8.73	12.46	15.83	14.84	9.72	5.03	2.22
Struct+Input	7.03	11.72	19.72	**9.17**↑	12.46	15.35	14.69	9.55	4.67	1.97
Struct+Hidden	**7.78**↑	**12.34**↑	**21.11**↑	**9.18**↑	**14.86**↑	14.93	**15.84**↑	9.47	3.93	**2.65**↑
Struct+2Way+Word	**7.46**↑	**12.69**↑	**20.59**↑	**9.03**↑	**13.00**↑	15.83	14.43	8.86	3.48	1.91
Struct+2Way+Relation	**7.35**↑	**12.07**↑	**20.59**↑	8.68	**13.47**↑	15.41	14.39	9.12	4.30	1.89

Table 10: Percentages of source dependency relations (of various types) preserved in the system summaries.

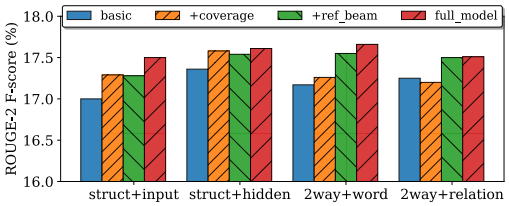

Table 11: Effects of applying the coverage regularizer and the reference beam search to structural models, evaluated on test-1951. Combining both yields the highest scores.

$\|V\|$	R-2	Train Speed	InVcb	InVcb+Src
1K	13.99	2.5h/epoch	60.57	76.04
2K	15.35	2.7h/epoch	69.71	80.72
5K	17.25	3.2h/epoch	79.98	86.51
10K	17.62	3.8h/epoch	88.26	92.18

Table 12: Results of the "Struct+2Way+Relation" system trained using output vocabularies of various sizes ($|V|$), evaluated on test-1951 w/o coverage or ref_beam. The training speed is calculated as the elapsed time (hours) per epoch, tested on a GTX 1080Ti GPU card.

Output vocabulary size. Finally, we investigate the impact of the output vocabulary size on the summarization performance in Table 12. All our models by default use an output vocabulary of 5K words in order to make the results comparable to state-of-the-art-systems. However, we observe that there is a potential to further boost the system performance (17.25→17.62 R-2 F1-score, w/o coverage or ref_beam) if we had chosen to use a larger vocabulary (10K) and can endure a slightly longer training time (1.2x). In Table 12, we further report the percentages of reference summary words covered by the output vocabulary ("InVcb") and covered by either the output vocabulary or the source text ("InVcb+Src"). The gap between the two conditions shortens as the size of the output vocabulary is increased.

5 Conclusion

In this paper, we investigated structure-infused copy mechanisms that combine source syntactic structure with the copy mechanism of an abstractive summarization system. We compared various system architectures and showed that our models can effectively preserve salient source relations in summaries. Results on benchmark datasets showed that the structural models are on-par with or surpass state-of-the-art published systems.

Abstract

Automatic image description systems typically produce generic sentences that only make use of a small subset of the vocabulary available to them. In this paper, we consider the production of generic descriptions as a lack of diversity in the output, which we quantify using established metrics and two new metrics that frame image description as a word recall task. This framing allows us to evaluate system performance on the head of the vocabulary, as well as on the long tail, where system performance degrades. We use these metrics to examine the diversity of the sentences generated by nine state-of-the-art systems on the MS COCO data set. We find that the systems trained with maximum likelihood objectives produce less diverse output than those trained with additional adversarial objectives. However, the adversarially-trained models only produce more types from the head of the vocabulary and not the tail. Besides vocabulary-based methods, we also look at the compositional capacity of the systems, specifically their ability to create compound nouns and prepositional phrases of different lengths. We conclude that there is still much room for improvement, and offer a toolkit to measure progress towards the goal of generating more diverse image descriptions.

1 Introduction

Automatic image description is a challenging task because natural language and the visual world both have an unbounded range of variation (Bernardi et al., 2016). Computational image description models are trained to generalize over datasets of images with multiple human descriptions, however, much of the variation present in these descriptions is lost in a trained model. Dai et al. (2017) note that the descriptions generated by recurrent neural networks using a maximum-likelihood objective are "overly rigid and lacking in variability." This rigidity and lack of variability in the output of state-of-the-art models is unfortunate because human descriptions are the exact opposite of this: Devlin et al. (2015) found that humans typically produce unique descriptions, i.e. only 4.8% of the human-described evaluation data in the MS COCO data set (Lin et al., 2014) also occur in the training data.

The lack of variability in machine-generated text is not limited to automatic image description; it is a general problem in natural language generation. Simply put: automatically generated text quickly becomes boring or repetitive. Recent efforts to address this problem include using maximum mutual information as an objective function, rather than the likelihood of the output, to improve the variablity of a neural conversation model (Li et al., 2016). Castro Ferreira et al. (2016) focused on the deterministic nature of NLG systems, in the sense that they repeatedly use the same referential forms to refer to the same entity in longer stretches of text. They addressed this problem by explicitly training their model to mimic human variability for referring expression generation.

In the image description literature, there have been two recent approaches to generating diverse outputs: (i) learn different description distributions simultaneously to generate multiple different descriptions for the same image (Wang et al., 2016); and (ii) augmenting a model with an additional (conditional) Generative Adversarial Network objective (Goodfellow et al., ; Mirza and Osindero, 2014, GAN)

Proceedings of the 27th International Conference on Computational Linguistics, pages 1730–1741
Santa Fe, New Mexico, USA, August 20-26, 2018.

to generate more natural and diverse descriptions. In this setting, the caption generator tries to fool a discriminator that is trying to distinguish human image descriptions from machine-generated ones (Dai et al., 2017; Shetty et al., 2017). From these papers, two definitions of diversity emerge:

Local diversity: The ability to generate many different descriptions for the same image.
Global diversity: The ability to use (many different combinations of) many different words.

The former is *local* because it can be evaluated for individual images. The latter is *global*, because it is a property at the corpus level. This paper focuses on global diversity, which means that we will study whether systems are able to produce as many different words and phrases as humans do in their descriptions of images. We know that word frequencies follow a *Zipfian* (or *power law*) distribution (Zipf, 1949; Van Heuven et al., 2014; Corral et al., 2015), which means that a small subset of the vocabulary accounts for the largest part of the data. Natural language processing systems trained on corpus data are sensitive to this, and tend to overfit on the head of the distribution (e.g. Postma et al., 2016). We will show that this also holds for the output of image description systems: all systems considered in this paper mainly use the top 20% most frequent words.

In this paper, we consider the following question: **How can we measure the diversity of the output generated by an image description model?** There is currently a lack of consensus about how to measure the diversity of model output but the metrics used thus-far fall into four broad areas:

(i) Modified[1] type-token ratio: the number of distinct unigrams or bigrams, divided by the total number of generated words (Li et al., 2016; Shetty et al., 2017).
(ii) mBLEU: compute the average BLEU score (Papineni et al., 2002) between each description and the other descriptions generated for the same image. This metric can only be used to evaluate models that produce multiple descriptions per image (Wang et al., 2016; Shetty et al., 2017).
(iii) Model-internal: a Generative Adversarial evaluator network that judges whether descriptions are more natural-sounding and semantically relevant than human descriptions (Dai et al., 2017); and
(iv) vocabulary size and the proportion of uniquely generated sentences (Shetty et al., 2017).

In addition to this lack of consensus about which metrics should be used to measure diversity, it is not known how state-of-the-art systems differ in terms of output diversity because it has not been standard practice to report this type of performance statistics. In this paper, we present an overview of metrics to assess the diversity of automatically generated English image descriptions, and compare them using nine state-of-the-art image description systems (Section 2). Besides covering existing metrics, like TTR and average sentence length, we also propose two word recall metrics that provide more information about the output vocabulary (Section 3). We also look at the compositional capacity of the different systems, by examining how many different compound nouns and prepositional phrases they can produce. We use these metrics to analyse how image description systems differ from human descriptions (Section 4). It is not our goal to evaluate the quality of the descriptions, though future research may find that more diverse descriptions are also more attractive for human readers (Section 5.2).

The main finding of our analysis is that recent GAN-based systems (Dai et al., 2017; Shetty et al., 2017), designed to produce more human-like image descriptions, do indeed produce more diverse output than the other MLE-based systems, but this increased diversity still mostly comes from the head of the vocabulary. In order to support future analyses, we release a toolkit to assess the output of any system and to compare the results with existing approaches.[2]

2 Existing metrics

This section discusses six general metrics to measure output diversity at the word level, along with a method to visually inspect the differences between systems. All of these methods require tokenized image descriptions – we use SpaCy 2.0.4 for this purpose and lowercase all of the tokens. The validation data is different from the system output, in that it consists of 5 reference descriptions per image, while

[1]This is similar to the type-token ratio (TTR; number of types divided by number of tokens), except that it is customary to compute TTR over a fixed number of tokens, as TTR decreases with corpus size (Youmans, 1990).

Table 1: System results: BLEU and Meteor scores; average sentence length; standard deviation of sentence length; mean-segmented type-token ratio (TTR); bigram TTR; percentage novel descriptions; coverage; and local recall with importance class 5. BLEU/Meteor scores are originally reported values, except for (Dai et al., 2017) and (Vinyals et al., 2017), which we computed on the validation set.

the systems only produce one description per image. Hence, for the validation data, we compute each score 5 times – once per reference description – and report the average.

1. The **average sentence length (ASL)** corresponds to the mean number of tokens per sentence.
2. The **standard deviation of the sentence length (SDSL)** is a measure of how much systems vary in their description lengths.
3. The **number of types** measures the number of unique word types in the output vocabulary.
4. The **mean segmented type-token ratio (TTR_1)** is the average number of types per 1000 tokens (Johnson, 1944). It is not affected by sentence length because it is computed for a fixed number of tokens. It is more difficult to artificially increase than the number of types because it is an average.
5. The **bigram TTR (TTR_2)** is the average number of bigram types per 1000 bigram tokens. This is based on Li et al.'s (2016) diversity metric (looking at bigram diversity), and the MSTTR metric (using a fixed size, averaging over multiple samples) so that it is not biased by description length.
6. The **percentage novel descriptions (%Novel)** refers to the generated descriptions that do not occur in the training data. Note that there may be duplicates among the novel descriptions.

2.1 Systems

For any analysis of output diversity, it is essential to have the generated descriptions. Unfortunately, this data is generally not available for most published systems. We contacted the authors of papers that appeared in relevant conferences and journals between 2016–2017[3], and received nine responses with descriptions generated for the MS COCO validation set. All these systems are listed in Table 1. With the exception of the two GAN-based systems (Dai et al., 2017; Shetty et al., 2017), the other systems are based on a conditioned recurrent neural network, trained using a Maximum Likelihood (MLE) objective.

2.2 Results

Table 1 presents the results for the metrics discussed above. We discuss each of them in turn.

Average sentence length. We observe that all models produce shorter sentences than humans, on average, perhaps also conveying less information. It also means that the BLEU *brevity penalty* (Papineni et al., 2002) and Meteor *length penalty* (Denkowski and Lavie, 2014) are affecting the metric scores. However, *producing shorter sentences* does not necessarily mean *producing worse descriptions*.

Standard deviation of sentence length. We observe that the GAN-based systems vary more than most other systems, but the systems by Liu et al. (2017) and Vinyals et al. (2017) have more variation than other MLE-based systems. Humans vary much more than any model in the length of their descriptions.

Number of types. The model by Liu et al. (2017) produces the fewest distinct word types (598), which severely limits the output diversity of the system. The two GAN-based models produce the most

[3]We surveyed AAAI, ACL, BMVC, COLING, CVPR, EACL, EMNLP, ICCV, ICLR, ICPR, IJCAI, NAACL, and NIPS.

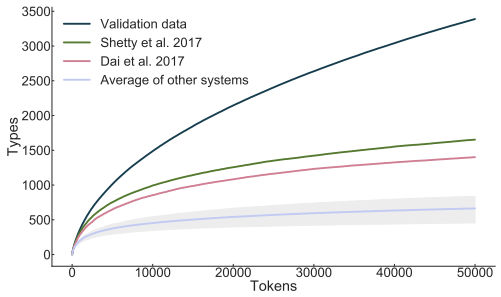

Figure 1: Type-token curves for nine systems. The validation data grows much faster than any of the systems and the GAN-based systems clearly outperform the other systems (shaded, with a line plotting the average performance).

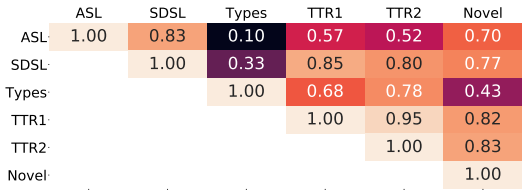

Figure 2: Absolute Spearman correlation between the different diversity metrics, computed over the results for the 9 different systems

distinct word types: 1,922 and 2,611. This is still much lower than the human type count, which averages at 9,200. The total number of types in the validation set is much higher, at 17,557.

TTR$_{\{1,2\}}$ We find that the GAN-based models again outperform the rest. But in terms of variation, there is still much room for improvement before they reach human parity.

Percentage novel descriptions. We find that the model by Vinyals et al. (2017) outperforms the rest (90.5% novel), with the GAN-based systems following close behind at 87.7% and 80.5% novel. The remainder of the systems reproduce a sentence from the training data approximately 50% of the time.

We visualize the differences between the systems using a **type-token curve (TTC)**, which shows how the number of types develops as one reads more output tokens (Youmans, 1990). This curve was originally proposed to compare different texts, which means that sentence order is fixed. With automatic image description, we do not have this constraint. Rather than taking a single sample, and reading the image descriptions in a single order, we randomized the order of the descriptions ten times, and computed the average TTC for the validation data for each system. Figure 1 shows the type-token curves for the validation data and all systems. We observe that the TTC for the validation data develops much more rapidly than that of the systems. Moreover, we can clearly see how the two GAN-based systems stand out from the others in producing more diverse output.

We now inspect how strongly the different existing metrics correlate with each other. Figure 2 shows the correlation matrix between the different general metrics for measuring diversity. We observe that TTR_1 and TTR_2 are almost perfectly correlated. We conclude from this that a single type-token ratio measure is enough to capture differences between systems in their use of different types. The number of novel descriptions is strongly correlated with the type-token ratio. An intuitive explanation for this is that whenever a model produces more varied output, it is also more likely to produce novel output. In this light, it is interesting to observe the lower correlation between the number of types and the percentage of novel sentences. An explanation for this may be that producing more different types in total does not necessarily mean more diverse output. A system has to *consistently* produce more different types to have an impact.

3 Image description as word recall

Image description can be simplified to a word recall problem, where the goal is simply to produce a bag of words that should overlap with the reference data. By ignoring sentence structure, we can focus on the richness of the vocabulary, and study system performance for different classes of words. We distinguish between global recall, looking at the corpus as a whole, and local recall, looking at the corpus image-by-image. We also introduce ranking measures based on these concepts.

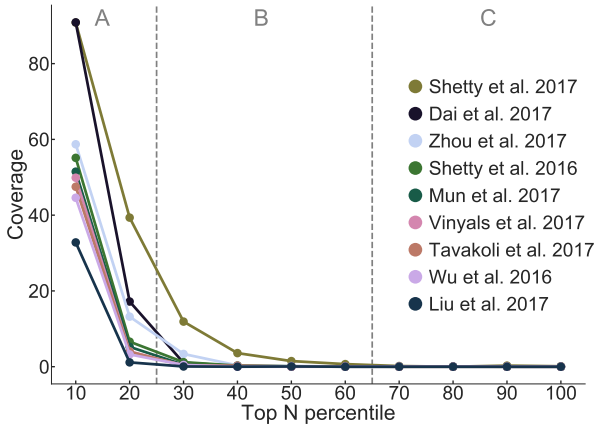

Figure 4: Coverage (equation 3) for different subsets of the learnable words. Recall for all systems is best for the top 10% most frequent words, but immediately drops for the next 10% of most frequent words.

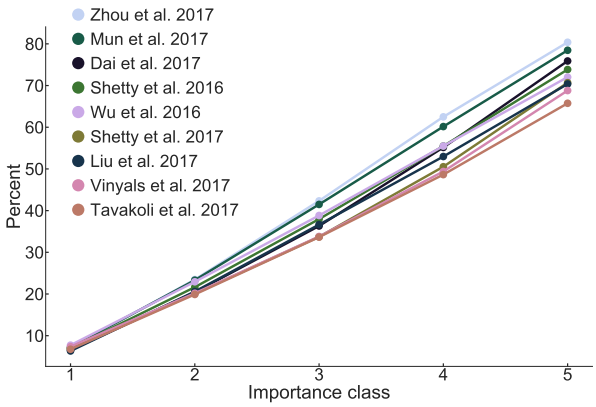

Figure 5: Local recall scores for all systems for each word importance class. Systems have low recall for words that occur only once in the reference descriptions, but their recall grows to 65-80% when all five references mention the same word.

3.1 Global recall

We formally define the *global recall* metrics in Figure 3. The sets TRAIN, EVAL, GEN correspond to the words that are in the training set, evaluation set, or those generated by the model. Any word type that is both in TRAIN and EVAL is *learnable* from the training data (Eq. 1).[4] Recalled words are those that are both learnable and generated by the model (Eq. 2). We quantify the success of a system as the percentage of learnable words it can recall, i.e. coverage (Eq. 3). Since the set of learnable word types is a subset of the word types in EVAL (this follows from (Eq. 1)), systems that are trained on the training data alone cannot recall *all* word types in EVAL. We define this limit in (Eq. 4). Intuitively, a model that has a higher coverage (Eq. 3) can recall more types from the learnable set (Eq. 1), therefore the model is producing a more globally diverse output.

Using the coverage metric to evaluate the nine systems, we find that the GAN-based systems of Shetty et al. (2017) and Dai et al. (2017) once again achieve the highest scores, achieving 15-20% coverage. This still leaves much room for improvement. We further explore coverage for 10 different subsets of the learnable word types, ranging from the 10% most to the 10% least frequent types in the validation data (based on the counts in the validation set).

$$\text{Learnable} = \text{TRAIN} \cap \text{EVAL} \quad (1)$$

$$\text{Recalled} = \text{GEN} \cap \text{Learnable} \quad (2)$$

$$\text{Coverage} = \frac{|\text{Recalled}|}{|\text{Learnable}|} \quad (3)$$

$$\text{Limit} = \frac{|\text{Learnable}|}{|\text{Eval}|} \quad (4)$$

Figure 3: Definitions for global recall.

Figure 4 shows the results. We see that the two GAN-based systems achieve almost 90% coverage of the most frequent types, but this score quickly degrades. Other systems only achieve about 60% coverage of the head, and degrade even more quickly than the GAN-based systems. Furthermore, we observe that the GAN-based systems only achieve better coverage than the other systems on the head of the distribution. Dai et al.'s system is only better for the $0-20\%$ most frequent terms (part A), and Shetty et al.'s (2017) system still shows higher coverage than the others up to the 60% mark (part B), but there is no difference for the rest of the lexicon (part C). We emphasize that, for global recall, a system only has to use a type *once* for it to be counted. The Limit for the MS COCO validation set is 0.75. This means that the other 25% (4356 words) in the validation set cannot be learned on the basis of the training set.

[4] We ignore zero-shot learning approaches that could learn to describe images using words outside the training data.

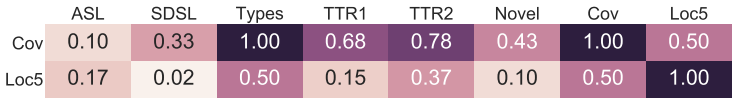

Figure 6: Spearman correlations between our coverage and local recall metric and the existing metrics.

3.2 Local recall

Local recall considers each image in the evaluation data as a separate word recall problem. We define the local target set as the union of the descriptions (sets of words, D) for an image I_i (Eq. 5). The goal is to recall the content words that are important to describe the image. We used SpaCy 2.0.4 to tag the descriptions and we only use adjectives, verbs, nouns, and adverbs as content words for the analysis.

Recalled words are those that are generated for a specific image I_i and occur in the local target set (Eq. 6). We define the importance of a word w for an image I in terms of the number of descriptions D that the word w occurs in (Eq. 7), resulting in a value between 1 and N (here N=5, as there are 5 descriptions per image). We use the importance metric to measure how well a system recalls the essential (with a score of 5) or the majority (3 or higher) words.

$$\text{Local}_i = \bigcup_{D_j \in I_i} \{w : w \in D_j\} \tag{5}$$

$$\text{Recalled}_i = \text{Gen}_i \cap \text{Local}_i \tag{6}$$

$$\text{Importance}(w, I) = |\{D : w \in D \wedge D \in I\}| \tag{7}$$

$$\text{Local recall score}_k = \frac{1}{|\text{Val}|} \sum_{I \in \text{Val}} \frac{|\{w : w \in \text{Recalled}_i \wedge \text{Importance}(w, I_i) = k\}|}{|\{w : w \in \text{Local}_i \wedge \text{Importance}(w, I_i) = k\}|} \tag{8}$$

The *local recall score* for words of *k* importance is computed by dividing the total number of recalled words with an importance of *k* by the total number of words with an importance of *k* (Eq. 8). Figure 5 shows the scores for all 9 systems. All models achieve local recall scores between 65% and 80% for types that are mentioned in all five references. This time, the GAN-based models do not outperform the rest, although they still have recalls around 75%. Although local recall is not strictly about diversity in output vocabulary, it does test each system's ability to use the right words at the right time (even if those words are rare).

Figure 6 shows the correlations between coverage (Eq. 3) and the local recall metric with the existing measures of diversity that were discussed earlier. We find that coverage and the number of types are perfectly correlated. Future work may find that these two measures do not always correlate perfectly, since coverage is based on the word types in the evaluation set. If future systems start producing more word types that are not in the evaluation set, we would see a divergence between coverage and number of types. Local recall (Loc_5 in the table), does not correlate as strongly with the other metrics.

3.3 Global ranking of omitted words

Instead of using local and global recall to produce scores summarizing model performance, we can use these metrics to construct a ranking of words typically produced by a model, or that a model typically fails to produce. We refer to ranking on the basis of global recall as *global ranking*. The most straightforward way to use global ranking is to construct a frequency table for all words in the evaluation set that are not recalled by a model. This gives us a list of the *most common omissions* for that model. Table 2 presents the 15 most frequent words that *all* systems failed to produce. The first ranking is based on the frequency in the training set; the second ranking on the basis of the validation set frequency. The advantage of the former is that we see which words are omitted even though there is sufficient evidence. The advantage of the latter is that we see which words are omitted, even though there are sufficient contexts in which those words could have been used.

Two types that immediately stand out are *'s* and *n't*. One possible reason that both these types were never produced by any system is that they are (cognitively) complex. The possessive *'s* indicates abstract

Global ranking	
Train	Validation
's	's
elderly	elderly
toast	toast
we	we
whole	thrown
laughing	whole
displays	ham
meadow	located
located	driver
ham	mat
nicely	n't
n't	heading
almost	displays
more	amongst
picking	simple

Local ranking		
Absolute	Relative	Relative$_{10}$
man	pillow	door
dog	kitten	paper
woman	flag	van
people	turkey	pink
cat	milk	head
umbrella	ice	doll
dogs	chips	hair
sign	rainbow	pool
pizza	potatoes	fork
ball	map	tray
cake	eggs	carrot
bear	cream	girls
bed	butter	apple
table	strawberries	women
elephant	pregnant	rice

Table 2: Global and local rankings of omitted words. These rankings show the most frequent words that *are not* produced at all (Global ranking), or that are most commonly omitted by the 9 image description systems (Local ranking).

relations between animate entities and objects that vary from scene to scene, making it difficult to learn how to use this type on the basis of visual information alone. The use of negations like *n't* typically requires the speaker to reason about whether or not an image conforms with their expectations (van Miltenburg et al., 2016). Another difficult case is *thrown*, which refers to a throwing action taking place before the picture was taken. Completing the top-3 in both rankings are *elderly* (253 occurrences in the training data, 140 in the validation data) and *toast* (237 and 124). These are less complex than the examples mentioned above, and could be determined on the basis of visual information alone. Further research is needed to determine why these words could not be produced by any system.

3.4 Local ranking of omitted words

We refer to rankings produced on the basis of local recall as *local ranking*. With local ranking, we can look at the words that models failed to produce most often. For reasons of space, we will only look at the words with importance class $k = 5$. Table 2 presents three local rankings:

1. An *absolute* ranking, where we look at the aggregate number of times each word was missed by the models under investigation.
2. A *relative* ranking, where we look at the rate at which each word was missed (Eq. 9). In the case of a tie, the most frequent word 'wins', so that words with the largest impact on model performance are ranked higher.

$$\text{MissRatio}(w) = \frac{\text{missed}(w)}{\text{missed}(w) + \text{recalled}(w)} \tag{9}$$

3. A relative ranking with an *occurrence threshold*, where each word with importance class $k = 5$ has to occur at least $n = 10$ times for each system. This eliminates words from the ranking that occur only a few times, but that are missed by all systems (so MissRatio(w) = 1).

All three rankings provide a starting point to explore system performance. For example, in the first ranking, we observe that some of the most common terms in the MS COCO dataset overall (*man* and *woman*) are often missed by image description systems, when all annotators *do* use those terms. Since these words are ranked high, they have a big impact on the quality of the descriptions. For reasons of space, we cannot discuss this example in depth, but a natural next step would be to look at example descriptions where systems fail to produce *man* or *woman* and identify potential causes of this behavior (e.g. an inability to determine people's gender using only visual information).

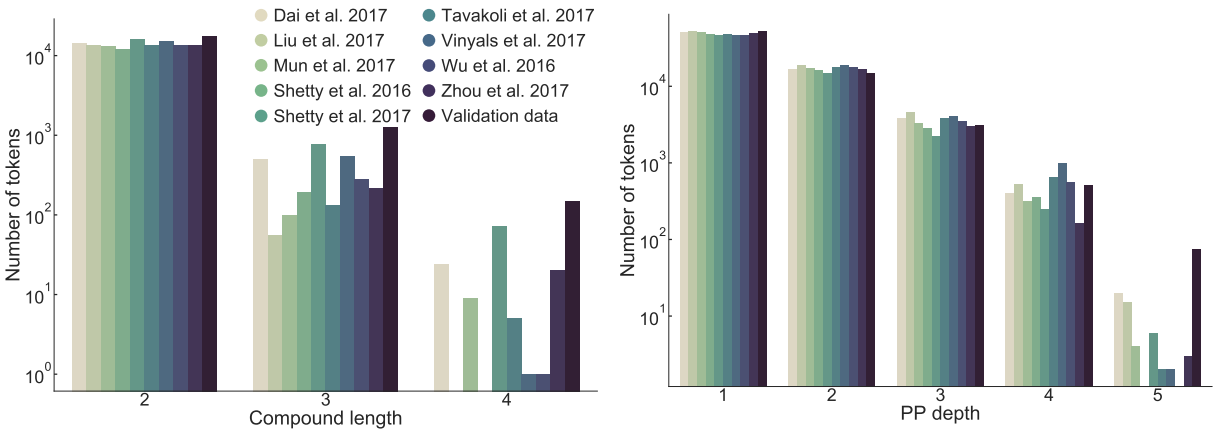

Figure 7: Histograms showing the number of tokens with compound length 2, 3, and 4, and the number of tokens with PP-depth 1–5, for all 9 systems and the MS COCO validation data. The validation data and the two GAN-based systems (Dai et al., 2017; Shetty et al., 2017) clearly have more compound tokens than the other systems. We do not observe this difference with PP depth.

4 Compound nouns and prepositional phrases

Beyond the word level, we can look at how words are combined to form new phrases (i.e. *compositionality* (Szabó, 2017)). We detect compound nouns using a part-of-speech tagger (SpaCy 2.0.4), assuming that any sequence of nouns is a nominal compound. We also compute the *compound ratio*: the average number of compounds per description. Figure 7 and Table 3 show the results. We observe that the validation data has a larger number of compound nouns, resulting in a higher compound ratio. When we separate the compounds by length, we see that humans produce most compounds in any category, and the GAN-based systems (Dai et al., 2017; Shetty et al., 2017) produce more compounds of length 3 and 4 than the other systems. The system by Vinyals et al. (2017) also stands out in this regard. Finally, we see that the GAN-based systems produce more compound types of length 2 than any other system, but there is still a big gap between the GAN-based systems and human performance.

We detect prepositional phrases (PPs), such as *in the kitchen*, using SpaCy's part-of-speech tagger and dependency parser. First, we identify each preposition in the description (e.g. *in, with, on*). Then we inspect the subtree headed by those prepositions. For each of those subtrees, we count their depth in terms of PP embeddings, e.g. *on top of a pan on a table* (1) has a depth of 3.

(1) [**on** top [**of** a pan [**on** a table]]]

We also compute the *preposition ratio*, which is the average number of prepositions per description. Table 3 shows the results. We do not see a big difference between the validation data and the systems. The only difference is that humans produce more types of PPs with depth 1: twice as many as the System by Dai et al. (2017). We conclude that image description systems still have much to gain in terms of compositionality. For further discussion of this topic, also see recent work by Lake and Baroni (2017).

	Compound stats		PP stats	
	Ratio	Types-2	Ratio	Types-1

Table 3: Statistics for nominal compounds and prepositional phrases. Compound ratio corresponds to the number of compounds per description. Types-2 refers to the number of compound types of length 2. Preposition ratio corresponds to the number of prepositional phrases per description. Types-1 refers to the number of PP types of depth 1.

5 Discussion and Future Research

5.1 Other metrics

In addition to the metrics proposed in this paper, there are other options that could be explored in future work. For reasons of space, we were also not able to cover metrics based on the **frequency distribution** of words in the training and validation data. We already mentioned Shetty et al.'s (2017) use of frequency ratios in the introduction. Their approach could be extended (perhaps also using log-likelihood (Rayson and Garside, 2000)) to produce a ranking of words that are over- or underused by a particular system. Overused words could be further analyzed by computing a '**local precision**' metric, measuring how often a generated word is also used in at least one reference description. Ferraro et al. (2015) present other metrics in their survey of datasets for vision and language research, including:

Yngve and Frazier measurements of syntactic complexity (Yngve, 1960; Frazier, 1985). Ferraro et al. (2015) found that the MS COCO and Flickr30K datasets have the most complex sentences, compared to other vision & language datasets. It is still an open question whether machine-generated descriptions are of equal complexity and, if not, what are the differences.

Abstract-to-concrete ratio The authors also compare the proportion of abstract words that each corpus contains. They count abstract words by using a list of abstract words compiled in earlier work. In the literature, there are two definitions of abstractness and concreteness. Concrete words are either said to be (1) more closely tied to perception, or (2) more specific (Spreen and Schulz, 1966; Theijssen et al., 2011). It is unclear which is meant by Ferraro et al., but it would be interesting to see whether machine-generated descriptions are more closely tied to perception than human descriptions, who also speculate about the context of the images (van Miltenburg, 2016).

Part-of-speech distribution Ferraro et al. (2015) compared the distribution of *nouns, verbs, adjectives*, and *other* parts of speech. Our work on detecting prepositional phrases and compound nouns (Section 4) suggests that differences in the distribution of parts of speech between human- and machine-generated descriptions could be an interesting avenue to explore.

Besides the measures discussed above, it may also be interesting to study some types of linguistic phenomena in more detail. For example, van Miltenburg et al. (2016) provide a thorough overview of the uses of *negations* in human-generated image descriptions. Even though this is a low-frequent (or long-tail) phenomenon, studying a subset of the image descriptions informs us about the human image description process, and the *cognitive requirements* to produce a description containing a negation. It remains to be seen whether image description systems could produce similar descriptions.

5.2 Limitations and human validation

Earlier work has shown that automated evaluation metrics do not correlate well with human judgments (Elliott and Keller, 2014; Kilickaya et al., 2017). For this reason, we should not blindly trust evaluation metrics in their assessment of system performance. Still, this paper only includes automatic, intrinsic metrics. This is by design: we want to gain insight into the descriptions, not to evaluate their quality.

While you cannot evaluate a system using only automated metrics, they do tell us something about how a system behaves. Future researchers could try to improve the diversity metrics while maintaining or improving the quality of the descriptions (ideally measured by human judgments). At that point, we should determine if more diverse descriptions (as measured by the metrics covered in this paper) are perceived by humans as more interesting to read. One issue is that it is unclear how human judgments could be used to rate the diversity of the generated descriptions, because diversity is a *global* property of the data. In other words: you cannot judge the diversity of a single description, because that is not what diversity is about. You can only judge the diversity of a larger collection of descriptions. One way to do this might be to generate descriptions for sets of very similar images, and have participants rate the diversity of different batches of descriptions.

6 Conclusion

We explored several metrics to analyze the richness of computer-generated image descriptions, most of which focus on diversity at the word level. In our analysis of the output of nine state-of-the-art systems, we found that there are clear differences between human and system output: humans produce more word types; more different types when averaged over multiple 1000-token samples; more compound nouns per description; more long compound nouns; and more compound noun types than image description systems. Not all of these observations hold for prepositional phrases: humans *don't* produce more prepositional phrases per description, and neither do they produce more embedded prepositional phrases, however, they *do* produce a larger number of different prepositional phrases than the systems. At the sentence level, we found that humans produce longer descriptions, vary more in their description length, and produce more novel descriptions. We also found that GAN-based systems produce more diverse descriptions than MLE-based systems. However, we caution that the GAN-based systems are the only ones in our evaluation that are designed with diversity in mind. Further research is needed to find out what kind of approach is best for producing diverse descriptions.

We also proposed to frame image description as a word recall task to further explore the differences highlighted above. *Global recall* looks at the types from all the validation data that are learnable from the training data. *Local recall* measures whether systems are able to produce content words that are mentioned in n reference descriptions for a single image. These metrics show that there is plenty of room for improvement, both in terms of vocabulary size, as well as using the right words at the right time. One way to approach this challenge is by *ranking* terms that are often missed by a system, and looking for ways to learn when to use these words.

We provide all the code and data to to apply the metrics discussed in this paper and compare systems. We encourage readers to use this overview to start exploring the output of their own image description systems, but note that the metrics covered here are just the tip of the iceberg. As more researchers focus on producing more diverse descriptions, we will hopefully also develop a better understanding of what makes a description human-like. Formalizing these notions enables us to measure our progress towards richer and more diverse descriptions.

Extractive Headline Generation Based on Learning to Rank for Community Question Answering

Tatsuru Higurashi[†] **Hayato Kobayashi**[†‡] **Takeshi Masuyama**[†] **Kazuma Murao**[†]

Abstract

User-generated content such as the questions on community question answering (CQA) forums does not always come with appropriate headlines, in contrast to the news articles used in various headline generation tasks. In such cases, we cannot use paired supervised data, e.g., pairs of articles and headlines, to learn a headline generation model. To overcome this problem, we propose an extractive headline generation method based on learning to rank for CQA that extracts the most informative substring from each question as its headline. Experimental results show that our method outperforms several baselines, including a prefix-based method, which is widely used in real services.

1 Introduction

Community question answering (CQA) is a service where users can post their questions and answer the questions from other users. The quality of a CQA service is inevitably linked to how many questions are answered in a short amount of time. To this end, the headline of a posted question plays a key role, as it is the first thing users see in a question list or push notification on a smartphone. However, questions in a CQA service do not always have appropriate headlines because the questions are written by various users who basically do not have any specialized knowledge in terms of writing such content, in contrast to news articles written by professional editors. In fact, the biggest CQA service in Japan, Yahoo! Chiebukuro[1], does not even provide an input field for headlines in the submission form of questions, as general users do not have enough patience and tend not to post questions if even just one required field is added to the form. This service alternatively uses the prefix of a question as its headline as in Figure 1(a), where the headline "はじめまして。よろしくお願いします。仕事…(*Nice to meet you. Thank you in advance. At work ...*)" is created from the prefix of the content. Obviously, this headline is uninformative because

Santa Fe, New Mexico, USA, August 20-26, 2018.

of the lack of actual content, which is related to an initial unrequited love of a woman in the workplace. Figure 1(b) shows how ineffective such an uninformative headline is for a smartphone push notification, where users would have practically zero motivation to click on it and answer since they cannot imagine what kind of question is being asked. This negative effect has been confirmed on a commercial CQA service (Section 2).

In this work, we take an extractive approach for improving uninformative headlines. Although there have recently been many studies on abstractive headline generation (as described in Section 6), we do not follow any of these approaches because the content we deal with has no correct headlines and also the abstractive methods can yield erroneous output. This latter issue is important in practical terms because correct output is critical for a commercial service. If by some chance an erroneous headline, or one including politically incorrect phrases, is sent to all users, the service's credibility can be lost instantly. Therefore, we formalize our task as an extraction problem of a fixed-length substring from a question as its headline. In this setting, we can assume that outputs never include such errors caused by the service, as the outputs are substrings of user-posted questions. Note that they have no coherence errors in selecting multiple sentences as in normal extractive summarization tasks. While it is true that these outputs might contain inappropriate expressions authored by users, this type of error is beyond our scope since it is a different inevitable problem. Furthermore, the situation of "the service generated an inappropriate expression by itself" is significantly worse than the situation of "a user posted an inappropriate question to the service, and the service displayed it". Therefore, it is difficult to directly use abstractive methods for commercial services from a business standpoint.

Our approach involves preparing headline candidates and ranking them. The formal description is as follows. Let q be a target question to be translated into a headline. We first prepare a set $S(q)$ of headline candidates from the question q. Note that the set $S(q)$ is restricted to a set of fixed-length substrings given a length n, i.e., $S(q) \subseteq \{x \mid x \preceq q, |x| = n\}$, where $x \preceq q$ means that x is a substring of q. Then we extract the best headline that maximizes a score function $f_q(x)$, which represents the "headline-ness" score of a candidate $x \in S(q)$ with respect to the target question q, as follows:

$$\mathrm{argmax}_{x \in S(q)} f_q(x). \tag{1}$$

To ensure simplicity of implementation and understandability from users, we use a set of the fixed-length prefixes of all sentences in a question q as the candidate set $S(q)$ (Section 3). Because the problem is to select the best candidate from among several targets, the score function $f_q(x)$ is naturally trained by learning to rank (Section 4).

The main contributions of this paper are as follows.

- We report empirical evidence of the negative effect of uninformative headlines on a commercial CQA service (Section 2). We additionally show that our task can reduce uninformative headlines by using simple dictionary matching, which dramatically improves the average answer rate of questions by as much as 2.4 times.
- We propose an extractive headline generation method based on learning to rank for CQA (Section 4) that extracts the most informative substring (prefix of mid-sentence) from each question as its headline. To the best of our knowledge, our work is the first attempt to address such a task from a practical standpoint, although there have been many related studies (Section 6). Experimental results show that our method outperforms several baselines, including the dictionary-based method (Section 5).
- We create a dataset for our headline generation task (Section 3), where headline candidates extracted from questions are ranked by crowdsourcing with respect to "headline-ness", that is, whether or not each headline candidate is appropriate for the headline of the corresponding question.

2 Negative Effect of Uninformative Headlines

We conducted A/B testing on the push notifications of smartphones in collaboration with Yahoo! Chiebukuro, as shown in Figure 1(b). We first prepared a dictionary of typical first sentences that cause uninformative headlines. This dictionary was manually selected from frequent first sentences and consists of 913 sentences including greetings such as "おはようございます (Good morning)", "こんにち

Changed uninformative	Unchanged uninformative	Informative
0.75%	0.31%	0.45%

Table 1: Average answer rates of three question groups in A/B testing.

は (Good afternoon)", and "はじめまして (Nice to meet you)", and fixed phrases such as "質問させてください (Can I ask you something)", "教えてください (Please tell me)", and "よろしくお願いします (Thank you in advance)". We assumed that a question with a prefix match in the dictionary has an uninformative prefix headline and classified such questions into an *uninformative group*. For convenience, we also classified the other questions into an *informative group*, although they might include not so informative headlines. We further randomly divided the uninformative group into two equal groups: *changed* and *unchanged*. In the changed uninformative group, each headline is extracted as the prefix of the first (informative) sentence that does not match with the dictionary, which is the same as `DictDel` explained in Section 5.2. The unchanged group remains in uninformative. For comparison of these groups, we used the average answer rate over notified questions in each group as an evaluation measure, defined as

$$\text{Average answer rate} = \frac{\text{No. of questions answered from the notification}}{\text{No. of notified questions}}. \quad (2)$$

Note that we use a percentage expression (%) for easy reading.

Table 1 shows the evaluation results of the A/B testing during a 1-month period (Feb. 2 – Mar. 4, 2018), where about three million questions were sent to users. Comparing the unchanged uninformative group with the informative group, we can see that the average answer rate of the uninformative questions, 0.31%, is actually lower than that of the informative questions, 0.45%. Comparing the changed and unchanged uninformative groups, the average answer rate of the changed questions, 0.75%, is much higher than that of the unchanged questions, 0.31%. This means that even a simple dictionary-based method can dramatically improve the quality of the uninformative headlines, i.e., by as much as 2.4 times. We confirmed that the difference is statistically significant on a one-tailed Wilcoxon signed-rank test ($p < 0.05$). Note that the average answer rate represents a conversion rate (or rate of target actions), which is more important than a click-through rate (or rate of initial actions). The average answer rate is one of the most important indicators for a CQA service, while the click-through rate can be meaninglessly high if the service sends headlines that are fake or too catchy. We should point out that low answer rates are sufficient for the service, since it has 44M users: i.e., each question has an average of 2.4 answers, as the service currently has 189M questions and 462M answers.

3 Dataset Creation

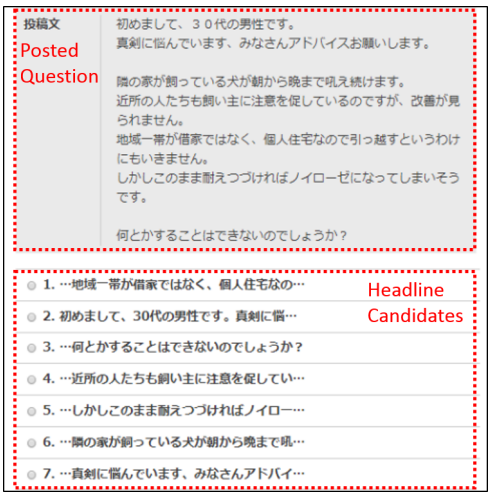
We created a dataset for our headline generation task based on the Yahoo! Chiebukuro dataset[2], which is a dataset including questions and answers provided from a Japanese CQA service, Yahoo! Chiebukuro. We first prepared headline candidates from this dataset as in Section 3.1 and then conducted a crowdsourcing task specified in Section 3.2. In Section 3.3, we report the results of the crowdsourcing task.

3.1 Preparation of Headline Candidates

We extracted only questions from the Chiebukuro dataset and split each question into sentences by using punctuation marks (i.e., the exclamation ("！"), question ("？"), and full stop ("。") marks). We regarded 20 Japanese characters that are basically extracted from each sentence as a headline candidate $x \in S(q)$ in Eq. (1), since this setting is used for push notifications in the actual service in Figure 1(b). More specifically, the headline candidate is created as follows:

1. If the sentence is the first one in the question, we extract the first 19 characters and put an ellipsis mark ("…") at the end.
2. Otherwise, we extract the first 18 characters and put ellipses at both the beginning and the end. This expression explicitly represents being mid-sentence so as to avoid weird headlines.

[2] `http://www.nii.ac.jp/dsc/idr/en/yahoo/yahoo.html`



(a) Example of our crowdsourcing task.

Posted Question:
Nice to meet you, I am a man in my 30s.
Please give me your advice on a pressing concern I have.

A dog kept in the next house barks from morning to night.
Neighbors have given the owner cautions against it, but there is no improvement.
This area has only private houses, not rented houses, so I cannot move out.
However, I will go crazy if I have to keep enduring this.

How can I effectively manage this problem?

Headline Candidates:
1. ... This area has only private houses, not rented ...
2. Nice to meet you, I am a man in my 30s. Please ...
3. ... How can I effectively manage this problem?
4. ... Neighbors have given the owner cautions against ...
5. ... However, I will go crazy if I have to keep ...
6. ... A dog kept in the next house barks from morning ...
7. ... Please give me your advice on a pressing concern ...

(b) English translation of left example.

Figure 2: Examples of (a) our crowdsourcing task and (b) its English translation.

In the case where the length of a candidate is less than 20 characters, we include some of the next sentence in order to maximize use of display space. We included questions with more than five sentences for the purpose of efficiently collecting ranking information. All told, we prepared 10,000 questions containing more than five headline candidates each.

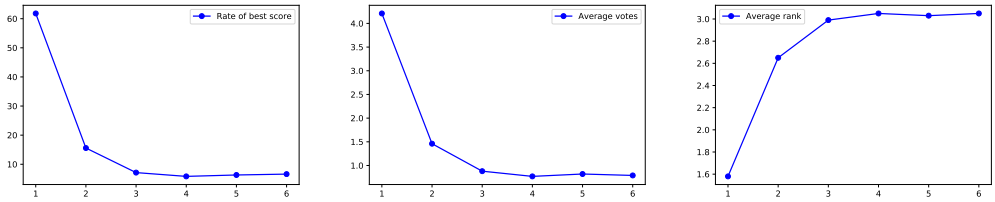
3.2 Crowdsourcing Task

Figure 2 shows an example of our crowdsourcing task (a) and its English translation (b). This task involves a posted question and headline candidates corresponding to the question. We asked workers to select the best candidate from options after reading the posted question. A relative evaluation, where workers select the best candidate, was used instead of an absolute evaluation, where workers select a score from 0 to 10 for each candidate, because we wanted to obtain as accurate a headline as possible, and it might be difficult for workers to select an appropriate absolute score. The workers were instructed as follows (English translation):

> Various candidate headlines are listed as options for a posted question in a Q&A service. After reading the question, please select the best option from the list so that users can guess the content of the question and distinguish it from other ones. Please remove uninformative ones such as greetings, self-introductions, and unspecific expressions.

We explain how to judge the appropriateness of each candidate by means of the example in Figure 2. After examining the posted question, we can assume that the most important content is "he is annoyed by the barking of a dog kept in the next house". On the basis of this assumption, option 6 is the best one, since the headline "A dog kept in the next house barks from morning" is enough to help answerers deduce that "the questioner is annoyed by the sound". Option 1 is inappropriate because although the answerers might be able to guess that "the questioner cannot move out", this matter is not the central one. Option 2 is uninformative because it consists merely of greetings and self-introduction, and option 3, while a question sentence, is unspecific. Option 4 enables answerers to guess that this question is related to an issue involving pets, but they cannot grasp the specific content. Option 5 specifies a likely damage due to the trouble, but the reason (trouble) is more important for the answering than the result (damage). Option 7 directly shows that "the questioner is annoyed and wants some advice", but answerers cannot understand why he/she is annoyed.

The detailed implementation of our task is as follows. First we randomly sorted the candidates of each question (shown in Figure 2(a)) to avoid position bias by the workers. We included ten actual questions and a dummy question so that workers would always have to answer one dummy question per every ten actual questions. A dummy question is a question with a clear answer inserted to eliminate fraud



(a) Ratio of true best candidates. (b) Average votes for position. (c) Average rank for position

Figure 3: Ratio of true best candidates and average votes/rank (for position) versus sentence position.

workers (i.e., workers who randomly select answers without actually reading them). Each question was answered by ten workers so each headline candidate had a vote score from 0 to 10 representing whether or not the candidate was appropriate for a headline. This task took nine days and was answered by 1,558 workers. As a result, our dataset consists of 10,000 questions, each of which has more than five headline candidates with accompanying "headline-ness" scores.

3.3 Analysis of Crowdsourcing Results

We analyzed our dataset to determine how much room for improvement our task has compared to the prefix headline. It is well known that the first sentence can be a strong baseline in many summarization tasks, so the prefix headline is also expected to perform well. Figure 3 shows the statistical information based on sentence position that includes the (a) ratio of the true best (most voted) candidates, (b) average votes, and (c) average rank (in order of votes) over the candidates at each sentence position. Looking at the true best candidates (a), the ratio 61.8% for the 1st sentence clarifies the effectiveness of the prefix headline, as expected. Conversely, we still have room for improvement for the prefix headline up to 38.2%. Our goal is to improve the uninformative headlines of 38.2% while keeping the remaining 61.8% unchanged. The other two figures (b) and (c) also support the above discussion.

Furthermore, we qualitatively checked the crowdsourcing quality. Workers successfully eliminated uninformative candidates including greetings and self-introductions, while one or two workers sometimes chose ones that included a fixed phrase such as "Please tell me ...". This is probably because workers had different criteria regarding the "unspecific expressions" described in the instructions. Since we cannot enumerate all of the concrete bad examples, we ignore this phenomenon with the expectation that a learning algorithm will reduce its negative effect.

4 Proposed Method

In this section, we explain how to construct a headline generation model from the dataset presented in Section 3. We took a ranking approach, i.e., learning to rank, for our task, rather than a simple regression one, since estimating absolute scores is not required for our purpose. Even if two headline candidates (of different questions) have the same expression, their votes can be significantly different since the votes in our dataset are based on relative evaluation. For example, the best candidate for Figure 2 was No. 6, but it might not be selected in other questions such as "A dog kept in the next house barks from morning. Does anybody know why dogs generally want to bark?".

Learning to rank is an application of machine learning that is typically used for ranking models in information retrieval systems. The ranking models are basically learned from a supervised dataset consisting of triples (q, x, y), where q is a user's query, x is a document corresponding to q, and y is a relevance score of x with respect to q. In this work, we formalize our task by regarding q, x, and y, as a posted question, a headline candidate, and a voted score in our dataset, respectively.

We used a pairwise ranking method that is also implemented as an instance of the well-known SVM tools LIBLINEAR (Lee and Lin, 2014) and LIBSVM (Kuo et al., 2014). We used a linear model based on LIBLINEAR, an L2-regularized L2-loss linear rankSVM, for the experiments. Let D be a dataset that consists of triples including a posted question q, a headline candidate x, and a voted score y, i.e., $(q, x, y) \in D$. In the pairwise ranking method, we train a ranking model as a binary classifier that determines whether the condition $y_i > y_j$ is true or false for two candidates x_i and x_j in the same

question ($q_i = q_j$). Specifically, we first define the index pairs of positive examples by $P = \{(i,j) \mid q_i = q_j, y_i > y_j, (x_i, y_i, q_i) \in D, (x_j, y_j, q_j) \in D\}$. Note that we do not need to consider the negative examples $N = \{(j,i) \mid (i,j) \in P\}$ since they yield the same formula as P in the optimization process. The training of the pairwise ranking method is achieved by solving the following optimization problem using the set P of the index pairs:

$$\min_w \ \frac{1}{2} w^\top w + C \sum_{(i,j)\in P} \ell(w^\top \tilde{x}_i - w^\top \tilde{x}_j), \tag{3}$$

where w is a weight vector to be learned, $\tilde{x}_i$ is a feature vector extracted from a headline candidate x, and C is the regularization parameter. The function ℓ is a squared hinge loss, which is defined as $\ell(d) = \max(0, 1-d)^2$. Finally, we define the score function in Eq. (1) as $f_q(x) = w^\top \tilde{x}$, where $\tilde{x}$ can be created by using q as well as x. This score means the relative "headline-ness" of x.

5 Experiments

5.1 Basic Settings

The basic settings of the experiments are as follows. We split our dataset into training and test sets consisting of 9,000 and 1,000 examples, respectively. We used an implementation[3] based on LIBLINEAR for training our ranking model, i.e., a linear L2-regularized L2-loss rankSVM model (Lee and Lin, 2014), as described in Section 4. The regularization parameter was optimized by cross validation and set as $C = 0.125$.

The feature vector for a headline candidate consists of three kinds of features: bag-of-words, embedding, and position information. The bag-of-words feature is a sparse vector of 30,820 dimensions based on the tf-idf scores of nouns, verbs, interjections, conjunctions, adverbs, and adjectives in a candidate, where we used a Japanese morphological analyzer, MeCab[4] (Kudo et al., 2004), with a neologism dictionary, NEologd[5] (Toshinori Sato and Okumura, 2017). The embedding feature is a dense vector of 100 dimensions based on a doc2vec model (Le and Mikolov, 2014) trained with all 3M sentences in the Chiebukuro dataset using the Gensim tool[6]. The position feature is a binary vector of ten dimensions, where each dimension represents the coarse position (or coverage) of a headline candidate for a question. Specifically, we equally split a question (character sequence) into ten parts and set one to each dimension if and only if the corresponding part overlaps a candidate. For example, candidate No. 2 in Figure 2 had a position feature $(1, 1, 0, \cdots, 0)$, since the candidate covers the first 2/10 of the whole question. Similarly, No. 6 and No. 3 had $(0, 0, 1, 1, 0, \cdots, 0)$ and $(0, \cdots, 0, 1)$, respectively. For constructing the feature vector of each headline candidate, we used the previous and next candidates in sentence order, in addition to the target candidate. This is based on the idea that near candidates might have useful information for the target candidate. Finally, we prepared each feature vector by concatenating nine feature vectors, i.e., the above three kinds of features for three candidates, and normalizing them.

5.2 Compared Methods

We compared our method, `MLRank`, with the baselines listed below. `Prefix`, `DictDel`, and `Random` are simple baselines, while `Prefix` and `DictDel` are practically strong. `ImpTfidf`, `SimTfidf`, `SimEmb`, and `LexRank` are unsupervised baselines, and `SVM` and `SVR` are supervised ones.

- `Prefix`: Selects the first candidate in sentence order.
- `DictDel`: Selects the first (informative) candidate that does not match in the dictionary of uninformative headlines (Section 2).
- `Random`: Randomly selects a candidate.
- `ImpTfidf`: Selects the most important candidate with the highest tf-idf value, where a tf-idf value is calculated by the sum of the elements in a bag-of-words feature (described in Section 5.1).

[3] `https://www.csie.ntu.edu.tw/~cjlin/libsvmtools/#large_scale_ranksvm`
[4] `https://taku910.github.io/mecab/`
[5] `https://github.com/neologd/mecab-ipadic-neologd`
[6] `https://radimrehurek.com/gensim/models/doc2vec.html`

- `SimTfidf`: Selects the most similar candidate to the original question, which is calculated by the cosine similarity between the bag-of-words features (in Section 5.1) of each candidate and the question.
- `SimEmb`: An embedding-based variation of `SimTfidf` with embedding features (in Section 5.1).
- `LexRank`: Selects the candidate with the highest score based on LexRank[7] (Erkan and Radev, 2004), which is a widely used unsupervised extractive summarization method based on the PageRank algorithm. The graph expression of each question was constructed on the basis of cosine similarity of the tf-idf vectors corresponding to candidates.
- `SVM`: Selects the candidate with the highest confidence based on a model learned as a classification task, where candidates with nonzero votes were labeled as positive. This setting was the best in our preliminary experiments. We used the L2-regularized L2-loss support vector classification model ($C = 0.0156$) in LIBLINEAR. The other settings were the same as those described in Section 5.1.
- `SVR`: Selects the candidate with the highest predicted votes based on a model learned as a regression task, where the target variable is the number of votes. We used the L2-regularized L2-loss support vector regression model ($C = 0.0625$) in LIBLINEAR. The other settings were the same as above.
- `MLRank`: Proposed method described in Section 4.

5.3 Evaluation Measures

We defined three evaluation measures for evaluating each method on our headline generation task.

Change Rate from Prefix Headline

We measured how much each method changed the default prefix headline in order to determine the effect of application to an actual CQA service. We defined this measure as *change rate from the prefix headline*, as follows:

$$\text{Change rate} = \frac{\text{No. of questions where the best candidate is not the prefix headline}}{\text{No. of all questions}}. \quad (4)$$

Clearly, the change rate of the default method that selects the prefix headline is 0%. If the value is small, the effect on the service will be small, but if the value is higher than the ideal change rate of 38.2% (Section 3), there can be side effects even if the average result is good. A higher change rate up to the ideal rate is desirable from a practical standpoint.

Winning Rate against Prefix Headline

We measured how much each method won against the prefix headline to directly assess the quality of changed headlines. We defined this measure as *winning rate against the prefix headline*, as follows:

$$\text{Winning rate} = \frac{\text{No. of questions where the best candidate got more votes than the prefix headline}}{\text{No. of questions where the best candidate is not the prefix headline}}. \quad (5)$$

We did not consider the first candidate (in sentence order) selected by each method, which is the same as the prefix headline, since they obviously have the same number of votes.

Average Votes

We measured how appropriate the candidates selected by each method are in order to determine the overall performance. We defined this measure as *average votes*, as follows:

$$\text{Average votes} = \frac{\text{Sum of votes for the best candidates for all questions}}{\text{No. of questions}}. \quad (6)$$

Note that the average votes score is different from the average votes score for position (Figure 3(b)) in that the former is the average over the selected candidates while the latter is the average over the candidates at a sentence position.

[7] `https://pypi.org/project/lexrank/0.0.1b0`

E.g.	Prefix method (Prefix)	Proposed method (MLRank)
1	27 歳女です。環境的になかなか新しい出… I am a 27-year-old woman. Owing to my environment, there is little chance of new ...	…環境的になかなか新しい出会いがなくて… ... Owing to my environment, there is little chance of new encounters with men ...
2	情緒不安定なものです。回答して下さった… I am emotionally unstable. Those who answered ...	…新婚旅行は、行きは別々で行き、現地で… ... For the honeymoon, we went separately and in the field ...
3	カテ違いならゴメンナサイ。今、財布が破… I am sorry if the category is wrong. Now, my wallet is torn	…今、財布が破れてツライ状況です。新し… ... Now, my wallet is torn, and I'm having a hard time. A new one ...
4	前にとても大変で嫌な思いをしたので携帯… Because things felt very hard and painful before, my mobile ...	…携帯メールお断りというのはこの落札者… ... Rejecting e-mails from a mobile phone means this winning bidder ...
5	現在、私の父は 60 歳で定年退職を迎えま… Currently my father is 60 years old and will retire from employment ...	…厚生年金の支払いは何歳までなんですか… ... Until what age should he pay the welfare pension ...

Table 2: Examples of prefix method Prefix and proposed method MLRank.

This measure is related to (normalized) discounted cumulative gain (DCG), which is widely used as an evaluation measure of ranking models. We often use DCG@k for evaluating top-k rankings, and the above definition acutally corresponds to DCG@1. According to a well-known paper (Järvelin and Kekäläinen, 2002) in the information retrieval field, DCG is appropriate for graded-relevance judgments like our task, while precision (described below) is appropriate for binary-relevance ones. Average votes is expected to be more appropriate than precision for our task because we want "averagely better headlines than default ones" rather than "best ones" from a practical standpoint.

Precision

Precision is a widely used evaluation measure for classification tasks, and we added it to support an evaluation based on average votes. We defined it with respect to the best candidate, i.e., precision@1, as follows:

$$\text{Precision} = \frac{\text{No. of questions where the best candidate had the maximum votes}}{\text{No. of questions}}. \quad (7)$$

5.4 Results

Qualitative Analysis

Table 2 shows examples of headlines generated by the prefix method, Prefix, and the proposed method, MLRank. Looking at the first example, we can see that our method successfully eliminated the self-introduction phrase ("I am a 27-year-old woman"). The headline (right) of our method allows answerers to know that the questioner is discouraged about how to encounter men from the phrase "little chance of new encounters with men", while the headline (left) of the prefix method lacks this important clue. The second and third examples show similar effects to the first example. In the second one, although there are few clues about what the question is with the prefix method, our method correctly included the important clue ("honeymoon"). In the third one, our method appropriately eliminated the uninformative long phrase ("I am sorry if the category is wrong"), which is not a frequent fixed phrase. The fourth example shows a slightly challenging case, where both headlines make it difficult to understand the question. However, the headline of our method included the term "winning bidder", so at least the answerer can assume that the question is about some sort of auction trouble. The fifth example is a clearly successful result, where our method extracted the main question point about "welfare pension" as a headline. These results qualitatively demonstrate the effectiveness of our method.

Quantitative Analysis

We compared our method MLRank with the baselines in Section 5.2 on the headline generation task for our dataset in Section 3. Table 3 shows the evaluation results based on the change rates, winning rates, average votes, and precision. Looking at the average votes and precision, which represent the overall performances, our method MLRank clearly performed the best among all methods. We confirmed that

	Change rate (%)	Winning rate (%)	Average votes	Precision (%)
Ref (reference)	38.2	100.0	5.56	100.0
Prefix (default)	0	–	4.19	61.8
DictDel	2.2	72.0	4.23	61.3
Random	85.9	11.7	1.39	16.1
ImpTfidf	81.1	12.7	1.68	20.0
SimTfidf	79.3	18.7	2.27	20.0
SimEmb	**88.2**	13.0	1.40	15.4
LexRank	55.7	19.3	2.27	29.9
SVM	16.7	50.1	4.09	60.3
SVR	52.5	25.7	3.00	42.1
MLRank (proposed)	9.9	**94.9**	**4.28**	**62.6**

Table 3: Evaluation results of our headline generation task for proposed method MLRank and baselines.

the relative improvement of the average votes of our method MLRank against every baseline including the prefix method Prefix is statistically significant on the basis of a one-tailed Wilcoxon signed-rank test ($p < 0.01$). The change and winning rates of our method are 9.9% and 94.9%, respectively. This means that our method detected 9.9% of the uninformative headlines and improved them with the high accuracy of 94.9%. In other words, our method could successfully improve the overall performance while simultaneously avoiding any negative side effects. The ideal results (Ref) based on correct labels suggest that our method still has room for improvement, especially for the change rate.

The results of the other baselines are as follows. Not surprisingly, the prefix method Prefix performed well. This is consistent with the fact that the first sentence can be a good summary in many summarization tasks. The random method Random performed the worst, also as expected. The dictionary-based deletion method DictDel was relatively useful, although the change rate was small. The reason the winning rate of DictDel is relatively low compared with MLRank is that there are some cases where a combination of uninformative expressions can yield likely clues. For example, the self-introduction "I am a newbie of this forum" itself is basically uninformative for a question, but a combination with additional information such as "I am a newbie of this forum. Where can I change the password ..." can be more informative than only the additional information "... Where can I change the password since I forgot it after ..." because the combination specifies the target site by the expression "this forum".

The unsupervised methods, SimTfidf, SimTfidf, SimEmb, and LexRank, which are widely used for summarization tasks, performed worse than the prefix method Prefix. Although the change rates are higher than our method, the winning rates are lower. In other words, they yielded many bad headlines. These results suggest that supervised learning specialized to the target task would be required. Comparing the important sentence extraction method ImpTfidf and the similarity-based summarization method SimTfidf, we found that SimTfidf performed better. This implies that the content information of each question is useful for our headline generation task, as is the case with other summarization tasks. The similarity-based method SimEmb with embeddings performed worse than our expectation. The reason seems to be that it was difficult to obtain meaningful document embeddings from long questions. The graph-based method LexRank had a similar performance to SimTfidf, because LexRank tends to select a candidate similar to the question when only one candidate was selected. The supervised methods, SVM and SVR, performed relatively well compared to the unsupervised methods, but they did not outperform the strong simple baselines, Prefix and DictDel, nor our method MLRank. These results support the appropriateness of our approach.

6 Related Work

In this section, we briefly explain several related studies from two aspects: headline generation task and CQA data. As discussed below, our work is the first attempt to address an extractive headline generation task for a CQA service based on learning to rank the substrings of a question.

After Rush et al. (2015) proposed a neural headline generation model, there have been many studies on the same headline generation task (Takase et al., 2016; Chopra et al., 2016; Kiyono et al., 2017; Zhou et al., 2017; Suzuki and Nagata, 2017; Ayana et al., 2017; Raffel et al., 2017). However, all of them are abstractive methods that can yield erroneous output, and the training for them requires a lot of

paired data, i.e., news articles and headlines. There have also been several classical studies based on non-neural approaches to headline generation (Woodsend et al., 2010; Alfonseca et al., 2013; Colmenares et al., 2015), but they basically addressed sentence compression after extracting important linguistic units such as phrases. In other words, their methods can still yield erroneous output, although they would be more controllable than neural models. One exception is the work of Alotaiby (2011), where fixed-sized substrings were considered for headline generation. Although that approach is similar to ours, Alotaiby only considered an unsupervised method based on similarity to the original text (almost the same as `SimTfidf` in Section 5.2), in contrast to our proposal based on learning to rank. This implies that Alotaiby's method will also not perform well for our task, as shown in Section 5.4. There have been several studies on extractive summarization (Kobayashi et al., 2015; Yogatama et al., 2015) based on sentence embeddings, but they were basically developed for extracting multiple sentences, which means that these methods are almost the same as `SimEmb` in Section 5.2 for our purpose, i.e., extraction of the best candidate. This also implies that they will not be suitable for our task. Furthermore, recent sophisticated neural models for extractive summarization (Cheng and Lapata, 2016; Nallapati et al., 2017) basically require large-scale paired data (e.g., article-headline) to automatically label candidates, as manual annotation is very costly. However, such paired data do not always exist for real applications, as in our task described in Section 1.

There have been many studies using CQA data, but most of them are different from our task, i.e., dealing with answering questions (Surdeanu et al., 2008; Celikyilmaz et al., 2009; Bhaskar, 2013; Nakov et al., 2017), retrieving similar questions (Lei et al., 2016; Romeo et al., 2016; Nakov et al., 2017), and generating questions (Heilman and Smith, 2010). Tamura et al. (2005) focused on extracting a core sentence and identifying the question type as classification tasks for answering multiple-sentence questions. Although their method is useful to retrieve important information, we cannot directly use it since our task requires shorter expressions for headlines than sentences. In addition, they used a support vector machine as a classifier, which is almost the same as `SVM` in Section 5.2, and it is not expected to be suitable for our task, as shown in Section 5.4. The work of Ishigaki et al. (2017) is the most related one in that they summarized lengthy questions by using both abstractive and extractive approaches. Their work is promising because our task is regarded as the construction of short summaries, but the training of their models requires a lot of paired data consisting of questions and their headlines, which means that their method cannot be used to our task.

7 Conclusion

We proposed an extractive headline generation method based on learning to rank for CQA that extracts the most informative substring in each question as its headline. We created a dataset for our task, where headline candidates in each question are ranked using crowdsourcing. Our method outperformed several baselines, including a prefix-based method, which is widely used for cases where the display area is limited, such as the push notifications on smartphones. The dataset created for our headline generation task will be made publicly available[8]. Although our task is basically designed for extractive summarization, this dataset can also be used for abstractive summarization as a side information for training abstractive models.

In future work, we will investigate how effectively our method can perform in practical situations, e.g., push notifications. In addition, we will consider how to improve the change rate of our method while keeping its winning rate and how to create a useful dataset even if removing the length limitation.

Abstract

Enabling a mechanism to understand a temporal story and predict its ending is an interesting issue that has attracted considerable attention, as in case of the ROC Story Cloze Task (SCT). In this paper, we develop a multi-attention based neural network (MANN) with well-designed optimizations, like Highway Network, and concatenated features with embedding representations into the hierarchical neural network model. Considering the particulars of the specific task, we thoughtfully extend MANN with external knowledge resources, exceeding state-of-the-art results obviously. Furthermore, we develop a thorough understanding of our model through a careful hand analysis on a subset of the stories. We identify what traits of MANN contribute to its outperformance and how external knowledge is obtained in such an ending prediction task.

1 Introduction

The prediction on story endings is an important and interesting application because it is involved with several essential issues, such as textual semantic understanding, logical reasoning and natural text generation. Most previous studies on the subject of common sense story understanding mainly focus on generating guesses for a missing event, such as matching explicit information in a given context (Chambers and Jurafsky, 2008), paying attention to specific types of common sense knowledge, like event schema (Chambers and Jurafsky, 2009), or concentrating on unsupervised learning (Chambers and Jurafsky, 2008). Although numerous studies have addressed the issue, training machines to be able to understand underlying narrative structures is still a challenging task. Previous research is limited at the shallow technique requirement of evaluation and noisy knowledge resources.

To facilitate the evaluation and benchmark the problem in the literature, the Story Cloze Task (SCT) has been introduced to predict what should be the "right" ending to a story (Mostafazadeh et al., 2016), which consists of daily events. The common strategies utilized to perform the task can be classified into two kinds of approaches: (1) traditional machine learning techniques with optimal feature engineering; and (2) deep learning-based models with effective strategies (Cai et al., 2017). The task is published with an unlabeled training set that consists of one-correct-ending stories, which is a notable impediment for further research. Some studies investigated fake ending generation, which obtained far more satisfying results. Most supervised learning approaches are trained from the finite evaluation set, ignoring the sheer volume of training corpus.

Understanding daily stories requires not only common sense experience sharing, but also a thorough understanding of text learned from common sense knowledge resources. We propose an effective multi-attention based neural network (MANN) and broaden our model with external knowledge. The model is superior in three aspects: (i) it adds features of sentences as embedding representations; (ii) it features a self-matched attention mechanism that functions through one sentence of the story, while interaction attention functions across the story plot and ending option to obtain word-level interaction; and (iii) it involves external knowledge to augment text coherence understanding.

Proceedings of the 27th International Conference on Computational Linguistics, pages 1754–1762
Santa Fe, New Mexico, USA, August 20-26, 2018.

The proposed model is comprehensively evaluated by comparing it with state-of-the-art approaches. Results show that the performance of the MANN strategy is superior to that of its competitors by up to 7% in terms of accuracy.

Furthermore, we conduct ablation experiments to illustrate the effect of each component in the MANN framework. Through elaborate evaluation, we demonstrate the superiorities and different characteristics of the components in the proposed model and the beneficial effect of the external knowledge utilized.

The contributions of this work are as follows:

- We build a MANN with deliberately devised structures, consisting of components that were not previously applied in this task, such as synthesis embeddings, multiple attentions and Highway, to characterize the semantic coherence of temporal stories from SCT.

- Unlike previous work on generating fake options or that trained only on the labeled set, we extend our model by regarding the unannotated corpus as proportions of external knowledge to enrich insufficient information to remedy the issue of limited resources.

- We conduct comprehensive analysis by manually labeling a subset of 300 stories to further study how our method performs in the story ending prediction task. We demonstrate that the proposed model outperforms the state-of-the-art methods by up to 7%. We will provide the full list of these annotated samples for further research.

2 Related Work

The issue of story ending prediction is related to several other research topics, such as reading comprehension and common sense learning, which will be briefly surveyed as follows.

Reading comprehension is the ability to read and understand text, and it has attracted much attention in natural language processing (NLP) to evaluate the level a machine can reach in understanding text. Two popular forms of evaluation tasks exist in this field: cloze-style query and text-span matching. Cloze-style query, such as SQuAD published by Stanford University, focuses on predicting existing text from the original corpus when given a relevant context. Text-span matching is different from selecting a possible word from the provided text to replenish the blank areas, such as CNN/DailyMail by Hermann and Hinton. Existing tasks are constructed with fragments, whereas examples from SCT are complete and independent stories that has short and meaningful sentence. SCT is also different in that it requires the prediction of development of a story, which is not provided in the given hypothesis. This novel task calls for stronger relation extraction and external inferential capability to identify the correct ending. Our model paid attention on through structure and proved to be effective during experiments.

Common sense learning is a challenging aspect in NLP. The limitation of other rich knowledge structures is that they mostly either focus on shallower representations, such as semantic roles like PropBank (Palmer et al., 2005), or pay attention to specific types of knowledge, i.e., unsupervised co-reference in the text (Chambers and Jurafsky, 2009) and event temporal relation (Modi and Titov, 2014). Learning from structural event knowledge is proposed to enrich this field, including narrative schema (Chambers and Jurafsky, 2009) and event frames (Sha et al., 2016). Unlike the above tasks, SCT (Mostafazadeh et al., 2016) provides large-scale supervised training stories of temporal and causal relations, ensuring a high-quality evaluation for common sense knowledge understanding of mechanisms.

However, the published ROCStories could not be used directly in supervised learning. Considering the use of the training set without negative endings, researchers proposed strategies to generate incorrect options. A conditional generative adversarial network has been proposed, achieving a moderate result with an accuracy of 60.9% (Wang et al., 2017). Roemmele (Roemmele et al., 2017) designed four generative models for fake options, namely, random, backward, nearest-ending and language model. The best result is produced from samples of all four types of endings (67.2%).

Other researchers have attempted to learn from the limit-scale validation set and augment the capability of the relation extractor. Schwartz (Schwartz et al., 2017) is the champion of the LSDSem 2017 Shared

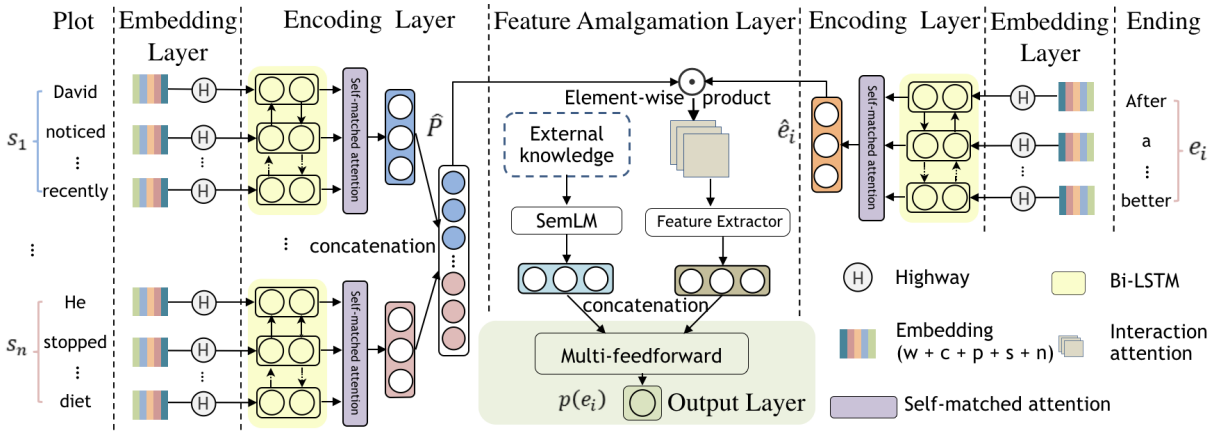

Figure 1: Architecture of our model.[1]

Task, which achieved a score of 75.2% by associating writing style features in endings and training a linear regression. HCM (Chaturvedi et al., 2017) trained a joint model with feature engineering to obtain representations of event sequence, sentiment, and topic from validation set and a hidden variable approach as a voter, thereby obtaining 77.6%. The previous NN-based models did not perform well. Cai (Cai et al., 2017) constructed a model with hierarchical long short-term memory network (LSTM) to encode plot and an ending2sentence attention, then concatenated the two representations through feed-forward network and outputting the final prediction, obtaining 74.7% accuracy. We pursue the same strategy to construct our principal model MANN and see opportunity to utilize external knowledge in the technique of combining semantic sequence information.

3 Proposed Model

This study aims to deduce the right ending given its previous context in the story. Formally, the story ending prediction task is defined as follows: given the story $\langle P, E\rangle$, where P=$\langle s_1, \ldots, s_n\rangle$ is a story plot, and the ending options E=$\langle e_1, \ldots, e_k\rangle$, the task is to select an appropriate ending e_i $(1 \leq i \leq k)$ from E. We address the task as a regression problem, mapping the right ending as 1 and the wrong ending as 0. We identify the highest-scored option as the answer. We first introduce the MANN model, followed with the extension of the model; this extension is constructed to learn from external knowledge. The whole model is shown in Fig.1.

3.1 Multi-attention Neural Network Model

The proposed MANN model consists of four layers. The embedding layer maps each word to a high-dimension vector representation. Then, the encoding layer encodes the representation of the context, and the feature amalgamation layer extracts features from the interaction between plot and the ending. Finally, the output layer provides the probability of the right ending.

Embedding Layer: We concatenate five representations: (i) word embedding; (ii) character feature; (iii) part-of-speech (POS) tagging; (iv) sentiment polarity of a word; and (v) negation.

Word embedding is conducted by converting a token to a high-dimensional vector space, and we obtain a fixed word embedding of each word by using pre-trained vocabulary. The character feature is obtained by mapping each word to a high-dimensional vector space to better handle out-of-vocab or rare words. We abstract character-level representations for tokens through a one-dimension convolutional neural network(CNN). The vectors embedded from characters have the same size as the input channel size of the CNN. By max-pooling the outputs of the CNN over the entire width, we obtain fixed-size vectors for words. By utilizing pre-processing tools, we tackle the last three aspects of a word as one-hot representations, while we collect the POS tagging feature with a natural language toolkit, sentiment polarity of a word with a look-up from pre-trained sentiment lexica, and negation with a corpus of

[1] w for word, c for character, p for POS, s for sentiment polarity, n for negation.

negation words (i.e., "not", "neither", "nor" and "n't"). The concatenation of the five representations of a word is then passed through a two-layer Highway Network (Srivastava et al., 2015) to fuse the information of features, which is processed as follows:

$$trans = ReLU(w_t x + b_t) \tag{1}$$

$$gate = \sigma(w_g x + b_g) \tag{2}$$

$$H(x) = gate * trans + x(1 - gate) \tag{3}$$

where $w_g, w_t \in \mathbb{R}^{D\times D}$ and $b_t, b_g \in \mathbb{R}^D$, D is the dimension of input.

Encoding Layer: The encoding layer encodes the sequence and semantic abstraction of a single sentence and then compromises them, which are from an identical plot to obtain a fusion premise.

Sentence encoding constructs an LSTM in both directions on top of the embeddings provided by the previous layer and concatenate the outputs of forward and backward LSTMs, to learn high-level abstractions from time-sequence features of the context. We obtain $s_{lj,(j=1,\ldots,n)} = [\overrightarrow{LSTM}; \overleftarrow{LSTM}]$ where ; represents the concatenation between two directional LSTM thus $s_{lj} \in \mathbb{R}^{T\times 2d}$ denotes each sentence in plot and $e_{li} \in \mathbb{R}^{G\times 2d}$ denotes the ending.

The new representations are passed into self-matched attention to model the temporal interactions between words. Taking vector V as example, self-matched attention $\widetilde{V} = att(V)$ is defined as follows:

$$M_{ij} = W^{\mathrm{T}}[V_i; V_j; V_i \circ V_j] \tag{4}$$

$$a_i = softmax(M_i) \tag{5}$$

$$\widetilde{V_i} = \sum_j a_{ij} V_j \tag{6}$$

where $W^T \in \mathbb{R}^{6d}$ is a weight matrix and $\circ$ is element-wise multiplication. The higher-level semantics can directly tackled from encoded sequences through the attention mechanism.

Plot encoding compounds the interacted representation of sentences from the same story context. We studied several commonly used implementations for sentence combination, such as LSTM, summation, weighted summation, and concatenation operations. We find simple concatenation useful. The encodings of the story plot is concatenated as $\hat{P} = [att(s_{l1}); \cdots ; att(s_{ln})]$, $\hat{P} \in \mathbb{R}^{nT\times 2d}$, while the ending is simply represented as $\hat{e} = att(e_{li})$, $\hat{e} \in \mathbb{R}^{G\times 2d}$.

Feature Amalgamation Layer: We focus on characterizing diverse interaction information among representations of the plot and the ending, thus extracting feature from them. This layer is inspired by the IIN model (Gong et al., 2018). We combine the plot vectors and ending representations to create a word-by-word interaction attention tensor, in which each channel represents the interaction of the word in one dimension. We tried processing, such as $F_{ij} = \hat{P}_i \circ \hat{e}_j$, $F_{ij} = \hat{P}_i + \hat{e}_j$ and $F_{ij} = |\hat{P}_i - \hat{e}_j|$ and found that the most effective one is $F_{ij} = \hat{P}_i \circ \hat{e}_j$, where we define $i \in [1, \ldots, nT]$, $j \in [1, \ldots, G]$, $\circ$ is element-wise multiplication and $F \in \mathbb{R}^{nT\times G\times 2d}$.

Then, we adapt a feature extractor on F to extract semantic features from word-by-word interaction.Unlike extractors (i.e., VGG and ResNets (He et al., 2016)), DenseNet (Huang et al., 2017) strengthens feature propagation and reduces information disappearance through time because of the structure of pre-activation.

Output Layer: A multi-feedforward neural layer is used. We apply three $tanh$ layers to calculate a score for prediction support.

3.2 Extension of MANN

Labeling large-scale examples requires considerable expertise and manpower. With the pattern of supervised learning, MANN can merely use limited annotated examples to train finite information, thereby preventing us from obtaining more powerful statistical model. To eliminate the restriction of labeled data scarcity and ensure the robustness of our model, we introduce semantic sequence information extracted from external knowledge onto MANN, thus building an extended model, i.e., sequence based MANN (SeqMANN).

External knowledge is mostly used to enrich word implication, thereby ensuring that semantic information can be extracted. To address the combination of external knowledge and the neural network model, Chen (Chen et al., 2017) added extra relation informations of word pair into the encoder. Other researchers studied embedding representations (Bordes et al., 2013) to learn complex reasoning capacities. Considering specific ending-prediction task, we aim to further derive coherence among sentences from stories. Directly working on the large-scale ROCStories is not easy due to its deficiency of negative samples. We use SemLM (Peng and Roth, 2016) to model the distribution over a meaningful sequence chain, with ROCStories regarded as portion of our extra resources while the other are from news data.

SemLM is a language model that first uses FrameNet to split sentences by semantic sequence, and then represents these pieces of sequence with semantic frames and discourse markers from an extended vocabulary. The abstraction of a sentence is $[f_1, dis_1, f_2, \cdots, o]$ where f_i denotes semantic frames, dis_i denotes discourse markers and o denotes period symbol. The SemLM is trained with a log-bilinear model (Mnih and Hinton, 2007) on ROC corpus and news data, and obtains the probability of two words appearing simultaneously in a sentence. The log-bilinear model computes the sequence probability of the next word w_i given the previous words (context), which is defined as follows:

$$p(w_i|c(w_i)) = \frac{exp(v(w_i)^{\mathrm{T}} u(c(w_i)) + b(w_i))}{\sum_{w \in V} exp(v(w)^{\mathrm{T}} u(c(w_i)) + b(w))} \tag{7}$$

We define $v(w)$ as the target vector, $v'(w)$ as the context vector, and $b(w)$ as a bias of a token. Here, V is the vocabulary, $u(c(w_i)) = \sum_{c_t \in c(w_i)} q_t \circ v'(c_t)$, $\circ$ is element-wise multiplication and q_i is a model parameter that depends on the position of a token in the context. The final sequence probability is $\prod_{i=1}^{k} p(w_i|c(w_i))$.

The trained language model is then used to calculate the conditional probability of semantic frames from each option when given the same hypothesis, inspired by HCM (Chaturvedi et al., 2017). For each ending e_i with frames represented as f_{e_i} and $\langle f_1, f_2, \cdots, f_T \rangle, T \geq n$ indicating semantic frames evoked in the story plot, the following features are captured considering the sequence of frames in corresponding story plot: $P(f_{e_i}|f_T), P(f_{e_i}|f_T, f_{T-1}), \ldots, P(f_{e_i}|f_T, f_{T-1}, \cdots, f_1)$.

Finally we learn the semantic sequence feature of plot-ending pairs which represents the interaction information between the plot and the ending of stories, extending the study on external knowledge. We fuse it with features extracted from DenseNet in the feature amalgamation layer through concatenation.

4 Experiments

4.1 Data

As described in (Mostafazadeh et al., 2016), SCT was constructed based on ROCStories. The ROC corpus consists of 100,000 five-sentence cases, each of which was written as a logically meaningful story. After eliminating original endings, writers develop both a "right" ending and a "wrong" ending for the context of examples which are randomly chosen from the corpus. The published SCT is constructed with ROCStories as a large training set, an evaluation set, and a test set, which have the same structure and a size of 1,871.

We evaluate our model by using the benchmark SCT (Mostafazadeh et al., 2016). Notably, the training set contains four-sentence articles with one correct ending, while the evaluation set consists of four-sentence stories with two ending options.

4.2 Training details

To train our neural algorithm, we apply word embeddings of a look-up from 100-d GloVe pre-trained on Wikipedia and Gigaword (Pennington et al., 2014). We set $hiddensize = 100$ for LSTM. An Adam optimizer with a mini-batch size of 120 and an initial learning rate of 0.01 is applied. In the feature amalgamation layer, DenseNet consists of three pairs of dense blocks with a following transition block. The number of layers in a dense block is set as 10, and a ReLU activation function is applied for the whole convolutions. In the output layer, we use three full-connected layers with ReLU activation function. We use mean squared error as the loss function. We decide the model based on the average accuracy of the held-out folds through 5-fold cross validation.

4.3 Results on Our Model

We compare our model with some distinctive methods and approaches that rank high in LSDSem 2017 Shared Task (Mostafazadeh et al., 2017) in Tabel 1. Cai (Cai et al., 2017) is state-of-the-art model in NN-methods while HCM (Chaturvedi et al., 2017) is state-of-the-art model in all published methods. Under the condition in which external resources are not used, MANN outperforms Cai by 3% and even performs better than the highest-level method. Benefiting from external knowledge, SeqMANN achieves a 6.4% improvement over MANN. Nevertheless, the superiority of SeqMANN does not rely on only the external resources utilized, but the correlated effect between MANN and the external resources, as we can see that after removing MANN from SeqMANN (as shown in Table 2 and will described in Section 4.4), the remaining external resources based model only obtained 71.3%[1].

4.4 Ablation Study

We conduct an ablation study on the proposed model to evaluate the effectiveness of each feature and component involved. Results are shown in Table 2.

Embedding Ablation: All embedding features contribute to MANN. However, the influence is not as crucial in SeqMANN. We conjecture that contextual information in the embedding process partly overlaps with the features in external knowledge.

Component Ablation: We respectively remove each component to study their contribution. For interaction attention ablation, we replace it with flattening between plot and ending representations, followed by removing DenseNet and replacing a three-layer $tanh$ operation as feature extractor. For MANN ablation, we only retain the extraction of external knowledge and the output layer (we model SemanticSequence by the same way as MANN ablation processing in Section 5).

5 Data Analysis

To further analyze the model, we seek to determine the abilities required to predict the right ending, and which aspects of questions among the specific dataset are solved by our model. We sample 300 examples from the validation set randomly and annotate them manually from two cognitive chunks, namely, by labeling samples with the difficulty degree in human-understandable rationale for prediction and by tagging samples according to the linguistic phenomena they contain.

[1]Code and the annotated samples are available at https://github.com/StoryDevelopment/SCT.

Table 3: Some examples from each human-understandable difficulty labeling category.

Category	Story plot	Ending options
Relevant Word	Kyle invited everyone he works with bowling one night. Most people could not go but Matt and John showed up. Matt had never been bowling before so they had to show him how to. After a few games, Matt picked up how to play better.	e_1: Now Matt and Kyle can go bowling more then. e_2: Kyle took the children shopping for a gift for their mother.
Compatible Sentence	It was the last day of our vacation.We were eating lunch on the patio of the hotel. We laughed and smiled because it was a great vacation.Then we packed our bags and drove to the airport.	e_1: We want to revisit someday. e_2: We all vowed to never go back again.
Plot-level Paraphrasing	Rory was allergic to gluten and strawberries.One day she sat down to eat lunch at school.She opened her lunch box, and stared at a sandwich with strawberries.Her new step mom had packed her lunch for the first time.	e_1: Rory had to buy a school lunch that day. e_2: Rory ate the sandwich.
Ambiguous Inference	Tina always wore a red bikini when she went to the beach. She was known for it and everyone expected to see her in one. One day she met her friends in a blue bikini and surprised them. They could not understand why she would wear something different.	e_1: They liked the new bikini though. e_2: Tina's friends knew how unpredictable she was.

5.1 Human-understandable Difficulty Labeling

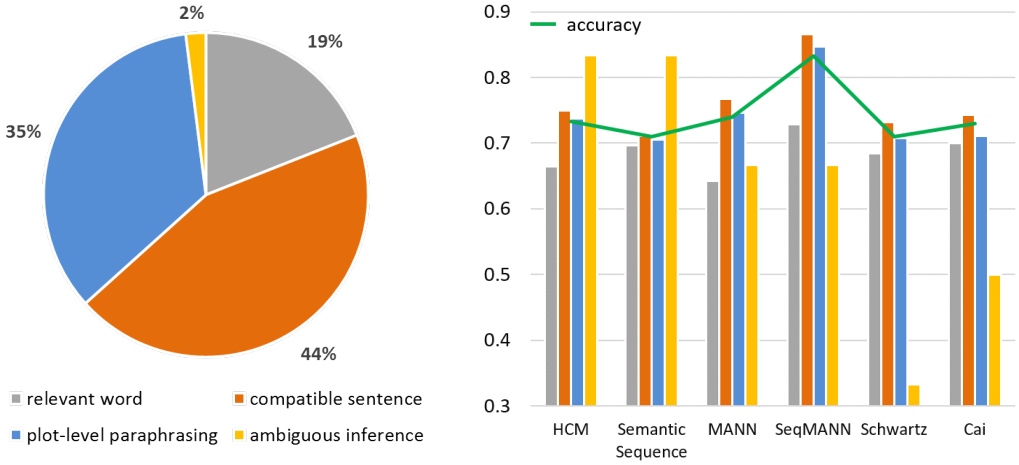
We classify the 300 samples into the following categories (as shown in Table 3, where the right ending is e_1 and the wrong ending is e_2):

Relevant Word. The verbs and noun phases in e_1 are more relevant to the plot than those in e_2. This category includes examples that are thought to be correctly predicted at the word level.

Compatible Sentence. We could derive the correct answer by understanding a single sentence in the hypothesis, which means that the answer is similar to some sentence in an earlier context.

Plot-level Paraphrasing. It requires a full understanding of multiple sentences to infer the answer.

Ambiguous Inference. It includes examples in which we think both endings are logically reasonable for the story, while the correct one is more answerable. This category consists of poorly designed cases, which we consider miscarriage examples in this task.



(a) The proportion of each category.

(b) Results in each category.

Figure 2: Results of human understandable difficulty labeling.

Fig.2a shows the proportion of each category. The second and third cases have the highest proportion, followed by the first and the least "Ambiguous Inference" cases. We observe that deeper information processing, which means sentence understanding (for "Compatible Sentence" case) and plot-level understanding (for "Plot-level Paraphrases" case), is crucial to good performance in this task. The low proportion of "Ambiguous Inference" shows the satisfactory quality of this task.

To further analyze the depth of prediction from our models compared with other methods, we reproduce the other methods and test the 300 annotated examples based on the above categorization. Results are presented in Fig.2b. We conclude the following: (i) The comparison between MANN and semantic sequence shows that semantic sequence is superior in shallow natural language comprehension, such as word-level understanding, while MANN performs better in deep contextual comprehension, such as sentence and plot level understanding; (ii) Successfully, SeqMANN combines the two advantages to out-

Table 4: Linguistic phenomena tagging results.

Phenomena Tag	Label Frequency	Cai	Schwartz	HCM	SemanticSequence	MANN	SeqMANN
CONDITIONAL	2.0	83.3	83.3	83.3	66.7	66.7	**100.0**

ACCURACY	—	72.3	71.3	73.3	71.0	74.0	83.3

perform other methods on this task. (iii) The model is a stable one with external knowledge resources, thus still maintaining high accuracy under decreasing training data.

5.2 Linguistic Phenomena Tagging

To obtain an idea of the linguistic phenomena in SCT and to conduct a detailed analysis of the semantical performance of these models, imitating MultiNLI (Williams et al., 2018), we design a set of annotation tags to label the subset as follows:

CONDITIONAL: Whether the example contains the word "if".
NEGATION: Whether the example contains negation words, e.g., not, none, neither.
SENTENCE LENGTH: Whether the right ending is longer than the other endings.
QUANTITY/TIME REASONING: Whether understanding the ending options contains quantity or time reasoning that needs to be explained from the plot.
COREF: Whether ending options contain referring expressions.
QUANTIFIER: Whether the example contains quantifier words, e.g., more, most, enough.
MODAL: Whether the example contains modal verbs.
BELIEF VERBS: Whether the example contains belief verbs such as think, believe and doubt.
CONVERSATIONAL PIVOTS: Whether the example contains discourse cohesion, e.g., but, yet, however, though, while.
ANTO: Whether the example contains an antonym pair.
EMOTIONAL COMMONALITY: Whether the sentiment throughout the plot is consistent with that through the right ending.
ENDING ONLY: Whether the ending options contradict themselves.

Results are shown in Table 4, and we observe the following: (i) The poor performances on SENTENCE LENGTH indicates that such feature, which is regarded as valuable bias (Cai et al., 2017; Schwartz et al., 2017), does not have an influential contribution to our model. (ii) Examples with ENDING ONLY tag shows that our attention components recognize not only paraphrases in relation among sentences but also the intra-semantic implications of each sentence. (iii) The model outperforms in terms of EMOTIONAL COMMONALITY, which shows effects of adding sentiment polarity in embedding representation.

6 Conclusion

In this paper, we proposed a MANN model with external knowledge. The results of this model outperformed state-of-the-art results by 7%. We carefully examined a subset of the corpora from SCT to analyze the performance of our models. The competitive model benefits not only from our thoughtfully designed structure but also from the combination of semantic relations learned from external resources.

Abstract

Visual Question Generation (VQG) aims to ask natural questions about an image automatically. Existing research focuses on training model to fit the annotated data set that makes it indifferent from other language generation tasks. We argue that natural questions need to have two specific textual attributes from the perspectives of content and linguistic respectively, namely, *natural* and *human-written*. Inspired by the setting of discriminator in adversarial learning, we propose two discriminators, one for each attribute, to enhance the training. We then use the reinforcement learning framework to incorporate scores from the two discriminators as the reward to guide the training of the question generator. Experimental results on a benchmark VQG dataset show the effectiveness and robustness of our model compared to some state-of-the-art models in terms of both automatic and human evaluation metrics.

1 Introduction

Recent years see the popularity of multi-modal research on vision and language. Visual caption generation (VCG) (Xu et al., 2015; Vinyals et al., 2015) and visual question answering (VQA) (Antol et al., 2015) attract increasing attention from research communities. VCG aims to generate descriptions for a given image with the goal of scene understanding, while VQA asks visual questions and requires an answer to it. Research for these two tasks are fueled by several manually generated corpora (Lin et al., 2014; Zhu et al., 2016).

Different from generating a statement (descriptions or answers) about an image, visual question generation (VQG) (Mostafazadeh et al., 2016) is tasked with generating a natural question which can potentially engage a human in starting a conversation when shown an image. Under this guidance, Mostafazadeh et al. (2016) collect natural questions for images via a crowd-sourcing platform and construct the first dataset for VQG. They also explore some neural network-based models for natural question generation. Those models are trained to better fit the VQG dataset that makes them indifferent from other language generation models and hard to identify the progress in naturalness for generated ones. Some human generated questions for VQG and questions for VQA are shown in Figure 1, we name questions for VQA descriptive questions and those for VQG natural ones. As we can see, VQA questions are much simpler and can be easily answered using information from the source image directly. In contrast, VQG questions are more complex and answers are not trivial. We therefore argue that the specialty in terms of content needs to be considered for natural question generation.

In this paper, We formulate the task of visual natural question generation as language generation task with specific attributes in terms of content and linguistics, i.e. *natural* and *human-written*. Recently, adversarial learning approaches (Goodfellow et al., 2014) have been applied to various tasks and show advantage of learning boundary for target data distribution. Inspired by the setting of discriminator, we propose to use two discriminators to better learn these two textual attributes. For the attribute of *human written*, we use a generative adversarial network (GAN) to learn a dynamic discriminator to

VQA:
1. How many plates are seen ?
2. Is this some sort of craft idea ?
3. How many different candies are visible ?

VQG:
1. Is this serving as a birthday cake ?
2. Where can I buy that birthday cake ?
3. How many different candies did you use to make this cake ?
4. Whose idea was it for a candy cake ?
5. Who made that candy cake ?

Figure 1: Annotated questions for tasks of VQG and VQA to an image from the dataset of MSCOCO (Antol et al., 2015).

distinguish human generated questions and machine generated questions. For the attribute of *natural*, we use questions from VQA as negative samples and questions from VQG as positive samples to train a static discriminator.

It is difficult to come up some differentiable objective function for our target. Recently, reinforcement learning has been introduced to optimize model in terms of non-differentiable metrics (Ranzato et al., 2015; Rennie et al., 2016; Zhang et al., 2017; Feng et al., 2018). Therefore, we propose a reinforcement learning framework (Williams, 1992) to incorporate scores from the two discriminators as the reward to guide the optimization of the question generator. Experiment results on a benchmark dataset show the effectiveness of our proposed framework in terms of both automatic and human evaluation.

We will introduce our framework in detail in section 2. In section 3, we present our experiment results. In section 4, we list some related works. In section 5, we conclude our work and point out some future directions.

2 Framework

Given an image I, we aim to train a generative model G_θ with parameter θ that is able to produce natural questions. The generator is designed following the fashion of Seq2Seq (Cho et al., 2014) that takes the representation of the image as input and generates a question word by word. We take two attributes of natural questions into consideration while training the generator. In particular, two discriminators are proposed to distinguish samples from two pairs of counter-question-distributions, namely *human written* vs *machine generated* and *natural* vs *descriptive*. A reinforcement learning framework is then used to combine results from the two discriminators as the reward to train the generator. The overall framework can be see in Figure 2.

2.1 Bi-discriminator configuration

We first introduce our setup of bi-discriminators in this sub-section starting with the design of a hierarchical structure for the distribution of questions.

Hierarchical structure for question distribution Suppose we have an overall domain $\mathcal{D}$ for all the questions, it can be split into two antithetic domains $\mathcal{D}_g$ (*machine generated*) and $\mathcal{D}_h$ (*human written*) according to linguistic attribute. The human written domain can be further split into $\mathcal{D}_{n+}$ (*natural*) and $\mathcal{D}_{n-}$ (*descriptive*) according to the content attribute *natural*. The hierarchical structure is described in Equation 1.

$$\begin{aligned} \mathcal{D} = \mathcal{D}_g \cup \mathcal{D}_h, \;\; \mathcal{D}_h = \mathcal{D}_{n+} \cup \mathcal{D}_{n-} \\ \mathcal{D}_{n+} \subset \mathcal{D}_h \subset \mathcal{D} \end{aligned} \tag{1}$$

To distinguish questions from the two pairs for counter-question-domains ($\mathcal{D}_g$ vs $\mathcal{D}_h$ and $\mathcal{D}_{n+}$ vs $\mathcal{D}_{n-}$), we propose two discriminators, D_1 and D_2. Discriminator D_1 is trained to discriminate whether a question comes from $\mathcal{D}_h$ or $\mathcal{D}_g$, and D_2 is trained to discriminate whether a question belongs to $\mathcal{D}_{n+}$

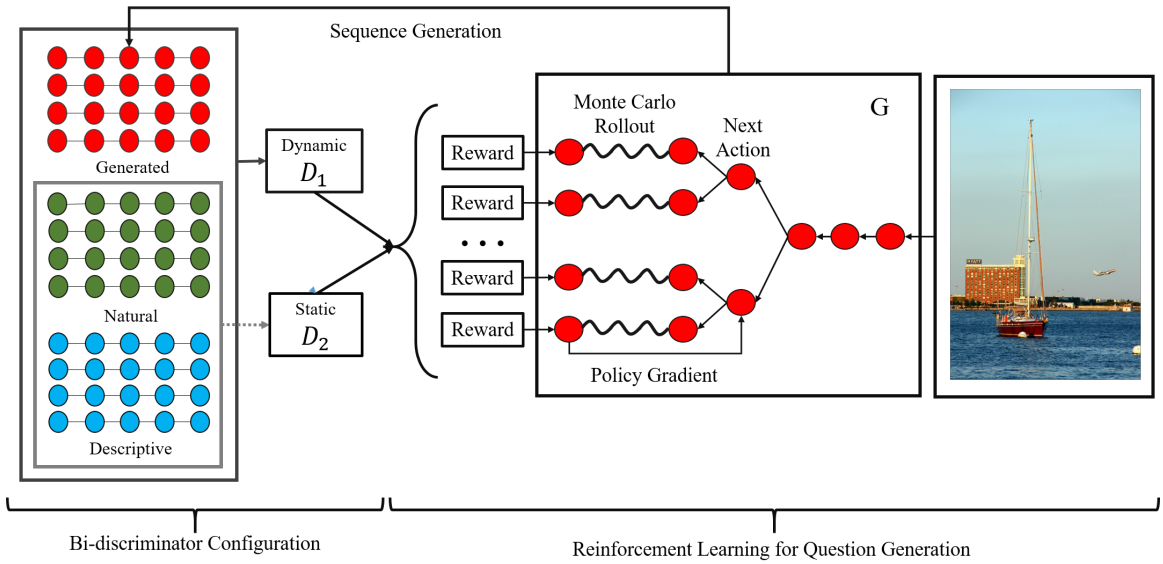

Figure 2: The overall framework of our proposed model.

or $\mathcal{D}_{n-}$. Final layer's activation of two discriminators is sigmoid, which represents the possibility that question belong to the positive domain $\mathcal{D}_*$ as formula 2 shown.

$$P_1\big(G_\theta(I) \in \mathcal{D}_h | I\big), \quad P_2\big(G_\theta(I) \in \mathcal{D}_{n+} | I\big) \tag{2}$$

where $G_\theta(I)$ stands for questions generated by the generator given image I, P_1 stands for the likelihood that a generated question is from domain $\mathcal{D}_h$ and P_2 stands for the likelihood that a generated question is from $\mathcal{D}_{n+}$.

Scores of the two discriminators are served as the reward in our reinforcement learning framework to guide G_θ to generate questions closer to questions in target domain $\mathcal{D}_*$. Under such setting, it is easy to observe that question similar to $\mathcal{D}_{n+}$ would be encouraged to generate by both D_1 and D_2, which means that our bi-discriminator environment configuration is able to encourage natural question generation in theory. In conclusion, maximizing score of $G_\theta(I)$ assigned by two discriminators is equal to encourage generate question with attributes of $\mathcal{D}_h$ (human-written) and $\mathcal{D}_{n+}$ (natural).

Discriminator D_1 for question domains $\mathcal{D}_g$ and $\mathcal{D}_h$ Discriminator D_1 is proposed to distinguish human written questions and machine generated questions. It is used to guide the generator to produce questions closer to samples from the domain of $\mathcal{D}_h$. We propose to use questions from a human generated dataset as positive samples while questions from our generator as negative samples. Considering the generator is updating during the training process, discriminator D_1 needs to be re-newed accordingly. We introduce generative adversarial network (GAN) for the training of D_1 to learn the border between $\mathcal{D}_h$ and $\mathcal{D}_g$ in pace with the updating of G_θ. The target of GAN is shown in Equation 3.

$$\min_G \max_D V(D,G) = \mathbb{E}_{p_{data}(\mathbf{x})}\big[log\, D(\mathbf{x})\big] + \mathbb{E}_{p_z(\mathbf{z})}\big[log\,\big(1 - D(G(\mathbf{z}))\big)\big] \tag{3}$$

The discriminator would converge to $D^*(\mathbf{x}) = p_{data}(x)/\big(p_{data}(\mathbf{x}) + p_g(\mathbf{x})\big)$ during the training. The optimal generator G in GAN aims to mock D to be unable to recognize generated samples. In our case, the optimal condition is that questions generated can be completely mixed with human-written questions, and the dynamic discriminator D_1 is incapable to distinguish these two kinds of questions and thus assign equal probabilities to both categories.

During training, once we have a batch of generated questions, we re-train the discriminator to minimize the loss in Equation 4,

$$L_{D_1} = -\mathbb{E}_{Q\sim D_g}\Big[log\,\big(1 - D_1(Q)\big)\Big] - \mathbb{E}_{Q\sim D_h}\Big[log\, D_1(Q)\Big] \tag{4}$$

where positive samples are from human-written domain $\mathcal{D}_h$, and negative samples are generated by current generator G_θ.

Discriminator D_2 for question domains $\mathcal{D}_{n+}$ and $\mathcal{D}_{n-}$ Discriminator D_2 is proposed to distinguish natural questions and descriptive questions. It is used to guide the generator to produce questions with information beyond the image to meet the attribute of *natural*. With human generated samples from both domains $\mathcal{D}_{n+}$ and $\mathcal{D}_{n-}$, discriminator can be trained before-hand and stay static during the training of the generator. Cross-entropy loss is used for the training of D_2. Considering that labeled samples for *natural* questions are much less than *descriptive* ones in reality, we need to consider the problem of class imbalance. As proved in the application of object detection (Lin et al., 2017b), focal loss can reduce the problem of imbalance. It slows the updating speed of a certain class when that class has been trained well. Similarly, we train the discriminator D_2 using focal loss following Equation 5.

$$
\begin{aligned}
p_t(Q,I) &= \begin{cases} P_2(Q \in \mathcal{D}_{n+}|I) & Q \in \mathcal{D}_{n+}|I \\ P_2(Q \in \mathcal{D}_{n-}|I) & Q \in \mathcal{D}_{n-}|I \end{cases} \\
L_{D_2} &= -\big(1 - p_t(Q,I)\big)^\gamma \, log \;\; p_t(Q,I)
\end{aligned} \tag{5}
$$

2.2 Reinforcement Learning for Question Generation

The reinforcement learning algorithm mainly consists of the generative model G_θ and the reward function R.

Generative model Our generator G_θ follows the design of Seq2Seq model. The only difference is that it takes image features as input instead of a sequence of words. We use *fc7* feature extracted from VGGNet to represent a given image. The decoder is a recurrent neural network that generates a question word by word. In the framework of reinforcement learning, the generation process can be described as a sequence of states and actions (known as trajectory as well), $\big(s_0, a_0, s_1, a_1, \cdots, s_T, a_T, s_{T+1}\big)$, where a_0 is the input image feature. $\mathcal{A}_t (t \geq 1)$ denotes the action space at time t. For text generation, action is the generation of a word, the action space is thus the whole vocabulary. In this task, when action is determined, the following state is also determined. Therefore, we can denote a trajectory as $\big(a_0, a_1, \cdots, a_T\big)$ for simplicity.

Reinforce learning and policy gradient training Based on the reward function R and the generative model G_θ, our goal is to maximize the expectation of reward $R(Q,I)$, where Q is a set of questions produced by G_θ and subject to $p_\theta(Q|I)$. By means of REINFORCE algorithm (Williams, 1992), the objective function is shown in Equation 6.

$$
\mathcal{J}(\theta) = \mathbb{E}_{Q \sim p_\theta(Q|I)}\big[R(Q,I)\big] \tag{6}
$$

Assuming that $p_\theta(Q|I)$ is continuously differentiable with respect to θ, the gradient of the equation 6 with respect to θ can be solved by policy gradient method shown in Equation 7 (Aleksandrov et al., 1968; Glynn, 1990; Williams, 1992).

$$
\frac{\partial \mathcal{J}(\theta)}{\partial \theta} = \mathbb{E}_{Q \sim p_\theta(Q|I)}\left[\left(\sum_{t=1}^{T} \frac{\partial}{\partial \theta} log\, p_\theta(a_t|a_{0:t-1})\right) R(Q,I)\right] \tag{7}
$$

During the training, after generating questions, we compute rewards based on reward function R and update G_θ using gradient ascent algorithm.

Monte Carlo Rollout The disadvantage of REINFORCE algorithm in language generation is that the reward can only be assigned to a complete sentence. Therefore, every single action taken for generating a complete sentence share the same reward. This hurts the effectiveness of training the generator.

To deal with such problem, we employ the strategy of Monte Carlo Rollout to assign a specific reward to each action. Suppose that we have a partial trajectory $a_{0:t-1}$ at t time, then we sample word a_t from

action space $\mathcal{A}_t$ according to policy G_θ. Next, we use Monte Carlo Rollout to generate the remaining $T-t$ tokens. The m_{th} Monte Carlo Rollout consequence is represented in equation 8:

$$\mathrm{MC}^m_{G_\theta}(a_{1:t-1}, a_t) = (a_{1:t-1}, a_t, a^m_{t+1:T}) \tag{8}$$

The reward for action a_t is computed as the mean reward of the sampling sentences, which is the following equation 9:

$$R\big((a_{0:t-1}, a_t), I\big) = \begin{cases} \frac{1}{M}\sum_{m=1}^{M} R\big(\mathrm{MC}^m_{G_\theta}(a_{1:t-1}, a_t), I\big) & t < T \\ R\big((a_{0:t-1}, a_t), I\big) & t = T \end{cases} \tag{9}$$

With Monte Carlo Rollout, the policy gradient is reconstructed as Equation 10.

$$\frac{\partial \mathcal{J}(\theta)}{\partial \theta} = \mathbb{E}_{p_\theta(Q|I)}\left[\left(\sum_{t=1}^{T} \frac{\partial}{\partial \theta} log\, p_\theta(a_t|a_{0:t-1})\right) R\big((a_{0:t-1}, a_t), I\big)\right] \tag{10}$$

Teacher Force As shown in Equation 10, ground-truth samples are not directly used to optimize the generator in the training process. In practice, this is usually in-efficient and is difficult to train a good question generator. Once the performance of generator G_θ is poor and the discriminator is able to do a good job identifying the origin of questions, it is non-trivial for the generator to find a way for improvement without guidance of ground-truth samples. To alleviate the issue, it is necessary for the generator to directly access the ground-truth questions, through which, generator G_θ learns the knowledge of target questions so that it is able to improve the performance. We follow Sutskever et al. (2014) to use the strategy of teacher force that trains the generator via MLE loss together with rewards from discriminators.

Training The overall training process of our proposed model is shown in Table 1.

3 Experiments

3.1 Dataset

We evaluate our models using MSCOCO part of Visual Question Generation (VQG) dataset[1] (Mostafazadeh et al., 2016). It contains 2500, 1250 and 1250 images for training, validation and testing respectively. Each image is accompanied with 5 natural questions produced by human annotators.

Another dataset involved is VQA. For each image in VQA, three questions are collected. The intention of building such dataset is to teach model to response to the questions with respect to concepts in some certain images. Therefore, questions in VQA are much simpler than those ones in VQG. VQG dataset contains about 80000, 40000, 80000 images for training, validation and testing respectively. VQA is used to pre-train our question generator and questions are also served as negative samples to train the discriminator D_2.

3.2 Models for Comparison

We compare our models with some baselines and some state-of-the-art methods.

- **KNN** (Mostafazadeh et al., 2016): using the question from the most similar image as the question for a target image. Cosine similarity based on *fc7* features is utilized to search for similar images.
- **Img2Seq**: it generates a question from image features following Seq2Seq fashion (Cho et al., 2014). The model is trained using the word-level loss maximum likelihood estimation (MLE).
- **Img2Seq**$_{pre-train}$: different from *Img2Seq*, this model is pre-trained on VQA.
- **MIXER-BLEU-4** (Ranzato et al., 2015): it follows the framework of reinforcement learning that uses BLEU-4 between the generated question and the human-written question as the reward to guide the parameter update of the generator with policy gradient. Since the model is trained by optimizing BLEU-4 directly, it is able to generate higher BLEU-4 score in general.
- **Reinforce**$_{\mathbf{D_1}}$: it uses the score of D_1 as the reward to guide the training of the generator. The setting is quite similar to *SeqGAN* (Yu et al., 2017). This model is a upgrade version of **Img2Seq**. It introduces adversarial learning network to better train the generator under the reinforcement learning framework.
- **Reinforce**$_{\mathbf{D_2}}$: it uses the score of D_2 as the reward to guide the training of the generator. This model is comparable to *MIXER-BLEU-4* because both models utilize a static way to produce reward (BLEU score with ground truth questions in *MIXER-BLEU-4* and classification confidence in Reinforce$_{\mathbf{D_2}}$)
- **Reinforce**$_{\mathbf{D_1+D_2}}$: this is our proposed model.

3.3 Training Details

For the generator, we use GRU cell and the number of cells is 512; the dimension of word embedding is 300 and is pre-trained using GloVe (Pennington et al., 2014). The image feature, *fc7* is the output of the 7th fully-connected layer in *VGGNet*. The original dimension of *fc7* is 4096, and we compress it to a 300-dimension vector using 2-layer fully-connected layer. The upper settings are the same for all neural network models. We set batch size, rollout size, D1-step, G1-step, G2-step and G3-step as 64, 16, 5, 1, 2 and 1, respectively. γ for the training of D_2 is set to 2.0 empirically.

3.4 Automatic Evaluation

There is no direct evaluation metric to determine whether a question is natural or not. We thus use several relevance scores for the automatic evaluation following the setting of existing researches, including Corpus BLEU-4, BLEU-4 (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), ROUGE (Lin and Hovy, 2003) and CIDEr (Vedantam et al., 2015). The overall experiment results in terms of five relevance scores are shown in Table 1. We have some findings as follows:

[1]The original dataset contains three parts, namely, MS-COCO, Flickr and Bing, *VQG-MSCOCO*. However, images from Flickr and Bing are quite different from those in Visual Question Answering (VQA) dataset (Antol et al., 2015), and this makes it difficult to use questions from VQA as negative samples to train D_2.

Model	BLEU-4	corpus BLEU-4	METEOR	ROUGE	CIDEr
KNN	37.062	19.799	22.413	52.324	50.199
Img2Seq	36.744	21.028	23.125	54.089	51.171
Img2Seq$_{pre-train}$	37.522	22.106	23.877	55.310	54.076
MIXER-BLEU-4	**41.674**	24.808	24.382	**57.777**	60.527
Reinforce$_{\mathbf{D_1}}$	38.945	24.420	24.665	56.196	59.513
Reinforce$_{\mathbf{D_2}}$	40.063	25.237	25.492	57.503	61.745
Reinforce$_{\mathbf{D_1+D_2}}$	41.098	**26.265**	**25.634**	57.679	**63.388**

Table 1: Overall experiment results of different models in terms of relevance scores. **bold**: the best performance in that column.

- Although *KNN* model retrieves questions from the original dataset, the result is not good enough. Further analysis reveals that questions generated are not relevant to the target image. Therefore, the strategy of reusing questions from similar images is not sufficient for generating question with high quality.
- Performance of *Img2Seq*$_{pre-train}$ is better than that of *Img2Seq* in terms of all the five metrics. This indicates that samples from the domain of $\mathcal{D}_{n-}$ are also helpful for generating high quality natural questions. This is reasonable because samples from VQA also locate in the domain of $\mathcal{D}_h$ therefore pre-training is able to guide the generator to better learn the attribute of *human written*.
- By incorporating the discriminator D_2, both models of *Reinforce*$_{\mathbf{D_2}}$ and *Reinforce*$_{\mathbf{D_1+D_2}}$ is able to improve the performance in terms of all the five relevance scores compared with their counter-part models *Img2Seq*$_{pre-train}$ and *Reinforce*$_{\mathbf{D_1}}$ respectively. This confirms the effectiveness of discriminator D_2. The existence of $\mathcal{D}_{n-}$ helps the generator G_θ learns more about the unique features for questions in $\mathcal{D}_{n+}$ and better demarcates the boundary of itself.
- By incorporating the discriminator D_1, both *Reinforce*$_{\mathbf{D_1}}$ and *Reinforce*$_{\mathbf{D_1+D_2}}$ produce better performance than their counter-part approaches *Img2Seq* and *Reinforce*$_{\mathbf{D_2}}$ respectively. The disadvantage of training using MLE is that only human-generated training samples are exposed to generator (known as exposure bias) and loss is computed in word-level without considering sentence-level performance. By adding D_1, the generator is able to observe generated question during training. Therefore the issue of exposure bias can be partially addressed. Besides, the sentence level performance is also computed and used as reward to guide the training process.
- *MIXER-BLEU-4* produces the highest score of BLEU-4 and ROUGE but it performs much worse in terms of other three metrics. This indicates that simply using one criteria value as the reward is not universal.
- Our proposed model *Reinforce*$_{\mathbf{D_1+D_2}}$ produces three best values out of the five evaluation metrics. This confirms the effectiveness of our proposed framework for natural question generation. Although our model is not optimizing BLUE-4 directly, it performs comparable to *MIXER-BLEU-4* in terms of BLUE-4, indicating the robustness of our model.

3.5 Human Evaluation

We also perform human evaluation on generated questions from different models to evaluate their naturalness (Mostafazadeh et al., 2016). For a given image, we first list questions generated by different models and randomly sample one question from ground-truth to form the question pool. Then we present the image and the corresponding question pool to the annotator. S/he is asked to assign a score to each single question in term of naturalness. A guidance from (Mostafazadeh et al., 2016) is presented during the annotation. We set the score range in $(1\ 2\ 3)$ following (Mostafazadeh et al., 2016). The better the question is, the higher score it would get.

KNN What type of bird are these ?
MIXER-BLEU-4 Are those bananas ?
Img2Seq What kind of bananas are those ?

Model	1	2	3	Avg
KNN	214	120	66	1.63
Img2Seq	182	147	71	1.72
MIXER-BLEU-4	153	172	75	1.81
Reinforce$_{\mathbf{D_1}}$	167	153	80	1.78
Reinforce$_{\mathbf{D_1+D_2}}$	149	160	91	1.86
Ground-truth	50	79	271	2.55

Table 2: Results of human evaluation for different models.

Two annotators are invited to label the questions independently. We collect the number of various ratings for different models and add up the value of the two annotators. We randomly choose 200 images for human evaluation. Result is shown in Table 2. Figure 3 shows two sample images and corresponding questions generated by different models. Based on the result of human evaluation and the sample questions generated by the system, we have some findings as follows:

- Relatively poor performance of retrieval model indicates that questions retrieved by KNN are not relevant to the image as we can see in Figure 3.

- The performance of *Reinforce*$_{\mathbf{D_1+D_2}}$ is the best among all automatic question generators in terms of the number of rating 3 it obtains. This reconfirms the effectiveness of our framework. Besides, the sample questions in Figure 2. also reveals that our system is able to ask more complex questions.

- The performance of *MIXER-BLEU-4* is middle-level. This indicates that optimizing a single evaluation metric is not sufficient enough for generating high quality natural questions.

- The gap between ground-truth questions and machine generated questions is still large. This indicates that there is still a large room for question generation system to improve.

4 Related Works

This paper locates in the research filed of question generation and reinforcement learning for sequence generation. We will focus on related works from these two domains.

Question Generation Question generation has been researched for years from textual input (Rus et al., 2010; Heilman, 2011). Researchers start from rule-based method that extracts key aspects from the input text and then insert these aspects into human generated templates for interrogative sentence generation (Heilman, 2011). Recently, sequence-to-sequence model is utilized for question generation in description-question pairs (Du et al., 2017; Tang et al., 2017; Serban et al., 2016). Although these models generate better performance, the characteristics of question is still ignored. On the other hand, research about visual question generation is much less (Ren et al., 2015; Vijayakumar et al., 2018;

Mostafazadeh et al., 2016; Shijie et al., 2017). Diversity as another important characteristic of question also draws much attention. Li et al. (2016) proposed to use Maximum Mutual Information (MMI) as the objective function for result diversification. Vijayakumar et al. (2018) proposed a diverse beam search for generated multiple questions. Fan et al. (2018) utilized question type driven framework to diversify question generation.

Natural question generation cares more about a specific attribute of the generated text in terms of content. Although some attempts have been explored for this task, researchers ignore the attribute of *natural* in general. In our work, we treat this task as language generation with an additional attribute and propose a reinforcement learning framework for it. Our framework can also be used to other language generation tasks like dialogue generation with emotion information.

Reinforcement Learning For Sequence Generation *MIXER* (Ranzato et al., 2015) model uses REINFORCE method with a baseline reward estimator, directly optimizes BLEU-4 score of generated sequence. In order to compensate same reward for all action in generation and lack of ground-truth sequence knowledge, curriculum learning is utilized. Although performance in corresponding metric gets better, but model still lacks robustness and distinguishing reward for every generate step. Actor-Critic algorithm (Konda and Tsitsiklis, 2000) in sequence generation (Bahdanau et al., 2017) utilizes value network to estimate reward for every generate step. Rennie et al. (2016) utilizes self-critic $\arg\max$ to estimate generator's reward more accurately and does not need additional value network. Different reward function also gets attention for better evaluation and robustness. Liu et al. (2017) uses a combination of different metrics as the reward. In the task of visual caption generation, visual-semantic embedding (Frome et al., 2013; Kiros et al., 2015) is used to be reward (Ren et al., 2017) for better matching image and caption. SeqGAN (Yu et al., 2017), RankGAN (Lin et al., 2017a), LeakGAN (Guo et al., 2018) are also based on Reinforcement Learning, they aim to generate sequence more similar to human-written ones, thus the similarity is assigned as reward to generator.

In our setting, we borrow the idea of GAN to train one of our discriminators. Adversarial training is effective in improving generator's capability in general tasks, and it helps our generator get better guidance of natural attribute. Most of existing research under reinforcement learning focuses on using a single reward to guide the training of the generator. In this paper, we propose a setting of bi-discriminator to consider two attributes of target text and it is easy to be generalized to multiple discriminators incorporating other information.

5 Conclusion and Future Work

In this paper, we propose a reinforcement learning framework for natural question generation. It incorporates two discriminators to take two specific attributes of natural question into consideration. Experimental results on a benchmark VQG dataset show the effectiveness and robustness of our proposed model. The proposed framework can be applied to other language generation tasks with additional attribute, such as dialogue generation with emotion information. Besides, the setting of bi-discriminators can be extended to multi-discriminators to incorporate more information.

The future research can be carried out in several directions. First, during our experiment, we find that the time and space consumption of Monte Carlo Rollout is expensive. More effective and powerful methods of assigning reward for every generate step deserve research in the future. Second, We will explore more structural scoring system and better collaborative method of multiple discriminators. Third, another future direction is to incorporate some automatic evaluation metrics into our reinforcement learning framework to improve the performance further.

Embedding Words as Distributions with a Bayesian Skip-gram Model

Abstract

We introduce a method for embedding words as probability densities in a low-dimensional space. Rather than assuming that a word embedding is fixed across the entire text collection, as in standard word embedding methods, in our Bayesian model we generate it from a word-specific prior density for each occurrence of a given word. Intuitively, for each word, the prior density encodes the distribution of its potential 'meanings'. These prior densities are conceptually similar to Gaussian embeddings of Vilnis and McCallum (2015). Interestingly, unlike the Gaussian embeddings, we can also obtain context-specific densities: they encode uncertainty about the sense of a word given its context and correspond to the approximate posterior distributions within our model. The context-dependent densities have many potential applications: for example, we show that they can be directly used in the lexical substitution task. We describe an effective estimation method based on the variational autoencoding framework and demonstrate the effectiveness of our embedding technique on a range of standard benchmarks.

1 Introduction

Distributed representations of words induced from large unlabeled text collections have had a large impact on many natural language processing (NLP) applications, providing an effective and simple way of dealing with data sparsity. Word embedding methods typically represent words as vectors in a low-dimensional space (Deerwester et al., 1990; Collobert et al., 2011; Mikolov et al., 2013; Pennington et al., 2014). In contrast, we encode them as probability densities (see Figure 1). Intuitively, the densities represent the distributions over possible meanings[1] of a word. Representing a word as a distribution provides many potential benefits. For example, such embeddings let us encode generality of terms (e.g., kakapo is a hypernym of bird), characterize uncertainty about semantic properties of the corresponding referent (e.g., a proper noun, such as John, encodes little about the person it refers to) or represent polysemy (e.g., kiwi may refer to a fruit, a bird or a New Zealander).

The main inspiration for this work is Gaussian embeddings (*word2gauss*, W2G) introduced by Vilnis and McCallum (2015). They represent words as Gaussian distributions and directly optimize an objective expressed in terms of divergences (e.g., the Kullback-Liebler divergence) between the distributions. In contrast, we approach the problem from the generative Bayesian perspective. Though, as in W2G, context-agnostic densities are present in our model (they correspond to data-dependent priors), unlike W2G, we can also perform posterior inference and obtain context-specific densities. These posterior densities encode semantic properties of a word in a given context. For example, in Figure 1, when 'kiwi' appears in a context suggesting the 'bird' sense, the posterior (represented by the shaded ellipsoid) becomes more 'peaky' and moves towards the representation of word 'bird'. We use a lexical substitution task (McCarthy and Navigli, 2007) to demonstrate that the posterior densities are effective in predicting potential replacements of a word given a context. Importantly, though the Gaussian assumption for context-agnostic embeddings is questionable (e.g., polysemous words would need multimodal distributions to accurately represent their meanings), the same assumption for the context-specific posterior

[1]We use the term 'meaning' somewhat liberally in this work: we are not arguing that embeddings capture actual meanings.

Proceedings of the 27th International Conference on Computational Linguistics, pages 1775–1789
Santa Fe, New Mexico, USA, August 20-26, 2018.

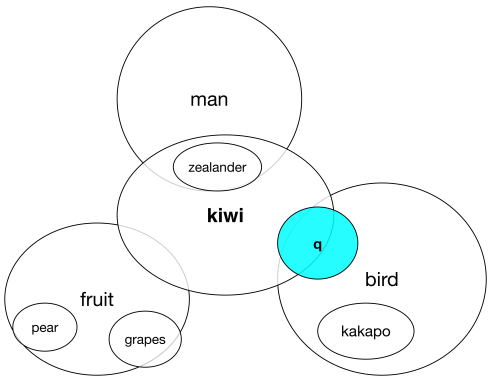

Figure 1: An idealized illustration of density embeddings. Unshaded ellipsoids encode prior densities. The shaded ellipsoid corresponds to the posterior for 'kiwi' when it appears in a context indicating that 'kiwi' refers to a bird.

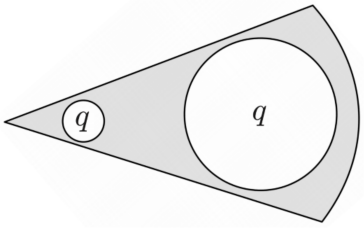

Figure 2: Shaded cone is a fixed angle, and ellipses are approximate posterior Gaussian distributions. The corner of the cone is at the origin.

densities is more reasonable: the word is likely to be disambiguated by the provided context and hence does not require complex families of distributions.

In principle, using densities to represent words provides a natural way of encoding entailment: the decision regarding entailment relation can be made by testing the level sets of the distributions for soft inclusion. For example, in Figure 1, the ellipse for 'kakapo' lies within the ellipse for 'bird'. Vilnis and McCallum (2015) proposed to use the KL divergence to detect entailment. In our analysis, we observe that, though the covariances indeed encode information relevant to entailment, their direct use is somewhat problematic both with W2G and with our model.

We are not the first to propose a Bayesian version of word embedding methods (Zhang et al., 2014; Sakaya, 2015; Barkan, 2017). However, our approach is crucially different from the previous work. The previous methods can be regarded as applications of Bayesian matrix factorization (BMF) (Salakhutdinov and Mnih, 2008) to word co-occurrence matrices. Hence they assume that every word is associated with a fixed (but unknown) real-valued vector which is shared across the entire text collection. Instead, in our approach, we acknowledge that word meaning inherently depends on a context and do not assume that any fixed vector exists at type level: we draw it at token level (i.e. for each word occurrence) from a parameterized word-specific prior distribution. Consequently, unlike us and also unlike densities in W2G, the posteriors in previous Bayesian embeddings models encode uncertainty about the embedding parameters; they will converge to a delta distribution as the amount of data increases. In contrast, our densities encode the distribution of senses and, as confirmed in our experiments, do not follow this trend.

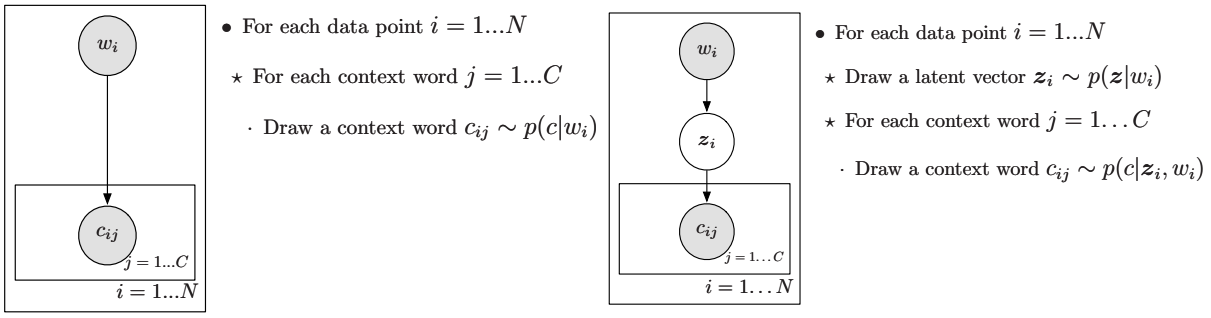
More formally, our model can be regarded as a form of coupled matrix factorization where each sliding window is factorized individually, but priors for words are shared across all the windows. We describe an effective estimation method based on the variational autoencoding (VAE) framework (Kingma and Welling, 2014). The context-specific densities are provided by the encoder component of VAE (i.e. the inference network). Our main contributions can be summarized as follows:[2]

- we proposed a Bayesian model for embedding words as probability densities;
- we derived a computationally-efficient inference algorithm, which, as a by-product, yields context-sensitives densities;
- we demonstrate their effectiveness, including on the lexical substitution task.

2 Bayesian Skip-gram

In this section, we provide detailed description of the novel model. To motivate our Bayesian extension of the Skip-gram model, consider the polysemous word 'kiwi' (Figure 1). Its meaning changes depending on the context: for example, when it appears in 'I like apples, kiwi, and bananas', we can

[2]The implementations of our model is available at `https://github.com/ixlan/BSG`.



(a) SG

(b) BSG

Figure 3: Bayesian networks corresponding to Skip-gram and Bayesian skip-gram.

deduce that 'kiwi' refers to a fruit. Polysemy cannot be effectively captured with a single representation induced by standard word embedding methods (e.g., skipgram (Mikolov et al., 2013)) or even with a single distribution, as in W2G. We also do not want to assume that there is a finite set of discrete senses, as made in multi-sense mixture models (Li and Jurafsky, 2015; Neelakantan et al., 2014). Sense distinctions are often gradual and discrete senses are only clusters that approximate underlying meaning distributions (Kilgarriff, 1997; Erk and McCarthy, 2009). Our Bayesian Skip-gram (BSG) model addresses this problem. It predicts a distribution of 'meanings' given a context. Intuitively, if the context is very discriminative, this density becomes very peaky, assigning the entire probability mass to the predicted 'meaning' (in the limit, encoding the word as a point vector). If the context is less informative, the distribution will remain flat, representing uncertainty about the word sense.

2.1 Generative model

The skip-gram (SG) model aims at maximizing the probability $p_{\boldsymbol{\theta}}(\mathbf{c}|w)$ of words in a context window given its central word. The log probability of each context word is assumed to be proportional to the dot product of its representation and that of the central word (see the graphical model in Figure 3a). In contrast, BSG assumes that the choice of context words is dependent on the context-specific (latent) meaning of the central word (see Figure 3b).

The generative story of BSG is the following: take a word from the dataset (e.g. 'kiwi'), sample its latent meaning $\mathbf{z} \sim p_{\boldsymbol{\theta}}(\mathbf{z}|w)$ (e.g., a vector that encodes the meaning 'bird'), and finally draw context words $c \sim p_{\boldsymbol{\theta}}(c|\mathbf{z})$ (e.g., 'flightless', 'forest', and 'feather').

2.2 Model definition

Ideally, we would like to maximize the log-likelihood, which is the sum of the following terms, one per each window:

$$\log p_{\boldsymbol{\theta}}(\mathbf{c}|w) = \log \int \prod_{j=1}^{C} p_{\boldsymbol{\theta}}(c_j|\mathbf{z}) p_{\boldsymbol{\theta}}(\mathbf{z}|w) \mathrm{d}\boldsymbol{z} \tag{1}$$

where C is the size of the context window $\mathbf{c}$, c_j is a context word for the central word w, and θ are model parameters. Unfortunately, as $p_{\boldsymbol{\theta}}(c_j|\mathbf{z})$ is a neural network, integration over the latent space is intractable. Hence, the marginal log-likelihood and its derivatives cannot be efficiently computed. In our case posterior distribution $p_{\boldsymbol{\theta}}(\mathbf{z}|\mathbf{c}) = p_{\boldsymbol{\theta}}(\mathbf{c}|\mathbf{z}) p_{\boldsymbol{\theta}}(\mathbf{z}) / p_{\boldsymbol{\theta}}(\mathbf{c})$ is intractable as well. This means that the expectation-maximization (EM) algorithm cannot be used. Instead, we rely on variational inference, specifically the variational auto-encoding (VAE) framework (Kingma and Welling, 2014).

2.3 Bayesian Skip-gram ELBO

For BSG model we optimize the variational lower bound of the marginal likelihood:

$$\log p_{\boldsymbol{\theta}}(\mathbf{c}|w) \geq \sum_{j=1}^{C} \mathbb{E}_{q_{\boldsymbol{\phi}}(\mathbf{z}|\mathbf{c},w)} \left[\log p_{\boldsymbol{\theta}}(c_j|\mathbf{z})\right] - \mathbb{D}_{KL}\left[q_{\boldsymbol{\phi}}(\mathbf{z}|\mathbf{c},w) \| p_{\boldsymbol{\theta}}(\mathbf{z}|w)\right] \tag{2}$$

where $q_{\boldsymbol{\phi}}(\mathbf{z}|\mathbf{c}, w)$ is the approximate posterior distribution, which can be used to infer the representation ('meaning') of the central word w in the context $\mathbf{c}$. For now, we will assume that the approximate posterior is a Gaussian distribution with a diagonal covariance matrix, namely $q_{\boldsymbol{\phi}}(\mathbf{z}|\mathbf{c}, w) = \mathcal{N}(\boldsymbol{z}|\boldsymbol{\mu}_q, \boldsymbol{\Sigma}_q)$. The covariance matrix of the approximate posterior encodes uncertainty or generality of meaning of the central word w in the context $\boldsymbol{c}$. Intuitively, if the meaning is concrete, we would like to get small variance values and large, otherwise.

Another important component of our model is $p_{\boldsymbol{\theta}}(\mathbf{z}|w)$, to which we will refer as a *prior*, and we will assume that it is also a Gaussian distribution with a diagonal covariance[3] and individual parameters for each central word $p_{\boldsymbol{\theta}}(\mathbf{z}|w) = \mathcal{N}(\boldsymbol{z}|\boldsymbol{\mu}_w, \boldsymbol{\Sigma}_w)$. Fortunately, the KL divergence term between two normal distributions can be expressed in closed form.

2.4 Reconstruction error

The most troublesome component of the lower bound is the expected reconstruction term $\mathbb{E}_{q_{\boldsymbol{\phi}}(\mathbf{z}|\mathbf{c},w)}\left[\log p_{\boldsymbol{\theta}}(c_j|\mathbf{z})\right]$ which can be decomposed as shown in Eq. (3):

$$\mathbb{E}_{q_{\boldsymbol{\phi}}(\mathbf{z}|\mathbf{c},w)}\left[\log p_{\boldsymbol{\theta}}(c_j|\mathbf{z})\right] = \mathbb{E}_{q_{\boldsymbol{\phi}}(\mathbf{z}|\mathbf{c},w)}\left[\log \frac{\exp(f_{\boldsymbol{\theta}}(\mathbf{z}, c_j))}{\sum_{k=1}^{|V|}\exp(f_{\boldsymbol{\theta}}(\mathbf{z}, c_k))}\right] \tag{3}$$

where $p_{\boldsymbol{\theta}}(c_j|\mathbf{z})$ is represented by a neural network with the softmax activation function and $f_{\boldsymbol{\theta}}(\mathbf{z}, c_j)$ is a function that models relationship between latent vector $\mathbf{z}$ and context word c_j. In the original skip-gram model it was the dot product. The dot product is based on the angle between two vectors scaled by their norms, which makes a lot of sense with point estimates. However, it is problematic when we use normal distributions. Consider the fixed angle cone and two densities in Figure 2. Both densities encode the same uncertainty about the angle, whereas their variances are very different. Hence, the uncertainty in the dot product can be increased either by moving the density towards the origin or by increasing the variance. In other words, the model has too many degrees of freedom. Consequently, words that are more general will not necessarily have a large variance. We observed this behaviour in our toy experiment.

To address this problem, we propose to use a different form of the function f: $f_{\boldsymbol{\theta}}(\mathbf{z}, c_j) = \log\left(\mathcal{N}(\mathbf{z}; \boldsymbol{\mu}_{c_j}, \boldsymbol{\Sigma}_{c_j}) \times p(c_j)\right)$:[4]

$$\mathbb{E}_{q_{\boldsymbol{\phi}}}\left[\log \frac{\exp(f_{\boldsymbol{\theta}}(\mathbf{z}, c_j))}{\sum_{k=1}^{|V|}\exp(f_{\boldsymbol{\theta}}(\mathbf{z}, c_k))}\right] = \mathbb{E}_{q_{\boldsymbol{\phi}}}\left[\log\left(\mathcal{N}(\mathbf{z};\boldsymbol{\mu}_{c_j}, \boldsymbol{\Sigma}_{c_j})p(c_j)\right) - \log\sum_{k=1}^{|V|}\mathcal{N}(\mathbf{z};\boldsymbol{\mu}_{c_k}, \boldsymbol{\Sigma}_{c_k})p(c_k)\right] \tag{4}$$

Intuitively, scaling with $p(c_j)$ (e.g., the empirical unigram probability) encodes that frequent words are more likely to appear in any context. The Gaussian density evaluates how well a word fits context given the meaning $\mathbf{z}$ of the central word and is more sensitive to the variance, hence addressing the above-mentioned problem.

2.5 Encoder

An important component of our model is the inference network $q_{\boldsymbol{\phi}}(\mathbf{z}|\mathbf{c}, w)$ (also known as an encoder), which approximates the posterior distribution $p_\theta(\mathbf{z}|\mathbf{c}, w)$. As we discussed, we make the Gaussian assumption for q. Similarly to Kingma and Welling (2014), we use a one-layer feed-forward neural network to compute variance and mean parameters of q. Its architecture is shown in Figure 4. The network takes embeddings of the central word and those of context words, passes each of them through a non-linearity (ReLU) and sums the vectors together: $\mathbf{h} = \sum_{j=1}^{C} relu\left(\mathbf{M}\begin{bmatrix}\mathbf{R}_{c_j}\\ \mathbf{R}_w\end{bmatrix}\right)$. The resulting vector is then used to generate $\boldsymbol{\mu}_q$ and $\log\sigma^2$ with a linear model: $\log\sigma_q^2 = \mathbf{W}\mathbf{h} + b_2; \boldsymbol{\mu}_q = \mathbf{U}\mathbf{h} + \mathbf{b}_1$. Using logarithm is necessary to ensure that the matrix is positive definite. The encoder can be understood as a parametrized

[3]Though this assumption is questionable for polysemous words, what is crucial is that in BSG (unlike W2G) we have access to approximate context-specific posterior densities encoding word senses. Nevertheless, using more expressive priors may be beneficial. Expressive data-dependent priors may also lead to over-fitting as using simple priors can be regarded as a form of regularization. We leave investigation of richer priors for future work.

[4]For brevity, we use q_ϕ to denote $q_{\boldsymbol{\phi}}(\mathbf{z}|\mathbf{c}, w)$.

function that produces distributions corresponding to meanings of central words in different contexts. Using this function, we can model infinitely many meanings of words without explicitly storing their representations.

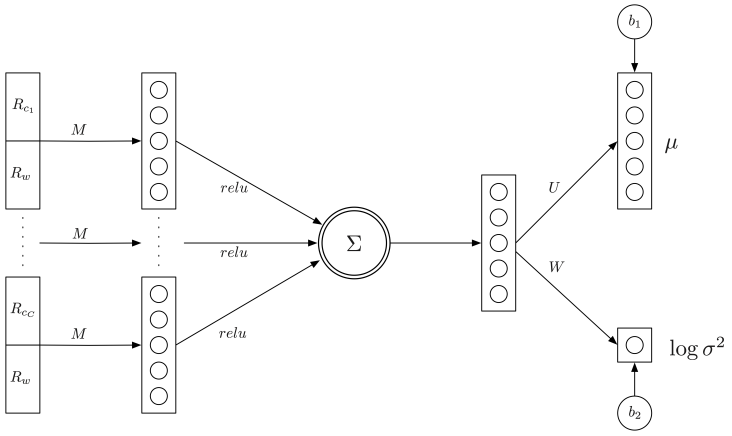


Figure 4: Encoder architecture.

2.6 Approximation of the log-partition function

While we can obtain a low-variance estimate of the first part of the expectation from the Eq. (4) using the re-parameterization trick (Kingma and Welling, 2014), the expected log-partition function (the second part) is very computationally demanding, as it involves summation over all words in the vocabulary. In order to scale it to large vocabularies, we compute the lower bound of the log-partition function and use a Monte Carlo (MC) approximation to obtain an unbiased estimate of the expectation over all words:

$$\mathbb{E}_{q_{\boldsymbol{\phi}}}\left[\log \mathbb{E}_{p(\tilde{c})}\left[\mathcal{N}(\mathbf{z}; \boldsymbol{\mu}_{\tilde{c}}, \boldsymbol{\Sigma}_{\tilde{c}})\right]\right] \geq \mathbb{E}_{q_{\boldsymbol{\phi}}}\left[\mathbb{E}_{p(\tilde{c})}\left[\log \mathcal{N}(\mathbf{z}; \boldsymbol{\mu}_{\tilde{c}}, \boldsymbol{\Sigma}_{\tilde{c}})\right]\right] \approx \mathbb{E}_{q_{\boldsymbol{\phi}}}\left[\log \mathcal{N}(\mathbf{z}; \boldsymbol{\mu}_{\tilde{c}_j}, \boldsymbol{\Sigma}_{\tilde{c}_j})\right] \quad (5)$$

The estimate involves only one word $\tilde{c}_j$ ('negative word') which can be easily sampled from $p(\tilde{c})$. By replacing the log-partition function from Eq. (4) with the unbiased estimate of its lower bound derived in Eq. (5), we can get the approximate lower-bound of marginal log-likelihood[5] shown in Eq. (6). The sum $\sum_{(j,k)}$ in the equation is now over pairs of positive c_j and negative $\tilde{c_k}$ context words. Furthermore, we can transform the difference of negative cross-entropies into the difference of Kullback-Leibler divergences by adding and subtracting entropy of $q_\phi(\mathbf{z}|\mathbf{c}, w)$:

$$\begin{aligned}\hat{\mathcal{L}} = &\sum_{(j,k)} \left(\mathbb{E}_{q_{\boldsymbol{\phi}}}\left[\log \mathcal{N}(\mathbf{z}; \boldsymbol{\mu}_{c_j}, \boldsymbol{\Sigma}_{c_j})\right] - \mathbb{E}_{q_{\boldsymbol{\phi}}}\left[\log \mathcal{N}(\mathbf{z}; \boldsymbol{\mu}_{\tilde{c_k}}, \boldsymbol{\Sigma}_{\tilde{c_k}})\right]\right) - \mathbb{D}_{KL}\left[q_{\boldsymbol{\phi}} \| p_{\boldsymbol{\theta}}(\mathbf{z}|w)\right] = \\ &\sum_{(j,k)} \left(\mathbb{D}_{KL}\left[q_{\boldsymbol{\phi}} \| \mathcal{N}(\mathbf{z}; \boldsymbol{\mu}_{\tilde{c}_k}, \boldsymbol{\Sigma}_{\tilde{c}_k})\right] - \mathbb{D}_{KL}\left[q_{\boldsymbol{\phi}} \| \mathcal{N}(\mathbf{z}; \boldsymbol{\mu}_{c_j}, \boldsymbol{\Sigma}_{c_j})\right]\right) - \mathbb{D}_{KL}\left[q_{\boldsymbol{\phi}} \| p_{\boldsymbol{\theta}}(\mathbf{z}|w)\right]\end{aligned} \quad (6)$$

The first term in the above equation suggests maximization of the margin between divergences that involve negative and positive words. We transform it into the hard-margin form (i.e. use the hinge loss, as done in Weston et al. (2013)). This is the final objective function that we maximize:

$$\sum_{(j,k)} \max\left(0,\ \mathbb{D}_{KL}\left[q_{\boldsymbol{\phi}} \| \mathcal{N}(\mathbf{z}; \boldsymbol{\mu}_{c_j}, \boldsymbol{\Sigma}_{c_j})\right] - \mathbb{D}_{KL}\left[q_{\phi} \| \mathcal{N}(\mathbf{z}; \boldsymbol{\mu}_{\tilde{c}_k}, \boldsymbol{\Sigma}_{\tilde{c}_k})\right] + m\right) + \mathbb{D}_{KL}\left[q_{\boldsymbol{\phi}} \| p_{\boldsymbol{\theta}}(\mathbf{z}|w)\right] \quad (7)$$

This transformation of the objective is necessary because the KL terms are unconstrained, and, during optimization, the model tends to assign extreme values for the frequent negative words and this has a detrimental effect on the overall performance. The hinge loss solves this problem by setting the gain to zero when the KL term involving a negative context word is larger by a margin than the KL term involving a positive one.

[5]Notice that $p(c_j)$ is omitted because it factors out as a constant and does not change the optimum.

The intuition behind the objective is the following: once we generated the posterior distribution $q_{\boldsymbol{\phi}}(\mathbf{z}|\mathbf{c}, w)$, we optimize parameters to make $\mathbb{D}_{KL}\left[q_{\boldsymbol{\phi}}(\mathbf{z}|\mathbf{c}, w)||p_{\boldsymbol{\theta}}(\mathbf{z}|w)\right]$ small, which can be intuitively understood as a regularization preventing $q_{\boldsymbol{\phi}}(\mathbf{z}|\mathbf{c}, w)$ ellipsoid from diverging from $p_{\boldsymbol{\theta}}(\mathbf{z}|w)$ ellipsoid. In addition, we discriminate positive context words from negative ones by comparing their divergences from $q_{\boldsymbol{\phi}}(\mathbf{z}|\mathbf{c}, w)$.

The expected value of the log-partition function in Eq. (3) is with the negative sign, and because we approximate its lower-bound, the resulting objective function in Eq. (6) is not a lower bound of the likelihood anymore. We still found that proposed approximation works quite well in practice. As an alternative, we considered a Monte Carlo approximation of the partition function proposed by Botev et al. (2017). However, this led to inferior performance on our benchmarks.

3 Experiments

In this section we empirically evaluate our approach. First, in subsections 3.2 - 3.4, we use standard benchmarks to evaluate and better understand properties of our context-agnostic embeddings (i.e. the prior distributions $\mathcal{N}(\mathbf{z}; \boldsymbol{\mu}_{c_j}, \boldsymbol{\Sigma}_{c_j})$). In these experiments, we can directly compare BSG to W2G and the vanilla version of skip-gram. In subsection 3.5, we also demonstrate that the context-sensitive posterior distributions $q_{\boldsymbol{\phi}}(\mathbf{z}|\mathbf{c}, w)$, estimated by the VAE inference network, can be used to select potential substitutes of a word in a given context.

3.1 Experimental settings

We train all our models on a concatenation of ukWaC and WaCkypedia (Baroni et al., 2009) corpora, resulting in approximately 3 billion tokens. The embedding dimensionality was set to 100 for all the models. For BSG, we used spherical covariances both for the posterior and prior densities, as they resulted in better performance in preliminary experiments: this is consistent with results reported for W2G in Vilnis and McCallum (2015). In order to enable fair comparison, we used our own implementation of W2G and SG, which shared the hyperparameters with BSG.[6] Throughout the text we use WG(S) and WG(D) to denote W2G with the spherical covariances and W2G with the diagonal covariance matrix, respectively. For additional details see supplementary materials.

[6]The original implementation of W2G is not publicly available. Our re-implementation yields stronger results on similarity benchmarks but weaker on the entailment dataset of Baroni et al. (2012). Our implementation is also stronger across the board (including entailment) than the third-party implementation used in Vulić et al. (2017) (`https://github.com/seomoz/word2gauss`). Athiwaratkun and Wilson (2017) also report W2G numbers very similar to ours.

3.2 Word similarity

Table 1 presents similarity results computed using the online tool of Faruqui and Dyer (2014). In these experiments, we used only the mean vectors (from the prior) and ignored the covariance information, both for BSG and W2Gs. First, we observe that BSG has a slight edge over both the original SG and also over W2G versions. Second, contrary to observations in Vilnis and McCallum (2015), W2G does not reach a performance of SG in our experiments. As their original implementation is not available, it is hard to pinpoint the reason for the discrepancy. Note that their SG baseline is considerably weaker than ours, so it may be easier to beat. Our SG baselines outperforms their reported results on all similarity datasets (they considered only 8 out of 12 in Table 1) and also in average (0.6248 vs. 0.5724).[7] The results suggest that prior means induced by BSG are indeed effective in capturing semantic properties of words.

3.3 Entailment recognition

In this section, we consider the lexical entailment task (i.e. essentially hyponymy detection). Note that, as with word similarity, word context is not provided, and, thus, we cannot showcase the main advantage of our approach: its disambiguation capabilities.

Given an ordered pair of words, the task is to predict if the first word (w_1) entails the second one (w_2). We use two entailment measures: the negated KL divergence $-D_{KL}\left[\mathcal{N}(\mathbf{z};\boldsymbol{\mu}_{w_1},\boldsymbol{\Sigma}_{w_1})\|\mathcal{N}(\mathbf{z};\boldsymbol{\mu}_{w_2},\boldsymbol{\Sigma}_{w_2})\right]$ and the cosine similarity between the means. We predict that w_1 entails w_2 if the corresponding score is above a certain threshold. As in Vilnis and McCallum (2015), the scores are optimistic, as the threshold is chosen on the test set. The thresholds are set individually for each method (including the baselines) and, hence, the comparison is fair.

Intuitively, KL should be a good choice: it would favor word pairs such that, not only their means are similar, but also such that the region, where the density function for w_1 is non-negligible, lies within the area where the density of w_2 is also high enough. Roughly speaking, level sets for w_1 should lie within level sets for w_2 (as with ('pear', 'fruit') in Figure 1).

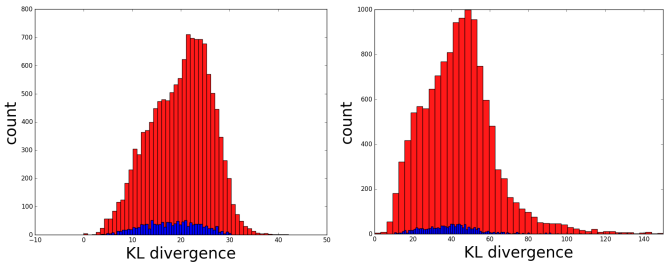
First, we consider the entailment benchmark of Baroni et al. (2012), we will refer to it as BBDS (Table 3, left part). The results are generally consistent with the ones reported by Vilnis and McCallum. The best W2G(S) model outperforms SG. They also have the edge over BSG. We also observe that, unlike W2G, covariance information appears not to be particularly beneficial for BSG (i.e. cosine performs essentially as well as KL).

Second, we turn to the BLESS dataset (Baroni and Lenci, 2011).[8] All the considered methods perform badly on BLESS. This is even more evident from Figure 5, where we plot the histogram of the KL divergence for the entailing and not entailing pairs. Clearly, the two classes cannot be separated based on KL alone, neither for BSG, nor W2G.

We hypothesize that the reason for these, seemingly inconsistent results, is that all considered methods struggle with distinguishing hypernymy ('dog' and 'pet') from co-hyponymy ('dog' and 'cat'), as well as from other types of semantic relatedness. Making such distinction is a challenging for an unsupervised method (Weeds et al., 2014). Indeed, the BLESS dataset is harder than BBDS: it is unbalanced and

[7] The popular Gensim SG implementation is even slightly stronger than ours (0.6365), though not really comparable because of major differences in optimization.

[8] The version we are using is from Levy et al. (2015)



(a) BSG (b) W2G(S)

word 1	word 2	KL	cosine sim.
dog	cat	15.47	0.71
dog	pet	18.52	0.70
dog	hound	21.20	0.64
dog	animal	27.69	0.52

Table 5: KL and cosine similarity of selected words. We used $D_{KL}\left[p(w_1)||p(w_2)\right]$, where $p(w)$ is the prior density for word w.

contains about ten times more negatives examples than positive ones, and the negative examples are often co-hyponyms.

So, why does KL not work as well as we expected? Intuitively, KL can be regarded as balancing two trade-offs: penalizing for divergences between means and also penalizing for the 'wrong' type of 'inclusion' between the distributions. It is very easy to see this for the one-dimensional case, where KL can be written as: $\log \frac{\sigma_2}{\sigma_1} + \frac{\sigma_1^2+(\mu_1-\mu_2)^2}{2\sigma_2^2} - \frac{1}{2}$, but holds for the multivariate case as well. If the variances are sufficiently similar, then the distance between means is all that matters. We hypothesize that for the Gaussian priors within BSG and for both versions of W2G, covariances end up playing a relatively minor role. Indeed, when we checked for correlations between KL and cosine similarity, we observed that it is very strong, confirming our hypothesis. For example, dog entails animal, but dog does not entail cat, while scores in Table 5 indicate the opposite (for more examples see supplementary materials). Generally, the Pearson correlation coefficient between cosine similarity and KL equals -0.652 and -0.703, for BLESS and BBDS, respectively, indicated a very strong (linear) relation between the two. Here, we considered W2G(S), as it seemed the most promising on the basis of BBDS results, but the trend is the same for BSG and W2G(D).

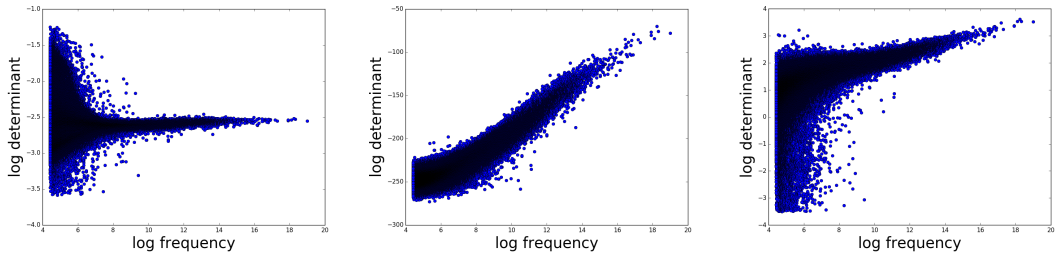
Though we see that KL on its own does not seem to be sufficient for detecting entailment, we still hypothesize that it does capture information directly relevant to this task, namely, represents a degree of 'generality' of a term. In order to see that this is the case, in next subsection, we consider a modification of the entailment task. It will also hint at why W2G performs better than BSG on BBDS, while, as we will see, BSG appears to capture generality more accurately.

3.4 Entailment directionality prediction

In these experiments, given a pair of words, the system needs to predict if the first word entails the second one or the other way around. In other words, it is known that entailment holds for the pair but its directionality needs to be predicted. As we would like to get extra insights into results obtained in the preceding section, we extract these pairs from the same datasets, BBDS and BLESS. As the symmetric cosine similarity would be useless here, we use only KL. As a baseline, we consider the following heuristic: we compare frequencies of the two words in our corpus and predict that the less frequent word (e.g., 'kiwi') entails the more frequent one (e.g., 'fruit').

Results are presented in Table 4. First, we observe that the situations are very different for the two datasets. On BBDS, the scores are much higher for all the approaches. However, depressingly, the frequency baseline appears the strongest: neither model manages to beat it. In contrast, on BLESS, the frequency baseline is weak (only 5% higher than chance), and both W2G versions achieve results very similar to the baseline. However, BSG outperforms them by a substantial margin (10%).

These results hint at the possibility that the main reason for slightly stronger results of W2Gs in the original set-up on BBDS (Table 3) is that covariances in W2Gs capture information about token frequencies. We verify this by plotting log-determinants of covariance matrices (representing the spread of the 'ellipsoids'), as a function of token frequencies (Figure 6). The plots confirm our hypothesis: covariances for W2Gs are growing with the frequency, and hence KL with W2Gs will prefer to label frequent words



(a) BSG $\rho = -0.0706$. (b) W2G(D) $\rho = 0.9098$. (c) W2G(S) $\rho = 0.5915$.

Figure 6: Log determinant vs. log frequency; ρ is the Pearson correlation coefficient.

as hypernyms. This is not the case at all for BSG. Note that BSG achieves similar results in directionality detection on BBDS without directly capturing frequency information (and hence 'mimicking' the frequency baseline). This, together with strong results on directionality detection for BLESS, suggests that covariances of BSG are better at capturing genuine information about the generality of a term.

3.5 Lexical substitution

We argued that the posterior densities in our model encode semantic properties of a word given its context. In other words, the posteriors can be used to disambiguate the word. In order to show that this is indeed the case, we consider the *lexical substitution* task, where the goal is to choose a suitable replacement for a word given its context. For example, the word 'bright' in an expression 'bright child' can be substituted with 'smart' or 'gifted' rather than 'shining'.

We used the SemEval-2007 task 10 dataset (McCarthy and Navigli, 2007). In this task, a system has to select a target word from a list of replacement candidates. We followed the set-up of Melamud et al. (2015) but kept the models the same as in the preceding sections. Namely, we did not use syntactic dependency information (shown highly beneficial in (Melamud et al., 2015)) but rather relied on a bag-of-word representation of a window of 5 words on each side. We also used 100 dimensional embeddings instead of 600 in Melamud et al. (2015).

Our model relies bag-of-word context, and the task is closely related to language modeling where representing ngrams is known to be crucial. Thus, we do not expect BSG to reach performance of state-of-the-art techniques relying on richer representations of context, such as LSTMs (e.g. (Melamud et al., 2016; Yuan et al., 2016)). We use the lexical substitution task as a way to test that the approximate posterior indeed encodes meaningful information, useful for predicting substitutions. To make the comparison fair, we use baselines which also rely on bag-of-word representations of context windows, and leave the investigation of BSG models with richer representations of context for future work.

For BSG, we ranked candidates s from the set of candidates S by the KL divergence: $\mathbb{D}_{KL}\left[q_{\boldsymbol{\phi}}(\mathbf{z}|\mathbf{c}, w)||p_{\boldsymbol{\theta}}(\mathbf{z}|s)\right]$, where $q_{\boldsymbol{\phi}}(\mathbf{z}|\mathbf{c}, w)$ is the approximate posterior computed by the encoder, and $p_{\boldsymbol{\theta}}(\mathbf{z}|s)$ is the prior distribution for the candidate word. As baselines, we used the two best performing approaches from Melamud et al. (2015), namely *Add* and *Mult*. Those heuristics score potential substitutes with respect to contexts and center words using cosine similarity of word embeddings, and mathematical operations as their names suggest. We used these heuristics on top of embeddings produced by SG and mean vectors for W2Gs and BSG. Note that they do not use covariance information.

The results (*generalized average precision*, GAP) are shown in Table 2. The encoder indeed appears substantially more effective in predicting word substitutes than the alternative methods. This shows that the posterior densities are effective at disambiguating words. In Table 6, we show top 3 substitutes proposed by the BSG encoder in several example sentences.

4 Related Work

Our model bears some relation to topic models: for example, one can interpret the latent meaning vector z of the central word as encoding topics of the window. Topic models relying on word embeddings has been considered in the past (Das et al., 2015; Li et al., 2016). However, their modeling approaches,

inference methods and applications have been quite different. Methods for inducing context-sensitive representations relying on syntactic dependency tree (using forward-backward-style algorithms) have also been studied in the past (Grave et al., 2014). Their approach is unlikely to be scalable. Very recent work of Peters et al. (2018) showed how LSTMs can be trained to provide dynamic word embeddings. These embeddings are context-aware but do not explicitly represent uncertainty about word meanings.

Reisinger and Mooney (2010) introduced a method that represents words as collections of prototype vectors. Their multi-prototype approach uses word sense discovery to partition contexts of a word and construct "sense-specific" prototypes for each cluster. Huang et al. (2012) extended this approach by incorporating global document context to learn multiple dense, low-dimensional embeddings using neural networks. This method performs word sense discrimination as a preprocessing step by clustering contexts for each word type. To model polysemous words Neelakantan et al. (2014) proposed an extension to the skip-gram model that efficiently learns multiple embeddings per word type. Their method performs word sense discrimination and embedding learning by using a nonparametric estimate of the number of senses per word type. In contrast, our model does not assume that there is a finite set of discrete senses per word. Liu et al. (2015) introduced an extension to the skip-gram model that can model the interaction between words and topics under different contexts using a tensor layer.

Our method and W2G are specifically designed to induce information about the generality of a word and capture entailment. Previous work has shown that entailment decision can also be made by 'post-processing' representations produced by standard embedding methods (e.g., (Weeds et al., 2014; Henderson and Popa, 2016)). Henderson and Popa (2016) is perhaps the most related one, as they use a probabilistic motivation for their preprocessing technique. All these post-processing methods deal with fixed rather than context-specific embeddings.

5 Conclusion

We introduced a method for embeddings words as probability densities. Our method produces two types of embeddings: (1) 'prior' / static embeddings representing a word type and collapsing all word senses; (2) 'posterior' / dynamic embeddings encoding a representation of a word given its context. The Gaussian embeddings of Vilnis and McCallum (2015) have been shown effective in a range of applications (e.g., modeling knowledge graphs (He et al., 2015) and cross-modal transfer from language to vision (Mukherjee and Hospedales, 2016)), our framework, providing more flexible context-sensitive alternatives, is likely to be beneficial in these settings.

2 Experimental settings

We train all our models on a concatenation of ukWaC and WaCkypedia (Baroni et al., 2009) corpora, resulting in approximately 3 billion tokens. We restricted the vocabulary size to 280,000 most frequent word types and used the sub-sampling procedure introduced in Mikolov et al. (2013) with $t = 10^{-4}$. The window size was set to 5 words on each side, the dimensionality of the embeddings and of the hidden layer of the encoder were both set to 100. The number of negative samples was equal to the number of positive ones (i.e. 10). For BSG, we used spherical covariances both for the posterior and prior densities, as they resulted in better performance in preliminary experiments: this is consistent with results reported for W2G in Vilnis and McCallum (2015). As an optimizer we used Adam (Kingma and Ba, 2014). We used large batches of 22,000 prediction tasks each. We used grid-search by running each model for 5 times on the concatenation of ukWaC and WaCkypedia dataset with different learning rates and selected the best ones based on their benchmark performance.

In order to enable fair comparison, we used our own implementation of W2G and SG, which shared the above hyperparameters with BSG.[1] The implementations of our model and the baselines will be publicly released should the paper get accepted. The initial learning rates were tuned for all models individually and set to 0.00055, 0.0065, 0.0015 and 0.0015 for BSG, W2G with the spherical covariances

[1]The original implementation of W2G is not publicly available. Our re-implementation yields stronger results on similarity benchmarks but weaker on the entailment dataset of Baroni et al. (2012). Our implementation is also stronger across the board (including entailment) than the third party implementation used in Vulić et al. (2017) (https://github.com/seomoz/word2gauss). Athiwaratkun and Wilson (2017) also report W2G numbers very similar to ours.

(WG(S)), W2G with the diagonal covariance matrix (WG(D)) and SG, respectively. All results presented in this work were obtained from one model of each type (i.e. no tuning was performed for individual benchmarks).

Abstract

An important component of achieving language understanding is mastering the composition of sentence meaning, but an immediate challenge to solving this problem is the opacity of sentence vector representations produced by current neural sentence composition models. We present a method to address this challenge, developing tasks that directly target compositional meaning information in sentence vector representations with a high degree of precision and control. To enable the creation of these controlled tasks, we introduce a specialized sentence generation system that produces large, annotated sentence sets meeting specified syntactic, semantic and lexical constraints. We describe the details of the method and generation system, and then present results of experiments applying our method to probe for compositional information in embeddings from a number of existing sentence composition models. We find that the method is able to extract useful information about the differing capacities of these models, and we discuss the implications of our results with respect to these systems' capturing of sentence information. We make available for public use the datasets used for these experiments, as well as the generation system.[1]

1 Introduction

As natural language processing strives toward language understanding, it is important that we develop models able to extract and represent the *meaning* of sentences. Such representations promise to be applicable across a variety of tasks, and to be more robust than non-meaning-based representations for any given task requiring meaning understanding. To accomplish meaning extraction, a particular need is that of mastering composition: systematic derivation of the meaning of a sentence based on its parts.

In this paper we tackle compositional meaning extraction by first addressing the challenge of evaluation and interpretability: after all, in order to improve meaning extraction, we need to be able to evaluate it. But with sentence representations increasingly taking the form of dense vectors (embeddings) from neural network models, it is difficult to assess what information these representations are capturing—and this problem is particularly acute for assessing abstract content like compositional meaning information.

Here we introduce an analysis method for targeting and evaluating compositional meaning information in sentence embeddings. The approach builds on a proposal outlined in Ettinger et al. (2016), and involves designing classification tasks that directly target the information of interest (e.g., "Given a noun n, verb v, and an embedding $\mathbf{s}$ of sentence s: is n the *agent* of v in s?"). By contrast to related work analyzing surface variables like word content and word order in sentence embeddings (Adi et al., 2016), we specifically target compositional meaning information relevant to achieving language understanding—and in order to isolate this more abstract information, we exert careful control over our classification datasets to ensure that we are targeting information arrived at by composition of the source

sentence, rather than general statistical regularities. Our approach is informed by methods in cognitive neuroscience and psycholinguistics, where such controls are standard practice for studying the brain.

In particular, to ensure validity of our tests we introduce three mechanisms of control. First, to create controlled datasets at the necessary scale, we develop a generation system that allows us to produce large sentence sets meeting specified semantic, syntactic and lexical constraints, with gold-standard meaning annotation for each sentence. Second, we control the train-test split so as to require more robust generalization in order to perform the tasks successfully. Third, we employ a sanity check leveraging known limitations of bag-of-words (BOW) composition models: for any tasks requiring order information *from the source sentence*, which BOW models cannot logically retain, we check to ensure that BOW composition models are at chance performance.

These controls serve to combat a problem that has gained increasing attention in recent work: many existing evaluation datasets contain biases that allow for high performance based on superficial cues, thus inflating the perceived success of systems on these downstream tasks (Gururangan et al., 2018; Bentivogli et al., 2016). In the present work, our first priority is careful control of our tasks such that biases are eliminated to the greatest extent possible, allowing more confident conclusions about systems' compositional capacities than are possible with existing metrics.

The contributions of this paper are threefold. 1) We introduce a method for analyzing compositional meaning information in sentence embeddings, along with a generation system that enables controlled creation of datasets for this analysis. 2) We provide experiments with a range of sentence composition models, to demonstrate the capacity of our method to shed light on compositional information captured by these models. 3) We make available the classification datasets used for these experiments, as well as the generation system used to produce the sentence sets, to allow for broader testing of composition models and to facilitate creation of new tasks and classification datasets.

Although we focus on neural composition models and sentence embeddings in the present paper—due to the current dominance of these methods and the need to evaluate their compositional capacities—it is important to note that this analysis method can also be applied more broadly. Since the method simply operates by classification of sentence representations, it can be applied to any format of sentence representation that can be input as features to a classifier.

2 Meaning and composition

In this section we will briefly explain the concepts of *meaning* and *composition*, which are the central targets of our analyses in this work.

Our approach assumes there to be identifiable components of *meaning* that we can expect in well-formed sentence representations. For instance, the sentence "the dog chased the girl" contains the information that there was a chasing event, and a dog was the chaser (*agent* of chasing) and a girl the chasee (*patient* of chasing). The sentence "the dog did not bark" conveys that a barking event did not happen.

Humans are able to extract meaning with remarkable robustness, and a key factor in human language understanding is *composition*: the productive combinatory capacity that allows sentence meaning to be derived systematically based on the meanings of its parts (Heim and Kratzer, 1998). To illustrate the power of this systematicity, consider a nonsensical sentence like the following:

The turquoise giraffe recited the sonnet but did not forgive the flight attendant.

Though this sentence describes an entirely implausible scenario, and though nothing like it should ever have occurred in any corpus or conversation, any English speaker is able to extract the meaning of this sentence without difficulty. This is because language is highly systematic, and the meanings of the parts of the sentence can be combined predictably to arrive at the full meaning.

Regardless of how closely NLP systems should draw on human strategies for language processing, the need for composition is clear: if systems do not construct meanings of sentences based on their parts, then the alternative is memorization of all possible sentences, which is neither practical nor possible.

In this work, critically, we are focused on the results of systematic compositional processes, to be distinguished from biases based on general statistical regularities. The importance of this distinction is

highlighted by the result reported in Adi et al. (2016), which shows a BOW composition model attaining 70% accuracy on a binary word order classification task. This result is surprising given that BOW models (which simply average together word-level representations) necessarily sacrifice any order information from the source sentence. This suggests that the above-chance performance relies on statistical regularities of word ordering in the data as a whole, independent of the source sentence—that is, the model's above-chance performance must be dependent on some correspondence between word orders being tested and word orders seen when training the word embeddings.

Although sensitivity to such regularities is often useful, in this work we are concerned with *systematic composition of the source sentence itself*, abstracting away from general statistical regularities. This is critical for our purposes: to master composition, models must be able to construct the meaning of a sentence not only when it matches commonly-seen patterns (e.g., "the cat chased the mouse") but also when it deviates from such patterns (e.g., "the mouse chased the cat"). This is the reasoning behind our BOW sanity check, discussed in Section 3.3, which serves to ensure that our tests cannot be solved by simple averaging. Additionally, the biases in naturally-occurring data, further highlighted by the Adi et al. result, motivate our use of generated data for the sake of maintaining the necessary level of control.

3 The present method

3.1 Approach

The approach that we take to probe for compositional meaning information in sentence embeddings is inspired by the neuroscience technique of multivariate pattern analysis (Haxby et al., 2014), which tests for encoding of information in patterns of neural data by means of classification tasks designed to be contingent on the information of interest. Our use of careful control in implementing this approach is also informed more generally by the methodologies of cognitive neuroscience and psycholinguistics, which standardly use these kinds of controls to draw conclusions about information in human brain activity. The approach that we develop here builds on the proposal of Ettinger et al. (2016)—which described the basic form of the method and provided a simple validation with a small set of active and passive sentences. In the present work we flesh out and strengthen the method with a number of more rigorous controls aimed at better isolating the information of interest, and we substantially expand the scope of the tests through the use of a more sophisticated sentence generation system.

3.2 Classification tasks

As proposed by Ettinger et al. (2016), we target two meaning components as our starting point: semantic role and negation. These components are priorities because they are fundamental to the meaning of a sentence, having bearing on the key questions of "what happened (and what didn't)" and "who did what to whom". Additionally, they represent information types that can be heavily distorted with respect to surface variables like word content and order: to know semantic role and negation information, it is not enough to know which words are in the sentence or which words come earlier in the sentence.

We formulate the semantic role classification task ("**SemRole**") as follows: "Given representation $\mathbf{n}$ of probe noun n, representation $\mathbf{v}$ of probe verb v, and embedding $\mathbf{s}$ of sentence s (with s containing both n and v), does n stand in the AGENT relation to v in s?" For example, an input of $\{n$: "professor", v: "help", s: "the professor helped the student"$\}$ would receive a positive label because *professor* is AGENT of *help* in the given sentence.

We formulate the negation classification task ("**Negation**") as follows: "Given a representation $\mathbf{v}$ of a probe verb v, and an embedding $\mathbf{s}$ of sentence s (with s containing v, one negation, and one other verb), is v positive or negated in s?" For example, an input of $\{v$: "sleep", s: "the professor is not actually helping the student who is totally sleeping"$\}$ receives a positive label because *sleep* is not negated in that sentence. To decouple this from a simpler task of identifying adjacency between negation and a verb, we insert variable-length adverb sequences (e.g., *not **really, actually** helping*) before the verbs in the dataset (negated and non-negated), to ensure that the negation is not always adjacent to the verb that it affects.

These formulations differ from those in the original Ettinger et al. (2016) proposal, instead making use of variable word probes as employed by Adi et al. (2016). This adjustment was made to maximize

the generalization required for strong performance on the tasks, and to further reduce vulnerability to biasing cues in the datasets. More detail on our implementation of this formulation is given in Section 5.

3.3 Means of control

The most critical consideration in this work is ensuring that we can draw valid conclusions about composition from performance on our classification tasks. To this end, we take a number of measures to control our data, to avoid biasing cues that would make the tasks solvable independent of the information of interest—a problem observed in many existing datasets, as mentioned above (Gururangan et al., 2018).

Generation system A critical component of isolating abstract meaning information is employing syntactic variation, such that the meaning information of interest is the single underlying variable distinguishing label categories. For instance, we might use sentences like "the professor helped the student", "the student was helped by the professor", and "the student that the professor helped was sleeping"—which vary in structure, but which share an underlying event of a professor helping a student.

In order to produce sentence sets that exhibit this level of variation—and that reach the necessary scale for training and testing classifiers—without allowing the statistical biases of naturally-occurring data, we developed a generation system that takes as input lexical, semantic and syntactic constraints, and that produces large sentence sets meeting those constraints. In addition to allowing us to produce controlled datasets, this system also ensures that the generated datasets are annotated with detailed semantic and syntactic information. This generation system is described in greater detail in Section 4.

Train/test splits To be confident that the classifier is picking up on underlying meaning information and not simply a union of different superficial cues across syntactic structures, we make careful provisions in our train/test split to ensure generalization (beyond the obvious split such that sentences in test do not appear in training). For our semantic role task, certain (n,v) probe combinations are held out for test, such that no combinations seen at test time have been seen during training. This is done to ensure that the classifier cannot rely on memorized sequences of words. For our negation task, which uses only one probe, we hold out certain adverbs from training (as described above, adverbs are used as material to separate the negation and the verb), such that at test time, the material separating the negation and the verb (or preceding the non-negated verb) has never been seen in training.

BOW as control As described above, it is logically impossible for BOW models to encode information that requires access to word order from the source sentence itself. We leverage this knowledge to create a sanity check baseline for use in monitoring for lexical biases: if, for any task requiring access to word order information, the BOW baseline performs above chance, we know that the datasets contain lexical biases affecting the classification results, and we can modify them accordingly.

4 Generation system

In this section we describe the generation system that we use to create large, controlled datasets for our classification tasks. As described above, this system takes input constraints targeting semantic, syntactic, and lexical components, and produces diverse, meaning-annotated sentences meeting those constraints.

4.1 Event/sentence representations

As a framework for specifying semantic and syntactic constraints, we use a class of event representations that contain both lexicalized semantic information and necessary syntactic information, such that there is a deterministic mapping from a fully-populated event representation to a corresponding surface sentence form. These representations fall roughly within the category of "lexicalized case frame" outlined by Reiter and Dale (2000) for natural language generation. Figure 1 shows an example representation, in fully-specified textual form, and in simplified graphical form.

Our representations are currently restricted to events denoted by transitive and intransitive verbs, with the arguments of those verbs and optional transitive or intransitive relative clauses on those arguments.

These representations are comparable in many ways to abstract meaning representation (AMR) (Banarescu et al., 2012), but rather than abstracting entirely away from syntactic structure as in AMR, our

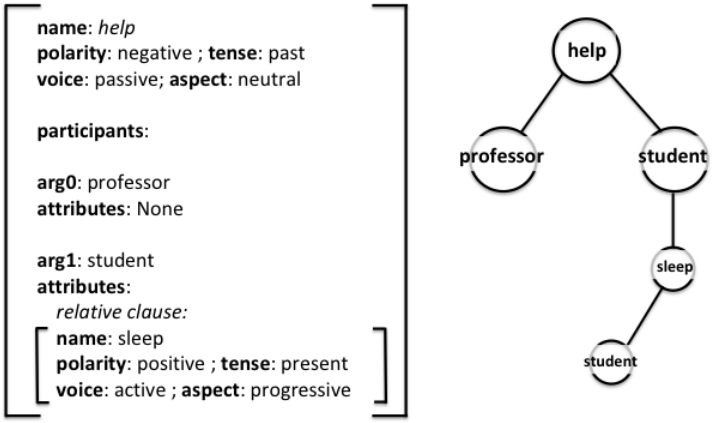

Figure 1: Event representation for *"The student who is sleeping was not helped by the professor"*

event representations encode syntactic information directly, along with the more abstract meaning information, in order to maintain a deterministic mapping to surface forms. Relatedly, while AMR uses PropBank frames (Palmer et al., 2005) to encode meaning information, we encode information via English lemmas, to maintain control over lexical selection during generation.

These representations can be partially specified to reflect a desired constraint, and can then be passed in this partial form as input to the generation system—either as a required component, or as a prohibited component. This allows us to constrain the semantic and syntactic characteristics of the output sentences. In addition to partial events, the system can also take lists of required or prohibited lexical items.

4.2 Event population

The system uses a number of structural templates into which partial events can be inserted. Structural templates vary based on the transitivity of verbs and the presence or absence of relative clauses on arguments—for instance, if the nodes in the right side of Figure 1 were unpopulated, it would depict an empty structural template consisting of a transitive main verb with an intransitive relative clause on arg1. Once we have inserted a partial event into a subsection of an empty structural template (events can be inserted into either the main clause or a relative clause), the system populates the remainder of the event components by iterating through available verbs and nouns of the vocabulary, and through available values for unfilled syntactic characteristics (such as polarity, tense, voice, etc.).

For simplicity, we control plausibility of argument/predicate combinations by setting the system vocabulary such that it contains only animate human nouns, and only verbs that can take any of those nouns in the relevant argument slots. This is a reasonable task due to the capacity of the system to generate thousands of sentences from only a handful of nouns and verbs. We leave incorporation of more sophisticated selectional preference methods (Van de Cruys, 2014; Resnik, 1996) for future work.

Our goal is to find the optimal balance between the critical need of this method for structurally variable, carefully controlled sentences, and the practical need to avoid substantial deviation from sentence types to which systems will have been exposed during training. To this end, we draw our vocabulary from comparatively frequent words, and we impose structural constraints to limit the complexity of sentences—specifically, in the current experiments we restrict to sentences with no more than one relative clause, by omitting templates that include relative clauses on both arguments of a main verb.

4.3 Syntactic realization

Once an event representation is fully populated, it is submitted to a surface realization module that maps from the event to a surface sentence via a simple rule-based mapping. Since the representations specify syntactic information and use lexicalized meaning information, there is no significant process of lexical selection required during surface realization—only morphological inflection derivable from syntactic characteristics. As a result, the event representations map deterministically to their corresponding surface

forms. We use a grammar specified using the NLTK feature grammar framework (Bird et al., 2009). Morphological inflections are drawn from the XTAG morphological database (Doran et al., 1994).

4.4 Sentence quality

To ensure the quality of generation system output, we manually inspected large samples of generated sentences throughout development and after generation of the final sets, to confirm that sentences were grammatical and of the expected form. Table 1 shows a representative sample of generated sentences.[2]

the men were sleeping
the woman followed the lawyer that the student is meeting
the women were being helped by the lawyers
the student called the man
the scientist that the professors met is dancing
the doctors that helped the lawyers are being recommended by the student

Table 1: Example generated sentences

5 Implementation of lexical variability

As discussed above, we adopt the variable probe formulation used by Adi et al. (2016). This adds a dimension to the learning task that is not present in the original Ettinger et al. (2016) task formulation: the classifier needs not only to identify meaning information in the input sentence—it needs to identify meaning information contingent on the identities of the particular probe words.

To identify the probe word(s) in the input features, Adi et al. (2016) use the source word embeddings, but this is problematic for our purposes, given that we want to test a wide variety of models, which use word embeddings of different types and sizes. To avoid this variability, it would be preferable to use one-hot vectors to identify word probes. To this end, we performed a series of experiments testing whether classification accuracy was affected by use of one-hot probe representations by comparison to embedding probes, in a replication of the word content task of Adi et al. (2016). Finding almost equivalent accuracies between the two input types, we use one-hot probe representations in all subsequent experiments.

Note that as a result, by contrast to Adi et al. (2016) we are not assuming the classifier to identify words in the sentence representation based on resemblance to their original word embeddings—this may not in fact be a safe assumption, given that the word's representation may distort during composition of the sentence. Instead, the classifier must learn a mapping from each one-hot representation to its manifestation in sentences. This means that all words must appear as probes in training. To facilitate the learning of this mapping, we restrict to a small (14-lemma) vocabulary of noun and verb probes in these experiments.[3] Because the generation system is able to produce thousands of sentences from even such a restricted vocabulary as this, this limitation does not prevent generation of adequately large datasets.

A note about the size and selection of the vocabulary: some composition tests will surely be sensitive to specific idiosyncrasies of individual words, in which case the choice of vocabulary will be of great importance. However, for the particular semantic role and negation tasks described here, the focus is on identification of structural dependencies between words, which are not in this case sensitive to the specific nouns/verbs used. Consequently, for these tasks—as long as vocabulary words are not out-of-vocabulary for the models (which we confirm below)—the important thing should be not what the words themselves are, but whether dependencies between them have been captured in the sentence embeddings.

6 Surface tasks: word content and order

Though our ultimate interest is in abstract meaning information, part of the goal of these experiments is to get a clear picture of the information currently captured by existing systems. For this reason, we

[2] More sentences can be found in the publicly available classification datasets.

[3] Sentences themselves contain various morphological inflections of these lemmas.

include the content and order experiments as performed by Adi et al. (2016), to see how encoding of these surface variables compares to encoding of meaning information—and to compare with the results of Adi et al. (2016) after the more rigorous controls used in our datasets.

We structure these tasks to be maximally parallel with our meaning tasks. To this end, we have two content tasks: one-probe ("**Content1Probe**") and two-probe ("**Content2Probe**"), with the one-probe task using verb probes as in the negation task, and two-probe using noun-verb probe pairs, as in the semantic role task. Similarly, for the order task ("**Order**") we use only noun-verb pairs. The order task is thus formulated as "Given representation $\mathbf{n}$ of probe noun n, representation $\mathbf{v}$ of probe verb v, and embedding $\mathbf{s}$ of sentence s (with s containing both n and v), does n occur before v in s?". The two-word content task is formulated as "Given representation $\mathbf{n}$ of probe noun n, representation $\mathbf{v}$ of probe verb v, and embedding $\mathbf{s}$ of sentence s, do both n and v occur in s?", and the one-word content task is formulated as "Given representation $\mathbf{v}$ of probe verb v, and embedding $\mathbf{s}$ of sentence s, does v occur in s?"

7 Classification experiments

To demonstrate the utility of our analysis, we use it to test several existing sentence composition models. Following Adi et al. (2016), for our classifier we use a multi-layer perceptron with ReLU activations and a single hidden layer matching the input size. For each of the above tasks we construct train/test sets consisting of 4000 training items and 1000 test items.[4] No tuning is necessary, as the hyperparameters of hidden layer number and size are fixed in accordance with the architecture used by Adi et al. (2016).

It is important to note that the training of the classifier, which uses the 4000 items mentioned above, is to be distinguished from the training of the sentence embedding methods. The sentence embedding models are pre-trained on separate corpora, as described below, such that they map sentence inputs to embeddings. Once these models are trained, they are used to produce the 4000 sentence embeddings that will serve as training input to the classifier (and the 1000 sentence embeddings used for testing).

Our use of a relatively simple classifier with a single hidden layer builds on the precedent not only of Adi et al. (2016), but also of related methods in neuroscience, which in fact typically use linear classifiers (an option that we could not employ due to our use of the variable probes). An important reason for use of simpler classifiers is to test for *straightforward* extractability of information from embeddings—if a complex classifier is necessary in order to extract the information of interest, then this calls into question the extent to which we might consider this information to be "captured" in the embeddings, as opposed to the information being somehow reconstructable from the embeddings' encoding of other information. That said, the question of how the complexity of the classifier relates to the encoding of the target information in these sentence embeddings is an interesting issue for future work.

For each experiment, we also run two corresponding experiments, in which random vectors are used in place of the sentence vectors and the probes, respectively. This serves as an additional check for biases in the datasets, to ensure that neither the sentence vectors nor the probe vectors alone are sufficient to perform above chance on the tasks. For all tasks, these random vectors produce chance performance.

7.1 Sentence encoding models

We test a number of composition models on these classification tasks. These models represent a range of influential current models designed to produce task-general sentence embeddings. They employ a number of different architectures and objectives, and have shown reasonable success on existing metrics (Hill et al., 2016; Conneau et al., 2017).

All sentence embeddings used are of 2400 dimensions. Because our pre-trained models (SDAE, Skip-Thought) are trained on the Toronto Books Corpus (Zhu et al., 2015), we use this as our default training corpus, except when other supervised training data is required (as in the case of InferSent). Before sentence generation, the chosen vocabulary was checked against the training corpora to ensure that no words were out-of-vocabulary (or below a count of 50).

[4] See footnote 1 for link to all classification datasets used in these experiments.

	Accuracy				
	Content1Probe	Content2Probe	Order	SemRole	Negation
BOW	100.0	97.1	55.0	51.3	50.9
SDAE	100.0	79.8	92.9	63.7	99.0
ST-UNI	100.0	88.1	93.2	62.3	96.6
ST-BI	96.6	79.4	88.7	63.2	74.7
InferSent	100.0	70.1	86.4	50.1	97.2

Table 2: Classification results

BOW averaging Our first sentence embedding model (**"BOW"**) is a BOW averaging model, for which we use the skip-gram architecture of the word2vec model (Mikolov et al., 2013) to learn word embeddings. As discussed above, the BOW model serves primarily as a sanity check for our purposes, but it is important to note that this model has had competitive results on various tasks, and is taken seriously as a sentence representation method for many purposes (Wieting et al., 2016; Arora et al., 2016).

Sequential Denoising Autoencoder Our second model (**"SDAE"**) is an autoencoder variant from Hill et al. (2016) for unsupervised learning of sentence embeddings. The model uses an LSTM-based encoder-decoder framework, and is trained to reconstruct input sentences from their vector representations (last hidden state of encoding LSTM) despite noise applied to the input sentence. We use a pre-trained model provided by the authors. This model has the advantage of an unsupervised objective and no need for sequential sentence data, and it shows competitive performance on a number of evaluations.

Skip-Thought Embeddings Our next two models are variants of the Skip-Thought model (Kiros et al., 2015), in which sentences are encoded with gated recurrent units (GRUs), with an objective of using the current sentence representation to predict the immediately preceding and following sentences. Following the model's authors, we use both the uni-skip (**"ST-UNI"**) and bi-skip (**"ST-BI"**) variants: uni-skip consists of an encoding based on a forward pass of the sentence, while bi-skip consists of a concatenation of encodings of the forward and backward passes of the sentence (each of 1200 dimensions, for 2400 total). We use the publicly available pre-trained Skip-Thought model for both of these variants.[5]

Skip-Thought sentence embeddings have been used as pre-trained embeddings for a variety of tasks. They have proven to be generally effective for supervised tasks and passable for unsupervised tasks (Hill et al., 2016; Triantafillou et al., 2016; Wieting et al., 2016). Like the SDAE model, the Skip-Thought model is able to use unsupervised learning, though it requires sequential sentence data. However, more than the SDAE model, the Skip-Thought model uses an objective intended to capture semantic and syntactic properties, under the authors' assumption that prediction of adjacent sentences will encourage more syntactically and semantically similar sentences to map to similar embeddings.

InferSent Our final model is the InferSent model (Conneau et al., 2017), which uses multi-layer BiLSTM encoders with max pooling on the hidden states of the last layer to produce vector representations of the sentences. This model is trained with a natural language inference (NLI) objective, and for this reason we train it on the SNLI dataset (Bowman et al., 2015).

The InferSent model is intended to produce "universal" sentence representations, and has been shown to outperform unsupervised methods like Skip-Thought on a number of tasks (Conneau et al., 2017). More generally, the NLI objective is believed to encourage learning of compositional meaning information, given that inference of entailment relations should require access to meaning information.

7.2 Results and Discussion

Table 2 shows the accuracy of the different models' sentence embeddings on our classification tasks.

The first thing to note is that our BOW control allows us to confirm nearly complete lexical balance in

[5] https://github.com/ryankiros/skip-thoughts

the sentence sets: the averaged word embeddings perform roughly at chance on all but the content tasks.[6] By contrast, BOW performs with near-perfect accuracy on the content tasks, lending support to the intuitive conclusion: the one thing that BOW *does* encode is word content. The quality of performance of the BOW model on this task exceeds that reported by Adi et al. (2016)—we speculate that this may be due to our use of a smaller vocabulary to facilitate the learning of the mapping from one-hot probes.

While BOW has very high performance on two-probe word content, SDAE, ST-UNI, ST-BI and InferSent have much lower accuracy (albeit still far above chance), suggesting that some detail with respect to word content is sacrificed from these representations in favor of other information types. This is exemplified by the order task, on which all non-BOW models show significantly higher accuracy than on the word content tasks, supporting the intuitive conclusion that such sequence-based models retain information about relative word position. This result is generally consistent with the Adi et al. (2016) result, but due to the additional control that brings BOW roughly to chance, we can conclude with greater confidence that the performance on this task pertains to order information in the source sentence itself.

Turning to our meaning information tasks, we see that with the exception of ST-BI, the sequence models perform surprisingly well on the negation task, despite the fact that this task cannot be solved simply by detecting adjacency between negation and the verb (due to our insertion of adverbs). Instead, we speculate that these sequence models may be picking up on the utility of establishing a dependency between negation and the *next* verb, even in the face of intervening words. This is not a complete solution to the problem of representing the meaning and dependencies of negation, but it is a useful step in that direction, and suggests that models may be sensitive to some of the behaviors of negation.

Interestingly, ST-BI shows markedly weaker performance on the negation task. We see two potential reasons for this. First, it may be due to the reduced dimensionality of each of the two concatenated encodings (recall that ST-BI involves concatenating 1200-dimensional encodings of the forward and backward passes). Second, the reduced performance could be influenced by the inclusion of the backward pass: while the forward pass can leverage the strategy of linking negation to the next verb, the backward pass cannot use this strategy because it will encounter the relevant verb before encountering the negation.

Turning to the semantic role task, we see a stark contrast with the high performance for the negation task. InferSent performs squarely at chance, suggesting that it retains as little compositional semantic role information as does BOW. SDAE, ST-UNI and ST-BI perform modestly above chance on the semantic role task at 62-63% accuracy, suggesting that they may provide some amount of abstract role information—but no model shows any substantial ability to capture semantic role systematically.

These results accomplish two things. First, they lend credence to this method as a means of gaining insight into the information captured by current models. Second, they give us a sense of the current capacity of sequence-based models to capture compositional meaning information. The picture that emerges is that sequence models are able to make non-trivial headway in handling negation, presumably based on a sequential strategy of linking negation to the next verb—but that these sequence models fall significantly short when it comes to capturing semantic role compositionally. Another point that emerges from these results is that despite the fairly substantial differences in architecture, objective, and training of these models, capacity to capture the compositional information is fairly similar across models, suggesting that these distinct design decisions are not having a very significant impact on compositional meaning extraction. We plan to test more substantially distinct models, like those with explicit incorporation of syntactic structure (Bowman et al., 2016; Dyer et al., 2016; Socher et al., 2013) in future work.

8 Related work

This work relates closely to a growing effort to increase interpretability of neural network models in NLP—including use of visualization to analyze what neural networks learn (Li et al., 2015; Kádár et al., 2016), efforts to increase interpretability by generating explanations of model predictions (Ribeiro et al., 2016; Lei et al., 2016; Li et al., 2016), and work submitting adversarial examples to systems in order to identify weaknesses (Zhao et al., 2017; Jia and Liang, 2017; Ettinger et al., 2017).

[6] The slightly higher accuracy on the order task is most likely the result of a very slight bias due to our use of only noun-verb order probe pairs for the sake of matching the SemRole task.

Methodologically the most closely related work is that of Adi et al. (2016), which uses classification tasks to probe for information in sentence embeddings. As discussed above, we depart from that work in targeting deeper and more linguistically-motivated aspects of sentence meaning, and we incorporate careful controls of our datasets to ensure elimination of bias in the results.

Our focus on assessing linguistically-motivated information relates to work on evaluations that aim for fine-grained analysis of systems' linguistic capacities (Rimell et al., 2009; Bender et al., 2011; Marelli et al., 2014). The present work contributes to this effort with new tasks that assess composition *per se*, and that do so in a highly targeted manner via careful controls. Our use of synthetically generated data to achieve this level of control relates to work like that of Weston et al. (2015), which introduces synthetic question-answering tasks for evaluating the capacity of systems to reason with natural language input.

Our examination of the capacity of neural sequence models to identify abstract relations in sentence representations also relates to work by Linzen et al. (2016), who explore whether LSTMs can learn syntactic dependencies, as well as Williams et al. (2017), who investigate the extent to which parsers that are learned based on a semantic objective produce conventional syntax.

Finally, importantly related work is that concerned specifically with testing systematic composition. Lake and Baroni (2017) investigate the capacity of RNNs to perform zero-shot generalization using composition, and Dasgupta et al. (2018) construct an entailment dataset with balanced lexical content in order to target composition more effectively. We contribute to this line of inquiry by establishing an analysis method that can take output embeddings from sentence composition models and query them directly for specific types of information to be expected in properly compositional sentence representations.

9 Conclusions and future directions

We have presented an analysis method and accompanying generation system designed to address the problem of assessing compositional meaning content in sentence vector representations. We make the datasets for these tasks, as well as the generation system used to create them, available for public use to facilitate broader testing of composition models. We have also presented the results of applying this method for analysis of a number of current sentence composition models, demonstrating the capacity of the method to derive meaningful information about what is captured in these models' outputs.

Having established a means of analyzing compositional meaning information in sentence embeddings, in future work we plan to apply this system to identify more precisely which design decisions lead to effective capturing of meaning information, in order to guide system improvement. As part of this effort, we will expand to more comprehensive testing of a diverse range of sentence embedding systems (Bowman et al., 2016; Subramanian et al., 2018). We also plan to investigate the potential of our generation system to create not just evaluation data, but training data—given that it allows us to produce large, meaning-annotated corpora. Finally, we plan to expand beyond semantic role and negation in the set of information types targeted by our method, in order to establish more comprehensive coverage of meaning information that can be assessed by this analysis system.

Abstract

Representation learning is the foundation of machine reading comprehension. In state-of-the-art models, deep learning methods broadly use word and character level representations. However, character is not naturally the minimal linguistic unit. In addition, with a simple concatenation of character and word embedding, previous models actually give suboptimal solution. In this paper, we propose to use subword rather than character for word embedding enhancement. We also empirically explore different augmentation strategies on *subword-augmented embedding* to enhance the cloze-style reading comprehension model (reader). In detail, we present a reader that uses subword-level representation to augment word embedding with a short list to handle rare words effectively. A thorough examination is conducted to evaluate the comprehensive performance and generalization ability of the proposed reader. Experimental results show that the proposed approach helps the reader significantly outperform the state-of-the-art baselines on various public datasets.

1 Introduction

A recent hot challenge is to train machines to read and comprehend human languages. Towards this end, various machine reading comprehension datasets have been released, including cloze-style (Hermann et al., 2015; Hill et al., 2015; Cui et al., 2016) and user-query types (Joshi et al., 2017; Rajpurkar et al., 2016). Meanwhile, a number of deep learning models are designed to take up the challenges, most of which focus on attention mechanism (Wang et al., 2017b; Seo et al., 2017; Cui et al., 2017a; Kadlec et al., 2016; Dhingra et al., 2017; Zhang and Zhao, 2018). However, how to represent word in an effective way remains an open problem for diverse natural language processing tasks, including machine reading comprehension for different languages. Particularly, for a language like Chinese with a large set of characters (typically, thousands of), lots of which are semantically ambiguous, using either word-level or character-level embedding alone to build the word representations would not be accurate enough. This work especially focuses on a cloze-style reading comprehension task over fairy stories, which is highly challenging due to diverse semantic patterns with personified expressions and reference.

In real practice, a reading comprehension model or system which is often called *reader* in literatures easily suffers from out-of-vocabulary (OOV) word issues, especially for the cloze-style reading comprehension tasks when the ground-truth answers tend to include rare words or named entities (NE), which are hardly fully recorded in the vocabulary. This is more challenging in Chinese. There are over 13,000 characters in Chinese[1] while there are only 26 letters in English without regard to punctuation marks. If a reading comprehension system cannot effectively manage the OOV issues, the performance will not be semantically accurate for the task.

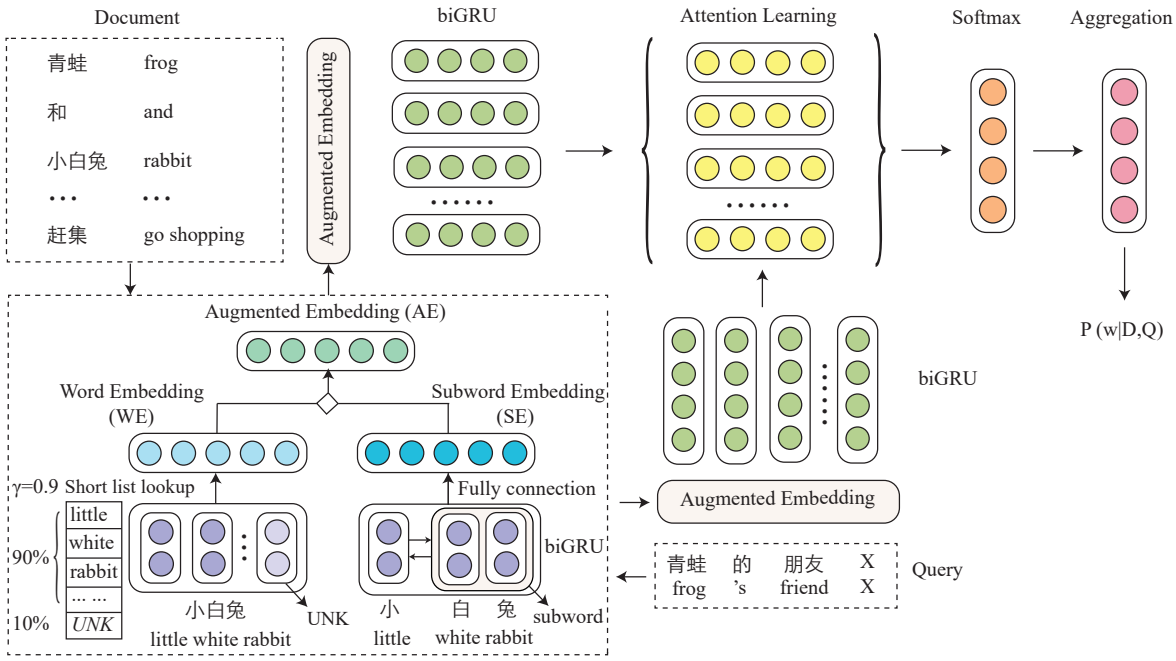

Figure 1: Architecture of the proposed Subword-augmented Embedding Reader (SAW Reader).

Commonly, words are represented as vectors using either word embedding or character embedding. For the former, each word is mapped into low dimensional dense vectors from a lookup table. Character representations are usually obtained by applying neural networks on the character sequence of the word, and their hidden states are obtained to form the representation. Intuitively, word-level representation is good at catching global context and dependency relationships between words, while character embedding helps for dealing with rare word representation.

However, the minimal meaningful unit below word usually is not character, which motivates researchers to explore the potential unit (subword) between character and word to model sub-word morphologies or lexical semantics. In fact, morphological compounding (e.g. *sunshine* or *playground*) is one of the most common and productive methods of word formation across human languages, which inspires us to represent word by meaningful sub-word units. Recently, researchers have started to work on morphologically informed word embeddings (Botha and Blunsom, 2014; Cao and Rei, 2016), aiming at better capturing syntactic, lexical and morphological information. With ready subwords, we do not have to work with characters, and segmentation could be stopped at the subword-level to reach a meaningful representation.

In this paper, we present various simple yet accurate subword-augmented embedding (SAW) strategies and propose SAW Reader as an instance. Specifically, we adopt subword information to enrich word embedding and survey different SAW operations to integrate word-level and subword-level embedding for a fine-grained representation. To ensure adequate training of OOV and low-frequency words, we employ a short list mechanism. Our evaluation will be performed on three public Chinese reading comprehension datasets and one English benchmark dataset for showing our method is also effective in multi-lingual case.

2 The Subword-augmented Word Embedding

The concerned reading comprehension task can be roughly categorized as user-query type and cloze-style according to the answer form. Answers in the former are usually a span of texts while in the cloze-style task, the answers are words or phrases which lets the latter be the harder-hit area of OOV issues, inspiring us to select the cloze-style as our testbed for SAW strategies. Our preliminary study shows even for the advanced word-character based GA reader, OOV answers still account for nearly 1/5 in the error results.

This also motivates us to explore better representations to further performance improvement.

The cloze-style task in this work can be described as a triple $< D, Q, A >$, where D is a document (context), Q is a query over the contents of D, in which a word or phrase is the right answer A. This section will introduce the proposed SAW Reader in the context of cloze-style reading comprehension. Given the triple $< D, Q, A >$, the SAW Reader will be built in the following steps.

2.1 BPE Subword Segmentation

Word in most languages usually can be split into meaningful subword units despite of the writing form. For example, "*indispensable*" could be split into the following subwords: $< in, disp, ens, able >$.

In our implementation, we adopt Byte Pair Encoding (BPE) (Gage and Philip, 1994) which is a simple data compression technique that iteratively replaces the most frequent pair of bytes in a sequence by a single, unused byte. BPE allows for the representation of an open vocabulary through a fixed-size vocabulary of variable-length character sequences, making it a very suitable word segmentation strategy for neural network models.

The generalized framework can be described as follows. Firstly, all the input sequences (strings) are tokenized into a sequence of single-character subwords, then we repeat,

1. Count all bigrams under the current segmentation status of all sequences.
2. Find the bigram with the highest frequency and merge them in all the sequences. Note the segmentation status is updating now.
3. If the merging times do not reach the specified number, go back to 1, otherwise the algorithm ends.

In (Sennrich et al., 2016), BPE is adopted to segment infrequent words into sub-word units for machine translation. However, there is a key difference between the motivations for subword segmentation. We aim to refine the word representations by using subwords, for both frequent and infrequent words, which is more generally motivated. To this end, we adaptively tokenize words in multi-granularity by controlling the merging times.

2.2 Subword-augmented Word Embedding

Our subwords are also formed as character n-grams, do not cross word boundaries. After using unsupervised segmentation methods to split each word into a subword sequence, an augmented embedding (AE) is to straightforwardly integrate word embedding $WE(w)$ and subword embedding $SE(w)$ for a given word w.

$$AE(w) = WE(w) \diamond SE(w)$$

where $\diamond$ denotes the detailed integration operation. In this work, we investigate concatenation (*concat*), element-wise summation (*sum*) and element-wise multiplication (*mul*). Thus, each document D and query Q is represented as $\mathbb{R}^{d \times k}$ matrix where d denotes the dimension of word embedding and k is the number of words in the input.

Subword embedding could be useful to refine the word embedding in a finer-grained way, we also consider improving word representation from itself. For quite a lot of words, especially those rare ones, their word embedding is extremely hard to learn due to the data sparse issue. Actually, if all the words in the dataset are used to build the vocabulary, the OOV words from the test set will not obtain adequate training. If they are initiated inappropriately, either with relatively high or low weights, they will harm the answer prediction. To alleviate the OOV issues, we keep a short list H for specific words.

$$H = \{w_1, w_2, \ldots, w_n\}$$

If w is in H, the immediate word embedding $WE(w)$ is indexed from word lookup table $M^w \in \mathbb{R}^{d \times s}$ where s denotes the size (recorded words) of lookup table. Otherwise, it will be represented as the randomly initialized default word (denoted by a specific mark UNK). Note that, this is intuitively

	CMRC-2017			PD			CFT
	Train	Valid	Test	Train	Valid	Test	human
# Query	354,295	2,000	3,000	870,710	3,000	3,000	1,953
Max # words in docs	486	481	484	618	536	634	414
Max # words in query	184	72	106	502	153	265	92
Avg # words in docs	324	321	307	379	425	410	153
Avg # words in query	27	19	23	38	38	41	20
# Vocabulary	94,352	21,821	38,704	248,160	536	634	414

Table 1: Data statistics of CMRC-2017, PD and CFT.

like "guessing" the possible unknown words (which will appear during test) from the vocabulary during training and only the word embedding of the OOV words will be replaced by UNK while their subword embedding $SE(w)$ will still be processed using the original word. In this way, the OOV words could be tuned sufficiently with expressive meaning after training. During test, the word embedding of unknown words would not severely bias its final representation. Thus, $AE(w)$ can be rewritten as

$$AE(w) = \begin{cases} WE(w) \diamond SE(w) & \text{if } w \in H \\ UNK \diamond SE(w) & \text{otherwise} \end{cases}$$

In our experiments, the short list is determined according to the word frequency. Concretely, we sort the vocabulary according to the word frequency from high to low. A frequency filter ratio γ is set to filter out the low-frequency words (rare words) from the lookup table. For example, γ=0.9 means the least frequent 10% words are replaced with the default UNK notation.

The subword embedding $SE(w)$ is generated by taking the final outputs of a bidirectional gated recurrent unit (GRU) (Cho et al., 2014) applied to the embeddings from a lookup table of subwords. The structure of GRU used in this paper are described as follows.

$$\begin{aligned} r_t &= \sigma(W_r x_t + U_r h_{t-1} + b_r), \\ z_t &= \sigma(W_z x_t + U_z h_{t-1} + b_z), \\ \tilde{h}_t &= \tanh(W_h x_t + U_h(rt \odot h_{t-1}) + b_h) \\ h_t &= (1 - z_t) \odot h_{t-1} + z_t \odot \tilde{h}_t \end{aligned}$$

where $\odot$ denotes the element-wise multiplication. r_t and z_t are the reset and update gates respectively, and $\tilde{h}_t$ are the hidden states. A bi-directional GRU (BiGRU) processes the sequence in both forward and backward directions. Subwords of each word are successively fed to forward GRU and backward GRU to obtain the internal features of two directions. The output for each input is the concatenation of the two vectors from both directions: $\overleftrightarrow{h_t} = \overrightarrow{h_t} \parallel \overleftarrow{h_t}$. Then, the output of BiGRUs is passed to a fully connected layer to obtain the final subword embedding $SE(w)$.

$$SE(w) = W\overleftrightarrow{h_t} + b$$

2.3 Attention Module

Our attention module is based on the Gated attention Reader (GA Reader) proposed by (Dhingra et al., 2017). We choose this model due to its simplicity with comparable performance so that we can focus on the effectiveness of SAW strategies. This module can be described in the following two steps. After augmented embedding, we use two BiGRUs to get contextual representations of the document and query respectively, where the representation of each word is formed by concatenating the forward and backward hidden states.

$$\begin{aligned} H_q &= \text{BiGRU}(Q) \\ H_d &= \text{BiGRU}(D) \end{aligned}$$

For each word d_i in H_d, we form a word-specific representation of the query $q_i \in H_q$ using soft attention, and then adopt element-wise product to multiply the query representation with the document word representation.

$$\alpha_i = softmax(H_q^\top d_i)$$
$$\beta_i = Q\alpha_i$$
$$x_i = d_i \odot \beta_i$$

where $\odot$ denotes the multiplication operator to model the interactions between d_i and q_i. Then, the document contextual representation $\tilde{H}_d = \{x_1, x_2, \ldots, x_k\}$ is gated by query representation.

Suppose the network has K layers. At each layer, the document representation $\tilde{H}_d$ is updated through above attention learning. After going through all the layers, our model comes to answer prediction phase. We use all the words in the document to form the candidate set C. Let q_t denote the t-th intermediate output of query representation H_q and H_D represent the full output of document representation $\tilde{H}_d$. The probability of each candidate word $w \in C$ as being the answer is predicted using a softmax layer over the inner-product between q_t and H_D.

$$p = softmax((q_t)^\top H_D)$$

where vector p denotes the probability distribution over all the words in the document. Note that each word may occur several times in the document. Thus, the probabilities of each candidate word occurring in different positions of the document are summed up for final prediction.

$$P(w|D,Q) \propto \sum_{i \in I(w,D)} p_i$$

where $I(w,d)$ denotes the set of positions that a particular word w occurs in the document D. The training objective is to maximize $\log P(A|D,Q)$ where A is the correct answer.

Finally, the candidate word with the highest probability will be chosen as the predicted answer.

$$A^* = \text{argmax}_{w \in C} P(w|D,Q)$$

Different from recent work employing complex attention mechanisms (Wang et al., 2017b; Cui et al., 2017a; Sordoni et al., 2016), our attention mechanism is much more simple with comparable performance so that we can focus on the effectiveness of SAW strategies.

3 Experiments

3.1 Dataset and Settings

To verify the effectiveness of our proposed model, we conduct multiple experiments on three Chinese Machine Reading Comprehension datasets, namely CMRC-2017 (Cui et al., 2017b), People's Daily (PD) and Children Fairy Tales (CFT) (Cui et al., 2016)[2]. In these datasets, a story containing consecutive sentences is formed as the *Document* and one of the sentences is either automatically or manually selected as the *Query* where one token is replaced by a placeholder to indicate the *answer* to fill in. Table 1 gives data statistics. Different from the current cloze-style datasets for English reading comprehension, such as CBT, Daily Mail and CNN (Hermann et al., 2015), the three Chinese datasets do not provide candidate answers. Thus, the model has to find the correct answer from the entire document.

Besides, we also use the Children's Book Test (CBT) dataset (Hill et al., 2015) to test the generalization ability in multi-lingual case. We only focus on subsets where the answer is either a common noun (CN)

[2]Note that the test set of CMRC-2017 and human evaluation test set (Test-human) of CFT are harder for the machine to answer because the questions are further processed manually and may not be accordance with the pattern of automatic questions.

or NE which is more challenging since the answer is likely to be rare words. We evaluate all the models in terms of accuracy, which is the standard evaluation metric for this task.

Throughout this paper, we use the same model setting to make fair comparisons. According to our preliminary experiments, we report the results based on the following settings. The default integration strategy is *element-wise product*. Word embeddings were 200d and pre-trained by word2vec (Mikolov et al., 2013) toolkit on *Wikipedia* corpus[3]. Subword embedding were 100d and randomly initialized with the uniformed distribution in the interval [-0:05; 0:05]. Our model was implemented using the Theano[4] and Lasagne Python libraries[5]. We used stochastic gradient descent with ADAM updates for optimization (Kingma and Ba, 2014). The batch size was 64 and the initial learning rate was 0.001 which was halved every epoch after the second epoch. We also used gradient clipping with a threshold of 10 to stabilize GRU training (Pascanu et al., 2013). We use three attention layers for all experiments. The GRU hidden units for both the word and subword representation were 128. The default frequency filter proportion was 0.9 and the default merging times of BPE was 1,000. We also apply dropout between layers with a dropout rate of 0.5 [6].

3.2 Main Results

CMRC-2017 Table 2 shows our results on CMRC-2017 dataset, which shows that our SAW Reader (mul) outperforms all other single models on the test set, with 7.57% improvements compared with Attention Sum Reader (AS Reader) baseline. Although WHU's model achieves the best besides our model on the valid set with only 0.75% below ours, their result on the test set is lower than ours by 2.27%, indicating our model has a satisfactory generalization ability.

We also list different integration operations for word and subword embeddings. Table 3 shows the comparisons. From the results, we can see that Word + BPE outperforms Word + Char which indicates subword embedding works essentially. We also observe that *mul* outperforms the other two operations, *concat* and *sum*. This reveals that *mul* might be more informative than *concat* and *sum* operations. The superiority might be due to element-wise product being capable of modeling the interactions and eliminating distribution differences between word and subword embedding. Intuitively, this is also similar to endow subword-aware "attention" over the word embedding. In contrast, concatenation operation may cause too high dimension, which leads to serious over-fitting issues, and sum operation is too simple to prevent from detailed information losing.

SAW Reader	**72.8**	**75.1**	**43.8**

Table 4: Accuracy on PD and CFT datasets. Results of AS Reader and CAS Reader are from (Cui et al., 2016).

PD & CFT Since there is no training set for CFT dataset, our model is trained on PD training set. Note that the CFT dataset is harder for the machine to answer because the test set is further processed by human evaluation, and may not be accordance with the pattern of PD dataset. The results on PD and CFT datasets are listed in Table 4. As we see that, our SAW Reader significantly outperforms the CAS Reader in all types of testing, with improvements of 7.0% on PD and 8.8% on CFT test sets, respectively. Although the domain and topic of PD and CFT datasets are quite different, the results indicate that our model also works effectively for out-of-domain learning.

CBT To verify if our method can only work for Chinese, we also evaluate the effectiveness of the proposed method on benchmark English dataset. We use CBT dataset as our testbed to evaluate the performance. For a fair comparison, we simply set the same parameters as before. Table 5 shows the results. We observe that our model outperforms most of the previously public works, with 2.4 % gains on the CBT-NE test set compared with GA Reader which adopts word and character embedding concatenation. Our SAW Reader also achieves comparable performance with FG Reader who adopts neural gates to combine word-level and character-level representations with assistance of extra features including NE, POS and word frequency while our model is much simpler and faster. This result shows our SAW Reader is not restricted to Chinese reading comprehension, but also for other languages.

4 Analysis

4.1 Merging Times of BPE

The vocabulary size could seriously involve the segmentation granularity. For BPE segmentation, the resulted subword vocabulary size is equal to the merging times plus the number of single-character types. To have an insight of the influence, we adopt merge times from 0 to $20k$, and conduct quantitative study on CMRC-2017 for BPE segmentation. Figure 2 shows the results. We observe that when the vocabulary size is $1k$, the models could obtain the best performance. The results indicate that for a task like reading comprehension the subwords, being a highly flexible grained representation between character and word, tends to be more like characters instead of words. However, when the subwords completely fall into characters, the model performs the worst. This indicates that the balance between word and character is quite critical and an appropriate grain of character-word segmentation could essentially improve the word representation.

Model	CBT-NE		CBT-CN

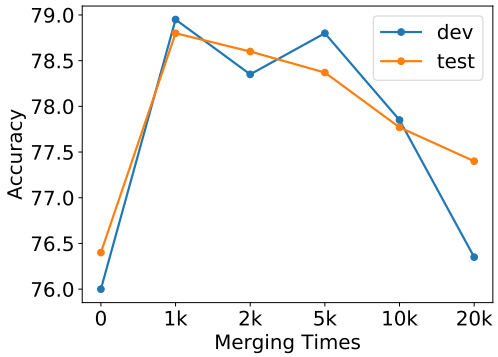

Figure 2: Case study of the subword vocabulary size of BPE.

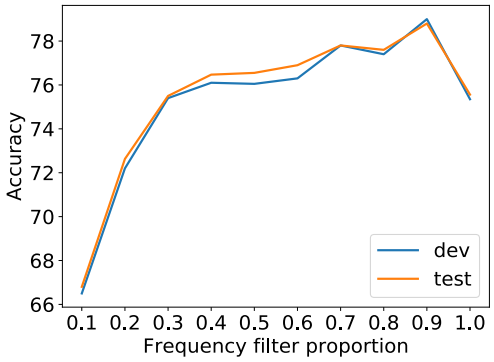

Figure 3: Quantitative study on the influence of the short list.

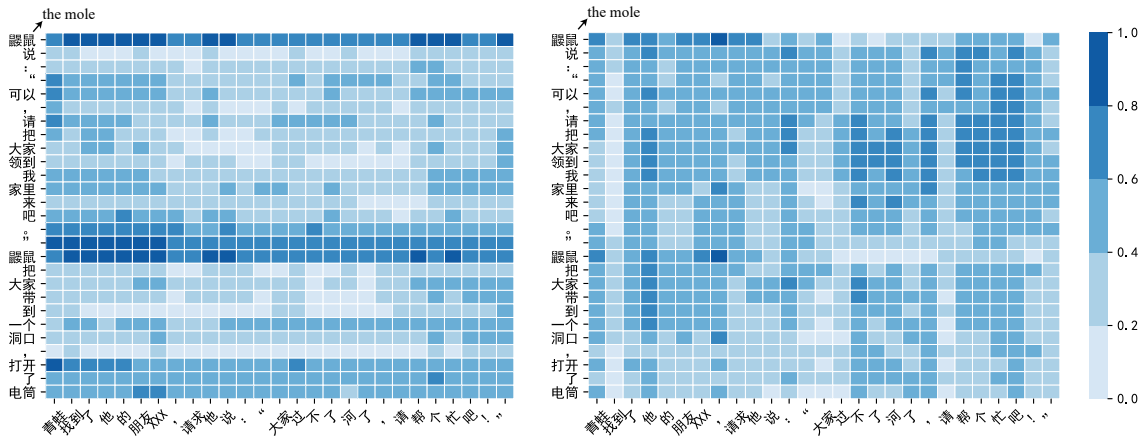
4.2 Filter Mechanism

To investigate the impact of the short list to the model performance, we conduct quantitative study on the filter ratio from [0.1, 0.2, ..., 1]. The results on the CMRC-2017 dataset are depicted in Figure 3. As we can see that when $\gamma = 0.9$ our SAW reader can obtain the best performance, showing that building the vocabulary among all the training set is not optimal and properly reducing the frequency filter ratio can boost the accuracy. This is partially attributed to training the model from the full vocabulary would cause serious over-fitting as the rare words representations can not obtain sufficient tuning. If the rare words are not initialized properly, they would also bias the whole word representations. Thus a model without OOV mechanism will fail to precisely represent those inevitable OOV words from test sets.

4.3 Subword-Augmented Representations

In text understanding tasks, if the ground-truth answer is OOV word or contains OOV word(s), the performance of deep neural networks would severely drop due to the incomplete representation, especially for cloze-style reading comprehension task where the answer is only one word or phrase. In CMRC-2017, we observe questions with OOV answers (denoted as "OOV questions") account for 17.22% in the error results of the best Word + Char embedding based model. With BPE subword embedding, 12.17% of these "OOV questions" could be correctly answered. This shows the subword representations could be essentially useful for modeling rare and unseen words.

To analyze the reading process of SAW Reader, we draw the attention distributions at intermediate



(a) Embedding of Document and query

(b) Final document and query representation

Doc (extract): The mole said, "That's fine, please bring them to my house." The mole took everyone to a hole, turned on the flashlight and asked the little white rabbit, the hedgehog, the big ant and the frog to follow him, saying, "Don't be afraid, just go ahead."
Query: The frog found his friend _____ and told him, We cannot get across the river. Please give us a hand!

Figure 4: Pair-wise attention visualization.

layers as shown in Figure 4. We observe the salient candidates in the document can be focused after the pair-wise matching of document and query and the right answer ("*The mole*") could obtain a high weight at the very beginning. After attention learning, the key evidence of the answer would be collected and irrelevant parts would be ignored. This shows our SAW Reader is effective at selecting the vital points at the fundamental embedding layer, guiding the attention layers to collect more relevant pieces.

5 Related Work

5.1 Machine Reading Comprehension

Recently, many deep learning models have been proposed for reading comprehension (Sordoni et al., 2016; Trischler et al., 2016; Wang and Jiang, 2016; Munkhdalai and Yu, 2017; Wang et al., 2017a; Dhingra et al., 2017; Zhang et al., 2018b; Wang et al., 2018b). Notably, Chen et al. (2016) conducted an in-depth and thoughtful examination on the comprehension task based on an attentive neural network and an entity-centric classifier with a careful analysis based on handful features. Kadlec et al. (2016) proposed the Attention Sum Reader (AS Reader) that uses attention to directly pick the answer from the context, which is motivated by the Pointer Network (Vinyals et al., 2015). Instead of summing the attention of query-to-document, GA Reader (Dhingra et al., 2017) defined an element-wise product to endowing attention on each word of the document using the entire query representation to build query-specific representations of words in the document for accurate answer selection. Wang et al. (2017b) employed gated self-matching networks (R-net) on passage against passage itself to refine passage representation with information from the whole passage. Cui et al. (2017a) introduced an "attended attention" mechanism (AoA) where query-to-document and document-to-query are mutually attentive and interactive to each other.

5.2 Augmented Word Embedding

Distributed word representation plays a fundamental role in neural models (Cai and Zhao, 2016; Qin et al., 2016; Zhao et al., 2017; Peters et al., 2018; He et al., 2018; Wang et al., 2018a; Bai and Zhao, 2018; Zhang et al., 2018a). Recently, character embeddings are widely used to enrich word representations (Kim et al., 2016; Yang et al., 2017; Luong and Manning, 2016; Huang et al., 2018). Yang et al. (2017) explored a fine-grained gating mechanism (FG Reader) to dynamically combine word-level and character-level representations based on properties of the words. However, this method is computationally complex and it is not end-to-end, requiring extra labels such as NE and POS tags. Seo et al. (2017)

concatenated the character and word embedding to feed a two-layer Highway Network.

Not only for machine reading comprehension tasks, character embedding has also benefit other natural language process tasks, such as word segmentation (Cai et al., 2017), machine translation (Luong and Manning, 2016), tagging (Yang et al., 2016; Li et al., 2018) and language modeling (Verwimp et al., 2017; Miyamoto and Cho, 2016). However, character embedding only shows marginal improvement due to a lack internal semantics. Lexical, syntactic and morphological information are also considered to improve word representation (Cao and Rei, 2016; Bergmanis and Goldwater, 2017). Bojanowski et al. (2017) proposed to learn representations for character n-gram vectors and represent words as the sum of the n-gram vectors. Avraham and Goldberg (2017) built a model inspired by (Joulin et al., 2017), who used morphological tags instead of n-grams. They jointly trained their morphological and semantic embeddings, implicitly assuming that morphological and semantic information should live in the same space. However, the linguistic knowledge resulting subwords, typically, morphological suffix, prefix or stem, may not be suitable for different kinds of languages and tasks. Sennrich et al. (2016) introduced the byte pair encoding (BPE) compression algorithm into neural machine translation for being capable of open-vocabulary translation by encoding rare and unknown words as subword units. Instead, we consider refining the word representations for both frequent and infrequent words from a computational perspective. Our proposed subword-augmented embedding approach is more general, which can be adopted to enhance the representation for each word by adaptively altering the segmentation granularity in multiple NLP tasks.

6 Conclusion

This paper presents an effective neural architecture, called subword-augmented word embedding to enhance the model performance for the cloze-style reading comprehension task. The proposed SAW Reader uses subword embedding to enhance the word representation and limit the word frequency spectrum to train rare words efficiently. With the help of the short list, the model size will also be reduced together with training speedup. Unlike most existing works, which introduce either complex attentive architectures or many manual features, our model is much more simple yet effective. Giving state-of-the-art performance on multiple benchmarks, the proposed reader has been proved effective for learning joint representation at both word and subword level and alleviating OOV difficulties.

Abstract

Pooling is an essential component of a wide variety of sentence representation and embedding models. This paper explores generalized pooling methods to enhance sentence embedding. We propose vector-based multi-head attention that includes the widely used max pooling, mean pooling, and scalar self-attention as special cases. The model benefits from properly designed penalization terms to reduce redundancy in multi-head attention. We evaluate the proposed model on three different tasks: natural language inference (NLI), author profiling, and sentiment classification. The experiments show that the proposed model achieves significant improvement over strong sentence-encoding-based methods, resulting in state-of-the-art performances on four datasets. The proposed approach can be easily implemented for more problems than we discuss in this paper.

1 Introduction

Distributed representation learned with neural networks has shown to be effective in modeling natural language at different granularities. Learning representation for words (Bengio et al., 2000; Mikolov et al., 2013; Pennington et al., 2014), for example, has achieved notable success. Much remains to be done to model larger spans of text such as sentences or documents. The approaches to computing sentence embedding generally fall into two categories. The first consists of learning sentence embedding with unsupervised learning, e.g., auto-encoder-based models (Socher et al., 2011), Paragraph Vector (Le and Mikolov, 2014), SkipThought vectors (Kiros et al., 2015), FastSent (Hill et al., 2016), among others. The second category consists of models trained with supervised learning, such as convolution neural networks (CNN) (Kim, 2014; Kalchbrenner et al., 2014), recurrent neural networks (RNN) (Conneau et al., 2017; Bowman et al., 2015), and tree-structure recursive networks (Socher et al., 2013; Zhu et al., 2015; Tai et al., 2015), just to name a few.

Pooling is an essential component of a wide variety of sentence representation and embedding models. For example, in recurrent-neural-network-based models, pooling is often used to aggregate hidden states at different time steps (i.e., words in a sentence) to obtain sentence embedding. Convolutional neural networks (CNN) also often uses max or mean pooling to obtain a fixed-size sentence embedding.

In this paper we explore generalized pooling methods to enhance sentence embedding. Specifically, by extending scalar self-attention models such as those proposed in Lin et al. (2017), we propose vector-based multi-head attention, which includes the widely used max pooling, mean pooling, and scalar self-attention itself as special cases. On one hand, the proposed method allows for extracting different aspects of the sentence into multiple vector representations through the multi-head mechanism. On the other, it allows the models to focus on one of many possible interpretations of the words encoded in the context vector through the vector-based attention mechanism. In the proposed model we design penalization terms to reduce redundancy in multi-head attention.

We evaluate the proposed model on three different tasks: natural language inference, author profiling, and sentiment classification. The experiments show that the proposed model achieves significant improvement over strong sentence-encoding-based methods, resulting in state-of-the-art performances on

Proceedings of the 27th International Conference on Computational Linguistics, pages 1815–1826
Santa Fe, New Mexico, USA, August 20-26, 2018.

four datasets. The proposed approach can be easily implemented for more problems than we discuss in this paper.

2 Related Work

There exist in the literature much previous work for sentence embedding with supervised learning, which mostly use RNN and CNN as building blocks. For example, Bowman et al. (2015) used BiLSTMs as sentence embedding for natural language inference task. Kim (2014) used CNN with max pooling for sentence classification. More complicated neural networks were also proposed for sentence embedding. For example, Socher et al. (2013) introduced Recursive Neural Tensor Network (RNTN) over parse trees to compute sentence embedding for sentiment analysis. Zhu et al. (2015) and Tai et al. (2015) proposed tree-LSTM. Yu and Munkhdalai (2017a) proposed a memory augmented neural networks, called Neural Semantic Encoder (NSE), as sentence embedding for natural language understanding tasks.

Some recent research began to explore inner/self-sentence attention mechanism for sentence embedding, which can be classified into two categories: self-attention network and self-attention pooling. Cheng et al. (2016) proposed an intra-sentence level attention mechanism on the base of LSTM, called LSTMN. For each step in LSTMN, it calculated the attention between a certain word and its previous words. Vaswani et al. (2017) proposed a self-attention network for the neural machine translation task. The self-attention network uses multi-head scaled dot-product attention to represent each word by weighted summation of all word in the sentence. Shen et al. (2017) proposed DiSAN, which is composed of a directional self-attention with temporal order encoded. Shen et al. (2018) proposed reinforced self-attention network (ReSAN), which integrate both soft and hard attention into one context fusion with reinforced learning.

Self-attention pooling has also been studied in previous work. Liu et al. (2016) proposed inner-sentence attention based pooling methods for sentence embedding. They calculate scalar attention between the LSTM states and the mean pooling using multi-layer perceptron (MLP) to obtain the vector representation for a sentence. Lin et al. (2017) proposed a scalar structure/multi-head self-attention method for sentence embedding. The multi-head self-attention is calculated by a MLP with only LSTM states as input. There are two main differences from our proposed method; i.e., (1) they used scalar attention instead of vectorial attention, (2) we propose different penalization terms which is suitable for vector-based multi-head self-attention, while their penalization term on attention matrix is only designed for scalar multi-head self-attention. Choi et al. (2018) proposed a fine-grained attention mechanism for neural machine translation, which also extend scalar attention to vectorial attention. Shen et al. (2017) proposes multi-dimensional/vectorial self-attention pooling on the top of self-attention network instead of BiLSTM. However, both of them didn't consider multi-head self-attention.

3 The Model

In this section we describe the proposed models that enhance sentence embedding with generalized pooling approaches. The pooling layer is built on a state-of-the-art sequence encoder layer. Below, we first discuss the sequence encoder, which, when enhanced with the proposed generalized pooling, achieves state-of-the-art performance on three different tasks on four datasets.

3.1 Sequence Encoder

The sequence encoder in our model takes into T word tokens of a sentence $\boldsymbol{S} = (w_1, w_2, \ldots, w_T)$. Each word w_i is from the vocabulary $\boldsymbol{V}$. For each word we concatenate pre-trained word embedding and embedding learned from characters. The character composition model feeds all characters of the word into a convolution neural network (CNN) with max pooling (Kim, 2014). The detailed experiment setup will be discussed in Section 4. The sentence $\boldsymbol{S}$ is represented as a word embedding sequence: $\boldsymbol{X} = (\boldsymbol{e}_1, \boldsymbol{e}_2, \ldots, \boldsymbol{e}_T) \in \mathbb{R}^{T \times d_e}$, where d_e is the dimension of word embedding which concatenates embedding obtained from character composition and pretrained word embedding.

To represent words and their context in sentences, the sentences are fed into stacked bidirectional LSTMs (BiLSTMs). Shortcut connections are applied, which concatenate word embeddings and input

hidden states at each layer in the stacked BiLSTM except for the first (bottom) layer. The formulae are as follows:

$$\overrightarrow{\boldsymbol{h}}_t^l = \text{LSTM}([\boldsymbol{e}_t; \overrightarrow{\boldsymbol{h}}_t^{l-1}], \overrightarrow{\boldsymbol{h}}_{t-1}^l)\,, \tag{1}$$

$$\overleftarrow{\boldsymbol{h}}_t^l = \text{LSTM}([\boldsymbol{e}_t; \overleftarrow{\boldsymbol{h}}_t^{l-1}], \overleftarrow{\boldsymbol{h}}_{t+1}^l)\,, \tag{2}$$

$$\boldsymbol{h}_t^l = [\overrightarrow{\boldsymbol{h}}_t^l; \overleftarrow{\boldsymbol{h}}_t^l]\,. \tag{3}$$

where hidden states $\boldsymbol{h}_t^l$ in layer l concatenate two directional hidden states of LSTM at time t. Then the sequence is represented as the hidden states in the top layer L: $\mathbf{H}^L = (\boldsymbol{h}_1^L, \boldsymbol{h}_2^L, \ldots, \boldsymbol{h}_T^L) \in \mathbb{R}^{T\times 2d}$. For simplicity, we ignore the superscript L in the remainder of the paper.

3.2 Generalized Pooling

3.2.1 Vector-based Multi-head Attention

To transform a variable length sentence into a fixed size vector representation, we propose a generalized pooling method. We achieve that by using a weighted summation of the T LSTM hidden vectors, and the weights are vectors rather than scalars, which can control every element in all hidden vectors:

$$\mathbf{A} = \text{softmax}(\mathbf{W}_2\text{ReLU}(\mathbf{W}_1\mathbf{H}^{\mathrm{T}} + \boldsymbol{b}_1) + \boldsymbol{b}_2)^{\mathrm{T}}\,, \tag{4}$$

where $\mathbf{W}_1 \in \mathbb{R}^{d_a\times 2d}$ and $\mathbf{W}_2 \in \mathbb{R}^{2d\times d_a}$ are weight matrices; $\boldsymbol{b}_1 \in \mathbb{R}^{d_a}$ and $\boldsymbol{b}_2 \in \mathbb{R}^{2d}$ are bias, where d_a is the dimension of attention network and d is the dimension of LSTMs. $\mathbf{H} \in \mathbb{R}^{T\times 2d}$ and $\mathbf{A} \in \mathbb{R}^{T\times 2d}$ are the hidden vectors at the top layer and weight matrices, respectively. The softmax ensures that $(\mathbf{A}_1, \mathbf{A}_2, \ldots, \mathbf{A}_T)$ are non-negative and sum up to 1 for every element in vectors. Then we sum up the LSTM hidden states $\mathbf{H}$ according to the weight vectors provided by $\mathbf{A}$ to get a vector representation $\boldsymbol{v}$ of the input sentence.

However, the vector representation usually focuses on a specific component of the sentence, like a special set of related words or phrases. We extend pooling method to a multi-head way:

$$\mathbf{A}^i = \text{softmax}(\mathbf{W}_2^i\text{ReLU}(\mathbf{W}_1^i\mathbf{H}^{\mathrm{T}} + \boldsymbol{b}_1^i) + \boldsymbol{b}_2^i)^{\mathrm{T}}\,, \forall i \in 1, \ldots, I\,, \tag{5}$$

$$\boldsymbol{v}^i = \sum_{t=1}^{T} \boldsymbol{a}_t^i \odot \boldsymbol{h}_t^i\,, \forall i \in 1, \ldots, I\,, \tag{6}$$

where $\boldsymbol{a}_t^i$ indicates the vectorial attention from $\mathbf{A}^i$ for the t-th token in i-th head and $\odot$ is the element-wise product (also called the Hadamard product). Thus the final representation is a concatenated vector $\boldsymbol{v} = [\boldsymbol{v}^1; \boldsymbol{v}^2; \ldots; \boldsymbol{v}^I]$, where each $\boldsymbol{v}^i$ captures different aspects of the sentence. For example, some heads of vectors may represent the predicate of sentence and other heads of vectors represent argument of the sentence, which enhances representation of sentences obtained in single-head attention.

3.2.2 Penalization Terms

To reduce the redundancy of multi-head attention, we design penalization terms for vector-based multi-head attention in order to encourage the diversity of summation weight across different heads of attention. We propose three types of penalization terms.

Penalization Term on Parameter Matrices The first penalization term is applied to parameter matrix $\mathbf{W}_1^i$ in Equation 5, as shown in the following formula:

$$P = \mu \sum_{i=1}^{I} \sum_{j=i+1}^{I} \max(\lambda - \|\mathbf{W}_1^i - \mathbf{W}_1^j\|_{\mathrm{F}}^2, 0)\,. \tag{7}$$

Intuitively, we encourage different heads to have different parameters. We maximum the *Frobenius* norm of the differences between two parameter matrices, resulting in encouraging the diversity of different heads. It has no further bonus when the *Frobenius* norm of the difference of two matrices exceeds the a threshold λ. Similar to adding an L2 regularization term on neural networks, the penalization term P will be added to the original loss with a weight of μ. Hyper-parameters λ and μ need to be tuned on a development set. We can also add constrains on $\mathbf{W}_2^i$ in a similar way, but we did not observe further improvement in our experiments.

Penalization Term on Attention Matrices The second penalization term is added on attention matrices. Instead of using $\|\mathbf{A}\mathbf{A}^{\mathrm{T}} - \mathbf{I}\|_{\mathrm{F}}^2$ to encourage the diversity for scalar attention matrix as in Lin et al. (2017), we propose the following formula to encourage the diversity for vectorial attention matrices. The penalization term on attention matrices is

$$P = \mu \sum_{i=1}^{I} \sum_{j=i+1}^{I} \max(\lambda - \|\mathbf{A}^i - \mathbf{A}^j\|_{\mathrm{F}}^2, 0)\,, \tag{8}$$

where λ and μ are hyper-parameters which need to be tuned based on a development set. Intuitively, we try to encourage the diversity of any two different $\mathbf{A}^i$ under the threshold λ.

Penalization Term on Sentence Embeddings In addition, we propose to add a penalization term on multi-head sentence embedding $\boldsymbol{v}^i$ directly as follows:

$$P = \mu \sum_{i=1}^{I} \sum_{j=i+1}^{I} \max(\lambda - \|\boldsymbol{v}^i - \boldsymbol{v}^j\|_2^2, 0)\,, \tag{9}$$

where λ and μ are hyper-parameters. Here we try to maximize the l^2-norm of any two different heads of sentence embeddings under the threshold λ.

3.3 Top-layer Classifiers

The output of pooling is fed to a top-layer classifier to solve different problems. In this paper we evaluate our sentence embedding models on three different tasks: natural language inference (NLI), author profiling, and sentiment classification, on four datasets. The evaluation covers two typical types of problems. The author profiling and sentiment tasks classify individual sentences into different categories and the two NLI tasks classify sentence pairs.

For the NLI tasks, to enhance the relationship between sentence pairs, we concatenate the embeddings of two sentences with their absolute difference and element-wise product (Mou et al., 2016) as the input to the multilayer perceptron (MLP) classifier:

$$\boldsymbol{v} = [\boldsymbol{v}_a; \boldsymbol{v}_b; |\boldsymbol{v}_a - \boldsymbol{v}_b|; \boldsymbol{v}_a \odot \boldsymbol{v}_b]\,, \tag{10}$$

where $\odot$ is the element-wise product. The MLP has two hidden layers with *ReLU* activation with shortcut connections and a *softmax* output layer. The entire model is trained end-to-end through minimizing the cross-entropy loss. Note that for the two classification tasks on individual sentences (i.e., the author profiling and sentiment classification task), we use the same MLP classifiers described above for sentence pair classification. But instead of concatenating two sentences, we directly feed a sentence embedding into MLP.

4 Experimental Setup

4.1 Data

SNLI The SNLI (Bowman et al., 2015) is a large dataset for natural language inference. The task detects three relationships between a premise and a hypothesis sentence: the premise entails the hypothesis

(*entailment*), they contradict each other (*contradiction*), or they have a neutral relation (*neutral*). We use the same data split as in Bowman et al. (2015), i.e., 549.367 samples for training, 9,842 samples for development and 9,824 samples for testing.

MultiNLI MultiNLI (Williams et al., 2017) is another natural language inference dataset. The data are collected from a broader range of genres such as fiction, letters, telephone speech, and 9/11 reports. Half of these 10 genres are used in training while the rest are not, resulting in-domain and cross-domain development and test sets used to test NLI systems. We use the same data split as in Williams et al. (2017), i.e., 392,702 samples for training, 9,815/9,832 samples for in-domain/cross-domain development, and 9,796/9,847 samples for in-domain/cross-domain testing. Note that, we do not use SNLI as an additional training/development set in our experiments.

Age Dataset To compare our models with that of Lin et al. (2017), we use the same Age dataset in our experiment here, which is an Author Profiling dataset. The dataset are extracted from the Author Profiling dataset[1], which consists of tweets from English Twitter. The task is to predict the age range of authors of input tweets. The age range are split into 5 classes: 18-24, 25-34, 35-49, 50-64, 65+. We use the same data split as in Lin et al. (2017), i.e., 68,485 samples for training, 4,000 for development, and 4,000 for testing.

Yelp Dataset The Yelp dataset[2] is a sentiment analysis task, which takes reviews as input and predicts the level of sentiment in terms of the number of stars, from 1 to 5 stars, where 5-star means the most positive. We use the same data split as in Lin et al. (2017), i.e., 500,000 samples for training, 2,000 for development, and 2,000 for testing.

4.2 Training Details

We implement our algorithm with Theano (Theano Development Team, 2016) framework. We use the development set (in-domain development set for MultiNLI) to select models for testing. To help replicate our results, we publish our code[3], which is developed from our codebase for multiple tasks (Chen et al., 2018; Chen et al., 2017a; Chen et al., 2016; Zhang et al., 2017). Specifically, we use Adam (Kingma and Ba, 2014) for optimization. The initial learning rate is 4e-4 for SNLI and MultiNLI, 2e-3 for Age dataset, 1e-3 for Yelp dataset. For SNLI and MultiNLI dataset, stacked BiLSTMs have 3 layers. For Age and Yelp dataset, stacked BiLSTMs have 1 layer. The hidden states of BiLSTMs for each direction and MLP are 300 dimension, except for SNLI whose dimensions are 600. We clip the norm of gradients to make it smaller than 10 for SNLI and MultiNLI, and 0.5 for Age and Yelp dataset. The character embedding has 15 dimensions, and 1D-CNN filters lengths are 1, 3 and 5, respectively. Each filter has 100 feature maps, resulting in 300 dimensions for character-composition embedding. We initialize word-level embedding with pre-trained *GloVe-840B-300D* embeddings (Pennington et al., 2014) and initialize out-of-vocabulary words randomly with a Gaussian distribution. The word-level embedding is fixed during training for SNLI and MultiNLI dataset, but updated during training for Age and Yelp dataset, which is determined by the performance on development sets. The mini-batch size is 128 for SNLI and 32 for the rest. We use 5 heads generalized pooling for all tasks. And d_a is 600 for SNLI and 300 for the other datasets. For the penalization term, we choose $\lambda = 1$; the penalization weight μ is selected from [1,1e-1,1e-2,1e-3,1e-4] based on performances on the development sets.

5 Experimental Results

5.1 Overall Performance

For the NLI tasks, there are many ways to add cross-sentence (Rocktäschel et al., 2015; Parikh et al., 2016; Chen et al., 2017a) level attention. To ensure the comparison is fair, we only compare methods that use sentence-encoding-based models; i.e., cross-sentence attention is not allowed. Note that this

Table 1: Accuracies of the models on the SNLI dataset.

follows the setup in the RepEval-2017 Shared Task. Table 1 shows the results of different models for NLI, consisting of results of previous work on sentence-encoding-based models, plus the performance of our baselines and that of the model proposed in this paper. We have three additional baseline models: the first uses max pooling on top of BiLSTM, which achieves an accuracy of 85.3%; the second uses mean pooling on top of BiLSTM, which achieves an accuracy of 85.0%; the third uses last pooling, i.e., concatenating the last hidden states of forward and backward LSTMs, which achieves an accuracy of 84.9%. Instead of using heuristic pooling methods, the proposed sentence-encoding-based model with generalized pooling achieves a new state-of-the-art accuracy of 86.6% on the SNLI dataset; the improvement over the baseline with max pooling is statistically significant under the one-tailed paired t-test at the 99.999% significance level. The previous state-of-the-art model ReSAN (Shen et al., 2018) used a hybrid of hard and soft attention model with reinforced learning achieved an accuracy of 86.3%.

Table 2 shows the results of different models on the MultiNLI dataset. The first group is the results of previous sentence-encoding-based models. The proposed model with generalized pooling achieves an accuracy of 73.8% on the in-domain test set and 74.0% on the cross-domain test set; both improve over the baselines using max pooling, mean pooling and last pooling. In addition, the results on cross-domain test set yield a new state of the art at an accuracy of 74.0%, which is better than 73.6% of shortcut-stacked BiLSTM (Nie and Bansal, 2017).

Table 3 shows the results of different models for the Yelp and the Age dataset. The BiLSTM with self-attention proposed by Lin et al. (2017) achieves better result than CNN and BiLSTM with max pooling. One of our baseline models using max pooling on BiLSTM achieves accuracies of 65.00% and 82.30% on the Yelp and the Age dataset respectively, which is already better than the self-attention model proposed by Lin et al. (2017). We also show that the results of baseline with mean pooling and last pooling, in which mean pooling achieves the best result on the Yelp dataset among three baseline models and max pooling achieves the best on the Age dataset among three baselines. Our proposed generalized pooling method obtains further improvement on these already strong baselines, achieving 66.55% on the Yelp dataset and 82.63% on the Age dataset (statistically significant $p < 0.00001$ against best baselines),

Model	In	Cross
CBOW (Williams et al., 2017)	64.8	64.5
BiLSTM (Williams et al., 2017)	66.9	66.9
BiLSTM gated-pooling (Chen et al., 2017b)	73.5	**73.6**
Shortcut stacked BiLSTM (Nie and Bansal, 2017)	**74.6**	**73.6**
BiLSTM max pooling	73.6	73.0
BiLSTM mean pooling	71.5	71.6
BiLSTM last pooling	71.6	71.9
BiLSTM **generalized pooling**	**73.8**	**74.0**

Table 2: Accuracies of the models on the MultiNLI dataset.

Model	Yelp	Age
BiLSTM max pooling (Lin et al., 2017)	61.99	77.30
CNN max pooling (Lin et al., 2017)	62.05	78.15
BiLSTM self-attention (Lin et al., 2017)	**64.21**	**80.45**
BiLSTM max pooling	65.00	82.30
BiLSTM mean pooling	65.30	81.78
BiLSTM last pooling	64.95	81.10
BiLSTM **generalized pooling**	**66.55**	**82.63**

Table 3: Accuracies of the models on the Yelp and Age dataset.

which are also new state of the art performances on these two datasets.

5.2 Detailed Analysis

Effect of Multiple Vectors/Scalars To compare the difference between vector-based attention and scalar attention, we draw the learning curves of different models using different heads on the SNLI development dataset without penalization terms as in Figure 1. The green lines indicate scalar self-attention pooling added on top of the BiLSTMs, same as in Lin et al. (2017), and the blue lines indicate vector-based attention used in our generalized pooling methods. It is obvious that the vector-based attention achieves improvement over scalar attention. Different line styles are used to indicate self-attention using different numbers of multi-head, ranging from 1, 3, 5, 7 to 9. For vector-based attention, the 9-head model achieves the best accuracy of 86.8% on the development set. For scalar attention, the 7-head model achieves the best accuracy of 86.4% on the development set.

Effect of Penalization Terms To analyze the effect of penalization terms, we show the results with/without penalization terms on the four datasets in Table 4. Without using any penalization terms, the proposed generalized pooling achieves an accuracy of 86.4% on the SNLI dataset, which is already slightly better than previous models (compared to accuracy 86.3% in Shen et al. (2018)). When we use penalization on parameter matrices, the proposed model achieves a further improvement with an accuracy of 86.6%. In addition, we also observe a significant improvement on MultiNLI, Yelp and Age dataset after using the penalization terms. For the MultiNLI dataset, the proposed model with penalization on parameter matrices achieves an accuracy of 73.8% and 74.0% on the in-domain and the cross-domain test set, respectively, which outperform the accuracy of 73.7% and 73.4% of the model without penalization, respectively. For the Yelp dataset, the proposed model with penalization on parameter matrices achieves the best results among the three penalization methods, which also improve the accuracy of 65.25% to 66.55% compared to the models without penalization. For the Age dataset, the proposed model with penalization on attention matrices achieves the best accuracy of 82.63%, compared to the 82.18% accuracy of the model without penalization. In general, the penalization on parameter matrices achieves the most effective improvement among most of these tasks, except for the Age dataset.

To verify whether the penalization term P discourages the redundancy in the sentence embedding, we

visualize the vectorial multi-head attention according. We compare two models with the same hyper-parameters except that one is with penalization on attention matrices and the other without penalization. We pick a sentence from the development set of the Age data: *Martin Luther King "I was not afraid of the words of the violent, but of the silence of the honest"* , with the gold label being the category of 65+. We plot all 5 heads of attention matrices as in Figure 2. From the figure we can tell that the model trained without the penalization term has much more redundancy between different heads of attention (Figure 3b), resulting in putting significant focus on the word "Martin" in the 1st, 3rd and 5th head, and on the word "violent" in the 2nd and 4th head. However in Figure 3a, the model with penalization shows much more variation between different heads.

6 Conclusions

In this paper, we propose a generalized pooling method for sentence embedding through vector-based multi-head attention, which includes the widely used max pooling, mean pooling, and scalar self-attention as its special cases. Specifically the proposed model aims to use vectors to enrich the expressiveness of attention mechanism and leverage proper penalty terms to reduce redundancy in multi-head attention. We evaluate the proposed approach on three different tasks: natural language inference, author profiling, and sentiment classification. The experiments show that the proposed model achieves significant improvement over strong sentence-encoding-based methods, resulting in state-of-the-art performances on four datasets. The proposed approach can be easily implemented for more problems than we discuss in this paper.

Our future work includes exploring more effective MLP to use the structures of multi-head vectors, inspired by the idea from Lin et al. (2017). Leveraging structure information from syntactic and semantic parses is another direction interesting to us.

Abstract

Interpreting noun compounds is a challenging task. It involves uncovering the underlying predicate which is dropped in the formation of the compound. In most cases, this predicate is of the form VERB+PREP. It has been observed that uncovering the preposition is a significant step towards uncovering the predicate.

In this paper, we attempt to paraphrase noun compounds using prepositions. We consider noun compounds and their corresponding prepositional paraphrases as parallelly aligned sequences of words. This enables us to adapt different architectures from cross-lingual embedding literature. We choose the architecture where we create representations of both noun compound (source sequence) and its corresponding prepositional paraphrase (target sequence), such that their similarity is high. We use LSTMs to learn these representations. We use these representations to decide the correct preposition. Our experiments show that this approach performs considerably well on different datasets of noun compounds that are manually annotated with prepositions.

1 Introduction

A noun compound is a sequence of two or more nouns which have a well-defined meaning when written together. For example, *orange juice*, *colon cancer*, *research paper submission*, *paper submission deadline*, *etc.* The fact that "*juice is made from orange*" is hidden in *orange juice*. Noun compound interpretation deals with uncovering such hidden relations.

Noun compounds are usually interpreted in two ways: labelling and paraphrasing. Labelling involves assigning a semantic relation to a noun compound *e.g.*, *student protest*: AGENT, *orange juice*: MADEOF, *etc.*. These relations come from a set of a predefined taxonomy of semantic relations (Lauer, 1995; Warren, 1978; Barker and Szpakowicz, 1998; Girju et al., 2003; Tratz and Hovy, 2010; Ponkiya et al., 2018). Such detailed, fine-grained information can be useful for downstream tasks such as machine translation (Baldwin and Tanaka, 2004; Balyan and Chatterjee, 2015), question answering (Ahn et al., 2005), text entailment (Nakov, 2013), *etc.* Unfortunately, there is a lack of standard taxonomy. There is no consensus on which set of labels should be uniformly used.

On the other hand, paraphrasing involves rewriting the noun compound as a paraphrase which conveys its meaning explicitly, *e.g.*, *orange juice*: "*juice made from orange*" or "*juice with orange flavour*". Generic paraphrasing has been relatively less pursued (Butnariu et al., 2009; Hendrickx et al., 2013).

Prepositional paraphrasing – paraphrasing using only prepositions, *e.g.*, *orange juice*: "*juice of orange*" – is a simpler version of generic paraphrasing. The advantage of prepositional paraphrasing as compared to labelling is that the set of prepositions is finite, limited and pre-defined. However, the shortcoming is that the information is too coarse-grained for downstream tasks.

Prepositional paraphrasing of noun compounds is a useful subtask to solve. Our preliminary analysis reveals a strong correlation between labels of certain taxonomies and prepositions (refer Section 3 for more details). This was also observed by Girju et al. (2005), who concluded that knowledge of preposition can aid labelling. Also, it filters out the verbs that go with the preposition for verb+preposition

Proceedings of the 27th International Conference on Computational Linguistics, pages 1827–1836
Santa Fe, New Mexico, USA, August 20-26, 2018.

(VERB+PREP) paraphrasing. For example, if the preposition used in paraphrase is *at*, the verbs that go along with mainly be of type LOCATION. Thus, it can aid verb+preposition paraphrasing. Moreover, uncovering of a preposition is enough for some NLP application like Hindi-to-English translation (Kulkarni et al., 2012). Thus, prepositional paraphrasing is a useful first step towards noun compound interpretation.

Deep learning has made tremendous progress in various fields. One of the significant contributions of deep learning in NLP is word embeddings. They are dense real-valued representations of words learnt in an unsupervised manner. Their use has advanced the state in many applications (word sense disambiguation - Rothe and Schütze (2015), named entity recognition - Lample et al. (2016), sentiment classification - Tang et al. (2014), sarcasm detection - Joshi et al. (2016), *etc.*). Word embeddings enable words to share statistical strength. For instance, pattern learnt for the word *hotel* could be used to a good extent for the word *motel*, since they are semantically similar (which is elicited by the similarity between their corresponding word embeddings). This motivates us to investigate the use of word embeddings for noun compound interpretation.

Another significant contribution of deep learning to the field of NLP is the introduction of Encoder Decoder architectures (Bahdanau et al., 2015) for different tasks involving sequences. In such models, an input sequence of words is converted to a sequence of corresponding embeddings, which is then encoded into a single embedding via a part of the network known as Encoder. The single embedding is known as sequence embedding, sequence representation, *etc.* The second part of the network, the Decoder, then uses this sequence embedding in tandem with other information to produce the desired output. Such architectures are commonly used in machine translation, where the sequence embeddings are learnt such that the embeddings of a sentence in a source language and its parallelly aligned sentence in target language have high similarity.

As far as prepositional paraphrasing is concerned, one can observe that both the noun compounds as well as their corresponding paraphrases are parallelly aligned sequences of words. Thus, we can also make use of various sequence learning models from deep learning such as RNN (Werbos, 1990; Rumelhart et al., 1986), LSTM (Hochreiter and Schmidhuber, 1997), *etc.* as encoders to learn their representations.

Thus, in this paper, we raise the following question:

Can sequence representations, learned from word embeddings of components of a noun compound, help in its prepositional paraphrasing?

We attempt to answer this question in the following manner: we encode a noun compound and its prepositional paraphrase through two different LSTMs. Then, we train a network such that the encodings of a noun compound and its corresponding prepositional paraphrase have high similarity. Using this core intuition, our approach is able to generate the correct prepositional paraphrase. We evaluated our approach on four different datasets. Our approach performs reasonably well on a relatively small dataset, and outperforms others on the larger datasets.

The rest of the paper is organized as follows: Section 2 furnishes the necessary background. Section 3 motivates the need for prepositional paraphrasing. Section 4 details the sequence learning based architecture for learning representations of noun compounds and prepositional paraphrases, which we use to generate the correct prepositional paraphrase. Section 5 provides the experimental setup: the datasets used and the training/testing procedure used. Section 6 discusses the results of our experiments and some analysis, followed by a conclusion and future work.

2 Background and Related Work

A relation between the components of a noun compound can be represented in either of the following two ways: (1) Labelling: assigning a relation from a predefined set of semantic relations (*e.g.*, *apple juice*: MADE_OF), or (2) Paraphrasing: using a paraphrase to convey the underlying semantic relation (*e.g.*, *apple juice*: *"juice extracted from an apple"* or *"juice with apple flavor"*).

Over the years, many sets of semantic relations have been proposed (Levi, 1978; Warren, 1978; Lauer, 1995; Ó Séaghdha, 2007; Rosario et al., 2002; Barker and Szpakowicz, 1998; Vanderwende, 1994;

Tratz and Hovy, 2010; Ponkiya et al., 2018). Most of these sets have been created with the assumption that most predicates are of the form verb+preposition. For example, The CAUSED-BY relation in Levi (1978), or the USER/RECIPIENT+THINGUSED/RECEIVED relation in Tratz and Hovy (2010) which paraphrases to *thing used by user*. One may observe that these labels are motivated from verb+preposition constructions. We believe that preposition uncovering will help in the verb+preposition paraphrasing of noun compounds.

A system for automatic uncovering of the predicate can be developed in two ways: rule-based or statistical. A rule-based system will involve linguistic analysis of both w_1 and w_2. In this case, we may end up with more exceptions than the rules. Thus statistical approaches are the way to go. Among statistical approaches, supervised approaches rely on annotated data that needs to be sufficiently large and representative enough of the underlying problem. However, such datasets are rare, and the ones that do exist are small and heavily skewed, which makes the learning more difficult. For example, ≈80% of noun compounds in Girju (2007)'s dataset are annotated with the preposition *of*. The problems arising in such a supervised setting have been well studied by Girju et al. (2005).

On the other hand, Lauer (1995) and Lapata and Keller (2004) have proposed unsupervised models for identifying preposition for an interpretation of noun compounds. Lauer (1995) models $P(prep|n_1, n_2)$ (probability of preposition given two components of a noun compound) using frequency of triples $\langle n_1, prep, n_2 \rangle$. In an alternative model to handle sparsity, she used the following:

$$prep^* = \arg\max_{prep} \sum_{t1 \in cats(n_1), t_2 \in cats(n_2)} P(t_1|prep)P(t_2|prep)$$

where t_1 and t_2 represent particular concepts from the sets of concepts $cats(n_1)$ and $cats(n_2)$, respectively. These sets come from Roget's thesaurus. She also used a lexical frequency based approach in the above formula using pattern searching from Grolier's encyclopedia. Lapata and Keller (2004) implemented the same lexical based model, but they used Altavista search engine and BNC corpus for computing the probability factors.

Recently, Dima and Hinrichs (2015) proposed a feed-forward neural network based system for noun compound interpretation via labelling. Their network takes concatenated word-vectors of components of the noun compound as input, and predicts one of the labels from the Tratz and Hovy (2010)'s label set. We also adapt their system to our problem setting for a comparison.

3 Why Prepositional Paraphrasing of Noun Compounds?

Uncovering a hidden relation or ellipsis from a construct is an important problem in NLP. For instance, when a customer searches for *15 inch laptop*, he/she is actually searching for *a laptop with 15-inch display*. But, when a customer searches for *30 inch tyres*, he/she is actually searching for *tyres with 60 inch diameter*.

Noun Compounds are one of the many such constructs where the relation is hidden. For example, *"WHO Geneva headquarter"* is *"(the) headquarter of WHO located in Geneva."* One way of explicitly revealing the hidden relation is to paraphrase the noun compound using a verb+preposition construction. For example, *city hospital*: *"hospital located in a/the city"*, *mango juice*: *"juice extracted from mango"*, *etc*.

Prepositions are ambiguous, and they have their own selectional preferences (Zapirain et al., 2013). Once, a preposition and its corresponding sense are known, the space of verb+preposition constructions that can be used for paraphrasing is severely reduced (illustrated in Table 1), thereby making the task of verb+preposition paraphrasing easy. Thus we believe prepositional paraphrasing to be an important step towards verb+preposition paraphrasing of noun compounds.

Noun compound interpretation via labelling is another avenue where prepositional paraphrasing is useful. We annotated Kim and Baldwin (2005)'s dataset with the correct paraphrasing prepositions. A comparison of preposition vs. the annotated semantic relation (Table 2) shows that knowing preposition for a noun compound helps the system in identifying the finer semantic relations. For instance, 29 samples in the annotated data have *from* preposition. Following is the distribution of those samples:

Correct Preposition	Intended Meaning	Possible Verb+Prep Constructions	Noun Compounds	Example Verb+Prep Paraphrases
from	Source	resulted from, produced from, grown in	forest product farm product bonds yield	product produced from forest product grown in farm yield resulted from the bonds
from	Purpose	provided during	pain relief	relief provided during pain

Table 1: Demonstrating how knowledge of prepositions with intended meaning can restrict the space of verb+preposition constructions

	about	at	for	from	in	of	on	with
AGENT	0	0	0	0	0	3	0	0
BENEFICIARY	0	0	4	1	2	3	0	0
CAUSE	0	0	6	3	15	29	3	0
CONTAINER	0	0	1	0	3	12	0	0
CONTENT	0	0	3	2	3	29	1	1
DESTINATION	0	0	0	0	0	2	0	0
EQUATIVE	0	1	4	0	0	1	0	0
INSTRUMENT	0	0	5	0	0	2	0	1
LOCATED	0	0	3	0	0	8	0	0
LOCATION	0	1	2	0	9	17	0	0
MATERIAL	0	0	0	1	0	11	0	0
OBJECT	1	0	7	0	16	55	1	0
POSSESSOR	0	0	8	1	0	21	0	0

TOPIC	9	5	74	5	45	227	8	3

Table 2: Comparison of semantic relations (SR) and prepositions in Kim and Baldwin (2005)'s dataset manually annotated with prepositions. Row labels are SRs and column labels are prepositions. Each entry indicates the number of examples labelled with corresponding semantic relation and preposition.

SOURCE: 13, TOPIC: 5, CAUSE: 3, PURPOSE: 3, CONTENT: 2, BENEFICIARY: 1, MATERIAL: 1, POSSESSOR: 1, and 0 for remaining 12 relations. The annotation frequencies indicate that, for a noun compound with *from* as preposition, SOURCE is a highly likely *e.g.*, *marketing profit*, *forest product*, *tax revenue*, *etc*, whereas the 12 relations with 0 counts are extremely unlikely. Girju et al. (2005) used true prepositions as an additional feature in their classifier for fine semantic relation prediction and reported significant improvement in their performance. Thus, knowledge of preposition will definitely help in predicting and labelling finer relations.

In some NLP tasks, prepositional paraphrasing of a noun compound yields sufficient information for solving the task. Knowledge of Hindi case markers is sufficient for proper Hindi to English translation of Hindi noun compounds (a subset of *samāsa*)(Kulkarni et al., 2012).

4 Approach

As discussed earlier, we learn representations of noun compounds and their prepositional paraphrases, such that the cosine similarity between the representation of a noun compound and the representation of

the corresponding prepositional paraphrase is high. To do this, we use LSTMs (Hochreiter and Schmidhuber, 1997) based encoders. The architecture of our network is shown in Figure 1.

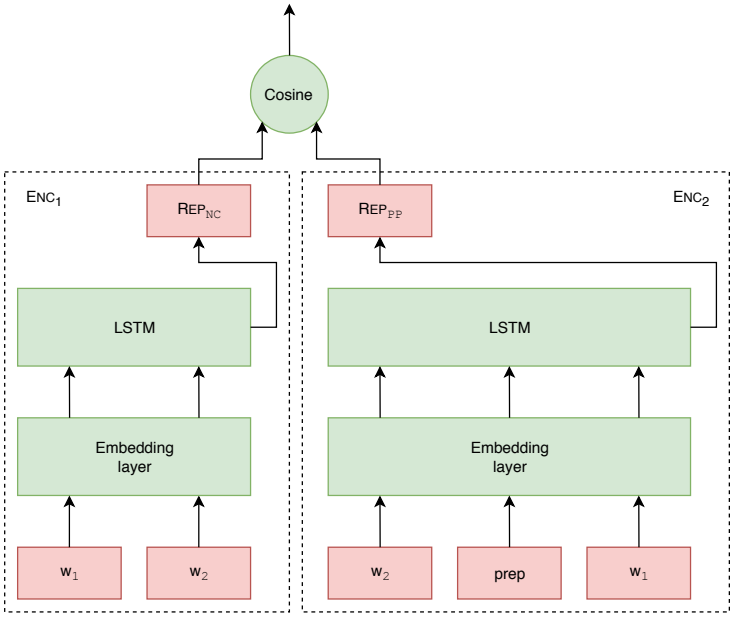

Figure 1: Architecture for learning representations of noun compounds (REP_{NC}) and prepositional paraphrases (REP_{PP}).

The network consists of two encoders: ENC_1 and ENC_2. ENC_1 embeds the constituents of an input noun compound and encodes those embeddings using an LSTM to get a representation REP_{NC} for the noun compound. ENC_2 embeds the words in an input prepositional paraphrase and encodes those embeddings using LSTM to get a representation REP_{PP} for the prepositional paraphrase. The architecture then computes the cosine similarity of these representations, which generates a value in the range $[-1, 1]$. The higher the similarity, the greater is the match between the noun compound and the prepositional paraphrase.

We initialize the embedding layer with Google's pre-trained embeddings[1]. For the 8-prepositions, we use 1-hot representations. We add padding of 0's to make them of same dimensions as that of word embeddings. The embedding layer is not updated during the training.

To calculate the correct prepositional paraphrase for a test noun compound NNC, we use the following procedure:

- Generate representation REP_{NNC} using the encoder ENC_1
- Generate a list of candidate prepositional phrases using the predefined set of prepositions
- For each candidate prepositional paraphrase CPP, generate the corresponding representation REP_{CPP} using the encoder ENC_2.
- Return that prepositional paraphrase PP^* such that cosine similarity between REP_{NNC} and REP_{PP^*} is maximum. Mathematically,

$$\text{PP}^* = \arg\max_{\text{CPP}} \; cosine(\text{REP}_{\text{NNC}}, \text{REP}_{\text{CPP}})$$

[1]Pre-trained embeddings available at `https://code.google.com/archive/p/word2vec/`

5 Experimental Setup

5.1 Datasets

For prepositional paraphrasing of noun compounds, Lauer (1995) and Girju et al. (2005) have proposed datasets. These datasets contain noun compounds annotated with correct preposition.

Lauer (1995)'s dataset is not publicly available. Thus, we extracted test samples from her thesis (Lauer, 1995). We dropped 118 samples out of 400 samples, as they had been marked as non-prepositional, and use the remaining 282 samples for our test experiments. Do note that this dataset is too small for effective learning. We have included it only for the sake of completeness.

Similarly, Girju et al. (2005)'s dataset is not available online[2]. Thus, we use Girju (2007)'s dataset (which has cross-lingual information along with English noun compounds) and extract relevant information to create a dataset. We extracted 832 samples. As our experiments are for Lauer (1995)'s set of 8 prepositions, we dropped examples annotated with prepositions that do not belong to this set. We use the remaining 805 examples for our experiments.

In addition to the above two datasets, we prepared a dataset by manually annotating noun compounds with Lauer (1995)'s prepositions. For annotation, we use 1,779 noun compounds (without labels) from Kim and Baldwin (2005)'s dataset. Each example was annotated by two annotators. The inter-annotator agreement is 51.48% (Cohen's kappa κ =0.36). For experiments, we have used only 1042 examples[3] where both annotators agreed upon. From here on, we refer to this dataset as Inhouse dataset.

In order to make learning more effective, we needed a lot more training samples. We adapted Lapata and Keller (2004)'s approach which use the web to automatically annotate noun compounds. We, however, use Netspeak[4]. We collected a list of noun compounds from existing noun compound interpretation datasets (Kim and Baldwin, 2005; Ó Séaghdha, 2007; Tratz and Hovy, 2010) and query each of them with a set of prepositions (as shown in Figure 2). The preposition with the highest frequency is chosen to form the *correct* prepositional paraphrase. For example, as shown in Figure 2, '*expert in (the) analysis*' has the highest frequency among all candidate paraphrases of *analysis expert*. So, we choose *in* as a correct preposition for the noun compound *analysis expert*. This dataset is used for training all systems.

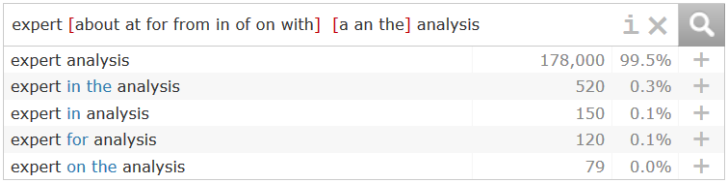

Figure 2: Example query result using Netspeak

5.2 Training

To train our system, we have noun compounds with their preposition paraphrases. Our objective is to learn representations such that similarity of a noun compound representation is higher with correct preposition compared with its similarity with any other prepositional paraphrase. Thus, for each noun compound, we treat the remaining prepositions as negative examples. For example, correct preposition for *analysis expert* is *in*. So, we treat (*analysis expert, 'expert in analysis'*) as a positive example and other pairs – like (*analysis expert, 'expert from analysis'*), (*analysis expert, 'expert about analysis'*), (*analysis expert, 'expert at analysis'*), *etc.* – as negative examples. We create such examples from the training dataset mentioned above.

We perform two different set of experiments. In one kind of experiments, we train our system (explained in Section 4) on the automatically annotated dataset and evaluate performance on the various datasets. In another type, for each dataset, we additionally fine-tune the trained-model using a portion of

[2]We requested the authors for the Girju et al. (2005)'s dataset, but they did not respond positively.

[3]The dataset is available at `http://www.cfilt.iitb.ac.in/nc-dataset`

[4]A search engine on Web 1T 5-gram available at `http://www.netspeak.org`.

the dataset. We use 75% of the dataset for tuning, and rest 25% of examples for testing. In both cases, we use the same test-set for a fair comparison. We discuss the performance of the models in the next section.

5.3 Evaluation metrics

We report Precision, Recall and F-score for our experiments. These values are weighted values in proportion to a number of test-examples for each preposition. For instance, following is a formula for computing (weighted) precision:

$$\text{Precision} = \sum_{prep} P_{prep} * \frac{N_{prep}}{N}; \quad P_{prep} = \frac{TP_{prep}}{TP_{prep} + FP_{prep}}$$

where P_{prep} is the precision score, TP_{prep} is the number of true-positives and FP_p is the number of false-positives for a preposition $prep$. N_{prep} is the number of instances with preposition $prep$ in the test set, and N is the total number of instances in a test-set.

To compare the results with previous work, we report micro-averaged accuracy[5]. The following formula computes micro-accuracy:

$$\text{Accuracy} = \frac{\text{Number of correcly classified instances}}{\text{Total number of instances in test-test}}$$

6 Results and Analysis

We compare the performance of our approach (referred to as NC-LSTM hereafter) with the performance reported by Lauer (1995), Lapata and Keller (2004), and Girju (2007) and performance computed for Dima and Hinrichs (2015)'s approach (referred to as NC-FFN hereafter) on different datasets.

We first compare NC-LSTM with NC-FFN. Table 3 shows that NC-LSTM performs comparably, if not better, than NC-FNN. Also, NC-LSTM easily outperforms NC-FFN by a significant margin when the network parameters are further tuned with a portion of the dataset. Thus, this also shows the importance of fine-tuning. This is easily explained by the fact that the original training data was extracted from the web, and is noisy in nature.

Dataset	Approach	Without Tuning			With Tuning		
		P	R	F	P	R	F
Lauer (1995)	NC-FFN	40.85	38.03	31.15	43.97	40.85	40.09
	NC-LSTM	50.84	45.07	40.66	48.72	46.48	**46.21**
Girju (2007)	NC-FFN	74.72	80.69	77.52	74.20	86.14	79.72
	NC-LSTM	76.86	74.26	75.50	84.74	88.61	**85.13**
Inhouse Dataset	NC-FFN	63.00	66.96	63.97	64.91	67.39	64.40
	NC-LSTM	62.32	65.65	63.09	73.50	72.17	**71.27**

Table 3: Comparison of performance of our LSTM based architecture (NC-LSTM) with Dima and Hinrichs (2015)'s feed-forward neural network based architecture (NC-FNN) on different datasets (P: Precision; R: Recall, F: F-score)

To demonstrate the effect of noisy data, we provide an analysis of the noun compound *apple tree*. The correct paraphrase of this noun compound is *'tree of apple'*. However, the system considers the paraphrase *'tree with apple'* to be correct. The following example sentences, which contributed to the count of *'tree with apple'*, demonstrate some errors made by the system:

[5]Mathematically, micro-averaged accuracy and weighted recall are same. We reported accuracy so that it can be compared with prior work. We reported F-score as it is the standard metric for classification evaluation. We reported recall as it used for computing f-score.

1. *if you combine a pine **tree with an apple** tree you do indeed get a pineapple tree.*
2. *What do you get if you cross a Christmas **tree with an apple?***

Clearly, the implicit assumption that *apple* is attached to the first occurrence of *tree* made by automatic web-based annotation algorithm which created the training dataset in sentence 1 is incorrect. Similarly, the implicit assumption that *apple* is attached to *tree* in sentence 2 is incorrect. Such errors add noise to the training dataset. However, using the tuning set fixes such errors, thereby improving performance considerably.

To check the extent to which such errors can impact effective training of the system, we estimate the accuracy of the automatic annotation process. We do this by testing the accuracy of automatic annotation on the common examples between automatically annotated and each of the three manually annotated datasets. The statistics of the common examples are shown in Table 4.

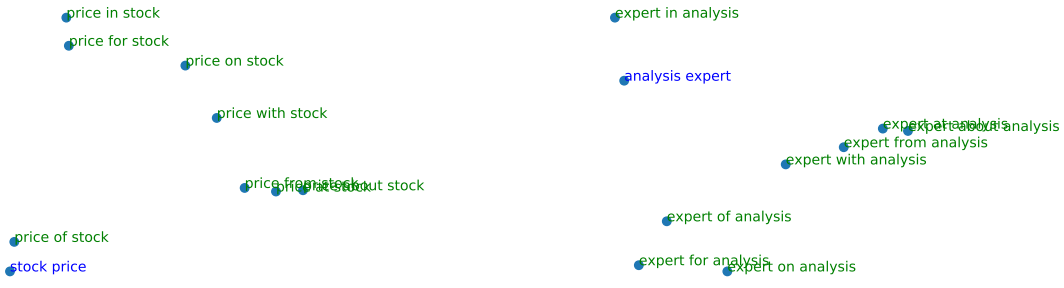
Dataset	**#of Common Examples**	**#of Common Examples with Matching Labels**
Lauer (1995)	31	12
Girju et al. (2005)	9	8
Inhouse Dataset	434	317

Table 4: Statistics of common examples between automatically created dataset and each of the three gold-standard dataset.

Table 5 compares reported results of various approaches with results from our approach. It shows that NC-LSTM outperforms Girju (2007)'s approach on their own dataset. We are unable to perform well on Lauer (1995) dataset. However, as mentioned earlier, given the relatively small size of the data, we refrain from commenting about our system's performance on the basis of this result.

Approach	**L95**	**G05**	**Inhouse**
Lauer (1995)	40.00		
Lapata and Keller (2004)	**55.71**		
Girju et al. (2005)	46.09	56.22	
NC-FFN	40.85	86.14	67.39
NC-LSTM	46.48	**88.61**	**72.17**

Table 5: Accuracy of various system reported in the literature. (L95: Lauer (1995); G05: Girju et al. (2005); Inhouse: Our manually created Inhouse dataset)



(a) *stock price* (b) *analysis expert*

Figure 3: PCA visualizations of noun compounds and their prepositional paraphrases for some examples

Figure 3 shows visualizations of noun compounds and their candidate prepositional paraphrases. One can observe from Figure 3a that among all candidate paraphrases, the embedding of *'price of stock'* is the closest to the embedding of *stock price*. Similarly, Figure 3b shows that among all candidate paraphrases, the embedding of *'expert in analysis'* is the closest to the embedding of *analysis expert*.

7 Conclusion and Future Work

In this paper, we proposed a novel way to perform prepositional paraphrasing of noun compounds. We learn representations for noun compounds and their corresponding prepositional paraphrases using LSTMs, such that cosine similarity of a noun compound and a prepositional paraphrase correlates with their semantic similarity. Our proposed method, when trained on noun compound data automatically annotated using the web, performs reasonably well on existing datasets. In the future, we would investigate adapting this approach for verb+preposition paraphrasing, *i.e.* given a noun compound *orange juice*, generate the verb+preposition paraphrase *'juice made from orange'*.

Abstract

The literature in automated sarcasm detection has mainly focused on lexical-, syntactic- and semantic-level analysis of text. However, a sarcastic sentence can be expressed with contextual presumptions, background and commonsense knowledge. In this paper, we propose a Context-tuAl SarCasm DEtector (CASCADE), which adopts a hybrid approach of both content- and context-driven modeling for sarcasm detection in online social media discussions. For the latter, CASCADE aims at extracting contextual information from the discourse of a discussion thread. Also, since the sarcastic nature and form of expression can vary from person to person, CASCADE utilizes user embeddings that encode stylometric and personality features of users. When used along with content-based feature extractors such as convolutional neural networks, we see a significant boost in the classification performance on a large Reddit corpus.

1 Introduction

Sarcasm is a linguistic tool that uses irony to express contempt. Its figurative nature poses a great challenge for affective systems performing sentiment analysis (Cambria et al., 2017). Previous research in automated sarcasm detection has primarily focused on lexical and pragmatic cues found in sentences (Kreuz and Caucci, 2007). In the literature, interjections, punctuations, and sentimental shifts have been considered as major indicators of sarcasm (Joshi et al., 2017). When such lexical cues are present in sentences, sarcasm detection can achieve high accuracy. However, sarcasm is also expressed implicitly, i.e., without the presence of such lexical cues. This use of sarcasm also relies on context, which involves the presumption of commonsense and background knowledge of an event. When it comes to detecting sarcasm in a discussion forum, it may not only be required to understand the context of previous comments but also the necessary background knowledge about the topic of discussion. The usage of slangs and informal language also diminishes the reliance on lexical cues (Satapathy et al., 2017). This particular type of sarcasm is tough to detect (Poria et al., 2016).

Contextual dependencies for sarcasm can take many forms. As an example, a sarcastic post from Reddit[1], *"I'm sure Hillary would've done that, lmao."* requires background knowledge about the event, i.e., Hillary Clinton's action at the time the post was made. Similarly, sarcastic posts like *"But atheism, yeah *that's* a religion!"* requires the knowledge that topics like *atheism* often contain argumentative discussions and, hence, they are more prone towards sarcasm.

The main aim of this work is sarcasm detection in online discussion forums. In particular, we propose a hybrid network, named CASCADE, that leverages both the *content* and the *context* required for sarcasm detection. It starts by processing contextual information in two ways. First, it performs user profiling to create user embeddings that capture indicative behavioral traits for sarcasm. Recent findings suggest that such modeling of the user and their preferences is highly effective for the given task (Amir et al.,

[1] http://reddit.com

Proceedings of the 27th International Conference on Computational Linguistics, pages 1837–1848
Santa Fe, New Mexico, USA, August 20-26, 2018.

2016). It makes use of users' historical posts to model their writing style (stylometry) and personality indicators, which are then fused into comprehensive user embeddings using a multi-view fusion approach, termed canonical correlation analysis (CCA) (Hotelling, 1936). Second, it extracts contextual information from the discourse of comments in the discussion forums. This is done by document modeling of these consolidated comments belonging to the same forum. We hypothesize that these discourse features would give the important contextual information, background cues along with topical information required for detecting sarcasm.

After the contextual modeling phase, CASCADE is provided with a comment for sarcasm detection. It performs content-modeling using a convolutional neural network (CNN) to extract its syntactic features. This CNN representation is then concatenated with the relevant user embedding and discourse features to get the final representation which is used for classification. The overall contribution of this work can be summarized as:

- We propose a novel hybrid sarcasm detector, CASCADE, that models both content and contextual information.
- We model stylometric and personality details of users along with discourse features of discussion forums to learn informative contextual representations. Experiments on a large Reddit corpus demonstrate significant performance improvement over state-of-the-art automated sarcasm detectors.

The remainder of the paper is organized as follows: Section 2 lists related works; Section 3 explains the process of learning contextual features comprising user embeddings and discourse features; Section 4 presents experimentation details of the model and result analysis; finally, Section 5 draws conclusions.

2 Related Work

Automated sarcasm detection is a relatively recent field of research. Previous works can be classified into two main categories: content- and context-based sarcasm detection models.

Content-based models: These networks model the problem of sarcasm detection as a standard classification task and try to find lexical and pragmatic indicators to identify sarcasm. Numerous works have taken this path and presented innovative ways to unearth interesting cues for sarcasm. Tepperman et al. (2006) investigate sarcasm detection in spoken dialogue systems using prosodic and spectral cues. Carvalho et al. (2009) use linguistic features like positive predicates, interjections and gestural clues such as emoticons, quotation marks, etc. Davidov et al. (2010), Tsur et al. (2010) use syntactic patterns to construct classifiers. González-Ibánez et al. (2011) also study the use of emoticons, mainly amongst tweets. Riloff et al. (2013) assert sarcasm to be a contrast to positive sentiment words and negative situations. Joshi et al. (2015) use multiple features comprising lexical, pragmatics, implicit and explicit context incongruity. In the explicit case, they include relevant features to detect thwarted sentimental expectations in the sentence. For implicit incongruity, they generalize Riloff et al. (2013) by identifying verb-noun phrases containing contrast in both polarities.

Context-based models: The usage of contextual sarcasm has increased in recent years, especially in online platforms. Texts found in microblogs, discussion forums, and social media are plagued by grammatical inaccuracies and contain information which is highly temporal and contextual. In such scenarios, mining linguistic information becomes relatively inefficient and the need arises for additional clues (Carvalho et al., 2009). Wallace et al. (2014) demonstrate this need by showing how traditional classifiers fail in instances where humans require additional context. They also indicate the importance of speaker and topical information associated to a text to gather such context. Poria et al. (2016) use additional information by sentiment, emotional and personality representations of the input text. Previous works have mainly used historical posts of users to understand sarcastic tendencies (Rajadesingan et al., 2015; Zhang et al., 2016). Khattri et al. (2015) try to discover users' sentiments towards entities in their histories to find contrasting evidence. Wallace et al. (2015) utilize sentiments and noun phrases used within a forum to gather context typical to that forum. Such forum-based modeling simulates user

communities. Our work follows a similar motivation as we explore the context provided by user profiling and the topical knowledge embedded in the discourse of comments in discussion forums (subreddits[2]).

Amir et al. (2016) performed user modeling by learning embeddings that capture homophily. This work is the closest to our approach given the fact that we too learn user embeddings to acquire context. However, we take a different approach that involves stylometric and personality description of the users. Empirical evidence shows that these proposed features are better than previous user modeling approaches. Moreover, we learn discourse features which has not been explored before in the context of this task.

3 Method

3.1 Task Definition

The task involves detection of sarcasm for comments made in online discussion forums, i.e., Reddit. Let us denote the set $U = \{u_1, ..., u_{N_u}\}$ for N_u-users, where each user participates across a subset of N_t-discussion forums (subreddits). For a comment C_{ij} made by the i^{th} user u_i in the j^{th} discussion forum t_j, the objective is to predict whether the comment posted is sarcastic or not.

3.2 Summary of the Proposed Approach

Given the comment C_{ij} to be classified, CASCADE leverages *content*- and *context*-based information from the comment. For content-based modeling of C_{ij}, a CNN is used to generate the representation vector $\vec{\boldsymbol{c}}_{i,j}$ for a comment. CNNs generate abstract representations of text by extracting location-invariant local patterns. This vector $\vec{\boldsymbol{c}}_{i,j}$ captures both syntactic and semantic information useful for the task at hand. For contextual modeling, CASCADE first learns user embeddings and discourse features of all users and discussion forums, respectively (Section 3.3). Following this phase, CASCADE then retrieves the learnt user embedding $\vec{\boldsymbol{u}}_i$ of user u_i and discourse feature vector $\vec{\boldsymbol{t}}_j$ of forum t_j. Finally, all three vectors $\vec{\boldsymbol{c}}_{i,j}$, $\vec{\boldsymbol{u}}_i$, and $\vec{\boldsymbol{t}}_j$ are concatenated and used for the classification (Section 3.6). One might argue that, instead of using one CNN, we could use multiple CNNs as in (Majumder et al., 2017), to get better text representations whenever a comment contains multiple sentences. However, that is out of the scope of this work. Here, we aim to show the effectiveness of user-specific analysis and context-based features extracted from the discourse. Also, the use of a single CNN for text representation helps to consistently compare our model with the state of the art.

3.3 Learning Contextual Features

In this section, we explain in detail the procedures to generate the contextual features, i.e., user embeddings and discourse features. The user embeddings try to capture users' traits that correlate to their sarcastic tendencies. These embeddings are created considering the accumulated historical posts of each user (Section 3.4). Contextual information are also extracted from the discourse of comments within each discussion forum. These extracted features are named as discourse features (Section 3.5). The aim of learning these contextual features is to acquire discriminative information crucial for sarcasm detection.

3.4 User Embeddings

To generate user embeddings, we model their stylometric and personality features and then fuse them using CCA to create a single representation. Below, we explain the generation of user embedding $\vec{\boldsymbol{u}}_i$, for the i^{th} user u_i. Figure 1 also summarizes the overall architecture for this kind of user profiling.

3.4.1 Stylometric features

People possess their own idiolect and authorship styles, which is reflected in their writings. These styles are generally affected by attributes such as gender, diction, syntactic influences, etc. (Cheng et al., 2011; Stamatatos, 2009) and present behavioral patterns which aid sarcasm detection (Rajadesingan et al., 2015).

We use this motivation to learn stylometric features of the users by consolidating their online comments into documents. We first gather all the comments by a user and create a document by appending them using a special delimiter `<END>`. An unsupervised representation learning method *ParagraphVector* (Le

[2] `http://reddit.com/reddits`

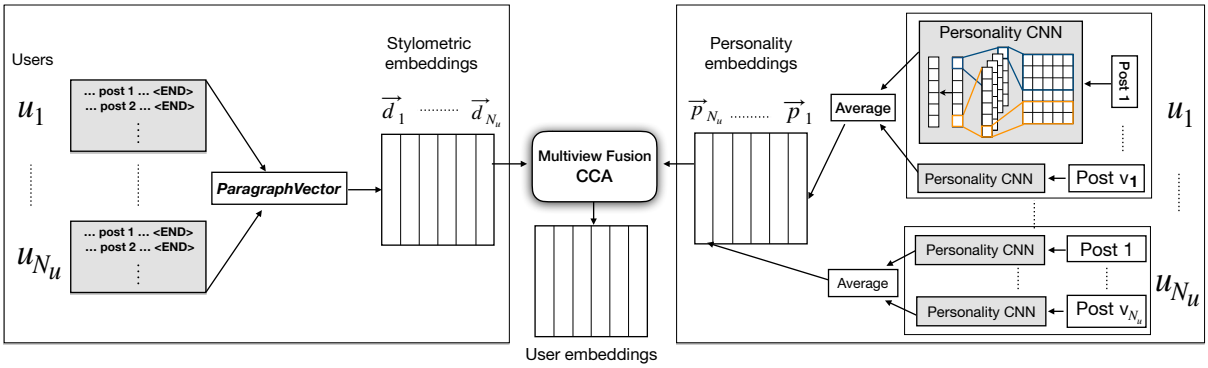

Figure 1: The figure describes the process of user profiling. Stylometric and personality embeddings are generated and then fused in a multi-view setting using CCA to get the user embeddings.

and Mikolov, 2014) is then applied on this document. This method generates a fixed-sized vector for each user by performing the auxiliary task of predicting the words within the documents. The choice of *ParagraphVector* is governed by multiple reasons. Apart from its ability to effectively encode a user's writing style, it has the advantage of applying to variable lengths of text. *ParagraphVector* also has been shown to perform well for sentiment classification tasks. The existence of synergy between sentiment and sarcastic orientation of a sentence also promotes the use of this method.

We now describe the functioning of this method. Every user document and all words within them are first mapped to unique vectors such that each vector is represented by a column in matrix $D \in \mathbb{R}^{d_s \times N_u}$ and $W_s \in \mathbb{R}^{d_s \times |V|}$, respectively. Here, d_s is the embedding size and $|V|$ represents the size of the vocabulary. *Continuous bag-of-words* approach (Mikolov et al., 2013) is then performed where a target word is predicted given the word vectors from its context window. The key idea here is to use the document vector of the associated document as part of the context words. More formally, given a user document d_i for user u_i comprising a sequence of n_i-words $\boldsymbol{w}_1, \boldsymbol{w}_2, ..., \boldsymbol{w}_{n_i}$, we calculate the average log probability of predicting each word within a sliding context window of size k_s. This average log probability is:

$$\frac{1}{n_i} \sum_{t=k_s}^{n_i - k_s} \log p(w_t | d_i, w_{t-k_s}, ..., w_{t+k_s}) \tag{1}$$

To predict a word within a window, we take the average of all the neighboring context word vectors along with the document vector $\vec{\boldsymbol{d}}_i$ and use a neural network with softmax prediction:

$$p(w_t | d_i, w_{t-k_s}, ..., w_{t+k_s}) = \frac{e^{\vec{\boldsymbol{y}}_{w_t}}}{\sum_i e^{\vec{\boldsymbol{y}}_i}} \tag{2}$$

Here, $\vec{\boldsymbol{y}} = [y_1, ..., y_{|V|}]$ is the output of the neural network, i.e.,

$$\vec{\boldsymbol{y}} = \mathrm{U}_d h(\vec{\boldsymbol{d}}_i, \vec{\boldsymbol{w}}_{t-k_s}, ..., \vec{\boldsymbol{w}}_{t+k_s}; D, W_s) + \vec{\boldsymbol{b}}_d \tag{3}$$

$\vec{\boldsymbol{b}}_d \in \mathbb{R}^{|V|}, U_d \in \mathbb{R}^{|V| \times d_s}$ are parameters and $h(\cdot)$ represents the average of vectors $\vec{\boldsymbol{d}}_i, \vec{\boldsymbol{w}}_{t-k_s}, ..., \vec{\boldsymbol{w}}_{t+k_s}$ taken from D and W_s. Hierarchical softmax is used for faster training (Morin and Bengio, 2005). Finally, after training, D learns the users' document vectors which represent their stylometric features.

3.4.2 Personality features

Discovering personality from text has numerous natural language processing (NLP) applications such as product recognition, mental health diagnosis, etc. Described as a combination of multiple characteristics, personality detection helps in identifying behavior, thought patterns of an individual. To model the dependencies of users' personality with their sarcastic nature, we include personality features in the user embeddings. Previously, Poria et al. (2016) also utilized personality features in sentences. However, we take a different approach of extracting the personality features of a user instead.

For user u_i, we iterate over all the v_i-comments $\{S^1_{u_i}, ..., S^{v_i}_{u_i}\}$ written by them. For each $S^j_{u_i}$, we provide the comment as an input to a pre-trained CNN which has been trained on a multi-label personality detection task. Specifically, the CNN is pre-trained on a benchmark corpus developed by Matthews and Gilliland (1999) which contains 2400 essays and is labeled with the Big-Five personality traits, i.e., Openness, Conscientiousness, Extraversion, Agreeableness, and Neuroticism (OCEAN). After the training, this CNN model is used to infer the personality traits present in each comment. This is done by extracting the activations of the CNN's last hidden layer vector, which we call as the personality vector $\vec{\boldsymbol{p}}^j_{u_i}$. The expectation over the personality vectors for all v_i-comments made by the user is then defined as the overall personality feature vector $\vec{\boldsymbol{p}}_i$ of user u_i:

$$\vec{\boldsymbol{p}}_i \;=\; \mathbb{E}_{j\in[v_i]}[\vec{\boldsymbol{p}}^j_{u_i}] \;=\; \frac{1}{v_i}\sum_{j=1}^{v_i}\vec{\boldsymbol{p}}^j_{u_i} \tag{4}$$

CNN: Here, we describe the CNN that generates the personality vectors. Given a user's comment, which is a text $S = [w_1, ..., w_n]$ composed of n words, each word w_i is represented as a word embedding $\vec{\boldsymbol{w}}_i \in \mathbb{R}^{d_{em}}$ using the pre-trained FastText embeddings (Bojanowski et al., 2016). A single-layered CNN is then modeled on this input sequence S (Kim, 2014). First, a convolutional layer is applied having three filters $F_{[1,2,3]} \in \mathbb{R}^{d_{em}\times h_{[1,2,3]}}$ of heights $h_{[1,2,3]}$, respectively. For each $k \in \{1, 2, 3\}$, filter F_k slides across S and extracts h_k-gram features at each instance. This creates a feature map vector $\vec{\boldsymbol{m}}_k$ of size $\mathbb{R}^{|S|-h_k+1}$, whose each entry $m_{k,j}$ is obtained as:

$$m_{k,j} = \alpha(\; F_k \cdot S_{[j:j+h_k-1]} + b_k \;) \tag{5}$$

here, $b_k \in \mathbb{R}$ is the bias and $\alpha(\cdot)$ is a non-linear activation function.

M feature maps are created from each filter F_k giving a total of $3M$ feature maps as output. Following this, a max-pooling operation is performed across the length of each feature map. Thus, for all M feature maps computed from F_k, output $\vec{\boldsymbol{o}}_{\boldsymbol{k}}$ is calculated as, $\vec{\boldsymbol{o}}_{\boldsymbol{k}} = [\; max(\vec{\boldsymbol{m}}^1_1), ..., \; max(\vec{\boldsymbol{m}}^{\mathrm{M}}_1) \;]$. Overall the max-pooling output is calculated by concatenation of each $\vec{\boldsymbol{o}}_{\boldsymbol{k}}$ to get $\vec{\boldsymbol{o}} = [\vec{\boldsymbol{o}}_{\boldsymbol{1}} \oplus \vec{\boldsymbol{o}}_{\boldsymbol{2}} \oplus \vec{\boldsymbol{o}}_{\boldsymbol{3}}] \in \mathbb{R}^{3M}$, where $\oplus$ represents concatenation. Finally, $\vec{\boldsymbol{o}}$ is projected onto a dense layer with d_p neurons followed by the final sigmoid-prediction layer with 5 classes denoting the five personality traits (Matthews et al., 2003). We use sigmoid instead of softmax to facilitate multi-label classification. This is calculated as:

$$\vec{\boldsymbol{q}} = \alpha(\; W_1\vec{\boldsymbol{o}} + \vec{\boldsymbol{b}}_1 \;) \tag{6}$$

$$\hat{\boldsymbol{y}} = \sigma(\; W_2\vec{\boldsymbol{q}} + \vec{\boldsymbol{b}}_2 \;) \tag{7}$$

$W_1 \in \mathbb{R}^{d_p\times 3M}, W_2 \in \mathbb{R}^{5\times d_p}, \vec{\boldsymbol{b}}_1 \in \mathbb{R}^{d_p}$ and $\vec{\boldsymbol{b}}_2 \in \mathbb{R}^5$ are parameters and $\alpha(.)$ represents non-linear activation.

3.4.3 Fusion

We take a multi-view learning approach to combine both stylometric and personality features into a comprehensive embedding for each user. We use CCA to perform this fusion. CCA captures maximal information between two views and creates a combined representation (Hardoon et al., 2004; Benton et al., 2016). In the event of having more than two views, fusion can be performed using an extension of CCA called *Generalized* CCA (see Appendix).

Canonical Correlation Analysis: Let us consider the learnt stylometric embedding matrix $D \in \mathbb{R}^{d_s\times N_u}$ and personality embedding matrix $P \in \mathbb{R}^{d_p\times N_u}$ containing the respective embedding vectors of user u_i in their i^{th} columns. The matrices are then mean-centered and standardized across all user columns. We call these new matrices as X_1 and X_2, respectively. Let the correlation matrix for X_1 be $R_{11} = X_1{X_1}^T \in \mathbb{R}^{d_s\times d_s}$, for X_2 be $R_{22} = X_2{X_2}^T \in \mathbb{R}^{d_p\times d_p}$ and the cross-correlation matrix between them be $R_{12} = X_1{X_2}^T \in \mathbb{R}^{d_s\times d_p}$. For each user u_i, the objective of CCA is to find the linear projections of both embedding vectors that have a maximum correlation. We create K such projections, i.e., K-canonical variate pairs such that each pair of projection is orthogonal with respect to the previous pairs. This is done by constructing:

$$W = X_1^T A_1 \text{ and } Z = X_2^T A_2 \tag{8}$$

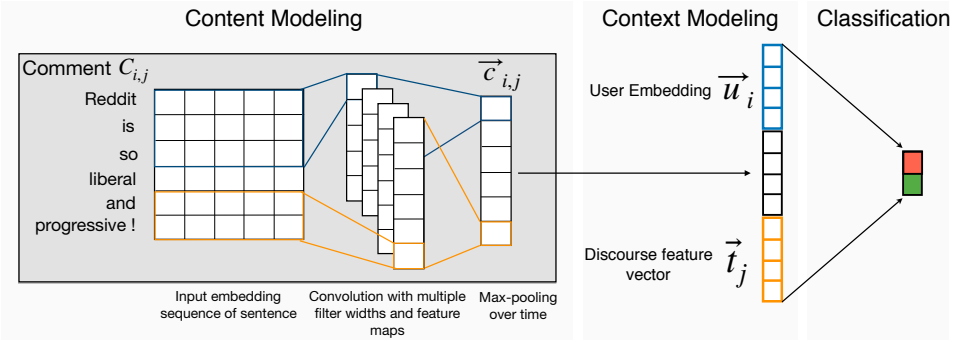

Figure 2: Overall hybrid network of CASCADE. For the comment $C_{i,j}$, its content-based sentential representation $\vec{c}_{i,j}$ is extracted using a CNN and appended with context vectors $\vec{u}_i$ and $\vec{t}_j$.

where, $A_1 \in \mathbb{R}^{d_s \times K}$, $A_2 \in \mathbb{R}^{d_p \times K}$ and $W^T W = Z^T Z = I$. To maximize correlation between W and Z, optimal A_1 and A_2 are calculated by performing singular value decomposition as:

$$R_{11}^{-\frac{1}{2}} R_{12} R_{22}^{-\frac{1}{2}} = A \Lambda B^\top \quad \text{, where} \quad A_1 = R_{11}^{-\frac{1}{2}} A \text{ and } A_2 = R_{22}^{-\frac{1}{2}} B \tag{9}$$

It can be seen that,

$$W^T W = {A_1}^T R_{11} A_1 = A^T A = I \quad \text{and} \quad Z^T Z = {A_2}^T R_{22} A_2 = B^T B = I \tag{10}$$

$$\text{also,} \quad W^T Z = Z^T W = \Lambda \tag{11}$$

Once optimal A_1 and A_2 are calculated, overall user embedding $\vec{u}_i \in \mathbb{R}^K$ of user u_i is generated by fusion of $\vec{d}_i$ and $\vec{p}_i$ as:

$$\vec{u}_i = (\vec{d}_i)^T A_1 + (\vec{p}_i)^T A_2 \tag{12}$$

3.5 Discourse Features

Similarly to how a user influences the degree of sarcasm in a comment, we assume that the discourse of comments belonging to a certain discussion forum contain contextual information relevant to the sarcasm classification. They embed topical information that selectively incur bias towards degree of sarcasm in the comments of a discussion. For example, comments on political leaders or sports matches are generally more susceptible to sarcasm than natural disasters. Contextual information extracted from the discourse of a discussion can also provide background knowledge or cues about the topic of that discussion.

To extract the discourse features, we take a similar approach of document modeling performed for stylometric features (Section 3.4.1). For all N_t-discussion forums, we compose each forum's document by appending the comments within them. As before, *ParagraphVector* is employed to generate discourse representations for each document. We denote the learnt feature vector of j^{th} forum t_j as $\vec{t}_j \in \mathbb{R}^{d_t}$.

3.6 Final Prediction

Following the extraction of text representation $\vec{c}_{i,j}$ for comment $C_{i,j}$ and retrieval of user embedding $\vec{u}_i$ for author u_i and discourse feature vector $\vec{t}_j$ for discussion forum t_j, we concatenate all three vectors to form the unified text representation $\hat{c}_{i,j} = [\vec{c}_{i,j} \oplus \vec{u}_i \oplus \vec{t}_j]$. Here, $\oplus$ refers to concatenation. The CNN used for extraction of $\vec{c}_{i,j}$ has the same design as the CNN we used to extract personality features described in Section 3.4.2. Finally, $\hat{c}_{i,j}$ is projected to the output layer having two neurons with a softmax activation. This gives a softmax-probability over whether a comment is sarcastic or not. This probability estimate is then used to calculate the categorical cross-entropy which is used as the loss function:

$$Loss = \frac{-1}{N} \sum_{i=1}^{N} \sum_{j=1}^{2} \boldsymbol{y}_{i,j} \, log_2(\hat{\boldsymbol{y}}_{i,j}) \quad \text{, where} \quad \hat{\boldsymbol{y}} = softmax(W_o \hat{\boldsymbol{c}}_{i,j} + \vec{\boldsymbol{b}}_o) \tag{13}$$

Here, N is the number of comments in the training set, y_i is the one-hot vector ground truth of the i^{th} comment and $\hat{\boldsymbol{y}}_{i,j}$ is its predicted probability of belonging to class j.

4 Experimental Results

4.1 Dataset

We perform our experiments on a large-scale self-annotated corpus for sarcasm, SARC[3] (Khodak et al., 2017). This dataset contains more than a million examples of sarcastic/non-sarcastic statements made on Reddit. Reddit comprises of topic-specific discussion forums, also known as subreddits, each titled by a post. In each forum, users communicate either by commenting to the titled post or other's comments, resulting in a tree-like conversation structure. This structure can be unraveled to a linear format, thus creating a discourse of the comments by keeping the topological constraints intact. Each comment is accompanied with its author details and parent comments (if any) which is subsequently used for our contextual processing. It is important to note that almost all comments in SARC are composed of a single sentence. We consider three variants of the SARC dataset in our experiments.

- **Main balanced:** This is the primary dataset which contains a balanced distribution of both sarcastic and non-sarcastic comments. The dataset contains comments from 1246058 users (118940 in training and 56118 in testing set) distributed across 6534 forums (3868 in training and 2666 in testing set).
- **Main imbalanced:** To emulate real-world scenarios where the sarcastic comments are typically fewer than non-sarcastic ones, we use an imbalanced version of the Main dataset. Specifically, we maintain a $20:80$ ratio (approx.) between the sarcastic and non-sarcastic comments in both training/testing sets.
- **Pol:** To further test the effectiveness of our user embeddings, we perform experiments on a subset of Main, comprising of forums associated with the topic of politics. Table 1 provides the comment distribution of all the dataset variants mentioned.

		Training set				Testing set			
		no. of comments		avg. no. of words per comment		no. of comments		avg. no. of words per comment	
		non-sarc	*sarc*	*non-sarc*	*sarc*	*non-sarc*	*sarc*	*non-sarc*	*sarc*
Main	balanced	77351	77351	55.13	55.08	32333	32333	55.55	55.01
	imbalanced	77351	25784	55.13	55.21	32333	10778	55.55	55.48
Pol	balanced	6834	6834	64.74	62.36	1703	1703	62.99	62.14

*non-sarc: non-sarcastic, sarc: sarcastic

Table 1: Details of comments in SARC.

The choice of using SARC for our experiments comes with multiple reasons. First, this corpus is the first of its kind that was purposely developed to investigate the necessity of contextual information in sarcasm classification. This characteristic aligns well with the main goal of this paper. Second, the large size of the corpus allows for statistically-relevant analyses. Third, the dataset annotations contain a small false-positive rate for sarcastic labels thus providing reliable annotations. Also, its self-annotation scheme rules out the annotation errors induced by third-party annotators. Finally, the corpus structure provides meta-data (e.g., user information) for its comments, which is useful for contextual modeling.

4.2 Training details

We hold out 10% of the training data for validation. Hyper-parameter tuning is performed using this validation set through RandomSearch (Bergstra and Bengio, 2012). To optimize the parameters, Adam optimizer (Kingma and Ba, 2014) is used, starting with an initial learning rate of $1e^{-4}$. The learnable parameters in the network consists of $\theta = \{U_d, D, W_{[1,2,o,s]}, F_{[1,2,3]}, \vec{\mathbf{b}}_{[1,2,o,d]}, b_{[1,2,3]}\}$. Training termination is decided using early stopping technique with a patience of 12. For the batched-modeling of comments in CNNs, each comment is either restricted or padded to 100 words for uniformity. The optimal hyper-parameters are found to be $\{d_s, d_p, d_t, K\} = 100$, $d_{em} = 300$, $k_s = 2$, $M = 128$, and $\alpha = ReLU$.

We manually analyze the effect in validation performance for different sizes of user-embedding dimension K (Figure 3a) and discourse feature vector size d_t (Figure 3b). In both cases, the performance trend suggests the optimal size to be approximately 100.

†:significantly better than CUE-CNN (Amir et al., 2016).

Table 2: Comparison of CASCADE with state-of-the-art networks and baselines on multiple versions of the SARC dataset. We assert significance when $p < 0.05$ under paired-t test. Results comprise of 10 runs with different initializations. The bottom row shows the absolute difference with respect to the CUE-CNN system.

For modeling the *ParagraphVector*, we use the open-sourced implementation provided by *Gensim*[4]. The CNNs used in the model are implemented using Tensorflow library[5].

4.3 Baseline Models

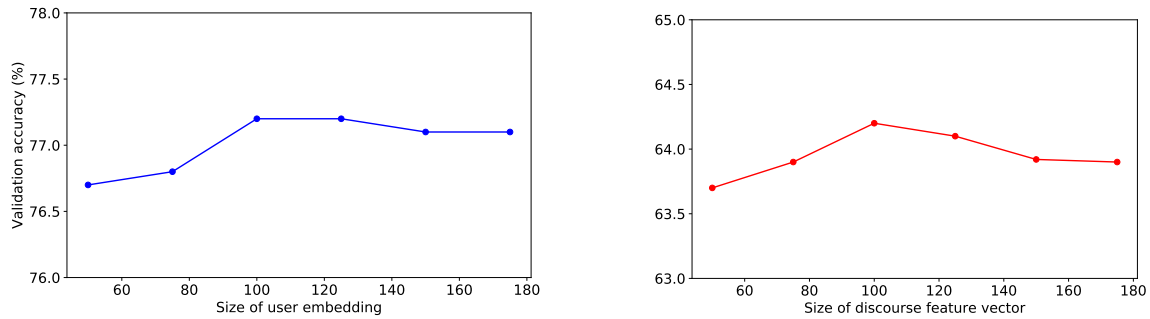
Here, we describe the state-of-the-art methods and baselines that we compare CASCADE with.

- **Bag-of-words:** This model uses an SVM classifier whose input features comprise of a comment's word-counts. The size of the vector is the vocabulary size of the training dataset.
- **CNN:** We compare our model with this individual CNN version. This CNN is capable of modeling only the *content* of a comment. The architecture is similar to the CNN used in CASCADE (see Section 3.2).
- **CNN-SVM:** This model proposed by Poria et al. (2016) consists of a CNN for content modeling and other pre-trained CNNs for extracting sentiment, emotion and personality features from the given comment. All the features are concatenated and fed into an SVM for classification.
- **CUE-CNN:** This method proposed by Amir et al. (2016) also models user embeddings with a method akin to *ParagraphVector*. Their embeddings are then combined with a CNN thus forming the CUE-CNN model. We compare with this model to analyze the efficiency of our embeddings as opposed to theirs. Released software[6] is used to produce results on the SARC dataset.

4.4 Results

Table 2 presents the performance results on SARC. CASCADE manages to achieve major improvement across all datasets with statistical significance. The lowest performance is obtained by the bag-of-words approach whereas all neural architectures outperform it. Amongst the neural networks, the CNN baseline

[4] http://radimrehurek.com/gensim/models/doc2vec.html
[5] http://github.com/dennybritz/cnn-text-classification-tf
[6] http://github.com/samiroid/CUE-CNN



(a) CASCADE with only user embeddings.

(b) CASCADE with only discourse features.

Figure 3: Exploration of dimensions for user embedding and discourse feature vector.

receives the least performance. CASCADE comfortably beats the state-of-the-art neural models CNN-SVM and CUE-CNN. Its improved performance on the Main imbalanced dataset also reflects its robustness towards class imbalance and establishes it as a real-world deployable network.

We further compare our proposed user-profiling method with that of CUE-CNN, with absolute differences shown in the bottom row of Table 2. Since CUE-CNN generates its user embeddings using a method similar to the *ParagraphVector*, we test the importance of personality features being included in our user profiling. As seen in the table, CASCADE without personality features drops in performance to a range similar to CUE-CNN. This suggests that the combination of stylometric and personality features are indeed crucial for the improved performance of CASCADE.

4.5 Ablation Study

We experiment on multiple variants of CASCADE so as to analyze the importance of the various features present in its architecture. Table 3 provides the results of all the combinations. First, we test performance for the *content*-based CNN only (row 1). This setting provides the worst relative performance with almost 10% lower accuracy than optimal. Next, we include contextual features to this network. Here, the effect of discourse features is primarily seen in the Pol dataset getting an increase of 3% in F1 (row 2). A major boost in performance is observed ($8 - 12\%$ accuracy and F1) when user embeddings are introduced (row 5). Visualization of the user embedding cluster (Section 4.6) provides insights for this positive trend. Overall, CASCADE consisting of CNN with user embeddings and contextual discourse features provides the best performance in all three datasets (row 6).

We challenge the use of CCA for the generation of user embeddings and, hence, replace it with simple concatenation. This, however, causes a significant drop in performance (row 3). Improvement is not observed even when discourse features are used with these concatenated user embeddings (row 4). We assume the increase in parameters caused by concatenation for this performance degradation. CCA, on the other hand, creates succinct representations with maximal information, giving better results.

4.6 User Embedding Analysis

We investigate the learnt user embeddings in more detail. In particular, we plot random samples of users on a 2D-plane using t-SNE (Maaten and Hinton, 2008). The users who have greater sarcastic comments (atleast 2 more than the other type) are termed as sarcastic users (colored red). Conversely, the users having fewer sarcastic comments are called non-sarcastic users (colored green). Equal number of users from both the categories are plotted. We aim to analyze the reason behind the performance boost provided by the user embeddings as shown in Table 3. We see in Figure 4 that both the user types belong to similar distributions. However, the sarcastic users have a greater spread than the non-sarcastic ones (red belt around the green region). This is also evident from the variances of the distributions where the sarcastic distribution comprises of 10.92 variance as opposed to 5.20 variance of the non-sarcastic distribution. From this observation, we can infer that the user embeddings belonging to this non-overlapping red-region provide discriminative information regarding the sarcastic tendencies of their users.

4.7 Case Studies

Results demonstrate that discourse features provide an improvement over baselines, especially on the Pol dataset. This signifies the greater role of the contextual cues for classifying comments in this dataset over the other dataset variants used in our experiment. Below, we present a couple of cases from the Pol dataset where our model correctly identifies the sarcasm which is evident only with the neighboring comments. The previous state-of-the-art CUE-CNN, however, misclassifies them.

- For the comment *Whew, I feel much better now!*, its sarcasm is evident only when its previous comment is seen *So all of the US presidents are terrorists for the last 5 years.*
- The comment *The part where Obama signed it.* doesn't seem to be sarcastic until looked upon as a remark to its previous comment *What part of this would be unconstitutional?*.

Such observations indicate the impact of discourse features. However, sometimes contextual cues from the previous comments are not enough and misclassifications are observed due to lack of necessary commonsense and background knowledge about the topic of discussion. There are also other cases where our model fails despite the presence of contextual information from the previous comments. During exploration, this is primarily observed for contextual comments which are very long. Thus, sequential discourse modeling using RNNs may be better suited for such cases. Also, in the case of user embeddings, misclassifications were common for users with fewer historical posts. In such scenarios, potential solutions would be to create user networks and derive information from similar users within the network, e.g., by means of community embeddings (Cavallari et al., 2017). These are some of the issues which we plan to address in future work.

5 Conclusion

In this paper, we introduced CASCADE, a Contextual Sarcasm Detector, which leverages both content and contextual information for the classification. For contextual details, we perform user profiling along with discourse modeling from comments in discussion threads. When this information is used jointly with a CNN-based textual model, we obtain state-of-the-art performance on a large-scale Reddit corpus. Our results show that discourse features along with user embeddings play a crucial role in the performance of sarcasm detection.

A Generalized Canonical Correlation Analysis

For user profiling with more than two views, we can use *Generalized* CCA (GCCA) as the multiview-fusion approach. In GCCA, the input data consists of I different views, $X_i \in \mathbb{R}^{d_i \times N} \quad \forall\ i \in [1, I]$, where, N is the total number of data points and d_i is the dimension of the ith view. Also, X_i represent the mean centered matrix of the data. We find a common representation $G \in \mathbb{R}^{N \times K}$ for all the input points. The *canonical covariates* $\vec{\boldsymbol{w}}_{\boldsymbol{i}} = X_i^T \vec{\boldsymbol{a}}_{\boldsymbol{i}}$ are chosen in such a way that the sum of the squared correlations between them and the group configuration is maximum:

$$\max R^2 = \sum_{i=1}^{N} r(\vec{\boldsymbol{g}}, X_i^T \vec{\boldsymbol{a}}_{\boldsymbol{i}})^2 \quad \text{s.t. } \vec{\boldsymbol{g}}^T \vec{\boldsymbol{g}} = 1 \tag{14}$$

For K-canonical variate pairs, the GCCA objective function can be formulated as follows:

$$\underset{G, A_i}{\operatorname{argmax}} \left\| G - X_i^T A_i \right\|_F^2 \quad \text{s.t. } G^T G = I \tag{15}$$

where $A_i \in \mathbb{R}^{d_i \times K}$. G can be obtained using the eigen equation:

$$(\sum_{i=1}^{N} P_i) G = G\Gamma \quad \text{, where,} \quad P_i = X_i^T (X_i X_i^T)^{-1} X_i \tag{16}$$

The matrices A_i can then be calculated as:

$$A_i = (X_i X_i^T)^{-1} X_i^T G \tag{17}$$

It is to be noted that GCCA with two views is equivalent to CCA (van de Velden, 2011).

Recognizing Humour using Word Associations and Humour Anchor Extraction

Andrew Cattle **Xiaojuan Ma**

Abstract

This paper attempts to marry the interpretability of statistical machine learning approaches with the more robust models of joke structure and joke semantics capable of being learned by neural models. Specifically, we explore the use of semantic relatedness features based on word associations, rather than the more common Word2Vec similarity, on a binary humour identification task and identify several factors that make word associations a better fit for humour. We also explore the effects of using joke structure, in the form of humour anchors (Yang et al., 2015), for improving the performance of semantic features and show that, while an intriguing idea, humour anchors contain several pitfalls that can hurt performance.

1 Introduction

Humour is a part of everyday communication. Although telling and understanding jokes comes naturally to most humans, the recognition and interpretation of humour is a very difficult task for computers. Beyond merely expressing a funny idea, great jokes choose evocative words and present them in a surprising structure (Attardo, 2008) often with pleasing phonetics (Mihalcea and Strapparava, 2005). In addition to this linguistic mastery, many jokes require world knowledge either by setting up and then subverting an expectation or by referencing a common piece of culture (Kukovačec et al., 2017). This makes computational humour a challenging yet very intriguing problem for natural language processing (NLP). As such, it is no surprise that computational humour, and humour recognition in particular, has received increased attention from the NLP community with SemEval-2017 devoting two tasks to it: ranking humorous tweets (Potash et al., 2017) and interpreting English puns (Miller et al., 2017).

This recent attention has lead to advancements such as sequence-based neural humour models capable of implicitly learning a joke structure and semantic features (Bertero and Fung, 2016a; Donahue et al., 2017). While these approaches offer good performance, their reliance on complicated neural architectures over explicitly engineered features present a problem for interpretability which may make it difficult to diagnose problems if results go wrong.

Works which take a more interpretable statistical machine learning approach have their own drawbacks. For example, the representation of joke semantics has been fairly basic, typically computing word embedding similarities between all word pairs in a document (Yang et al., 2015), and bear little resemblance to the way humans actually interpret humour. Additionally, many works fail to take advantage of joke structure, treating texts as unordered bags-of-words (Bertero and Fung, 2016b; Mihalcea and Strapparava, 2005; Yan and Pedersen, 2017).

This paper aims to marry the interpretability of statistical machine learning approaches with the more nuanced models of joke structure and joke semantics of neural approaches. Specifically, we explore the effectiveness modelling joke semantics using semantic relatedness features based on word associations, rather than the more common semantic similarity features based on word embeddings. We present evidence not only that relatedness in general is better suited than similarity for computational humour tasks

Proceedings of the 27th International Conference on Computational Linguistics, pages 1849–1858
Santa Fe, New Mexico, USA, August 20-26, 2018.

due to its broader nature, but also that word associations are particularly well suited due to their ability to map more nuanced relationships (De Deyne and Storms, 2008) and asymmetric nature. While such features have been explored in the past (Cattle and Ma, 2016; Cattle and Ma, 2017b), this work presents a more in depth analysis, focusing on a more fundamental task (binary humour classification vs. relative humour ranking) on with a dataset that better represents natural language (oneliners and puns vs. Twitter hashtag games), and is the first work to incorporate interpolated word association strengths. Furthermore, we introduce a novel method for targetting our semantic features using joke structure to help reduce noise and increase reliability. Specifically, we experiment with integrating the extraction of humour anchors, the "meaningful, complete, minimal set of word spans" (Yang et al., 2015) that allow humour to occur, into the humour classification process itself, the first work to do so. We are also making the code used to run these experiments publicly available[1].

2 Related Work

Informally, jokes are generally divided into setups and punchlines, with the setup establishing a context and the punchline delivering the humour. More formally, according to the Semantic Script Theory of Humor (SSTH) introduced in Raskin (1985), humour is derived from the resolution of two overlapping, but incongruent scripts of differing levels of obviousness (Labutov and Lipson, 2012). That is to say, humour comes from causing listeners to make assumptions about a situation (i.e. implying the obvious script) and then subverting them (i.e. forcing a re-evaluation which results in the choosing of the less obvious one). Consider the following joke taken from Raskin (1985):

> "Is the doctor at home?" the patient asked in his bronchial whisper. "No," the doctor's young and pretty wife whispered in reply. "Come right in."

The use of the words *doctor*, *patient*, and *bronchial* in the setup lead the listener to assume that the man is seeking medical advice. However, the punchline, the doctor's wife's response along with her description, reveals the man's true intent.

The General Theory of Verbal Humor (GTVH), introduced in Attardo and Raskin (1991), expanded on SSTH, retaining the notion of script opposition but highlighting other factors which also affect humour. These include "target (i.e., the person or group made fun of in the joke), the situation (i.e., the background assumed by the joke, such as the props for the story), the narrative strategy (the 'genre' of the joke), and the language (i.e., the lexical, syntactic choices of the text)." (Attardo, 2008)

While target, situation, and the overlapping but incongruent nature of the scripts speak to the importance of semantics in humour, narrative strategy, language, and the fact that listeners should pick the more obvious script first speak to the importance of structure. Although these two aspects are not entirely independent, for the purposes of this paper, it is useful to consider them separately.

2.1 Joke Semantics

Following SSTH, we expect that punchlines that do not sufficiently overlap with their setup are unfunny as they do not flow logically from the context. Similarly, punchlines that are not sufficiently incongruent with their setup are unfunny as there is no re-evaluation. As overlap and incongruity are difficult to measure directly, one common approach is instead to use word embeddings, such as Word2Vec (Mikolov et al., 2013), to calculate the cosine similarities between pairs of vectors representing words in a document (Yang et al., 2015; Shahaf et al., 2015; Kukovačec et al., 2017). However, measuring incongruity and overlap in terms of similarity is a rather odd choice. Just because two scripts overlap does not imply they are similar. In the "doctor" example in Section 2, the two scripts, namely *[the patient is seeking medical advice]* and *[the patient is having an affair with the doctor's wife]*, overlap in terms of the people and locations involved but otherwise are quite different. Similarly, incongruent scripts such as *[dog bites man]* and *[man bites dog]* are very similar in all but the assignment of the roles.

Compared with *similarity*, *relatedness* is a much broader concept. It is easy to think of concepts that are related but not similar. For example, "beer" and "glass" are not similar, describing very different

[1] https://github.com/acattle/HumourTools

concepts, but are quite closely related in that beer often comes in glasses (Ma, 2013). However, it is difficult to think of two concepts which are similar but not related. Although similarity is much more common, several semantic relatedness measures do exist. Extended Lesk (Banerjee and Pedersen, 2003), for example, compute the relatedness between two words as a function of the size of the overlap of their glosses. However, such measures do not fully address the short comings of word embedding similarities.

Any measure based on a distributional semantic approach, including both Extended Lesk and Word2Vec, at its core relies on word co-occurrence to extract relationships. However, not all relationships are evidenced by co-occurrence. For example, "yellow" and "banana" are so closely related that "yellow banana" occurs relatively infrequently since bananas are assumed to be yellow unless told otherwise (De Deyne et al., 2016).

Word associations capture relationships between concepts, are not reliant on distributional semantics, and have long been used in psychology and cognitive science dating back to Galton (1879). Furthermore, some word association-based metrics have been shown to perform better than Word2Vec on a series of similarity tasks (De Deyne et al., 2016). Although the collection of word association datasets is much more labour intensive than distributional semantic approaches, several word association datasets do exist, the most popular being the Edinburgh Associative Thesaurus (EAT), collected in Kiss et al. (1973), and the University of South Florida Free Association Norms (USF), collected in Nelson et al. (2004). Both these datasets were compiled by presenting participants with a cue word and asking them to respond with the first word that comes to mind. The proportion of respondents who give a specific response for a specific cue is called the *forward strength* from the cue to the target. This approach does have its drawbacks, forward strengths are relative instead of absolute (Nelson et al., 2004) and accepting only a single response causes weaker relationships to be under-represented (De Deyne and Storms, 2008), but it is a straightforward and widely accepted way of collecting word association data.

This not the first work to propose word associations for humour recognition. Cattle and Ma (2016) and its follow up, Cattle and Ma (2017b), previously explored the effectiveness of word association strengths on a relative humour ranking task with encouraging results. Most notably, they examined the role of word association asymmetry. While the cosine similarity function preferred by vector space models like Word2Vec and TFIDF is symmetrical, word associations are not. Someone shown the word "beer" may be likely to say "glass" but someone shown the word "glass" may be unlikely to say "beer" (Ma, 2013). This allows for finer grained exploration of the relationship between setups and punchlines. In fact, Cattle and Ma (2016) shows evidence that punchlines tend to be funnier if the strength from the setup to the punchline, which they claim represents how obvious a punchline is, is weaker than the strength of the punchline back to the setup, which they claim represents how easy a punchline is to understand.

While our approach is similar to that of Cattle and Ma (2017b), we note several key differences. First, they perform a relative humour ranking task as opposed to our binary humour classification task. As relative ranking is a more difficult task in general (Potash et al., 2017), Cattle and Ma (2017b)'s results were far from convincing. By pursuing the easier binary classification task, we intend to present a clearer evaluation of word association features for humour recognition. Second, Cattle and Ma (2017b) focused on Twitter hashtag games, a type of online game where participants submit their best responses to a central topic or theme. Compared to the oneliners and puns explored in this work, not only are hashtag war entries slightly shorter, but hashtag wars also include a clear and explicitly marked setup in the form of the central hashtag (Cattle and Ma, 2016). Third, Cattle and Ma (2017b) exclusively utilize a graph-based method for extracting association strengths. This led to coverage issues due to the relatively small vocabularies of the word association datasets. We address this issue by using an machine learning-based approach capable of predicting strengths between arbitrary word pairs, similar to the one introduced in (Cattle and Ma, 2017a).

The association strength prediction method introduced in Cattle and Ma (2017a) is in turn very similar to the WordNet Evocation (Boyd-Graber et al., 2006) prediction method introduced in Hayashi (2016). In all cases, association strengths are estimated using a variety of WordNet (Miller and Fellbaum, 1998) and vector space features which are fed into a multi-layer perceptron.

2.2 Joke Structure

Early humour generation systems tended to model jokes' setup/punchline structure explicitly. HAHAcronyms (Stock and Strapparava, 2002) takes well-known acronyms as setups and, using listener's preconceived notions of that acronym's canonical expansion, generates novel expansions as punchlines which present an ironic clash. Petrović and Matthews (2013) generate jokes of the form "I like my *X* like I like my *Y*, *Z*," where the punchline *Z* acts as a link between the setups *X* and *Y*. Labutov and Lipson (2012) invokes SSTH directly, generating setups by mixing compatible elements of two overlapping but incongruent scripts of varying degrees of obviousness, generated using the common-sense knowledge-base ConceptNet (Speer and Havasi, 2012), and punchlines which introduce information compatible with only the second, less obvious script.

The punning riddle generators, such as Binsted and Ritchie (1994), present an rather unique version of setups and punchlines. Considering the example "What do you call a *sour assistant*? A *lemon aide*." (Binsted, 1996), the setup, instead of establishing an expectation to be subverted, actually establishes a context in which the somewhat odd reading of *lemon aide* can be preferred over the much more common and phonetically identical reading *lemonade*. However, it should be noted that clearly defined setups and punchlines still exist.

Given humour generation's firm grasp of punchline/setup structure, it is somewhat surprising that humour recognition has largely ignored it despite humour recognition starting in earnest with Mihalcea and Strapparava (2005), a full decade after early humour generation works such as Binsted and Ritchie (1994). Early humour recognition works starting with Mihalcea and Strapparava (2005) and its follow-up Mihalcea and Pulman (2007), up to more recent works such as Radev et al. (2016) and Yan and Pedersen (2017) employ bag-of-words models. Such systems are unable to capture document-level structure, such as that setups tend to precede punchlines.

As mentioned in Section 1, joke structure and joke semantics are not entirely independent. This means poor models of joke structure can affect the performance of features designed to capture joke semantics. Despite the issues mentioned in Section 2.1, Yang et al. (2015)'s "incongruity" feature set, maximum and minimum word embedding similarities between pairs of words in a document, perform fairly well. Cattle and Ma (2017b) takes a similar approach with their word association features. The problems comes from the fact that both works compute these values across *all* possible pairs of words in a document. This can introduce noise as not all word pairs are meaningful (e.g. pairs of stopwords) and internally-cohesive setups and punchlines can bias maximum similarity scores. While this can be somewhat alleviated by judicial filtering of stopwords, this does not guarantee meaningful word pairs either.

Yang et al. (2015), in addition to their humour classifier, also introduces a method for identifying jokes' humour anchors (HAs), the "meaningful, complete, minimal set of word spans" that allow humour to occur. While this is slightly different from identifying a joke's setup and punchline, focusing only on pairs of HAs would help reducing noise by increasing the precision of meaningful word pairs selection without sacrificing recall. However, Yang et al. (2015) does not use their extracted HAs to improve their humour classification performance. Likely this is due to the fact that their proposed HA extraction method requires a separate, fully trained humour prediction model which is robust to word order. Furthermore, the quality of the extracted HAs is directly tied to the quality of the humour model. However, both issues could have been alleviated using some form of co-training or bootstrapping between the overall humour prediction model and the HA extractor's internal humour prediction model. The HA extractor works by generating a list of HA candidates for each document following a heuristic method. After removing various combinations of HA candidates from the original document, these modified documents are fed into a trained humour prediction model, with the HAs being the combination of HA candidates which causes the largest drop in humour score. Since the humour prediction model is by design robust against word order, words can be freely omitted with few side effects.

It should be noted that sequence-based humour models such as Bertero and Fung (2016b) or Donahue et al. (2017) should theoretically be capable of implicitly learning HAs, especially Bertero and Fung (2016a)'s Long Short-Term Memory-based approach. However, these models are much more complex than Yang et al. (2015)'s approach, require more training data, and suffer from a lack of interpretability.

3 Methodology

3.1 Datasets

We evaluate our classifiers across two separate datasets: Pun of the Day (PotD), collected in Yang et al. (2015), and 16000 One-Liner (OL), collected in Mihalcea and Strapparava (2005). PotD consists of positive examples collected from the Pun of the Day website[2] and negative examples collected from a combination of news sources, question/answer forums, and lists of proverbs (Yang et al., 2015). OL consists of positive examples scraped from humour websites and negative examples taken from a combination of new headlines, sentences from the British National Corpus, and proverbs.

3.2 Baseline

For our baseline we implemented our own version of Yang et al. (2015)'s highest performing classifier. This model was chosen due to its high performance and its use of statistical machine learning techniques which make it a fair point of comparison. Features include, for each document, minimum and maximum Word2Vec similarities between all word pairs, the total number of word sense combinations in each document according to WordNet, minimum and maximum WordNet path similarities between all word pairs, number of words with negative/positive polarity as well as weak/strong subjectivities according to the Wilson et al. (2005) sentiment lexicon, number of and length of longest alliteration and rhyme chains according to the CMU Pronouncing Dictionary[3], labels of the five nearest neighbours in the training set according to word frequencies, and an averaged Word2Vec embedding across all words for a total of 318 feature dimensions. We then train a Random Forest Classifier using the scikit-learn[4] Python library with 100 estimators but otherwise default settings.

All Word2Vec features, including those described below, use Google's pre-trained 300 dimension Word2Vec embeddings[5].

3.3 Semantic Features

Similar to Yang et al. (2015), we compute the minimum, maximum, and average Word2Vec similarity between ordered word pairs. Not only is this a common humour recognition feature (Yang et al., 2015; Shahaf et al., 2015; Kukovačec et al., 2017), but it also acts as a point of comparison for word association strength.

For our word association features we compute the minimum, maximum, and average association strength between ordered word pairs, which we refer to this as the *forward* strength. Since, as described in Section 2.1, word associations are directional, we also compute the minimum, maximum, and average associations strengths between the reverse ordered word pairs, which we refer to as the *backward* strength. Following Cattle and Ma (2016), we also compute the difference between these two values on both a micro (per word) and macro (per document) level. We refer to these sets of features as the *diff* strengths. Forward, backward, and diff strengths are extracted for both the EAT and USF word association datasets.

We also compare two methods for computing our word association strength features. The first method uses the graph-based method described in Cattle and Ma (2016). We refer to this approach as *graph*. The second uses an in-house association strength predictor using an machine learning-based method similar to the one described in Cattle and Ma (2017a). We refer to this approach as *ML*. Unlike Cattle and Ma (2017a), which uses three different types of word embeddings, we use only Word2Vec. In addition to Word2Vec similarity and vector offsets (the difference between the cue and response vectors), we also include LDA similarity (300 dimensions, trained using Gensim[6] on English Wikipedia), AutoExtend (Rothe and Schütze, 2015) similarity, and a variety of WordNet-based features described in Cattle and Ma (2017a).

[4] http://scikit-learn.org/
[5] https://code.google.com/archive/p/word2vec/
[6] https://radimrehurek.com/gensim/

3.4 Humour Classifier

In addition to the semantic features described above, we also calculate each document's perplexity according to a 3gram language model (LM) trained on the WMT15 English news discussion corpus (Bojar et al., 2015) using KenLM[7]. This feature is included not only because document perplexity has been shown to be useful for humour recognition (Shahaf et al., 2015) but also to act as a baseline for our semantic features. Because both the datasets described in Section 3.1 draw negative examples from news sources, we were concerned that training an LM on a general English corpus might unfairly bias the perplexity scores against those negative examples. Similarly, training an LM on a news corpus might unfairly bias perplexity towards those negative examples. Therefore, the news discussion corpus was chosen as a happy medium between news vocabulary and informal writing styles.

As with our baseline, our extracted features are used to train a Random Forest Classifier using scikit-learn with 100 estimators and default settings using a 10 fold cross validation.

3.5 Humour Anchors

By default, word association and Word2Vec features are computed across all word pairs in a document. However, we also experiment computing these features only across pairs of humour anchor (HA) words. HAs are extracted using the method described in Yang et al. (2015) using the same baseline humour model described in Section 3.2 for anchor candidate evaluation.

HA extraction's requirement of a fully trained anchor candidate evaluator raises the problem of what data that evaluator should be trained on. Given that, as described in Section 3.1, we experiment on two separate humour datasets, we train the anchor candidate evaluator on the opposite dataset from the overall humour classifier. This is to avoid overfitting or biasing the anchor candidate evaluator by training on the test data.

4 Results and Discussion

The results of our experiments are reported in Table 1. In general, our model performs slightly worse than the Yang et al. (2015) baseline. One interesting aspect to note is that our model uses only 28 feature dimensions compared to Yang et al. (2015)'s 318. While this is not exactly a fair comparison in the case of our ML-based word association strengths (our ML strength predictor takes 415 feature dimensions as input), graph-based associations perform similarly and do truly use only 28 dimensions. Overall performance is similar across both datasets with the only notable exception being graph-based USF performing better on OL than PotD. This is likely due to OL being better suited than PotD to USF's relatively smaller set of associations (72,176 pairs and 10,617 unique words versus EAT's 325,588 and 23,218).

4.1 Word Association Strengths

As shown in Table 1, word association strength features outperform Word2Vec similarity. This provides the first clear evidence of their usefulness in humour recognition. This is particularly notable in the case of graph-based associations as they are based on a much smaller dataset and vocabulary.

Despite differences in their individual feature performance on PotD, our model's overall performance is very similar for both graph- and ML-based word association features. This was somewhat unexpected as ML-based associations were included specifically to address coverage issues with graph-based associations noted in Cattle and Ma (2017b). However, graph-based associations seem to exhibit an acceptable level of performance on both datasets, even outperforming ML on OL. One possible explanation is document length. Tweets in Potash et al. (2017)'s dataset averaged 5.5 words (after removing each game's hashtag and the source TV show's Twitter username) versus 13.3 for PotD puns and 10.6 for OL one-liners. As document length increases, the number of word pairs increases exponentially, raising the likelihood of finding at least one word pair with a valid word association strength.

It was expected that ML-based associations would outperform Word2Vec similarity since, as noted in Section 3.3, our association strength prediction model uses Word2Vec similarity as an input. However,

Table 1: Selected Results of Binary Humour Classification Experiments

it should be noted that, like Cattle and Ma (2017a)'s model, the single highest performing feature was not Word2Vec similarity but vector offset (the difference between two word's Word2Vec embeddings). This further highlights the limitations of Word2Vec similarity described in Section 2.1 as our strength predictor is clearly learning something that cannot be captured by cosine similarity alone.

While Cattle and Ma (2016) provided evidence that the difference between the forward and backward word association strengths was more useful than forward or backward strengths alone, this is not the case here. Both micro and macro difference performed worse than either forward or backward. Furthermore, forward and backward perform similarly. This is likely due to Cattle and Ma (2016)'s use of Twitter hashtag wars, meaning setup and punchline were clearly marked. As such, forward strengths were guaranteed to represent associations from the setup to the punchline and backward strengths were guaranteed to be from the punchline back to the setup. In our approach, setups and punchlines were not explicitly defined. This meant it was difficult to know if a specific word pair represented setup to punchline, punchline to setup, or even setup to setup or punchline to punchline. Even using humour anchors (HAs) does not solve this problem since, as referenced in Section 2.2, identifying HAs is slightly different from identifying setups and punchlines. While labelling a word span as a setup or a punchline gives us some insight into its purpose in the joke (i.e. whether it is meant to establish context or to trigger a reframing, respectively), HAs do not include this information.

4.2 Humour Anchors

As mentioned in Section 2.2, using HAs for humour recognition is an appealing notion and would allow semantic features to be targeted only to meaningful word pairs, potentially increasing their effectiveness. The wonderfully simple extraction method described in Yang et al. (2015) only makes HAs more intriguing. Unfortunately, as can be seen in Table 1, HA targetting actually hurts the performance of our humour model.

One obvious suspect for this drop in performance is the quality of the extracted HAs, a sample of which is shown in Table 2. While the *Honeymoon* and *LASER* examples seem relatively accurate, many

I'll **[Marry]** You Tomorrow But Let's **[Honeymoon Tonight]**.
Caution! Do not look into **[LASER]** with **[remaining eye]**.
Newsflash! Dyslexic Christian **[sells]** soul to **[Santa]**.
[Dark] is faster than light, **[otherwise]** you would see it.
If there **[were]** a single **[word]** to **[describe]** me it would have to be profectionist.

Table 2: Sample extracted humour anchors

extracted anchors were either incomplete, as is the case with *Dark* and *Santa*, or nonsensical, like *profectionist*.

As described in Section 2.2, Yang et al. (2015)'s HA extraction algorithm requires a fully trained humour model, the accuracy of which undoubtedly affects the quality of the extracted HAs. For this reason we also experimented with training our anchor candidate scorer using the test data, to maximize its performance. While this approach is problematic, it does provide an upper bound for our HA extraction performance. While using such HA targetted models did result in increased humour classification performance ($ACC = 0.740$, $P = 0.735$, $R = 0.754$, $F1 = 0.744$ on PotD. $ACC = 0.706$, $P = 0.678$, $R = 0.783$, $F1 = 0.727$ on OL.), it still failed to exceed our non-HA models.

We chose our baseline Yang et al. (2015) humour classifier as our anchor candidate scorer for simplicity but their HA extraction algorithm is able to work with any humour recognition model so long as it is robust to word order and capable of generating a humour score (in our case, we used humour probability). Therefore, using a more accurate humour model may have led to better performance.

Another reason HAs may have hurt humour recognition performance is that it may be make non-humorous documents more humorous. Yang et al. (2015)'s method finds the combination of humour anchor candidates that cause the largest drop humour score, i.e. by design it selects a subset of words which positively effect humour scores. As such, HAs may be more likely to be judged as humorous even if the documents they are extracted from are not.

5 Conclusion and Future Work

In this paper we have presented a humour classification system based on word associations and shown performance, across two datasets, above state-of-the-art non-neural models. Furthermore, we show that word association features outperform Word2Vec similarity on this task, providing the first significant evidence that word associations are particularly well suited to computational humour tasks. Furthermore, we explored the effectiveness of humour anchors for humour recognition and found they actually hurt performance.

Possible next steps include exploring the usefulness of word association features on other computational humour tasks such as relative humour ranking or even humour generation. On a more fundamental level, there are still many aspects of word association features left to explore such as examining different datasets or even different strength metrics (e.g. overlap strength, the proportion of shared associations between two words).

Abstract

The 2017 Fake News Challenge Stage 1 (FNC-1) shared task addressed a stance classification task as a crucial first step towards detecting fake news. To date, there is no in-depth analysis paper to critically discuss FNC-1's experimental setup, reproduce the results, and draw conclusions for next-generation stance classification methods. In this paper, we provide such an in-depth analysis for the three top-performing systems. We first find that FNC-1's proposed evaluation metric favors the majority class, which can be easily classified, and thus overestimates the true discriminative power of the methods. Therefore, we propose a new F1-based metric yielding a changed system ranking. Next, we compare the features and architectures used, which leads to a novel feature-rich stacked LSTM model that performs on par with the best systems, but is superior in predicting minority classes. To understand the methods' ability to generalize, we derive a new dataset and perform both in-domain and cross-domain experiments. Our qualitative and quantitative study helps interpreting the original FNC-1 scores and understand which features help improving performance and why. Our new dataset and all source code used during the reproduction study are publicly available for future research[1].

1 Introduction

Recently, Pomerleau and Rao (2017) organized the first Fake News Challenge[2] (FNC-1) in order to foster the development of AI technology to automatically detect fake news. The challenge received much attention in the NLP community: 50 teams from both academia and industry participated. The goal of the FNC-1 challenge is to determine the perspective (or *stance*) of a news article relative to a given headline. An article's stance can either *agree* or *disagree* with the headline, *discuss* the same topic, or it is completely *unrelated*. Table 1 shows four example documents illustrating these classes.

Stance detection is a crucial building block for a variety of tasks, such as analyzing online debates (Walker et al., 2012; Sridhar et al., 2015; Somasundaran and Wiebe, 2010), determining the veracity of rumors on twitter (Lukasik et al., 2016; Derczynski et al., 2017), or understanding the argumentative structure of persuasive essays (Stab and Gurevych, 2017). While stance detection has been previously focused on individual sentences or phrases, the systems participating in FNC-1 have to detect the stance of an entire document, which raises many new challenges. Although the disagreeing article of Table 1 clearly leans against the headline's claim, the fourth sentence would agree to it if considered in isolation.

To properly learn from a scientific shared task, there are typically overview and analysis papers that compare the architectures, features, and results of the participating systems. To date, there is, however, no such paper for FNC-1, which is why we conduct a reproduction study of the top three participating systems. Our goal is to independently verify the results reported in the challenge, which is an important asset in empirical research, to critically assess the experimental setup of FNC-1, and to learn building

Headline: Hundreds of Palestinians flee floods in Gaza as Israel opens dams	
Agree (AGR)	GAZA CITY (Ma'an) – Hundreds of Palestinians were evacuated from their homes Sunday morning after Israeli authorities opened a number of dams near the border, flooding the Gaza Valley in the wake of a recent severe winter storm. The Gaza Ministry of Interior said in a statement that civil defense services and teams from the Ministry of Public Works had evacuated more than 80 families from both sides of the Gaza Valley (Wadi Gaza) after their homes flooded as water levels reached more than three meters [..]
Discuss (DSC)	Palestinian officials say hundreds of Gazans were forced to evacuate after Israel opened the gates of several dams on the border with the Gaza Strip, and flooded at least 80 households. Israel has denied the claim as "entirely false". [..]
Disagree (DSG)	Israel has rejected allegations by government officials in the Gaza strip that authorities were responsible for released storm waters flooding parts of the besieged area. "The claim is entirely false, and southern Israel does not have any dams," said a statement from the Coordinator of Government Activities in the Territories (COGAT). "Due to the recent rain, streams were flooded throughout the region with no connection to actions taken by the State of Israel." At least 80 Palestinian families have been evacuated after water levels in the Gaza Valley (Wadi Gaza) rose to almost three meters. [..]
Unrelated (UNR)	Apple is continuing to experience 'Hairgate' problems but they may just be a publicity stunt [..]

Table 1: Headline and text snippets from document bodies with respective stances from the FNC dataset

better methods by understanding their merits and drawbacks. Based on our analysis of the shared task data, we first propose a new evaluation metric for FNC-1 and related document-level stance detection tasks, which is less affected by highly imbalanced datasets. To understand the headroom of the state-of-the-art performance, we additionally estimate the upper bound for this task. In a feature ablation study, we then identify which features contribute to solving the stance detection task. On the basis of our analysis, we combine ideas from previous systems and propose a novel architecture that performs on par with the state-of-the-art systems, but is better able to correctly classify difficult cases. Since generalizability is crucial for the method's future impact, we finally introduce a new evaluation dataset and evaluate how well the FNC-1 models generalize to unseen data from a different domain. In addition to in-domain experiments, we also conduct cross-domain experiments in order to analyze the transfer potential of a method.

2 Related Work

Previous works in stance detection mostly considered target-specific stance prediction, whereby the stance of a text entity with respect to a topic or a named entity is determined. Target-specific stance prediction has been performed for tweets (Mohammad et al., 2016; Augenstein et al., 2016; Zarrella and Marsh, 2016) and online debates (Walker et al., 2012; Somasundaran and Wiebe, 2010; Sridhar et al., 2015). Such target-specific approaches are based on structural (Walker et al., 2012), linguistic and lexical features (Somasundaran and Wiebe, 2010) and they jointly model disagreement only and collective stance using probabilistic soft logic (Sridhar et al., 2015) or neural models (Zarrella and Marsh, 2016; Du et al., 2017) with conditional encoding (Augenstein et al., 2016). Stance prediction in tweets (Mohammad et al., 2016; Augenstein et al., 2016; Du et al., 2017) and in online debates (Hasan and Ng, 2013) is different from that of stance detection in a news article, which – while similar – is concerned with stance detection of a news article relative to a statement in natural language.

To the best of our knowledge, there is yet no overview or analysis paper on FNC-1 similar to the shared task on detecting stance in twitter (Mohammad et al., 2016; Derczynski et al., 2017; Taulé et al., 2017). To demonstrate the best scientific practices and achieve research transparency, we close this gap by systematically reviewing the top-ranked systems at FNC-1.

The FNC-1 stance detection task is inspired by Ferreira and Vlachos (2016), who classify the stance of a single sentence of a news headline towards a specific claim. In FNC-1, however, the task is document-level stance detection, which requires the classification of an entire news article relative to a headline. The top performing system in FNC-1 is called *SOLAT in the SWEN* (Sean et al., 2017) by Talos Intelligence (henceforth: Talos). They use a combination of deep convolutional neural networks and gradient-boosted decision trees with lexical features. Team *Athene* (Hanselowski et al., 2017) won the second place with

Dataset	headlines	documents	tokens	instances	AGR	DSG	DSC	UNR
FNC-1	2,587	2,587	372	75,385	7.4%	2.0%	17.7%	72.8%

Table 2: Corpus statistics and label distribution for the FNC-1 dataset

an ensemble of five multi-layer perceptrons (MLP) with six hidden layers each and handcrafted features. For the prediction they used hard voting. Finally, *UCL Machine Reading* (*UCLMR*) (Riedel et al., 2017) were placed third using a multi-layer perceptron with bag-of-words features. Additionally, recently published work on FNC-1 use a two-step logistic regression based classifier (Bourgonje et al., 2017) and a stacked ensemble of five classifiers (Thorne et al., 2017) which achieve 9th and 11th places respectively. Although multiple systems[3] participated at FNC-1, we focus on the top three systems in this paper, due to the availability of source code and our goal of analyzing what contributes most to good performance. In the remaining paper, we introduce and analyze these three systems in detail.

3 Reproduction of the Fake News Challenge FNC-1

In this section, we take a closer look at the challenge. We briefly discuss the task and dataset of FNC-1, describe the three top-ranked systems and reproduce their results.

FNC-1 task and dataset. The task in FNC-1 is learning a classifier $f\colon (d, h) \mapsto s$ that predicts one of four stance labels $s \in S = \{\text{AGR}, \text{DSG}, \text{DSC}, \text{UNR}\}$ for a document d with regard to a headline h. If headline and document cover different topics, the stance is $s = \text{UNR}$ (unrelated). Otherwise, s is AGR if d agrees and DSG if d disagrees with h. If h and d merely discuss the same topic, but d does not take a definite position, s will be DSC.

To evaluate the challenge, the organizers provide a dataset[4] of 300 topics. The topics are represented by claims with 5–20 news article documents each. The dataset is derived from the Emergent project (Silverman, 2017) which addressed rumor debunking. In the project, each news article document was summarized into a headline that reflects the stance of the whole document. Other than for rumor debunking, the FNC-1 organizers match each document with every summarized headline and then label the (d, h) pair with one of the four stance labels S. To generate the unrelated class UNR, headlines and documents belonging to different topics are randomly matched. Document–headline pairs of 200 topics are reserved for training, the remaining document–headline pairs of 100 topics for testing. Topics, headlines, and documents are therefore not shared between the two data splits. To prevent teams from using any unfair means by deriving the labels for the test set from the publicly available Emergent data, the organizers additionally created 266 instances. Table 2 shows the corpus size and label distribution.

Participating systems. For our reproduction study, we consider FNC-1's three top-ranked systems. Talos Intelligence's SOLAT in the SWEN team (Sean et al., 2017) won the FNC-1 using their weighted average model (*TalosComb*) of a deep convolutional neural network (*TalosCNN*) and a gradient-boosted decision trees model (*TalosTree*). *TalosCNN* uses pre-trained word2vec embeddings[5] passed through several convolutional layers followed by three fully-connected and a final softmax layer for classification. *TalosTree* is based on word count, TF-IDF, sentiment, and singular-value decomposition features in combination with the word2vec embeddings.

Team *Athene* (Hanselowski et al., 2017) was ranked second. They propose a multi-layer perceptron (MLP) inspired by the work of Davis and Proctor (2017). They extend the original model structure to six hidden and a softmax layer and they incorporate multiple hand-engineered features: unigrams, the cosine similarity of word embeddings of nouns and verbs between headline and document tokens, and topic models based on non-negative matrix factorization, latent Dirichlet allocation, and latent semantic indexing in addition to the baseline features provided by the FNC-1 organizers. Depending on the feature type, they either form separate feature vectors for document and headline, or a joint feature vector.

Table 3: FNC, F_1m, and class-wise F_1 scores for the analyzed models on in-domain experiments

The UCL Machine Reading (*UCLMR*) team propose an MLP as well, but use only a single hidden layer (Riedel et al., 2017). Their system was ranked third. As features, they use term frequency vectors of unigrams of the 5,000 most frequent words for the headlines and the documents. Additionally, they compute the cosine similarity between the TF-IDF vectors of the headline and document. The resulting term frequency feature vectors of headline and document are concatenated along with the cosine similarity of the two TF-IDF vectors.

Reproduction. Following the instructions from the GitHub repositories of the three teams,[6] we could successfully reproduce the results reported in the competition without significant deviations. Table 3 shows these results in the FNC column of the *FNC-FNC* setup, which means that the models were trained and tested on the FNC dataset. Since Talos use a combination of two models, we have also included the results of *TalosCNN* and *TalosTree*. A first interesting finding is that *TalosTree* even outperforms the combined model, since the CNN component performed poorly. To understand the merits and drawbacks of the systems, we analyze the performance metrics and the features used, as discussed in the following sections.

4 Performance evaluation

In this section, we critically assess the FNC-1 evaluation methodology and we determine a human upper bound for this task in order to identify the room for improvement for the document-level stance detection task.

Evaluation metrics. The FNC-1 organizers propose the hierarchical evaluation metric FNC, which first awards .25 points if a document is correctly classified as related (i.e., $s \in \{\text{AGR}, \text{DSG}, \text{DSC}\}$) or UNR to a given headline. If it is related, .75 additional points are assigned if the model correctly classifies the document-headline pair as AGR, DSG, or DSC. The goal of this weighting schema is to balance out the large number of unrelated instances.

Nevertheless, the metric fails to take into account the highly imbalanced class distribution of the three related classes AGR, DSG, and DSC illustrated in Table 2. Thus, models, which perform well on the majority class and poorly on the minority classes are favored. Since it is not difficult to separate related from unrelated instances (the best systems reach about $F_1 = .99$ for the UNR class), a classifier that just randomly predicts one of the three related classes would already achieve a high FNC score. A classifier that always predicts DSC for the related documents even reaches FNC = .833, which is even higher than the top-ranked system.

We therefore argue that the FNC metric is not appropriate for validating the document-level stance detection task. Instead, we propose the class-wise and the macro-averaged F_1 scores (F_1m) as a new metric for this task that is not affected by the large size of the majority class. The class-wise F_1 scores

[6] https://github.com/Cisco-Talos/fnc-1; https://github.com/hanselowski/athene_system; https://github.com/uclmr/fakenewschallenge

are the harmonic means of the precisions and recalls of the four classes, which are then averaged to the F_1m metric. The naïve approach of perfectly classifying UNR and always predicting DSC for the related classes, would achieve only F_1m = .444, which is clearly different from the proposed systems. By averaging over the individual classes' scores, F_1m is also applicable to other datasets, which have a different class distribution than the FNC-1 dataset. While the averaged F_1m objectively reflects the quality of the prediction rather than the class distribution, we can also analyze which classes cannot be properly predicted yet.

As the scores in Table 3 indicate, the performance of the three top-ranked systems reach only about F_1m = .6. Our analysis reveals that *TalosCNN* does not predict the DSC class yielding an F_1 score of zero. Also the overall performance of this model is low and according to the FNC metric, *TalosTree* would even outperform *TalosComb*. In contrast, *TalosTree* returns almost no predictions for the DSG class, although it performs exceptionally well in terms of FNC. This is because it often predicts the majority class DSC for the related documents. Since there are only few DSG instances in the dataset, the overall performance of this model appears high.

Considering the FNC-1 results according to our proposed F_1m metric, the ranking of the three systems changes: The *TalosComb* and *TalosTree* systems are slightly outperformed by *UCLMR* and clearly outperformed by the Athene system. This is because the two Talos models benefit from the FNC metric definition, favoring the prediction of the majority classes UNR and DSC. On smaller classes, such as DSG, they perform much worse than Athene and *UCLMR*. Using F_1m as a metric, the Athene system would be ranked first, as it outperforms *UCLMR* by 2.1 percentage points. In addition to that, Athene also works best on the DSG, DSC, and UNR class.

Human upper bound. In addition to the issues with the evaluation metric, there is also no upper bound reported for the FNC-1 data, although this will help estimating the headroom of the proposed systems with regard to human performance. Therefore, we ask five human raters to manually label 200 instances. The raters reach an overall inter-annotator agreement of Fleiss' $\kappa = .686$ (Fleiss, 1971), which is substantial and allows drawing tentative conclusions (Artstein and Poesio, 2008). However, when ignoring the UNR class, the inter-annotator agreement dramatically drops to $\kappa = .218$. This indicates that differentiating between the three related classes AGR, DSG, and DSC is difficult even for humans.

On the basis of the annotation, we also determine the most probable stance labels according to MACE (Hovy et al., 2013), and compare them to the ground truth from the Emergent project. The agreement of the labels in this case is better, reaching a Fleiss' κ of .807 overall and .552 for the three related classes. The MACE-based most probable label allows us to compute the human upper bound as F_1m = .754, which we include in Table 9 along with the upper bound per class F1 scores UNR = .997 AGR = .588, DSG =.667, and DSC = .765.

5 Analysis of models and features

In this section, we first perform an error analysis in order to be able to find out what the three best performing models are learning and in which cases they fail. In order to address the identified drawbacks, we conduct a systematic feature analysis and derive an alternative model based on our findings.

5.1 Error analysis

Our error analysis for the three analyzed systems shows that the models fail in the following cases: (1) If there is lexical overlap between the headline and the document, the models classify the instance as one of the related classes, even in cases in which the two are unrelated. (2) If the document–headline pair is related, but only contains synonyms rather than the same tokens, the model often misclassifies the case as UNR. (3) If keywords like *reports*, *said*, or *allegedly* are detected, the systems classify the pair as DSC. (4) The DSG class is especially difficult to determine, as only few lexical indicators (e.g., *false*, *hoax*, *fake*) are available as features. The disagreement is often expressed in complex terms which demands more sophisticated machine learning techniques. For example: "If the bizarre story about... sounded outlandish, that's because it was". In appendix A.2, we illustrate these errors with concrete examples.

The analysis shows that the models exploit the similarity between the headline and the document in terms of lexical overlap. Lexical cue words, such as *reports*, *said*, *false*, *hoax* play an important role in classification. However, the systems fail when semantic relations between words need to be taken into account, complex negation instances are encountered, or the understanding of propositional content in general is required. This is not surprising since the three models are based on n-grams, bag-of-words, topic models and lexicon-based features instead of capturing the semantics of the text. In this section, we test these features systematically and we propose new features and a new architecture for FNC-1.

5.2 Feature analysis

Throughout our feature analysis, we use the Athene model, which performed best in terms of F_1m and allows a large number of experiments due to its fast computation. All tests are performed on the FNC-1 development set with 10-fold cross-validation. In the remaining section, we first discuss and evaluate the performance of each feature individually and then conduct an ablation test for groups of similar features. Detailed feature descriptions are included in the supplementary material (section A.1). Figure 1 shows the system performance of the individual features discussed below.

FNC-1 baseline features. The FNC-1 organizers provide a gradient-boosting baseline using the co-occurrence (COOC) of word and character n-grams in the headline and the document as well as two lexicon-based features, which count the number of refuting (REFU) and polarity (POLA) words based on small word lists. Figure 1 indicates that COOC performs well, whereas both lexicon-based features are on par with the majority vote baseline.

Challenge features. The three analyzed FNC-1 systems rely on combinations of the following features: Bag-of-words (BoW) unigram features, topic model features based on non-negative matrix factorization (NMF-300, NMF-cos) (Lin, 2007), Latent Dirichlet Allocation (LDA-cos) (Blei et al., 2001), Latent Semantic Indexing (LSI-300) (Deerwester et al., 1990), two lexicon-based features using NRC Hashtag Sentiment (NRC-Lex) and Sentiment140 (Sent140) (Mohammad et al., 2013), and word similarity features which measure the cosine similarity of pre-trained word2vec embeddings of nouns and verbs in the headlines and the documents (WSim). The topic models use 300 topics. Besides the concatenated topic vectors, we also consider the cosine similarity between the topics of document and headline (NMF-cos, LDA-cos). The BoW features perform best in terms of F_1m. While LSI-300, NMF-300 and NMF-cos topic models yield high scores, LDA-cos and WSim fall behind.

Novel features. We also analyze a number of novel features for the FNC-1 task which have not been used in the challenge. Bag-of-character 3-grams (BoC) represent subword information. They show promising results in our setup. The structural features (STRUC) include the average word lengths of the headline and the document, the number of paragraphs in the document and their average lengths. The low performance of this feature indicates that the structure of the headline and the documents is not indicative of their stance. Furthermore, we test readability features (READ) which estimate the complexity of a text. Less complex texts could be indicative of deficiently written fake news. We tried the following metrics for headline and document as a concatenated feature vector: SMOG grade (Mc Laughlin, 1969), Flesch-Kincaid grade level and Flesch reading ease (Kincaid et al., 1975), Gunning fog index (Štajner et al., 2012), Coleman-Liau index (Mari and Ta Lin, 1975), automated readability index (Senter and Smith, 1967), LIX and RIX (Jonathan, 1983), McAlpine EFLAW Readability Score (McAlpine, 1997), and Strain Index (Solomon, 2006). However, in the present problem setting these features show only a low performance. The same is true for the lexical diversity (LexDiv) metrics, type-token ratio, and the measure of textual diversity (MTLD) (McCarthy, 2005). We finally analyze the performance of features based on the following lexicons: MPQA (Wilson et al., 2005), MaxDiff (Kiritchenko et al., 2014), and EmoLex (Mohammad and Turney, 2010). These features are based on the sentiment, polarity, and emotion expressed by headlines and documents, which might be good indicators of an author's opinion. However, our results show that these lexicon-based features are not helpful. Even though the considered lexicons are important for fake-news detection (Shu et al. (2017), Horne and Adali (2017)), for stance detection, the properties captured by the lexicon-based features are not very useful.

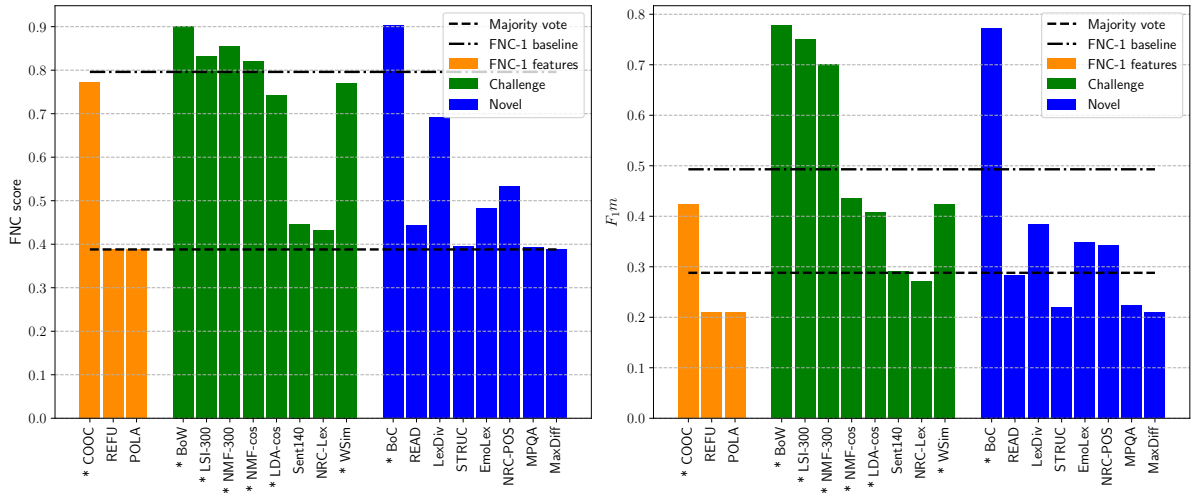

Figure 1: Performance of the system based on individual features

Feature ablation test. We first remove all features that are more than 10% below the FNC-1 baseline, since they mostly predict the majority class and thus harm the F_1m score. In Figure 1, we mark these features with an asterisk (*). To quantify their contribution, we perform an ablation test across three groups of related features: (1) BoW and BoC (BoW/C), (2) LSI-topic, NMF-topic, NMF-cos, LDA-cos (Topic), and (3) NRC-POS and WSim (Oth).

Table 4 show the results of our ablation test. The BoW and BoC features have the biggest impact on the performance. While the topic models yield further improvements, the NRC-POS and WSim features are not helpful. Hence, we suggest BoW, BoC, and the four topic model based features as the most promising feature set.

We evaluate this feature set on the FNC-1 test dataset. The results are included in the *featMLP* row of Table 3 for the *FNC-FNC* setting. Although *featMLP* with the revised feature selection outperforms the best performing FNC-1 system Athene in terms of F_1m and FNC score, the margin is not significant. Similar to the three FNC-1 systems, we observe a .2 performance drop between the development and test dataset. This is most likely because of the 100 new topics in the test dataset, which have not been seen during training. Thus, the evaluation on the test set can be considered as an out-of-domain prediction.

5.3 Model analysis

In order to increase the overall performance, we conduct additional experiments with an ensemble of the three models *featMLP*, *TalosComb*, and *UCLMR* using hard voting. However, we could not significantly improve the results. Since all models struggle with the DSG class, we have applied different under- and over-sampling techniques to balance the class distribution, but also this technique did not yield improved results.

In the error analysis, we observed that the feature-based systems lack semantic understanding. Therefore, we combine a feature-based system with a model that is better able to capture the semantics based

	Baselines		**Only**			**All without**

Headline: NHL expansion ahead? No, says Gary Bettman
Article body: It wasn't very long ago that NHL commissioner Gary Bettman was treating talk of expansion as though he was being asked if he'd like an epidemic of Ebola. But recently the nature of the rhetoric has changed so much that the question is becoming not if, but when. ...

Table 5: A correctly classified DSG instance by the *stackLSTM*

on word embeddings and sequential encoding. Sequential processing of information is important in order to get the meaning of the whole sentence, e.g. "It wasn't long ago that Gary Bettman was ready to expand NHL." VS. "It was long ago that Gary Bettman wasn't ready to expand NHL." In Figure 2, we introduce this *stackLSTM* model, which combines the best feature set found in the ablation test with a stacked long short-term memory (LSTM) network (Hermans and Schrauwen, 2013). We use 50-dimensional GloVe word embeddings[7] (Pennington et al., 2014) in order to generate sequences of word vectors of a headline–document pair. For this, we concatenate a maximum of 100 tokens of the headline and the document. These embedded word sequences $v_1, v_2, \ldots, v_n$ are fed through two stacked LSTMs with a hidden state size of 100 with a dropout of 0.2 each. The last hidden state of the second LSTM is concatenated with the feature set and fed into a 3-layer neural network with 600 neurons each. Finally, we add a dense layer with four neurons and softmax activation function in order to retrieve the class probabilities.

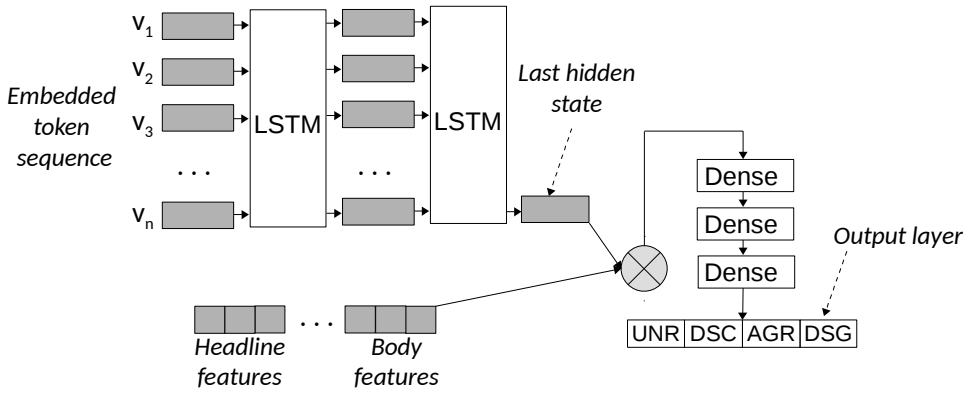

Figure 2: Model Architecture of the feature-rich stackLSTM

Table 3 shows the performance of *stackLSTM* for the *FNC-FNC* setup. Our model outperforms all other methods in terms of F_1m. The difference to Athene and *featMLP* is, however, not significant. An important advantage of *stackLSTM* is its improved performance for the DSG class, which is the most difficult one to predict due to the low number of instances. This means that *stackLSTM* correctly classifies a larger number of complex negation instances. The difference on this difficult DSG class between *stackLSTM* and all other methods is statistically significant (using Student's t-test). The model predicts more often for the DSG class and gets more of these examples correct without compromising the overall performance. One challenging DSG example, which was correctly classified by the *stackLSTM*, is given in Table 5.

6 Analysis of the generalizability of the models

To test the robustness of the models (i.e. how well they generalize to new datasets), we introduce novel test data for document-level stance detection based on the Argument Reasoning Comprehension (ARC) task proposed by Habernal et al. (2018). In this section, we describe the dataset, analyze the models' performance, and perform cross-domain experiments.

ARC dataset. Habernal et al. (2018) manually select 188 debate topics with popular questions from the user debate section of the New York Times. For each topic, they collect user posts, which are highly ranked by other users, and create two claims representing two opposing views on the topic. Then, they

[7] `http://nlp.stanford.edu/data/glove.twitter.27B.zip`

Dataset	headlines	documents	tokens	instances	AGR	DSG	DSC	UNR
ARC	4,448	4,448	99	17,792	8.9%	10.0%	6.1%	75.0%

Table 6: Corpus statistics and label distribution for the ARC dataset

Example from the original ARC dataset		
Topic	Do same-sex colleges play an important role in education, or are they outdated?	
User post	Only 40 women's colleges are left in the U.S. And, while there are a variety of opinions on their value, to the women who have attended ... them, they have been ... tremendously valuable. ...	
Claims	**1.** Same-sex colleges are outdated **2.** Same-sex colleges are still relevant	
Label	Same-sex colleges are still relevant	
Generated instance in alignment with the FNC problem setting		
Stance	**Headline**	**Document**
AGR	Same-sex colleges are still relevant	Only 40 women's colleges are left in the U.S. ...

Table 7: Example of the original ARC dataset and the generated instance to align with FNC dataset

ask crowd workers to decide whether a user post supports either of the two opposing claims or does not express a stance at all. This Argument Reasoning Comprehension (ARC) dataset consists of typical controversial topics from the news domain, such as *immigration*, *schooling issues*, or *international affairs*. While this is similar to the FNC-1 dataset, there are significant differences, as a user post is typically a multi-sentence statement representing one viewpoint on the topic. In contrast, the news articles of FNC-1 are longer and usually provide more balanced and detailed perspective on an issue.

To allow using the ARC data for our FNC stance detection setup, we consider each user post as a document and randomly select one of the two claims as the headline. We label the claim–document pair as AGR if the claim has also been chosen by the workers, as DSG if the workers chose the opposite claim, and as DSC if the workers selected neither claim. Table 7 shows an example of our revised ARC corpus structure. In order to generate the unrelated instances, we randomly match the user posts with claims, but avoid that a user post is assigned to a claim from the same topic. Table 6 provides basic corpus statistics. For training and testing, we split the corpus into 80% training/validation set and 20% testing set.

As for the FNC-1 corpus, we have also determined a human upper bound for the ARC dataset. Five subjects annotate 200 samples using the four classes. Even though the overall Fleiss' $\kappa = .614$ is slightly lower compared to the FNC-1 corpus, the agreement for the three related classes AGR, DSG, and DSC is higher ($\kappa = .383$) than for FNC-1. The human upper bound based on MACE is F_1m = .773. Table 9 contains also the class-wise F_1 scores.

In-domain experiments ARC-ARC: The in-domain results for the ARC corpus listed in Table 8 show that the overall performance of all models decreases. Since the models have been constructed to perform well on the FNC-1 dataset, this is not surprising. Nevertheless, for the ARC corpus, the models are better able to distinguish between AGR and DSG instances. We assume this is because the number of DSG instances is substantially larger and is similar to the number AGR instances. The classification of the DSC instances, on the other hand, turns out to be more challenging on the ARC corpus. This is because even if a user post is related to the claim, it often does not explicitly refer to it. With *TalosComb* being best, the Talos models were better able to generalize to the new data. Even though the *stackLSTM* is again better on the more difficult minority class (in this case DSC), the structure and features of *TalosComb* seem to be more appropriate for this problem setting.

Cross-domain experiments: In the cross-domain setting we train on the training data of one corpus and evaluate on the test data of the other corpus. The experiments in Table 9 show that the performance of the models is substantially better than the majority vote baseline. We therefore conclude that the two problem settings are related and exhibit a common structure. The results suggest that *TalosComb* is best able to learn from the ARC corpus, as it is also superior in the *ARC-FNC* setting. The *stackLSTM*, on the

other hand, yields best results when trained on the FNC corpus as the *FNC-ARC* setting suggests.

7 Discussion and conclusion

In this paper, we conducted a thorough analysis of the Fake News Challenge stage one stance detection task. Although this is common for shared tasks, there is yet no analysis or reproduction study of this task, which is why we close this gap. Given that the challenge has attracted much attention in the NLP community with 50 participating teams, a detailed analysis is valuable as it provides insights into the problem setting and lessons learned for upcoming competitions. In our investigation, we evaluated the performance of the three top-scoring systems, critically assessed the experimental setup, and performed a detailed feature analysis, in which we identify high-performing features for the task yielding a new model. We conducted an error analysis and found that the models mostly rely on the lexical overlap for classification. To assess how well the models generalize to a similar problem setting, we experimented with a second, newly derived corpus. We also propose a new evaluation metric based on F_1 scores, since the challenge's metric is highly affected by the imbalanced class distribution of the test data. Using this evaluation setup, the ranking of the top three systems changes. Based on our analysis, we conclude that the investigated stance detection problem is challenging, since the best performing features are not yet able to resolve the difficult cases. Thus, more sophisticated machine learning techniques are needed, which have a deeper semantic understanding, and are able to determine the stance on the basis of propositional content instead of relying on lexical features.

A Supplemental Material

A.1 Features: Detailed description

BoW/BoC features We use bag-of-words (BoW) 1- and 2-grams with 5,000 tokens vocabulary for the headline as well as the document. For the BoW feature, based on a technique by Das and Chen (2007), we add a negation tag "_NEG" as prefix to every word between special negation keywords (e.g. "not", "never", "no") until the next punctuation mark appears. For the bag-of-characters (BoC) 3-grams are chosen with 5,000 tokens vocabulary, too. For the BoW/BoC feature we use the TF to extract the vocabulary and to build the feature vectors of headline and document. The resulting TF vectors of headline and document get concatenated afterwards. Feature *co-occurrence* (FNC-1 baseline feature) counts how many times word 1-/2-/4-grams, character 2-/4-/8-/16-grams, and stop words of the headline appear in the first 100, first 255 characters of the document, and how often they appear in the document overall.

Topic models We use non-negative matrix factorization (NMF) (Lin, 2007), latent semantic indexing (LSI) (Deerwester et al., 1990), and latent Dirichlet allocation (LDA) (Blei et al., 2001) to create topic models out of which we create independent features. For each topic model, we extract 300 topics out of the headline and document texts. Afterwards, we compute the similarity of headlines and bodies to the found topics separately and either concatenate the feature vectors (NMF, LSI) or calculate the cosine distance between them as a single valued feature (NMF, LDA).

Lexicon-based features These features are based on the NRC Hashtag Sentiment and Sentiment140 lexicon (Kiritchenko et al., 2014; Mohammad et al., 2013; Zhu et al., 2014), as well as for the MPQA lexicon (Wilson et al., 2005) and MaxDiff Twitter lexicon (Rosenthal et al., 2015; Kiritchenko et al., 2014). All named lexicons hold values that signal the sentiment/polarity for each word. The features are computed separately for headline and document, and constructed as proposed by Mohammad et al. (2013): First, we count how many words with positive, negative, and without polarity are found in the text. Two features sum up the positive and negative polarity values of the words in the texts and another two features are set by finding the word with the maximum positive and negative polarity value in the text. Finally, the last word in the text with negative or positive polarity is taken as a feature. Since the MaxDiff Twitter lexicon also contains 2-grams, we decide to take them into account as well, whereas for the other lexicons only 1-grams incorporated. Additionally, we base features on the EmoLex lexicon (Mohammad and Turney, 2010, 2013). For all its words, it holds up to eight emotions (anger, fear, anticipation, trust, surprise, sadness, joy, disgust), based on the context they frequently appear in. For headline and document respectively, the emotions for all words are counted as a feature vector. The resulting vectors for headline and document are then concatenated. Lastly, the baseline features *polarity words* and *refuting words* are added. The first one counts refuting words (e.g. "fake", "hoax"), divides the sum by two, and takes the remainder as a feature signaling the polarity of headline or document. The latter one sets a binary feature for each refuting word (e.g. "fraud", "deny") appearing in the headline or document.

Readability features We measure the readability of headline and document with SMOG grade (only document), Flesch-Kincaid grade level, Flesch reading ease, and Gunning fog index (Štajner et al., 2012), Coleman-Liau index (Mari and Ta Lin, 1975), automated readability index (Senter and Smith, 1967), LIX and RIX (Jonathan, 1983), McAlpine EFLAW Readability Score (McAlpine, 1997), Strain Index (Solomon, 2006). The SMOG grade is only valid if a text has at least 30 sentences, and thus is only implemented for the bodies.

Lexical features As lexical features we implement the type-token-ratio (TTR) and the measure of textual lexical diversity (MTLD) (McCarthy, 2005) for the document, and only type-token-ratio for the headline, since MTLD needs at least 50 tokens to be valid. Also, the baseline feature *word overlap* belongs to this group. It divides the cardinality of the intersection of unique words in headline and document by the cardinality of the union of unique words in headline and document.

POS features The POS features amongst others include counters for nouns, personal pronouns, verbs and verbs in past tense, adverbs, nouns and proper nouns, cardinal numbers, punctuations, the ratio of quoted words, and also the frequency of the three least common words in the text. The headline feature also contains a value for the percentage of stop words and the number of verb phrases, which showed good results in the work of Horne and Adali (2017). For the *word-similarity* feature, [which are mainly based on Ferreira and Vlachos (2016) we calculated average word embeddings (pre-trained word2vec model[8]) for all verbs (retrieved with Stanford Core NLP toolkit[9]) of headline/document separately. The cosine similarity between the averaged embeddings of headline and document is taken as a feature, as well as the hungarian distance between verbs of headline and document based on the paraphrase database[10]. The same computation is done for all nouns of headline and document. Additionally the average sentiment of the headline and the average sentiment of the document is used as a feature. A count of negating words of the headline and the document is added to the feature vector as well as the distance from the negated word to the root of the sentence. The number of average words per sentence of headline and document is another feature. The aforementioned features are improved by only selecting a predefined number of sentences of document and headline. Therefore the sentences are ordered by TF-IDF score.

Structural features The structural features contain the average word length of the headline and document, and the number of paragraphs and average paragraph length of the document.

A.2 Misclassified examples identified in the error analysis

Example 1.
(ground truth: "unrelated", system predicts: "agree")
Headline: CNN: Doctor Took Mid-Surgery Selfie with Unconscious Joan Rivers

Document: "A TEENAGER woke up during brain surgery to ask doctors how it was going. Iga Jasica, 19, was having an op to remove a tumour at when the anaesthetic wore off and she struck up a conversation with the medics still working on her."

Example 2.
(ground truth: "agree", system predicts: "unrelated")
Headline: Three Boobs Are Most Likely Two Boobs and a Lie

Document: The woman who claimed she had a third breast has been proved a hoax.

Example 3.
(ground truth: "disagree", system predicts: "discuss")
Headline: Woman pays 20,000 for third breast to make herself LESS attractive to men

Document: The woman who reported that she added a third breast was most likely lying.

Example 4.
(ground truth: "disagree", system predicts: "agree")

[8] https://code.google.com/archive/p/word2vec/

Abstract

Humor recognition is an interesting and challenging task in natural language processing. This paper proposes to exploit syntactic structure features to enhance humor recognition. Our method achieves significant improvements compared with humor theory driven baselines. We found that some syntactic structure features consistently correlate with humor, which indicate interesting linguistic phenomena. Both the experimental results and the analysis demonstrate that humor can be viewed as a kind of style and content independent syntactic structures can help identify humor and have good interpretability.

1 Introduction

Humor, as a human-specific attribute, plays an important role in human communication. In addition to the tremendous help for human social success, humor also has positive and far-reaching effects on human psychology and physical health (Martineau, 1972; Anderson and Arnoult, 1989; Lefcourt and Martin, 1986). In recent years, the development of artificial intelligence has reinforced the human requirement for the intelligence of machines. As one of the qualities that embodies human wisdom, humor has attracted wide interests and attention (Mihalcea and Strapparava, 2005; Friedland and Allan, 2008; Zhang and Liu, 2014; Yang et al., 2015). The establishment of humor understanding mechanism promotes the development of language intelligence.

With the encouragement of exploring the essence of humor, great progress has been made in the research of humor theories in recent decades. Well recognized theories including superiority theory (Gruner, 1997), relief theory (Rutter, 1997) and incongruity theory (Suls, 1972) have been successively put forward, which explain the origin and essence of humorous feelings. Inspired by these theories, many computational methods are designed to model humor and make some achievements (Mihalcea and Strapparava, 2005; Friedland and Allan, 2008; Zhang and Liu, 2014; Yang et al., 2015).

Although many linguistic cue features have been studied, one aspect is often ignored that humor is a kind of style as well. An interesting question is whether we can explain humor from the perspective of styles. In this paper, we attempt to answer this question by exploring the syntactic structures, which are content independent and style related, for recognizing humor in text. The main contributions can be summarized as below:

(1) We extract production rules, dependency relations and statistics of structural elements as features to model humor. The syntactic structures significantly improve the performance of humor recognition.

(2) We demonstrate that some syntactic structures, which are differently distributed in humorous and non-humorous texts, indicate some interesting linguistic phenomena about humor.

2 Humor Recognition

The main goal of humor recognition is to judge whether the given text expresses humor (Mihalcea and Strapparava, 2005). It can be viewed as a typical classification task.

*corresponding author

Proceedings of the 27th International Conference on Computational Linguistics, pages 1875–1883
Santa Fe, New Mexico, USA, August 20-26, 2018.

Inspired by highly-recognized theories, many studies put forward interpretable features to model humor. We build the baseline features by following the work of (Yang et al., 2015). Next, we explain the features in detail.

Incongruity Structure. Incongruity theory (Suls, 1972) is a widely accepted theory. It believes that the core of humor is inconsistency or conflict. Following the work of (Yang et al., 2015), we describe incongruity through the following two features: (1) the largest semantic distance between word pairs in a sentence. (2) the smallest semantic distance between word pairs in a sentence.

Ambiguity. Another important way to create humor is semantic ambiguity (Miller and Gurevych, 2015), in which misunderstandings of author's intentions often produce unexpected feelings (Bekinschtein et al., 2011). In order to model the semantic ambiguity, we use WordNet (Fellbaum and Miller, 1998) to obtain all senses of word w in current text t. Then the probability of producing semantic ambiguity will be calculated through $\log \prod_{w \in t} sense(w)$, where $sense(w)$ indicates the number of the meanings that word w has. In addition, we also compute the sense farmost and sense closest features which are described in (Yang et al., 2015) to measure ambiguity.

Interpersonal Effect. Interpersonal effect is considered to be closely related to humor (Zhang and Liu, 2014). Some studies suggest that the occurrence of emotions and subjectivity increases the possibility of humor, so we use the resources in (Wilson et al., 2005) to build the following features: (1) the number of words with positive and negative polarity. (2) the number of subjective words.

Phonetic Style. According to the description in (Mihalcea and Strapparava, 2005), phonetic is also an important factor to create comedy effects. In this paper, we follow the work of (Mihalcea and Strapparava, 2005) and (Yang et al., 2015) to extract alliteration chains and rhyme chains in text by using CMU speech dictionary[1]. The alliteration chain is a set of words which have the same first phonemes and the words in rhyme chain have the same last syllable. The corresponding features are as follows: (1) the number of alliteration chains and rhyme chains. (2) the length of the longest alliteration chain and rhyme chain.

KNN features. In addition to humor-related features, we also use the semantic similarity as an indicator to build a KNN feature set that contains the labels of the top 5 sentences in the training data, which are closest to the target instance.

As described, most commonly used features are inspired by humor theories and linguistic knowledge. Few work researches syntactic styles of humorous expressions.

3 Exploiting Syntactic Structures for Humor Recognition

Syntactic information has been successfully used for analyzing text styles. We are going to exploit syntactic structures to reveal stylistic characteristics of humor. We use both constituent parsing and dependency parsing and derive features from parsed trees.

Consider the following sentence:

Never go to a doctor whose office plants have died.

The constituent tree is shown in Figure 1(a), while the dependency tree is shown in Figure 1(b). Both are provided by the Stanford parser (Klein and Manning, 2003) .

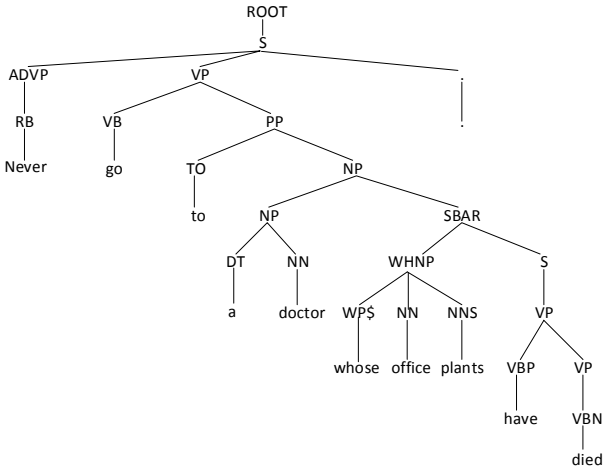
We mainly construct 3 types of features. Such features indicate statistics of basic structural elements and their relations.

3.1 Statistics of Structural Elements

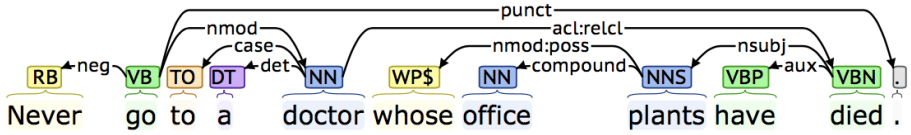
Statistics of structural elements on constituent have been proven to be effective in evaluating the linguistic quality of text (Nenkova et al., 2010). We borrow some features for human recognition.

- Complexity Metrics: Humorous texts and non-humorous texts may differ in the way they express intentions. We expect to measure the differences from the perspective of sentence complexity. Therefore, the number of noun phrases($NPcount$), verb phrases($VPcount$), prepositional

[1] http://www.speech.cs.cmu.edu/cgi-bin/cmudict



(a) a constituent tree.



(b) a dependency tree.

Figure 1: Examples of syntactic parsing.

phrases($PPcount$) and subordinating conjunctions($SBARcount$) are counted respectively as features.

- Phrase Length Ratio: The length ratio(LR) of PP, NP, VP is computed respectively. For each phrase type, the value of its length ratio equals the number of words in the phrase divided by the length of the sentence.

- Average Phrase Length: The average length of a phrase is calculated by dividing the number of words per phrase by the number of corresponding phrase types. It is worth noting that there are two different ways to calculate, one (APL_1) is to consider nested phrases. Consider a VP phrase (VP_1...(...VP_2...)), the length of VP is equal to *length*(VP_1)+ *length*(VP_2). Another way (APL_2) is to only consider the maximum length of the phrase, so the phrase length is *length*(VP_1).

- Normalized Phrase Length: This feature (NPL) just is considered for PP, NP and VP. The value is equal to the average length of each phrase type divided by the length of the sentence. The nested phrases are not considered in this situation.

- Phrase Ratio: Phrase ratio (PR), for each phrase type, is calculated by dividing the number of phrases that appear in the sentence by the length of the sentence.

- Ratio of PP or NP within a VP ($RPNV$): If a VP contains NP or PP, then this value is equal to the average length of the NP or PP divided by the length of the VP.

- Modifiers Change: There are several ways to modify the head noun. This feature is designed to model the modification of the head noun. Finally, two types of feature values are considered. One (MN) is the length of all the modified structures corresponding to the head noun. The other (NMN) is the normalization of the length of the modified structures.

3.2 Production Rules

Production rules describe the composition of phrases at all levels to form a complete sentence. We extract all production rules except the specific words at leaves of each instance as features.

The resulting features, corresponding to the example, include: *ROOT→S*, *S→ADVP VP .*, *ADVP→RB*, *VP→VB PP*, *PP→TO NP*, *NP→NP SBAR*, *NP→DT NN*, *SBAR→WHNP S*, *WHNP→*WP$ NN NNS, *S→*VP, *VP→VBP VP*, *VP→VBN*.

For a given production rule a, we set its feature value as $v(a) := count(a)/count(*)$, where $count(a)$ denotes the number of production rule a, and $count(*)$ represents the number of all production rules extracted from the current instance.

3.3 Dependency Relations

Compared with constituent parsing, dependency parsing indicates relation types between words. Thus, we directly design features for dependency relations. We build a feature for a dependency relation and normalize the count of the dependency relation by the number of all dependency relations in the sentence as the feature value.

We also attempt to combine part of speech (POS) tags and dependency relations. For the example shown in Figure 1(b), there is a dependency from *go* to *never* with type *neg*, therefore we construct a feature $VB \circ neg \circ RB$, where VB and RB are the POS tags of *go* and *never* respectively. But such features don't perform as well as using dependency relations only.

4 Experiment and Analysis

4.1 Data

The data includes humorous sentences as positive instances and non-humorous sentences as negative instances. The humorous sentences are from the work by (Mihalcea and Strapparava, 2005).

One-Liner includes10200 short humorous texts, which are crawled from the Web sites that containing the tags of $humor$, $humour$, $oneliner$, $one\text{-}liner$, $funny$ and $joke$.

They also provide a set of non-humorous short texts.

RPBN contains about 10000 sentences from Reuters titles, Proverbs and British National Corpus.

We found that the average number of tokens in a sentence is 9 in PRBN and 12 in One-Liner. Since we used statistics of structural elements and relations as features, such bias may affect the evaluation, although we have normalized most features. To reduce artifacts and increase the data diversity, we also extracted sentences from the newswire dataset provided by CoNLL-2012 for the task of coreference resolution (Pradhan et al., 2012). These sentences are samples from the OntoNotes corpus (Hovy et al., 2006). We filtered out the texts shorter than 5 words to reduce data noise. We finally sampled 10000 sentences to form a set of negative instances. Their average sentence length is 16.

We conducted experiments on three datasets. All three datasets use One-Liner as the positive instances. The first data set uses RPBN as negative instances, noted as RPBN as well; the second dataset uses sentences extracted from OntoNotes as negative instances, noted as CoNLL and the third dataset was built by sampling negative instances from both RPBN and CoNLL, half from RPBN and half from CoNLL, to keep a balanced positive and negative instance distribution, noted as Mixed.

Random Forest in Scikit-learn (Pedregosa et al., 2011) is used as the classifier. We ran 10-fold cross-validation on the datasets and the average performance would be reported.

4.2 Baselines

- Humor Theory driven Features (HTF). This method uses all features described in Section 2 except the KNN features. Thus all the used features are motivated by the humor theories. These features don't depend on specific content. We expect to use these features to capture the nature of humor.

- Human Centric Features (HCF). The method is a complete re-implementation of the proposed method in (Yang et al., 2015), which uses all features described in Section 2, i.e., HTF plus the KNN features.

Feature	RPBN				CoNLL				Mixed				
	Acc.	P	R	F_1	Acc.	P	R	F_1	Acc.	P	R	F_1	Average ΔF_1
HTF	0.709	0.702	0.749	0.725	0.801	0.771	0.862	0.814	0.707	0.683	0.793	0.734	—

Table 1: Humor recognition performance of four baselines and their combinations with syntactic structure features. HTF: Humor Theory driven Features, HCF: HTF plus KNN features.

- Word2Vec. The method makes use of the semantic representation of the sentences by using the averaged word embeddings as features. Similar to KNN features, it is also sensitive to content. We used the pre-trained word embeddings that were learned using the Word2Vec toolkit (Mikolov et al., 2013) on Google News dataset.[2]
- HCF+Word2Vec. The method combines HCF and Word2Vec. Since the combination of two strong methods, it achieved best evaluation scores in (Yang et al., 2015). It is more dependent on content, since both KNN features and Word2Vec features are used.

4.3 Results

The results are shown in Table 1 with accuracy ($Acc.$), precision (P), recall (R) and F_1 score. To verify the effectiveness of proposed features, we add syntactic structure features (Syntactic) to the four baselines respectively. The performance can be improved to varying degrees.

We can see that after adding syntactic features, HTF achieves significant improvements on all datasets, with an average improvement of 7.9% in accuracy and 7.2% in F_1 score. This indicates that syntactic structure features can complement humor theory driven features and benefit humor recognition. Syntactic structure features don't depend on specific content of texts and their performance is consistent on different datasets, whose sentences have different distribution of the number of tokens. It means that syntactic features can capture some key properties of humor.

Other baselines all consider content features and their performance is greatly superior to HTF. However, such great improvements may come from the artifacts in the datasets rather than capture the nature of humor. The non-humorous samples in our experiments contain news titles, which may involve different vocabularies compared with humorous samples. It is highly probable that these models match specific content and topics better. Even so, after adding syntactic features, all these baselines still achieve improvements, although the margins become small.

(b) Discriminative production rules in One-Liner and CoNLL non-humorous dataset

Table 3: The top discriminative production rules and their distributions in corresponding humorous and non-humorous datasets, sorted by Pearson correlation coefficient. Rules in bold have the same correlation trend in Table 3(a) and Table 3(b).

types of syntactic structure features improve the performance on three datasets. Generally, their contributions are close. Production rule features perform slightly better. This may mean that different kinds of syntactic representations have similar effect. Next, we analyze the three types of syntactic structure features respectively.

Statistics of Structural Elements. The performance of features related to the statistics of structural elements is fairly good on three datasets. We calculate the Pearson correlation coefficient between the specific features and humor on RPBN and CoNLL datasets. We found that not all structural elements have the same correlation on two datasets but some are consistently discriminative. The features that have best positive correlations are the phrase ratio of verb phrases (PR_VP) and the number of subordinating conjunctions (SBAR_Count). In contrast, the features that have consistent negative correlations are the length ratio (LR_NP) and the average length of noun phrases (APL_2_NP).

Production Rules. As shown in Table 2, production rule features can lead to great improvements. We also compute the Pearson correlation coefficient between production rules and humor and the ratio of each production rule in humorous instances or in non-humorous instances of two datasets. Table 3 shows the results. The production rules are ranked according to the correlation coefficient. We can see that some rules are discriminative on both datasets such as *S→NP VP*, *SBAR→IN S* and *WHADVP → WRB*. Their distributions in humorous and non-humorous texts are quite different. This analysis demonstrates that syntactic structures can provide useful information for distinguishing humorous texts from non-humorous texts.

Dependency Relations. Table 4 shows the discriminative power of dependency relations with Pearson correlation coefficient. We can see that the most discriminative features are related to the dependency relation *nsubj*, *compound*, *case*, *aux*. The relation *case* and *compound* are less in humorous instances. The relation *nsubj* together with pronouns (*PRP*) occurs more in humorous instances, while the relation *nsubj* together with noun phrases are less in humorous instances.

Generally, three types of features describe syntactic features from different angles so that their contributions have overlap but also supplement each other in certain degree. One interesting question is that do these features indicate some linguistic interpretation? We attempt to discuss it in next part.

4.4 Linguistic Interpretation

The experimental results show that our proposed syntactic structures do help to identify humor. In this section, we explain how these syntactic structures relate to linguistic phenomena. We found that humorous texts have the following characteristics that can be explained by the syntactic features.

1) Humorous texts use simpler words but more complex syntactic structures.

We can see that compound phrases appear much less in humorous texts. This can be revealed by the average length of noun phrases and the dependency relation *compound*, which have negative correlations

Dependency Relations	Pearson	One-Liner	RPBN
NNP*∘ *compound*∘ *NNP	-0.167	8%	17%
VBP*∘ *nsubj*∘ *PRP	0.163	18%	5%
VBZ∘ *nsubj*∘ *NNP*	-0.138	2%	7%
NNS∘ *compound*∘ *NNP*	-0.127	2%	6%
VB*∘ *nsubj*∘ *PRP	0.121	16%	6%
VB*∘ *aux*∘ *VBP	0.114	7%	2%
VBZ∘ *dobj*∘ *NN*	-0.112	5%	8%
VBP∘ *mark*∘ *IN*	0.105	6%	2%
NNP*∘ *case*∘ *IN	-0.104	5%	9%
VBP∘ *advmod*∘ *WRB*	-0.104	4%	0.5%

(a) Discriminative dependency relations in One-Liner and RPBN

Dependency Relations	Pearson	One-Liner	CoNLL
VBP*∘ *nsubj*∘ *PRP	0.229	18%	3%
VB*∘ *nsubj*∘ *PRP	0.220	16%	3%
NNP*∘ *case*∘ *IN	-0.203	5%	25%
NNP*∘ *compound*∘ *NNP	-0.190	8%	34%
VB∘ *neg*∘ *RB*	0.174	12%	4%
NNS∘ *amod*∘ *JJ*	-0.165	10%	32%
CD∘ *compound*∘ *CD*	-0.161	0.1%	7%
VB*∘ *aux*∘ *VBP	0.160	7%	0.8%
NNS ∘ *case*∘ *IN*	-0.151	15%	36%
NN∘ *nmod:poss*∘ *PRP$*	0.142	15%	8%

(b) Discriminative dependency relations in One-Liner and CoNLL

Table 4: The top discriminative dependency relations and their distributions in corresponding humorous and non-humorous datasets, sort by Pearson correlation coefficient. Dependency relations in bold have the same correlation trend in both datasets.

with humor. The reason may be that many jokes are about events in life so that common words are more often used, while complex and professional words are less used. In contrast, humorous texts often have subordinate conjunctions, which means that subordinate clauses are often used. This can be seen in features involving $SBAR$, such as *NP→NP SBAR*, *SBAR→WHADVP S* and *SBAR→IN S*, all have positive correlations with humorous instances. Considering the following sentence,

I've learned that we are responsible for what we do, $unless$ we are celebrities.

Here, subordinated conjunction $unless$ is used to bring an $unexpected$ feeling to the readers, which results in comedy effect. To break the expectation, complex syntactic structures are often utilized.

2) Humorous texts are more vivid and specific.

We can see that aux relation appears much more in humorous instances as shown in Table 4. This is because humorous texts usually describe some details to let reader imagine the situation, so that auxiliary words are used more to enhance such descriptions.

In addition, aux often related to negation. For example, the feature $VB \circ aux \circ VBP$ mostly describes "do/don't + verb" pattern. The use of negation is usually related to an attitude change or contrast effect, which may lead to humor.

We also see that *WHADVP→WRB* and *SBAR→WHADVP S* have a positive correlation. This is because interrogative adverb why are often used to produce a satirical effect, such as

If ignorance is bliss, why aren't more people happy?

Such rhetoric questions are useful to enhance the expressiveness of a sentence.

3) Humorous texts are more like conversations.

We can see that personal pronouns often appear in humorous texts, including first-person, second-person and third-person pronouns. The corresponding features include the production rule *NP→PRP* and the dependency relation $VBP \circ nsubj \circ PRP$. These words appear more often in conversations. Besides, the rhetoric questions as we discussed earlier also build an effect like conversation.

This phenomenon can be explained by superiority theory (Keith-Spiegel, 1972; Gruner, 1997) that humor is the result of comparing with others. As a result, it is unavoidable to mention people with pronouns. Also, many jokes involve dialogues between people so that they are naturally a kind of conversation.

5 Related Work

Much existing work models humor according to psychological theories. For example, in early studies, Taylor and Mazlack (2004) proposed a computational approach to identify humor based on the humor theory of Raskin (1984). This method took into account the constraint set of all possible jokes, which

took wordplay as a component. The algorithm used in their method learned the statistical patterns of text in N-grams, which provided a heuristic focus for the location of wordplay. Purandare and Litman (2006) identified humor by modeling the distinction of prosodic characteristics between humorous and non-humorous speech by utilizing acoustic-prosodic and linguistic features. Mihalcea and Pulman (2009) presented and analyzed the most frequent features including human-centeredness and negative polarity, which solved two questions related to humor recognition: One is whether humorous and non-humorous texts are separable. Another is whether the characteristics of humor are special.

Recently, Zhang and Liu (2014) designed features according to influential humor theories, linguistic rules and affective dimensions. These features can be applied to distinguish humorous tweets from non-humorous tweets. Motivated by humor theories, Yang et al. (2015) modeled humor by using the semantic structures including incongruity structure, ambiguity, interpersonal effect and phonetic styles. We used their method as one of our baselines. A recent work (Liu et al., 2018) studied sentiment association in discourse for humor recognition.

Some work considers content features. Mihalcea and Strapparava (2005) reported that using content-based features could achieve big improvements. However, content features may overfit the dataset, because in most existing work, non-humorous instances are sampled according to some assumptions which may bring in artifacts. Our work describes humorous expressions by exploring syntactic structures and treats humor as a kind of style. The syntactic structure features don't depend on specific content or topics.

6 Conclusion

In this paper, we have presented a method for humor recognition by exploiting syntactic structure features. We derive features from parsing trees and demonstrate that such features can improve the performance of humor recognition. Moreover, they are not dependent on specific content, which reduces the risk of satisfying artifacts during dataset construction and helps capture the essence of humor.

We analyzed the linguistic insights behind the features and found that humorous texts tend to 1) use simple words but with complex sentence structures; 2) be more vivid with auxiliary adverbs, negations and rhetoric questions; 3) be like conversations, involving more personal pronouns and questions. These observations indicate stylistic characteristics of humor and provide an opportunity to humor computation in a new perspective.

An Attribute Enhanced Domain Adaptive Model for Cold-Start Spam Review Detection

Zhenni You [1], **Tieyun Qian** [1*], **Bing Liu** [2]

Abstract

Spam detection has long been a research topic in both academic and industry due to its wide applications. Previous studies are mainly focused on extracting linguistic or behavior features to distinguish the spam and legitimate reviews. Such features are either ineffective or take long time to collect and thus are hard to be applied to cold-start spam review detection tasks. Recent advance leveraged the neural network to encode the textual and behavior features for the cold-start problem. However, the abundant attribute information are largely neglected by the existing framework.

In this paper, we propose a novel deep learning architecture for incorporating entities and their inherent attributes from various domains into a unified framework. Specifically, our model not only encodes the entities of reviewer, item, and review, but also their attributes such as location, date, price ranges. Furthermore, we present a domain classifier to adapt the knowledge from one domain to the other. With the abundant attributes in existing entities and knowledge in other domains, we successfully solve the problem of data scarcity in the cold-start settings. Experimental results on two Yelp datasets prove that our proposed framework significantly outperforms the state-of-the-art methods.

1 Introduction

Online reviews and ratings are playing more and more critical roles in E-Commerce places. The Mintel flagship report showed that 69 percent of Americans seek out others' advice online before making a purchase [1]. This gives strong incentives for imposters to game the system. As a result, fraudulent reviews flood the e-market websites. Forbes news [2] reported that Amazon's fake review problem is now worse than ever in 2017. Fake reviews are perceived as threats to the ecosystem of the e-business sites, companies, and users, and thus it becomes an urgent task to detect fake or spam reviews.

Existing approaches in spam review detection mainly focused on exacting linguistic features and behavioral features. However, linguistic features are ineffective when they are used to detect the real-life fake reviews (Mukherjee et al., 2013b; Wang et al., 2017b), and it usually requires a large number of samples to make the observations on behavior features. When dealing with the cold-start problem, i.e., *a review is just posted by a new reviewer*, it is hard to construct effective behavioral features for the new reviewer. More recently, Wang et al. (2017b) proposed a neural network model to jointly encode the textual and behavioral information into the review embeddings. This was a good try. However, due to the lack of sufficient information, the results reported in (Wang et al., 2017b) are not promising enough (with an accuracy less than 65%).

Proceedings of the 27th International Conference on Computational Linguistics, pages 1884–1895
Santa Fe, New Mexico, USA, August 20-26, 2018.

Our study is inspired by the work (Wang et al., 2017b) but moves one step further, i.e., we incorporate not only the entities, but also the attributes into a unified framework. The rationale is that similar reviewers' comments on items with similar attributes will result in similar review contexts. For example, the review for luxury restaurants may focus on their atmosphere and personal services while for ordinary restaurants one cares about their tastes. Here the luxury or ordinary is the key property of an restaurant, and might be reflected by the *price range* attribute.

An attribute is the inherent characteristic of an entity and is available for all users (reviewers), items or reviews no matter whether it is in a cold-start setting. For example, when a new user joins a website, the location is automatically recorded as his/her attribute. Such a property makes attributes extremely suitable for our cold-start spam detection problem. Furthermore, while an entity may be new, its attributes may not be new. For example, the attributes for a hotel like "price range" or "having wifi or not" must have been appeared in many other hotels' attributes. Hence we can piece together the profile of new users, items, and reviews by using attributes from others.

To further alleviate the data scarcity in cold-start spam review detection, we turn to seek more available information from other domains. The basic idea is that the entities in different domains may have same attributes. For example, both a hotel and a restaurant have an attribute of "price range". Hence we aim to leverage the shared attributes across different domains. The challenge of this task arises from the discrepancy between two domains. For example, a price of 200 USD may be high for a restaurant but it is low for a hotel. Inspired by prior work on domain adaption (Ben-David et al., 2007; Ben-David et al., 2010; Tzeng et al., 2015), we extend the idea of knowledge transferring between domains to learn a generalized representation for the entity.

Based on the above analysis, we propose an attribute-enhanced domain adaptive (AEDA) embedding model in this paper. Our model not only exploits the inherent attributes of reviewers, items and reviews, but also captures the domain correlations. In summary, the main contributions of our work are as follows.

- We propose to leverage the attributes of entities and their relations to enhance the representations of entities. These attributes are inherent for the entities and thus do not need any experts' experience or time-consuming procedure to collect.
- we present a novel neural network to jointly encode the attributes, entities, and their relations, as well as to adapt the knowledge from one domain to the other. The abundant information greatly alleviate data scarcity problem in the cold-start scenario of spam review detection.
- Extensive experiments demonstrate that our model significantly outperforms the state-of-the-art baseline methods.

The rest of the paper is structured as follows. In Section 2, we present the related work. In Section 3, we introduce our methodology. In Section 4, we show the experimental evaluation. We conclude the paper in Section 5.

2 Related Work

2.1 Review Spam Detection

The problem of spam review detection has aroused great research interests in recent years. This problem was first introduced in (Jindal and Liu, 2008), and the focus of this work was to find effective features to represent the fake and real reviews. Later, a variety of linguistic features were introduced in the literature (Ott et al., 2011; Xu and Zhao, 2013; Harris, 2012; Feng et al., 2012a; Kim et al., 2015; Li et al., 2013; Li et al., 2014b; Fornaciari and Poesio, 2014; Li et al., 2014a; Hovy, 2016). However, an in-depth study (Mukherjee et al., 2013b) found that the linguistic features were insufficient for detecting fake reviews in real business website. Therefore, the features besides review contents were exploited, and the behavioral features of reviewers were intensively studied in (Lim et al., 2010; Jindal et al., 2010; Feng et al., 2012b; Mukherjee et al., 2012; Xie et al., 2012; Fei et al., 2013; Li et al., 2015; KC and Mukherjee, 2016; Wang et al., 2011; Akoglu et al., 2013; Mukherjee et al., 2013a; Mukherjee et al., 2013b). The intuition is that the reviewers with spammer-like behaviors are more likely to post fake reviews. Several methods (Li

et al., 2011; Rayana and Akoglu, 2015) were proposed to utilize multiple information mentioned above. Overall, the traditional features are manually constructed and depend heavily on the experts' knowledge.

More recently, deep learning techniques are applied to fake review detection. Ren and Zhang (Ren and Zhang, 2016) compared several neural networks and found that CNN was more effective than RNN on review text encoding in spam review detection task. Hai et al. (2016) implemented a semi-supervised multi-task learning method, which introduced a covariance matrix to capture the relation between tasks and a Laplacian regularizer to leverage the unlabeled data. Wang et al. (2016) employed a tensor decomposition based on the global behavioral information to learn the representation of the reviewer and item.

The cold-start problem in spam review detection was first introduced in (Wang et al., 2017b), where the authors proposed an embedding learning model to jointly utilize the behavioral information of reviewers and the textual information. While we aim to solve the same cold start problem as that in (Wang et al., 2017b), we propose a totally different framework which leverage both the new attribute and domain knowledge information.

2.2 Domain Adaption

Domain adaption has been applied to addressing the scarcity of labeled data in a variety of real-world applications. It has been well studied in many tasks in the area of computer vision, such as the image classification and object recognization. These methods mainly differ in network structure or objectives, including parameter sharing (Yosinski et al., 2014; Liu et al., 2017), minimizing the distance between source and target distributions (Baktashmotlagh et al., 2013; Tzeng et al., 2014; Long et al., 2015), maximizing of the loss of domain classifier (Ganin and Lempitsky, 2015; Tzeng et al., 2015; Tzeng et al., 2017; Gopalan et al., 2011), and applying semi-supervised or selective learning techniques (Ao et al., 2017; Tan et al., 2017).

Recent years also witnessed the applications of domain adaption technique in many other areas, especially in natural language processing tasks. To name a few, typical applications include question answering (Min et al., 2017), machine translation (Chu et al., 2017; Johnson et al., 2016; Wang et al., 2017a), sentiment analysis (Li et al., 2017), recommendation system (Man et al., 2017) and image-text retrieval (Huang et al., 2017).

While domain adaption technique was introduced in the above research fields, it was rarely adopted in spam review detection. We aim to exploit this technique to help alleviate the problem of data scarcity in the cold-start scenario of spam detection.

3 Methodology

In this section, we present the details of our attribute-enhanced domain adaptive embedding model (AEDA). The key idea is to leverage the relations between entities and attributes and adapt knowledge from one domain to the other. Motivated by recent advances in deep learning which has been proven to be powerful in learning nonlinear representations, we design a novel deep neural network to jointly encode the rich information in entities, attributes, and domains.

3.1 Attribute Enhanced Objective

When a reviewer comments on an item (or product), a review is posted along with a rating score. This process involves three kinds of entities: reviewers, items, and reviews. All these entities consist in a number of attributes. For example, when an item, e.g., a newly opened restaurant, first registers on Yelp, its location and other attributes are recorded in the website. The attributes are essential for legitimate users to learn about the entity. For example, a user on a business trip may care about whether the hotel is close to a metro station.

The attributes provide additional information of the entity and form the background of the comment action. Such information and background are particularly useful when dealing with the cold start spam review detection problem. Since these attributes are inherent components of an entity, we can simply piece together the profile for a new entity using the attributes in existing entities of the same type. Hence

we collect all the attributes and aim to incorporate them into our framework. Below is a brief introduction to these attributes.

- **Reviewer attributes** are recorded when the reviewer registers on the review system. The *YelpJoinDate* is the date when the reviewer joins the system, while the *Location* indicates where the reviewer comes from, which is filled by him/herself.
- **Item attributes** reflects the basic information of each item, such as its *Location*, *Average Rating*, *Price Ranges* (from 1 to 5). The *AcceptCreditCards*, *WiFi*, *WebSite*, and *PhoneNumber* are the attributes about whether the item provides the specific service or not. We convert them into boolean values like "hasWifi" or "ifAcc".
- **Review attributes** include the *Date* when the review is posted and the *Rating* score the reviewer rates on the item.

Overall, there are three kinds of entities and eight kinds of attributes, which further form three types of relations: entity-attribute, attribute-attribute, and entity-entity. We aim to leverage these relations between the attribute and the entity. We will give details below.

Relation 1: entity-attribute relation In order to exploit the rich information contained in the entity-attribute relation, we propose an attribute-enhanced objective L_{ea} to maximize the conditional probability $P(v|e)$ of an entity e's attribute a with a value of v. The intuition is that the attributes can be treated as the contexts of the entities, and the attribute information can be encoded into the representations of entities. We formalize it as follows:

$$\begin{aligned} L_{ea} &= P(v|e) \\ P(v|e) &= \frac{exp(V_v \cdot V_e)}{\sum_{u \in A} exp(V_u \cdot V_e)} \end{aligned} \tag{1}$$

where V_i indicates the embedding of i, including entities and attributes, and A is the corresponding value set of attribute a. Note that we employ negative sampling (Mikolov et al., 2013) to transform the objective. By maximizing the attribute-enhanced objective L_{ea}, the entities with similar contexts (attributes) tend to be similar and the attributes of similar entities become associated. In this way, the representations of attributes become informative and we obtain the attribute-enhanced entity embeddings.

Relation 2: attribute-attribute relation Several attributes, i.e., date, location, and rating, are shared by different entities. In order to capture the relation between these attributes, we take their difference as a new feature. Specifically, we subtract *Date* (review) from *YelpJoinDate* (reviewer) as the new *dateDif* feature, and subtract *Rating* (review) from *Average Rating* (item) as the new *ratingDif* feature, and treat the new *locDif* feature as 1 when the reviewer and item have same location otherwise 0.

Relation 3: entity-entity relation While the entity-attribute and attribute-attribute relations are proposed by us, the entity-entity relation has been examined before (Wang et al., 2017b). For a fair comparison, we follow the work of (Wang et al., 2017b) by applying the TransE model on our attribute-enhanced entity embedding. More formally, we propose an entity-interacted objective L_{ee} as follows:

$$\begin{aligned} L_{ee} = \sum_{(i,r,t) \in S} \sum_{(i',r,t') \in S'} & max\{0, 1 + d(i+r,t) - d(i'+r,t')\} \\ d(i+t,c) =& ||V_i + V_r - V_t||_2^2, \\ s.t.\ ||V_i||_2^2 =& ||V_r||_2^2 = ||V_t||_2^2 = 1 \end{aligned} \tag{2}$$

where S is a set of triples (i, r, t) in the training set of reviews, including the item $i \in I$ (item set) which the review talk about, the reviewer $r \in R$ (reviewer set) who posts this review, and the review text $t \in T$ (review set). S' denotes the corrupted set which is constructed by replacing the item *i* (or text *t*) with a random chosen i' (or t').

The entity-entity and entity-attribute relation can be encoded into the embedding of the entities and attributes in our model by the proposed attribute-enhanced and entity-interacted objective. To make full of them, we concatenate the review text embedding generated by CNN and all the attribute embeddings

of item, reviewer and review into a long vector V_{rcon} to represent the review. This is our basic attribute enhanced (AE) model. The representations of reviews can then be used as the features to train a spam review classifier and make a classification of the new reviews.

3.2 Domain Adaptive Objective

Our AE model is trained in the single domain, i.e., all the embeddings are trained using data merely from one hotel or restaurant domain. As proved in (Hai et al., 2016), the detection of spam review in different domains may have strong correlations. We are curious about whether the cold-start problem can be alleviated by borrowing knowledge from other domains. This is reasonable because entities in different domains may have same attributes. For example, both hotel and restaurant have an attribute of "price range". If we can confuse the domain difference and focus on the relations of attributes from different domains, we may complement the attribute embeddings and subsequently enhance entity embeddings.

Motivated by the recent advances in domain adaption (Ben-David et al., 2007; Ben-David et al., 2010; Tzeng et al., 2015), we add a domain classifier to perform domain classification of reviews in the training set based on the review embedding V_{rcon} mentioned before. Then an adversarial loss is adopted to intensify the domain confusion.

Domain Classifier The domain classifier is implemented by adding a dense layer to identify which domain a review belongs to according to its representation V_{rcon}. We aim to minimize the domain label prediction loss L_{dcla} (defined as the cross-entropy between the predicted label and the true label) by updating the parameters of the domain classifier using a softmax function.

$$q = softmax(W \cdot V_{rcon} + b) \tag{3}$$

$$L_{dcla} = -\sum_{d} \mathbf{1}[y_{dtrue} = d] \, log \, q_d \tag{4}$$

where q is the predicted domain distribution, d is the index of the corresponding domain, y_{dtrue} is the true domain where the review comes from, and W and b are the parameters of the domain classifier.

Adversarial Loss The target of the domain confusion is to adjust the representation to become too domain-invariant to distinguish its domain label. To this end, we minimize the domain confusion loss L_{dcon}, which is defined as the cross entropy between domain label distribution predicted by the domain classifier and a uniform distribution, by updating all parameters in our model except those of domain classifier. We formalize it as follows:

$$L_{dcon} = -\sum_{d} \frac{1}{D} \, log \, q_d \tag{5}$$

where D is the number of the domain in our training set.

After the adversarial training, we can reach a point at which the review representation can not be classified into the true domain label by the best domain classifier. This is what our attribute enhanced domain adaptive (AEDA) model does for training the representations.

Although the domain correlation problem was introduced in (Hai et al., 2016), our task is completely different from that in (Hai et al., 2016). We deal with the domain adaption problem while Hai et al. (Hai et al., 2016) address the multi-task learning problem. In addition, their method was heavily dependent on the labeled data, while our method is totally unsupervised when adapting the knowledge from other domains.

3.3 Model Architecture and Learning Procedure

We present the architecture of our AEDA model in Figure 1. It consists of three layers. The bottom layer of the architecture integrates various attributes into the model. The middle layer aims to capture three relations, i.e., entity-entity, entity-attribute, and attribute-attribute relations. The top layer is used to implement a domain classifier to capture the domain correlation.

We now discuss the learning procedure of our AEDA model in Algorithm 1. It works as follows. Line 1 initializes the parameters. Most parameters of model are randomly initialized, with the exception that the review texts E_t which are generated from the CNN based on the pre-trained word embedding by CBOW

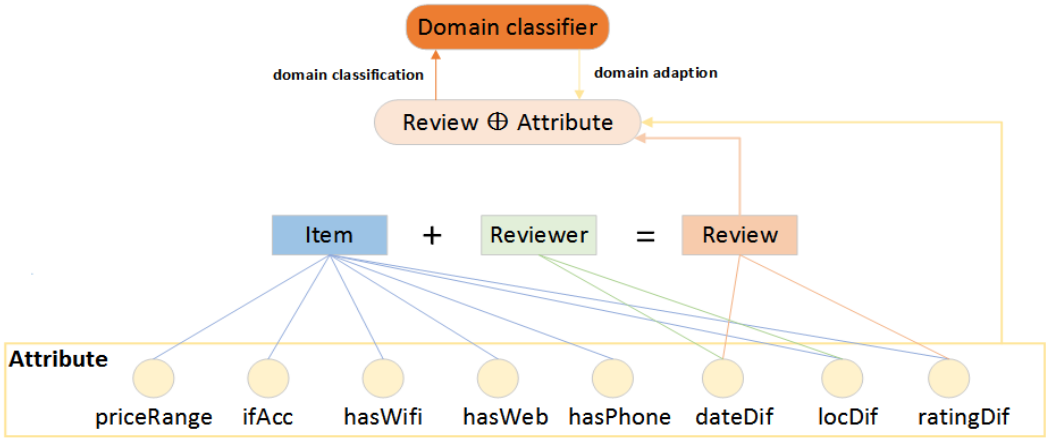

Figure 1: Architecture of AEDA model

(Mikolov et al., 2013). Then for each batch in the training set, we sequentially train entity-attribute relation in reviewer, item, and review, as shown in lines 4 to 6. Next, we use Eq.(2) to capture the entity-entity relation in line 7, which updates the parameters for the entities. Finally we minimize the Eq.(4) to train an accurate domain classifier, and minimize the Eq.(5) to confuse the review representations from different domains. Lines 8, 9 show this adversarial training procedure. After the model is properly trained, through the input of training sets and testing sets, we can obtain the representations of reviews in both sets. These embeddings of reviews can be fed into the traditional classification model like SVM to train the classifier and evaluate the performance of our model.

Algorithm 1 Attribute-enhanced domain adaptive (AEDA) model

Input: The combined training set of different domains, $X_{train} = \{x_i, y_{dtrue,i}\}_{i=1}^{n_{train}}$. Each x_i is composed of several parts including reviewer, item, review text, and their attributes, and $y_{dtrue,i}$ is the domain label of review i;

Output: The trained AEDA model

1: Initialize the parameters of the model, including embeddings of reviews E_t and their attributes E_{ta}, embeddings of reviewers E_r and their attributes E_{ra}, embeddings of items E_i and their attributes E_{ia}, the parameters of CNN Ψ_{tc} and those of domain classifier W, b
2: **repeat**
3: **for** each batch in X_{train} **do**
4: update E_r, E_{ra} by maximizing Eq.(1), where e is the reviewer, v is the value of reviewers' attributes.
5: update E_i, E_{ia} by maximizing Eq.(1), where e is the item, v is the value of items' attributes.
6: update E_t, Ψ_{tc}, E_{ta} by maximize Eq.(1), where e is the review generated from CNN, v is the value of reviews' attributes.
7: update E_r, E_i, E_t, Ψ_{tc} by minimizing Eq.(2)
8: update W, b by minimizing Eq.(4)
9: keep W, b fixed and update all other parameters in the model by minimizing Eq.(5)
10: **end for**
11: **until** converge or reach the predetermined number of epoches
12: **return** the trained AEDA model

4 Experiments

4.1 Experimental Settings

We verify the effectiveness of our proposed model on two cold-start datasets (Wang et al., 2017b), which are the subset of the Yelp datasets used in a number of previous studies (Mukherjee et al., 2013b; Rayana and Akoglu, 2015; Mukherjee et al., 2013a). To deal with the cold-start problem, the original datasets are divided into two parts (Wang et al., 2017b). The reviews posted before January 1, 2012 are used as the training data, and the first new reviews posted by the new reviewers after January 1, 2012 are used as the test data.

We use the SVM method to train the classifier on the training data and test it on the test data. We choose precision (P), recall (R), F1-Score (F1), and accuracy (Acc) as the evaluation metrics. Both the SVM method and the metrics are same as as those in (Wang et al., 2017b; Mukherjee et al., 2013b; Rayana and Akoglu, 2015; Mukherjee et al., 2013a).

4.2 Baseline Methods

We compare our model with eight state-of-the-art methods based on linguistic features and behavioral features, which are listed as follows.

LF (Mukherjee et al., 2013a) captures the linguistic features by extracting bigrams on the labeled review data.

Supervised-CNN uses the same textual information as LF but its features are trained in a supervised convolutional neural network.

LF+BF (Mukherjee et al., 2013a) is a concatenation of linguistic features (LF) and behavioral features (BF).

BF_EditSim+LF (Wang et al., 2017b) first calculates the edit distance between the current review and existing reviews and find the most similar one, then uses its reviewer's behavioral features as the approximation of the new reviewer.

BF_W2VSim+W2V (Wang et al., 2017b) is similar to the BF_EditSim+LF, but uses the similarity of averaged word embedding (pretrained by Word2vec (Mikolov et al., 2013)) to find the most similar review, and concatenates the behavioral features with the average word embedding instead of bigram.

RE* (Wang et al., 2017b) jointly utilizes the TransE (Bordes et al., 2013) to model the behavioral information of reviewers, CNN with same parameter settings of supervised-CNN to encode the textual information, and a constraint to preserve semantics of the sentiment polarity in rating.

RE+RRE+PRE* (Wang et al., 2017b) is an improved version of RE, which further concatenates the review embedding, the review's rating embedding and the item's average rating embedding into a long vector as the feature of the review.

ATT+LF uses the all the attribute values used in our model as the features and then directly concatenates them with bigrams.

For the baselines, we report the results in (Wang et al., 2017b) if they have been implemented, since we conduct experiments on the exactly same datasets and training/testing splits. In addition, we use the same hyper-parameters for our model as those in (Wang et al., 2017b) for a fair comparison.

4.3 Comparison with Baselines

We conduct the comparison experiments on two Yelp datasets. The results are shown in Table 1. AEDA denotes our proposed attribute-enhanced domain adaptive model, and AE refers to a variation of AEDA, which only trains in the single domain without domain-adaption.

It is clear that the proposed AEDA model and its variant AE significantly consistently outperform all the baseline methods on both hotel and restaurant datasets in terms of precision, F1, and accuracy. The slight decreases in recall can be due to the trade off between the precision and recall. The significant improvements of F1 values over baselines clearly demonstrate the effectiveness of our attribute-enhanced method (AE) plus domain adaption technique (AEDA) in cold-start spam review detection task. We have more observations for Table 1.

Table 1: Comparison with baselines.

Row	Features	Hotel				Restaurant			
		P	**R**	**F1**	**Acc**	**P**	**R**	**F1**	**Acc**
1	LF	54.5	71.1	61.7	55.9	53.8	80.8	64.6	55.8
2	Supervised-CNN	61.2	51.7	56.1	59.5	56.9	58.8	57.8	57.1
3	LF+BF	63.4	52.6	57.5	61.1	58.1	61.2	59.6	58.5
4	BF_EditSim+LF	55.3	69.7	61.6	56.6	53.9	82.2	65.1	56.0
5	BF_W2Vsim+W2V	58.4	65.9	61.9	59.5	56.3	73.4	63.7	58.2
6	RE*	62.1	68.3	65.1	63.3	58.4	75.1	65.7	60.8
7	RE+RRE+PRE*	63.6	71.2	67.2	65.3	59.0	78.8	67.5	62.0
8	ATT+LF	71.1	74.7	72.8	72.1	64.0	73.2	68.3	66.0
9	AE (ours)	**76.7**	74.2	**75.4**	**75.8**	**80.3**	66.2	**72.6**	**75.0**
10	AEDA (ours)	**83.9**	74.2	**78.7**	**80.0**	**82.4**	65.1	**72.8**	**75.6**

(1) The LF and Supervised-CNN methods (rows 1-2) which only use linguistic features of reviews are the worst in terms of F1 or accuracy.

(2) Adding the behavioral features (rows 3-6) can improve the performance to some extents, but it is important to choose a good combination method. BF_EditSim+LF and BF_W2Vsim+W2V are both based on the idea of approximating the behavioral features of new reviewer with the existing one with the most similar text. RE* encodes the correlated behavioral information with a neural network framework and thus performs better than simple approximation.

(3) With the additional attribute information (rows 7-10), all the remaining methods outperform those without attributes. For example, our AE shows an increase of 10.3% in F1 and 12.5% in accuracy over RE(*) in hotel domain, and 6.9% in F1 and 14.2% in accuracy in restaurant domain.

(4) Among the methods with additional attributes (rows 7-10), our basic model AE is already significantly better than RE+RRE+PRE*. The improvements may be due to the fact that AE captures the relationship of the common attributes between two entities like the dateDif in Figure 1. Also note that both RE* and RE+RRE+PRE* take all the existing reviews posted before January 1, 2012 to train their models while we only use a small subset. More details about the effects of data size will be discussed in the next section. Furthermore, compared with ATT+LF, our AE leads to an improvement of 9.0% and 3.7% of accuracy, and 4.3% and 2.6% of F1 in restaurant and hotel domain, respectively. This shows that our neural framework can well captures the joint effects of attribute and behavioral information.

(5) Between our AEDA and its simple variant AE (rows 9-10), AEDA is better. The reason is that the attribute-attribute relation in different domains is captured by domain-adaptive objective in AEDA and thus knowledge in the restaurant domain can complement that in the hotel. We find that the performance of AEDA in restaurant does not improve too much. This is because the training set of hotel domain is too small to provide much information for restaurant domain.

4.4 With or Without Unlabeled Data

In the Yelp datasets, 99.18% and 92.58% reviews are unlabeled in hotel and restaurant domain. Wang et al. (2017b) exploited the large-scale unlabeled reviews into their neural network to encode the global behavioral information into the embeddings. Results shows that their model RE* benefits a lot from unlabeled data. However, this is at the expense of efficiency since the training set size increases dramatically when the unlabeled data are added. Our model is trained on the small subset consisting of labeled data. So the problem is how about the performance of RE* without unlabeled data and that of our AE

model with unlabeled data.

Table 2: Impacts of unlabeled data. * indicates that unlabeled data are included

Methods	Hotel				Restaurant			
	P	**R**	**F1**	**Acc**	**P**	**R**	**F1**	**Acc**
RE	53.2	57.6	55.3	53.5	59.8	62.2	61.0	60.2
AE (ours)	76.7	74.2	75.4	75.8	80.3	66.2	72.6	75.0
RE*	62.1	68.3	65.1	63.3	58.4	75.1	65.7	60.8
AE* (ours)	82.4	71.4	76.5	78.1	80.0	67.7	73.3	75.4

We investigate the impacts of unlabeled data and the results are shown in Table 2. It can be seen that whether we use unlabeled data or not, our model is significantly better than that in (Wang et al., 2017b). On one hand, our AE model trained on the small labeled data significantly outperforms the RE* model trained on the whole dataset, let alone our enhanced AE* model. On the other hand, when RE* is reduced to RE, its performance drops a lot. For example, the F1 value decreases from 65.1% to 55.3%. This suggests that the performance of RE* is highly dependent on the size of training data. In contrast, our model is less sensitive to the training size than RE. We believe the reason is that we make good use of attributes. Our model can get discriminative representations even with a very small number of data with the help of attribute information.

4.5 Attribute Effects

To evaluate the effectiveness of each attribute, we remove one attribute from our model at a time, and the results are listed in Table 3.

Table 3: Attribute effects

Removed attribute	Hotel		Restaurant	
	F1	**Acc**	**F1**	**Acc**
location (locDiff)	-0.9	-0.9	0.0	-0.2
date (dateDif)	-22.5	-19.8	-12.1	-12.1
rating (ratingDif)	-1.2	-0.9	-1.0	-0.6
price range	0.5	0.7	0.0	-0.3
ifAcc	0.1	0.0	-0.3	-0.4
hasWifi	1.2	1.2	-0.1	-0.2
hasWeb	-0.3	-0.5	-0.2	-0.4
hasPhone	-0.5	-0.7	0.4	0.1

We find that three attributes (location, date, and rating) are the most important features in both domain. This is reasonable because they are not only the components of the entity itself, but also they are shared by two entities. In particular, we find that the date (dateDif) feature plays a critical role in spam review detection. This is an interesting finding which indicates that spammers may write reviews right after they register at the website. The location difference is more important in hotel than in restaurant. The reason can be that a legitimate user needs an accommodation usually when he/she is out for travelling or business, while a spammer just makes comments and does not care about the location of the hotel.

Among the single attributes, removing "hasWeb" results in the decrease of performance in both hotel and restaurant domains. We suppose that users prefer to search the website of the hotel or restaurant for further information before they make a decision to put it into the schedule. However, these information do not make any sense for spammers. Hence the attribute of "hasWeb" is a good indicator of spam review detection.

5 Conclusion

We introduce an attribute-enhanced domain adaptive embedding (AEDA) model to cope with the cold-start problem in spam review detection. With a carefully designed neural network, our model can jointly encode the inherent attributes of entities, behavioral information, and domain correlations into the review representations. The learnt embeddings are then fed into the traditional SVM machine learning framework to train a classifier and to detect the spam reviews. Experimental results demonstrate the superiority of our proposed AEDA model over all the baseline methods. In the future, we will exploit more available information to enhance the review embedding.

Abstract

Neural network approaches to Named-Entity Recognition reduce the need for carefully hand-crafted features. While some features do remain in state-of-the-art systems, lexical features have been mostly discarded, with the exception of gazetteers. In this work, we show that this is unfair: lexical features are actually quite useful. We propose to embed words and entity types into a low-dimensional vector space we train from annotated data produced by distant supervision thanks to Wikipedia. From this, we compute — offline — a feature vector representing each word. When used with a vanilla recurrent neural network model, this representation yields substantial improvements. We establish a new state-of-the-art F1 score of 87.95 on ONTONOTES 5.0, while matching state-of-the-art performance with a F1 score of 91.73 on the over-studied CONLL-2003 dataset.

1 Introduction

Named-Entity Recognition (NER) is the task of identifying textual mentions and classifying them into a predefined set of types. Various approaches have been proposed to tackle the task, from hand-crafted feature-based machine learning models like conditional random fields (Finkel et al., 2005) and perceptron (Ratinov and Roth, 2009), to deep neural models (Collobert et al., 2011; Ma and Hovy, 2016; Strubell et al., 2017).

Word representations (Turian et al., 2010; Mikolov et al., 2013), also known as word embeddings, are a key element for multiple NLP tasks including NER (Collobert et al., 2011). Due to the small amount of named-entity annotated data, embeddings are used to extend, rather than replace, hand-crafted features in order to obtain state-of-the-art performance (Lample et al., 2016). Recent studies (Yang et al., 2017; Søgaard and Goldberg, 2016) have explored methods for supplying deep sequential taggers with complementary features to standard embeddings. Peters et al. (2017) and Tran et al. (2017) tested special embeddings extracted from a neural language model (LM) trained on a large corpus. LM embeddings capture context-dependent aspects of word meaning using future (forward LM) and previous (backward LM) context words. When this information is added to standard features, it leads to significant improvements in NER. Also, Chiu and Nichols (2016) showed that external knowledge resources (namely gazetteers) are crucial to NER performance. Gazetteer features encode the presence of word n-grams in predefined lists of NEs.

In this work, we discuss some of the limitations of gazetteer features and propose an alternative lexical representation which is trained offline and that can be added to any neural NER system. In a nutshell, we embed words and entity types into a joint vector space by leveraging WiFiNE (Ghaddar and Langlais, 2018), a ressource which automatically annotates mentions in Wikipedia with 120 entity types. From this vector space, we compute for each word a 120-dimensional vector, where each dimension encodes the similarity of the word with an entity type. We call this vector an LS representation, for Lexical Similarity. When included in a vanilla LSTM-CRF NER model, LS representations lead to significant gains. We

Proceedings of the 27th International Conference on Computational Linguistics, pages 1896–1907
Santa Fe, New Mexico, USA, August 20-26, 2018.

establish a new state-of-the-art F1 score of 87.95 on ONTONOTES 5.0, while matching state-of-the-art performance on the over-studied CONLL-2003 dataset.

In the rest of this paper, we motivate our work in Section 2. We describe how we compute LS vectors in Section 3. We present our system in Section 4 and report results in Section 5. In Section 6, we discuss related works before concluding in Section 7.

2 Motivation

Gazetteers are lists of entities that are associated with specific NE categories. They are widely used as a feature source in NER, and have been successfully included in feature-based (Ratinov and Roth, 2009) and neural (Chiu and Nichols, 2016) models. Typically, lists of entities are compiled from structured data sources such as DBpedia (Auer et al., 2007) or Freebase (Bollacker et al., 2008). The surface form of the title of a Wikipedia article, as well as aliases and redirects are mapped to an entity type using the `object_type` attribute of the related DBpedia (or Freebase) page. Ratinov and Roth (2009) use this methodology to compile 30 lists of fine-grained entity types extracted from Wikipedia, while Chiu and Nichols (2016) create 4 gazetteers that map to CoNLL categories (PER, LOC, ORG and MISC). Despite their importance, gazetteer-based features suffer from a number of limitations.

- **Binary representation.** Gazetteer features encode only the presence of an n-gram in each list and omit its relative frequency. For example, the word "France" can be used as a person, an organization, or a location, while it likely refers to the country most of the time. Binary features cannot capture this preference.

- **Generation.** At test time, we need to match every n-gram (up to the length of the longest lexicon entry) in a sentence against entries in the lexicons, which is time consuming. In their work, Chiu and Nichols (2016) use 4 lists that count over 2.3M entries.

- **Non-entity words.** Gazetteer features do not capture signal from non-entity words, while earlier feature-based models strived to encode that some words (or n-grams) trigger specific entity types. For instance, words such as "eat", "directed" or "born" are words that typically appear after a mention of type PER.

To overcome those limitations, we propose an alternative approach where we embed annotations mined from Wikipedia into a vector space from which we compute a feature vector that represent words. This vector compactly and efficiently encodes both gazetteer and lexical information. Note that at test time, we only have to feed our model with this feature vector, which is efficient.

3 Our Method

3.1 Embedding Words and Entity Types

Turning Wikipedia into a corpus of named-entities annotated with types is a task that received continuous attention over the years (Nothman et al., 2008; Al-Rfou et al., 2015; Ghaddar and Langlais, 2017). It consists mainly in exploiting the hyperlink structure of Wikipedia in order to detect entity mentions. Then, structured data from a knowledge base (for instance Freebase) are used to map hyperlinks to entity types. Because the number of anchored strings in Wikipedia is no more than 3% of the text tokens, Ghaddar and Langlais (2017) proposed to augment Wikipedia articles with mentions unmarked in Wikipedia, thanks to a mix of heuristics that benefit the Wikipedia structure (Ghaddar and Langlais, 2016a), as well as a coreference resolution system adapted specifically to Wikipedia (Ghaddar and Langlais, 2016b).

The authors applied their approach on English Wikipedia and produce coarse (4 classes) and fine-grained (120 labels) named-entity annotations, leading to WiNER (Ghaddar and Langlais, 2017) and WiFiNE (Ghaddar and Langlais, 2018). In this work, we adopt WiFiNE which is publicly available at `http://rali.iro.umontreal.ca/rali/en/wifiner-wikipedia-for-et` as our source of annotations. Each entity mention is mapped (via its Freebase `object_type` attribute) to a pre-defined set of 120 entity types. Types are stored in a 2-level hierarchical structure

(e.g. `/person` and `/person/musician`). The corpus consist of 3.2M Wikipedia articles, comprising 1.3G tokens that we annotated with 157.4M named-entity mentions and their types. We used this very large quantity of automatically annotated data for jointly embedding words and entity types into the same low-dimensional space. The key idea consists in learning an embedding for each entity type using its surrounding words. For instance, the embedding for `/product/software` will be trained using context words that surround all entities that were (automatically) labelled as `/product/software` in Wikipedia. In practice, we found that simply concatenating a sentence (v1) with its annotated version (v2), as illustrated in Figure 1, offers a simple but efficient way of combining words and entity types so that embeddings can make good use of them.

(v1) On **October 9, 2009**, the **Norwegian Nobel Committee** announced that **Obama** had won the **2009 Nobel Peace Prize**.
(v2) On `/date`, the `/organization/government_agency` announced that `/person/politician` had won the `/award`.

Figure 1: Example of the two variants of a given sentence.

We use the FastText toolkit (Bojanowski et al., 2016) to learn the uncased embeddings for both words and entity types. We train a skipgram model to learn 100-dimensional vectors with a minimum word frequency cutoff of 5, and a window size of 5. This configuration (recommended by the authors) performs the best in the experiments described in Section 5. Since FastText learns representations of character *n*-grams, it has the ability to produce vectors for unknown words.

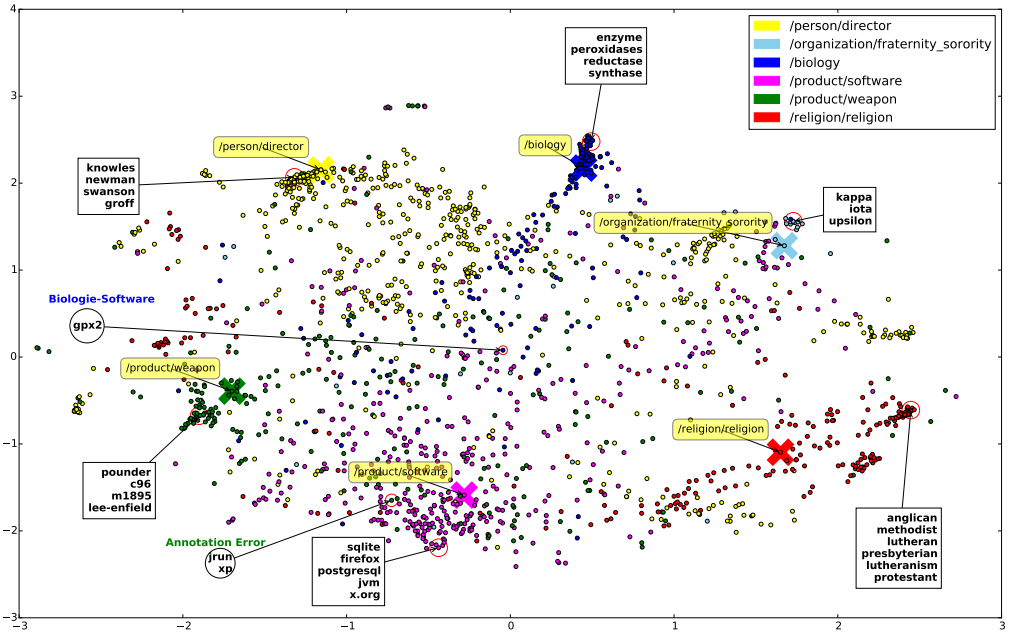

Figure 2: Two-dimensional representation of the vector space which embeds both words and entity types. Big Xs indicate entity types, while circles refer to words (i.e. named-entities, here).

Figure 2 illustrates a T-SNE (van der Maaten, 2014) two-dimensional projection of the embedding of 6 entity types and a sample of 1500 words. Entity type embeddings are marked by big Xs, while circles indicate words. For visualization proposes, we only plot single-word mentions that were annotated in WiFiNE with one of those 6 types. Words were randomly and proportionally sampled according to the frequency of each entity type. In addition, words have the color associated with the most frequent type they were annotated with in WiFiNE.

We observe that mentions often annotated by a given type in our resource tend to cluster around this entity type. For instance, "firefox" is close to the type /product/software, while "enzyme" is close to the /biology entity type. We also notice that words that are labelled with different types tend to appear between types they were annotated with. For instance, "gpx2", which is used both as a software and as a gene, has its embedding in between /product/software and /biology. We inspected some of the words plotted in Figure 2, and found that "jrun" and "xp" are incorrectly labelled as /product/weapon in WiFiNE. But since these words are seen in a *software* context, their embeddings are closer to the /product/software embedding than the /product/weapon one. We feel this tolerance to noise is a desirable feature, one that hopefully allows a more efficient use of distant supervision. Last, we also observe the tendency of rare words to cluster around their entity type. For instance, "iota" and "x.org" are embedded near their respective types, despite the fact that they appear less than 30 times in the version of Wikipedia used to compile WiFiNE.

3.2 LS Representation

This joint vector space only serves the purpose of associating to each word a LS representation, that is, a 120-dimensional vector where the ith coefficient is a value in the $[-1, +1]$ interval, equal to the cosine similarity[1] between the word embedding and the embedding of the ith entity type (we have 120 types).

Word	Entity Type	Sim	Word	Entity Type	Sim
hilton	/building/hotel	0.58	located	/location	0.47
	/building/restaurant	0.46		/location/city	0.44
	/person/actor	0.37		/building	0.40
gpx2	/biology	0.69	directed	/person/director	0.60
	/product/software	0.56		/art/film	0.55
jrun	/product/software	0.64	in	/date	0.58
	/product/weapon	0.23		/location/city	0.54
dammstadt	/location/city	0.45	won	/award	0.53
	/location/railway	0.44		/event/sports_event	0.53

Table 1: Topmost similar entity types to a few single-word mentions (left table) and non-entity words (right table).

Table 1 shows the topmost similar entity types for proper names (left column) and common words (right column). We observe that ambiguous mentions (those annotated with several types) are adequately handled. For instance, the LS representation of the word "hilton" encodes that it more often refers to a hotel or a restaurant than to an actress. Also, we observe that entity words that are either not or rarely annotated in WiFiNE are still adequately associated with their right type. For instance, "dammstadt", which appears only 5 times in WiFiNE, and which refers to the Damm city in Germany, is most similar to /location/city and /location/railway. Interestingly, this mention does not have its page in English Wikipedia. Furthermore, we observe that non-entity context words have a strong similarity to types they precede or succeed. For instance the verb "directed" is very close to /person/director, an entity type that usually precedes it, and to /art/film, that usually follows it. Likewise, the preposition "in" is near /date and /location/city, which frequently follow "in".

3.3 Strength of the LS Representation

To summarize, we propose a compact lexical representation which is computed offline, therefore incurring no computation burden at test time This representation encodes the preference of an entity-mention word for a given type, an information out of reach of binary gazetteer features. It also lends itself nicely to the inclusion of lexical features that have been successfully used in earlier feature-based systems (Ratinov and Roth, 2009; Luo et al., 2015). Also, because entity types are well represented in WiFiNE, their

[1]The cosine similarity outperforms other metrics in our experiments.

embeddings are robust: Our representation does accommodate unfrequent words and seems tolerant to the inherent noise of distant supervision.

4 Our NER System

In order to test the efficiency of our lexical feature representation, we implemented a state-of-the-art NER system we now describe.

4.1 Bi-LSTM-CRF Model

We adopt the popular Bi-LSTM-CRF architecture (Figure 3), a *de facto* baseline in many sequential tagging tasks (Lample et al., 2016; Søgaard and Goldberg, 2016; Chiu and Nichols, 2016).

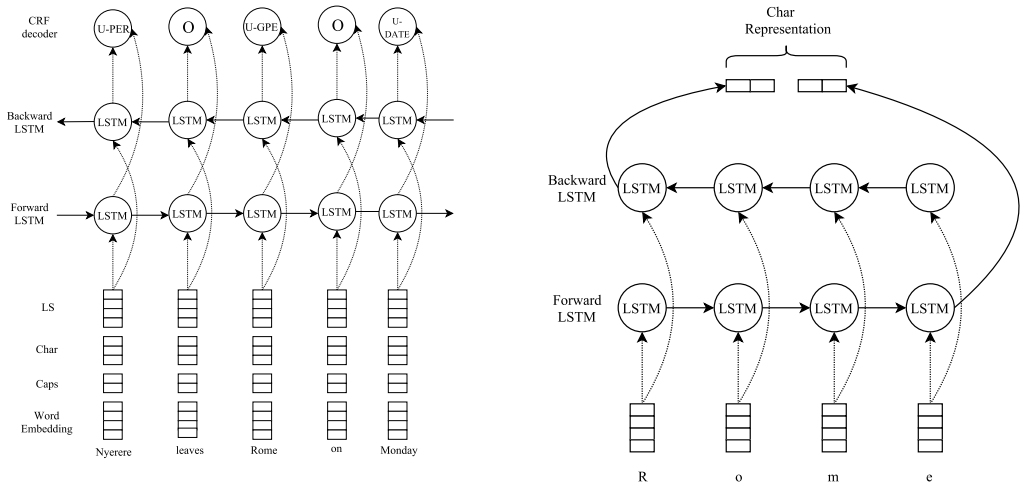

Figure 3: **Left Figure:** Main architecture of our NER system. **Right Figure:** Character representation of the word "Roma" given to the word-level bi-LSTM.

4.2 Features

In addition to the LS vector, we incorporate publicly available pre-trained embeddings, as well as character-level, and capitalization features. Those features have been shown to be crucial for state-of-the-art performance.

4.2.1 Word Embeddings

We experimented with several publicly available word embeddings, such as Senna (Collobert et al., 2011), Word2Vec (Mikolov et al., 2013), GloVe (Pennington et al., 2014), and SSKIP (Yulia et al., 2015). We find that the latter performs the best in our experiments. SSKIP embeddings are 100-dimensional case sensitive vectors that where trained using a *n*-skip-gram model (Yulia et al., 2015) on 42B tokens. These embeddings were previously used by (Lample et al., 2016; Strubell et al., 2017), who report good performance on CONLL, and state-of-the-art results on ONTONOTES respectively. Note that these pre-trained embeddings are adjusted during training.

4.2.2 Character Embeddings

Following (Lample et al., 2016), we use a forward and a backward LSTM to derive a representation of each word from its characters (right part of Figure 3). A character lookup table is randomly initialized, then trained at the same time as the Bi-LSTM model sketched in Section 4.1.

4.2.3 Capitalization Features

Similarly to previous works, we use capitalization features for characterizing certain categories of capitalization patterns: `allUpper`, `allLower`, `upperFirst`, `upperNotFirst` , `numeric` or

noAlphaNum. We define a random lookup table for these features, and learn its parameters during training.

4.2.4 LS Vectors

Contrarily to previous features, lexical vectors are computed offline and are not adjusted during training. We found useful in practice to apply a MinMax scaler in the range $[-1, +1]$ to each LS vector we computed; thus, $[.., 0.095, .., 0.20, .., 0.76, ..]$ becomes $[.., -1, .., -0.67, .., 1, ..]$.

5 Experiments

5.1 Data and Evaluation

We consider two well-established NER benchmarks: CoNLL-2003 and OntoNotes 5.0. Table 2 provides an overview of the two datasets. As we can see, OntoNotes is much larger. For both datasets, we convert the IOB encoding to BILOU, since Ratinov and Roth (2009) found the latter to perform better. In keeping with others, we report mention-level F1 score using the conlleval script[2].

The CoNLL-2003 NER dataset (Tjong Kim Sang and De Meulder, 2003) is a well known collection of Reuters newswire articles that contains a large portion of sports news. It is annotated with four entity types: *Person (*PER*), Location (*LOC*), Organization (*ORG*) and Miscellaneous (*MISC*)*. The four entity types are fairly evenly distributed, and the train/dev/test datasets present a similar type distribution.

Dataset		Train	Dev	Test
CoNLL-2003	*#tok*	204,567	51,578	46,666
	#ent	23,499	5,942	5,648
OntoNotes 5.0	*#tok*	1,088,503	147,724	152,728
	#ent	81,828	11,066	11,257

Table 2: Statistics of the CoNLL-2003 and OntoNotes 5.0 datasets. *#tok* stands for the number of tokens, and *#ent* indicates the number of named-entities gold annotated.

The OntoNotes 5.0 dataset (Hovy et al., 2006; Pradhan et al., 2013) includes texts from five different genres: broadcast conversation (200k), broadcast news (200k), magazine (120k), newswire (625k), and web data (300k). This dataset is annotated with 18 entity types, and is much larger than CoNLL. Following previous researches (Chiu and Nichols, 2016; Strubell et al., 2017), we use the official train/dev/test split of the CoNLL-2012 shared task (Pradhan et al., 2012). Also, we exclude (both during training and testing) the New Testaments portion as it does not contain gold NE annotations.

5.2 Training and Implementation

Training is carried out by mini-batch stochastic gradient descent (SGD) with a momentum of 0.9 and a gradient clipping of 5.0. The mini-batch is 10 for both datasets, and learning rates are 0.009 and 0.013 for CoNLL and OntoNotes respectively. More sophisticated optimization algorithms such as AdaDelta (Zeiler, 2012) or Adam (Kingma and Ba, 2014) converge faster, but none outperformed SGD with exponential learning rate decay in our experiments.

Our system uses a single Bi-LSTM layer at the word level whose hidden dimensions are set to 128 and 256 for CoNLL and OntoNotes respectively. For both models, the character embedding size was set to 25, and the hidden dimension of the forward and backward character LSTMs are set to 50. To mitigate overfitting, we apply a dropout mask (Srivastava et al., 2014) with a probability of 0.5 on the input and output vectors of the Bi-LSTM layer. For both datasets, we set the dimension of capitalization embeddings to 25 and trained the models up to 50 epochs.

We tuned the hyper-parameters by grid search, and used early stopping based on the performance on the development set. We varied dropout ($[0.25, 0.5, 0.65]$), hidden units ($[50, 128, 256, 300]$), capitalization ($[10, 20, 30]$) and char ($[25, 50, 100]$) embedding dimensions, learning rate ($[0.001, 0.015]$ by step

[2] http://www.cnts.ua.ac.be/conll2000/chunking/conlleval.txt

0.002), and optimization algorithms and fixed the other hyper-parameters. We implemented our system using the Tensorflow (Abadi et al., 2016) library, and ran our models on a GeForce GTX TITAN Xp GPU. Training requires about 2.5 hours for CoNLL and 8 hours for OntoNotes.

5.3 Results on the Development Set

Table 3 shows the development set performance of our final models on each dataset compared to the work of Chiu and Nichols (2016). The authors use an architecture similar to ours, but use a binary gazetteer feature set, while we use our LS representation. Since our systems involve random initialization, we report the mean as well as the standard deviation over five runs. The improvements yielded by our model on the CoNLL dataset are significant although modest, while those observed on OntoNotes are more substantial. We also observe a lower variance of our system over the 5 runs.

	CoNLL	**OntoNotes**
(Chiu and Nichols, 2016)	94.03 ($\pm$ 0.23)	84.57 ($\pm$ 0.27)
Our model	**94.80 ($\pm$ 0.10)**	**86.44 ($\pm$ 0.14)**

Table 3: Development set F1 scores of our best hyper-parameter setting compared to the results reported in (Chiu and Nichols, 2016).

5.4 Results on CoNLL

Table 4 reports our model's performance[3] on the CoNLL test set, as well as the performance of systems previously tested on this test set (the figures are those published by the authors). Because of the small size of the training set, some authors (Chiu and Nichols, 2016; Yang et al., 2017; Peters et al., 2017; Peters et al., 2018) incorporated the development set as a part of training data after tuning the hyper-parameters. Consequently, their results are not directly comparable, so we do not report them.

Table 4: F1 scores on the CoNLL test set. The first four systems are feature-based, the others are neuronal. The feature configuration of each system is encoded with: LEX which stands for LEXical feature, GAZ for GAZetteers, CAP for CAPitalization, EMB for pre-trained EMBeddings, CHE for CHaracter Embeddings, LME for Language Model Embeddings, and LS for the proposed LS feature representation. + indicates that the model uses the feature set.

First, we observe that our model significantly outperforms models that use extensive sets of hand-crafted features (Ratinov and Roth, 2009; Lin and Wu, 2009) as well as the system of (Luo et al.,

[3] Standard deviation on the test set is reported in Table 7

2015) that uses NE and Entity Linking annotations to jointly optimize the performance on both tasks. Second, our model outperforms as well other NN models that only use standard word embeddings, which indicates that our lexical feature vector is complementary to standard word embeddings. Third, our system matches state-of-the-art performances of models that use either more complex architectures or more elaborate features. Tran et al. (2017) use three layers of stacked residual RNN (Bi-LSTM) with bias decoding. Our model is much simpler and faster. They report a performance of 90.43 when using an architecture similar to ours. The two systems that have slightly higher F1 scores on the CoNLL dataset both use embeddings obtained from a forward and a backward Language Model trained on the One Billion Word Benchmark (Chelba et al., 2013). They report gains between 0.8 and 1.2 points by using such LM embeddings, which suggests that LS vectors are indeed efficient. Unfortunately, due to time and resource constraints,[4] we were not able to measure whether both features complement each other. This is left for future investigations.

5.5 Results on OntoNotes

Table 5 reports the F1 score of our system compared to the performance reported by others on the OntoNotes test set. To the best of our knowledge, we surpass previously reported F1 scores on this dataset. In particular, our system significantly outperforms the Bi-LSTM-CNN-CRF models of (Chiu and Nichols, 2016) and (Strubell et al., 2017) by an absolute gain of 1.68 and 0.96 points respectively. Less surprisingly, it surpasses systems with hand-crafted features, including Ratinov and Roth (2009) that use gazetteers, and the system of Durrett and Klein (2014) which uses coreference annotation in OntoNotes to jointly model NER, entity linking, and coreference resolution tasks.

Model	LEX	GAZ	CAP	EMB	CHE	LME	LS	**F1**
(Finkel and Manning, 2009)	+	+	+	•	•	•	•	82.42
(Ratinov and Roth, 2009)	+	+	+	•	•	•	•	84.88
(Passos et al., 2014)	+	+	+	•	•	•	•	82.24
(Durrett and Klein, 2014)	+	+	+	•	•	•	•	84.04
(Chiu and Nichols, 2016)	•	+	+	+	+	•	•	86.28
(Shen et al., 2017)	•	•	+	+	+	•	•	86.52
(Strubell et al., 2017)	•	•	+	+	+	•	•	86.99
This work	•	+	+	+	+	•	+	**87.95**

Table 5: F1 scores on the OntoNotes test set. The first four systems are feature-based, the following ones are neuronal. See Table 4 for an explanation of the column of features.

The OntoNotes benchmark is annotated with 18 types (e.g. LAW, PRODUCT) and contains many rare words, especially in the Web data collection. Chiu and Nichols (2016) note that the 4-class gazetteer they used yielded marginal improvements on OntoNotes, contrarily to CoNLL. In particular, they observe that mentions that match LOC entries in their gazetteer often match GPE, NORP and FAC lists.

Model	**BC**	**BN**	**MZ**	**NW**	**TC**	**WB**
(Finkel and Manning, 2009)	78.66	87.29	82.45	85.50	67.27	72.56
(Durrett and Klein, 2014)	78.88	87.39	82.46	87.60	72.68	76.17
(Chiu and Nichols, 2016)	85.23	89.93	84.45	88.39	72.39	78.38
This work	**86.33**	**90.46**	**85.91**	**89.75**	**75.41**	**80.39**

Table 6: Per-genre F1 scores on OntoNotes (numbers taken from Chiu and Nichols (2016)). BC = broadcast conversation, BN = broadcast news, MZ = magazine, NW = newswire, TC = telephone conversation, WB = blogs and newsgroups.

[4] LM embeddings are not publicly available, and according to Jozefowicz et al. (2016), they require three weeks to train on 32 GPUs.

They suggest that a finer-grained gazetteer could improve the performance of their system on ONTONOTES. Our results confirm this, since we use 120 types. We further detail the gains we observed for each sub-collection of texts in the test set. Table 6 reveals that major improvements over the model of (Chiu and Nichols, 2016) are on noisier collections such as telephone conversations (+3 points) and blogs or newsgroups (+2 points). Those type of texts are characterized by a large set of infrequent words, for which classical embeddings are typically poorly trained. Our approach does not seem to suffer from this problem as severely, as discussed in Section 2.

5.6 Ablation Results

In this experiment, we directly compare the LS representation with the SSKIP word-embedding feature set. In order to maintain a high level of performance, both character and capitalization features are used in all configurations. We want to point out that LS vectors are not adapted during training, contrarily to the SSKIP embeddings. Similarly to Section 5.3, we report in Table 7, for each feature configuration, the average F1 score as well as the standard deviation over five runs.

Model	CONLL	ONTONOTES
SSKIP	90.52 ($\pm$ 0.18)	86.57 ($\pm$ 0.10)
LS	89.94 ($\pm$ 0.16)	85.92 ($\pm$ 0.12)
all	**91.73 ($\pm$ 0.10)**	**87.95 ($\pm$ 0.13)**

Table 7: F1 scores of differently trained systems on CONLL and ONTONOTES 5.0 datasets. Capitalization (Section 4.2.3) and character features (Section 4.2.2) are used by default by all models.

We observe that on both CONLL and ONTONOTES, the SSKIP model outperforms our feature vector approach by 0.65 F1 points on average. The difference is not has high as we first expected, especially since the SSKIP model is adjusted during training, while our representation is not. Still, LS vectors seem to encode a large portion of the information needed to model the NER task. Also, it is worth mentioning that our embeddings are trained on 1.3B words compared to 42B for SSKIP.

We also observe that models that use both feature sets significantly outperform other configurations. To confirm that the gains came from our feature vector and not from increasing the number of hidden units, we tested several SSKIP models by increasing the LSTM hidden layer dimension so that number of parameters is the same as the model with LS vectors. We observed a degradation of performance on both datasets, mostly due to overfitting on the training set. From those results, we conclude that our lexical representation and the SSKIP one are complementary.

6 Related Works

Traditional approaches to NER, like CRF-based (Finkel et al., 2005) and Perceptron-based systems (Ratinov and Roth, 2009) have dominated the field for over a decade. They rely heavily on hand-engineered features (Luo et al., 2015) and external resources such as gazetteers. One major drawback of such an approach is its weak generalization power (Lample et al., 2016). Current state-of-the art systems (Chiu and Nichols, 2016; Strubell et al., 2017) use a combination of Convolutional Neural Networks (CNNs), Bi-LSTMs, along with a CRF decoder. CNNs are used to encode character-level features (prefix and suffix), while LSTM is used to encode word-level features. Finally, a CRF is placed on top of those models in order to decode the best tag sequence. Pre-trained embeddings obtained by unsupervised learning are core features of those models. In this work, we show that deep NN architectures can also benefit from lexical features, at least when encoded in the compact form we propose.

Tran et al. (2017) and Peters et al. (2017) propose an alternative approach different from ours. They incorporate LM embeddings that were pre-trained on a large unlabelled corpus as features for NER. These embeddings allow to generate a representation for a word depending on its context. For instance, the LM embeddings of the word *France* in "*France is a developed country*" is different than that in "*Anatole France began his literary career*". Such embeddings are trained on very large amount of texts.

Our feature set is crafted from distant supervision applied to Wikipedia, a much less time-consuming process which we showed to be nevertheless adapted to rare words. Chiu and Nichols (2016) used gazetteer features in order to establish state-of-the-art performance on both CoNLL and OntoNotes. They mined DBPedia in order to compile 4 lists of named-entities that contain over 2.3M entries. We show that LS representations outperform their gazetteer features.

7 Conclusion and Future Work

We have explored the idea of generating lexical features for NER out of Wikipedia data automatically annotated with fine-grained entity types. We used WiFiNE (Ghaddar and Langlais, 2018), a Wikipedia dump annotated with fine entity type mentions, for training a vector space that jointly embeds words and named-entities. This vector space is used to compute a 120 dimensional vector per word, which encodes the similarity of the word to each of the entity types. Our results show that our proposed lexical representation, even though it is not adjusted at training time, matches state-of-the-art results compared to more complex approaches on the well-studied CoNLL dataset, and delivers a new state-of-the-art F1 score of 87.95 on the more diversified OntoNotes dataset. We further observe larger gains on collections with more unfrequent words.

The source code and the data we used in this work are publicly available at `http://rali.iro.umontreal.ca/rali/en/wikipedia-lex-sim`, with the hope that other researchers will report gains, when using our lexical representation. As a future work, we want to investigate the usefulness of our LS feature representation on other NER tasks, including NER in tweets where out-of-vocabulary and low-frequency words represent a challenge; as well as finer-grained NER which suffers from the lack of manually annotated training data.

A Pseudo Label based Dataless Naive Bayes Algorithm for Text Classification with Seed Words

Ximing Li, Bo Yang*

College of Computer Science and Technology, Jilin University, China
Key Laboratory of Symbolic Computation and Knowledge Engineering of Ministry of Education, China
liximing86@gmail.com; ybo@jlu.edu.cn

Abstract

Traditional supervised text classifiers require a large number of manually labeled documents, which are often expensive to obtain. Recently, dataless text classification has attracted more attention, since it only requires very few seed words of categories that are much cheaper. In this paper, we develop a pseudo-label based dataless Naive Bayes (PL-DNB) classifier with seed words. We initialize pseudo-labels for each document using seed word occurrences, and employ the expectation maximization algorithm to train PL-DNB in a semi-supervised manner. The pseudo-labels are iteratively updated using a mixture of seed word occurrences and estimations of label posteriors. To avoid noisy pseudo-labels, we also consider the information of nearest neighboring documents in the pseudo-label update step, i.e., preserving local neighborhood structure of documents. We empirically show that PL-DNB outperforms traditional dataless text classification algorithms with seed words. Especially, PL-DNB performs well on the imbalanced dataset.

1 Introduction

Automatic text classification is one of the most popular directions in the machine learning community. A typical procedure for creating a classifier in supervised learning consists of two steps: (1) Given a collection of text documents, human experts define a number of category labels, and then manually assign these pre-defined labels to documents. We refer to these labeled documents as training dataset; (2) A supervised learning algorithm, e.g., support vector machines (SVMs), is trained on the training dataset, outputting a classifier for predicting future documents.

Manually labeling documents, i.e., step (1), is very expensive and time-consuming. Unfortunately, supervised learning algorithms often require massive labeled documents to avoid learning issues such as overfitting (Cawley and Talbot, 2010). A common way to reduce the labeling effort is developing semi-supervised learning algorithms, where one trains text classifiers on a mixture collection of a few labeled documents and a larger number of unlabeled documents (Nigam et al., 2000; Hu et al., 2017). However, semi-supervised learning still requires labeled documents, and manually labeling a small number of documents remains very expensive in many real world applications.

Recently, researchers have proposed a number of dataless text classification algorithms (Liu et al., 2004; Chang et al., 2008; Downey and Etzioni, 2008; Druck et al., 2008; Hingmire et al., 2013; Hingmire and Chakraborti, 2014; Chen et al., 2015; Li et al., 2016), which do not require labeled documents as training instances. Instead, they train text classifiers using unlabeled documents with seed words, i.e., the selected representative words for categories. Actually, manually choosing seed words is significantly cheaper than labeling documents (Raghavan et al., 2006; Druck et al., 2008), saving many human efforts. This kind of dataless algorithm has empirically achieved promising classification results, and it has become a practical alternative to supervised learning algorithms, especially when the labeled documents are extremely expensive to obtain.

Proceedings of the 27th International Conference on Computational Linguistics, pages 1908–1917
Santa Fe, New Mexico, USA, August 20-26, 2018.

A straightforward way of dataless classification is to construct a pseudo training dataset using the supervision information provided by seed words, before applying a traditional supervised classification algorithm (Liu et al., 2004; Druck et al., 2008). However, this methodology suffers from two problems. First, the documents containing no seed words can not be marked with any category label, resulting in a waste of instances to some extent. Unfortunately, there may exist a large number of such "unlabeled" documents, especially when the seed words are scarce. Second, the seed word based pseudo-labels are often quite noisy. That is because many documents may not contain the seed words from the true categories, but only contain the ones from unassociated categories.

To address the problems mentioned above, we develop a novel extension of the Naive Bayes classifier for dateless text classification, named pseudo-label based dataless Naive Bayes (PL-DNB). First, following (Nigam et al., 2000) we employ the expectation maximization (EM) algorithm to train PL-DNB in a semi-supervised manner, so that all the documents with and without pseudo-labels can be used for creating a classifier. Second, we iteratively update the pseudo-labels with highly acceptable confidence. The confidence values of pseudo-labels are measured by a mixture of seed word occurrences and estimations of label posteriors. Additionally, we aim to further avoid noisy pseudo-labels by preserving local neighborhood structure of documents. That is, for each document we update its pseudo-label by also considering the information of its nearest neighboring documents. We empirically compare the proposed PL-DNB algorithm against the dataless classification algorithms and traditional supervised algorithms. Experimental results indicate that our PL-DNB outperforms the existing dataless algorithms with seed words, and especially performs well on the imbalanced dataset

The rest of this paper is organized as follows: In Section 2, we introduce recent related works. In Section 3, we describe the proposed PL-DNB algorithm for dataless text classification. Section 4 presents the empirical results, and the conclusion is shown in Section 5.

2 Related Work

In this section, we review recent related works on dataless text classification and semi-supervised naive Bayes.

Dataless text classification There are some previous dataless text classifiers based on pseudo-labels. For example, the seed word naive Bayes (SNB) (Liu et al., 2004) computes information gain values of words over document clusters computed by k-means, and manually selects some top-ranked words as seed words to represent each category. It assigns pseudo-labels or probabilistic pseudo-labels to documents using these selected seed words. A naive Bayes classifier is then trained by the EM algorithm in a semi-supervised manner. Another dataless classification algorithm (Ko and Seo, 2004) constructs context-clusters as the basic unit using sliding windows, instead of documents. These context-clusters are associated with pseudo-labels using representative words occurring in category labels and titles. A naive Bayes classifier is also trained over these bootstrapped context-clusters. Compared with these previous algorithms, our PL-DNB creates pseudo-labels by further considering the information of nearest neighboring documents.This can lead to more accurate pseudo-labels than only using seed words.

Specifically, other dataless text classifiers aims to accurately categorize text documents by understanding the labels, i.e., embedding documents and category labels into a same semantic space (Chang et al., 2008; Palatucci et al., 2009; Elhoseiny et al., 2013; Song and Roth, 2014). The work of (Chang et al., 2008) builds a semantic space by exploiting the concepts of Wikipedia, and uses explicit semantic analysis to measure the distance between documents and labels. In some sense, this algorithm can be considered as a text classifier based on distant supervision (Mintz et al., 2008). Recently, the authors of (Song and Roth, 2014) further investigate dataless hierarchical text classification tasks. These dataless algorithms empirically performed well, however, they require auxiliary knowledge bases that are not always available.

Additionally, researchers have investigated some dataless text classifiers based on topic models, such as latent Dirichlet allocation (LDA) (Blei et al., 2003). The dataless classification algorithm proposed in (Hingmire et al., 2013), named classifyLDA, involves three steps: 1) learn a set of original topics by inferring the unsupervised LDA model over the concerned dataset; 2) manually assign a category

label to each topic, and then combine the topics that are associated with a same label into a new single topic; 3) classify test documents using the document-level posterior of those combined topics learned by unsupervised LDA. An extension algorithm (Hingmire and Chakraborti, 2014) of classifyLDA allows the original topics to be assigned to more than one category label in step 2, making the algorithm more flexible. Recently, the authors of (Li et al., 2016) propose a seed-guided topic model (STM), which simultaneously considers category word probability and initial document category distribution based on seed words. In STM, each category label is associated with a category-topic, and it further incorporates a new type of topic, i.e., general-topic, to filter out the noise words during Gibbs sampling. Empirical study in (Li et al., 2016) shows that STM consistently outperforms many existing dataless text classification algorithms. We present comparison results of this state-of-the-art STM in the experiment section.

Semi-supervised naive Bayes To the best of our knowledge, an early semi-supervised naive Bayes proposed in (Nigam et al., 2000) uses the EM algorithm to train a classifier over labeled and unlabeled documents, named NB-EM. The pooling multinomials algorithm (Yao et al., 2009) incorporates training documents with auxiliary knowledge, building a composite naive Bayes classifier for semantic analysis tasks. Recently, (Zhao et al., 2016) extends NB-EM by leveraging the word-level statistical constraint. These semi-supervised naive Bayes algorithms can be directly applied to text classification applications with a few labeled documents. However, manually collecting a small number of labeled documents remains expensive in many text analysis applications. In contrast, our PL-DNB only requires a much cheaper set of seed words, making it more practical.

3 Algorithm

We briefly review the framework of semi-supervised naive Bayes, and then present the proposed pseudo-label based dataless naive Bayes (PL-DNB) algorithm for dataless text classification with seed words.

3.1 Semi-supervised Naive Bayes

Suppose that there exists a collection of text documents $\mathcal{D}$, consisting of a subset of labeled documents $\mathcal{D}_L = \{(d_i, y_i)\}_{i=1}^{i=|\mathcal{D}_L|}$ and a subset of unlabeled ones $\mathcal{D}_U = \{d_i\}_{i=1}^{i=|\mathcal{D}_U|}$. Let $\mathcal{C} = \{c_i\}_{i=1}^{i=|\mathcal{C}|}$ and $\mathcal{W} = \{w_i\}_{i=1}^{i=|\mathcal{W}|}$ denote the set of category labels and the vocabulary of words, respectively.

The goal of semi-supervised text classification is to train a classifier over $\mathcal{D}$, which can automatically assign a correct category label for any test document. Semi-supervised naive Bayes is built on the Bayesian rule. Thanks to the bag-of-words assumption, it can classify a document *d* by a fully factored posterior distribution of labels:

$$y = \max_{c_i \in \mathcal{C}} \Pr(y = c_i|d), \qquad \Pr(y = c_i|d) \propto \Pr(y = c_i) \prod_{j=1}^{|\mathcal{W}|} \Pr(w_j|y = c_i)^{N_{d,w_j}} \tag{1}$$

where N_{d,w_j} is the occurrence number of word w_j in document *d*.

To achieve the parameter $\theta = \{\Pr(y), \Pr(w_j|y)\}$, semi-supervised naive Bayes employs the EM algorithm to maximize the following objective $\mathcal{L}(\theta)$, a mixture of the joint likelihood of labeled documents and marginal likelihood of unlabeled ones:

$$\mathcal{L}(\theta) = \sum\nolimits_{d \in \mathcal{D}_L} \log p(d, y) + \lambda \sum\nolimits_{d \in \mathcal{D}_U} \log p(d) \tag{2}$$

where $\lambda \in [0, 1]$ is a tuning parameter, controlling the importance of unlabeled documents.

3.2 Pseudo-label based Dataless Naive Bayes

Algorithm outline Overall, our PL-DNB is built on semi-supervised naive Bayes.

In the context of dataless classification, there are no labeled documents available. To address this, we initialize pseudo-labels $\widehat{y}^{(0)}$ for documents using seed word occurrences, leading to a set of documents with pseudo-labels $\mathcal{D}_L^{(0)}$ and a set of unlabeled documents that contain no seed words $\mathcal{D}_U^{(0)}$. After this initialization, PL-DNB iteratively performs the following two steps until the maximum iterative number is reached.

- **Step 1**: At each iteration *t*, use the EM algorithm to estimate the naive Bayes parameter $\theta^{(t)}$ by maximizing the following semi-supervised objective:

$$\mathcal{L}^{(t)}(\theta) = \sum\nolimits_{d \in \mathcal{D}_L^{(t-1)}} \log p(d, \widehat{y}^{(t-1)}) + \lambda \sum\nolimits_{d \in \mathcal{D}_U^{(t-1)}} \log p(d) \tag{3}$$

- **Step 2**: Given the optimum of $\theta^{(t)}$, compute the label posterior distributions for each document. We update pseudo-labels $\widehat{y}^{(t)}$ using these label posteriors and seed word occurrences. Only the pseudo-labels with acceptable confidence are left, leading to new document sets of $\mathcal{D}_L^{(t)}$ and $\mathcal{D}_U^{(t)}$.

Given the final optimum of θ, we can classify test documents using the label posterior distributions computed by Eq.1. For clarity, PL-DNB is summarized in *Algorithm 1*. We then introduce details of pseudo-label initialization, naive Bayes parameter θ update and pseudo-label $\widehat{y}$ update .

Algorithm 1 PL-DNB outline

1: **Initialize** pseudo-labels $\widehat{y}^{(0)}$ by seed word occurrences, obtaining $\mathcal{D}_L^{(0)}$ and $\mathcal{D}_U^{(0)}$
2: **For** $t = 1, 2, \ldots,$ MaxIter
3: **Update** the naive Bayes parameter $\theta^{(t)}$ using EM. Details are outlined in *Algorithm 2*
4: **Set** $\mathcal{D}_L^{(t)} = \mathcal{D}_U^{(t)} = \emptyset$
5: **For** $i = 1, 2, \ldots, |\mathcal{D}|$
6: **Assign** d_i a pseudo-label $\widehat{y}_i^{(t)}$ with acceptable confidence and **add** $(d_i, \widehat{y}_i^{(t)})$ into $\mathcal{D}_L^{(t)}$, otherwise
7: **add** d_i into $\mathcal{D}_U^{(t)}$
8: **End For**
9: **End for**

Pseudo-label initialization To incorporate the supervision information provided by seed words, we initialize pseudo-labels for each document using seed word occurrences. Since the selected seed words are representatives for categories, we suppose that a document containing more seed words of a category is more likely to be associated with this category. Following this, for each document *d* we compute the normalized seed word occurrence vector π_d as follows:

$$\pi_d(c_i) = \frac{SF_d(c_i) + \gamma}{\sum_{j=1}^{|\mathcal{C}|} SF_d(c_j) + |\mathcal{C}|\gamma} \tag{4}$$

where $SF_d(c_i)$ denotes the number of times that the seed words of category c_i have occurred in document *d*, and γ is a smoothing parameter used to avoid dividing by zero.[1] Then, the pseudo-label is initialized by the following rule:

$$\widehat{y}_d^{(0)} = \begin{cases} \infty & \text{if } \pi_d(c_1) = \pi_d(c_2), \cdots, = \pi_d(c_{|\mathcal{C}|}) \\ \underset{c_i \in \mathcal{C}}{\operatorname{argmax}}\, \pi_d(c_i) & \text{otherwise} \end{cases} \tag{5}$$

We do not assign a pseudo-label to document *d* without any seed word occurrence, denoted by ∞. We can obtain $\mathcal{D}_L^{(0)}$ and $\mathcal{D}_U^{(0)}$ by applying this initialization rule to all documents in $\mathcal{D}$.

Naive Bayes parameter θ update Given $\mathcal{D}_L^{(t-1)}$ and $\mathcal{D}_U^{(t-1)}$, the optimization of Eq.3 becomes a standard semi-supervised naive Bayes. We can use the EM algorithm to find the (local) optimum of $\theta^{(t)}$. This is achieved by iterating the following E-step and M-step. Due to the space limitation, we directly present the update equations without derivations.

In the **E-step**, we estimate the label posterior for each unlabeled document *d* using the Bayesian rule:

$$\Pr(y = c_i|d) = \frac{\Pr(y = c_i) \prod_{j=1}^{|\mathcal{W}|} \Pr(w_j|y = c_i)^{N_{d,w_j}}}{\sum_{c_h \in \mathcal{C}} \Pr(y = c_h) \prod_{j=1}^{|\mathcal{W}|} \Pr(w_j|y = c_h)^{N_{d,w_j}}} \tag{6}$$

[1] We empirically set γ to 0.01 in this work.

In the **M-step**, we update the naive Bayes parameter $\theta = \{\Pr(y), \Pr(w_j|y)\}$ with Laplace smoothing:

$$\Pr(y = c_i) = \frac{1 + \widehat{N}_{c_i} + \lambda \sum_{d \in \mathcal{D}_U} \Pr(y = c_i|d)}{|\mathcal{C}| + |\mathcal{D}_L| + \lambda |\mathcal{D}_U|} \tag{7}$$

$$\Pr(w_j|y = c_i) = \frac{1 + N_{c_i,w_j} + \lambda \sum_{d \in \mathcal{D}_U} N_{d,w_j} \Pr(y = c_i|d)}{|\mathcal{W}| + N_{c_i} + \lambda \sum_{d \in \mathcal{D}_U} \sum_{j=1}^{|\mathcal{W}|} N_{d,w_j} \Pr(y = c_i|d)} \tag{8}$$

where $\widehat{N}_{c_i}$ is the number of labeled documents marked with label c_i; N_{c_i,w_j} and N_{c_i} are the number of word w_j occurring and total number of words occurring in documents marked with label c_i, respectively. For clarity, we outline this EM procedure in *Algorithm 2*.

Algorithm 2 EM procedure outline for θ update

1: **Repeat**
2: **E-step**: Estimate the label posteriors for unlabeled documents using Eq.6
3: **M-step**: Update θ using Eqs.7 and 8
4: **Until convergence**

Pseudo-label $\widehat{y}$ update To update pseudo-labels $\widehat{y}^{(t)}$, for each document d we compute a label weight vector $\widehat{\pi}_d$ as follows[2]:

$$\widehat{\pi}_d(c_i) = \frac{\Pr^{(t)}(y = c_i|d) + \pi_d(c_i)}{2} \tag{9}$$

where $\Pr^{(t)}(y|d)$ is the label posterior distribution of document d estimated using the current $\theta^{(t)}$, and π_d the normalized seed word occurrence vector that has been shown in Eq.4. The pseudo-label is updated by the following rule:

$$\widehat{y}_d^{(t)} = \begin{cases} \underset{c_i \in \mathcal{C}}{\operatorname{argmax}}\, \widehat{\pi}_d(c_i) & \text{if } \max\limits_{c_i \in \mathcal{C}} \widehat{\pi}_d(c_i) > \delta \\ \infty & \text{otherwise} \end{cases} \tag{10}$$

where δ denotes an acceptable confidence threshold. This means that the dominate label in $\widehat{\pi}_d$ becomes the new pseudo-label for document d, if its weight in $\widehat{\pi}_d$ is larger than δ.

To avoid noisy pseudo-labels, we further consider the information of nearest neighboring documents. Following the intuition that the neighboring documents are more likely from a same category, we re-write the equation of $\widehat{\pi}_d$ by:

$$\widehat{\pi}_d(c_i) = \frac{\Pr^{(t)}(y = c_i|d) + \pi_d(c_i) + \sum_{j \in \Omega_d} \left(\Pr^{(t)}(y = c_i|j) + \pi_j(c_i) \right)}{2 \times (1 + |\Omega_d|)} \tag{11}$$

where Ω_d denotes the set of nearest neighboring documents for document d. In this work, we find Ω using the cosine similarity of TF-IDF representations, and empirically set $|\Omega_d|$ to 5.

4 Experiment

In this section, we empirically compare the proposed PL-DNB against both the existing dataless classification algorithms and traditional supervised algorithms.

4.1 Experimental Setup

Dataset and seed word set We employed two datasets of *Reuters*[3] and *Newsgroup*[4], which are usually used in text classification evaluations. In terms of *Reuters*, we left the 10 largest categories in the original

[2]Note that $\sum_{i=1}^{|\mathcal{C}|} \widehat{\pi}_d(c_i) = 1$

[3]http://kdd.ics.uci.edu/database/reuters21578/reuters21578.html

[4]http://qwone.com/∼jason/20Newsgroups/

Table 1: Statistics of datasets and sets of seed words. *#Train* / *#Test*: number of training/test documents; *#AvgDoc*: average length of documents; *#Label*: number of categories; *#Word*: number of unique words; S^L/S^D: average number of seed words in S^L/S^D.

Dataset	*#Train*	*#Test*	*#AvgDoc*	*#Label*	*#Word*	S^L	S^D
Reuters	5228	2057	70.8	10	7419	1	6
Newsgroup	11314	7532	152.1	20	52761	1	4.75

dataset, obtaining a dataset of 7285 documents in total. The training and test sets consist of 5228 and 2057 documents, respectively. Besides, the *Reuters* dataset is very imbalanced, where the largest category has 3713 documents but the smallest one has only 90 documents. In terms of *Newsgroup*, we used the "bydate" version, which contains totally 18846 documents divided into 20 categories. The training and test sets consist of 11314 and 7532 documents, respectively. The *Newsgroup* dataset is extremely balanced, where each category has about 900 documents. We apply traditional pre-processing methods to both datasets, i.e., removal of the standard stopwords, and the words that are shorter than 2 characters or occur in less than 5 documents.

Following (Chen et al., 2015; Li et al., 2016), we used two sets of seed words, denoted by S^L and S^D respectively. The seed words of S^L are directly selected from the category labels. We only left a single seed word for each category. The seed words of S^D are manually selected with the domain knowledge from additional candidate sets obtained by unsupervised learning algorithms. In contrast to S^L, the set of S^D contains more seed words.

For clarity, we show the statistics of the datasets and sets of seed words in Table 1.

Baseline algorithm To evaluate the effectiveness of PL-DNB, we compare it against four baseline algorithms, described as follows:

- **Seed word based naive Bayes (SNB)** (Liu et al., 2004): SNB is an early dataless naive Bayes algorithm that directly trains a classifier over the training documents with pseudo-labels in a semi-supervised manner. For a fair comparison, we omit the representative word selection step of SNB, but use the seed words of S^L and S^D just as other dataless algorithms

- **Seed-guided topic model (STM)** (Li et al., 2016): STM is a topic model based dataless text classification algorithm.[5] All crucial parameters of STM are tuned following the suggestions provided by its authors.

- **Naive Bayes (NB)**: We implement an in-house code of the supervised version of NB. The TF-IDF representation is used for documents.

- **Support vector machines (SVMs)**: We employ the *sklearn* tool[6] of SVMs with default parameter settings. The TF-IDF representation is also used.

Following the settings of (Li et al., 2016), we run dataless algorithms (i.e., SNB, STM and PL-DNB) over all documents, and only evaluate the classification results of test documents. For supervised algorithms (i.e., NB and SVMs), we train them over the training set, and also evaluate the results of test documents.

For the proposed PL-DNB, the numbers of the outer iteration and inner EM iteration are set to 10 and 5, respectively. The acceptable confidence threshold δ is set to 0.3. Besides, we empirically set the tuning parameter λ to 0 for *Reuters* and 0.3 for *Newsgroup*, respectively.

4.2 Comparison of Baseline Algorithms

In the experiment, we use Micro-F1 and Macro-F1 to evaluate the classification performance. For each algorithm, we independently run it 10 times, and show the average results in Tables 2 and 3.

Comparison of dataless algorithms In contrast to SNB, we can observe that the proposed PL-DNB algorithm performs better in all settings. Overall, the performance gain of Micro-F1 is about 0.05∼0.21, and that of Macro-F1 is about 0.06∼0.22. More importantly, PL-DNB significantly outperforms SNB with the seed word set of S^L. The result indicates that PL-DNB can achieve high classification performance with very few seed words. This makes PL-DNB more practical for the text analysis tasks, where even seed words are expensive to obtain. Additionally, since the main difference between SNB and PL-DNB is that PL-DNB exploits nearest neighboring documents to improve the pseudo-label update, the performance gain over SNB indicates that this nearest neighbor scheme is effective.

In contrast to STM, we can observe that PL-DNB gets higher scores in most settings. In terms of S^L, the Micro-F1 and Macro-F1 scores of PL-DNB are higher than those of STM across both datasets. For example, the improvements of Micro-F1 and Macro-F1 over STM are about 0.03 and 0.06 on *Reuters*, respectively. This further supports the above observation that PL-DNB can perform well with a few seed words. In terms of S^D, PL-DNB is competitive with STM, where PL-DNB gets higher Macro-F1 scores but slightly lower Micro-F1 scores.

Comparing between the two dataless baselines, STM gains better performance in all settings. This result is consistent with the empirical results reported in (Li et al., 2016). The possible reason is that STM incorporates the category word probability to exploit the discriminative power of words, which can effectively improve classification results.

Comparison of supervised algorithms First, we can observe that PL-DNB is a little worse than NB, where the performance gap is not very obvious. For example, the Micro-F1 and Macro-F1 scores of PL-DNB+S^D are only about 0.01 and 0.025 lower than those of NB on *Newsgroup*. That is, PL-DNB may approach the supervised version of NB given sufficient seed words. Second, PL-DNB performs worse than SVMs, however it uses very limited supervision during classifier training. In some sense, our PL-DNB can be considered as an important candidate algorithm for text classification, especially when collecting labeled documents for training is extremely expensive.

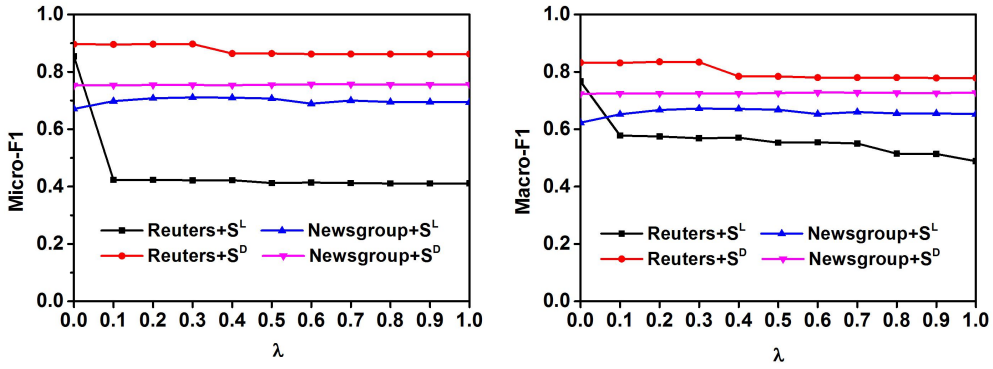

Figure 1: Evaluation on different values of λ

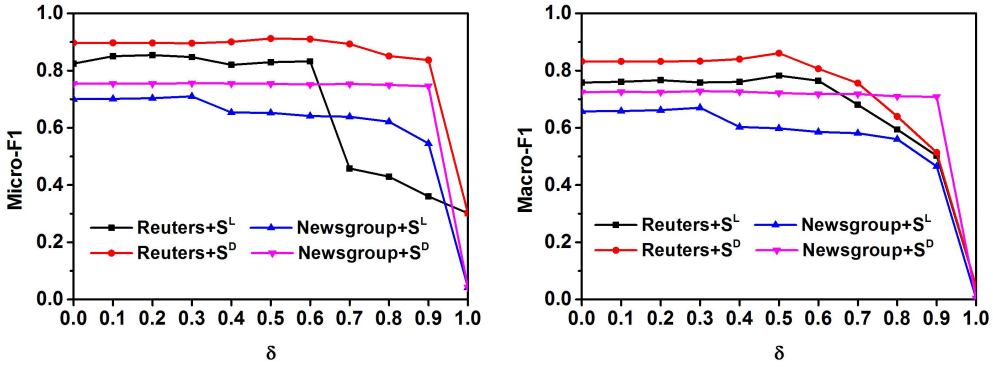

Figure 2: Evaluation on different values of δ

4.3 Evaluation of Parameters

In this section, we empirically evaluate two crucial parameters of PL-DNB, i.e., λ and δ.

Analysis of λ The parameter λ is used to control the importance of unlabeled documents during semi-supervised learning (ref. Eq.3). Note that $\lambda = 1$ means that unlabeled documents are equally important with labeled ones, and $\lambda = 0$ means that unlabeled documents are not utilized.

To evaluate the impact of λ, we examine the classification results of different values of $\lambda \in \{0, 0.1, 0.2 \cdots, 1\}$ when δ is fixed to 0.3. The experimental results of Micro-F1 and Macro-F1 are shown in Figure 1.

In terms of *Reuters*, we can observe that PL-DNB achieves higher scores when the value of λ is relatively smaller. Especially when the seed word set of S^L is utilized, the best scores are achieved at $\lambda = 0$, and significantly higher than scores of other λ values. The Micro-F1 score of $\lambda = 0$ is over 0.85, but those of other λ values are only about 0.4. Besides, the gap of Macro-F1 between $\lambda = 0$ and other values is about 0.2. Since S^L provides only one seed words for each category, a great majority of documents can not be initialized with pseudo-labels. At the beginning of optimization iterations, these unlabeled documents that are without any supervision prefer equally contributing to all categories, resulting in worse estimations of naive Bayes parameters. This problem grows worse for imbalanced datasets, because the smaller categories are much more sensitive to the noise. Additionally, smaller values of λ still perform better than larger ones when using the seed word set of S^D, but the gap is not obvious. The reason is that S^D can assign pseudo-labels to most of the documents. In summary, this evaluation result implies that for the imbalanced dataset PL-DNB prefers smaller λ values. We thus set $\lambda = 0$ for *Reuters* in our experiment.

In terms of *Newsgroup*, we can roughly observe that PL-DNB performs stable as λ varies. Overall, the

reason may be that *Newsgroup* is very balanced, so that PL-DNB is insensitive to unlabeled documents at the beginning of optimization iterations. For the setting of *Newsgroup*+S^D, both Micro-F1 and Macro-F1 scores are mostly the same with different values of λ. This is because only a small number of documents can not be initialized with pseudo-labels[7] by S^D. That is to say, λ only affects a few documents during the semi-supervised optimization step. Additionally, we see that the scores of PL-DNB are a bit higher when λ is in the interval $[0.1, 0.5]$ when using S^L. We empirically set $\lambda = 0.3$ for *Newsgroup* in our experiment.

Analysis of δ The parameter δ is a threshold used to determine whether a document can be marked with a pseudo-label in the pseudo-label update step (ref. Eq.10). On one hand, $\delta = 0$ means that all documents will be associated with pseudo-labels; On the other hand, a higher δ value implies that the updated pseudo-labels must be more "accurate".

We evaluate the classification results of different values of $\delta \in \{0, 0.1, 0.2 \cdots, 1\}$ by holding λ fixed to 0 for *Reuters* and 0.3 for *Newsgroup* respectively. The experimental results of Micro-F1 and Macro-F1 are shown in Figure 2.

Overall, we can observe that the classification performance is fast dropped as δ becomes larger. For example, the Micro-F1 score drops from 0.8 to 0.4 across *Reuters*+S^L when δ becomes larger; and especially all scores of $\delta = 1$ are very poor. The main reason of this trend is that the number of documents with pseudo-labels decreases as δ becomes larger. That is, less labeled documents can be used for training naive Bayes (ref. Eq.3). This result indicates that in the context of dataless classification, the number of labeled documents may be a bit more important then the quality of pseudo-labels.

In terms of *Reuters*, PL-DNB performs relatively stable as $\delta \in [0.1, 0.6]$, but worse when δ becomes larger than 0.6. In contrast, the performance of *Newsgroup* gets stable before δ achieves 0.9, especially when the set of S^D is utilized. This comparison indicates that the balanced dataset may be less sensitive to the value of δ than the imbalanced dataset. Additionally, the best scores of *Reuters* are achieved at $\delta = 0.5$ in most settings, but it is only a bit better than $\delta = 0.1, 0.2, 0.3, 0.4, 0.6$. The best scores of *Newsgroup* are mostly at $\delta = 0.3$. Empirically, we set δ to 0.3 for both datasets in our experiment.

5 Conclusion

In this paper, we develop a novel dataless PL-DNB classification algorithm, which can be directly trained on unlabeled documents with seed words, instead of labeled documents. In PL-DNB, we create pseudo-labels for documents and train a naive Bayes classifier over the pseudo training set in semi-supervised learning. The pseudo-labels are iteratively updated, and the information of nearest neighboring documents is considered to avoid noisy pseudo-labels. We examine the effective of PL-DNB on two popular datasets in classification evaluations, where one is imbalanced and the other is balanced. Empirical results indicate that PL-DNB performs better than the state-of-the-art dataless text classifiers, especially for the imbalanced dataset. Specially, PL-DNB achieves competitive performance with supervised naive Bayes in some settings.

Abstract

Visual question answering (VQA) is a challenging task that requires a computer system to understand both a question and an image. While there is much research on VQA in English, there is a lack of datasets for other languages, and English annotation is not directly applicable in those languages. To deal with this, we have created a Japanese VQA dataset by using crowdsourced annotation with images from the Visual Genome dataset. This is the first such dataset in Japanese. As another contribution, we propose a cross-lingual method for making use of English annotation to improve a Japanese VQA system. The proposed method is based on a popular VQA method that uses an attention mechanism. We use attention maps generated from English questions to help improve the Japanese VQA task. The proposed method experimentally performed better than simply using a monolingual corpus, which demonstrates the effectiveness of using attention maps to transfer cross-lingual information.

1 Introduction

Visual question answering (VQA) is the automated task of answering questions about a given image, which is a difficult task because the computer system must understand both the question (natural language processing, or NLP) and the image (computer vision). Recently there has been much research on VQA but the existing literature focuses only on English. Because each language differs in its grammar and resources, there is a pressing need to develop VQA systems for different languages. The effort to develop such systems is hindered by a lack of language resources. In this paper, we discuss two ways to address the lack of datasets for languages besides English. First, by using images from the Visual Genome dataset (Krishna et al., 2016) and annotation through crowdsourcing, we have created the first VQA dataset for Japanese. We call it the Japanese Visual Genome VQA dataset. It consists of 99,208 images with a total of 793,664 Japanese question answering (QA) pairs, for an average of eight QA pairs per image. The examples of obtained Japanese questions are shown along with the English version of Visual Genome questions in Figure 1. Second, we propose a cross-lingual method of exploiting the information in an existing English dataset to help improve the performance of our Japanese system in a VQA setting.

The difficulty of applying a cross-lingual method for VQA is the diversity of questions that one can ask about an image. For image captioning (Miyazaki and Shimizu, 2016), English and Japanese captions on the same image are generally considered as comparable corpora. Questions for VQA, however, can be quite diverse as compared to image captions, because they are not necessarily specific to the image. For example, questions about the time of day can be asked for almost any image available. As such questions might appear in one language but not in another, it is much tougher to exploit questions across languages.

On the other hand, striking features of an image are usually picked up by several questions. The motivation of our approach is based on experiences as a bilingual and a second language learner. Sometimes

E17: What is in the distance?
E18: What website is on the bottom of the photo?
E19: What is under the plane?

Figure 1: Examples of (a) Japanese questions from our dataset and (b) English questions from the Visual Genome dataset. A Japanese question with an equivalent English question is matched, for example J2 – E2. The translations of J1, J3, J4, and J7 are as follows. J1: What form of transport is it? J3: What is the color of the letters on the body? J4: What is the airplane doing? J7: In which direction is the airplane going?

we can infer what a foreign language speaker is saying simply from the situation we are in. If we happen to be paying attention to the same object, we share the contexts and are likely to have similar perceptions.

We thus propose the first-ever method for cross-lingual VQA, enabling us to exploit questions in English to improve the performance of our VQA system in Japanese. In our method, we first generate attention maps for the English questions about an image. We then input these attention maps to the Japanese VQA system. We use the method given in Lu et al. (2016) both to generate the attention maps and to provide an experimental baseline. Our proposed cross-lingual method is simple yet effective, as we simply replace the input image feature from Lu et al. (2016) in our Japanese system with the attention maps generated from English questions. In our experiment, the proposed method using cross-lingual information produced better results than did the method using only a monolingual corpus. Because the attention maps generated from English questions tended to focus on salient objects in the images, our results also suggest the possibility of improving VQA through saliency modeling.

Our contribution is thus twofold. First, we have created a Japanese VQA dataset, which we believe is the first such dataset to be released[1]. Second, by using cross-lingual information to perform the VQA task, we obtain better results than by simply using a monolingual corpus, demonstrating the effectiveness of cross-lingual information.

The remainder of the paper is organized as follows. In section 2, we discuss English VQA datasets and related work using attention maps for the VQA task. In section 3 we introduce our dataset, including its construction and statistics. We then explain both the method used to generate attention maps from English questions and our proposed cross-lingual method in section 4. Experimental results are given in section 5 and we conclude the paper with a brief summary in section 6.

2 Related Work

In this section we discuss three related topics: first, four English datasets that have been generally used in VQA; second, some recent work on VQA with attention mechanisms, which have become a popular approach for VQA tasks; and last, cross-lingual models used in NLP. The attention-based approach involves generating image regions, called "attention maps," that are relevant to answering questions and then using the attention maps to generate answers.

[1]The dataset is to be released at `https://research-lab.yahoo.co.jp/en/software/`.

2.1 Datasets

A typical VQA dataset contains at least an image, a question for the image and the answer. Sometimes additional annotations, such as image regions relevant to the answers, or image captions, are provided as well. A number of datasets have been proposed for the VQA task in recent years; however, most of them are in English. In the following paragraphs we list the VQA datasets that have been generally used in this field and one multi-lingual VQA dataset with Chinese original VQA pairs and their English translations. The details are presented below.

The VQA dataset (Antol et al., 2015) contains 614,163 questions and 7,984,119 answers (including answers provided by humans either looking or not looking at the corresponding images) for 204,721 images from Microsofts COCO dataset (Lin et al., 2014), along with 150,000 questions and 1,950,000 answers for 50,000 abstract scenes. This dataset has two modalities for answering questions: open-ended and multiple-choice; in contrast, our dataset focuses on open-ended answers.

The Visual Genome (Krishna et al., 2016) dataset contains 1,773,258 QA pairs. On average, an image has 17 QA pairs. This dataset has two types of QA pairs (freeform QAs, which are based on the entire image, and region-based QAs, which are based on selected regions of the image) and six types of questions (what, where, when, who, why, and how). A subset of the freeform QA portion of Visual Genome is released as Visual 7W (Zhu et al., 2016). Because the release date of Visual 7W precedes that of Visual Genome, evaluations of VQA systems on freeform QA pairs are often conducted in Visual 7W instead of Visual Genome.

The COCO-QA (Ren et al., 2015) dataset was automatically generated from captions in the COCO dataset. It contains 78,736 training questions and 38,948 test questions, with the questions divided into four types: object questions, number questions, color questions, and location questions. Each answer consists of one word.

The DAQUAR (Malinowski and Fritz, 2014) dataset was built on top of the NYU-Depth V2 dataset (Silberman et al., 2012).The answers are mostly single-word answers. The complete dataset has 6,795 training QA pairs and 5,674 test pairs. On average, an image has nine QA pairs and the answers encompass 894 categories. The Reduced DAQUAR dataset is a subset of the complete DAQUAR dataset and contains 3,876 training samples, 297 test samples, and answers in 37 categories.

The Chinese Baidu dataset FM-IQA (Gao et al., 2015) uses 123,287 images sourced from the COCO dataset. The difference from COCO-QA is that the questions and answers were provided by human annotators through a crowdsourcing platform operated by Baidu. The annotators were free to add any type of question if it related to the content of the given image. This led to a much greater diversity of questions than in previously available datasets. Answering such questions typically requires both understanding the visual content of the image and incorporating prior "common sense" information. The dataset contains 120,360 images and 250,560 QA pairs, which were originally provided in Chinese and then converted to English by human translators.

Besides FM-IQA, the lack of datasets in languages other than English is striking. This situation hinders VQA research in other languages, such as Japanese. We intend our dataset to remedy this situation by providing resources in a morphologically rich language for the first time.

2.2 Attention-Based Methods for VQA

Previous studies have used information from whole images, but many questions and answers relate specifically to local regions in images. Many recent studies have thus focused on attention models, which select image regions relevant to answering questions, to deal with the VQA task (Xu and Saenko, 2016; Xiong et al., 2016; Shih et al., 2016; Yang et al., 2016; Lu et al., 2016). Shih et al. (2016) developed an approach for learning to answer visual questions by selecting image regions relevant to a text-based query. The approach maps textual queries and visual features from various regions into a shared space in which they are compared for relevance by applying an inner product. Yang et al. (2016) presented stacked attention networks (SANs), which account for the fact that VQA often requires multiple reasoning steps. The stacked attention model locates image regions relevant to the question for answer prediction via multi-step reasoning. While the above two approaches only use attention maps based on image regions,

Lu et al. (2016) proposed a co-attention model for VQA, which jointly considers attention to both the image and the question. Attention to the question (which should be valued equally with attention to the image) represents the importance, in terms of probability, of each word in the question for answering the question. Because Lu et al. (2016) released work describing the implementation of this co-attention model and their results are easy to reproduce, we adopted their implementation as the foundation of our proposed method. We also used their work as a monolingual baseline.

2.3 Cross-Lingual Model

While resources in English have been quickly developed and are abundant by now, other languages have fallen behind in terms of the size and variety of their resources. To remedy this, some research leverages the existing knowledge in English to help process other languages. These multilingual resources capture valuable information that can be used in many fields and is especially useful for languages lacking resources. Many cross-lingual models have been proposed in NLP. These models are trained on a parallel corpus and find ways to connect between two languages, usually through supervised or semi-supervised learning. Cross-lingual information retrieval is another task that requires cross-lingual modeling (Jagarlamudi and Kumaran, 2007; Ballesteros and Croft, 1996), in which the query and results are written in different languages. In word embedding research, some studies have tried to transfer linguistic knowledge from one language to another, especially from English to low-resource languages, through distributed representations at the word level (Hermann and Blunsom, 2013; Haghighi et al., 2008; Klementiev et al., 2012).For image captions, Miyazaki and Shimizu (2016) proposed a caption generation model that transfers cross-lingual information from English to Japanese through pretraining of the model. Our proposed method shows that image attention maps can be used to transfer information cross-lingually. While the transfer in Miyazaki and Shimizu (2016) occurs at a fully connected layer after fc7 in the VGG16 model, our information transfer occurs at the attention-map level and is spatially interpretable.

Cross-lingual information is very useful, especially when dealing with sparse language resources. Although many cross-lingual learning models have been proposed, to our knowledge there has been no such prior research for the VQA task. This paper, we believe, reports the first work done on using cross-lingual information in the VQA field.

3 Statistics for Japanese Dataset

To create a Japanese version of a VQA corpus that would be comparable to the English version, we chose the Visual Genome dataset as a starting point. As noted previously, Visual Genome has two types of QA pairs: freeform and region-based. Our dataset is meant to be comparable to the freeform QA part of Visual Genome, which is similar to other VQA corpora, except for its focus on six types of questions (what, where, when, who, why, and how). Krishna et al. (2016) stated the benefits of focusing on those six question types as follows:

> First, they offer a considerable coverage of question types, ranging from basic perceptual tasks (e.g. recognizing objects and scenes) to complex common sense reasoning (e.g. inferring motivations of people and causality of events). Second, these categories present a natural and consistent stratification of task difficulty ... For instance, why questions that involve complex reasoning lead to the poorest performance ... of the six categories. This enables us to obtain a better understanding of the strengths and weaknesses of todays computer vision models, which sheds light on future directions in which to proceed.

3.1 Crowdsourcing Procedure

Visual Genome was created with Amazon Mechanical Turk (AMT), a well-known crowdsourcing platform for microtasks. To create a comparable Japanese dataset, we used a similar platform called Yahoo! Crowdsourcing, operated by Yahoo Japan Corporation. While AMT participants can be from anywhere in the world and have any mother language, participants in Yahoo! Crowdsourcing can be safely assumed to be proficient in Japanese, since such proficiency is required for signing up, navigating the user interface, and participating in the microtask market.

For collecting the freeform QA data in Visual Genome, consider a procedure with the following conditions: (1) Crowdsourcing participants are asked to view an image and write eight QA pairs related to it. (2) The participants are instructed that each question should start with one of the six question words - what, where, when, who, why, and how. (3) To encourage diversity, the participants are asked to write questions using at least three different question words out of the six.

While the above conditions are simple for English, we encountered several problems in creating a Japanese procedure with similar conditions. The second condition was especially troublesome. First, in the Japanese language, creating an interrogative sentence out of a declarative one does not require changing the word order. Since Japanese questions typically do not start with a question word, asking participants to write a question starting with such a word did not make sense. Second, just as English allows the phrase "what time" instead of "when," Japanese allows "what place" for "where," "what reason" for "why," "what number" for "how many," and so on. We thus attempted to list Japanese interrogative words similar to the six English question words used in Visual Genome: *nani* (what), *dare* (who), *doko* (where), *donna* (what kind), *dorekurai* (how much), *dou* (how), *itsu* (when), *ikutsu* (how many), and *naze* (why). We recognized, however, that the Japanese equivalent *nani* for "what" could become a catch-all category used for questions that would otherwise be asked with when/where/how/why and so on in English.

Once we came up with the Japanese equivalents of the six question words, we posted a pilot task that asked participants to view an image and write eight QA pairs. We found that some participants reused the same QA pairs over and over, on the basis of common knowledge. Consider, for example, the QA pair of "What color is the sky?" and "Blue." Such a pair could be applicable to any outdoor image in the daytime. Given this experience with the pilot task, we modified the instructions to disallow such repeated QA pairs. All instructions and examples are provided in Japanese. The following instructions (translated into English) are the modified version:

> Please enter eight pairs consisting of a question and its answer in Japanese about the image linked by the URL.
>
> Please follow the following four rules in writing the question/answer pairs.
>
> Rule 1: Every question must use one of the following question words: *nani* (what), *dare* (who), *doko* (where), *donna* (what kind), *dorekurai* (how much), *dou* (how), *itsu* (when), *ikutsu* (how many), or *naze* (why). Example of a rule violation: "Question: Which is it, raining or sunny?" Reason for the violation: The word "which" is not in the list of question words.
>
> Rule 2: Every question must be distinct and ask something different. Furthermore, the eight questions must include at least three different question words from the list. Example of a rule violation: The eight questions use only the question words *nani* (what) and *dare* (who). Reason for the violation: The eight questions do not use at least three of the question words from the list.
>
> Rule 3: All eight questions must have a commonly agreed answer. Example of a rule violation: "Question: What is the man in the image thinking?" Reason for the violation: The answer is not commonly agreed.
>
> Rule 4: All eight questions must require the image content for the correct answer. Example of a rule violation: "Question: What is the color of the sunset? Answer: Red." Reason for the violation: This question is answerable with common knowledge, so it does not require the image content.

After conducting the pilot task, we examined the results and selected promising participants (comprising a whitelist) for future task requests, so that only participants on the whitelist could perform the next task. We repeated this selection process until the final whitelist included about 1,500 participants. About 200-250 of them regularly participated in the actual VQA collection task. We posted tasks in small batches over the course of six months to prevent participants from working long hours. Despite

	Nine question types									other
	nani what	*dare* who	*doko* where	*donna* what kind	*dorekurai* how much	*dou* how	*itsu* when	*ikutsu* how many	*naze* why	
Whole set	386,113	21,294	78,568	146,493	21,195	24,826	85,893	15,748	3,135	10,883
Test set	29,765	1,392	6,076	11,167	1,586	1,743	6,408	1,066	215	1,124

Table 1: Numbers of QA pairs in each category.

these measures, some participants eventually started to enter short, meaningless characters. To remove such noise, we removed sets of eight QA pairs whose question lengths averaged less than four characters.

3.2 Dataset Statistics and Analysis

The resulting Japanese VQA dataset consists of 99,208 images from Visual Genome, together with 793,664 QA pairs in Japanese, since every image has eight QA pairs.

Data quality. To ensure the consistency and integrity of the corpus, we randomly sampled and manually checked 800 QA pairs. Among those pairs, we found that six contained a minor typo, ten had a wrong answer, and two had an ambiguous question. In addition, four had questions answerable with common knowledge, while 29 had questions that were not based on one of the six question words and thus answerable with "yes" or "no." Thus, we found that 93.6% of the QA pairs correctly conformed to the specification. If we include the four pairs related to common knowledge, the figure increases to 94.1%, and if we also include the 29 pairs with a yes-no question and the six questions with a minor typo, it increases to 98.5%. Overall, we found that the quality of the QA pairs was very good.

Question type distribution. Unlike with English questions, which are easily classified according to the six question words (what, where, when, who, why, how), with Japanese questions grammar makes such classification more difficult. As mentioned in section 3.1, the questions in the Japanese dataset were classified into nine question types by nine words: *nani* (what), *dare* (who), *doko* (where), *donna* (what kind), *dorekurai* (how much), *dou* (how), *itsu* (when), *ikutsu* (how many), and *naze* (why). These nine words cover most Japanese questions. In addition to checking 800 QA pairs, we also examined 100 sets of eight QA pairs each and found twelve sets of questions that did not have at least three different question words. While the crowdsourcing participants sometimes did not follow the instructions exactly, we believe that this did not significantly decrease the diversity of question types. As shown by the statistics listed in Table 1, the question types in the corpus varied considerably.

Question and answer length distributions. We used MeCab to tokenize the Japanese questions and answers. Figure 2 shows the resulting distribution of average lengths for each category.

Comparison with English version. Manual examination of our corpus revealed that questions were very similar to the original English version of Visual Genome. An image with Japanese and English samples is shown in Figure 1. Generally, there are two to three times more QA pairs per image for the English version than for the Japanese version and questions often overlap. In Figure 1, J2 and E2, J5 and E14, J5 and E14, J6 and E1, and J8 and E15 are paired because they are essentially the same question.

4 Methodology

The method introduced in section 4.1 was used both to generate attention maps from English questions and to provide an experimental baseline. Section 4.2 describes how we used cross-lingual information (that is, the attention maps generated from the English data) to improve the performance of the Japanese VQA system.

4.1 Baseline

In this section, we briefly introduce material from Lu et al. (2016). That work proposed a VQA co-attention model, which jointly considers attention to both the image and the question. We used this approach for two purposes: first, to generate visual attention maps for English; and second, to provide a baseline for our experiment.

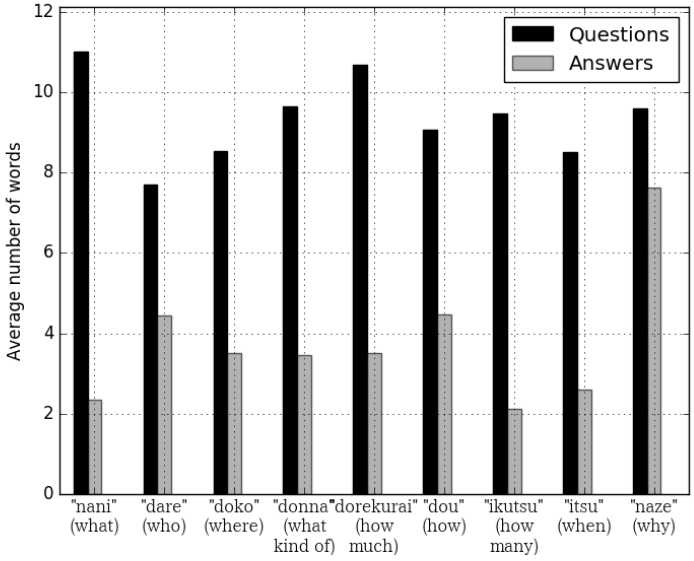

Figure 2: Average lengths of questions and answers for each question type.

A question consisting of T words is represented by $\mathbf{Q} = \{\mathbf{q}_1, ..., \mathbf{q}_T\}$, where $\mathbf{q}_t$ is the feature vector for the t-th word. Then, $\mathbf{q}_t^w$, $\mathbf{q}_t^p$, and $\mathbf{q}_t^s$ represent respectively the word embedding, phrase embedding, and question embedding at position t. The feature vectors are extracted the same way as in Lu et al. (2016) using LSTM (Hochreiter and Schmidhuber, 1997). The image feature is represented by

$$\mathbf{V} = \{\mathbf{v}_1, ..., \mathbf{v}_i, ..., \mathbf{v}_N\}, \tag{1}$$

where $\mathbf{v}_i$ is the feature vector for the i-th spatial location. N is the number of grids in an image, which in our case is 96 (14 by 14). The co-attention features of the question and image at each level in the hierarchy are respectively denoted as $\hat{\mathbf{q}}^r$ and $\hat{\mathbf{v}}^r$, where $r \in \{w, p, s\}$ (i.e., the level of a word, phrase, or question).

As noted in section 2, there are two attention maps in this model, for attention to the image and to the question. Depending on the order in which the image and question attention maps are generated, there are two co-attention mechanisms in Lu et al. (2016): parallel co-attention, and alternating co-attention. Because Lu et al. showed that parallel co-attention outperforms alternating co-attention, we chose the former as a baseline model and building block of our proposed model. We forgo explaining the mechanism of the latter here.

Parallel Co-Attention. The parallel co-attention mechanism generates the image and question attention maps simultaneously. Given an image feature map $\mathbf{V} \in R^{d \times N}$ and a question representation $\mathbf{Q} \in R^{d \times T}$, the mechanism calculates the similarity between the image and question features for all pairs of image locations and question positions:

$$\mathbf{C} = \tanh(\mathbf{Q}^\top \mathbf{W}_b \mathbf{V}), \tag{2}$$

where $\mathbf{C} \in R^{T \times N}$ is the resulting affinity matrix, and $\mathbf{W}_b \in R^{d \times d}$ contains weights. Then, the mechanism uses the affinity matrix as a feature for learning to predict the image and question attention maps:

$$\begin{aligned}
\mathbf{H}^v &= \tanh(\mathbf{W}_v \mathbf{V} + (\mathbf{W}_q \mathbf{Q})\mathbf{C}) \\
\mathbf{H}^q &= \tanh(\mathbf{W}_q \mathbf{Q} + (\mathbf{W}_v \mathbf{V})\mathbf{C}^\top) \\
\mathbf{a}^v &= softmax(\mathbf{w}_{hv}^\top \mathbf{H}^v) \\
\mathbf{a}^q &= softmax(\mathbf{w}_{hq}^\top \mathbf{H}^q),
\end{aligned} \tag{3}$$

where $\mathbf{W}_v, \mathbf{W}_q \in R^{k \times d}$, $\mathbf{w}_{hv}$, and $\mathbf{w}_{hq} \in R^k$ are weight parameters. Then, the image attention map is $\mathbf{a}^v \in R^N$ and the question attention map is $\mathbf{a}^q \in R^T$. These represent respectively the attention probabilities for each image region $\mathbf{v_n}$ and word $\mathbf{q_t}$. Finally, the mechanism calculates the image and question attention vectors:

$$\hat{\mathbf{v}} = \sum_{n=1}^{N} a_n^v \mathbf{v}_n, \ \hat{\mathbf{q}} = \sum_{t=1}^{T} a_t^q \mathbf{q}_t. \tag{4}$$

The parallel co-attention mechanism is applied at each level in the hierarchy, leading to $\hat{\mathbf{v}}^r$ and $\hat{\mathbf{q}}^r$, where $r \in \{w, p, s\}$.

4.2 Proposed Method

The goal of our method is to use the information learned from the English dataset to help improve the performance of the Japanese dataset. First, we use the method introduced in the previous section to generate attention maps for each image by using English questions. Then, for the Japanese Visual Genome QA dataset, we define an image feature $\mathbf{V}_{new}$ created from the attention maps and the image feature defined by eq. (1). Finally, we replace the image feature $\mathbf{V}$ in eqs. (2) and (3) with $\mathbf{V}_{new}$, and the method then proceeds as in Lu et al. (2016). We discuss the details below.

First, our method learns information from the English dataset. For each English question and image pair in Visual Genome, we generate one visual attention map $\mathbf{a}^v = \{\mathbf{a}_1^v, ..., \mathbf{a}_i^v, ..., \mathbf{a}_N^v\}$, where $\mathbf{a}_i^v$ contains the attention probabilities for image region $\mathbf{v}_n$. An image with $\mathbf{M}$ English questions thus has $\mathbf{M}$ attention maps $\mathbf{a}^v$, which we average to obtain a final attention map:

$$\mathbf{a} = \frac{1}{M} \sum_{m=1}^{M} \mathbf{a}_m^v, \ where \ \mathbf{a} \in R^N. \tag{5}$$

Then, the information learned from the English dataset (i.e., the image attention maps) is used for Japanese VQA prediction. The motivation for using these attention maps is that although the English and Japanese questions for the same image are usually different, the foci of attention most likely overlap. Letting $\mathbf{a} = (a_1, ..., a_N)$, we represent the image feature as $\mathbf{V}_{new} = \mathbf{Va} = (a_1\mathbf{v}_1, .., a_n\mathbf{v}_n)$. Finally, after replacing $\mathbf{V}$ with $\mathbf{V}_{new}$, our proposed method proceeds as in section 4.1 to learn the Japanese VQA model and predict Japanese answers. When the method is not considering information learned from the English dataset, it sets $\mathbf{a} = I$ (a vector with all elements set to 1).

5 Experiment

5.1 Setup

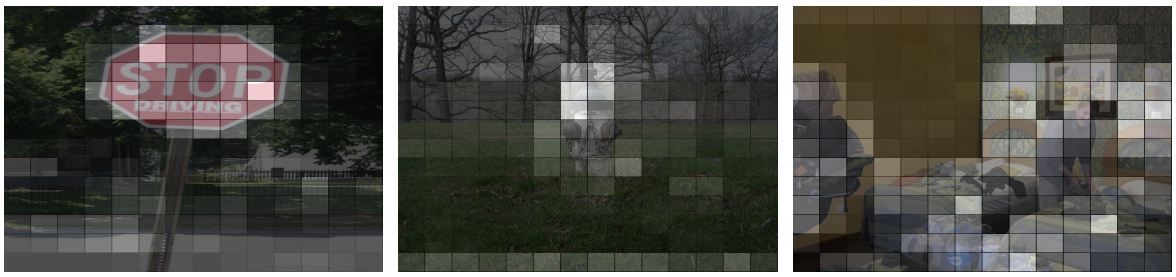
Our experimental baseline was the parallel co-attention model trained using the Japanese corpus. The proposed method uses the same model but with the attention maps initialized with the English corpus and then trained with the Japanese corpus. We divided our dataset into two parts for training and testing. The numbers of images in the training and test sets are respectively 91,609 and 7,599. The test set has 60,525 QA pairs. There are 135,740 unique answers in our dataset. We used the top 1,000 most frequent answers as the possible outputs, which covers 66.7% of the answers found in our dataset.

We used the RMSProp optimizer with a base learning rate of 4e-4, momentum 0.99, and weight decay 1e-8 and set the batch size to 20. We used VGG-19 (Simonyan and Zisserman, 2014), which is based on CNN (Fukushima, 1980; LeCun et al., 1989), to extract image features and MeCab (Kudo, 2005) to tokenize Japanese sentences. We performed 250,000 iterations.

5.2 Results and Analysis

For evaluation, we used the following definition of ***accuracy***:

$$\text{accuracy} = \frac{\text{No. of correctly classified questions}}{\text{No. of questions}} \tag{6}$$



(a) "mannaka ni utsutteiru hyoushiki ha naniiro desuka?" (b) "mannaka ni utsutteiru mono ha nan desuka?" (c) "ningen no mae ni donna kagu ga arimasu ka?"

Figure 3: Examples of attention maps for which the proposed method predicted the correct answer but the baseline method without cross-lingual attention maps did not. Questions: (a) What color is the road sign? (b) What is the object in the middle of the picture? (c) What is the furniture in front of the man?

	# images in training set		
Method	30,536	61,072	91,609
baseline	17.1%	17.7%	18.3%
proposed	**18.0%**	**18.8%**	**19.2%**

Table 2: Average accuracy with varying training set sizes. Each cell contains the average accuracy over four runs. All differences are statistically significant according to McNemar's test.

Figure 3 shows examples of attention maps that were generated from English questions and correctly predicted the answers for the Japanese dataset. For the same images, the baseline system without cross-lingual attention maps predicted wrong answers. We found that the attention maps usually focused on foreground objects and that accuracy tended to improve for images with clear foreground objects. Table 3 lists the accuracy by question type. For all question types except "why" questions, the cross-lingual attention maps improved the performance.

Because we trained and evaluated both our model and the baseline three times, Table 2 lists the average accuracies for each case. Our proposed model achieves 19.2% accuracy with 91,609 images in the training set. Note that our task is much tougher than in prior work (Zhu et al., 2016; Lu et al., 2016). In Zhu et al. (2016), the outputs are chosen from four multiple choices. While in Lu et al. (2016) the outputs are chosen from the same top 1,000 frequently occurring answers, the coverage of this set for their VQA corpus is 86.54%, unlike our 66.7%. The table also illustrates how the accuracy increased with the number of training images. Our method consistently performed around 1% better than the baseline method in all cases. As the performance increase was consistent across systems, we believe that using cross-lingual information should also improve performance in other situations. We can also see from Table 2 that the performance difference between the proposed method and the baseline did not decrease as the number of training images increased, which shows the value of our method for both larger and smaller datasets.

6 Conclusion

We have created a Japanese visual question answering (VQA) dataset comparable to the freeform question answering portion of the Visual Genome dataset (Krishna et al., 2016). This dataset is the first such dataset in Japanese. To show the utility of our corpus, we proposed a cross-lingual method for making use of English annotation to improve the Japanese VQA system. The proposed method experimentally

	Accuracy (%)

baseline	19.9	26.1	14.4	20.3	15.5	24.4	53.1	18.9	**5.1**
proposed	**21.1**	**27.5**	**15.2**	**21.9**	**17.6**	**25.8**	**55.2**	**19.1**	**5.1**

Table 3: Accuracy for each of the nine Japanese question types.

performed better than simply using a monolingual corpus, which demonstrates the effectiveness of using attention maps to transfer cross-lingual information.

While VQA is mainly a testbed for monolingual image understanding, our data together with the original English Visual Genome allows modeling how a bilingual person understands images and two languages, which we call bilingual image understanding. We believe the release of our dataset will add significant resources to the research in this direction.

Abstract

Modern and post-modern *free verse poems* feature a large and complex variety in their poetic prosodies that falls along a continuum from a more fluent to a more disfluent and choppy style. As the poets of modernism overcame rhyme and meter, they oriented themselves in these two opposing directions, creating a *free verse spectrum* that calls for new analyses of prosodic forms. We present a method, grounded in philological analysis and current research on cognitive (dis)fluency, for automatically analyzing this spectrum. We define and relate six classes of poetic styles (ranging from *parlando* to *lettristic decomposition*) by their gradual differentiation. Based on this discussion, we present a model for automatic prosodic classification of spoken free verse poetry that uses deep hierarchical attention networks to integrate the source text and audio and predict the assigned class. We evaluate our model on a large corpus of German author-read post-modern poetry and find that classes can reliably be differentiated, reaching a weighted f-measure of 0.73, when combining textual and phonetic evidence. In our further analyses, we validate the model's decision-making process, the philologically hypothesized continuum of fluency and investigate the relative importance of various features.

1 Introduction

One of the most important explanations for modern art is the theory of aesthetic pleasure, which claims that the fluency of cognitive processing is the cause for the positive effect of aesthetic experience (Topolinski and Strack, 2009). Similarly, cognitive research on fluency showed that people rate stimuli that are processed more easily higher (Belke et al., 2010). On the other hand, many modern artists like Picasso or Schönberg complicated the processability of their works using processes of abstraction in order to prevent such automated or fluid forms of art comprehensibility. Regarding this development, Bullot and Reber introduced the term *disfluency* as an artistic strategy to bring more analytical forms of art experience to the fore (Bullot and Reber, 2013). Other researchers suggested that disfluency prompts people to process information more carefully, deeply, and on a higher level of abstraction (Smith and Smith, 2006).

We present a computational analysis that tests these two trends in the current discussion on art experience by focusing on the prosodic feature of (dis)fluency in modern and post-modern poetry. We assume that the rhythmical quality of modern poetry is "not properly measurable by the rules of traditional verse" (Wesling, 1996), since modern poetry often rejects the traditional metrical verse. Most modern and post-modern poetry uses rhythmical features beyond the metrical forms, preferring the imitation of naturalness of everyday language and its very fluent speech prosody. At the same time, modern poetry uses disfluent processes to introduce the kinds of obstructions to ease consumption as outlined above. Since Dadaism, many avantgarde poets developed certain kinds of disfluencies like line-breaks as well as segments and "micro-particles" known from sound poetry. In this paper, we offer a classification of modern and post-modern poetry along the continuum of fluency, going back to a similar idea developed in Eleanor Berrys theory of a 'Free Verse Spectrum' (Berry, 1997).

Proceedings of the 27th International Conference on Computational Linguistics, pages 1929–1940
Santa Fe, New Mexico, USA, August 20-26, 2018.

We develop a method to identify poetic features that relate to literary prosodic classes and with a special regard to the modelling of prosodic (dis)fluency, hence a form of style detection. Style detection has been a long-running topic in literary study: Tools for style analysis like *Metricalizer* (Bobenhausen, 2011) analyze metrical patterns given in a poem's text (see also (Agirrezabal et al., 2016) for more recent work on English metrical poems) and *Sparsar* (Delmonte and Prati, 2014) have used similar analyses to aid speech synthesis for metrical poems. Style modeling has also been used to automatically generate poems such as limericks (Manurung et al., 2000) or, more recently, traditional Chinese poetry (Zhang and Lapata, 2014; Wang et al., 2016). The above approaches feature poetic styles with very restrictive patterns far from the breadth of free verse. Focusing on contemporary American poetry, Kaplan and Blei (2007) analyze and visualize (textual) features of poems with respect to their poetic properties and Kao and Jurafsky (2015) estimate whether poems were written by professionals or amateurs. All the above works have used only the textual form of the poem. In contrast, music genre classification frequently relies on both audio and lyrics. Particularly close to our work is Tsaptsinos (2017) who uses a hierarchical attention network (Yang et al., 2016), which, however, is using just the lyrics. In our work, we extend the hierarchical network to comprise both speech and text in order to differentiate poetic styles that are primarily differentiated by their recitation.

In our own prior work, we have tried to differentiate classes of post-modern poetry using conventional feature extraction-based classification approaches. In (Hussein et al., 2018a), we havedifferentiated two enjambment-dominated styles using simple features from pausing and POS tagging and achieved an f-measure of 0.69; in (Hussein et al., 2018b), we differentiate *parlando* and *variable foot* styles with similar features, again reaching an f-measure of 0.69.

2 Classifying the 'Free Verse Spectrum'

At least 80 per cent of modern and post-modern poems have neither rhyme nor metrical schemes such as iambic or trochaic meter. Does this, however, mean that they lack any rhythmical features? According to the theory of free verse prosody, the opposite is true. Modern poets like the Imagists (Silkin, 1997; Cooper, 1998; Beyers, 2001), the Black Mountain poets (Golding, 1981; Steele, 1990; Silkin, 1997; Berry, 1997; Finch, 2000), as well as European poets before and after the second world war (Meyer-Sickendiek, 2012; Lüdtke et al., 2014) developed a post-metrical idea of prosody that employs rhythmical features of everyday language, prose, and musical styles including jazz and hip hop. In parts, they intended to create a fluent, in parts a disfluent prosody, for example in Dadaistic poetry. Donald Wesling (1971) offered a number of examples to illustrate the stylistic range of free verse poetry, focusing on the typical line arrangements in modern poems: (1) "Whitmanic", referring to Walt Whitman's adaptation of "the biblical verset and syntax" in "end-stopped lines . . . with boundaries so often equivalent to those of larger units of grammar," which Wesling sees as "constitut[ing] the precomposition or matrix of free verse in English"; (2) "line-sentences," as developed by Ezra Pound in *Cathay* on the basis of Ernest Fenollosa's theories of the sentence, in turn derived from the study of Chinese; (3) dismemberment of the line, whereby the line becomes "ground to the figures of its smaller units," and, as a sub-category, spatial dismemberment of the line by indentation, as William Carlos Williams does in his triadic line verse; (4) systematic enjambment (breaking a sentence or phrase into two lines), whereby the lines are "figures on the ground of the larger unit, the stanza"; (5) dismemberment with enjambment of the line, such that "the middle units on the rank scale engage in a protean series of identity shifts as between figure and ground" (Wesling, 1971). As can be seen, these five classes imply a continuous development from more to less fluent styles using an increase in dismemberments and enjambments.

Based on these examples, Eleanor Berry (1997) called for the investigation of poetry with regards to their features in 'the multidimensional space of free verse' on the basis of five 'axes' of form: (1) line-length, including extent of variability in length; (2) line-integrity, as determined by intralinear features as well as line-divisions; (3) line-grouping, whether stichic (ungrouped), in verse paragraphs, in stanzas, or dispersed on the page; (4) sensory basis of the verse form, whether aural, visual, or both; and (5) semantic function, that is, the relation of the verse form to the semantic aspect of the text, characterized in such terms as organic, iconic, and abstract (Berry, 1997). Berry used these five axes in order to classify

the spectrum of free verse in modern and post-modern poetry.

In this paper, we add prosody to this aforementioned free verse spectrum and establish a gradual one-dimensional continuum, whose two poles are denoted by the terms fluent and disfluent. We illustrate this prosodic spectrum by ranking six different poetic styles respectively prosodic patterns within the free verse spectrum, starting with the most fluent one: (a) The **parlando** pattern was coined by the German poet Gottfried Benn, who created a colon (word group)-based line grouping as in (3) above, but ignored the gap to the run-on-line – i.e. the part after the enjambment – by a fluent reading not emphasizing the enjambment. This fluency was typical for his conversational idiom. The second poetic pattern, (b) the **variable foot** is is identical to the "triadic line verse" (3 above) invented by W. C. Williams (Cushman, 1985). Like the parlando, the variable foot uses a "soft enjambment", but the poet now emphasizes the gap to the run-on-line. As long as this run-on-line also occurs between each singular colon of the poem, i.e. the noun and verbal phrases, this gap does not really affect the flow of the stanza and the poem still sounds quite natural.

In the third pattern, the (c) **unemphasized enjambment**, the poet now creates a more disfluent, choppy style by using the so-called "hard enjambments" that interrupts the reading flow of the poem. This occurs when the enjambment runs across stanzas; separates articles or adjectives from their nouns or splits a word across a line. Finally, the (d) **gestic rhythm** even emphasizes these hard enjambments, which makes the poem sound way more disfluent than in the two previous patterns. Bertolt Brecht coined this technique by calling it a "gestic rhythm", preventing the ear from gliding past the message. Gestic rhythm is any rhythm that causes some difficulty in listening to it.

Even more radical kinds of poetic disfluency have been developed in modern "sound poetry" by dadaistic poets like Hugo Ball and Kurt Schwitters or concrete poets like Ernst Jandl and Oskar Pastior. Within the genre of sound poetry, there are two main patterns: the (e) **syllabic decomposition** and the (f) **lettristic decomposition**, the last and most disfluent pattern. A typical example for syllabic decomposition in sound poetry is the *Ursonate* [The Sonata in Primal Speech] by Dadaist Kurt Schwitters, which begins with "Fümms bö wö tää zää Uu." A typical example for the most disfluent lettristic decomposition can be found in Ernst Jandl's *schtzngrmm*, which is presented in Figure 2 (b) below.

Given this spectrum of free verse poetry, we can add a simple hierarchy of linguistic units to clarify the range from fluency to disfluency. In a grammatical hierarchy, letters are the smallest units and they combine to form morphemes, which combine to form words, to groups, to clauses and finally sentences. Dominating units differ between the different styles along the fluency continuum, from lettristic decompositions to parlandos which are dominated by the largest units. In addition, the recitation style itself can be less or more fluent, and the formation and emphasis of the enjambments at the end of each line is indicative of the fluency of the style.

3 Modeling the Prosody of Spoken Free Verse Poetry

In this section, we describe our model, which is inspired by Yang et al. (2016), as well as our high-level decisions for modeling. Poetry, in particular post-modern poetry, is challenging material for computational modeling and statistical natural language processing. The very purpose of art (and post-modern poetry in particular) is to stand out and to defy or re-define rules, making generalization difficult. Poems, as compared to normal language use, contain unusual words (or no words at all in the case of decompositions, see above), and there is generally only very little data available as compared to most other domains. The automatic alignment of text and audio in spoken poetry is non-trivial (in particular for decompositions in more abstract poetry) and important clues may be contained not only in how the textual material is spoken, but also in the gaps between textual material, such as extra white-space or the pausing between the lines of a poem.

Given the broad variety of the poems in combination with their relatively small number (see below), our model must deal well with *data sparsity*, i.e. use as few free parameters as possible that need to be optimized during training. For this reason, we decide to focus our textual processing on character-by-character encoding of the lines in the poem (and using character embeddings). We use a bidirectional recurrent neural network (RNN, using gated recurrent unit (GRU) cells (Cho et al., 2014)) which encodes

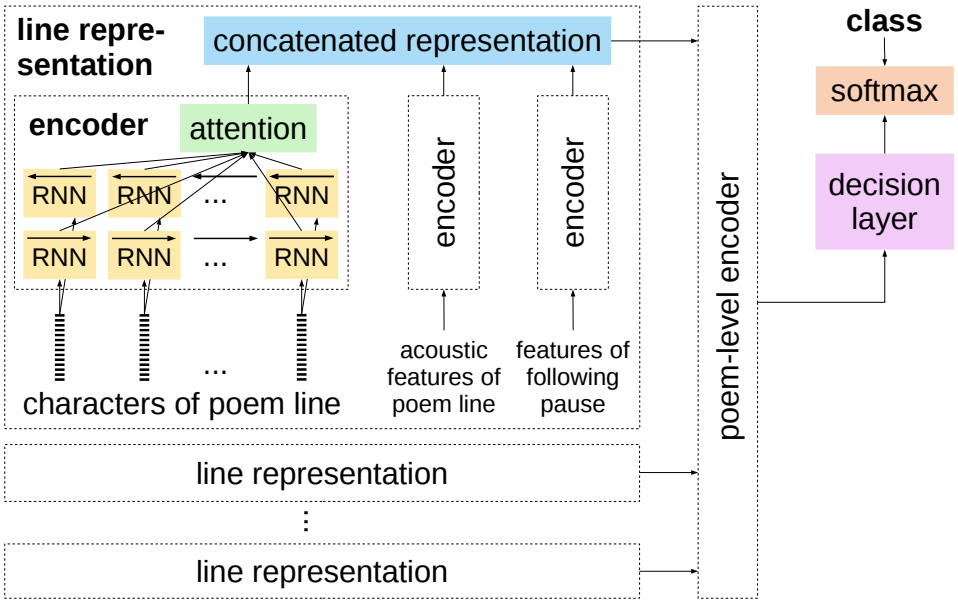

Figure 1: Full model for poetry style detection: each line is encoded character-by-character by a recurrent neural network (using GRU cells) with attention. Acoustic features of each line, as well as of the pause following up to the next line, are encoded similarly. Per-line representations are concatenated and passed to a poem-level encoder. The final decision layer optimizes for the poem's class.

the sequence of characters into a multi-dimensional representation that, although it is not directly applicable to human interpretation, is trained to be optimal towards differentiating the prosodic classes.

Our model is not trained using an explicit notion of words. Instead, it may implicitly encode word-level information (such as parts of speech) via the constituting sequences of characters. This is in line with recent work on end-to-end learning, e.g. for speech recognition (Hannun et al., 2014; Graves and Jaitly, 2014), which no more explicitly models phonemes nor words, but directly transfers audio features to character streams. While processing on the word level might allow our model to build a better higher-level understanding of the poem's meaning, this semantic information would likely not help in style differentiation. In addition, word representations would not capture the usage of whitespace, e.g. for indentation, to create justified paragraphs, or other uses, nor special characters.

We encode the speech (after feature extraction) in a similar way in order to capture the notion of fluency of speech delivery in the author's recitation. As for the text, we use speech line-by-line so that the model may synchronize what it 'hears' and what it 'reads'. A more fine-grained alignment of text and speech would be much harder to produce and might plausibly fail for sound poetry (although it would certainly be desirable). Finally, in order to differentiate the reading of enjambments, we also encode the pauses in-between lines, which may also contain important information about breathing, pausing, in-breath, etc.

For a model to be a suitable and acceptable tool for (digital) humanistic research, it should provide insight into its decision making process, as our primary goal is not so much the automatic classification of poetry but to learn about and better understand poetic styles. To satisfy this requirement of inspectability of the decision making process (at least to some extent), we implement a notion of *inner attention* (Liu et al., 2016) that is to learn how to combine the sequential states of each line's encodings (text, audio, and final pause) to a representation that is best suited towards our training objective. Attention (a) may improve the model's representations and hence yield better performance (although some initial testing did not show a large impact), and (b) can be observed during the application of the model and gives an indication of what the model pays attention to, and can be discussed wrt. its philological plausibility.

We combine the line-by-line representations using a poem-level encoder which is fed to a decision layer and a final softmax to determine the poem's class, yielding the hierarchical attention network as shown in Figure 1. While our network is similar to those of Yang et al. (2016) and Tsaptsinos (2017), we base ours on characters instead of words as textual input and include the audio stream into the analysis via

Table 1: Descriptive characteristics of the data used in the experiments.

		poems	lines	characters	audio
lyrikline: German subcorpus		2392	61849	2025484	52 h
	parlando	34	1435	44323	67 min
	variable foot	34	878	23684	39 min
	unemphasized enjambment	36	1090	33178	48 min
	gestic rhythm	33	897	27741	44 min
	syllabic decomposition	21	540	12390	26 min
	lettristic decomposition	17	684	10007	31 min
deutschestextarchiv.de		—	34291	996714	—

additional encoders.

Our model is implemented in *dyNet* (Neubig et al., 2017) and the software to replicate our experiments is available at `https://bitbucket.org/timobaumann/deeplyrik` in order to foster research on free verse poetry. Our implementation is flexible towards the number of classes to distinguish and can be configured to ignore some of the features (cmp. Table 3). We make use of this flexibility and perform a range of classification experiments in Section 5, once we have described our data in more detail.

4 Data and Setup

We collected German poems available on the webpage *lyrikline*[1] and classified 175 of a total of ~2400 German poems into the six prosodic classes defined above, with a special focus on poets known for the use of such prosodic patterns. Manual classification of the data was carried out by the third author, a philologist and literary scholar and following criteria from the literature as outlined above. We also collected the corresponding audio recording of each poem as spoken by the original author, yielding 52 h of audio. Checking manually, we found some poems tagged as German that actually were not (<1 %) and discarded these from further processing. For pre-training (see below), we also downloaded from the German Text Archive (Geyken et al., 2011)[2] additional text-only poetry published between 1800 and 1930 (and hence most likely not post-modern; more recent poems are hard to find as they are typically still copyrighted).

Some key descriptive statistics of the poems as assigned to their classes are reported in Table 1. In order to check whether poetic classes can already be singled out based on their length (in lines, characters, or audio duration) alone, we checked for significant deviations from the overall corpus. For none of the classes, the poems' durations, or number of lines significantly differ from the average poem in the corpus (two-tailed t-tests, $p > .05$ for all tests). However, variable foot poems, as well as syllabic and lettristic decompositions have significantly fewer characters than average poems.

4.1 Preprocessing

We perform forced-alignment of text and speech for the poems in our six classes using the text-speech aligner published by Baumann et al. (2018) which uses a variation of the SailAlign algorithm (Katsamanis et al., 2011) implemented via Sphinx-4 (Walker et al., 2004). The alignments are stored in a format that guarantees the original text to remain unchanged which is important to be able to recreate the exact white-spacing in the poem and would be helpful when adding further annotations (e.g. parts of speech, syntax or semantics) to the poem in the future.

We extract the line-by-line timing (start of first and end of last word of the line) for each line. Forced alignment of poetry is far from trivial and often individual words cannot be aligned. Lettristic and syllabic decompositions, being a form of sound poetry, are notoriously hard to align automatically and we resorted to manual alignment of those lines that could not be aligned automatically.

[1] `http://www.lyrikline.org`
[2] `http://www.deutschestextarchiv.de`

We extract Mel-frequency cepstral coefficients (MFCC) for every 10 milliseconds of the audio signal as well as fundamental frequency variation (Laskowski et al., 2008, FFV) vectors, which are a continuous representation of the speaker's pitch. We z-normalize all feature dimensions. In order to not overwhelm the model with acoustic sequence information, and given that relevant speech phenomena are typically much longer than 10 milliseconds, we compute the mean and standard deviation of 10 consecutive frames for every feature.

4.2 Pre-training

The manually classified corpus is small and hence the quality of intermediate representations is limited by data sparsity. As an example: a strongly distinctive characteristic of syllabic and lettristic decomposition is the presence of repetitive consonant-vowel sequences in the poem (which occur frequently in syllabic decompositions). Yet, in the two-class problem of distinguishing the sub-types of decompositions, it is hard to infer the differentiation of characters into consonants and vowels from only 38 example poems (which feature a wealth of other characteristics). It would be similarly unreasonable to ask a student of literary studies to learn to differentiate poetic styles based on just a few examples in a language and writing script unknown to them. We mitigate this problem by using pre-training methods (Erhan et al., 2010) to help bootstrap the generation of reasonable intermediate representations (i.e., we teach the model some notion of poetic language as a foundation before teaching it to differentiate styles).

We pre-train the character embeddings and the line encoder using a recurrent autoencoder that aims to build a representation of the line that best allows it to re-create the original line (using combined costs of both forward and backward decoding as training objective); in other words: we ask our model to memorize poetic lines but given its limited memory it has to learn an abstraction of each line that helps it to remember the line. We train this on the whole poetry corpus including poems collected from deutschestextarchiv.de.

We pre-train our representations for the acoustic features of each line similarly to the textual pre-training in that we train a recurrent autoencoder that aims to re-create the original line-by-line features, as well as the length of the acoustic stimulus. Re-creating the length of the original stimulus is particularly important as this feature is directly relevant for measuring the pause between two lines and is otherwise only a very indirect objective in pre-training. Given that line-by-line alignments are only available for the 175 poems that were manually classified, we pre-train the acoustic representations on inter-pausal units for the line representations (pausal units for between-line representations) detected using voice activity detection.

It would also be desirable to pre-train the model's poem-level encoding (i.e. not just teach it about lines in a poem by having it memorize lines, but also teach how lines are combined into a poem). Unfortunately, line-by-line text-audio alignments are not available for the full corpus and hence we are limited to either pre-train based on textual information only (reported as 'text-only' in Section 5) or to use audio information but not use pre-trained poem-level information.

4.2.1 Training Procedure

Even when using pre-trained internal representations, only 175 training instances are too few for training the deep model towards the classification objective. However, poems typically display their structural properties on the vast majority of the lines they are composed of. We hence split training into two steps by first training a decision network that learns to classify individual lines of the poem in order to adapt the pre-trained network. While we here ignore the run-on-line in the case of enjambements, we do include the pausing information to model enjambments at least partially. Coming back to Figure 1, we first leave out the poem-level encoding and directly pass each line representation to a line-by-line decision layer.

Afterwards, we replace the line-by-line decision layer with the poem-level encoder and final decision layer and train towards the per-poem decisions based on the parameters estimated before. Thus, the final model is able to steer its attention mechanism towards the important lines and can learn to sacrifice the initially trained per-line optimization for the overall per-poem optimization.

For all classification experiments reported below, we perform 15 training epochs and use a dropout probability of 0.3 (Srivastava et al., 2014) to reduce overfitting. Each encoder is two layers deep and

Table 2: Per-class f-measures as well as the confusion matrix for the six-class classifier.

	f-measure	parlando	var. foot	unemph. enj.	gestic	syll. dec.	lettr. dec.
parlando	0.83	30	2	2			
variable foot	0.60	3	20	6	5		
unemph. enj.	0.71	2	4	27	3		
gestic rhythm	0.68		6	5	21		1
syllabic dec.	0.81	2	1			17	1
lettristic dec.	0.77	1				4	12

Table 3: Results (weighted f-measure) for reduced feature sets; $^{\text{NS}}$ indicates that the classifier does not perform significantly above chance level.

	all features	no pause	text-only
all six classes	0.73	0.66	0.47
parlando vs. variable foot	0.85	0.85	0.65
unemphasized enjambment vs. gestic rhythm	0.78	0.66	0.57^{NS}
syllabic vs. lettristic dec.	0.82	0.92	0.82

has a 20-dimensional state. Our character embeddings are 20-dimensional as well as are the attention representations.

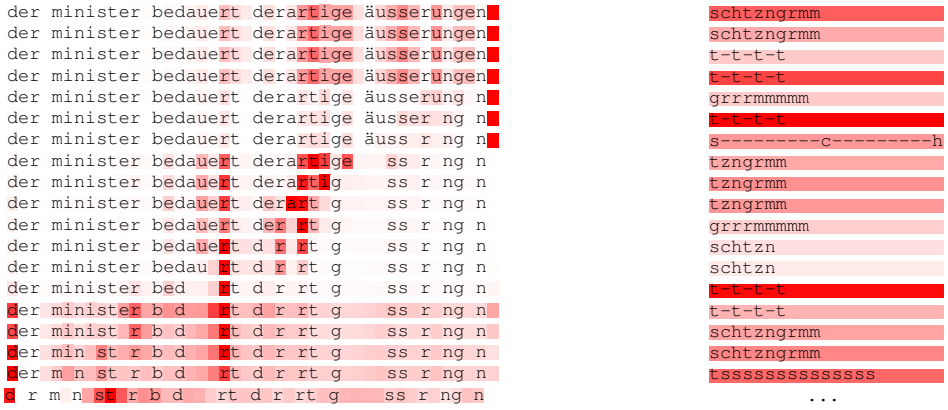
5 Classification Experiments

We train a classifier to distinguish the six classes of poetic style with all features (text, speech, and pause) using pre-processing and pre-training as described in the previous section; given the little available data, we use 25-fold cross-validation (5 poems per test fold). We report the per-class f-measures and confusion matrix in Table 2. The average f-measure (weighted by class size) is 0.73, indicating that it is indeed possible to distinguish the postulated prosodic classes based on text, speech, and pauses and using a deep neural model.

Analyzing the confusion matrix (in which we ordered the classes by their postulated fluency), we furthermore find that most misclassifications are clustered near the central diagonal. We take this as an indicator that classes close to each other on the fluency continuum are more easily misclassified with each other. In contrast, none of the very fluent classes is taken for a decomposition and only rarely are decompositions misclassified as member of the fluent classes. The picture is less clear for the three classes of variable foot, unemphasized enjambment and gestic rhythm. Given that all of these styles feature enjambments of some sort, they might be somewhat harder to differentiate, or the limited performance might point to the importance of higher-level information in the manual classification which our model is unable to pick up.

In Table 3 we show the weighted f-measure (as the most descriptive single performance metric) for the full six-class classifiers, as well as for binary classifiers that we train to differentiate (a) the two most fluent styles which are still regarded as relatively fluent to read and listen to; (b) the two styles that build on enjambments and mostly differ by whether these enjambments are unemphasized or emphasized as in gestic rhythm, and (c) the two types of decomposition which differ quite strongly in their textual appearance. We train each of these classifiers for the full feature set, we leave out pause information and only use audio during speech, and finally use on the textual information.

The results in Table 3 indicate that indeed, (a) parlando and variable foot can hardly be differentiated based on textual features alone but only with access to the recitation style (yet do not require pausing information). (b) Pause information is crucial to differentiate the enjambment-dominated styles which differ mostly between the lines. In fact, these styles cannot be differentiated at all based on textual information alone, in which case the classifier does not significantly outperform the chance level. Finally,



(a) Jaap Blonk: Der Minister I

(b) Ernst Jandl: schtzngrmm

Figure 2: Visualization of attention in two lettristic poems: (a) attention to characters within the line, (b) attention to lines (including the audio) in the poem.

the (c) decomposition styles can already be differentiated based on textual information. Access to the recitation style improves classification performance but adding the pausal features shrinks this advantage, presumably because the pausing information is irrelevant to distinguish the classes and confuses the classifier during training. We also find that the neural model substantially outperforms our previous feature-based approaches (Hussein et al., 2018a; Hussein et al., 2018b), at least when using the full feature sets.

6 Model Analysis

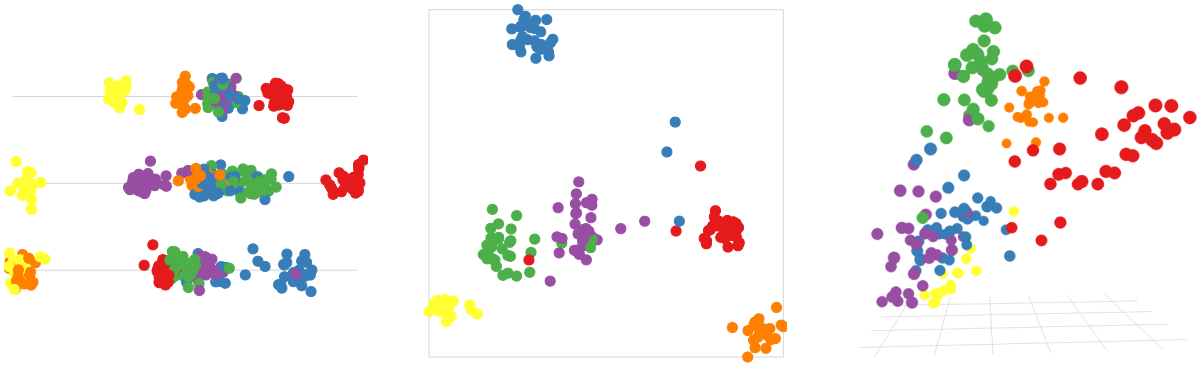
In order to gain additional insight into the classification performance and to investigate whether the model is observing the philologically 'correct' features of poems, we perform further analyses on the attention sub-model, as well as by analyzing the poem-level representations in a lower dimensional space.

Attention models can provide insight into the decision making of the model. In particular, they allow to analyze the weighing of parts of the input in the decision making process. This enables us to test whether the model has actually learned to classify similarly to how a human might.

We plot attention results for two exemplary poems in Figure 2: As can be seen, the poem in Figure 2 (a) repeats the same line over and over which gradually decomposes from the right. This leads to a diagonal frontier in the poem and the model attends to this frontier, at least to some extent. Another poem by the same author (which decomposes from the left) shows a similar pattern. The poem in Figure 2 (b) is about trench[3] warfare during World War II and onomatopoeically mimics the noises of war (leaving out all vowels in doing so). The model singles out those lines in the poem that deviate most from fluent language – both textually and acoustically. The decision layer trained in line-by-line training can be used for further analysis. For example, in the poem in Figure 2 (a), the line-by-line classification is wrong for some of the first few lines, mirroring the fact that decomposition only gradually sets in.

We have postulated in Section 2 that the six classes of poetic style can be ordered along a (dis)fluency continuum, with *parlando* being the most fluent (and similar to normal spoken language) and *lettristic decomposition* the least. While we have provided external evidence that the classifier does differentiate the fluency classes with the confusion matrix presented in Section 5, we wonder if the internal poem representation also reflects the ordering in this continuum. In order to visualize the internal representations of the poetic model, we train another classifier which injects a low-dimensional *bottleneck layer* immediately before the final decision layer, thus forcing the model to represent every poem as a point in low-dimensional space (we use 1-3 dimensions). We then plot each poem's representation as a point and color-code classes by color. Resulting plots are shown in Figure 3: on the left, we show the results of three 1D mappings resulting from different random initializations of the model. It can be seen that the first model represents the classes in the order of fluency but fails to differentiate the enjambment-based

[3]German: 'Schützengraben' which is reduced to 'schtzngrmm' by Jandl.



(a) three trials of linear mapping (b) 2D-mapping (c) Projection of 3D-mapping[4]

Figure 3: Visualization of low-dimensional mapping of the poems contained in the six classes (parlando: red, variable foot: blue, unemphasized enjambment: green, gestic rhythm: purple, syllabic decomposition: orange, lettristic decomposition: yellow).

classes. The second mapping better differentiates the classes but more strongly deviates from the fluency continuum, which the third mapping ignores alltogether.

The center and right of the figure show 2D and 3D mappings[4]. As can be seen, the classes are mapped into separate areas of the representation space and cluster nicely (except for a few outliers). However, their ordering only partially corresponds to the fluency continuum. For the 3D mapping[4] we find differentiations in the representations that could be interpreted as aspects of fluency modeling: (a) the naturalness of the text (with both types of decomposition and their generally non-word content set apart from the other poems in one dimension) and (b) auditory vs. textual fluency, with enjambment and syllabic decomposition being auditorily similarly fluent to *parlando* but textually not.

7 Conclusion

With our analysis, we have captured the spectrum of free verse prosody in modern poetry, using computational techniques, along the fluency/disfluency continuum which also plays a central role in the discussion on the cognitive processing of aesthetic artifacts; to the best of our knowledge, we are the first to do so. We have trained classifiers that integrate for each line the textual information, the spoken recitation, as well as the pausing information, and integrate information across the lines within the poem. We deem the overall classification performance as high (although classification is not our primary goal). In addition, we have trained classifiers for sub-problems and using reduced feature sets and the results obtained in these experiments support the expectations based on philological understanding.

Our classifiers provide some insight into the decision making process via the attention mechanism and the possibility to map the internal state into lower-dimensional spaces for visualization. We find that our model indeed seems to internally re-create some notion of fluency. However, we also find that the mappings to lower dimensions do not fully support the claim of one single dimension of fluency. In particular in 3D-mapping, a more complex picture evolves. This may be due to shortcomings in the model, the underlying data and annotated classes. It may also question our initial hypothesis calling for a further refinement of the fluency theory.

In our future work, we intend to analyze the whole *lyrikline* corpus (and beyond) in order to gain insights about this broad sample of post-modern poetry. We hope to semi-automatically find additional poems that belong into one of our classes (and could be added as further training material after manual validation). We also intend to analyze the corpus for clusters of outliers from our current classification in order to determine further and refine the existing classes using an iterative "human in the loop" appoach (Baumann and Meyer-Sickendiek, 2016). Our goal is the mutual benefit of the model (which requires human input) and the philological expert who will be able to quickly scan, analyze and browse vastly larger collections of poetry than has been possible in the past.

[4]An interactive version of the 3-D plot is available at `https://timobaumann.bitbucket.io/colingfreeversepoetry/`.

Our model so far is still far from optimal (beyond the fact that we have not searched meta-parameters that yield best classification results) and we want to point out some aspects of future work: enjambments are linked to syntactic characteristics and we could integrate syntactic information (such as part-of-speech (POS) tags) or try to pre-train our character encoding to decode the POS tag sequence. It would be helpful if we could inject philological insight about what to pay attention to into the training process (and extract it out of the application process) in order to increase the philological validity of our model. With regards to the neural network, we could link the text and speech streams using connectionist temporal classification (Graves et al., 2006) for it to relate auditory to textual information in more detail, and we could connect the (sequential) line and pause encodings of audio in order for the model to better normalize out speaker specific (but not style-specific) characteristics.

Abstract

Most question answering (QA) systems are based on raw text and structured knowledge graph. However, raw text corpora are hard for QA system to understand, and structured knowledge graph needs intensive manual work, while it is relatively easy to obtain semi-structured tables from many sources directly, or build them automatically. In this paper, we build an end-to-end system to answer multiple choice questions with semi-structured tables as its knowledge. Our system answers queries by two steps. First, it finds the most similar tables. Then the system measures the relevance between each question and candidate table cells, and choose the most related cell as the source of answer. The system is evaluated with TabMCQ dataset, and gets a huge improvement compared to the state of the art.

1 Introduction

Question answering is a practical task, and there are many related challenges. Due to the complexity of natural language, those challenges are hard to solve. A QA model requires knowledge, which contains facts, and fetches the answer from the knowledge. For most QA systems, raw text and structured knowledge graph are used as their knowledge. However, raw text corpora are hard to understand for machine. Besides, most knowledge graphs contain too much noise and still need manual intervention. In contrast, the semi-structured data are more flexible to be comprehended than raw text corpora, and much easier to build from text automatically than knowledge graphs. Besides, there are many documents which can be easily converted to semi-structured tables, such as announcements published by institutions and knowledge in science books, etc. We would like to utilize these kinds of knowledge in QA systems.

There are many works on QA based on other knowledge. Some of them are based on raw text corpora, such as Miller et al. (2016), Min et al. (2017), Yin et al. (2016). Besides, QA models based on knowledge graphs are improving rapidly. Freebase (Bollacker et al., 2008) and Wikidata (Vrandecic and Krötzsch, 2014) are well-known structured knowledge bases, which are built almost manually by their users. Although there are some studies on automatic knowledge graph construction, like Sateli and Witte (2015), it is not good enough. There are also many studies on those structured data, like Yih et al. (2015), Yao and Durme (2014). Some of them focused on text description of each item, while others, such as Zhang et al. (2016), try to obtain embeddings of the items.

Although there is limited work on semi-structured tables, there has already been research of QA based on simple tables. HILDB (Dua et al., 2013) is a QA system which converts questions in natural language to SQL queries. Vakulenko and Savenkov (2017) offer another data structure of tables, and introduce a QA system based on tabular knowledge. However, those methods are limited to the specific structure of tables, and cannot take advantage of semi-structured data.

In previous work, candidate table selection is based on manually selected features, such as TF-IDF, which makes it hard to transfer to other environment. Besides, all columns in each row are considered equally, but for some questions, some of columns in the table are completely unrelated to question, and those cells can mislead the model to give a wrong answer.

Figure 1: The structure of semi-structured table knowledge and one of its corresponding MCQs.

In this paper, we will propose a neural system for answering multiple choice questions (MCQs) based on semi-structured tabular data. Our model contains two parts: 1) *candidate table selection*: for each query, tables are ranked according to relevance to the question, and the model fetches candidate cells from the most relevant tables, 2) *cell scoring and answer selection*: the model measures the relevance of query and each candidate cell, and finally the model obtains an answer based on the most relevant cells to the query.

Our first contribution is offering an end-to-end model to select candidate tables before scoring and ranking the answers, instead of using hand-crafted features in previous work. According to our evaluation, recall of the model on the top three tables is more than 98.9%, which leads the system to be efficient and accurate.

Another contribution of our work is a new relevance scorer between table cells and text. We use an attention layer to make the model focus on useful information of the table. With effort of the new scorer, our system has better performance than state-of-the-art on the task. Besides, the model has fewer parameters, which makes it easier to be trained.

Base on our evaluation, our system gets a high performance on the answer scoring task of TabMCQ. Our system achieves an accuracy of 79.0% on test set, while the state-of-the-art system TabNN (Jauhar, 2017) only answers 56.8% of questions correctly.

2 Task Description

The knowledge contains some semi-structured tables $\mathbb{T} = \{T_i | i \in 1...n\}$. And each case contains a MCQ query. There is an example of knowledge and queries in Figure 1. There are several semi-structured tables in its knowledge base.

Each semi-structured table has a title, like *Resource Type Organism* in Figure 1. Different from structured tables, semi-structured tables have some columns used to link other cells, which makes each row is a complete sentence, and those columns are not tagged. Except for those columns, each column in the tables has a tag.

Each query contains a question and three or four candidate choices, i.e. $Q = (q, c_1, c_2, c_3, c_4)$. Our task is to predict the correct choice C of query Q based on $\mathbb{T}$. We assume that each case has one correct answer. In training set, each case contains a MCQ query Q, its correct choice C, and source cells of answer $\left\{T_i(j,k) | i \in 1...n, j \in 1...d_r^{T_i}, k \in 1...d_c^{T_i}\right\}$, where $T_i(j,k)$ is the cell at i-th row and j-th column of T_i, and $d_r^{T_i}$ and $d_c^{T_i}$ are the numbers of rows and columns of T_i. The system is evaluated by accuracy of correct selections.

3 System Architecture and Training

To narrow down the range of candidate tables, our system uses an end-to-end model which has high recall to filter out unrelated tables. After that, our model searches in candidate tables, and obtains a list

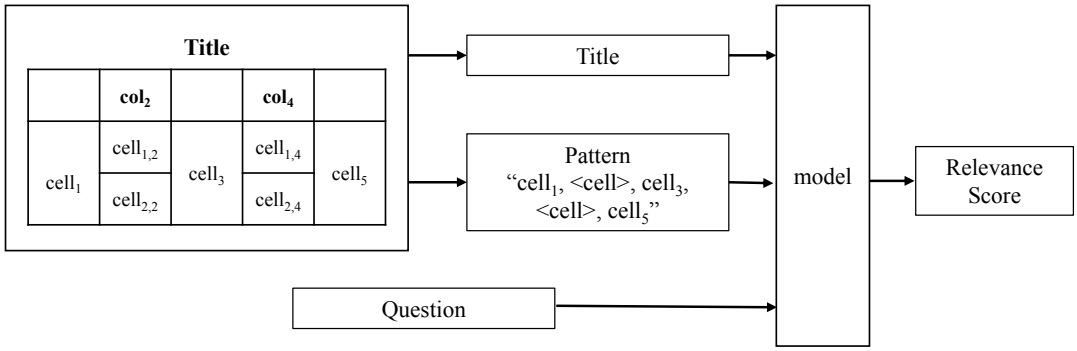

Figure 2: The system structure to select candidate tables.

of candidate cells. Then an attentive recurrent model will measure the relevance of all these cells with the query.

3.1 Candidate Table Selection

In this section, we will introduce the model to select related tables of a given question. The structure is shown in Figure 2. We use DiSAN (Shen et al., 2017) to encode the tables and questions separately, and then measure relevance. The tables with highest relevance scores are selected as input of answer selection model.

Directional Self-Attention Network (DiSAN): DiSAN is a network to learn sentence representations, instead of convolution neural networks (CNN) and recurrent neural networks (RNN), it is based on the attention mechanism. DiSAN is made up by directional self-attention (DiSA) blocks. For each block, assume the input sequence is $x = [x_1, x_2, ..., x_n]$, we have

$$\boldsymbol{h} = \sigma_h(W^h \boldsymbol{x} + b^h), \tag{1}$$

where σ_h is an activation function. Then given masks M, we can use masks to encode temporal order information into the output. In DiSA, the masks are the forward mask and the backward mask, i.e.

$$M_{ij}^{fw} = \begin{cases} 0 & i < j, \\ -\infty & \text{otherwise.} \end{cases}, \tag{2}$$

$$M_{ij}^{bw} = \begin{cases} 0 & i > j, \\ -\infty & \text{otherwise.} \end{cases}, \tag{3}$$

Define $p(z_k = i|x, q)$ as the probability of the k-th feature of token x_i contributes important information to q, and $\mathbf{1}$ represents all-one vector. In the multi-dimensional attention layer, we have a feature-wise score vector instead of a single scalar score, that is

$$f(h_i, h_j) = c \cdot \tanh\left([W^{(1)} h_i + W^{(2)} h_j + b^{(1)}]/c\right) + M_{ij}\mathbf{1}, \tag{4}$$

$W^{(1)}, W^{(2)} \in \mathbb{R}^{d_h \times d_h}$ and $b^{(1)} \in \mathbb{R}^{d_h}$ are parameters. When $M = M^{fw}$, only the relation of later j and earlier i will be in attention, and when $M = M^{bw}$, only earlier j and later i will be focused. Now, we can obtain the importance weight of each feature k in each token i, i.e.

$$P(z_k = i|\boldsymbol{h}, h_j) = \text{softmax}(f(h_i, h_j)). \tag{5}$$

Then, the output of x_j can be written as

$$\boldsymbol{s} = [\mathbb{E}_{i \sim p(z_k|\boldsymbol{h}, h_j)} x_{ki}]_{k=1}^{d_e} = \sum_{i=1}^{n} p(z.|\boldsymbol{h}, h_j) \odot x_i. \tag{6}$$

	CHARACTERISTIC Physical characteristic of an animal or human		INHERITED? Is the characteristic inherited, learned, or acquired?
An	facial scar	is	acquired
	blue eyes	are	inherited
	long hair	is	acquired
A	broken leg	is	acquired
	strong muscles	are	acquired
	telling a story	is	learned

Figure 3: An example of the tables with a few link words.

The final output u of a DiSA block is gotten by input h and output s of the block by a fusion gate.

$$F = sigmoid(W^{(f1)}h_i + W^{(f2)}h_j + b^{(f)}), \tag{7}$$

$$\boldsymbol{u} = F \odot \boldsymbol{h} + (1 - F) \odot \boldsymbol{s}, \tag{8}$$

$W^{(f1)}, W^{(f2)} \in \mathbb{R}^{d_h \times d_h}$ and $b^{(f)} \in \mathbb{R}^{d_h}$ are parameters to be learned. DiSAN firstly applies forward blocks and backward blocks, and their outputs $\boldsymbol{u}^{fw}, \boldsymbol{u}^{bw} \in \mathbb{R}^{d_h \times n}$ are concatenated and sent to another self-attention block called source2token block, which compresses $[\boldsymbol{u}^{fw}, \boldsymbol{u}^{bw}]$ into a single vector, i.e.

$$f(u_i) = W^T(W^{(1)}u_i + b^{(1)}) + b, \tag{9}$$

$$s_{\text{disan}} = [\mathbb{E}_{i \sim p(z_k|u)} u_{ki}]_{k=1}^{d_e} = \sum_{i=1}^{n} p(z.|\boldsymbol{u}) \odot u_i \tag{10}$$

Compared to other methods, DiSAN contains fewer parameters and takes less time to train, and it works well on encoding tables and questions separately. In table selection, there are many query-table pairs, and we need to score them accurately and time-efficiently. Inspired by this method, when tables and questions are encoded, they are self-attentioned without extra information, which can reduce computation complexity of this part.

Candidate Table Selection Model: For each (query, table) pair, we will score the relevance between them. Consider a table $[x, T]$ and a question $q = \{w_{i,q}\}_{i=1}^{n}$, where x is the title of a table, T is content of the table, and $w_{i,q}$ is the i-th word in q.

We first convert words in questions into representations $I_q = \mathbb{R}^{d_w \times n}$, which are concatenation of the word-level embeddings of the words $\{e_{w_{i,q}}\}_{i=1}^{n}$ and their POS-tag embeddings $\{e_{p_{i,q}}\}_{i=1}^{n}$. The embeddings of POS tags are randomly initialized and are trained together with parameters, and the word-level embeddings are initialized by GloVe (Pennington et al., 2014) vectors. We then use a DiSAN layer described above to encode each question q:

$$E(q) = \text{DiSAN}(I_q). \tag{11}$$

Then we convert tables into their vector representations. A table contains a title and some structured data, and we encode them respectively. In some tables, there are some columns filled with link words, and each row in the table is a complete sentence, while others have few or even no link words (like Figure 3). We put those columns, which link the cells, and tags of other columns into a DiSAN encoder, and then, we measure the relevance between each table and the question by their representations, i.e.

$$E([x, T]) = W[\text{DiSAN}(I_x), \text{DiSAN}(T)] + b, \tag{12}$$

$$o(q, [x, T]) = \cos\left(E(q), E([x, T])\right). \tag{13}$$

For each question, we select the l most relevant tables. Then, rows in those tables are selected by their intersection of text with the query. Those rows are sent into the cell scoring model.

Question: Which period of daylight is the summer solstice related?

	ORBITAL EVENT		PERIOD OF DAYLIGHT		PERIOD OF NIGHT	
The	summer solstice	is the day with the	longest	period of daylight and the	shortest	period of night
The	winter solstice	is the day with the	shortest	period of daylight and the	longest	period of night
The	spring equinox	is the day with the	midrange	period of daylight and the	midrange	period of night
The	fall equinox	is the day with the	midrange	period of daylight and the	midrange	period of night

Figure 4: The table contains the answer of "Which period of daylight is the summer solstice related?", relevant rows and columns, and their intersection are marked.

3.2 Cell Scoring and Answer Selection

After finding candidate rows, we introduce a model that focuses on useful parts of tables and tries to score each answer by its relevance with the query. For most queries, answers can be selected based on cells from candidate tables, so we score each cell directly. As Figure 4 shows, for question "Which period of daylight is the summer solstice related?", we can find a row in table, which tells us summer solstice has longest period of daylight and shortest period of night, but "shortest period of night" has nothing to do with answering the query, and may mislead model to make a wrong decision. Therefore, to focus on useful information of the table, a soft attention layer is on the top of table encoder. The structure of our answer selection model is shown in Figure 5.

Soft Attention: The r-th row of table T contains several cells $\{T(r,i)\}_{i=1}^{d_c}$. The attention layer needs to find out useful cells in the candidate row (like those marked in Figure 4). When we obtain attention weights, rows in the table will be transformed to the unstructured sentences. Suppose we have m words in q and n words in $T(c)$, for each query Q and candidate row, we build a matrix $S_{q,T(r,\cdot)} = \{\text{sim}(i,j)\}_{m\times n}$, $\text{sim}(i,j)$ is cosine similarity between the vector representation of the i-th word of q and j-th word of sent$(T(r,\cdot))$. Then, attention weights W_a are calculated by a CNN, which have S as its input. Convolution layers are used to measure the similarity of n-grams between q and sent$(T(r,\cdot))$, and a pooling layer on the dimension with variable length is applied before we obtain W_a, i.e.

$$W_a = \tanh(\text{pool}(\text{conv}(S))). \tag{14}$$

Here, we add an activation layer to make sure the weights are in a small range.

Cell Scoring: In most cases, the answer candidate cells in each row are not components of a question. Therefore, for each $(q, T(r,c))$, input of the encoder does not contain the candidate answer cell $T(r,c)$, and it is replaced by a tag "⟨SPACE⟩". For some rows in same table, if we remove the answer cell, they are in same pattern (such as, in the table "Country Hemispheres", both "China" and "Japan" are in the north hemisphere, if we remove "country" cells, those two rows are both in pattern "⟨SPACE⟩ / is in / north hemisphere"). For these cells, we merge them into one group. Also, a row in the table is hard to be encoded directly, we convert each row into a word sequence, in which different cells in a row are separated by sign "||".

Suppose we have a question q with n words, and a row $T(r)$ with m words, let $I_q \in \mathbb{R}^{d_w\times n}$ and $I_{T(r,c)} \in \mathbb{R}^{d_w\times m}$ denote the embeddings of words in question q and row $T(r)$, where d_w is the dimension of word representations. Question encoding $E(q)$ and $E(q,T(r,c))$ can be obtained through a bidirectional Gated Recurrent Unit (Bi-GRU) Network:

$$E(q) = \text{Bi-GRU}(I_q), \tag{15}$$

$$E(q,T(r,c)) = \text{Bi-GRU}(W_a \cdot I_{T(r,c)}). \tag{16}$$

We concatenate the final states of two directions of Bi-GRU and take it as the representation of the question and the selected cells. Then for each $(q,T(r,c))$, we put $E(q)$ and $E(q,T(r,c))$ into a fully-connected layer and then obtain the score of each pair, i.e.

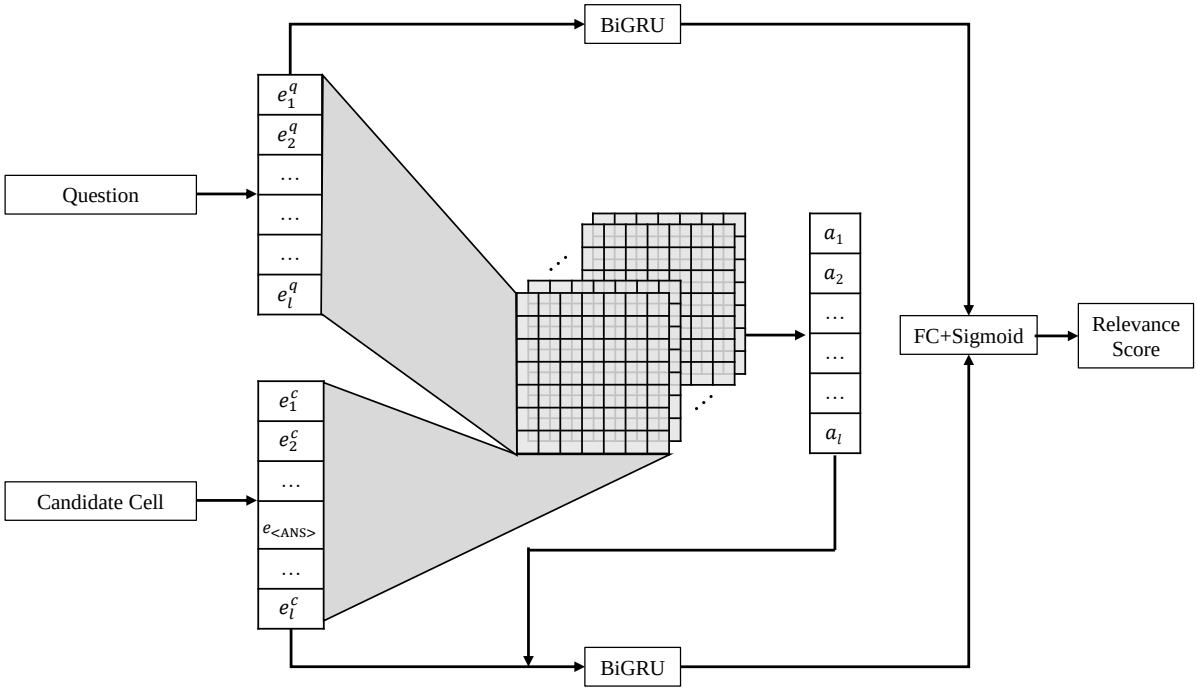

Figure 5: The structure of the answer scoring model.

$$s = rel(q, T(r, c)) = \text{sigmoid}(W \cdot \text{FC}(E(q), E(q, T(r, c))) + b). \tag{17}$$

Answer Selection from the candidate cells: After we score each rows, we need to select the best answer from the three or four candidates. Because of some queries have a choice like "none of above", we should also determine whether there are true answers in all choices. For each query Q, we order all patterns by their scores, and for each pattern, we will find the matched words between selected cells and the choices. For those queries can not be determined by the most relevant patterns, the next pattern will be used to select choices and get its intersection with the answer set. The process finishes when only one choice is remained, or no answer is left in the answer set.

Our model is a scorer model, which can answer MCQs with multiple answers. There are two different kinds of those queries. In some of those queries, the answers are in same pattern set, and it is easy to find them out. For those cases that answers are in different set, a straightforward solution is selecting candidates of which the score is above a threshold as answers. However, there is no such case in both the training and testing set, we did not explore the way to measure the threshold.

3.3 Training

Instead of measuring the system by an absolute score for relevant and irrelevant cells, we train the model to score the best cell with the highest score. For each query, we select some wrong cells from the candidate tables of each query randomly, and train the model based on triples $(q, T(r_+, c_+), T(r_-, c_-))$. We measure the loss of each triple by:

$$L(q, T(r_+, c_+), T(r_-, c_-)) = \max(0, \alpha - s_+ + s_-) \tag{18}$$

In (18), s_+ and s_- are relevance scores between question and $T(r_+, c_+)$, $T(r_-, c_-)$, and α is a hyper-parameter to control the gap between the two scores.

4 Experiment

In this section, we will evaluate our QA system based on semi-structured knowledge. Firstly, we will introduce our dataset, evaluation metrics and setup. Then, we compare our system with other work.

Finally, we analysis the result of evaluation.

4.1 Dataset

We use the TabMCQ (Jauhar et al., 2016) dataset to evaluate our system. TabMCQ contains 9092 manually annotated multiple choice questions (MCQs) with their answers, and 63 tables as its knowledge. Tables in this task are semi-structured tables, rows in each table are sentences with well-defined recurring filler patterns. For those tables built by sentences, some of the tables contain some link words to make the sentence complete, while in other tables, all cells are meaningful. Same as simple tables, analogies between rows of tables also exist.

The target domain for the tables is the *4th grade science exam*, and most tables are constructed based on the topic. MCQs in the dataset are created by information of the row containing the target cell, and the other choices of the question should be built according to other cells of the same table. Therefore, for all MCQs in the dataset, we know the source cell to answer the MCQs, which makes it easier to train based on the dataset.

Jauhar (2017) also evaluates his model on Elementary School Science Questions (ESSQ) dataset. However, the structure of those two datasets are quite different. Length of questions in TabMCQ is much shorter than ESSQ, and in ESSQ, many questions can not be solved by searching, but analogy and reasoning. Our system is not aimed at working on these questions. Besides, ESSQ contains only 108 MCQs in its training set, which is hard to train a model. Therefore, ESSQ is not in the sources of evaluation.

4.2 Evaluation Metric

For each query, there are three or four choices. We measure the systems by their accuracy on answering questions. The cases will be set to wrong when the correct group is selected, but the model returns the wrong choice. On table selection task, the goal is to get more correct recall in limited return, so we evaluate the models by their mean average precision (acc@n), which means the proportion of correct table of the query in n most relevant tables returned by the model.

4.3 Experiment Setup

When preprocessing the corpus, we use tokenizer from Natural Language Toolkit (NLTK) (Bird, 2006). The representations of words are pre-trained by GloVe (Pennington et al., 2014), and all these embeddings are fine-tuned in the training process. The dimension of word representations in all components is 300.

Two parts of the system are trained separately. For the DiSAN layer, we have a dropout layer (Srivastava et al., 2014) with dropout rate being 0.2, and the activation function is ELU (Clevert et al., 2015). The model is trained as a classifier, whose loss is measured by cross entropy with softmax, and we minimize the loss by using Adagrad (Duchi et al., 2011) with learning rate set to 0.05. When getting attention weights, we apply padding and masking to make input into fix length. Candidate cells of the answer scoring model are from table selection model we describe in section 3.1. We use the three tables with the highest scores as its source. The size of the GRU hidden layer is 100, and input and output of each GRU layer have a dropout rate of 0.2. We train the model on batches of 32 queries, and for each query, a correct answer and a wrong answer are used to construct a training sample. Attention layer is trained together with the whole model, and the loss of the answer scoring model is minimized by Adadelta (Clevert et al., 2015) with learning rate set to 0.08. Representation of words in our system is trainable, and we evaluate our model on both pre-trained word embeddings and randomly initialized word embeddings.

To compare with other work, we split queries from TabMCQ into three parts, 10% of queries are in testing set, 10% of the rest queries are in validation set, and the remaining queries are in training set. We train our system on the training set, and finish training when accuracy on the validation set stops increasing. Besides, we also evaluate our system without pre-trained vector and attention.

4.4 Baselines

To evaluate our system, we compare our system with other work. We take some experiments to show the influence of each components of our system. For systems that need to be trained (Bi-LSTM, TabNN, and our model), models are learned by using training set and validation set, and evaluations on all models are based on test set.

Random: The answer is selected from all choices randomly. It's used to measure whether the model gains the result on this task. Because there are a few questions with only three choices, the accuracy of random selection is a little higher than 0.25.

Bi-LSTM: Each row is converted into a sequence, and put into a bidirectional LSTM network. The hidden size of the LSTM layer is 100 or 200. The model is trained by Adadelta. The model's output is the relevance score of query and row. Candidate rows of the query is obtained from the model in 3.1, and the final choice is selected by matched words.

Bi-GRU: Structure of the system is similar with Bi-LSTM, but the recurrent layer is changed to bidirectional GRU. The hidden size of the model is 120 or 200. The model is trained by Adadelta.

Lucene: Lucene is a tool for retrieving unstructured information, and it is well known as a search engine. We convert semi-structured tables into unstructured sentences, which can be indexed and searched by Lucene. For each query, the top hit returned by Lucene is regarded as the answer, and the sentence is compared with the choices, and the choice with most coincidence is selected.

TabNN: TabNN, proposed by (Jauhar, 2017), represents the state-of-the-art on the task. It is composed of two scorers: a scorer between questions and rows and the other one between choices and columns. In each component, the basic unit of table encoder is cell-LSTM, which is an LSTM layer to encode cells. Output of cell-LSTM can be used by the following row and column encoders as their input. In the evaluation, TabNN-fixed is the model with fix word representations, while TabNN-learned is the model with trainable word representations.

4.5 Results

For the whole system, accuracy on the test set of TabMCQ is shown in Table 1. Count of parameters does not include those from word representations. As we can see from Table 1, our system performs better than existing work by a large margin. Because our training is based on (query, relevant cell, improper cell) triples, and does not train by all wrong cells directly, test accuracy of our system is very close to train accuracy. Training accuracy of our model is 79.27%, while TabNN has accuracy of 68.0% on the training set, and 56.8% on the test set.

Besides, our model is less complicated than TabNN. As we can see from Table 1, our scorer has only half of the parameters, compared to the number of TabNN. In most deep learning system trained by a small dataset, model with fewer parameters can be trained more easily than complicated ones, and is less likely to overfit.

For different components of our system, soft attention is significant. As we can see from the Table 1, the system with Bi-GRU as its scorer works poor in the task, although it has similar settings in other parts with our model. That is because ordinary models are hard to classify whether the information in the tables is useless or not, but a soft attention layer can help filter out the cells, which helps ordinary models work much better. Our system benefits from using pre-trained word embedding to initialize our system.

4.6 Analysis of Candidate Selection

In section 3.1, we offer a table selection model. To evaluate the effort of the model, we compare it with some baselines, which is shown on Table 2. In our experiment, LSTM with attention has a hidden size of 120, and CNN has filters in size $(n, d_w)(n = 2, 3, 5)$ and a fully-connected layer with activation. Each of them is trained by AdaGrad optimizer.

As we can see from the result, LSTM takes a poor performance on selecting the most relevant table of the question. On acc@1, both our model and CNN work well, but the correct tables achieve higher score

Systems	Hidden Size	# Parameters	Test Accuracy
Random	-	-	25.1%
Lucene	-	-	52.2%
Bi-LSTM	100	807,005	32.9%
Bi-LSTM	200	1,930,205	32.2%
Bi-GRU	120	755,005	35.4%
Bi-GRU	200	1,445,405	34.7%
TabNN-fixed (Jauhar, 2017)	160	1,131,843	31.9%
	320	3,902,083	30.9%
TabNN-learned (Jauhar, 2017)	160	1,131,843	56.8%
	320	3,902,083	50.8%
Ours w/o pre-trained	100	**605,846**	75.1%
Ours			**79.0%**

Table 1: Comparison between systems.

Model	Acc@1	Acc@2	Acc@3
LSTM with attention	89.9%	95.7%	96.3%
CNN	94.2%	96.0%	97.1%
Ours (based on DiSAN)	96.4%	98.4%	99.0%

Table 2: Comparison between models on table selection.

on our model, which means our model selects fewer tables on the same recall of the accurate tables, and the system can obtain the correct answer more easily than using CNN.

Besides, our model runs faster than LSTM, and has almost the same running time with CNN for each batch of data. Therefore, DiSAN works well on this task in our model. There are much more relevant tables when using the three most relevant tables than the top two, and the proportion of relevant tables is not selected is small (acc@4 of our model is 99.0%, and acc@5 is 99.2%, the gap between acc@3 and acc@5 is smaller than those shown in table 2, and the improvement is little on using more candidate tables. Therefore, for each query, we have three candidate tables sent into answer scoring.

4.7 Error Analysis

Although our system is much better than existing work, there is also a big room to improve. We randomly analysis some queries that our system can not select the correct choice, including those from the training set and the test set.

Some of the errors are due to candidate selection. Although we choose the three most relevant tables as candidates, there are still a few queries matched with wrong tables. Most of those queries' corresponding tables contain only few columns, and has little feature on their patterns. An example is shown on Figure 3. Besides, in some queries, words in different patterns cannot be recognized by the system. For example, the correct choice is "USA", while the representation in the relevant cell is "the united states". It's hard to recognize by our model, and it can be solved by using large knowledge to get better representations of those words. Otherwise, for some question, we have obtained the correct group with several cells, but our answer selection method is not accurate enough, the wrong choice is selected based on other cells in the same group.

There are also some faults of tagging in the dataset. Some queries in the training set are labeled with wrong cells as their "relevant cell", such as the question "Yucatan is a state located in ?", is asking for the country of Yucatan, the "relevant cell" should be "country", but the question is marked as "subdivision". Besides, there are a few questions with two correct choices. For question "Which of the following is a carnivore?", both "Andean Cat" and "Arctic fox" are in choices, and only one of them is marked as correct.

5 Conclusion

In this paper, we present a question answering system based on semi-structured tabular data. Our system is composed of two parts, which are used to select candidate tables and give out answers. Then we take some experiments with different settings on the system, and our model is compared with previous work by their performance. Besides, we evaluate the effect of the components of the model. Due to the effect of attention layer and efficient model, our system performs better than state-of-the-art work on TabMCQ dataset.

In further research, there are still much work to be done. MCQs with multiple correct choices can be added to the dataset, and then the system can solve answer MCQs with multiple answers. Besides, recall of table selection model still can be improved. Making decision on choice selection more accurate is another important point. Answering questions with induction and reasoning is also a point to improve. Otherwise, representation of cells are also important. An embedding with both text and structure information can be helpful to improve the model. Otherwise, the manners to convert raw text and structured-tables to semi-structured tables can also be explored.

Abstract

The lack of large-scale question matching corpora greatly limits the development of matching methods in question answering (QA) system, especially for non-English languages. To ameliorate this situation, in this paper, we introduce a large-scale Chinese question matching corpus (named LCQMC), which is released to the public[1]. LCQMC is more general than paraphrase corpus as it focuses on intent matching rather than paraphrase. How to collect a large number of question pairs in variant linguistic forms, which may present the same intent, is the key point for such corpus construction. In this paper, we first use a search engine to collect large-scale question pairs related to high-frequency words from various domains, then filter irrelevant pairs by the Wasserstein distance, and finally recruit three annotators to manually check the left pairs. After this process, a question matching corpus that contains 260,068 question pairs is constructed. In order to verify the LCQMC corpus, we split it into three parts, i.e., a training set containing 238,766 question pairs, a development set with 8,802 question pairs, and a test set with 12,500 question pairs, and test several well-known sentence matching methods on it. The experimental results not only demonstrate the good quality of LCQMC, but also provide solid baseline performance for further researches on this corpus.

1 Introduction

Question matching is a fundamental task of QA, which is usually recognized as a semantic matching task, sometimes a paraphrase identification task. The goal of the task is to search questions that have similar intent as the input question from an existing database. QA system learns from a large and noisy question matching corpus, and can span a diverse set of topics (Fader et al., 2013). Semantic matching is often regarded as a binary classification problem. Given a pair of sentences, the system is asked to judge whether two sentences express the same meaning. Semantic matching algorithms are widely used in NLP applications, such as information retrieval, machine translation and knowledge-based question answering. Emerging research also shows that first story detection (Petrovic et al., 2012) and text normalization (Xu et al., 2013; Ling et al., 2013) can also benefit from semantic matching techniques.

Chinese is one of the most widely used languages in the world, and the proportion of Chinese using Internet is increasing rapidly (Qiu et al., 2013). Just the same as the English sentence matching task, many Chinese applications can also benefit from Chinese sentence matching. Though some English paraphrase corpora were published for sentence-level matching tasks, the scales are still not enough to meet the data requirements of deep learning techniques. The problem is even worse in Chinese. Researchers can rarely find large-scale Chinese semantic matching corpora (Hu et al., 2015).

One of the critical challenges in constructing sentence-level matching corpus is how to collect sentence pairs that may have the same meaning. The works in paraphrase corpora can provide some references. Some existing paraphrase corpora over the last decade try to overcome this issue with various machine

learning techniques. The Quora question corpus (Iyer et al., 2017) contains sentences from the online question answering forum where the sentences are mainly questions. In the Microsoft Research Paraphrase corpus (MSRP) (Dolan et al., 2004; B. Dolan and Brockett, 2005) the sentences are distilled from a corpus of news articles gathered from thousands of news sources over an extended period (Rus et al., 2014). Multilingual corpus has also been used to construct the Paraphrase Database(PPDB, (Ganitkevitch et al., 2013; Ganitkevitch and Callison-Burch, 2014)) with machine translation methods. Twitter is also used as a source of paraphrase sentences (Xu et al., 2015).

The collection of general purpose sentence pairs with the same intent is quite difficult, but there are plenty of duplicate questions but with different forms on community question answering websites like Baidu Knows(a popular Chinese community question answering website). Some researchers (Zhang et al., 2016; Zhou and Huang, 2017) had proposed to use the resources on BaiduKnows for question retrieval repectively. However, the main difference is that these researches focused on the judgment of relevance between questions or between the candidate questions and queries instead of semantic equivalence. It naturally inspires a question that could we construct a large-scale question matching corpus based on such websites? To answer this question, in this paper, we tried to construct an open-domain large-scale Chinese question matching corpus.

The main contributions of this paper are listed as follows: 1) Based on publicly available community QA website, we construct and manually annotate an open-domain large-scale Chinese question matching corpus that contains 260,068 pairs; 2) We verify the high quality of the corpus through experiments and detailed sample analysis, which prove the feasibility of the proposed corpus constructing method. 3) We present solid baseline performances of several well-known sentences matching methods on the proposed corpus, which is very helpful for its further using in future research works.

This paper is organized as follows. Section 2 reports related works. Section 3 introduces the procedure of constructing and the annotating of the corpus in detail. Section 4 presents evaluation methods and experimental results. Section 5 gives the detailed analysis of the properties and qualities of the corpus. Section 6 makes the conclusion.

Iyer et al. (2017) released the Quora question corpus, collected from the Quora forum. The corpus contains over 400,000 question pairs with binary labels corresponding to semantic equivalence or not. As we known, the Quora question corpus is by far the largest manually annotated corpus.

Dolan et al. (2004) released Microsoft Research Paraphrase Corpus. MSRP investigate unsupervised techniques to acquire monolingual sentence-level paraphrases from a corpus of temporally and topically clustered news articles collected from thousands of web-based news sources (Dolan et al., 2004). Levenshtein distance and a heuristic strategy are employed on the construction of the corpus. MSRP consists of 5,801 sentence pairs, 3,900 of which were annotated as paraphrases by human annotators with a binary judgment as to whether the pair constitutes a paraphrase. The MSRP corpus is divided into a training set (4,076 pairs) and a test set (1,725 pairs), and paraphrases in both sets are about twice more than that are not (Rus et al., 2014).

The User Language Paraphrase corpus (ULPC, (McCarthy and McNamara, 2011)) comprises about two thousand target-sentence/student response text-pairs, or protocols. Unlike existing paraphrase corpora, these pairs in ULPC have been evaluated by expert human raters along 10 dimensions of paraphrase characteristics, with a six-point scale rather than traditional binary value evaluating (Rus et al., 2014). From a total of 1,998 pairs, 1,436 (71%) are classified by experts as being paraphrases.

The Question Paraphrase corpus (Bernhard and Gurevych, 2008) contains 1,000 questions along with their paraphrases(totally 7,434 question paraphrases). These questions are randomly selected from 100 FAQ files in the education category of the WikiAnswers website. The question paraphrase corpus constitutes paraphrases by retrieving question paraphrases with the input questions from social Q&A sites.

Rus et al. (2012) developed the SIMILAR corpus to foster a deeper and qualitative understanding of word-to-word semantic similarity metrics. They focus on the more general problem of text-to-text semantic similarity (Rus et al., 2012). They reuse the sentences from MSRP with word-to-word semantic

Seeds	Returned sentences
学英语，快点 English learning, Efficient	S_1:怎样学习英语才能又快又好? En:How to be fast and efficient when learning English?
	S_2:怎样快速提高英语的学习能力 En:How to improve the ability of learning English quickly
	S_3: 英语零基础怎么学习才可以很快进步? En:How to improve on learning English without any foundations?
	S_4:希望你快点学好中文英语怎么说 En:How to say "I hope you learn Chinese fast" in English
	S_5:有什么软件可以快点学英语 En:Is there any software to help to learn English fast

Table 1: Simplified example of returned questions by Baidu Knows with the seed query "English learning, Efficient". Each "En" labelled sentence is the English translation of corresponding Chinese sentence.

similarity information. There are 700 pairs in the SIMILAR corpus, and the creators relabelled the semantic equivalence of the selected pairs. 63%(442) TRUE paraphrases are yielded for an overall agreement rate with the MSRP annotations.

There are two versions of the Paraphrase database(PPDB, (Ganitkevitch et al., 2013; Ganitkevitch and Callison-Burch, 2014)), either of which contains millions of multilingual sentence pairs. The available Chinese part tends to concentrate on lexical, phrasal and syntactic forms, rather than complete sentences. Since these paraphrase pairs are automatically constructed, there is no manual annotation.

The other paraphrase corpora mainly come from SemEval task, e.g. the semantic textual similarity corpus(SRA, (Dzikovska et al., 2013)), semantic textual similarity (Agirre et al., 2013), and Twitter paraphrase corpus (Xu et al., 2015; Lan et al., 2017).

As can be seen, there is a myriad of data sets with a large variety of distributions, annotation styles, data sources, etc. To the best of our knowledge, there are no more than 50 thousand manually annotated pairs contained in existing corpora except the Quora corpus.

3 Constructing LCQMC Corpus

In this paper, we use Baidu Knows as the original data source to collect the large-scale sentence pairs. On Baidu Knows, a registered user puts a question and motivates other members to answer it. Each time we feed a query into Baidu Knows, the search engine returns a list of ranked links that point to the question pages with relevant results. Question pages are made up of question sentences, question descriptions, and their corresponding answers. We do this for two reasons: 1) there are nearly one billion real Chinese questions asked by substantial users; 2) there are plenty of duplicate questions with the great variant of expressions, which provide the possibility of constructing large-scale sentence-level pairs for question matching.

3.1 Data Collection

Table 1 illustrates a simplified example of returned questions for a given seed query. It shows that the returned sentences are most relevant, and some sentence pairs that have the same intent can be treated as matching pairs (e.g. the sentences that have the same intent as each other, i.e., S_1, S_2 and S_3). Meanwhile, we should also note that many relevant sentences imply different intents and should be non-matching. (e.g. the pairs S_4 and S_5). So it requires us to identify the matching pairs among these returned sentences, either manually or automatically.

We collect high-frequency words from a wide range of domains, including daily life, education, entertainment, computer games, social, natural science, and sports etc. About 50 unique words of each domain are selected as initial seeds. These initial seeds are feed into Baidu Knows and the top 100 returned pages of each seed are collected. Each page contains a certain number of sentences(e.g. question sentences, question descriptions and their corresponding answers). The purpose of this step is to generate

more seeds. We apply term frequency and inverse document frequency(tf.idf) weight on the sentences retrieved by initial seeds. The words in each sentence are calculated and ranked by tf.idf in descending order. Words with higher ranks are selected as the additional seeds and feed into Baidu Knows again. Top 50 pages of each seed are retained, and the question sentences are extracted to compose candidate pairs. The pairs that are identical or differ only by punctuation were discarded. By this way, more than five million question pairs are created.

3.2 Wasserstein Distance based Filtering

Candidate pairs created in the above step are extremely redundant. It's a waste of efforts to annotate all the pairs. To further filter the candidate question pairs, a Wasserstein distance based algorithm called word mover distance(WMD) (Kusner et al., 2015) is employed.

WMD can be cast as an instance of the Wasserstein distance, a well studied transportation problem for which several highly efficient solvers have been developed. WMD relies on word embeddings. It measures the dissimilarity between two sentences as the minimum amount of distance that the embedded words of one sentence need to "travel" to reach the embedded words of another sentence. The more similar the pair is, the smaller the distance value between two sentences is.

We calculate the WMD of each pair and find that almost all the pairs with the distance falling into the interval between 0 and 0.15 are matching, but their expressions do not show big differences. At the same time, all the pairs falling into the interval between 0.45 and 1 are obviously not matching. The rest pairs with WMD values between 0.15 and 0.45 contain both matching and non-matching pairs. It is very hard for WMD to distinguish these pairs. Then we randomly select 10% pairs of this part (that is 260,068 pairs) for manually annotation.

3.3 Annotating Corpus

The main difference between annotating question pairs and paraphrases is the definition of "matching". A paraphrase is a restatement of a text, passage giving the meaning in another form. Though the definition of matching in LCQMC is to some extent similar, it takes the intent of questions into consideration. So, LCQMC will not only focus on the form of words or phrases, which means that even some pairs are different on the semantic meaning, they may still be regarded as matching pairs. The pair " S_6:*After a tense stand-off, the battlewagon turned back.*" and " S_7:*After the French threatened to open fire, the battlewagon turned back*" from MSRP is a typical case in paraphrase definition, sentence S_6 is a restatement of sentence S_7 with words or phrases in another form. While the pair "S_8:我手机丢了，我想换个手机(*My cell phone was lost, now I will have to change another one.*)" and "S_9:我想买个新手机，求推荐(*I want to buy a new cell phone, any advice?*)" is the case that satisfies the definition of question matching with the same intent. The meaning in a single sentence is clear and seems to be different with the other, but if we consider the intent in the questions, we know that both sentences are asked for the same answer: *suggestion for cell phone*.

The annotation is conducted via crowdsourcing. The selected pairs are scored by three annotators. All annotators have professional Chinese background and have been trained on making the judgment for ambiguous pairs. The annotators follow the 3-point Likert scale to measure the degree of semantic similarity between sentences with the score "1", "0" and "0.5". The measurement is the same as defined by Agirre et al. (2012). According to our statistics, in our constructing process, there are about 15% pairs completely inconsistent among three annotators and about 20% pairs uncertain annotations by the annotators. For these pairs, we make a second annotation by other annotators until at least 2/3 annotators give the consistent and certain decisions. Besides, after annotating all pairs, the proportion of positive examples and negative examples is about 7:3, in order to balance the distribution, we first discard some positive pairs that show low quality and supplement some random negative pairs, then we select positive and negative pairs to construct LCQMC. Finally, the annotation pairs are divided into three parts: the training set, the validation set, and the test set. The validation set and test set are further reviewed by expert annotations. The distribution of LCQMC corpus is given in Table 2.

Data	Total	Positive	Negative
training	238,766	138,574	100,192
validation	8,802	4,402	4,400
test	12,500	6,250	6,250

Table 2: The distribution of different data sets in LCQMC corpus.

4 Evaluation and Experimental Results

We evaluate the LCQMC corpus with unsupervised and supervised methods respectively. These methods have been proven effective on semantic matching. Unsupervised methods simply make the matching judgment by using two types of similarity computing methods: string similarity methods and vector space methods. Supervised methods, those algorithms have been proven effective on sentence matching tasks conducted on English corpus(e.g. the Quora question corpus, MSRP, SemEval, PPDB etc.).

For each evaluation data set, we compute the precision(P), recall(R) and F1 score of matching. We also compute the main summary metric (Dzikovska et al., 2013): accuracy(Acc). Accuracy is the overall percentage of correctly classified examples.

4.1 Evaluation Methods

4.1.1 Unsupervised Question Matching

To measure the difficulties of the corpus, we firstly use unsupervised matching methods based on word overlap, n-gram overlap, edit distance and cosine similarity respectively. Word overlap coefficient is the average of simple word overlap, that is the number of common words divided by the average length of the two sentences (Dolan et al., 2004). It is computed by the following formula:

$$C_{wo} = \frac{|S_1 \cap S_2|}{avg(|S_1|, |S_2|)} \tag{1}$$

Similarly, the n-gram overlap coefficient is computed by the following formula:

$$C_{ngram} = \frac{1}{N} \sum_{n=1}^{N} \frac{|G_n(S_1) \cap G_n(S_2)|}{avg(|G_n(S_1)|, |G_n(S_2)|)} \tag{2}$$

where $G_n(S)$ is the set of n-grams in sentence S, and N is usually set to 4 (Barzilay and Lee, 2003).

The edit distance(D_{edt}) of two sentences is the number of words that need to be substituted, inserted, or deleted, to transform one sentence into the other (Bernhard and Gurevych, 2008).

The cosine similarity S_{cos} is computed based on the tf.idf coefficient.

4.1.2 Supervised Question Matching

For supervised question matching, we compare the continuous bag of words and deep neural network methods that have been proven useful for paraphrase task. To provide baseline performance on LCQMC, we run several methods on this corpus in the following sections. The training set is used to train each model, validation set is for parameters selecting and the results are reported on the test set. These baseline methods are introduced below.

- Continuous bag of words(CBOW): first we represent each character or word in one sentence with embeddings orderly. The embeddings are pre-trained with the original sentences. Second, each sentence is represented as the sum of the embedding representations. Third, the output is predicted by feeding concatenated representation of both sentence into a softmax classifier (Blacoe and Lapata, 2012; Yin and Schütze, 2015).

Methods	Emb	P	R	F1	Acc
1.baseline	c	67.0	81.2	73.4	70.6
(WMD)	w	64.4	78.6	70.8	60.0
2.C_{wo}	-	61.1	83.6	70.6	70.7
3.C_{ngram}	-	52.3	89.3	66.0	61.2
4.D_{edt}	-	46.5	86.4	60.5	52.3
5.S_{cos}	-	60.1	88.7	71.6	70.3
6.CBOW	c	66.5	82.8	73.8	70.6
	w	67.9	89.9	77.4	73.7
7.CNN	c	67.1	85.6	75.2	71.8
	w	68.4	84.6	75.7	72.8
8.BiLSTM	c	67.4	91.0	77.5	73.5
	w	70.6	89.3	78.92	76.1
9.BiMPM	c	77.6	**93.9**	**85.0**	**83.4**
	w	**77.7**	93.5	84.9	83.3

Table 3: The performance of different methods on LCQMC test set. 'c' means embeddings are character-based and 'w' means word-based.

- Convolutional neural network(CNN): each sentence is represented as an embedding matrix, and the matrix goes through a convolutional neural network (Hu et al., 2014). In this experiment, we make two sentence matrices sharing the same weight of convolution layers, and the convolutional operations follow the convolution in Kim (2014).
- Bi-directional Long Short Term Memory(BiLSTM): first, two sentences go through the same LSTM unit and are encoded into sentence vectors with LSTM encoder in forward and backward direction. Second, we concatenate the representations of both sentences and use softmax to make a classification (Mueller and Thyagarajan, 2016; Tomar et al., 2017).
- Bilateral Multi-Perspective Matching(BiMPM (Wang et al., 2017)): BiMPM uses a character-based LSTM at its input representation layer, a layer of BiLSTMs for computing context information, four different types of multi-perspective matching layers, an additional BiLSTM aggregation layer, followed by a two-layer feedforward network for prediction. BiMPM model has shown state-of-art performance on several NLP task, e.g. paraphrase identification, natural language inference and answer sentence selection.

4.2 Experimental Results

4.2.1 Experimental details

The tool for Chinese word segmentation is jieba[2] and toolkit for computing distance and tf.idf is sklearn[3]. In unsupervised methods, we take the validation set out to choose the threshold for unsupervised methods. The thresholds used to distinguish matching pairs for word overlap coefficient, n-gram overlap coefficient, edit distance, and cosine similarity are 0.65, 0.2, 0.2, 0.7 respectively, the value over thresholds means the pair is matching. In supervised methods, the methods are based on word2vec. We apply gensim[4] to calculate word embeddings on LCQMC. The dimension of embeddings is 200.

4.2.2 Results

Table 3 shows the results of baseline(line 1), unsupervised methods(line 2-5) and supervised paraphrase methods(line 6-9) on the test set. We list WMD performance as the baseline just because it is used to filter the original question pairs. Unsupervised methods try to evaluate the quality of the corpus. The

Example	Matching?	Pairs
1	No	S_{10}:飞行员没钱买房怎么办? En: What can pilots do since they could not **afford** a **house**? S_{11}:父母没钱买房子 En: Parents can not **afford** the **house**.
2	Yes	S_{12}: 聊天室都有哪些好的 En: Are there any better **chat rooms**? S_{13}:聊天室哪个好 En: Which **chat room** is better?
3	Yes	S_{14}:不锈钢上贴的模怎么去除 En: How to wipe off the **film** on **stainless steel** S_{15}:不锈钢上的胶怎么去除 En: How to wipe off the **glue** on **stainless steel**
4	No	S_{16}:动漫人物的口头禅 En: The pet phrase of **character in animation** S_{17}:白羊座的动漫人物。 En: The **characters in animation** who are Aries

Table 4: Examples from the same keywords.

results of each method are listed from line 2 to line 5 in Table 3. All methods show a high recall but with very low precision. This is because the matching pairs in LCQMC indeed share some overlaps, but at the same time, the non-matching pairs also satisfy the overlaps. Obviously, the best performance of unsupervised methods stays around 70% either F1 or Acc. In supervised methods, BiMPM shows the best performance on F1 measure is 85.0% reached by char-based model, which outperforms the char-based WMD 11.6% of F1. The other methods also show significant improvements after being trained with the training set. The performance of CNN model is slightly lower than BiLSTM model, this may be that in CNN model we follow the TextCNN structure while it is not fit for sentence matching, which is actually proposed for classification.

Comparing the experimental results for unsupervised and supervised methods(shown in line 2-5 and line 6-9 of Table 3 respectively), we can see that there is about the average of 10% absolute improvement on both F1 and Acc score, and up to about average of 15% improvement on precision. It not only shows the effectiveness of supervised methods but also proves the effectiveness of the proposed LCQMC corpus. Though through training on LCQMC, we get a big performance gain for the questions matching task, compared to other natural language processing tasks, there is still a big margin left for further research, especially the precision of matching on this corpus is far from satisfaction.

5 Discussion

In this section, we discuss three key issues about the principle of our corpus construction methodology, i.e., the keyword based methodology, the overlap in sentence pairs and the distribution of matching types in the corpus. We make the discussion based on a random selection of 1000 samples form LCQMC.

5.1 Keyword based Methodology

In this paper, to overcome the bottleneck of collecting large-scale real questions that may have the same intent, the keyword-based method is proposed. In general, keyword matching is not a requirement of paraphrase construction and solely relying on keyword matching may limit the quality of the corpus. Taking this issue into consideration, in this paper, the keyword-based searching technology just provides a source for matching instead of the final decision. Keywords give the specific domain information, but the intent of the sentences with the same keywords may differ a lot.

Example 1 in Table 4 is a pair of sentences selected from the search results of the same keywords (bold words). We can clearly see that the sentences S_{10} and S_{11} in the pair are expressing different meaning.

Example	Matching?	Categories	Pairs	Proportion(%)
5	No	High lexical overlap but not paraphrase	S_{18}:从广州到长沙在哪里定高铁票 En: Where to buy high-speed rail tickets from Guangzhou to Changsha S_{19}:在长沙那里坐高铁回广州？ En: Where to take high-speed rail to Guangzhou in Changsha?	14.4%
6	Yes	Low lexical overlap but paraphrase	S_{20}:请问现在最好用的听音乐软件是什么啊 En: Please tell me what is the best software for listening music now. S_{21}:听歌用什么软件比较好 En: Which software is better for listening popular songs?	1.1%
7	Yes	Intent-based	S_{22}:谁有吃过完美的产品吗？如何？ En: Has anyone ate the product of company "PERFECT"? How? S_{23}:完美产品好不好 En: How about the product from company "PERFECT"?	2.8%
8	Yes	Elaboration	S_{24}:朱熹是哪个朝代的诗人 En: What dynasty is poet Zhuxi in? S_{25}:朱熹是宋明理学的集大成者,他生活在哪个朝代 En: Zhuxi is the integration of science in Song and Ming Dynasty? Which one does he live in?	2.4%
9	Yes	Phrasal	S_{26}:这是哪个奥特曼？ En: Which Ultraman is this? S_{27}:这是什么奥特曼… En: What Ultraman is this...	5.3%
10	Yes	Synonymy	S_{28}:网上找工作可靠吗 En: Is job hunting online available ? S_{29}:网上找工作靠谱吗 En: Is job hunting online accessible?	4.7%
11	Yes	Reordering	S_{30}:你们都喜欢火影忍者里的谁啊 En: Who do you like in Naruto? S_{31}:火影忍者里你最喜欢谁 En: In Naruto, who do you like most?	11.7%

Table 5: Categories and the corresponding pairs in LCQMC.

Example 2 in Table 4 are from the search results of the keyword "chat room", where the meanings of the sentences S_{12} and S_{13} are not determined by the keyword, but by the rest parts in the sentences. Though the lexicons are little different, we can still make the judgment that these two sentences asked for the recommendation of chat rooms and thus are matching. This kind of examples are quite common in LCQMC, we only list some in Table 4. Here Example 3 are matching while Example 4 is not.

5.2 Lexical Overlap of Questions

Another issue that we are concerning about is the high lexical overlaps between pairs of sentences. We have mentioned it in Section 4.1.1, e.g. the results by unsupervised methods. In fact, the high lexical overlaps have been common in several existing paraphrase data sets, especially those studying sentence-level paraphrases. In MSRP, the average lexical overlap equals about 70% while in the ULPC corpus the average lexical overlap is about 60%. In LCQMC, the average lexical overlap is about 75%. Of course, the problems are brought by the building method, but one main reason is that it is too hard to get such cases with low overlaps but matching in the natural background, especially for manual annotation.

The other reason may be the commonness of users to express the same thing when asking questions in the search engine. Matching pairs with low lexical overlaps are ideal instances. We cannot make the corpus cover all these cases, but the cases indeed contribute to the diversity of matching pairs. Luckily, since we annotate plenty of pairs, there is also a small part falling into the low lexical overlap area. According to our statics, the cases that are matching with less than 50% overlaps are about 2.5% of the

whole corpus. Example 6 in Table 5 is an example of matching pairs with low lexical overlaps. In this kind of pairs, the overlaps are far less than 50%.

Besides, non-matching pairs are another aspect to prove the quality of the corpus. The lexical overlaps in non-matching pairs have a great influence. Just opposite to the matching pairs, non-matching pairs need to be lexical overlaps as many as possible. The more lexical overlaps there are, the harder it is for algorithms to identify. In LCQMC, the non-matching pairs satisfy the requirement very well, because the non-matching pairs are selected by WMD and only kept with smaller Wassertein distance. In most cases, the smaller distance shares the views with higher lexical overlaps except those are expressed with synonyms. Example 5 in Table 5 is a non-matching pairs. The differences between the two sentences are only a few words, which is extremely hard for algorithms to identify.

5.3 Question Matching Types

To explore types of matching pairs in LCMQC, we manually examined the random 1000 samples of sentence pairs from the corpus. The categories of intent-based, elaboration, phrasal, synonymy and reordering often appear in matching pairs.

- Intent-based: Sentence pairs are matching because of the intent instead of the semantic meaning.
- Elaboration: Sentence pairs are different on text content, with an extra word, phrase or clause in one sentence that has no counterpart in the other.
- Phrasal: A phrase in one sentence is changed with another words or phrases in the other.
- Synonymy: Sentences share a little difference but the differences are synonymy.
- Reordering: Words, phrases or other constituents occur in different orders between two sentences.

Table 5 list some categories and the corresponding pairs in LCQMC, the last column is the proportion of each category in the random 1000 samples. The sum of the proportion listed in the Table is about 44%, this is because that some common cases are not listed, e.g. matching pairs with some unnecessary words and non-matching pairs.

The categories in matching pairs are far from comprehensive, there are still some other types that a matching corpus is expected to contain. Some possible categories(e.g. Requiring world knowledge, Metaphoric, Named entity, etc.) referred from (Bernhard and Gurevych, 2008) are what semantic matching algorithms expect and need to handle.

6 Conclusion

In this paper, a large-scale Chinese question matching corpus is constructed from Baidu Knows and is manually annotated. The evaluation is conducted through unsupervised and supervised sentence matching methods. Experimental results not only show that the proposed corpus is helpful for further research on Chinese question matching and other related tasks, they also present solid baseline performance on the proposed corpus. Additionally, our further discussions show the feasibility of the proposed corpus construction methodology. Different from the word-level paraphrase corpus, the LCQMC is mainly focused on the variance of expressions for the same intent, rather than the variance of vocabularies for the same meaning.

In addition to current work, the application of more bootstrapping techniques could be one of the most fruitful research direction for further increasing the scale of the corpus. Seeking for different types of available resources is also a key work for further improving the quality of the corpus.

Abstract

Recent advances in Natural Language Processing are finding ways to place an emphasis on the hierarchical nature of text instead of representing language as a flat sequence or unordered collection of words or letters. A human reader must capture multiple levels of abstraction and meaning in order to formulate an understanding of a document. In this paper, we address the problem of developing approaches which are capable of working with extremely large and complex literary documents to perform Genre Identification. The task is to assign the literary classification to a full-length book belonging to a corpus of literature, where the works on average are well over 200,000 words long and genre is an abstract thematic concept. We introduce the Gutenberg Dataset for Genre Identification. Additionally, we present a study on how current deep learning models compare to traditional methods for this task. The results are presented as a baseline along with findings on how using an ensemble of chapters can significantly improve results in deep learning methods. The motivation behind the ensemble of chapters method is discussed as the compositionality of subtexts which make up a larger work and contribute to the overall genre.

1 Introduction

Literary computing poses unique challenges for Natural Language Processing (NLP) and Information Retrieval (IR). Literature itself is not structured like the usual expository corpora commonly made up of Wikipedia articles or short online reviews of products and services. Rather than communicating succinct and directed information, literature is artistic and conveys complicated themes over the course of very long narratives. Given our research which shows these documents on average contain well over 200,000 words, compared to the 100-1000 words in traditional document modeling datasets, it is apparent that new techniques should be considered to effectively model documents with a much higher fidelity.

This work offers a modern take on the classification problem of Genre Identification (Kessler et al., 1997). The goal of this problem is to assign the correct literary genre, such as *Adventure stories*, *Love stories*, etc., to a piece of literature using the title and body of the work. A solution to this problem would be beneficial to all organizations which supply literary services, such as libraries, online bookstores and search engines. Specifically, approaches to solve the Genre Identification problem would provide decision making aids to library scientists, but could also help with recommendation systems and information retrieval. Additionally, this work builds further insight into the study of literature, themes and genre. The problem of Genre Identification also works toward a greater topic of full length literature understanding and comprehension with complex and evolving themes throughout the course of an entire narrative.

Given the complicated and expansive nature of these documents, traditional approaches such as bag-of-word and bag-of-n-gram models are naturally unable to capture the enduring information which can persist across paragraphs and chapters. The themes which contribute to the assignment of genre to a book are not based purely on the frequencies of words used, but the abstract concepts presented over the course of the entire work. For example, it is not uncommon for Romance novels to dive deep into dark stories of murder and deceit, while still maintaining the overall theme of Romance. With this in mind,

Proceedings of the 27th International Conference on Computational Linguistics, pages 1963–1973
Santa Fe, New Mexico, USA, August 20-26, 2018.

neural modeling approaches which learn fixed-length semantic representations of text are considered here, along with traditional bag-of-word approaches, as solutions when working on pieces of literature.

Most Neural Language Models which have been proposed are designed to capture text in a sequential fashion. These models are aimed at encoding the meanings of words or sentences based on previous items in a sequence. These works have begun to explore the application of successful architectures, such as Convolutional Neural Networks (CNNs), Recurrent Neural Networks (RNNs), Long Short-Term Memory Networks (LSTMs) or combination thereof to tasks such as sentiment classification and topic modeling (Kim, 2014; Tang et al., 2015).

However, when working with extremely long pieces of text, many of these Neural Networks quickly become impractical. Some of the models, such as the CNN, grow increasingly larger as the inputs grow, leading to unfeasibly large network implementations. The sequential models, such as the RNNs and LSTMs, are sensitive to extremely long sequences as gradients are likely to vanish during training and they require more and more time to train as the input sequence grows, eventually becoming too slow to train. Due to these limitations, it is evident that neural language models which are capable of processing an entire work of literature end to end would require very powerful systems and specialized machinery. In an effort to apply these neural network solutions to literature datasets, this work researches the effect of modeling smaller portions of text which are extracted from the greater work. These subtexts are used to train models, and results are presented which show the compositionality of the literature; that is, how the individual subtexts, such as chapters, contribute to the whole. The following questions on compositionality are addressed through this research: how do themes evolve over the course of a book and how do these evolving themes contribute to the overall genre of a book?

2 Related Work

This research builds on current deep learning approaches to text classification and sentiment analysis. CNN-Kim has been generally credited as one of the first neural network implementations for text classification (Kim, 2014). This model incorporated a simple CNN whose convolutions would capture neighborhoods of word embeddings. It was shown that on small text classification tasks, CNN-Kim could achieve competitive results when compared to other state-of-the-art models. This work laid a foundation for neural text classification, and while it focused on classifying sentences with an average length of 10-20 words, many researchers have built on this to work with longer documents (Glorot et al., 2011; Xiao and Cho, 2016; Zhang et al., 2015).

Since this time, there have been many more complex network architectures proposed for document modeling and classification. One such work proposes a novel architecture which models documents for sentiment classification using a hierarchy of LSTMs and bidirectional Gated Neural Networks (GNNs) (Tang et al., 2015). This hierarchy was designed to capture the natural structure of language where word representations are composed into sentence representations, which are in turn used to compose a document representation. This model produced competitive results on short text classification datasets with an average word count of 150. Other hierarchical approaches have been proposed that operate on a similar structure. Another proposed technique uses an autoencoder capable of capturing an unsupervised document representation with hierarchies of LSTMs (Li et al., 2015). The training goal is to reconstruct the text from the document representation using a hierarchical decoder. Two separate works have proposed alternative techniques to learning entire document representations in a hierarchical unsupervised fashion (Le and Mikolov, 2014; Kiros et al., 2015). All of these works, while exploring very different techniques, work on short documents where a document is composed of a list of sentences.

It has been shown that many NLP architectures can be significantly improved with the introduction of one or more Attention Mechanisms (Bahdanau et al., 2014). These Attention Mechanisms work to determine how informative individual elements of text are in regards to the task being trained over. These mechanisms employ a technique that learns a set of weights used to capture relevant meaning in a sequence through a weighted average. Using multiple levels of this mechanism, a Hierarchical Attention Network has been proposed for the task of document classification (Yang et al., 2016). This technique showed sweeping improvements over all other models on the same common text classification datasets.

In parallel to the research of deep learning models capable of performing complex text classification, significant efforts have been made towards finding optimal autoencoding solutions which are capable of compressing and representing variable-length text into fixed-length semantic vectors. The most notable of these is the word2vec embeddings which use a neural autoencoder in the skip-gram fashion to build fixed-length vectors which capture the contextual meaning of individual words (Mikolov et al., 2013b). Following this, Le and Mikolov (2014) and Kiros et al. (2015) both proposed the concept of embedding entire paragraphs and documents into fixed length vectors. While there has been reasonable discussion on the effectiveness of these embeddings, it is an important aspect to consider when building deep learning approaches to NLP.

Along with the extensive work that has been produced in applying deep learning techniques to text classification problems, there is also a wealth of solutions which apply traditional machine learning techniques and NLP representations such as bag of words (BOW). Liu et al. (2009) provide an in-depth study into models and weighted term representations to be leveraged when working with imbalanced text classification datasets. Their work compared BOW, term frequency - inverse document frequency (tf-idf) and custom weighting schemes while employing naive Bayes and support vector machines (SVMs) for their classification tasks. Other works have studied the impact that models such as random forests and k-nearest neighbors (kNN) have on text classification (Xu et al., 2012). While deep learning approaches have stolen the spotlight, these techniques are still highly relevant and are strong contenders for solving the Genre Identification problem.

3 Problem Definition and Hypothesis

This paper takes an approach where a literary genre is considered to be a writing style family where texts that contain similar themes are grouped together. The idea of genre used here is the same as the poetic genre defined by Miller and Greenberg (1981): "The term GENRE refers to a mode of writing that follows certain literary rules or conventions that have come down to the poet through custom and use... just as a word has connotations, a particular genre has a wealth of associations the poet may use." With this in mind, a classification task is envisioned that will learn these literary rules and conventions in a supervised environment.

The Genre Identification problem can formally be defined as: Given a book $d \in D$, referred to as a document from here out, with word length l_w where l_w has an order of magnitude of 4 or higher, determine the genre label $g \in G$ which represents the overall theme and categorization of the document. D is the set of documents in a corpus and G is the set of unique genre labels which the books may belong to. Both D and G are supplied by the literary dataset proposed in Section 3.2. In this work only one genre label is assigned to each document and $|G| = 6$. Given the extreme lengths and literary composition of these documents, the hierarchical nature which comprises them should be noted. Each document d is composed of l_c^d chapters or sections, and each chapter c in d is composed of $l_w^{d,c}$ terms. This notation will be used to reflect the hierarchical nature of the documents.

3.1 Text Composition Hypothesis

This work hypothesizes that genre, as an overarching theme of a piece of literature, is influenced over the course of the novel by individual subtexts, such as paragraphs and chapters. This hypothesis, if true, would mean that models which are used to assign a genre to a document could leverage an ensemble of subtexts or take a hierarchical approach in order to better classify the document. The experiments and evaluations presented here will evaluate how different subtexts of these long documents can be leveraged to improve the performance of the presented models.

3.2 Gutenberg Dataset

The Project Gutenberg is an extensive web catalog containing over 56,000 e-books. Along with providing the text for all of these books, Project Gutenberg also reports a detailed index for each book which contains the title, author, publication date and Library of Congress Subject Headers (LCSHs). All of

Genre	Count	Length	Mean Chapter Count	Mean Chapter Length
Science Fiction	1,186	165,874	8.2	21,309.2
Adventure stories	595	459,556	24.5	22,288.5
Love stories	508	480,265	24.2	25,684.9
Detective and mystery stories	485	475,883	25.1	25,301.2
Historical fiction	410	558,343	27.8	26,046.5
Western stories	393	463,569	23.1	26,013.3
Total	3,577	379,101.5	19.4	23,694.6

Table 1: Gutenberg Dataset Statistics

these e-books, along with the related index file, is publicly available on the Project Gutenberg website[1]. This work proposes the Gutenberg Dataset, a subset of the full Project Gutenberg catalog, which includes works with the following LCSHs: *Science fiction*, *Adventure stories*, *Historical fiction*, *Love stories*, *Detective and mystery stories* and *Western stories*. These 6 subject headers are the genres which we attempt to classify under the Genre Identification problem. Details of the Gutenberg Dataset can be found in Table 1. Scripts to download and assemble the Gutenberg Dataset as defined here can be found in the *ai-lit* project repository[2]. All of the authors' work is also available at this repository. 30% of the documents were held out in a test set which was used to evaluate performance.

4 Approaches and Architectures

Experiments are performed using both deep learning and standard text classification models. Additionally, multiple strategies are evaluated for representing the data during training in order to compensate for the extreme lengths of the documents. The objective is to establish a baseline evaluation to the Genre Identification task as well as to research how individual subtexts, such as chapters, contribute to the overall genre of a book.

4.1 Data Preprocessing

A minimal amount of preprocessing was performed on the dataset in order to prepare it for experimentation. First, the vocabulary of the entire dataset was extracted to build a distribution of all the unique terms found in the corpus. This vocabulary was captured and used to index the terms found in each book. In order to perform the indexing, the 5,000 most common terms from the vocabulary, along with the extra term $\langle unk \rangle$, used to indicate words which are outside of the 5,000 most common, were assembled to form the term index. This term index is used to convert each document, initially represented as a list of terms, into a list of integers which index words found in the term index. It is important to note that no additional text processing was performed on the data. Traditional NLP solutions continue to remove stop words and translate each word into its linguistic stem. However, in pursuit of a complete end-to-end deep learning architecture that does not require complicated preprocessing, these steps are omitted, which will force each model to learn the significance of stop word patterns and grammatical modifiers such as tense and plurality.

The neural network architectures proposed in this work utilize the concept of word-embeddings which represents each term found in a dataset as a N-dimensional vector. These vectors capture semantic and relational meaning of terms in regards to the goal on which they are trained (Mikolov et al., 2013b). These architectures can learn their own embeddings during training time, in which each vector is learned and optimized under the constraint of genre classification (Kim, 2014). This embedding layer works like a mapping where each term index corresponds to a meaningful vector, similar to the popular *word2vec* embeddings (Mikolov et al., 2013a).

4.2 Input Methodology

Due to the length of the records in the dataset, it is very prohibitive to design neural networks which can operate on an entire record all at once. Where traditional methods, such as bag of words, will sacrifice the structure and order of terms in a record in order to reduce dimensionality, here we propose alternative methods which allows the neural network models to capture the order and structure while still maintaining reasonable model sizes. These input methodologies follow the pattern proposed by Kolcz et al. (2001) in which smaller segments of a larger work are used for classification. Input methods which are utilized for both deep learning and traditional approaches are described below.

First 5,000: The first 5,000 input methodology both trains and evaluates on only the first 5,000 words in each record. In this case, the remainder of each book is discarded. There are no records in the dataset which are shorter than 5,000 terms, thus no padding is needed with this methodology.

Last 5,000: The last 5,000 input methodology, like the first 5,000, trains and evaluates on only the last 5,000 terms found in the dataset. Again, there is no need for padding as every document is longer than 5,000 terms.

Random 5,000: The random 5,000 method will randomly extract a 5,000 term window from a record on every training batch and evaluation batch. This method effectively expands the dataset as each epoch will see a different subtext for each book. While there is no guarantee that a book will be entirely processed, this random sampling process significantly grows the content which is trained and evaluated.

All Chapters: This input methodology applies a simple pattern matching algorithm to each book in order to split the books up into chapters. In this case, entire books, both in the training set and testing set, will be processed. However, chapter lengths vary significantly from 158 terms up to 169,588 terms, and we must select a fixed length for each (given the nature of the applied models). For this method, 2,500 terms are kept from each chapter. For the chapters which are shorter than this length, a padding token, $\langle pad \rangle$, is used to bring it up to the appropriate length. When using this method, results are computed across the individual chapters, and across full books by applying a voting scheme across all the chapters in each book.

Bag-of-words: BOW is a simple vector representation of an entire document where each dimension is representative of a unique word in the corpus. Thus, the input dimensionality is equivalent to the number of terms which are maintained when building the BOW representation. This method is a very simple and useful technique for representing documents as the frequency of terms which it is made of, while sacrificing the order of the words. In these experiments, all BOW representations are normalized so that the length of a document is not favored by any learning model.

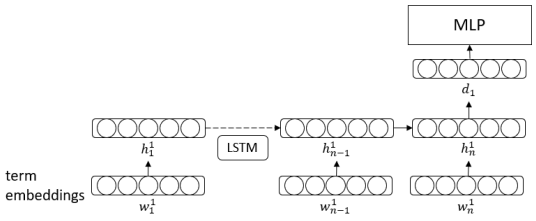
The models which are employed herein require both flat representations of the data and hierarchical representations. Hierarchical inputs will be labeled with an "*h2*" indicator to show that it is broken up into two hierarchical levels. In this case, each record, either a chapter or 5,000 term slice, is further parsed into paragraphs. Then a fixed size representation of 50 paragraphs each made up of 50 terms are captured in order to structure the records in the dataset. Thus, for all $d \in D$, $l_c^d = 50$ and $l_w^{d,c} = 50$. These numbers were selected in an effort to reduce the amount of padding included in the hierarchical models.

4.3 Models

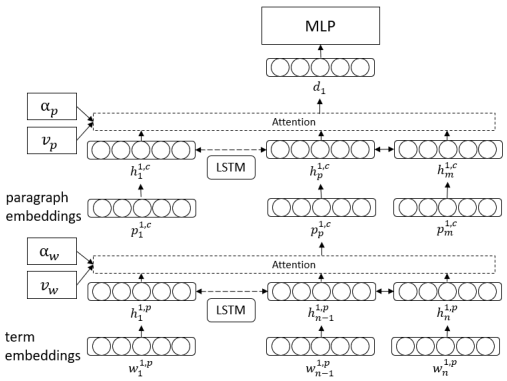
The models which are applied to the Genre Identification problem are detailed in this section. This work presents results with the CNN-Kim architecture (Kim, 2014), a flat LSTM model (Hochreiter and Schmidhuber, 1997), the Hierarchical Attention Network (HAN) (Yang et al., 2016) and a host of traditional machine learning algorithms. The authors also experimented with LSTM models for classification (Hochreiter and Schmidhuber, 1997), however due to the size of the data, they were prohibitively slow to train. Future research is needed to apply more optimized and hierarchical LSTMs to this data given the length of each text.

4.3.1 CNN-Kim

The deep learning model applied to the Genre Identification problem is the convolutional neural network (CNN) proposed by Kim (2014). This model begins with an embedding layer that learns a dense k-



(a) LSTM Architecture



(b) HAN Architecture

dimensional vector representation for each word during the training process. These experiments set $k = 100$ dimensions. Then, these word embeddings are processed in a convolutional layer by a set of filters $w \in W$ where $w \in \mathbb{R}^{hk}$. Here h is the size of the neighborhood around each word which is processed in the convolutional filter. This model employs four different h values, [3, 4, 5, 6], and 128 filters per filter shape. Following the convolutional layers, a max pooling layer is employed in order reduce the dimensionality of the previous layer and select the most informative dimensions. Finally, a fully connected layer, referred to as a multi-layer perceptron (MLP), is used to produce the network outputs. During training a dropout probability of 0.5 is applied following the convolutional layer as regularizer.

The problem is a multi-class classification task with high dependencies across very long sequences of terms. As such, this model will produce a softmax distribution of the confidence that a record belongs to each of the available classes. The softmax unit is defined as:

$$\sigma(z)_j = \frac{e^{z_j}}{\sum_{k=1}^{K} e^{z_k}} \tag{1}$$

for network output vector z and unit j. In order to optimize each model for solving the classification problem, the cross-entropy between the softmax distribution p and the true genre distribution q of document x is minimized:

$$H(p, q) = -\sum_{x} p(x) \log q(x). \tag{2}$$

After the the loss of the CNN is computed, the Adam optimizer is used to train all of the network weights (Kingma and Ba, 2014) in order to minimize the loss with a learning rate of 10^{-4}.

4.3.2 LSTM

The next model applied to the Genre Identification problem is a text based Long Short-term Memory (LSTM) network. This model follows the standard LSTM architecture with a single layer where a document is represented as a sequence of term vectors (Hochreiter and Schmidhuber, 1997). Preceding the LSTM, the term index is embedded into a vector space through the embedding layer. As each term-embedded vector t is passed into the network, an LSTM cell c_t produces output h_t. The architecture of this model can be found in Figure 1a. While multiple values for the term and document embeddings were experimented with, the highest performing values were 100 and 500 respectively. The output of the LSTM is the hidden unit which represents the network output at timestep t. At each LSTM cell a dropout probability of 0.5 is applied as a regularizer.

The final LSTM hidden vector of a document sequence of length d, h_d, is used as the input to a softmax layer for performing classification over the set of possible genres and the loss is the same log loss. This loss value is minimized using the RMSProp optimzier (Tieleman and Hinton, 2012) with a learning rate of 10^{-3}.

4.4 HAN

The hierarchical nature of the HAN, plus the addition of the popular attention mechanisms make HAN a good fit for the Genre Identification problem. The encoding layers of the HAN will be made up of LSTM layers designed to capture the forward context of the text elements while focusing primarily on the element encoded at time step t (Li et al., 2015; Yang et al., 2016). The HAN architecture is detailed in Figure 1b. The attention layers of the HAN are designed to learn which encoded elements from the previous layer contribute to the classification task and which elements do not. This layer is made up of three components. The first is a simple MLP trained to build annotations over each element. The annotations learn to represent the contribution made by the element to the classification task. The measurement of the importance of the element is then computed using a softmax function over all elements at this layer. Finally a weighted sum of the encoding layer using the importance measurement is produced as a representation for the element at the next hierarchical level (Bahdanau et al., 2014). The attention mechanism at each layer is represented as:

$$u_t = \tanh(Wh_t + b) \tag{3}$$

$$\alpha_t = \frac{\exp(u_t^T u)}{\sum_t \exp(u_t^T u)} \tag{4}$$

$$s_t = \sum_t \alpha_t h_t \tag{5}$$

where h_t is the hidden state of cell t. W and b are the trainable components of the attention MLP and s_t is the weighted average output of the attention mechanism. The hierarchical nature of this model leads to three different embedding sizes, term, paragraph and document. After experimentation, the highest performing values were found to be 50, 100 and 150 respectively.

Again the architecture is finished off with a softmax layer and the loss is computed. This model employs a dropout probability of 0.5 at both the term layer and the sentence layer. Again, the Adam optimizer is employed (Kingma and Ba, 2014) with a learning rate of 10^{-3}.

4.4.1 Comparison Models

Along with the detailed deep learning models, we employed traditional machine learning models for classification in order to establish a performance baseline for the Genre Identification task. Naive Bayes (Rish, 2001), k-Nearest Neighbor (*kNN*) (Cover and Hart, 1967), Random Forest (Breiman, 2001) and XGBoost (Chen and Guestrin, 2016) are all evaluated with the BOW input method. *kNN* is different than the other models in that it simply employs a distance metric in order to identify which other documents in the dataset a new record is found to be close to. The set of nearest neighbors then vote on what the label of the new record should be. In these experiments, *k* is set to 1, 5 and 10 and the standard Euclidean distance is used (Huang, 2008).

The Random Forest model is made up of an asynchronous collection of small decision trees which are trained on random selections of features from the dataset. In this case the features are the unique tokens within the BOW input method. It has been shown that Random Forest is an effective model for classification and regression and is not prone to overfitting (Breiman, 2001). XGBoost is a highly optimized, award winning Gradient Boosting solution which is made up of a boosted set of sequential trees learned from the gradients of some differentiable loss function (Chen and Guestrin, 2016). This model often produces state-of-the-art results and is trained on the BOW form of the Gutenberg Dataset in this work.

5 Results

After training, each model was used to assign genres to the records reserved in the test set. Accuracy and the F1-Measure are used as a measure of a model's performance. The F1-Measure is defined in terms of precision and recall (Powers, 2011). The results of each experiment can be found in Table 2. Our results show that each of the models were able to generalize and capture elements that pertain

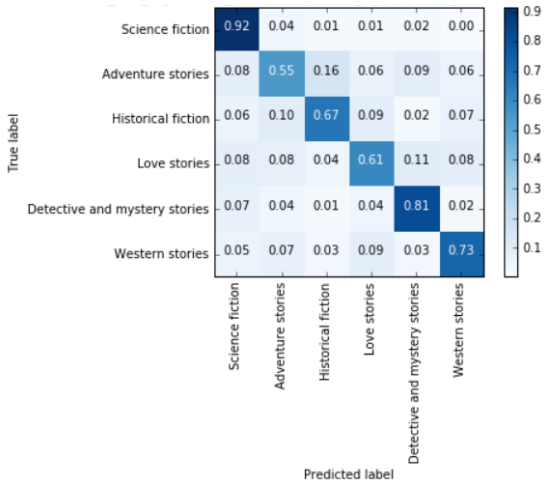


Figure 2: All Chapters CNN Confusion Matrix

Input	Model	Acc.	F1
First 5,000	CNN	0.62	0.55
Last 5,000	CNN	0.56	0.42
Random 100	LSTM	0.42	0.35
Random 5,000	LSTM	0.34	0.20
Random 5,000	CNN	0.65	0.61

All Chap. (h2)	HAN	0.52	0.53
BOW	Naive Bayes	0.63	0.59
BOW	kNN k=1	0.64	0.58
BOW	kNN k=5	0.61	0.55
BOW	kNN k=10	0.61	0.55
BOW	Rand Forest	0.82	0.79
BOW	XGBoost	**0.84**	**0.81**

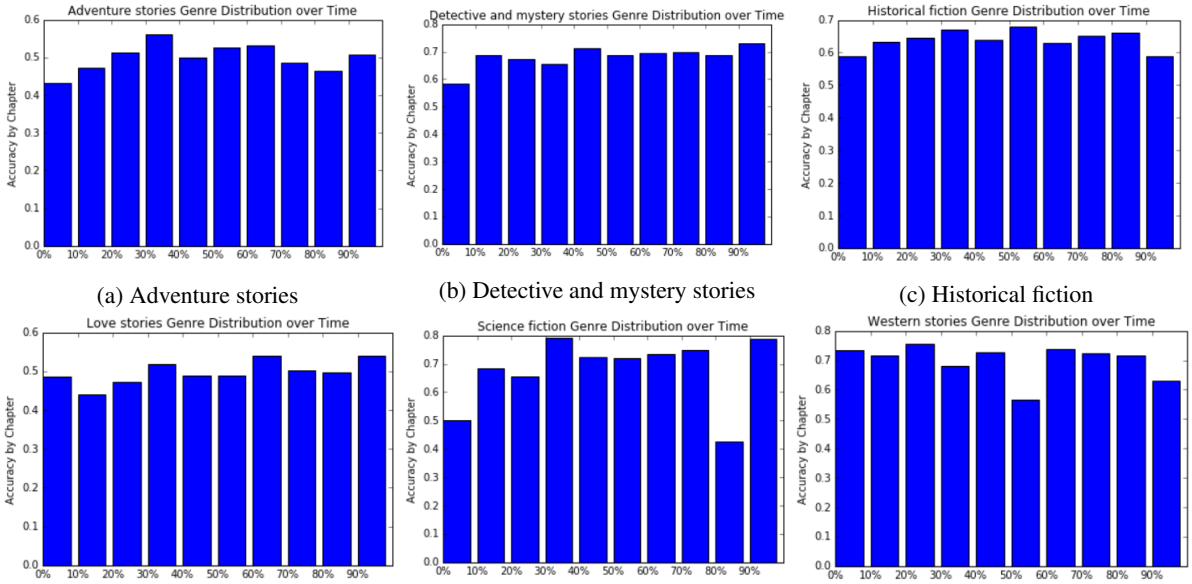
Table 2: Genre Identification Results

to genre across the different works in literature. However each model had weaknesses when working with this dataset. CNN-Kim had the most reliable performance of the deep learning models, scoring a total of 75% accuracy on the "All Chapters" input. Surprisingly, the HAN model had a difficult time converging on this dataset, frequently being fooled by the more represented classes such as *Adventure Stories* and *Science Fiction*. The LSTM, the lowest scoring neural network architecture, collapsed and was unable to learn relevant features over the long sequences. Further experiments showed that an LSTM trained on random 100 term slices from each document actually outperformed the 5,000 term model by 8% accuracy. XGBoost outperformed all models to have the highest accuracy at 84% and F1-Measure at 81%. This shows that while the deep learning models have garnered a lot of attention, tree-based methods still come out on top, and took minutes, instead of days, to train.

These results fall short of similar experiments performed by Kim (2014) using CNNs, however, the difference in data can be credited for this deviation. On a simple question classification task CNN-Kim received an accuracy rating between 91.2% and 93.6%. Lai et al. (2015) report results of 47.47% for another multi-label classification task using a CNN. Similar results have also been published using RNNs and LSTMs for sentiment classification tasks with evaluations ranging between 40% and 71% (Tang et al., 2015; Yang et al., 2016). Additionally, Liu et al. (2009) have shown the common distribution of text classification results given traditional BOW and tf-idf methods. The recorded Naive Bayes F1-Measures from this research range between 45% and 80% across many different experiments and datasets (Liu et al., 2009).

Additionally, this research has shown that across the corpus, there was a 6% gain in accuracy when training and evaluating on the first 5,000 words of each book over training and evaluating on the last 5,000. However, there was an additional 2% increase in accuracy when training and evaluating on the random 5,000 word subtexts extracted from each book. This gain in accuracy provided the insight that training our model on every chapter, and then setting up a voting algorithm where all the chapters of a book get to vote on the genre of the book could prove beneficial. Intuitively, each subtext is unique and can be leveraged in a way that expands the dataset during training allowing the models to train on new subtexts each epoch. As such, the All Chapters CNN-Kim experiment received a large 10% gain in accuracy over the best performing deep learning model with an accuracy of 75% and an F1-Measure of 71%. Figure 2 shows the confusion matrix over all classes in the test set.

Following the voting scheme method employed in the "All Chapters" technique, which yielded a high increase in performance, we digitized each chapter within their respective books into one of ten bins based on the chapter index relative to the number of chapters. That is, chapter $c \in C$ was placed in bin $b = \lfloor \frac{c}{|C|} * 10 \rfloor$. Following this, the accuracy for each bin was computed, relative to the actual genre label, to show the accuracy over the course of each book in the genre. These accuracy over time compositions



(a) Adventure stories (b) Detective and mystery stories (c) Historical fiction

(d) Love stories (e) Science fiction (f) Western stories

Figure 3: Genre composition over the course of the narrative - All Chapters CNN-Kim

for the CNN-Kim experiment are shown in Figure 3. While it is interesting to note the slight pattern variations that have emerged across the books in each genre, such as"Adventure story" novels being more difficult to classify in the first third, it is important to show that accuracy is fairly consistent across all chapters. There is no strong emerging patterns which indicate that some genres would consistently look like others at certain points in the narrative. However, this composition also provides certainty to the voting method as all chapters can be considered relatively reliable when assembling a genre classifier.

6 Future Work

Following the proposal of the Genre Identification problem and the research presented within, which shows the benefits of taking a compositional approach when working with text of this magnitude, future research will focus on building and refining hierarchical models for gains in performance. Applying a hierarchical model, like HAN, on the chapter encodings to learn classification from chapters could yield improved results over the voting scheme employed here, as a model will have the capability to learn patterns over the courses of each chapter. Given the limitations of traditional LSTMs in this context, there is a wealth of future research opportunities to apply specialized models to this domain.

Additionally, we propose future research into the compositionality of literature in the forms of comparing chapter and book similarity across the genres. Future research will study how similar chapters are to each other, and how books of the same genre may vary given additional parameters such as the title, region of origin and publication date. A study on how the title of a book contributes to the assigned genre is the next step in working with the Gutenberg dataset. There is still a lot to be learned when analyzing literature.

7 Conclusion

This work has presented the Genre Identification problem, which is a very long text classification task that requires both syntactic and thematic analysis in order to assign a literary genre to a book from a corpus. Not only is genre a challenge because it is comprised of long running themes which can span paragraphs and chapters, but these documents are significantly longer than the usual text classification datasets.

Along with the Genre Identification problem, different machine learning approaches are presented and evaluated as solutions for assigning genre. Convolutional Neural Networks, LSTMs, HAN, Naive

Bayes, k-Nearest Neighbors, Random Forests and XGBoost are considered along with different data representation schemes to help manage the extreme lengths of the documents. We showed that results were improved when training on random slices of 5,000 words from each document. Following this intuition, an ensemble method was assembled in which each chapter can vote towards the total genre of the book. This ensemble yielded a 10% increase in accuracy. Finally, the genre composition of chapters belonging to each genre has been evaluated to show how chapters contribute to the genre as a whole. There will continue to remain a significant amount of work to be done in researching new deep learning models and gaining more insight into genre and literature.

Abstract

In this reproduction paper, we replicate and extend several past studies on transfer learning for entity recognition. In particular, we are interested in entity recognition problems where the class labels in the source and target domains are different. Our work is the first direct comparison of these previously published approaches in this problem setting. In addition, we perform experiments on seven new source/target corpus pairs, nearly doubling the total number of corpus pairs that have been studied in all past work combined. Our results empirically demonstrate when each of the published approaches tends to do well. In particular, simpler approaches often work best when there is very little labeled target data, while neural transfer approaches tend to do better when there is more labeled target data.

1 Introduction

Transfer learning methods can play an important role in improving the performance of machine learning algorithms in scenarios where in-domain data is scarce, such as entity extraction of protected health information in electronic health records. These methods make use of data in a *source* domain to improve performance in a *target* domain. Many transfer learning techniques have been developed for tasks such as named entity recognition (Daumé III, 2007) and sentiment classification (Blitzer et al., 2007). A broad taxonomy of transfer learning scenarios in machine learning (only some of which are applied to NLP tasks) is given in (Zhang et al., 2017).

In this paper we focus on the entity recognition task[1] in which both the source and target domains have labeled data, but the class label sets are different. As is common in the literature, we frame entity recognition as a sequential classification problem, and restrict ourselves to local (sentence-level) supervised techniques.

Most transfer learning methods have been developed under the assumption that the source and target domains have the same class labels (e.g., (Jiang and Zhai, 2007; Daumé III, 2007)), and many NER corpora only annotate a small number of categories (e.g., 4 labels for the CoNLL 2003 corpus (Sang and Meulder, 2003) and 7 labels for the MUC 6 corpus (Grishman and Sundheim, 1996)). In many situations one would like to recognize categories that were not labeled in a given corpus, but that may be semantically related. This includes, for instance, recognizing companies or sports teams (Ritter et al., 2011), rather than organizations in general, or recognizing actors (Liu et al., 2013b), rather than people in general.

In addition, techniques for transfer learning with different class labels may be useful even when the class label set is the same across domains. As Florian et al. (2004) point out, the same labels may be used in very different ways across corpora due to different annotation guidelines. For example, determiners may or may not be annotated as part of an entity, and annotations may or may not include nominal as well as named entities.

[1] Although some researchers use the terms *entity recognition* and *named entity recognition* (NER) interchangeably, we shall refer to the task of recognizing named and nominal entities as entity recognition.

Proceedings of the 27th International Conference on Computational Linguistics, pages 1974–1985
Santa Fe, New Mexico, USA, August 20-26, 2018.

To the best of our knowledge, a direct comparison of existing transfer learning techniques for entity recognition with different labels does not exist. The results in the literature are hard to compare directly for several reasons: in some cases the datasets used are not publicly available, different evaluation measures are used for evaluation (macro-averaged vs micro-averaged scores, for instance), and in some cases, crucial implementation details are missing.

In this paper we replicate and extend several transfer learning methods for recognizing novel entities, using both standard corpora and datasets that have not been used for this task before. To the best of our knowledge, this is the first direct comparison of these transfer learning methods. In addition, we perform experiments on seven new source/target domain corpus pairs, nearly doubling the total number of corpus pairs that have been studied in all past work combined. We also share our code[2] so that others may verify our results and compare future transfer learning techniques against our benchmarks.

2 Transfer Learning for Novel Classes

2.1 Transfer learning scenarios

It is helpful to distinguish between three different scenarios for the transfer learning problem with different class labels:

1. The source domain entities are more fine-grained than the target domain entities and source domain entities can be mapped to target domain entities.

2. The source domain entities are generally coarser than the target domain entities, yet it may not be possible to map every target entity to a source entity.

3. There is no overlap in the labels in the source and target domains, and entities they correspond to have little in common.

While these three scenarios do not exhaust the possibilities that may be encountered in practice, they are helpful to categorize previous transfer learning experiments in the literature.

Under scenario 1, it is possible to map source domain labels to target domain labels without losing much information, to insure that both domains have the same label set. For example, if transferring from ACE 2005 (Walker et al., 2006) to CoNLL 2003, one could map the GEOPOLITICAL and FACILITY entities to LOCATION. This is often done manually (Daumé III, 2007; Augenstein et al., 2017), though Kim et al. (2015) introduced a method to automate this mapping: labels from both domains are embedded in a common vector space using Canonical Correlation Analysis (CCA), and k-nearest neighbors are used to find the target label closest to each source label. In their experiments the appropriate label mappings were not obvious and the CCA label embedding approach outperformed manual mappings. CCA is a dimensionality reduction technique (Hotelling, 1936) that will be described in Section 2.2.

One expects that transfer learning would be hardest in scenario 3, given that the source and target entities have little in common. For example, Qu et al. (2016) show that transfer from CoNLL 2003 (news) to CADEC (a biomedical corpus) is very difficult.

In this paper we focus on scenario 2, which is more challenging than scenario 1 and also of great practical importance. Many corpora have been published with coarse-grained entities, and it would be advantageous to harness this data to recognize other kinds of entities in other domains.

Figure 1 shows the combinations of datasets that have been used in previous transfer learning experiments relevant to the problem of disparate label sets, together with the additional experiments in this paper. We were unable to access TAC-KBP 2015 (Ji et al., 2015), i2b2 2016 (Stubbs et al., 2017) or MIMIC (Dernoncourt et al., 2017b). The TAC-KBP 2015 corpus consists mainly of news text, so we used MUC 6 and NIST IE-ER (NIST, 1999) as substitutes to see if we could obtain results consistent with those of (Obeidat et al., 2016). MIMIC is a manually corrected subset of the MIMIC-III dataset (Johnson et al., 2016). It was unclear how to replicate the manual corrections, so we leave experiments with

[2] https://github.com/ciads-ut/transfer-learning-ner

MIMIC to future work. We decided not to use ACE 2005; the annotated entities in this corpus are nested, and it was unclear which entities should be selected to fit the sequential classification framework.[3]

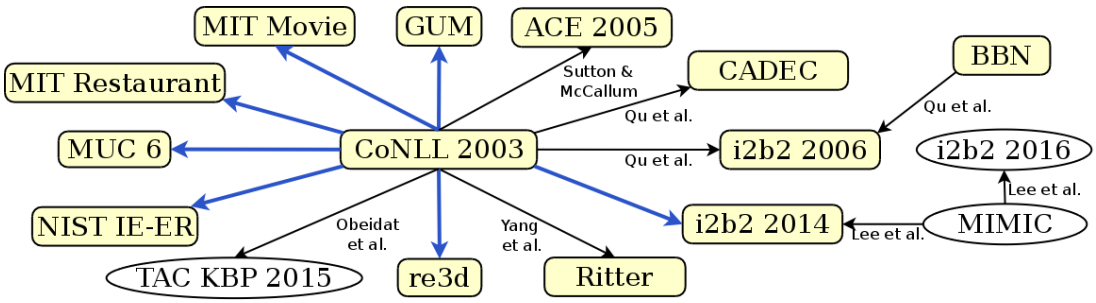

Figure 1: Source and target domains used in transfer learning experiments

Of the datasets shown in Figure 1, only CoNLL 2003, MIMIC and BBN (Weischedel and Brunstein, 2005) have been used as the source domain. Most past experiments use CoNLL 2003 as the source corpus. We replicate most of these past experiments, and extend experiments using CoNLL 2003 as a source corpus to seven additional target corpora that have not previously been used in transfer learning with novel classes for entity recognition. In future work, we plan to extend our study to additional source/target corpus pairs, particularly those that do not use CoNLL 2003 as the source corpus. Details on the datasets that we used for experiments are provided in Section 3.1.

2.2 Transfer learning frameworks

Here we briefly describe the transfer learning frameworks which are able to handle the problem of novel entity types. We use the term *framework*, rather than *algorithm*, because each of these can be implemented with a variety of machine learning models. It is important to emphasize that most existing transfer learning methods assume the label sets are the same across domains (Day and Khoshgoftaar, 2017; Weiss et al., 2016; Zhang et al., 2017). In addition, most of the methods which can handle disparate labels are designed for image and text classification rather than sequence classification problems (Day and Khoshgoftaar, 2017); some examples include (Shi et al., 2009; Shi et al., 2010; Quadrianto et al., 2010; Tommasi et al., 2010; Jie et al., 2011; Qi et al., 2011; Xiang et al., 2011; Patricia and Caputo, 2014; Feuz and Cook, 2015; Bhatt et al., 2016; Moon and Carbonell, 2016). To the best of our knowledge, the only two transfer learning approaches that have been proposed for entity recognition with different class labels are:

- **PRED:** train one classifier on the source domain, and use its predictions on the target domain as features for a second classifier.
- **Pre-training:** train a neural network on the source domain, use the trained weights to initialize a new neural network, and fine-tune the weights on the target domain.

In this paper we shall compare two variants of PRED against the Pre-training approach.

We note that transfer learning is closely related to work in *multi-task learning*. Multi-task learning consists in simultaneously training a classifier (e.g., a neural network with shared weights) to solve more than one task. In multi-task learning, however, the goal is to improve performance across all domains, rather than to optimize performance on the target domain. (Yang et al., 2017) is the only work we are aware of that uses multi-task learning on NER tasks with different label sets. For the sake of restricting the scope of this paper, in our experiments we restrict ourselves to approaches that train on the source and target data separately. A comparison to multi-task learning techniques that train simultaneously on source and target data is planned in future work.

[3]From a practical perspective, using the largest entity span is not always desirable.

PRED and PRED-CCA

It is common in NLP to use the outputs of one classifier as inputs to another one, but usually this is done for different tasks (e.g., using part-of-speech tags as features for NER), rather than for the same task with different class labels. Sutton and McCallum (2005) refer to this as "cascaded transfer"; we shall denote it PRED, following (Daumé III, 2007). A few researchers have used this approach for the entity recognition task with different class labels. Florian et al. (2004) use the output of entity taggers trained on corpora with different label types as features for a second classifier to tag entities in the ACE 2003 evaluation. They report an increase of 2% in F1 score over a baseline using lexical features with a Maximum Entropy classifier. Sutton and McCallum (2005) use PRED to transfer from CoNLL 2003 to ACE 2005, and show an improvement in F1 scores for several classes (e.g., an increase of 5.9% for person names and an increase of 1.2% for person nominals). Daumé III (2007) uses PRED to transfer from ACE 2005 to CoNLL 2003 (though source entities are mapped to target entities before the transfer[4]), and obtain a 0.82% increase in accuracy.

PRED-CCA[5] was introduced by Obeidat et al. (2016) as a variant of PRED. In PRED-CCA label embeddings rather than the predicted entities themselves are used as features for the second classifier. Label embeddings are obtained through CCA as in (Kim et al., 2015). CCA is a dimensionality reduction technique for paired data. In this case, every word is paired with its label. CCA is used to obtain label embeddings by finding a sequence of projections of the words and labels such that the correlations between the projections are maximized.

Obeidat et al. (2016) shows an improvement of 9% in micro-averaged F1 score of PRED-CCA over CCA when transferring from CoNLL 2003 to TAC-KBP 2015.

Pre-training

Fine tuning pre-trained neural networks has been used successfully in computer vision tasks, but seems comparatively less common in NLP. Mou et al. (2016) use pre-training to improve the performance of sentence and sentence-pair classification; two of their experiments transfer between corpora with different label sets. Kim et al. (2015) also experiment with pre-training for slot tagging, but only after the source domain labels have been mapped to target domain labels.

The only works we are aware of that apply pre-training to the entity recognition task are (Lee et al., 2017) and (Qu et al., 2016). Lee et al. (2017) use pre-trained neural networks to improve the performance of de-identification of protected health information in medical records, though they use two datasets with the same label set.[6] Qu et al. (2016) use pre-training in experiments with novel entities, using two conditional random fields (CRFs) rather than two neural networks. Unfortunately, we were not able to obtain the code used in Qu et al.'s experiments or to replicate their approach using new code.

Lee et al. (2017) use a bidirectional LSTM CRF (BiLSTM-CRF) neural network for their transfer learning experiments. Their network architecture is described in (Dernoncourt et al., 2017b), and is similar to the BiLSTM-CRF in (Lample et al., 2016). They experiment with transferring successive layers of the network: character embeddings, word embeddings, the character BiLSTM layer, the word BiLSTM layer, the fully connected layer, and the CRF layer. They experiment with transferring from MIMIC to i2b2 2014 and from MIMIC to i2b2 2016, and show that transferring weights of a pre-trained network boosts performance, with better results as more layers are transferred. While transferring the last (most task-specific) layers does not help as much as transferring the lower layers, it also does not hurt performance.

The results in (Lee et al., 2017) were produced with the NeuroNER program[7] (Dernoncourt et al., 2017a). Unfortunately, NeuroNER requires both source and target corpora to have the same label set, so we were not able to use it for our experiments. To run experiments similar to those in (Lee et al., 2017),

[4](Daumé III, 2007) does not explicitly describe this preprocessing step, but we infer it based on the other methods that PRED is compared against.

[5]Obeidat et al. (2016) refer to it as "AugmntTr"; we call it PRED-CCA in order to emphasize its relation to PRED.

[6]The label sets were slightly different, but in the few cases where entities were different they were mapped to a common type.

[7]Available at `https://github.com/Franck-Dernoncourt/NeuroNER/`

but with different label sets, we implemented a variant of their neural network architecture. Since our goal is to replicate the transfer learning approach, not the exact network architecture, we made one simplification: we replaced the character-level embeddings with casing embeddings following (Reimers and Gurevych, 2017). This has two advantages: it makes the neural network experiments more comparable to the CRF experiments with PRED and PRED-CCA (which use simple token features), and it reduces the number of layers that can be transferred. In our experiments the only layers that can be transferred are the word embedding layer and the word BiLSTM layer, since the last two layers depend on the target domain's label set. Details of our implementation and our choice of hyperparameters are listed in Section 3.2.

3 Experimental Setup

Our experiments compare the performance of the transfer learning methods in different settings: we vary both the target corpus and the size of the target training set. We run every experiment 5 times, using different subsets of the target data to train with, and average results.

3.1 Datasets

We used CoNLL 2003 with the standard train/test split as the source corpus for our experiments . CoNLL 2003 is annotated with Person, Location, Organization and Miscellaneous entities. Table 1 shows the corpora that we used as the target, together with their entity types. The entities which overlap with the CoNLL 2003 entities are italicized; we refer to the others as "novel entities" [8].

Corpus	**Domain**	**Annotated entities**
Ritter	Twitter	*Person*, *geo-loc*, facility, company, sportsteam, band, product, tv-show, movie, other
i2b2 2006	Medical	Date, doctor, hospital, ID, *location*, patient, phone
i2b2 2014	Medical	Age, username, ID, patient, doctor, profession, hospital, street, state, zip, city, country, *organization*, date, medical record, phone
CADEC	Medical	Adverse reaction, disease, drug, finding, symptom
MUC 6	News	*Person*, *location*, *organization*, date, percent, money
NIST IE-ER	News	*Person*, *location*, *organization*, date, duration, percent, money, cardinal
GUM	Wikinews wikihow wikivoyage	Abstract, animal, event, object, *organization*, *person*, *place*, plant, quantity, substance, time
MIT Movie	Spoken queries	Actor, character, director, genre, plot, year, soundtrack, opinion, award, origin, quote, relationship
MIT Restaurant	Spoken queries	Amenity, cuisine, dish, hours, *location*, price, rating, restaurant name
re3d	Defense and security	Document reference, *location*, military platform, money, nationality, *organization*, *person*, quantity, temporal, weapon

Table 1: Corpora used as the target domain in our experiments

Entities which occured less than 20 times in a corpus were removed[9]. We used the standard train/test splits for the i2b2 2006 (Uzuner et al., 2007), i2b2 2014 (Stubbs and Uzuner, 2015), MIT Movie (Liu et al., 2013b) and MIT Restaurant (Liu et al., 2013a) corpora. For the Ritter corpus (Ritter et al., 2011)

[8]We consider subtypes of CoNLL 2003 entities such as "doctor" and "hospital" to be novel. Although "geo-loc" and "place" are used in slightly different ways, we identify them with "location", so do not consider them to be novel.

[9]In particular, "time" was removed from both MUC 6 and NIST IE-ER; "age" was removed from i2b2 2006; "healthplan", "URL", "fax", "email", "device", "location-other" and "bioID" were removed from i2b2 2014; "commsIdentifier", "frequency" and "vehicle" were removed from re3d.

we used the same train/test split as in (Yang et al., 2017)[10]. We used stratified random sampling at the sentence level to create suitable test sets for CADEC (Karimi et al., 2015), GUM (Zeldes, 2017), NIST IE-ER (NIST, 1999), re3d (DSTL, 2017) and MUC 6 (Grishman and Sundheim, 1996)[11]. Unlike i2b2 2006, the i2b2 2014 corpus is not tokenized. To stay consistent with (Lee et al., 2017), we used the scripts included with NeuroNER with the *spacy* tokenizer to convert i2b2 2014 to the CoNLL 2003 format.

CoNLL 2003, Ritter, and i2b2 2014 also have default train/test/dev splits. In order to have more control over the sizes of the training and development sets (in particular, to have the same train/dev ratio over increasing sizes of the training set), we decided not to use the standard train/dev splits.

The available target training data is randomly shuffled, and for every shuffle we use increasing subsets of the target corpus (with 20, 50, 100, 250, 500, 1000, 1500 and 2000 sentences) as target training data. In order not to give the neural network methods an unfair advantage over PRED and PRED-CCA, we do not use a hold-out development set for them, and instead use 20% of the available training data for validation.

3.2 Implementation Details

We used the IOB2 tagging scheme for all our experiments. For every experiment we compute the micro and macro-averaged chunk-based precision, recall and F1 scores, as well as micro and macro-averaged scores over novel classes, as was done in (Qu et al., 2016). Due to space limitations we only include the micro-averaged scores in this paper, but our full results (including scores for specific labels) will be available online.

PRED and PRED-CCA

Obeidat et al.'s experiments comparing PRED and PRED-CCA were performed using *Stanford NER*, which is an implementation of a second-order linear CRF. Since we are replicating the PRED and PRED-CCA approaches rather than Obeidat's exact setup, we perform our experiments with *CRFSuite*. Although Stanford NER has an extensive set of built-in features, it is harder to modify them than it is for CRFSuite. We use the following features when evaluating PRED and PRED-CCA: (1) the current token x_i and tokens in a window of size 2, (2) initial capitalization of tokens in a window of size 2, (3) word shape information for x_i (uppercase, alphanumeric, or all digits), and (4) token prefixes of lengths 3 and 4, and token suffixes of lengths 1 through 4.

These features were used in (Zhang and Johnson, 2003)[12], and were also used as baseline features in (Turian et al., 2010). Augenstein et al. (2017) also evaluate CRFSuite on NER across a variety of datasets with features similar to these. Due to limitations of CRFSuite, we did not include second-order label transitions or features of the form $\mathbb{I}_{tag_i \wedge x_i}$. We also opted against using gazeteer, word embedding, part-of-speech or chunking features, since the goal of this paper is to compare transfer learning approaches and not achieve state-of-the-art results.

While Kim et al. (2015) and Obeidat et al. (2016) use the predicted entities without the IOB prefix as features, we experimented with using the IOB-prefixed entities for both PRED and PRED-CCA. Preliminary experiments suggested the differences were minimal, so we ran all our experiments with entity labels without the IOB prefix as features. In addition, Obeidat et al. (2016) do not specify whether they included the "O" entity label when computing the CCA label embeddings. If "O" is not included in the calculation, one must find a suitable label embedding for "O" separately. We experimented with excluding "O" from the computation and mapping "O" to the zero vector. The difference was minimal, so we ran our full experiments with the "O" label included in the CCA computation.

We use the same embedding dimension as (Obeidat et al., 2016), k=5, for all our experiments.

[10] Available at `http://kimi.ml.cmu.edu/transfer/data.tar.gz`

[11] We used 1000 sentences for the test sets of CADEC, GUM, and MUC6; for NIST IE-ER and re3d we used 690 and 200 sentences, respectively.

[12] Specifically the combination B+D+E+F, listed in their Table 1.

Pre-training

We used the same network architecture and hyperparameters as in (Lee et al., 2017) [13], with the following exceptions: (1) we replaced the character embedding layer with a casing layer as in (Reimers and Gurevych, 2017), (2) we used the IOB2 tagging scheme rather than the BIOES tagging scheme, and (3) we used RMSprop rather than stochastic gradient descent (SGD) for fine-tuning on the target dataset. Preliminary experiments showed that SGD with a learning rate of 0.005 and 100 epochs (the defaults in (Lee et al., 2017)) failed to converge for many of our datasets. We experimented with learning rates of 0.05 and 0.5, as well as with optimizers with adaptive learning rates (Adam, Adagrad, and RMSprop). Since RMSprop tended to have the highest F1 scores, and in order not to have to tune the learning rate of SGD for each dataset, we ran our final fine-tuning experiments with RMSprop, with a learning rate of 0.001.

We ran experiments with three settings: no transfer (training the network from scratch on the target corpus), transferring the word embedding layer, and transferring both the word embedding layer and the BiLSTM layer. We observed that the difference between not transferring any layers and transferring one layer was often small; this was also noted in (Lee et al., 2017). We therefore only include the results with transferring both layers and when discussing pretraining below we are referring to this case.

4 Results

We are particularly interested in comparing the behavior of the transfer learning methods as the size of the target dataset varies. This can help practitioners decide which approach is best suited to their situation. Plots of micro-averaged precision, recall and F1 scores with error bars for a few target domain datasets are shown in Figures 2, 3 and 4 [14]. We denote the no-transfer (training on the target only) baselines for the CRF and the BiLSTM-CRF as CRF-TGT and BiLSTM-TGT, respectively.

4.1 Comparing PRED/PRED-CCA and neural network approaches

The PRED/PRED-CCA approaches have greater precision than the neural network approaches in most cases (the only exceptions being GUM, with 1500 and 2000 sentences), with the greatest difference occurring when the number of target training sentences is small. For recall, the situation is not so clear. For MIT Restaurant, MIT Movie, CADEC, i2b2 2014 and i2b2 2006 (Figure 2), the neural network approaches have better recall than PRED and PRED-CCA across all dataset sizes; this results in the neural network approaches having a greater F1 score for these datasets in most cases (the exceptions being MIT Restaurant with under 500 sentences, and CADEC with 500 sentences).

On the other hand, for GUM, re3d, NIST IE-ER, MUC 6 (Figure 4) and Ritter (Figure 3), we observe that initially PRED and PRED-CCA have higher recall than the neural network approaches, but the neural networks' recall surpasses them once the target domain dataset is large enough. This occurs at 500 sentences for Ritter, NIST IE-ER and MUC 6, and at 250 sentences for re3d and GUM; it leads to a similar pattern in F1 scores: for Ritter, GUM, MUC 6 and NIST IE-ER, PRED and PRED-CCA have higher F1 scores than either of the neural network approaches for smaller target training sets, but the situation is reversed once the target domain dataset is large enough.

4.2 Comparing PRED and PRED-CCA

For most corpora, the PRED/PRED-CCA approaches improved the F1 score over the "target-only" (CRF-TGT) baseline. MIT Restaurant and MIT Movie were the only corpora where the F1 scores for CRF-TGT, PRED, and PRED-CCA were about the same. For CADEC the F1 scores for the 20 and 50 sentence settings decreased.

PRED-CCA outperformed PRED in most cases, but not always by very much. MUC 6, NIST IE-ER and Ritter show the greatest increase in F1 score, due to an increase in recall. The improvements in F1

[13] The hyperparameters can be found in the `parameters.ini` file in NeuroNER; they include using dropout of 0.5 after the word embedding layer, using the 100-dimensional Glove 6B word embeddings, and using 100 LSTM hidden units. Training on the source corpus is done using SGD with 100 epochs and patience of 10, with a learning rate of 0.005 and a gradient clipping value of 5.0.

[14] We only include three due to space limitations; the plots for the other transfer learning experiments will be available online.

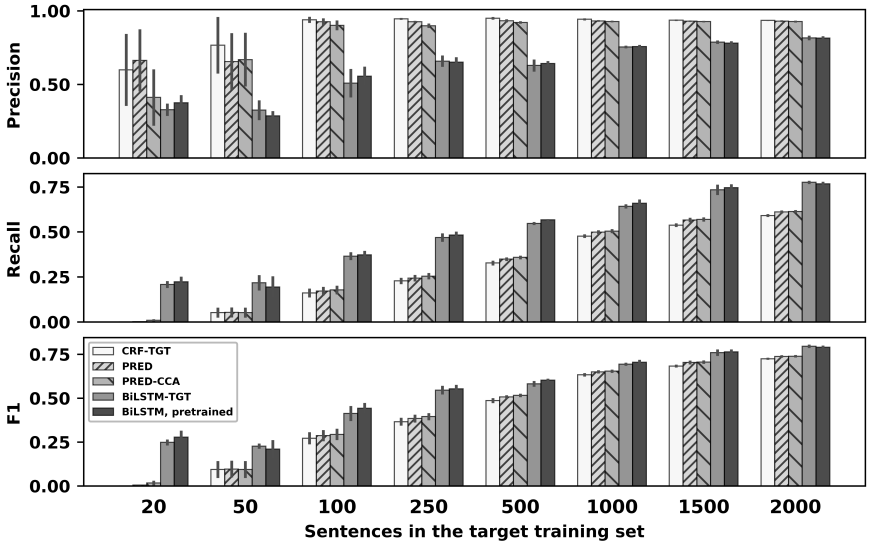

Figure 2: Micro-averaged scores for the i2b2 2006 corpus

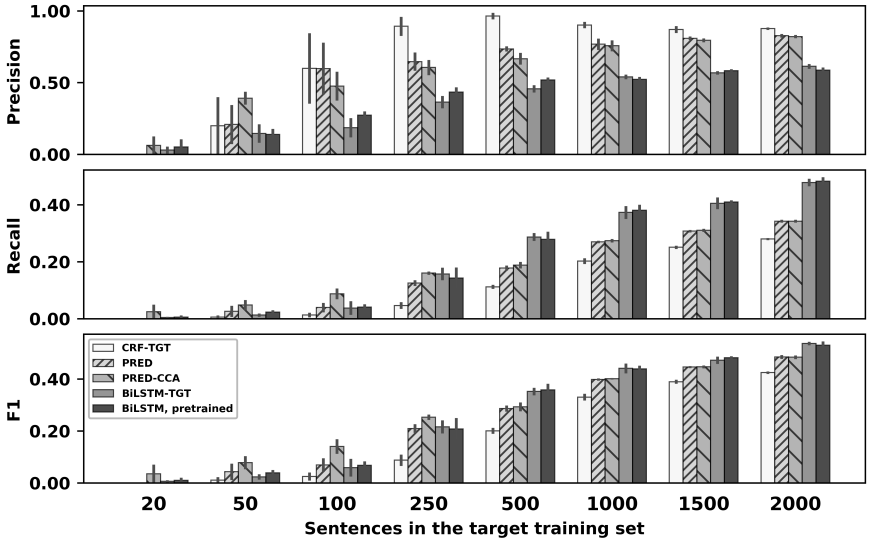

Figure 3: Micro-averaged scores for the Ritter corpus

score are highest for smaller target training datasets, and rapidly decrease with increasing dataset size. Figure 5 shows the change in F1 score between PRED and PRED-CCA for the MUC 6 and Ritter corpora. NIST IE-ER displayed a pattern similar to MUC 6, so it was omitted. re3d showed an improvement of 2% under the 20 sentence setting; the improvement for the other datasets was under 1%.

We note that in most cases, using PRED-CCA rather than PRED results in a small drop in precision; this is consistent with the results in (Obeidat et al., 2016), who observe a drop of 1% between PRED and PRED-CCA for the TAC-KBP 2015 corpus. The large increase in F1 score for MUC 6 and NIST IE-ER are consistent with the 9% increase for TAC-KBP 2015 reported in (Obeidat et al., 2016). Although the label sets are different in each case, MUC 6, NIST IE-ER and TAC-KBP 2015 are all news corpora, as is CoNLL 2003. We hypothesize that the reason PRED-CCA does so much better than PRED in these cases is that there is more of an overlap in the source and target domains' vocabularies. This would lead to more semantically similar source and target labels being mapped closer together.[15]

[15]We did not lowercase the tokens before computing the label embeddings. We expect to obtain higher F1 scores in this case, particularly for the MIT Movie and MIT Restaurant corpora, but leave this for future work.

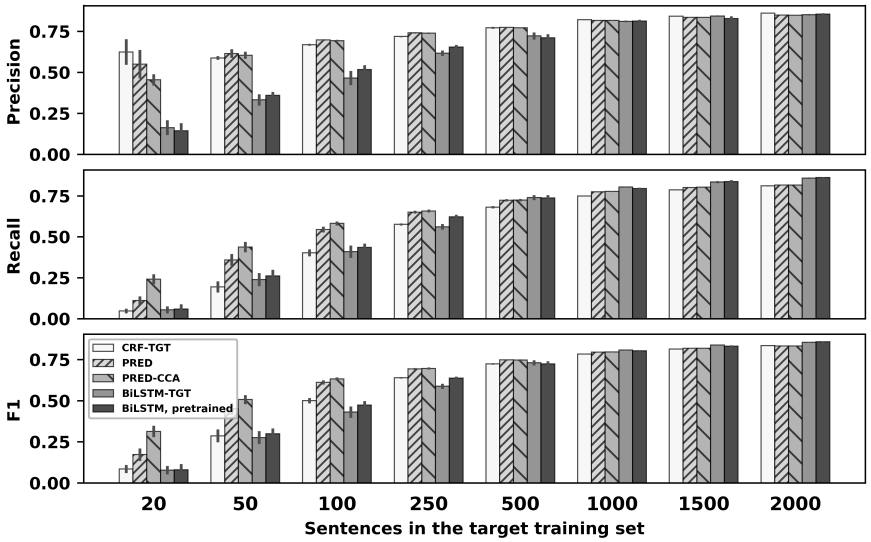

Figure 4: Micro-averaged scores for the MUC 6 corpus

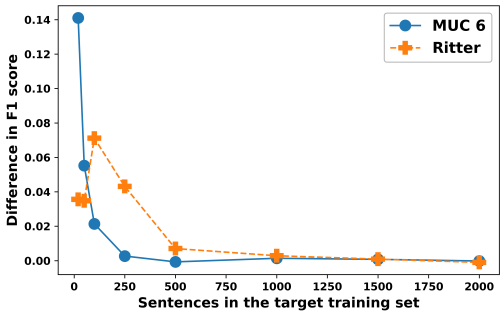

Figure 5: Difference in F1 score between PRED and PRED-CCA

4.3 Comparing the BiLSTM-CRFs with and without pre-training

The results for the pre-trained neural network were less clear. On i2b2 2006, i2b2 2014, and MIT Movie, using pre-training generally led to an improvement in F1 scores over the BiLSTM-TGT baseline. When these datasets had over 500 sentences the improvement was minimal (under 1%); for less than 500 sentences the improvement varied, but was often between 2% and 3%. In these scenarios pre-training also performed better than PRED and PRED-CCA as well. The improvement in F1 score of i2b2 2014 with 1500 sentences was 0.7%. For comparison, Lee et al. (2017) report an increase of 3% when transferring from MIMIC to i2b2 2014, when using 5% of their target set (roughly 1600 sentences) and reusing all layers up to the token layer.

For MUC 6, NIST IE-ER, re3d, Ritter, MIT Restaurant, and GUM, pre-training often achieved a higher F1 score than training from scratch; this mostly occurred when there were 500 target training sentences or less. The increase in F1 score was highest for MUC 6 (2%-5%) and for re3d (2-3%). However, in nearly all of these cases pre-training was outperformed by PRED-CCA.

5 Summary and Conclusion

In this reproduction paper, we have compared three existing methods that can be applied to the setting of transfer learning with novel entities in the target domain. These methods have not been compared against each other before in the literature.

In summary, our results show that in some situations (particularly when there is less labeled target data), PRED and PRED-CCA outperform pre-training neural networks for the entity recognition task.[16]

[16]This may not generalize to other neural network architectures, hyperparameter choices, or domain pairs.

With sufficient labeled data, the neural transfer approaches tend to do well, but of course, these correspond to cases with less data scarcity.

Thus, we encourage researchers to compare neural network approaches with simpler baselines such as PRED and PRED-CCA, rather than only comparing against the "no tranfer" option, and to report not only F1 scores, but also precision and recall, which may be useful when deciding which transfer learning approach to use.

A number of extensions to our study are possible in future work. For example, we hope to run similar comparisons with multi-task and few-shot learning approaches. In particular, we believe methods for few-shot learning in image classification could potentially be adapted to sequential classification problems such as entity recognition. A more thorough study of hyperparameter tuning (versus replicating previously published hyperparameters) would also be interesting future work, particularly for the neural network approaches, which are known to be sensitive to choices in hyperparameters.

Location Name Extraction from Targeted Text Streams using Gazetteer-based Statistical Language Models

Hussein S. Al-Olimat, Krishnaprasad Thirunarayan, Valerie L. Shalin and Amit Sheth

{hussein;tkprasad;valerie;amit}@knoesis.org

Abstract

Extracting location names from informal and unstructured social media data requires the identification of referent boundaries and partitioning compound names. Variability, particularly *systematic* variability in location names (Carroll, 1983), challenges the identification task. Some of this variability can be anticipated as operations within a statistical language model, in this case drawn from gazetteers such as OpenStreetMap (OSM), Geonames, and DBpedia. This permits evaluation of an observed n-gram in Twitter targeted text as a legitimate location name variant from the same location-context. Using n-gram statistics and location-related dictionaries, our Location Name Extraction tool (LNEx) handles abbreviations and automatically filters and augments the location names in gazetteers (handling name contractions and auxiliary contents) to help detect the boundaries of multi-word location names and thereby delimit them in texts.

We evaluated our approach on 4,500 event-specific tweets from three targeted streams to compare the performance of LNEx against that of ten state-of-the-art taggers that rely on standard semantic, syntactic and/or orthographic features. LNEx improved the average F-Score by 33-179%, outperforming all taggers. Further, LNEx is capable of stream processing.[1]

1 Introduction

In context-aware computing, location is a fundamental component that supports a wide-range of applications (Hazas et al., 2004; Licht et al., 2017). During natural disasters, location is crucial for situational awareness during disaster response (Son et al., 2008). When available, targeted streams of social media data are therefore particularly valuable for disaster response (Munro, 2011)[2]. For example, the tweet "water level in Ganapathy Colony is around 2 m" refers to a location. But, unless we know where "Ganapathy Colony" is, the water level data cannot enhance situational awareness and inform disaster response applications such as storm surge modeling or forecasting.

However, pragmatic influences on writing style shorten names to reduce redundant content in social media. We call this the *location name contraction problem*. For example, "Balalok School", appears in the Chennai flood tweets in contrast to the full gazetteer name–"Balalok Matriculation Higher Secondary School". Carroll (1983) examined the complex phenomenon of alternate name forms (called Nameheads). He distinguishes between four shortening processes: (1) Appellation Formation, (2) Explicit Metonomy, (3) Category Ellipsis, and (4) Location Ellipsis.

Appellation Formation occurs when, for example, the author refers to the location name "The Erie Canal" as "The Canal". People may also refer to the only airport in the affected area as just "The Airport". Referring to "University of Michigan" as "Michigan" is an example of Explicit Metonomy. Common ground or shared understanding between the author and the recipient establishes the referent (Resnick et al., 1991). Both Appellation formation and Metonomy pose *disambiguation* problems, and require context such as the author's location to resolve.

[1] Data and the tool is available at https://github.com/halolimat/LNEx

[2] We define a *targeted stream* as a set of tweets that has the potential to satisfy an event-related information need (Piskorski and Ehrmann, 2013) crawled using keywords and hashtags, to contextualize the event (e.g., "#HarveyFlood").

Proceedings of the 27th International Conference on Computational Linguistics, pages 1986–1997
Santa Fe, New Mexico, USA, August 20-26, 2018.

In contrast, Category Ellipsis and Location Ellipsis pose *delimitation* problems that can be resolved with a statistical language model. Category Ellipsis occurs when the author strips words related to the location category (e.g., "City" from "Houston City" to become "Houston"). Location Ellipsis occurs when an author drops the specific location reference in the location name (e.g., when "New York Yankee Stadium" becomes "Yankee Stadium" or "Cars India - Adyar" becomes "Cars India").

This distinction between delimitation and disambigution is important in the location extraction literature. Entity delimitation is typically the first step of location extraction, to identify the boundaries of a location mention in the text. To address this problem, previous research (Liu et al., 2014; Malmasi and Dras, 2015; Hoang and Mothe, 2018) has applied both syntactic heuristics (using lexical cues, e.g., "*in* New Orleans") as well as semantic heuristics (i.e., content-based, for different types of locations such as *buildings* and *streets*). These heuristics have serious limitations, such as failing to delimit metonyms and location names that begin sentences (i.e., outside locative expressions, e.g., "*New Orleans* is flooded") and they cannot assist in hashtag segmentation (needed to extract locations from hashtags). Moreover, simply identifying a location name still leaves open the problem of linking the entity to a corresponding gazetteer record for geocoding. Simple fixed phrase matching with gazetteers entries, as in (Middleton et al., 2014; Malmasi and Dras, 2015), solves the linking problem, but remains vulnerable in two respects. With simple fixed phrase matching, the tendency for authors to shorten names while the gazetteers extend names, creates conflicting conditions causing poor recall. On the other hand, simply relaxing matching criteria exacerbates the disambiguation problem.

To address delimitation, we treat location names as a sequence of ordered words known as *collocations* (Manning and Schütze, 1999). Collocations are neither strictly compositional nor always atomic. We cannot identify them with grammatical rules, and fixed phrase matching is not reliable for longer names. Fortunately, the gazetteer provides a resource to establish region-specific naming regularities. Given a region-specific gazetteer, which retains the same location-context as the text, we can construct a statistical model of the *token sequences* it contains. However, current gazetteers are overly specific in two respects. First, consistent with (Carroll, 1983), they do not always represent Category Ellipsis and Location Ellipsis. To mimic these processes, we judiciously apply a skip-gram method to token sequences in the gazetteers, thereby including, for example, "Balalok School" as a variant of the complete name (which is a special case of Category Ellipsis where we retain only the last category token and drop the other ones). Second, we eliminate auxiliary or ambiguous gazetteer content (e.g., "George, Washington") that would otherwise threaten recall.

Here we answer the research question: ***Can we accurately and rapidly spot location mentions in text solely relying on a statistical language model synthesized from augmented and filtered region-specific gazetteers?*** Although LNEx works on a targeted Twitter stream collected using event-specific keywords, it does not rely on rarely available tweets geo-coordinates and it does not need any supervision (i.e., training data). It is well-suited for stream processing, and needs only freely available data. Our contributions include:

1. A method for preparing high-quality gazetteers from online open data, such as OSM, Geonames, and DBpedia, and deriving a language model from them; and a comprehensive analysis of the contribution of gazetteer quality to overall performance.

2. A referent corpus representing the full scope of location name extraction challenges and a challenge-based categorization of place names found in the corpora resulting from targeted streams. We annotate three different Twitter streams from flooding events in three different locations: the 2015 Chennai flood, the 2016 Louisiana flood, and the 2016 Houston flood, for our own evaluation and also for use by others.

3. A demonstration that LNEx convincingly outperforms commercial-grade NER and Twitter-specific tools with at least a 33% improvement on average F-Score. Examples reveal the true challenges of location name extraction and the locus of tool failure in the face of these challenges.

LNEx provides the foundation for localizing information, and with increased availability of open data, we expect our approach based on region-specific knowledge to be widely applicable in practice.

2 The LNEx Method

We discuss the details of LNEx in four subsections. First, we present the general idea of statistical inference via n-gram models; the core of LNEx is a statistical language model consisting of a probability distribution over sequences of words (collocations) that represent location names in preexisting, region-specific gazetteers. Then we separately discuss several modifications to both gazetteers and text samples, including gazetteer augmentation and filtering, and tweet preprocessing. Finally, we illustrate the full location analysis and matching process that reliably spots location names.

2.1 Statistical Inference via n-gram Models

LNEx constructs an n-gram model from the collocations that exist *in the gazetteer* to determine the valid location names (LNs) that might appear in tweets. Given tweet content such as "texas ave is closed", the model can then check the validity of one to n-grams. From the gazetteer, "texas" and "ave" are valid gazetteer unigrams but "is" and "closed" are not. Similarly, "texas ave" is a valid and preferred bigram (over two unigrams).

Specifically, as shown in Algorithm 1, we first tokenize all location names in the gazetteer to construct the n-gram model and then save the resulting lists of unigrams, bigrams, and trigrams (Lines 2-5). Next, for bigrams and trigrams, in Lines 6-9 we create conditional frequency distributions (CFD) to count the collocations (i.e., $c(\cdot)$ in equations 1-2). Conditional probability distributions (CPD) are then constructed from the recorded n-grams using maximum likelihood estimation (MLE). We make the assumption that only the previous two words determine the probability of the next word (Markovian assumption of order two)[3]. MLE assumes zero probability values to tokens missing from the gazetteers. *This data sparsity problem is mitigated by augmenting the gazetteers with location name variants* (see Section 2.2). In lines 11-13, we determine the validity of an n-gram (the string s) using the boolean function `VALID-N-GRAM` with the help of equations 1-4, where $c(w_x^y) \equiv c(w_x w_{x+1} \dots w_y)$, w_x^y is the collocation count (i.e., the occurrences of the consecutive words, w_x to w_y), $P(w_z|w_x^y)$ is the conditional probability of a word w_z given previous collocation w_x^y, and the chain of probabilities P_1 (for unigrams), P_2 (for bigrams), and P_3 (for tri or larger grams).

$$P(w_z|w_x^y) = \frac{c(w_x^z)}{c(w_x^y)} \quad (1)$$

$$P_1 = P(w_1^1) = \frac{c(w_1)}{\sum_{i=1}^{|\text{unigrams}|} c(w_i)} \quad (2)$$

$$P_2 = P(w_1^2) = P_1 \times p(w_2 \mid w_1^1) \quad (3)$$

$$P(w_1^n) = P_2 \times \prod_{i=3}^{n} P(w_i \mid w_{i-2}^{i-1}), n \geq 3 \quad (4)$$

        return P(w_1^n) > 0          ▷ calculated using the equations (1-4);
13: end procedure
```

2.2 Gazetteer Augmentation and Filtering

We faced two primary challenges when building our language model using raw gazetteers, which are not adequately explored in (Middleton et al., 2014; Weissenbacher et al., 2015):

1. **Conditional Collocation Contractions**: Some atomic n-gram location names (collocations) cannot be shortened, e.g., "New York". However, contraction does preserve the meaning of some longer names, especially when the first and the last words denote a specific part and a generic part respectively, such as in "Balalok School".

2. **Auxiliary and Spurious Content**: Gazetteer entries may contain extraneous content that can cause location matching to fail. Cleaning such entries can improve matching reliability (see Table 1).

[3] We found in our dataset that roughly 98% of location mentions in tweets have less than three words.

To address these challenges, we took inspiration from Category Ellipsis (for collocation contraction) and Location Ellipsis (for filtering the auxiliary content) as follows:

1. **Skip-grams**: Given a location name $t_1 \dots t_n$, we retain t_1 and t_n while varying $t_2 \dots t_{n-1}$. To avoid adding "City York" as a legitimate variant of the location name "City College of New York", we require t_n to be a location category name (e.g., building, road). Therefore, "Balalok Matriculation Higher Secondary School" generates {`Balalok School, Balalok Secondary School,` ...}. This technique results in a small number of contractions that are either useful collocations or are too random to cause many false positives (Guthrie et al., 2006).

2. **Filtering**: To address bracketed auxiliary content, we compiled a generic list of phrases to remove specific words on a case-by-case basis (e.g., 1-2 in Table 1). The remaining bracketed names are deemed legitimate alternatives (e.g., 3-4 in Table 1). We treat hyphenated location names as Location Ellipsis and split them on the hyphen and add the two splits (e.g., 5 in Table 1). We expect that the majority of these location names represent a partonomy relationship where the hyphen may be read as a "part of" relation between split tokens. We do not add the second token as a variant when it already exists in the gazetteer on its own as location name entity (e.g., "Hammond" in "Pilot - Hammond").

	Content Description	Example Gazetteer Record
1	Descriptive Tags	(Private Road)
2	Life-cycle/Status Tags	Little Rock School (historical)
3	Alternative/Old Names	Scenic Road (Frontage Road)
4	Acronyms	International House of Pancakes (IHOP)
5	Hyphenations	Cars India - Adyar, Pilot - Hammond

Table 1: Extraneous text in raw gazetteers

These two methods augment and filter partial OSM, Geonames, and DBpedia gazetteers sliced from the original sources using a bounding box. Further, we can attach the metadata of the original location name to the generated variants. Moreover, by treating derived names as synonyms for existing names, we avoid creating additional demands on disambiguation or equivalencing. We add the derived, variant location name to the gazetteer as long as it does not collide with an existing location name. Additional filtering of proposed variants is required to prevent false alarms. Similar to the use case in (Weissenbacher et al., 2015; Gelernter and Balaji, 2013), we compiled a list of 11,203 words including 678 inseparable bigrams, such as "Building A", as gazetteer stop words. This list also includes unusual location names (e.g., "Boring" in Maryland and "Why" in Arizona) and proper nouns (e.g., "James" in Mississippi) that could appear as non-location tokens. We then eliminate from all gazetteers the location names that overlap with our gazetteer stop words to reduce false positives.

2.3 Tweet Preprocessing

To complement the gazetteer preprocessing, we also require potentially non-trivial tweet preprocessing. We start by removing the retweet handles, URLs, non-ASCII characters, and all user mentions. Then, we tokenize tweets using TweetMotif's Twokenizer (O'Connor et al., 2010), which treats hashtags, mentions, and emoticons as a single token. We do not tokenize on periods (e.g., "U.S.").

Hashtag Segmentation: In our datasets, on average, around 29% of the hashtags include location names. Excluding hashtags used to crawl the data, around 17% of the unique hashtags contain locations. As the number of locations in hashtags is significant, similar to (Malmasi and Dras, 2015), we adopted a statistical word segmentation algorithm to break hashtags for location spotting (Norvig, 2009).

Spelling Correction: We consider a tweet token as misspelled if it is an out-of-vocabulary token, where the vocabulary is gazetteer words and a large English vocabulary word list[4]. LNEx corrects all misspelled tokens using the Symmetric Delete Spelling Correction algorithm (SymSpell)[5] that is six orders of magnitude faster than Norvig's spelling corrector (Norvig, 2009), which was used by (Gelernter and Zhang, 2013) in their location extraction tool. As we shall see, spelling correction has only a small influence on system accuracy.

[5] `https://github.com/wolfgarbe/symspell`

2.4 Extracting Location Names using LNEx

After the modifications to gazetteers and texts, LNEx extracts locations as illustrated in Fig. 1. In ⓐ, LNEx reads the raw tweet text, preprocesses it (as in Section 2.3) starting with case-folding. After tokenizing the tweet, the hashtag segmenter breaks hashtags into tokens. Later, stop words are used to split a tweet into consecutive word fragments where each tweet split of size n can have zero to n potential location names. We custom build the tweet stop list starting with around 890 words[6] excluding the gazetteer unigrams.

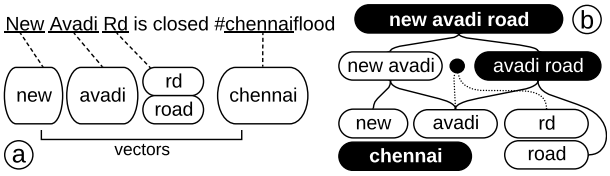

Figure 1: Extracting Locations using LNEx

LNEx now takes each tweet split and converts its tokens into a vector of tokens v using two dictionaries: the USPS street suffixes dictionary[7] and the English OSM abbreviations dictionary[8]. This adds possible expansions and abbreviations of a token (e.g., "Rd" to "Road", and vice versa). This overcomes the lexical variations between location mentions in tweets and their corresponding gazetteer entries.

In ⓑ, the language model is used to find the valid n-grams from the Cartesian product of the consecutive vectors. It builds a bottom up tree for each tweet split starting from 1 to n-grams by gluing the consecutive tokens together if they represent a valid segment in the gazetteer. We improve the speed of the algorithm significantly by splitting the tweet and eliminating invalid n-grams (i.e., n-grams with zero probability values). LNEx then selects a subset of valid n-grams from the tree; for the overlapping n-grams, we prefer the longest full mentions (e.g, "New Avadi Road" over "Avadi Road") and keep both if they are of the same length. When full location names appear inside partial ones, we keep only full names (e.g., extracting "Louisiana" from "The Louisiana").

Time and Space Complexities: LNEx extracts and links a full location mention to its corresponding gazetteer entry through a simple dictionary lookup that takes constant time $\mathcal{O}(1)$. The location extraction time is bounded by the time for creating the bottom up tree of tokens which takes $\mathcal{O}(|v|^s)$ where $|v|$ is the length of the longest vector of token synonyms (i.e., all the expansions and abbreviations of a token) and s is the largest number of tokens with synonyms in a location name. Luckily, splitting the tweet into smaller fragments using stop words significantly lowers the asymptotic growth of the algorithm, thereby enabling stream processing. In practice, for our dictionaries and gazetteers, $|v| \leq 4$ and $s \leq 3$. So, a pessimistic upper bound on the number of candidates for each location (though rarely realized) is 4^3. The space complexity of the method is bounded by the product of number of gazetteer entries, L, and the number of variants of a location name (Skip-gram method 1), that is, 2^{m-2}, where m is the number of tokens in a location name. Effectively, the space complexity is $\mathcal{O}(L.2^{m-2})$ where typically, $2 \leq m \leq 5$. Further, according to our tests, LNEx needed only up to 650 MB of memory to initialize and is able to process, on average, 200 tweets per second.

3 Experimental Results

To demonstrate the effectiveness of our context-aware location extractor, we used a set of event-specific hashtags and keywords to collect 4,500 geographically limited, disaster-related tweets from three different targeted streams corresponding to floods in Chennai, Louisiana, and Houston. Below, we categorize and annotate these tweets used for benchmarking each component of LNEx, and for comparing LNEx with other state-of-the-art tools for the location extraction task.

3.1 Benchmarking and Annotations

Consistent with the problem of determining whether a location mention is inside the area of interest, our benchmark categorization scheme is not content based as in (Matsuda et al., 2015; Gelernter and Balaji, 2013). To better identify and characterize the challenges in extracting location names accurately, our

[6] http://www.ranks.nl/stopwords
[7] http://pe.usps.gov/text/pub28/28apc_002.htm
[8] wiki.openstreetmap.org/wiki/Name_finder:Abbreviations

annotation scheme is based on where these locations lie in relation to the area of interest. For example, with respect to Chicago, IL, USA:

1. in**LOC**: Locations inside the area of interest, (e.g., Millennium Park or Burlington Ave.)
2. out**LOC**: Locations outside the area of interest, (e.g., Central Park, 5th Ave, New York.)
3. amb**LOC**: Ambiguous locations that need context for identification, (e.g., "our house")

In contrast to (Matsuda et al., 2015; Gelernter and Balaji, 2013), our categorization is not based on location types (e.g., buildings, facilities, schools) but on the relative position (i.e., inLOC or outLOC) and the nature of the location mention (i.e., inLOC or ambLOC). This approach identifies the true scope of challenges in extracting location names. Other schemes that annotate for a limited set of location types, such as "Geoparse Twitter Benchmark Dataset" (Middleton et al., 2014), miss obvious location mentions in tweets, such as "New Zealand" and "Christchurch", making the dataset incompatible for testing the tools mentioned in this paper including LNEx.[9]

Tweet Annotations Figure 2 shows an example of manual annotation from the Louisiana flood tweets using the BRAT tool (Stenetorp et al., 2012). It allows us to define search functionalities and additional resources for the annotators to use such as Google Maps.

Figure 2: Example Annotations using BRAT

The annotators annotated three datasets: the 2015 Chennai flood, the 2016 Louisiana flood, and the 2016 Houston flood. In Chennai, they spotted 4,589 location names (75% inLOC, 4% outLOC, and 21% ambLOC); in Louisiana, 2,918 (66% inLOC, 13% outLOC, and 22% ambLOC); and in Houston, 4,177 (66% inLOC, 7% outLOC, and 27% ambLOC). We randomly selected 1,000 tweets (500 each from Chennai and Louisiana) as a development set and the remaining 3,500 as the test set for evaluation.

3.2 Evaluation Strategy

Because BRAT records the start and the end character offsets of the annotated LNs, we evaluate the extraction task by checking the character offsets of the spotted location name in comparison with the annotated data. We used the standard comparison metrics: Precision, Recall, and the balanced F-Score. In the case of overlapping or partial matches, we penalize all tools by adding $\frac{1}{2}FP$ (False Positive) and $\frac{1}{2}FN$ (False Negative) to the precision and recall equations (e.g., if the tool spots "The Louisiana" instead of "Louisiana").

We evaluate all tools based on the category of the extracted location in our annotation scheme. For the inLOC mentions, we count all hits and misses of a tool and ignore all hits when the category of the extracted location is outLOC or ambLOC. However, we take a particularly conservative approach and additionally penalize LNEx for extracting location names of outLOC and ambLOC categories, counting them as false positives (FPs) as our tool is not supposed to extract these.

Spell Checking: This led to 1% increase in recall but the F-Score decreased by 2% on average due to the influence of increased false positives on precision. In the final system, we excluded the spelling corrector component.

Hashtag Breaking: We evaluated the performance of the hashtag breaking component only on the hashtags that contain locations. The accuracies were 97%, 87%, and 93% for Chennai, Louisiana, and Houston respectively, reduced due to examples such as "#lawx", which was broken into "law" and "x".

Picking a Gazetteer: The augmentation and filtering of gazetteers improved the F-Scores (see Figure 3-a). After this process, combinations of gazetteer sources had similar performance where the difference between the worst and the best was around 0.02 F-Score units (see Figure 3-b). In the final system, we relied on OSM, which performed the best. Moreover, DBpedia is not focused on geographical information; therefore, it does not contain the metadata useful for the system's future use (e.g., extents and full addresses). Also, OSM has more fine-grained locations and more accurate geo-coordinates than Geonames (Gelernter et al., 2013).

[9]Our dataset can be used to test any location extraction tool by ignoring the optional additional expressivity, which makes our dataset more compatible than other available ones.

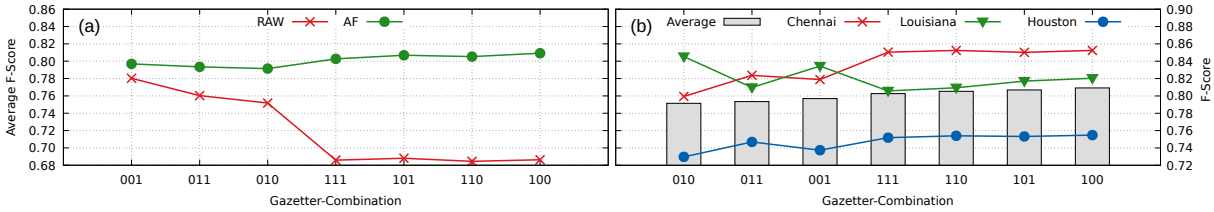

Figure 3: (a) Raw vs. augmented and filtered (AF) gazetteers combinations. (b) Combinations Performance. Each of the seven combinations is a subset of {OSM Geonames DBpedia}.

Google NLP	Location, Organization

DBpedia Spotlight	Place, Organization
OSU TwitterNLP	Geo-Location, Company, Facility
TwitIE-Gate	Location, Organization

Table 2: Types considered as Locations per tool

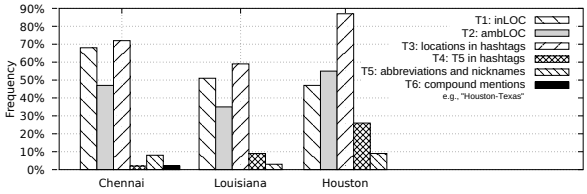

Figure 4: Random Sample Evaluation.

Comparing LNEx with other tools: We compared LNEx with the following tools:

1. **Commercial Grade**: Google NL[10], OpenCalais[11], and Yahoo! BOSS PlaceFinder[12]. All of these tools have REST APIs and are black box tools that use Machine Learning.
2. **General Purpose NER**: Stanford NER and OpenNLP Name Finder. Stanford NER learns a linear chain Conditional Random Field (CRF) sequence model (Finkel et al., 2005), while OpenNLP uses the maximum entropy (ME) framework (Bender et al., 2003). We trained both tools interchangeably on our annotated datasets in addition to all the data from W-NUT '16[13] while retaining the annotations and unifying the classes we consider as locations (i.e., geo-loc, company, facility) into one type. We used LNEx-OSM gazetteer's features while training Stanford NER. Additionally, we used DBpedia Spotlight (Mendes et al., 2011).
3. **Twitter NLP**: OSU Twitter NLP (Ritter et al., 2011) and TwitIE-Gate (Bontcheva et al., 2013). Both are pipelined systems of POS-tagging followed by NER. TwitIE-GATE also supports normalization, gazetteer lookup, and regular expression-based tagging. For fair comparison, we also augmented them with LNEx OSM gazetteers.
4. **Twitter Location Extraction**: Geolocator 3.0 (Gelernter and Zhang, 2013) and Geoparsepy (Middleton et al., 2014). Geolocator 3.0 uses a tweet-trained CRF classifier and other rule-based models to extract street names, building names, business names, and unnamed locations (i.e., location names containing a category such as "School").

All tools have been evaluated using the same metrics and on the same annotated data. In the case of hashtags, we count all hits for all tools and when a tool missed, we penalized only the ones that were designed to break hashtags (namely, TwitIE-Gate and LNEx). Additionally, we consider all spotted mentions from PlaceFinder, Geolocator 3.0, Geoparsepy, Stanford NER, and OpenNLP as location names but, for other tools, we consider only the entity types in Table 2 as location entities.

Fig. 4 shows that the prevalence of various challenges differ in the three corpora. Neverthe-

[11] http://www.opencalais.com/
[12] https://developer.yahoo.com/boss/geo/
[13] http://noisy-text.github.io/2016

less, LNEx outperformed all other tools on all datasets in terms of F-Score, and the average F-Score (see Table 3). LNEx showed stability on the test and development sets from Louisiana with only a 0.2% F-Score reduction and around a 2.6% reduction on the test set from Chennai.

The augmentation and filtering method significantly improved the average F-Score from 0.69 to 0.81 (See Table 3). However, limitations of the gazetteer augmentation and filtering methods did contribute to lowering precision. For example, on average, around 5% of the extracted location names were outLOC and ambLOC, mistakenly extracted from Chennai, Louisiana, and Houston tweets. Example errors include the augmentation of location names such as "The x Apartments" to "The Apartments", causing LNEx to extract the phrase "The Apartments" as an actual full location name. Fixing such limitations should contribute to around 2% F-Score improvement on average.

We trained Stanford NER and OpenNLP to emulate their use in other studies mentioned in Section 4. Their performances were calculated by interchangeably training them using three datasets at a time and testing on the fourth one (the gazetteer of the area of the test data was also used in training the Stanford NER models). We always used the W-NUT '16 dataset to train the models with more than 10,000 tweets each time.

We observed that the ill-formatted text of tweets with ungrammatical text and missing orthographic features impact the F-Score of tools we compared with LNEx. While the performance of each tool differs, we observed that Google heavily relies on orthographic features and expects grammatical texts (even though it scored a 0.38 average F-Score). Additionally, TwitIE-GATE was not always successful in extracting location names from hashtags or text even if these location names were part of the tool's gazetteers. Finally, OpenCalais extracts only well-known location names of coarser granularity than street and building levels unless a location has an attached location category (e.g., school or street).

Table 4: Example tool outputs: bracketed bold text are the identified LNs and braces highlights the types from Fig. 4.

Illustrative Examples: Table 4 shows the comparative handling of three tweets one each from Chennai, Louisiana, and Houston datasets, covering most challenging cases for all the tools. The location name "Oxford school" allowed us to examine if a tool relies on capitalization for delimitation. Only OpenCalais, Geolocator and LNEx were able to extract the name correctly while the rest either partially extracted it or missed it. For example, PlaceFinder extracted "Oxford" and geocoded it with the geocodes of Oxford city in England. Although Stanford NER and OpenNLP were trained on the same datasets, OpenNLP extracted Oxford while Stanford NER did not, which suggests that the cue word "near" was insufficient evidence for Stanford NER to spot at least Oxford. Correspondingly, since "New Iberia" is a correctly capitalized full location name, almost all tools were able to

extract it. However, TwitIE-Gate missed it although it is part of the gazetteer we added to the tool, and Geoparsepy extracted Iberia in addition to the full mention, not favoring the longest mention as LNEx. OpenCalais is a black box so we don't know why it failed.

Regarding T3-T5 annotations, LNEx and TwitIE-Gate are designed to break hashtags but TwitIE-Gate was not able to extract any locations from the hashtags in the table. LNEx extracted "Louisiana" but was not able to extract "la" from "#lawx" due to the statistical method which broke the hashtag into "law" and "x" since this combination is more probable. Only Geolocator was able to extract the Houston nickname "htown". In the future, a dictionary of region-specific acronyms, abbreviations, and nicknames can augment LNEx's region-specific gazetteers.

Google NLP does not handle T6. Adding space between the dot and "west" to create "... school. west ...", results in the extraction of "west mambalam" but omits "Oxford school". Google NLP relies on capitalization, so changing the case of "s" to create "Oxford School" does help. OpenCalais cannot extract "west mambalam" despite fixing all grammatical mistakes, normalizing the orthographic features, and even introducing cue words. The tool only extracts well-known location names of coarser granularity than street and building levels unless they have an attached location category (e.g., school or street). PlaceFinder, on the other hand, tries to find geocodable location names in text. Therefore, the tool extracts "th" as the country code of Thailand and "Oxford" as the city in England. Hence, geocoding is influencing some of the mistakes of the tool.

4 Related Work

Twitter messages (tweets) lack features exploited by main stream NLP tools. Informality, ill-formed words, irregular syntax and non-standard orthographic features of tweets challenge such tools (Kaufmann and Kalita, 2010). We agree with (Baldwin et al., 2013) that some issues might be exaggerated. Indeed we found that spelling corrections only contributed to 1% recall improvement. Nevertheless, text normalization alone is insufficient for NER (Derczynski et al., 2015). Specially designed tools such as (Ritter et al., 2011; Gelernter and Zhang, 2013) use pipelined systems of POS tagging followed by NER. The latter also perform Regex tagging, normalization, and gazetteer lookup.

Relying on the orthographic features for POS tagging or Regex tagging, previous methods extract locations from the text chunks and phrases of sentences using the following techniques:

1. **Gazetteer search or n-gram matching**: Li et al. (2014) and Gelernter and Zhang (2013) use a gazetteer matching technique that relies on a segment-based inverted index. Sultanik and Fink (2012) use an exhaustive n-gram technique. Middleton et al. (2014) use location-specific gazetteers for matching phrases from tweets. TwitIE-GATE uses a gazetteer lookup component. All of these techniques do not deal with the important issue of the gazetteers' auxiliary content and noise.

2. **Handcrafted rules**: Weissenbacher et al. (2015) and Malmasi and Dras (2015) use pattern and Regex matching which rely on cue words or orthographic features for POS-tagging. TwitIE-GATE adapts rules from ANNIE (Cunningham et al., 2002) for extraction.

3. **Supervised Methods**: *Tweet-trained models*: The majority of the methods trained Stanford NER on tweets (Gelernter and Zhang, 2013; Yin et al., 2014) or retrained OpenNLP (Lingad et al., 2013). *News-trained models*: Malmasi and Dras (2015) use tools like Stanford NER and OpenNLP.

4. **Semi-supervised methods**: Ji et al. (2016) use beam search and structured perceptron for extraction and linking to Foursquare entities. However, they did not address the noise that is prevalent in such sources (e.g., "my sofa" or "our house") (Dalvi et al., 2014).

The closest works to ours are TwiNER (Li et al., 2012) and LEX (Downey et al., 2007). Both use Microsoft Web n-grams (which capture language statistics) for chunking but the former uses DBpedia for entity linking. However, our method exploits a region-specific gazetteer for delimitation and linking. Moreover, LEX worked with web data and relies heavily on capitalization.

Finally, few other methods extract locations from hashtags. Malmasi and Dras (2015) uses a statistical hashtag breaker technique similar to ours. Ji et al. (2016) removes only the # symbol and treats the hashtag as a unigram. Yin et al. (2014) uses a greedy maximal matching method for breaking. TwitIE-GATE

uses two methods for hashtag breaking: a dynamic programming-based method for finding subsequences and a camel-case-based method for tokenization.

5 Conclusions and Future Work

LNEx accurately spots locations in text relying solely on statistical language models synthesized from augmented and filtered region-specific gazetteers. It outperforms state-of-the-art techniques and mainstream location name extractors. By exploiting the knowledge in the gazetteer, we extract (delimit) location mentions and then materialize them as location metadata for future/further processing. LNEx does not employ any training and does not depend on syntactic analysis or orthographic conventions. We compensate for limitations in fixed phrase matching with gazetteer augmentation and filtering. Although we do not solve the disambiguation problem here, still the geo/geo ambiguity is reduced by preserving the spatial context through location-specific gazetteers. Furthermore, systematic gazetteer augmentation ties legitimate variants to known locations, minimizing potential ambiguity.

Certainly, LNEx does not solve all location extraction problems. It actually presents an effective precision-recall trade-off apparent in the F-Score. But as the method is driven by the linking procedure, it does not extract location names missing from gazetteers (e.g., "our house"). However, in the future, we might consider extracting them at a reduced cost by integrating LNEx with an incremental learning method (Al-Olimat et al., 2018). Additionally, a more sophisticated name model that ignores the generic parts and retains the specific parts when augmenting a location name (e.g., adding "Sam's" as a variant of "Sam's Club") can be used (Dalvi et al., 2014).

Abstract

In this paper, we study the problem of question answering over knowledge base. We identify that the primary bottleneck in this problem is the difficulty in accurately predicting the relations connecting the subject entity to the object entities. We advocate a new model architecture, APVA, which includes a verification mechanism responsible for checking the correctness of predicted relations. The APVA framework naturally supports a well-principled iterative training procedure, which we call turbo training. We demonstrate via experiments that the APVA-TUBRO approach drastically improves the question answering performance.

Title and Abstract in Chinese

面向知识库问答的 APVA-TURBO 方法

本文主要围绕目前基于知识库的问答方法中的存在的问题展开研究。经过对现有各类问答方法的调查与分析，我们发现目前知识库问答的瓶颈主要体现在关系预测上，即如何准确地预测出问题中的实体与答案实体之间的关联，是需要面临的最大挑战。因此本文在现有问答框架的基础上，加入了负责对预测关系的可靠性进行评价检验的验证机制，用以增强关系预测效果，并提出了一种新的知识库问答框架“APVA”。另外，文中为 APVA 设计了一种具有良好理论基础的迭代训练过程，我们称之为“涡轮式(turbo)训练”。通过实验证明，APVA-TUBRO 方法可以在问答数据集上取得优异效果，大大提升了目前问答方法的准确性。

1 Introduction

Knowledge bases (KBs), such as YAGO, DBPedia, and Freebase contain an enormous volume of facts, or knowledge, about the real world. Each of these facts is represented as a triple (s, r, o), where s is a *subject entity*, r is a *relation*, and o is an *object entity*. This representation allows the KB to be interpreted as a graph in which entities are vertices, triples are edges, and relations are edge labels. Such a structured representation has enabled the development of query languages, such as RQL(Karvounarakis et al., 2002), Versa(Ogbuji, 2005) and SPARQL(Prud et al., 2006), for retrieving knowledge stored in the KB. Despite the usefulness of these languages, it is highly desirable that the query-processing engine of a KB is capable of processing queries presented in human language directly. This stimulates intense research in question answering over KB.

Briefly, question answering over KB, or QA-KB, aims at taking as input a question presented in a natural language and outputs the answer in terms of a fact triple or a collection of fact triples in the KB. In a general setting, the answer is a set of *paths*, where each path connects the subject entity of the question to the object entity via a sequence of relations. We refer to this relation sequence as a *path label*.

There are two main lines of solutions to QA-KB. The first centres around semantic parsing, which translates the natural-language question into a logical form and uses it to query the KB. This line of

solutions includes, for example, (Berant et al., 2013; Dong et al., 2017; Yih et al., 2015; Xu et al., 2016; Reddy et al., 2017).

The second line of solutions centres around learning with neural network models, which follows what we call an APA architecture or its variants. Specifically, the APA architecture includes three components: an *entity alignment* component, which identifies the subject entity implied in the question, a *path label prediction* component, which predicts a path label, and an *object answering* component, which finds the object entitie(s). This line of solutions includes, for example, (Dong et al., 2015; Hsiao et al., 2017; Yin et al., 2016; Yu et al., 2017; Lukovnikov et al., 2017; Jain, 2016; Hao et al., 2017; Bordes et al., 2014).

Despite the success of the existing approaches to QA-KB, particularly that of the APA architecture, we observe that the primary bottleneck for further improving the model performance lies in the model's limited accuracy in label path prediction. Motivated by this observation, this work extends the APA methodology into an "APVA" framework, which incorporates a verification mechanism in the model. Such a mechanism is responsible for checking if the predicted relation or path label is correct and hence improving the answering performance. Unifying APVA's components in a probabilistic modelling set-up, we show that such an APVA architecture allows the joint training of its model components. More specifically, the joint training can exploit coordinate descent in the optimization of the loss function. This naturally gives rise to an iterative training procedure, which we call turbo training. We develop a concrete model and its training algorithm based on this APVA-TURBO approach. Experimental study demonstrates that the proposed APVA-TURBO model outperforms the existing models by a large margin, thereby establishing itself as a new state of the art in QA-KB.

2 Problem Statement

For a given KB $\mathcal{K}$, we will denote its set of entities by $\mathcal{E}$ and its set of relations by $\mathcal{R}$. The KB $\mathcal{K}$ contains a set of factual triples $\mathcal{F}$ in which each triple is in the form of (s, r, o), with $s, o \in \mathcal{E}$ and $r \in \mathcal{R}$. For example, (CarlosGomez, baseball.baseballPlayer.position, CenterFielder) is one such triple taken from Freebase. It specifies the fact that Carlos Gomez plays the Center Fielder position in baseball. It is customary to interpret the triple set $\mathcal{F}$ in $\mathcal{K}$ as an edge-labelled graph in which vertices are entities in $\mathcal{K}$, edges are triples in $\mathcal{F}$, and on each edge (s, r, o), r is the edge label.

Additionally the KB $\mathcal{K}$ usually also prescribes a set $\mathcal{T}$ of entity types. Specifically, for each entity $e \in \mathcal{E}$, its type $t(e)$ is a token in $\mathcal{T}$. Note that in KBs like Freebase, an entity e may be associated with multiple types. In this work, for simplicity, we take $t(e)$ as the *primary type* of e (which is referred to as the "notable type" of e in Freebase).

We will denote by q the question presented in natural language. Specifically q is a sequence $(w_1, w_2, \ldots, w_n)$ of words, where each w_i is a word in a vocabulary $\mathcal{V}$, and n depends on q. The objective of the *question answering over KB*, or simply QA-KB, is then to develop an answering algorithm which returns the correct answer triple (s, r, o) for any given question q. For example, when a user asks a question "What position does Carlos Gomez play", the answering algorithm is expected to retrieve the triple (CarlosGomez, baseball.baseballPlayer.position, CenterFielder) from the KB.

The above form of QA-KB is in fact in its most basic form. The problem can be made more general in at least the following two ways. First, the answer to q may be multiple triples which form a path in the KB graph. For example, the answer could involve two triples (a, r_1, b) and (b, r_2, c) concatenated in tandem. This corresponds to the path (a, r_1, b, r_2, c) in the KB graph. We will call such an answer a *multi-hop answer*, and call the pair (r_1, r_2) of edge labels the *path label*. Furthermore, there can be multiple answers for a given question q. For example, if the question is "what are the provinces of Canada", then more than one answer is expected.

This paper in fact deals with a general setting of QA-KB, namely, a question may have *multiple multi-hop* answers. We do impose a restriction that we only consider the case in which all answers of any given question have *the same* path label. We note that this simplification does not imply that our proposed framework and model do not extend further. It is solely due to that this restriction sufficiently well describes the datasets we work with.

Denote by $\mathcal{R}^*$ the set of all finite-length sequences consisting of relations in $\mathcal{R}$. We still denote an

answer, multi-hop or single-hop, as a triple (s, r, o) while considering $r \in \mathcal{R}^*$. For any given question q, let $\mathcal{A}(q)$ be the set of all answers, for q, where each answer is in the form of (s, r, o) with $r \in \mathcal{R}^*$.

A machine learning model for QA-KB relies on a training set $\mathcal{D}$ consisting of many pairs $(q, \mathcal{A}(q))$. We will use $\mathcal{D}_{\text{q}}$ to denote the set of all questions in $\mathcal{D}$. After the model is trained on $\mathcal{D}$, one expects it to output the answers $\mathcal{A}(q)$ for an arbitrary question q, unseen in $\mathcal{D}_{\text{q}}$.

3 APVA Modelling Framework

3.1 The Conventional APA Architecture

Conventionally, a QA-KB model, if put into a probabilistic framework, can be regarded as learning a conditional distribution $p(s, r, o|q)$, where for each configuration of (s, r, o, q), the value $p(s, r, o|q)$ is probability that the triple (s, r, o) is an answer in $\mathcal{A}(q)$. Note that in this formulation, we have suppressed the dependency of (s, r, o) on the given KB $\mathcal{K}$.

By the chain rule of probability,

$$p(s, r, o|q) = p(s|q)p(r|q, s)p(o|q, s, r).$$

A QA-KB model factorizing this way essentially assumes three components: an *entity alignment* component $p(s|q)$ to identify the subject entity s in the question q, a *path label prediction* component $p(r|q, s)$ to predict the path label r that leads the subject entity to the object entities, and an *object answering* component to provide the list of object entities o's each forming an answer (s, r, o). We call such a model an *APA* model.

The existing neural network models for QA-KB largely fall in the APA architecture, or its variants, in which instead of having the three components separable, the model may combine some of the components or have parameters shared between them. We now summarize these models.

In (Yin et al., 2016; Lukovnikov et al., 2017), a word/character-level encoder is used for question encoding and to match the subject entity and the relation in a fact candidate with the question. In (Yu et al., 2017; Hsiao et al., 2017) a bi-directional LSTM is used to score and rank the question and relation pairs. In (Ture and Jojic, 2017), only simple RNN is used both for entity alignment and for relation prediction.The approach of (Jain, 2016) extracts candidate triples and finds a path to the object entity using multi-hop reasoning and refinement. In (Dong et al., 2015; Hao et al., 2017), a multi-column CNN or a cross-attention mechanism is introduced to match the question with the answer path, the answer context and the answer type. In (Bordes et al., 2014), questions and their answer subgraphs from KB are both embedded into a lower dimensional to be matched.

3.2 The APVA Framework

Despite the successes with the APA approaches, we observe that the bottleneck in the existing models lies primarily in the accuracy of predicting the path labels. In fact our experiments suggest that, if the correct (s, r) can be obtained, a good object answering accuracy can be easily achieved. For example, on the WebQuestion dataset(Berant et al., 2013), we see that a simple SVM classifier followed by a search of the KB (see section 5.2) achieves an answering precision of 89.68% and a recall of 93.20%.

The fact that path label prediction forms the primary bottleneck can be attributed to the enormous number of entities and the extremely high dimension of the question space. Relative to the space of (q, s), the dataset $\mathcal{D}$ is in fact very sparse. This makes path label prediction prone to error and limits the performance of a QA-KB model.

To increase the accuracy of path label prediction, this paper augments the APA models with an additional component, which we call *subject-path verification*. The basic idea here is to use a verification mechanism to check if a predicted pair (s, r) is correct. We call this architecture the *APVA* architecture.

3.2.1 The APVA Architecture

In APVA framework, for each question q, we assume that there is another variable y, taking values in $\{0, 1\}$ and indicating whether the obtained (s, r) is correct (1 for correct). The overall objective of

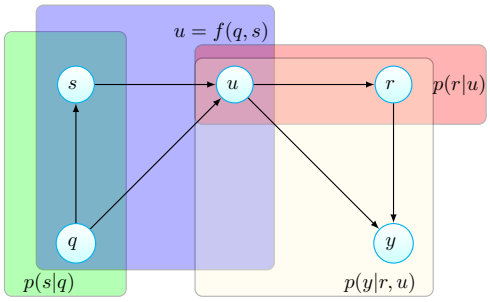

Figure 1: The $p(s, r, y|q)$ part of APVA

learning is then to learn a distribution $p(s, r, o, y|q)$, which factors as

$$p(s, r, o, y|q) = p(s, r, y|q)p(o|q, s, r, y). \tag{1}$$

The term $p(o|q, s, r, y)$ in (1) essentially characterizes the *object answering* component (where we are only interested in the case of $y = 1$). The term $p(s, r, y|q)$ further factors as

$$p(s, r, y|q) = p(s|q)p(r|q, s)p(y|q, s, r) \tag{2}$$

In (2), the terms $p(s|q)$ and $p(r|q, s)$ respectively correspond to an *entity alignment* component and a *path label prediction* component. The term $p(y|q, s, r)$ on the other hand is the new *subject-path verification* component.

For the path label prediction component, APVA further expresses $p(r|q, s)$ by

$$u := f(q, s) \tag{3}$$
$$p(r|q, s) := p(r|u) \tag{4}$$

where f is an appropriate *encoder* (ENC) function, and (4) is referred to as the *decoder* (DEC). Here f serves to compress the high-dimensional representation of (q, s) to a low dimensional space so as to deal with the sparsity of (q, s).

Furthermore APVA expresses $p(y|q, s, r)$ as

$$p(y|q, s, r) := p(y|u, r). \tag{5}$$

Since (5) essentially defines a binary classifier, we call it the *verification classifier* (CLS).

In summary, the APVA framework consists of the following components: entity alignment, path label prediction (ENC-DEC), subject-path verification (CLS) and object answering. Figure 1 shows the overall model architecture of APVA, with the object answering component excluded.

3.2.2 Loss Functions and Training

For each of the components, we can derive an appropriate loss function: the (entity) alignment loss ℓ_{al}, the (path label) prediction loss ℓ_{pr}, the (subject-path) verification loss ℓ_{ve}, and the (object) answering loss ℓ_{an}. It is worth noting that to properly define the verification loss ℓ_{ve}, we need to introduce "negative examples" for CLS.To that end, denote

$$\mathcal{D}_{\text{qsr}} := \{(q, s, r) : q \in \mathcal{D}_{\text{q}}, (s, r, o) \in \mathcal{A}(q)\}$$

That is, $\mathcal{D}_{\text{qsr}}$ is the set of all training examples for path label prediction (ENC-DEC). It is also the set of all positive training examples for the verification classifier CLS.

For each positive example $(q, s, r) \in \mathcal{D}_{\text{qsr}}$, we can create several negative examples by replacing the path label r in (q, s, r) with a random wrong path label r'. This gives rise to a negative training set $\mathcal{D}^{-}_{\text{qsr}}$.

If the four loss functions do not share parameters, then one can separately minimize each loss and learn its parameters. If there is a sharing of parameters among some of these losses , one can take a

joint approach to minimize the (possibly weighted) sum of these losses. A generic approach for this joint minimization is coordinate descent, namely, we hold some parameter fixed and optimize the sum loss over other parameters, and keep iterating this process. We will give a concrete example of this training method in a later section.

Although APVA is derived from probabilistic modelling, its overall methodology extends to non-probabilistic models. Indeed, all we need are those well-defined losses, whether or not they result from probabilistic modelling.

4 The APVA-TURBO Model

We now describe a concrete model in the proposed APVA framework, which we refer to as the APVA-TURBO model. The model can be divided into three models which are trained separately. They are the Entity Alignment Model, the Prediction-Verification Model, and the Object Answering Model. Note that the Prediction-Verification Model is a joint model containing both path label prediction and subject-path verification.

The key innovation in this model architecture is the Prediction-Verification Model, where the Entity Alignment Model is a modest extension of a previous model and the Object Answering Model is a standard application of SVM on a selected choice of feature. To stay focused, details of the Entity Alignment Model and Object Answering Model are presented in section 5.2.

We now present the central piece of APVA-TURBO, the Prediction-Verification Model. It decomposes further into an encoder-decoder (or ENC-DEC) model for *path label prediction* and a classifier model (CLS) for subject-path verification.

4.1 ENC-DEC Model

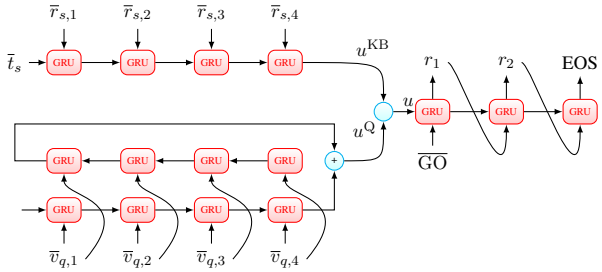

Figure 2: ENC-DEC Model

Recall that in APVA, the ENC component, Equation (3), encodes (q, s) into a vector u and the DEC component, Equation (4), maps u to a desired distribution on the path labels in $\mathcal{R}^*$. The structure of ENC-DEC in APVA-TURBO is shown in Figure 2, which we describe below.

For the identified subject entity s, let $\mathcal{R}(s) := (r_{s,1}, r_{s,2}, \ldots, r_{s,L})$ be the list of all relations in $\mathcal{R}$ that are labels of at least one edge in the KB graph connecting to entity s. Let $\overline{\mathcal{R}}(s) := (\overline{r}_{s,1}, \overline{r}_{s,2}, \ldots \overline{r}_{s,L})$ be the embeddings of $\mathcal{R}(s)$ and $\overline{t}_s$ be the embedding of the type $t(s)$ of s , both of which are obtained from a KB schema embedding model, called KSE. KSE is an separately pre-trained model to embed the relations and types in KB in an Euclidean space, by using an adaptation of the TransH (Wang et al., 2014) to the "schema graph", which is a graphical representation of the KB schema set $\mathcal{S}$ of all "schema triples" $(t, r, t') \in \mathcal{T} \times \mathcal{R} \times \mathcal{T}$ for which knowledge triples (s, r, o) with $t(s) = t$ and $t(o) = t'$ are allowed. We take $\overline{t}_s$ as the initial state of a GRU network, and take $\overline{\mathcal{R}}(s)$ as the input sequence to the network. We denote the final state of the GRU network by u^{KB}. We note that u^{KB} encodes the subject entity s and its relative position in $\mathcal{K}$. We refer to u^{KB} as the *KB-based encoding*. In this encoding step, although order of the elements in $\overline{\mathcal{R}}(s)$ is irrelevant, we still feed them to the GRU network sequentially due to its superiority in processing variable-length input and automatically selecting relevant feature.

On the other hand, for the question $q = (w_1, w_2, \ldots, w_n)$, its subsequence $\mu := (w_m, w_{m+1}, \ldots, w_{m+k})$ of words that corresponds to the subject entity s in the KB $\mathcal{K}$ is referred to

as the *subject mention*. we remove the subject mention μ from the word sequence and replace it with a placeholder token "$\langle e \rangle$" representing the subject entity s. Let $v := (v_{q,1}, v_{q,2}, \ldots, v_{q,n'})$ denote the modified word sequence from q, and let $\overline{v} := (\overline{v}_{q,1}, \overline{v}_{q,2}, \ldots, \overline{v}_{q,n'})$ be its word2vec(Mikolov et al., 2013) embeddings. We simply create a random embedding for "$\langle e \rangle$" and include it in the dictionary.

The sequence $\overline{v}$ is then entered to a Bi-GRU network and the sum of the two final states from the network is denoted by u^{Q}. We then set the output u of the ENC model as the concatenation of u^{Q} and u^{KB}. This completes the ENC block.

The DEC block is a simple GRU network following the usual Seq2Seq(Sutskever et al., 2014) decoder structure. The network takes vector u as its initial state. The input to the network at $t = 1$ is the embedding of a contrived special relation label "GO", signalling the beginning of the input. The input at any other time $t > 1$ is the embedding of the $(t-1)^{\mathrm{th}}$ relation r_{t-1} in the path label r. The embedding dictionary of the relations here is a learnable parameter. Each output of the GRU network at time t is passed to a soft-max function (with learnable parameters) to generate the predictive distribution for the t^{th} relation r_t in r.

Under the maximum-likelihood principle, the loss function $\ell_{\mathrm{pr}}(q, s, r)$ of ENC-DEC is the sum of cross-entropy losses, each between a generated distribution at t and a observed relation r_t in r. We note that, as is standard, a special "EOS" token is included in r to indicate the termination of r.

4.2 CLS Model

The verification classifier CLS is constructed as a Multilayer Perceptron (MLP). The input of the MLP is the concatenation of u with the KSE embedding of a relation r. The MLP outputs the predictive distribution of y. Its loss function $\ell_{\mathrm{ve}}(q, s, r, y)$ for training CLS is defined as the cross entropy between the predictive distribution and the observed class label y.

4.3 Turbo Training of ENC-DEC and CLS

Let θ_{enc}, θ_{dec}, and θ_{cls} denote respectively all parameters in ENC, in DEC and in CLS. The total prediction loss is then

$$\mathcal{L}_{\mathrm{pr}}(\theta_{\mathrm{enc}}, \theta_{\mathrm{dec}}) := \sum_{(q,s,r) \in \mathcal{D}_{\mathrm{QSR}}} \ell_{\mathrm{pr}}(q, s, r; \theta_{\mathrm{enc}}, \theta_{\mathrm{dec}}) \tag{6}$$

and the total verification loss is

$$\begin{aligned} \mathcal{L}_{\mathrm{ve}}(\theta_{\mathrm{enc}}, \theta_{\mathrm{cls}}) := & \sum_{(q,s,r) \in \mathcal{D}_{\mathrm{QSR}}} \ell_{\mathrm{ve}}(q, s, r, 1; \theta_{\mathrm{enc}}, \theta_{\mathrm{cls}}) \\ & + \sum_{(q,s,r) \in \mathcal{D}^{-}_{\mathrm{QSR}}} \ell_{\mathrm{ve}}(q, s, r, 0; \theta_{\mathrm{enc}}, \theta_{\mathrm{cls}}) \end{aligned} \tag{7}$$

It is worth noting that the loss ℓ_{ve} does not depend on θ_{dec}, since r is observed in the CLS model. It however depends on θ_{enc} through u.

We define the overall loss for training the Prediction-Verification Model as

$$\mathcal{L} := \mathcal{L}_{\mathrm{pr}}(\theta_{\mathrm{enc}}, \theta_{\mathrm{dec}}) + \lambda \mathcal{L}_{\mathrm{ve}}(\theta_{\mathrm{enc}}, \theta_{\mathrm{cls}}). \tag{8}$$

Here λ is chosen larger than 1 by a decent margin. This is because when using the trained model for answering questions, we will primarily rely on CLS rather than ENC-DEC.

We now present a training algorithm, which we call "turbo training", to minimize the loss function $\mathcal{L}$. Turbo training consists of two phases.

Base Phase.Train ENC-DEC, namely minimizing $\mathcal{L}_{\mathrm{pr}}$ over $(\theta_{\mathrm{enc}}, \theta_{\mathrm{dec}})$.

Turbo Phase. In this phase, we iterate over the following three steps in order.

A.Train CLS, namely, minimizing $\mathcal{L}_{\mathrm{ve}}$ over θ_{cls} for the current setting of $(\theta_{\mathrm{enc}}, \theta_{\mathrm{dec}})$.

B.Train ENC, namely, minimizing $\mathcal{L}_{\mathrm{pr}} + \lambda \mathcal{L}_{\mathrm{ve}}$ over θ_{enc} for the current setting of $(\theta_{\mathrm{dec}}, \theta_{\mathrm{cls}})$.

C.Train DEC, namely, minimizing $\mathcal{L}_{\mathrm{pr}}$ over θ_{dec} for the current setting of $(\theta_{\mathrm{enc}}, \theta_{\mathrm{cls}})$.

A diagram showing the turbo training algorithm is given in Figure 3. It can be proved that the three

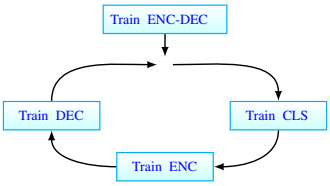

Figure 3: Turbo training

steps in the turbo phase correspond precisely to coordinate-descent minimization of $\mathcal{L}$. Therefore iterations in the turbo phase *provably* decreases the loss $\mathcal{L}$ monotonically and are guaranteed to converge.

In the implementation of turbo training, for each phase and the each step within, the minimization can be carried out via mini-batched SGD over a number of mini-batches. Additionally, when the learning rate of SGD is small, the updates of θ_{enc} in the turbo phase (step B) are primarily dominated by gradient signal of $\mathcal{L}_{\text{ve}}$, due to the large value of λ. Thus step B of the turbo phase can be simplified to minimizing only the loss $\mathcal{L}_{\text{ve}}$.

4.4 Question Answering with APVA-TURBO

At this end, we have completed explaining APVA-TURBO and the training of each component within. After it is trained, APVA-TURBO can be used to solve a QA-KB task according to the following steps.

To answer a question q, the Entity Alignment model is first applied to q and the KB $\mathcal{K}$. A list of M_{s} subject entities are generated as candidates according to their ranking under the model.

Each candidate entity is used as a hypothetic subject entity s, and passed to ENC-DEC together with q and $\mathcal{K}$. In this step, a list of M_{r} candidate path labels are generated. Specifically these candidate path labels are the highest ranked M_{r} path labels among all path labels r for which there is a path with label r in the KB that leaves from s. The ranking of the path labels is according to the learned prediction loss ℓ_{pr}. At the end of this step, a total of $M_{\text{s}}M_{\text{r}}$ (s, r) pairs are generated for question q.

Each of these subject-path pairs (s, r) is then passed to CLS, and the highest ranked (s, r) pair is declared as the correct subject-path pair. Here the ranking is according to the verification loss ℓ_{ve}.

Finally, submitting the declared (s, r) (together with q if needed) to the Object Answering model gives a list $\widehat{\mathcal{A}}(q)$ of answer paths, which APVA-TURBO declares as the answers to question q.

5 Experiments

5.1 Datasets and Pre-Processing

Two popular datasets, SimpleQuestions (Bordes et al., 2015) and WebQuestions (Berant et al., 2013) are used in our experiments.

SimpleQuestions (SQ) consists of 108,442 questions written by human English-speaking annotators. The dataset is partitioned randomly into 75,910 training questions, 10,845 validation questions and 21,687 test questions. The questions in SQ are all single-hop single-answer.

WebQuestions (WQ) consists of 5,810 questions. The dataset is partitioned randomly into 3000 training questions, 778 validation questions and 2032 test questions. The questions in WQ can be multi-hop multi-answer.

The answer triples or paths in SQ and WQ are all in Freebase. A subset of Freebase, FB2M (Bordes et al., 2015), is also used in our study. It includes 2,150,604 entities, 6701 relations and 14,180,937 triples. Since FB2M does not contain the entity type information, we retrieve this information from Freebase to annotate the type for each entity. Specifically, Freebase contains two kinds of types, "common.topic.notable_types" (or "notable type") and "type.object.type". Each entity in Freebase is designed to have a unique notable type while allowed to have many object types. We use notable types as the entity types. For an entity with the notable type missing in Freebase, we annotate it as "NO TYPE".

The answer triples in SQ can all be found in FB2M, whereas not all answer paths in WQ are within FB2M. Thus, for the QA-KB tasks, the KB associated with SQ is chosen as FB2M, and that with WQ is chosen as the entire Freebase.

For both SQ and WQ, the subject mention μ in each question q is also annotated by matching the surface name of the subject entity with the words in q. Each answer triple (s, r, o) in SQ is presented directly in terms of the unique ID's specifying the involved entities and the unique string specifying the relation r. In WQ, however, for each answer path, the path label r is not given, and the entities s and o are only given in terms of their names. We therefore perform a simple search and screening to reconstruct each answer path in its unique (s, r, o) representation.

5.2 Implementations

Given the subject mention μ, the subject entity s in $\mathcal{K}$ can be found easily, as long as the question is well formed and the subject entity s exists in $\mathcal{K}$ unambiguously. Determining the subject entity s from subject mention μ usually only involves matching the words in u with the surface name string of the entities in $\mathcal{K}$. So the problem of entity alignment reduces to determining the subject mention μ in q. Conventionally, such a problem is treated as sequence labelling problem. In this work, our entity alignment model combines the recent BiGRU-CRF model (Dai et al., 2016) with joint character-level word encoding (Zhang et al., 2015). The entity alignment model is trained separately. In the model, the state/output dimension of the GRU network, the dimension of word embeddings and that of character encoding vectors are all set to 50.

The KSE model is also trained separately. In this model, FB2M is used to construct the schema graph for both SQ and WQ datasets, and the dimension of the embedding space is chosen as 100.

For ENC-DEC, the state dimension for the GRU network encoding u^{KB} and the input dimension are both chosen as 100. The state dimension for each of the two GRU networks for encoding u^{Q} is set to 200. Each input to these networks is a 200-dimensional word2vec vector (pre-trained on a large corpus WikiAnswers (Fader et al., 2013)) concatenated with a 10-dimensional position vector indicating the relative location of the word in the question. The state dimension for the GRU network in DEC is set to 300.

In CLS, the MLP has two ReLU activated latent layers, with dimensions 200 and 100 respectively.

Turbo training with mini-batch SGD is used to jointly train ENC-DEC and CLS. The batch size is set to 128. In the BASE phase, the ENC-DEC model is trained for 8000 batches on SQ, and 1500 batches on WQ. In the first round of TURBO phase, the number of batches in Steps A, B, and C are respectively 2000, 1000, 100 on SQ, and 1000, 500, 50 on WQ. In the remaining rounds, every step uses 100 batches on SQ, and 50 batches on WQ.

For the given question q, we denote the set of entities by $\mathcal{O}(s, r)$, such that there is a path in the KB graph that connect entity s to entity o via a path with label r. For a multiple-answer question q, not necessarily all entities in $\mathcal{O}(s, r)$ give rise to a correct answer. A usual approach to deal with this is to learn a separate binary classifier to screen the entities in $\mathcal{O}(s, r)$. In this work, we use a simple SVM classifier as the object answering model. The input feature vector for the SVM is the concatenation of three vectors: the average word2vec vectors of all words in q, the KSE embedding vector $\overline{r}_T$ of the final relation r_T in the path label r (assuming the path is T-hop), and the KSE embedding of $\bar{t}_o$ is the type $t(o)$ of the candidate object entity $o \in \mathcal{O}(s, r)$.

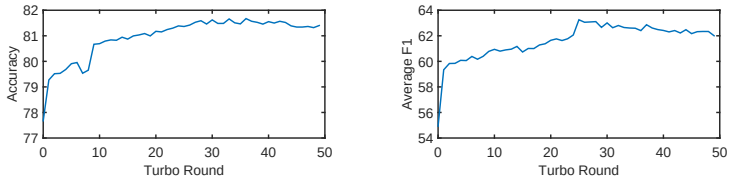
5.3 Question Answering Performance

Extensive experiments are performed to evaluate the proposed APVA-TURBO model in QA-KB tasks, relative to other existing models and various reductions of APVA-TURBO.

In experiments on SQ, the single answer triple (s, r, o) in $\widehat{A}(q)$ produced by a model is regarded as correct, if it matches the *unique* correct answer triple. The *accuracy* of a model is defined as the percentage of test questions for which the model produces the correct answer. On SQ, we use this accuracy to measure model performance.

On WQ, a given question q may have multiple answer paths (s, r, o) in the ground-truth answer set $\mathcal{A}(q)$. The model's *precision* for answering a question q is defined as the fraction of answers in $\widehat{\mathcal{A}}(q)$ that are in $\mathcal{A}(q)$, and the model's *recall* for answering q is the fraction of answers in $\mathcal{A}(q)$ that are in $\widehat{\mathcal{A}}(q)$. In such a setting, the overall performance is usually measured by the harmonic mean of precision and

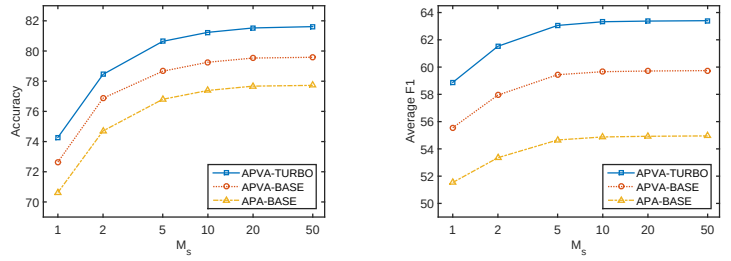
recall, namely, F1. We then use the average F1 value of a model over all test questions to measure the model's performance on WQ.



(a) SimpleQuestions (b) WebQuestions

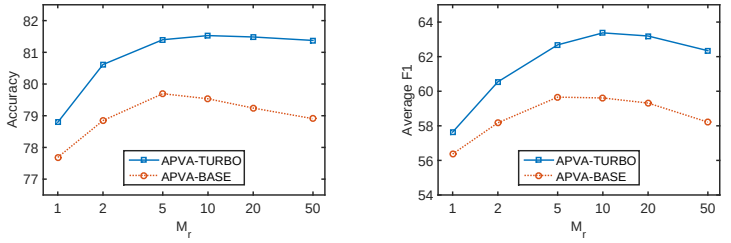
Figure 4: The performance of APVA-TURBO over TURBO iterations. $M_{\mathrm{s}} = 20$, $M_{\mathrm{r}} = 10$.

Analysis of APVA-TURBO The performance of APVA-TURBO over turbo iterations is shown in Figure 4. It can be seen that the performance increases with turbo iterations until 25 to 30 rounds. This demonstrates the effectiveness of turbo training. The performance starts to take a slight decreasing trend at around 30 to 40 rounds, due to overfitting, a phenomenon commonly arising when a model is overtrained. In the rest of the experiments, the number of Turbo rounds is taken as 30 for SQ and 25 for WQ.



(a) SimpleQuestions (b) WebQuestions

Figure 5: Performances of APVA-TURBO and its reductions vs M_{s}. $M_{\mathrm{r}} = 10$.



(a) SimpleQuestions (b) WebQuestions

Figure 6: Performances of APVA-TURBO and its reductions vs M_{r}. $M_{\mathrm{s}} = 20$.

Figure 5 plots the performances of APVA-TURBO and its various reductions as functions of the number M_{s} of candidate subject entities. APVA-BASE is the APVA-TURBO model without full turbo training. Specifically, after training in the Base Phase, it only enters the Turbo Phase once and stops right after the training of CLS. APA-BASE is a reduction of APVA-BASE by completely ignoring CLS. Including the verification classifier CLS appears to give a much significant boost of the performance (seen in APVA-BASE vs APA-BASE). Yet another leap in performance is achieved by including turbo training (seen in APVA-TURBO vs APVA-BASE).

It is also seen in Figure 5 that as M_{s} increases, the performances of the compared models all improve and eventually saturate after $M_{\mathrm{s}} = 20$. This performance improvement is expected since when more candidate subject entities are included, it increases the chance that the correct (s, r) pairs are selected.

In addition, although a high value of $M_{\rm s}$ also increases the chance of selecting a spurious (s, r) pair, we see no drop in performance. This is because the training of ENC-DEC has always been using *only the correct* subject entities. When a wrong entity is submitted to ENC-DEC, the path labels output from ENC-DEC tend to be a random draw, which are not competitive against the correct ones.

Figure 6 plots the performances of APVA-BASE and APVA-TURBO models against the number $M_{\rm r}$ of candidate path labels. Comparing the performance gap between the two models, it is apparent that turbo training brings in significantly benefit.

Figure 6 also shows that as $M_{\rm r}$ increases, the performances of the compared models all first increase and then gradually drop. This is because increasing $M_{\rm r}$ has two effects. The first is increasing the chance of selecting the correct path labels. The second is increasing the number of spurious path labels. It is sensible that a small increment of $M_{\rm r}$ makes the first effect dominate while a large increment makes the second dominate. The curves in the figure also show that the stronger a model is, at a higher $M_{\rm r}$ the performance trend reverts.

Table 1: Performance comparison on WQ

Model	F1(%)
(Yih et al., 2015)	52.5
(Xu et al., 2016)	53.3
(Yavuz et al., 2016)	52.6
(Jain, 2016)	**55.7**
(Reddy et al., 2017)	49.5
(Hao et al., 2017)	42.9
(Dong et al., 2017)	50.7
(Yue et al., 2017)	53.9
(Cheng et al., 2017)	50.1
APVA-BASE	**59.7**
APVA-TURBO	**63.4**

Table 2: Performance comparison on SQ

Model	Accuracy (%)
(Yin et al., 2016)	76.4
(Lukovnikov et al., 2017)	71.2
(Hsiao et al., 2017)	76.7
(Yu et al., 2017)	**78.7**
(Ture and Jojic, 2017)	**88.3**
APVA-BASE	**79.5**
APVA-TURBO	**81.5**

Performance Comparison with Existing Models The performance of APVA-TURBO is compared with the published performances of the existing models in Tables 1 and 2.

On WQ, the best known previous performance achieves an F1 value of 55.7%, due to (Jain, 2016). But this state of the art has been surpassed by APVA-BASE, with a F1 score 59.7%. This demonstrates the effectiveness of augmenting a model with a verification mechanism. With turbo training, APVA-TURBO further boosts its performance and presents a new F1 record of 63.4%. This performance, exceeding the current art by a stunning margin of nearly 8%, demonstrates the power of the APVA-TURBO approach developed in this paper.

On SQ, the best performance except that of (Ture and Jojic, 2017) achieves an accuracy of 78.7%. This performance has been surpassed by APVA-BASE, and further exceeded by APVA-TURBO at an accuracy of 81.5%. However that the current reported state of art is still that of (Ture and Jojic, 2017),

which achieves an accuracy of 88.3%. But that paper did not report sufficient details for us to understand in what respect APVA-TURBO under-performs. Neither does it contain all necessary details for us to implement the model and reproduce its reported performance.

6 Conclusion

This work demonstrates that incorporating a verification mechanism in a QA-KB model can be a powerful means of improving the model. Built on such a mechanism, the proposed APVA framework is also naturally facilitated with an iterative learning procedure, which we call turbo training. Turbo training is shown capable of significantly boosting the model performance. This makes APVA-TURBO a new state of art in QA-KB.

Abstract

Multi-relation Question Answering is a challenging task, due to the requirement of elaborated analysis on questions and reasoning over multiple fact triples in knowledge base. In this paper, we present a novel model called **Interpretable Reasoning Network** that employs an interpretable, hop-by-hop reasoning process for question answering. The model dynamically decides which part of an input question should be analyzed at each hop; predicts a relation that corresponds to the current parsed results; utilizes the predicted relation to update the question representation and the state of the reasoning process; and then drives the next-hop reasoning. Experiments show that our model yields state-of-the-art results on two datasets. More interestingly, the model can offer traceable and observable intermediate predictions for reasoning analysis and failure diagnosis, thereby allowing manual manipulation in predicting the final answer.

1 Introduction

Open-domain Question Answering (QA) has always been a hot topic in AI and this task has recently been facilitated by large-scale Knowledge Bases (KBs) such as Freebase (Bollacker et al., 2008). However, due to the variety and complexity of language and knowledge, open-domain question answering over knowledge bases (KBQA) is still a challenging task.

Question answering over knowledge bases falls into two types, namely single-relation QA and multi-relation QA, as argued by Yin et al. (2016). Single-relation questions, such as *"How old is Obama?"*, can be answered by finding one fact triple in KB, and this task has been widely studied (Bordes et al., 2015; Xu et al., 2016; Savenkov and Agichtein, 2017). In comparison, reasoning over multiple fact triples is required to answer multi-relation questions such as *"Name a soccer player who plays at forward position at the club Borussia Dortmund."* where more than one entity and relation are mentioned. Compared to single-relation QA, multi-relation QA is yet to be addressed.

Previous studies on QA over knowledge bases can be roughly categorized into two lines: semantic parsing and embedding-based models. Semantic parsing models (Yih et al., 2014; Yih et al., 2016) obtain competitive performance at the cost of hand-crafted features and manual annotations, but lack the ability to generalize to other domains. In contrast, embedding-based models (Bordes et al., 2014b; Hao et al., 2017; Yavuz et al., 2017) can be trained end-to-end with weak supervision, but existing methods are not adequate to handle multi-relation QA due to the lack of reasoning ability.

Recent reasoning models (Miller et al., 2016; Wang et al., 2017) mainly concentrate on Reading Comprehension (RC) which requires to answer questions according to a given document. However, transferring existing RC methods to KBQA is not trivial. For one reason, the focus of reasoning in RC is usually on understanding the document rather than parsing questions. For another reason, existing reasoning networks are usually designed in a black-box style, making the models less interpretable. While in multi-relation question answering, we believe that an interpretable reasoning process is essential.

In this paper, we propose a novel Interpretable Reasoning Network (IRN) to equip QA systems with the reasoning ability to answer multi-relation questions. Our central idea is to design an interpretable

reasoning process for a complex question: the reasoning module decides which part of an input question should be analyzed at each hop, and predicted a KB relation that corresponds to the current parsed results. The predicted relation will be used to update the question representation as well as the state of the reasoning module, and helps the model to make the next-hop reasoning. At each hop, an entity will be predicted based on the current state of the reasoning module.

Different from previous models, our model is ***interpretable*** in that the predicted relation and entity at each hop are ***traceable and observable***. At each hop our model has a specific aim to find an appropriate relation based on the iterative analysis of a question, and intermediate output at each hop can be interpreted by the corresponding linked entity. In this manner, IRN offers the ability of visualizing ***a complete reasoning path*** for a complex question, which facilitates reasoning analysis and failure diagnosis, thereby allowing manual manipulation in answer prediction as detailed in our experiments.

The contributions of this paper are in two folds:

1. We design an Interpretable Reasoning Network which can make reasoning on multi-relation questions with multiple triples in KB. Results show that our model obtains state-of-the-art performance.

2. Our model is more interpretable than existing reasoning networks in that the intermediate entities and relations predicted by the hop-by-hop reasoning process construct traceable reasoning paths to clearly reveal how the answer is derived.

2 Related Works

Recent works on QA can be roughly classified into two types: one is semantic-parsing-based and the other is embedding-based. Semantic parsing approaches map questions to logical form queries (Pasupat and Liang, 2015; Yih et al., 2016; Abujabal et al., 2017). These systems are effective but at the cost of heavy data annotation and pattern/grammar engineering. What's more, parsing systems are often constrained on a specific domain and broken down when executing logical queries on incomplete KBs.

Our work follows the line of Embedding-based models (Bordes et al., 2014b; Dong et al., 2015; Xu et al., 2016; Hao et al., 2017; Yavuz et al., 2017) which are recently introduced into the QA community where questions and KB entities are represented by distributed vectors, and QA is formulated as a problem of matching between vectors of questions and answer entities. These models need less grammars as well as annotated data, and are more flexible to deal with incomplete KBs. To make better matching, subgraphs of an entity in KB (Bordes et al., 2014a), answer aspects (Dong et al., 2015; Hao et al., 2017) and external contexts (Xu et al., 2016) can be used to enrich the representation of an answer entity. Though these methods are successful to handle simple questions, answering multi-relation questions or other complex questions is far from solved, since such a task requires reasoning or other elaborated processes.

Our work is also related to recent reasoning models which focus on Reading Comprehension where memory modules are designed to comprehend documents. State-of-the-art memory-based Reading Comprehension models (Sukhbaatar et al., 2015; Kumar et al., 2015; Shen et al., 2016; Wang et al., 2017; Celikyilmaz et al., 2017) make interactions between a question and the corresponding document in a multi-hop manner during reasoning. MemNN (Weston et al., 2015), KVMemN2N (Miller et al., 2016) and EviNet (Savenkov and Agichtein, 2017) transferred the reading comprehension framework to QA where a set of triples is treated as a document and a similar reasoning process can be applied. However, reading comprehension makes reasoning over documents instead of parsing the questions.

Other studies applying hop-by-hop inference into QA can be seen in Neural Programmer (Neelakantan et al., 2015; Neelakantan et al., 2016) and Neural Enquirer (Yin et al., 2015), where deep networks are proposed to parse a question and execute a query on tables. However, Neural Programmer needs to predefine symbolic operations, while Neural Enquirer lacks explicit interpretation. Mou et al. (2017) proposed a model coupling distributed and symbolic execution with REINFORCE algorithm, however, training such a model is challenging. Neural Module Network (Andreas et al., 2015; Andreas et al., 2016) customized network architectures for different patterns of reasoning, making the reasoning network interpretable. However, a dependency parser and the REINFORCE algorithm are required.

3 Interpretable Reasoning Network

3.1 Task Definition

Our goal is to offer an interpretable reasoning network to answer multi-relation questions. Given a question q and its topic entity or subject e_s which can be annotated by some NER tools, the task is to find an entity a in KB as the answer.

In this work, we consider two typical categories of multi-relation questions, a path question (Guu et al., 2015) and a conjunctive question (Zhang et al., 2016), while the former is our major focus.

A path question contains only one topic entity (subject e_s) and its answer (object a) can be found by walking down an answer path consisting of a few relations and the corresponding intermediate entities. We define an **answer path** as a sequence of entities and relations in KB which starts from the subject and ends with the answer like $e_s \xrightarrow{r_1} e_1 \xrightarrow{r_2} ... \xrightarrow{r_n} a$. Relations ($r_i$) are observable (in various natural language forms) in the question, however, the intermediate entities ($e_1 \cdots e_H$) are not. For example, for question *"How old is Obama's daughter?"*, the subject is *Barack_Obama* and the answer path is *Barack_Obama* $\xrightarrow{Children}$ *Malia_Obama* $\xrightarrow{Age}$ *18*. Note that since there are 1-to-many relations[1], the range of the intermediate entities can be large, resulting in more than one answer path for a question.

A conjunctive question is a question that contains more than one subject entity and the answer can be obtained by the intersection of results from multiple path queries. For instance, the question *"Name a soccer player who plays at forward position at the club Borussia Dortmund."* has a possible answer as the intersection of results from two path queries[2] $FORWARD \xrightarrow{plays\_position^{-1}} Marco\_Reus$ and $Borussia\_Dortmund \xrightarrow{plays\_in\_club^{-1}} Marco\_Reus$. The details for dealing with conjunctive questions are shown in Fig 2.

3.2 Overview

The reasoning network has three modules: input module, reasoning module, and answer module. The input module encodes the question into a distributed representation and updates the representation hop-by-hop according to the inference results of the reasoning module. The reasoning module initializes its state by the topic entity of a question and predicts a relation on which the model should focus at the current hop, conditioned on the present question and reasoning state. The predicted relation is utilized to update the state vector and the question representation hop-by-hop. The answer module predicts an entity conditioned on the state of the reasoning module.

The process can be illustrated by the example as shown in Figure 1. For question *"How old is Obama's daughter?"*, the subject entity *Barack_Obama* is utilized to initialize the state vector. IRN predicts the first relation *"Children"* at the first hop. The *"Children"* relation is added to the state vector to encode the updated parsing result, and the corresponding natural language form of this relation in the question (here is *"daughter"*) is subtracted from the question to avoid repeatedly analyzing the relation-relevant word *"daughter"*. This procedure is repeated until the *Terminal* relation is predicted.

3.3 Input Module

The input module encodes a question to a vector representation and updates the representation of the question at each hop of the reasoning process: the predicted relation will be subtracted from the current representation to compel the reasoning process to attend to other words that should be analyzed.

Formally, the question $\boldsymbol{X} = x_1, x_2, ..., x_n$ can be initialized by the sum of the word embeddings and updated by subtracting the relation predicted by the reasoning module at the previous hop:

$$\boldsymbol{q}^0 = \sum_{i=1}^{n} \boldsymbol{x}_i \quad (1)$$

$$\boldsymbol{q}^h = \boldsymbol{q}^{h-1} - \boldsymbol{M}_{rq}\hat{\boldsymbol{r}}^h \quad (2)$$

[1]For instance, relation *Children* is one-to-many, where a person may have more than one child.

[2]Superscript -1 stands for the inverse relation.

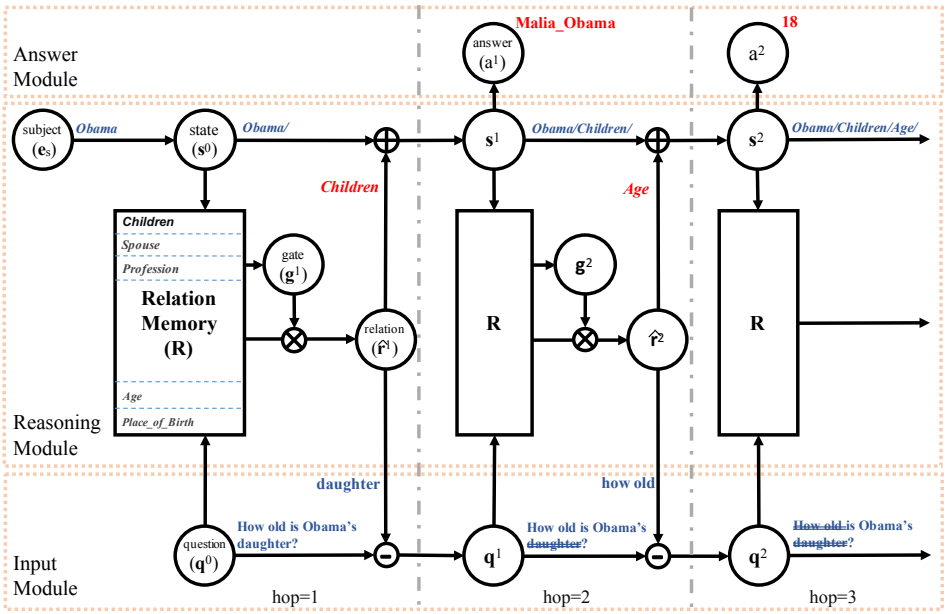

Figure 1: Interpretable Reasoning Network. At each hop IRN computes the probability of selecting the next relation as $\boldsymbol{g}^h$ and obtains a predicted relation $\hat{\boldsymbol{r}}^h$. The predicted relation $\hat{\boldsymbol{r}}^h$ is used to update the question $\boldsymbol{q}^h$ and the state $\boldsymbol{s}^h$ with different projections. The state is initialized by subject as $\boldsymbol{s}^0 = \boldsymbol{e}_s$. The answer path ($Obama \xrightarrow{Children} Malia\_Obama \xrightarrow{Age} 18$) is composed of the predicted relations and entities (in red).

where $\boldsymbol{M}_{rq}$ is a matrix projecting the KB relation space to the natural language question space, $\boldsymbol{q}^{h-1}$ is the question representation at hop $h-1$, and $\hat{\boldsymbol{r}}^h$ defined by Eq. 4 is the predicted relation at hop h. The intuition of such update is that the already analysed part of the question should not be parsed again.

Representing a question as a bag of words might be too simple. However, this method works well in our setting. Future work would consider other sophisticated encoders such as CNN or LSTM.

3.4 Reasoning Module

The reasoning module aims to attend to a particular part of the question at each hop, predict an associated relation in knowledge base, and then update its state.

The reasoning module takes as input the previous state vector ($\boldsymbol{s}^{h-1}$) and the previous question vector ($\boldsymbol{q}^{h-1}$), and then predicts a relation ($\hat{\boldsymbol{r}}^h$) based on the analysis at the current hop. Once the predicted relation ($\hat{\boldsymbol{r}}^h$) is obtained, the relation will be used to update the next question representation ($\boldsymbol{q}^h$) and the state of the reasoning module ($\boldsymbol{s}^h$). In this manner, the reasoning network is traceable and interpretable.

The process can be formally described by the following equations[3]:

$$g_j^h = P(r^h = r_j | \boldsymbol{q}^{h-1}, \boldsymbol{s}^{h-1}) = \text{softmax}((\boldsymbol{M}_{rq}\boldsymbol{r}_j)^T \boldsymbol{q}^{h-1} + (\boldsymbol{M}_{rs}\boldsymbol{r}_j)^T \boldsymbol{s}^{h-1}) \tag{3}$$

$$\hat{\boldsymbol{r}}^h = \sum_j g_j^h * \boldsymbol{r}_j \tag{4}$$

$$\boldsymbol{s}^h = \boldsymbol{s}^{h-1} + \boldsymbol{M}_{rs}\hat{\boldsymbol{r}}^h \tag{5}$$

where $\boldsymbol{r}_j$ is the embedding of a relation in KB and all the relation embeddings are stored in a static memory R, and $\boldsymbol{s}^h$ is the state of the reasoning module at hop h. g_j^h is the probability of selecting the j^{th} relation in KB and $\boldsymbol{M}_{rs}$ is the projection matrix mapping $\boldsymbol{r}$ from the relation space to the state space. $\boldsymbol{M}_{rq}$ is the same projection matrix used in Eq. 2 to map $\boldsymbol{r}$ from the relation space to the question space.

We initialize the state vector with the topic entity (subject) $\boldsymbol{s}^0 = \boldsymbol{e}_s$. IRN will learn to enrich the state representation hop by hop, for instance, at the first hop $\boldsymbol{s}^1 \approx \boldsymbol{e}_s + \boldsymbol{r}_1$, and at the second hop $\boldsymbol{s}^2 \approx \boldsymbol{e}_s + \boldsymbol{r}_1 + \boldsymbol{r}_2$, intuitively. In this manner, the state vector encodes historical information.

[3] $\boldsymbol{a}^T\boldsymbol{b}$ is the inner-product of vector $\boldsymbol{a}$ and $\boldsymbol{b}$.

In order to signify when the reasoning process should stop, we augment the relation set with the *Terminal* relation. Once the reasoning module predicts the *Terminal* relation, the reasoning process will stop, and the final answer will be the output when the last non-terminal relation is added to the state $\boldsymbol{s}$.

3.5 Answer Module

The answer module chooses the corresponding entity from KB at each hop (denoted as a^h). At the last hop, the selected entity is chosen as the final answer, while at the intermediate hops, the predictions of these entities can be inspected to help reasoning analysis and failure diagnosis.

More formally, an entity at each hop can be predicted as follows:

$$\boldsymbol{e}^h = \boldsymbol{M}_{se}\boldsymbol{s}^h \tag{6}$$

$$o_j^h = P(a^h = e_j|\boldsymbol{s}^h) = \text{softmax}(\boldsymbol{e}_j^T\boldsymbol{e}^h) \tag{7}$$

$\boldsymbol{M}_{se}$ is used to transfer from the state space ($\boldsymbol{s}^h$) to the entity space ($\boldsymbol{e}^h$) to bridge the representation gap between the two spaces. $\boldsymbol{e}_j$ is the embedding vector of the j^{th} entity in KB.

3.6 Loss Function

We adopt cross entropy to define the loss function. The first loss term is defined on the intermediate prediction of relations, while the second term on the prediction of entities.

The loss on one instance is defined as follows:

$$\mathcal{L} = \sum_h \mathcal{C}_r(h) + \lambda\mathcal{C}_a(h) \tag{8}$$

$$\mathcal{C}_r(h) = -\sum_{j=1}^{n_r}[\hat{g}_j^h \ln g_j^h]\ ,\ \mathcal{C}_a(h) = -\sum_{i=1}^{n_e}[\hat{o}_i^h \ln o_i^h]$$

where n_r/n_e is the number of relations/entities in KB respectively, $\hat{\boldsymbol{g}}^h$ is the gold distribution (one-hot) over relations at hop h, $\boldsymbol{g}^h$ is the predicted distribution defined by Eq. 3, $\hat{\boldsymbol{o}}$ is the gold distribution over entities, which is also one-hot representation, and $\boldsymbol{o}$ is defined by Eq. 7. λ is a hyper parameter to balance the two terms.

Note that the training data is in the form of $(q, < e_s, r_1, e_1, ..., a >)$, which indicates that the model can incorporate supervision not only from the final answer (referred to as IRN-weak), but also from the intermediate relations and entities along the answer path (referred to as IRN).

3.7 Multitask Training for KB Representation

In order to incorporate more constraints from KB[4], we learn the embeddings of entities and relations as well as the space transition matrix with a multitask training schema. For a given fact triple in KB, (e_s, r, e_o), the representations of the entities and the relation apply the following constraint:

$$\boldsymbol{M}_{se}(\boldsymbol{e}_s + \boldsymbol{r}) = \boldsymbol{e}_o \tag{9}$$

where $\boldsymbol{e}_s, r, \boldsymbol{e}_o$ are embeddings of the subject (or head) entity, relation, and the object (or tail) entity. This idea is inspired by TransE (Bordes et al., 2013), but we adopt $\boldsymbol{M}_{se}$ (see Eq. 6) as a transfer matrix to bridge the representation gap between the state space (here $\boldsymbol{e}_s + \boldsymbol{r} = \boldsymbol{s}$) and the entity space (here $\boldsymbol{e}_o = \boldsymbol{e}$).

The parameters are updated with a multi-task training schema. We first learn the KB embeddings $\boldsymbol{e}$/$\boldsymbol{r}$ and the transformation matrix $\boldsymbol{M}_{se}$ to fit Eq. 9 with several epoches. This is the task of KB embedding training. Then, we update all the parameters of IRN under supervision from the QA task with one epoch, which is the task of QA training. We run the two tasks iteratively.

With the help of the auxiliary KB embedding training, IRN not only utilizes the additional information from KB to make better inferences, but also has an ability to deal with incomplete answer paths. For example, even if the connection between *Barack_Obama* and *Malia_Obama* is not present in KB, our model can still make correct prediction thanks to $\boldsymbol{M}_{se}(\boldsymbol{e}_{Barack\_Obama} + \boldsymbol{r}_{Children}) \approx \boldsymbol{e}_{Malia\_Obama}$.

[4]Constraint from KB means that two entities and a relation form a triple in KB, as (e_s, r, e_o).

3.8 Dealing with Conjunctive Questions

IRN is not limited to only path questions. For a conjunctive question that contains more than one topic entity, the answer can be found by executing multiple IRNs with the same parameters in parallel and then obtaining the intersection of individual results.

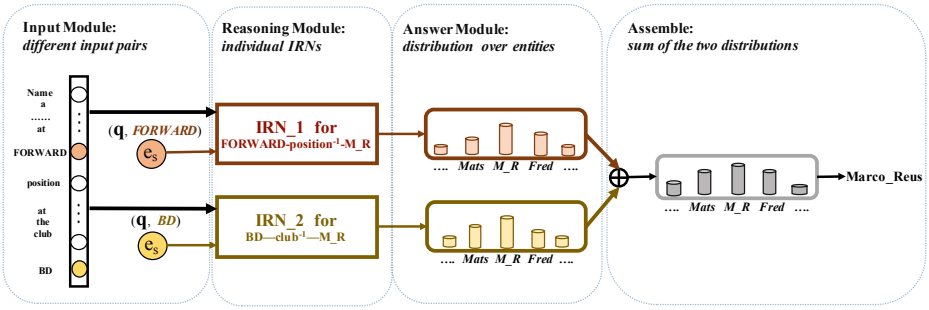

Figure 2: An assembly of two IRNs to handle a conjunctive question with two subjects. Different IRNs take as input the same question but different subjects and output the distribution over the candidate answers. The final answer is selected after summing the two distributions.

This process is exemplified by Figure 2. The input question *"Name a soccer player who plays at forward position at the club Borussia Dortmund"* has two subject entities, *"FORWARD"* and *"Borussia_Dortmund(BD)"*. One IRN (IRN_1) takes the original question and *"FORWARD"* as input, and then predicts possible objects for path query *"FORWARD* $\xrightarrow{plays\_position^{-1}}$ *?(Marco_Reus)"*.[5] The output is a distribution over entities. Similarly, another IRN (IRN_2) tackles the path query *"BD* $\xrightarrow{plays\_in\_club^{-1}}$ *?(Marco_Reus)"* where the input is the same question but another subject entity *"Borussia Dortmund(BD)"*. After summing the two output distributions, the answer *"Marco_Reus"* is chosen with the largest probability.

4 Data Preparation

We prepared two KBQA datasets to evaluate our Interpretable Reasoning Network: one is PathQuestion[6], constructed by ourselves, and the other is WorldCup2014, adopted from (Zhang et al., 2016).

4.1 PathQuestion

We adopted two subsets of Freebase (Bollacker et al., 2008) as Knowledge Bases to construct the PathQuestion (PQ) and the PathQuestion-Large (PQL) datasets. We extracted paths between two entities which span two hops ($e_s \xrightarrow{r_1} e_1 \xrightarrow{r_2} a$, denoted by -2H) or three hops ($e_s \xrightarrow{r_1} e_1 \xrightarrow{r_2} e_2 \xrightarrow{r_3} a$, denoted by -3H) and then generated natural language questions with templates. To make the generated questions analogical to real-world questions, we included paraphrasing templates and synonyms for relations by searching the Internet and two real-world datasets, WebQuestions (Berant et al., 2013) and WikiAnswers (Fader et al., 2013). In this way, the syntactic structure and surface wording of the generated questions have been greatly enriched.

PQL is more challenging than PQ in that PQL utilizes larger KB and provides less training instances. The statistics are shown in Table 1 and more details are described in the Appendix 6.

4.2 WorldCup2014

We also evaluated our model on the WorldCup2014 (WC2014) dataset constructed by (Zhang et al., 2016). The dataset contains single-relation questions (denoted by WC-1H), two-hop path questions (WC-2H), and conjunctive questions (WC-C). WC-M is the mixture of WC-1H and WC-2H. The statistics of *WorldCup2014* are listed in Table 1.

[5]The question mark indicates the entity to be predicted and the entity in bracket is the expected answer.

[6]This dataset is available at `https://github.com/zmtkeke/IRN`

Dataset	#Entity	#Relation	#Question	Exemplar Question
PQ-2H / 3H	2,215	14	1,908 / 5,198	What does the son of princess_Sophia's mom do for a living?
PQL-2H / 3H	5,035	364	1,594 / 1,031	What is the notable type of Jody_Harris's profession?
WC-1H / 2H / M / C	1,127	6	6,482 / 1,472 / 7,954 / 2,208	Name a player who plays at Forward position from Mexico?

Table 1: Statistics and exemplar questions of PathQuestion (PQ), PathQuestion-Large (PQL) and WorldCup2014 (WC).

5 Experiment and Evaluation

5.1 Implementation Details

ADAM optimizer (Kingma and Ba, 2015) was used for parameter optimization. The dimension of all the embeddings (words in question, entities and relations in KB) was set as $d_x = d_e = d_r = 50$. The hyper-parameter λ (see Eq. 8) is set to 1 . We partitioned the entire dataset into the train/valid/test subset with a proportion of $8:1:1$ and set the batch size as 50.

5.2 Performance of Question Answering

In this section, we evaluated the performance of multi-relation question answering on **PathQuestion** and **WorldCup2014** respectively. To further show that IRN is able to handle more challenging datasets, we evaluated the model with two configurations:

Incomplete KB To simulate the real KBs which are often far from complete, we removed half of the triples (entities and relations are retained but the connections between entities were removed) from the KB of the PQ-2H dataset.

Unseen KB To simulate a real QA scenario where out-of-vocabulary(OOV) words is one of the major challenges, we removed questions whose answer path includes relation *"Cause_of_Death"*, *"Gender"* or *"Profession"* from the PQ-2H training set. The models need to cope with questions related to these three OOV relations during the test.

Several baselines are included here:

Embed (Bordes et al., 2014b) deals with factoid QA over KB by matching a question with an answer in the embedding spaces.

Subgraph (Bordes et al., 2014a) improves the *Embed* model by enriching the representation of an answer entity with the entity's subgraph.

Seq2Seq (Sutskever et al., 2014) is a simplified seq2seq semantic parsing model, which adopts an LSTM to encode the input question sequence and another LSTM to decode the answer path.

MemN2N (Sukhbaatar et al., 2015) is an end-to-end memory network that can be used for reading comprehension and question answering. The memory units consist of the related triples in a local subgraph of the corresponding answer path, where the settings are the same as (Bordes et al., 2015).

KVMemN2N (Miller et al., 2016) improves the MemN2N for KBQA as it divides the memory into two parts: the key memory stores the head entity and relation while the value memory stores the tail entity.

IRN-weak is our model that employs only supervision from the final answer entity rather than the complete answer path. This can be implemented by simply ignoring the loss from the intermediate hops except the final entity in Eq. 8.

The performance is measured by accuracy[7]: correct if a predicted entity is in the answer set of input question. Since there are many 1-to-many relations in Freebase and WC2014, a question may have several possible answer paths, resulting in multiple answers. For example, given the question *"How old is Obama's daughter?"*, the original path can be *"Barack_Obama* $\xrightarrow{Children}$ *Malia_Obama* $\xrightarrow{Age}$*18"* or *"Barack_Obama* $\xrightarrow{Children}$*Sasha_Obama* $\xrightarrow{Age}$ *14"*, thus the answer can be either *"18"* or *"14"*. For this question, either answer is correct.

The results in Table 2 demonstrate that our system outperforms the baselines on single-relation questions (WC-1H), 2-hop-relation questions (PQ-2H/PQL-2H/WC-2H) as well as 3-hop-relation questions (PQ-3H/PQL-3H). Furthermore, assembled IRNs obtain strong performance when dealing with conjunctive questions in WC-C .

[7]Reported accuracy is the average accuracy of five repeated runs.

	PathQuestion		PathQuestion Large		WorldCup2014				Challenging PQ-2H	
	PQ-2H	PQ-3H	PQL-2H	PQL-3H	WC-1H	WC-2H	WC-M	WC-C	Incomplete	Unseen
Random	0.151	0.104	0.021	0.015	0.085	0.064	0.053	0.073	-	-
Embed	0.787	0.483	0.425	0.225	0.448	0.588	0.518	0.642	-	-
Subgraph	0.744	0.506	0.500	0.213	0.448	0.507	0.513	0.692	-	-
IRN-weak(*Ours*)	0.919	0.833	0.630	0.618	0.749	0.921	0.786	0.837	-	-
Seq2Seq	0.899	0.770	0.719	0.647	0.537	0.548	0.538	0.577	-	-
MemN2N	0.930	0.845	0.690	0.617	0.854	0.915	**0.907**	0.733	0.899($\downarrow 3.3\%$)	0.558
KVMemN2N	0.937	**0.879**	0.722	0.674	**0.870**	0.928	0.905	0.788	0.902($\downarrow 3.7\%$)	0.554
IRN(*Ours*)	**0.960**	0.877	**0.725**	**0.710**	0.843	**0.981**	**0.907**	**0.910**	0.937($\downarrow 2.3\%$)	0.550

Table 2: Accuracy on different QA datasets. WC-C is for conjunctive questions while other datasets for path questions. Challenging PQ-2H are two more difficult configurations of PQ-2H. The models in the second block utilize the answer path information but those in the first block do not.

We have further observations as follows:

• *IRN-weak* outperforms *Embed* and *Subgraph*, indicating that multi-hop reasoning indeed helps to answer complex questions even when our model is trained end-to-end in the same configuration of weak supervision[8].

• The *Seq2Seq* baseline performs worse than *IRN*. Though they are both interpretable, *IRN* is more powerful when dealing with complicated KBs and questions.

• *IRN* is better than *MemN2N* and *KVMemN2N* on most of the datasets, and both models are much better than other baselines using the path information. Note that the memory in *(KV)MemN2N* consists of fact triples which are distilled from KB using answer path. In this sense, *(KV)MemN2N* indirectly employs strong supervision from answer path. In contrast, *IRN* has a better (or easier) mechanism to supervise the reasoning process thanks to its interpretable framework.

• The highest accuracy on PQL-2H/3H reveals that *IRN* performs better when faced with larger datasets. IRN deals with relations and entities separately, where the number of entities and relations is much less than that of triples. However, *(KV)MemN2N* has to handle much more triples in its memory.

• *IRN* is more robust than the baselines ($\downarrow 3.7\%$ vs. $\downarrow 2.3\%$) when dealing with incomplete KB, which is probably because auxiliary KB embedding training facilitates the prediction of missing triples. While the baselines are more sensitive to the incomplete information stored in the memory units.

• Both *IRN* and the baselines degrade remarkably (0.9→0.5) in the unseen setting because wrong distributed representations are influential in embedding-based QA models. In addition, the size of the training set is much smaller than that of the original PQ-2H, which also leads to worse performance.

• *IRN* is more interpretable compared with *(KV)MemN2N* , attributed to the structure of *IRN*. The relation/entity predicted at each hop is a part of the answer path. The intermediate outputs offer the possibility to trace the complete reasoning process, diagnose failures, and manipulate answer prediction through intermediate interactions (see Section 5.3).

5.3 Interpretable Path Reasoning

In this section, we demonstrated how IRN is interpretable by both quantitative and qualitative analysis. For the quantitative analysis, we can measure how it performs during the reasoning process by investigating the prediction accuracy of intermediate relations and entities. In this task, we collected all the relations and entities with largest probabilities (see Eq. 3 and Eq. 7) at each hop $\{r^1, a^1, r^2, .., a^H\}$ and compared these intermediate outputs with the ground truth $\{r_1, e_1, r_2, .., a\}$. As for KVMemN2N, we also fetched an entity at each hop by an answer distribution, similar to that at the final hop.

According to the structure of IRN, the relation/entity predicted at each hop constitutes an answer path. Results[9] in Table 3 indicate that IRN can predict intermediate entities more accurately than final answers, due to the cascading errors in the consecutive prediction.

Though KVMemN2N (KVM) predicts the exact answers well, it lacks interpretability. On the one hand, KVM can not predict relations to trace the answer path. On the other hand, the hops in KVM all

[8]Only supervision from question-answer pairs, but without answer path information from KB.

[9]Note here that only if an output matches the labeled entity exactly, the prediction will be judged as correct.Thus, the accuracy here has a different definition from that in Table 2.

	r_1		e_1		r_2		e_2		r_3		a	
	IRN	KVM	IRN	KVM	IRN	KVM	IRN	KVM	IRN	KVM	IRN	KVM

Table 3: Accuracy at different hops along the answer path from IRN and KVMemN2N (KVM). r_i indicates the relation at hop i, e_i indicates the entity at hop i. a indicates the final answer. NA means not applicable.

aim at finding the answer entity rather than the intermediate entities along the answer path.

To illustrate how our model parses a question and predicts relations hop-by-hop, we studied the distributions over all the relations ($\boldsymbol{g}^h$, see Eq. 3) and chose an example from PathQuestion as shown in Figure 3. It is clear that IRN is able to derive the relations in correct order. For question *"What does john_hays_hammond's kid do for a living?"*, IRN first detects relation *Children* (the corresponding word/phrase in the question is *kid*) and then *Profession* (*what does..do*). When detecting the *Terminal* relation, IRN will stop the analysis process.

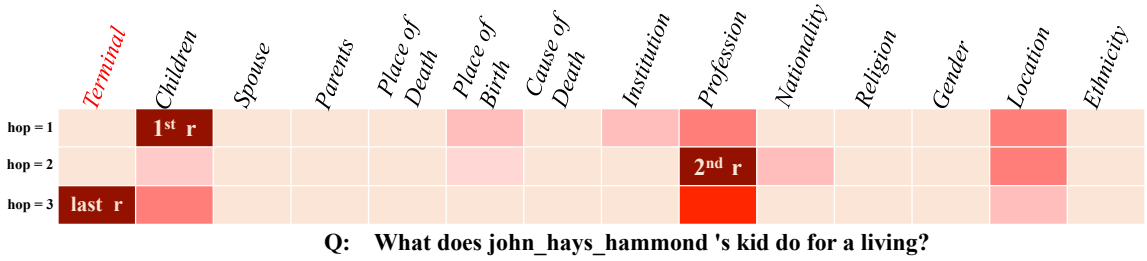

Figure 3: The predicted relations at each hop. Each row represents a probability distribution over relations. Darker color indicates larger probability. The terminal relation is highlighted in red.

Our model can map relations in KB to words in question. We sampled some relations in KB and projected them to the question space by $\boldsymbol{r}^q = \boldsymbol{M}_{rq}\boldsymbol{r}$ (see Eq. 2). We then obtained words whose embeddings are most close to $\boldsymbol{r}^q$ measured by cosine similarity $cos(\boldsymbol{r}^q, \boldsymbol{x}_i)$. The result in Table 4 indicates that IRN can establish reasonable mapping between KB relation and natural language, such as linking *Profession* to words like *working, profession*, and *occupation* . Besides mapping to single words, relation in KB can be associated with some complicate templates, such as *Profession* $\rightarrow$ *"what does ... do"* .

Relation	Similar words in natural language questions
Profession	profession, do, working, occupation
Insititution	institution, organization, work, where
Religion	faith, religion, what, belief
Cause_of_Death	died, killed, how, death
Place_of_Birth	hometown, born, city, birthplace

Table 4: Most similar words in questions for some exemplar relations.

The above analysis demonstrates that our model is interpretable. Specifically, IRN has merits at:
•Providing a traceable reasoning path for question answering. With the aid of these intermediate entities and relations, we can obtain not only the final answer but also the complete path that infers the answer.

•Facilitating failure diagnosis. For instance, IRN fails to answer the question *"Where did the child of Joseph_P_Kennedy_Sr die ?"*. The true answer path should be *"Joseph_P_Kennedy_Sr* $\xrightarrow{Children}$ *Patricia_kennedy_Lawford* $\xrightarrow{Place\_of\_Death}$ *New_York_County"*. However, the middle entity decided by IRN is *"Rosemary_Kennedy"* who is also a child of *"Joseph_P_Kennedy_Sr"*, but her death is not included in KB.

•Allowing manual manipulation in answer prediction. We updated the state (Eq. 5) and the question (Eq. 2) in IRN with the ground-truth relation vectors and compared the performance. The higher

accuracy in Table 5 implies that we can improve the final prediction by correcting intermediate predictions.

Dataset	PQ-2H	PQ-3H	PQL-2H	PQL-3H
Acc	0.980 (↑ 2.0%)	0.900 (↑ 2.3%)	0.755 (↑ 3.0%)	0.744 (↑ 3.4%)

Table 5: Accuracy when the intermediate predictions are replaced by ground truth.

6 Conclusion

We present a novel Interpretable Reasoning Network which is able to make reasoning hop-by-hop and then answer multi-relation questions. Our model is interpretable in that the intermediate predictions of entities and relations are traceable and the complete reasoning path is observable. This property enables our model to facilitate reasoning analysis, failure diagnosis, and manual manipulation in answer prediction. Results on two QA datasets demonstrate the effectiveness of the model on multi-relation question answering.

As future work, there is much room for complex question answering. For instance, answering *"How old is Obama's younger daughter?"* needs to handle arithmetic operation. Furthermore, multi-constraint questions will also be considered in this framework.

Appendix A. PathQuestion Construction and Question Templates

We constructed a synthesis dataset by generating questions with templates. The knowledge base for PathQuestion has more than 60,000 triples which are adopted from FB13 (Socher et al., 2013) with 13 relations and thousands of entities. As for PathQuestion-Large, we adopted another more complex subset of Freebase (Bollacker et al., 2008). **First**, we extracted all the paths with two hops ($< e_s, r_1, e_1, r_2, a >$), or three hops ($< e_s, r_1, e_1, r_2, e_2, r_3, a >$) among these triples. **Second**, we crafted templates to generate natural language questions from these paths. **Last**, we collected question and answer path pairs $(q, < e_s, r_1, e_1, ..., a >)$ to construct the *PathQuestion (PQ)* dataset.

We crafted templates to transfer an answer path extracted from KB to natural language questions. To make the generated questions analogical to real-world questions, those templates are firstly written manually, and then enriched by replacing synonyms. Besides, we searched for different syntactical structures and paraphrases in real-world datasets including WebQuestions (Berant et al., 2013) and WikiAnswers (Fader et al., 2013) as well as on the Internet. In this manner, the templates have been greatly diversified and are much closer to real questions.

Synonyms used in templates for PathQuestion are shown in Table 6 and templates for 2-hop paths (PQ-2H) are shown in Table 7. The datasets are available at `https://github.com/zmtkeke/IRN`.

Relation	**Synonyms**
Spouse	couple, wife, husband
	other half, darling
Children	child, offspring, kid
	daughter, son, heir
Parents	parent, father, mother
	dad, mom
Profession	job, occupation, work
Institution	organization
	educational institution
Ethnicity	race
Gender	sex
Nationality	nation, country
Location	address
Religion	faith, religious belief
	type of religion

Abstract

Distributed word representation plays a pivotal role in various natural language processing tasks. In spite of its success, most existing methods only consider contextual information, which is suboptimal when used in various tasks due to a lack of task-specific features. The rational word embeddings should have the ability to capture both the semantic features and task-specific features of words. In this paper, we propose a task-oriented word embedding method and apply it to the text classification task. With the function-aware component, our method regularizes the distribution of words to enable the embedding space to have a clear classification boundary. We evaluate our method using five text classification datasets. The experiment results show that our method significantly outperforms the state-of-the-art methods.

1 Introduction

Learning word representation is a fundamental step in various natural language processing tasks. Tremendous advances have been made by distributed representations (also known as word embeddings) which learn a transformation of each word from raw text data to a dense, lower-dimensional vector space. Most existing methods leverage contextual information from the corpus (Mikolov et al., 2013; Pennington et al., 2014) and other complementary information, such as subword information (Cao and Lu, 2017), implicitly syntactic dependencies (Shen et al., 2018a; Shen et al., 2018b), and semantic relations (Bollegala et al., 2016; Liu et al., 2018).

In traditional evaluations such as word similarity and word analogy, the aforementioned context-aware word embeddings work well since semantic information plays a vital role in these tasks, and this information is naturally addressed by word contexts. However, in real-world applications, such as text classification and information retrieval, word contexts alone are insufficient to achieve success in the absence of task-specific features. Figure 1 illustrates this problem with the classification task as an example. Several sentences from different categories are given at the far left of the figure where the words in bold are salient words for the category distinction. We also illustrated expected word distribution of these salient words in the embedding space. To obtain a good classification performance, the expected word distribution should have a clear classification boundary: words within the same category are close to each other and far away from words in other categories as illustrated in Figure 1. However, the actual distribution obtained from Word2Vec at the far right of Figure 1 is normally not satisfactory because Word2Vec only focuses on context similarity. For example, although *learning* and *educational* are with similar context as recognized by Word2Vec, they are salient words to distinguish categories of *AI* and *Sociology*, so they should be far away from each other. Apparently, using word embedding directly from Word2Vec would not obtain good performance on the text classification task due to the fact that words' functional features in the real tasks are ignored in the training process.

In this paper, we propose a task-oriented word embedding method (denoted as ToWE) to solve the aforementioned problem. It learns the distributed representation of words according to the given specific

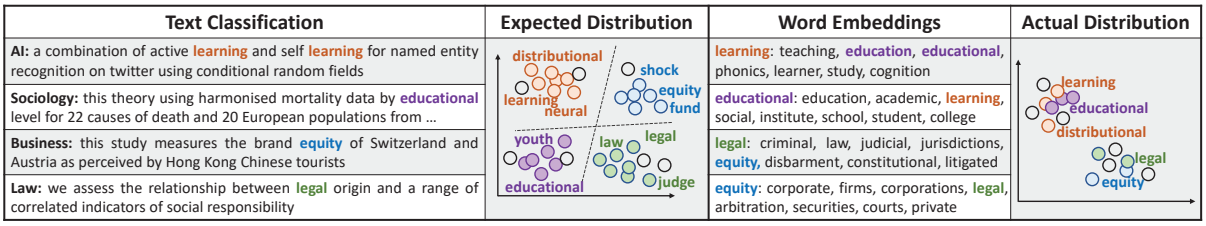

Figure 1: The example sentences from the text classification dataset. Words in bold are salient words to distinguish the sentence category. Their most similar words in the Word2Vec space are shown in the right-hand column. The word color indicates the category, and the words in black are general words for the task.

NLP task. Specifically, we focus on text classification. In our method, the words' contextual information and task information are inherently jointed to construct the word embeddings. In the joint learning framework, the contextual information is captured following the context prediction task introduced by (Mikolov et al., 2013). To model the task information, we regularize the distribution of the salient words to have a clear classification boundary, and then adjust the distribution of the other words in the embedding space correspondingly. To give an intuitive understanding on how our method works from the classification perspective, we design a 5AbstractsGroup dataset (detailed in Section 4.1) and conduct a qualitative analysis. Experiments show qualitative improvements of our method over context-based Skip-gram method on word neighbors for classification. We also perform empirical comparisons on five text classification datasets, which demonstrate the effectiveness of our method over the other state-of-the-art methods.

The contributions of this paper can be summarized as following:

- We propose a task-oriented word embedding method that is specially designed for text classification. It introduces the function-aware component and highlights word's functional attributes in the embedding space by regularizing the distribution of words to have a clear classification boundary.
- We design a 5AbstractsGroup dataset and present a qualitative analysis, giving an intuitive understanding on how our method works from the classification perspective. Experimental results on five text classification datasets also show that the proposed method is more optimal for classification on account of revealing functional attributes of words.

2 Related Work

Word embeddings that provide continuous low-dimensional vector representations of words have been widely studied by NLP communities (Yu et al., 2017; Liu et al., 2017; Li et al., 2017b; Chih et al., 2017). The last few years have seen the development of word embedding methods purely based on the co-occurrence information in a corpus (Bengio et al., 2003; Mnih and Hinton, 2008; Collobert et al., 2011; Mikolov et al., 2013; Mnih and Kavukcuoglu, 2013; Lebret and Collobert, 2014; Pennington et al., 2014; Cao and Lu, 2017; Bollegala et al., 2018). Some studies also pay attention to the semantic knowledge stored in the knowledge bases (Nie et al., 2015). For example, Faruqui et al. (2015) refine word representations using relational information from semantic lexicons, Liu et al. (2015b) represent semantic knowledge as a number of ordinal similarity inequalities of related word pairs to learn semantic word embeddings.

Recent works have thrown light on the problems associated with directly applying word embeddings into real-world applications. Diaz et al. (2016) demonstrated that the globally trained word embedding underperform corpus and query-specific embeddings for retrieval tasks. They proposed locally training word embeddings in a query-specific manner for the query expansion task. Zamani and Croft (2017) indicated that the underlying assumption in typical word embedding methods is not equal to the need of IR tasks, and they proposed relevance-based models to learn word representations based on query-document relevance information, which is the primary objective of most IR task. For the sentiment

analysis task, Yu et al.(2017) refined word embedding to avoid generating similar vector representations for sentimentally opposite words. For the contradiction detection task, Li et al. (2017a) developed contradiction-specific word embedding to recognize contradiction relations between a pair of sentences. These studies show that general trained word embeddings cannot be optimized for a specific task, thus, they are likely to be suboptimal. To meet the needs of real-world applications, rational word embeddings should have the ability to capture both the semantics of words and the task-specific features of words.

In this work, we focus on task-oriented word embedding for the text classification task. Several attempts have shown that revised word embeddings can boost the performance of classification. For example, topical information is shown to be effective in generating high quality word embeddings (Liu et al., 2015c; Liu et al., 2015a), which can enhance the performance of text classification. On the other hand, to enhance the performance of sentiment classification, Chih et al.(2017) proposed a word embedding refinement model to refine existing semantically oriented word vectors using sentiment lexicons in order to distinguish words with similar vector representations but opposite sentiment polarities. Our work departs from previous work in that it directly models task-specific features to construct the embedding space with a clear boundary for classification.

3 Method

Given the unlabeled corpus C and the labeled training set $\mathcal{D} = \{\mathcal{D}_1, \mathcal{D}_2, \cdots, \mathcal{D}_g\}$ with g text categories, our method aims to train the task-oriented d-dimensional word embedding $\mathbf{w_i} \in \mathcal{R}^d$ for the i-th word w_i in vocabulary $\mathcal{V}$. Formally, the document collection belonging to the k-th category is denoted as $\mathcal{D}_k$. Our proposed joint learning framework contains two components, i.e., the context-aware component and function-aware component. The context-aware part models the co-occurrence in corpus C and captures the word semantic features. The function-aware part reveals the word's functional attributes following the task-specific features observed in $\mathcal{D}$. We next describe these two parts respectively.

3.1 Context-aware Component

Our method uses the Word2Vec method to model the context information and uses log-linear models to produce word embeddings. It applies a sliding window moving on the corpus. The word in the center of the window is the target word and the others are context words. Word2Vec has two versions, i.e., CBOW and Skip-gram. The CBOW model uses the average/sum of context words as input to predict the target, and the Skip-gram model uses the target word as input to predict each context word. To simplify, we represent the objective of each prediction as

$$\mathcal{L}_{context} = Pr(w|\mathbf{c}) = \frac{\exp(\mathbf{w} \cdot \mathbf{c})}{\sum_{w' \in \mathcal{V}} \exp(\mathbf{w'} \cdot \mathbf{c})}. \tag{1}$$

In CBOW, w is the target word, and $\mathbf{c}$ is the vector of the context words, and in Skip-gram, w is each word in the context, and $\mathbf{c}$ is the vector of the target word.

3.2 Function-aware Component

In the function-aware component, we define salient words as those words with the ability to distinguish the document category. These salient words are first extracted from the labeled training set $\mathcal{D}$ in an offline process. Then the correlations among these words are used to model the functional features in the embedding space.

Each salient word w of the k-th category is offline extracted according to the following the two principles: (1) The term frequency of the word w in this category (i.e., $\mathcal{D}_k$) is much higher than that in other categories; (2) w is common in other categories, expressed as a small variance of term frequencies in other categories. Formally, we design the following formula to measure the importance of word w to the k-th category as a salient word:

$$Score(w, k) = \frac{t_k - \frac{1}{g}\sum_{1 \le i \le g} t_i}{var(T_{-k}(w))}, \tag{2}$$

where t_i is the term frequency in the i-th category, $T_{-k}(w)$ is the collection of term frequencies except the k-th category (i.e., $T_{-k}(w) = \{t_j | 1 \leq j \leq g, j \neq k\}$), and $var(\cdot)$ is the variance.

According to this importance score, we generate a salience words set by selecting the top N words for each category, denoted as $S_k = \{w_j | 1 \leq j \leq N\}, k \in [1, g]$. Then, for the task, the words in the salient words set $S = \{S_1, S_2, \cdots, S_g\}$ have the ability to distinguish different categories.

The salient words are next utilized to capture the functional relations between words in the embedding space. In the learning framework, if the predicted word w is in S, the function-aware component will be activated. As to modeling the correlations of function-salient words, we expect to constrain w to be close to the words in the same category and far away from the words in different categories. According to this idea, we construct a set $P(w)$ with n word-pairs for each salient word w. Each word-pair contains a positive word u and a negative word v. The positive words are randomly selected from S which belong to the same category with w, and the negative words are randomly sampled from other categories. We maximize a margin-based ranking criterion over the training set S:

$$\mathcal{L}_{function} = argmax \sum_{<u,v> \in P(w)}^{n} [\gamma + s(\mathbf{w}, \mathbf{u}) - s(\mathbf{w}, \mathbf{v})], \tag{3}$$

where γ is a margin hyper parameter, n is the size of sample set $P(w)$, and $s(\cdot, \cdot)$ is similarity measure. Following the recommendations in prior work on word similarity measurement, we apply the cosine similarity of a pair of words by computing $s(\mathbf{a}, \mathbf{b}) = \frac{\mathbf{a} \cdot \mathbf{b}}{|\mathbf{a}| \cdot |\mathbf{b}|}$. The objective function favors higher values of the similarity for positive word-pairs than for negative word-pairs, and is thus a natural implementation of the intended criterion.

3.3 Joint Learning

The context-aware component and the function-aware component are jointly optimized, so we then obtain the following object function:

$$\mathcal{L} = \underset{\Theta}{argmax} \quad \lambda \mathcal{L}_{context} + (1 - \lambda) \mathcal{L}_{function}, \tag{4}$$

where Θ is a set of all parameters in $\mathcal{L}_{context}$ and $\mathcal{L}_{function}$, and λ is the combination parameter which balances the contribution of each component in the training process.

The goal of the training objective is to maximize $\mathcal{L}$ with respect to the model parameters. The optimization process is conducted via Stochastic Gradient Descent (SGD). The optimization of $\mathcal{L}_{context}$ follows the negative sampling introduced in (Mikolov et al., 2013). If the predicted word w is in the salient words set S, the corresponding optimization process for $\mathcal{L}_{function}$ will be activated, and the parameters are updated as $\mathbf{w} \leftarrow \mathbf{w} + \eta \frac{\partial \mathcal{L}}{\partial \mathbf{w}}$, $\mathbf{u} \leftarrow \mathbf{u} + \eta \frac{\partial \mathcal{L}}{\partial \mathbf{u}}$, and $\mathbf{v} \leftarrow \mathbf{v} + \eta \frac{\partial \mathcal{L}}{\partial \mathbf{v}}$, where η is the learning rate, and the gradients are calculated as follows:

$$\begin{aligned}
\frac{\partial \mathcal{L}}{\partial \mathbf{w}} &= \lambda \sum_{<u,v> \in P(w)}^{n} \frac{\partial s(\mathbf{w}, \mathbf{u})}{\partial \mathbf{w}} - \frac{\partial s(\mathbf{w}, \mathbf{v})}{\partial \mathbf{w}}, \\
\frac{\partial \mathcal{L}}{\partial \mathbf{u}} &= \lambda \sum_{<u,v> \in P(w)}^{n} \frac{\partial s(\mathbf{w}, \mathbf{u})}{\partial \mathbf{u}}, \\
\frac{\partial \mathcal{L}}{\partial \mathbf{v}} &= \lambda \sum_{<u,v> \in P(w)}^{n} - \frac{\partial s(\mathbf{w}, \mathbf{v})}{\partial \mathbf{v}},
\end{aligned} \tag{5}$$

where w is the predicted word, u is its positive word and v is its negative word. Since we apply cosine distance to compute the similarity between two words, the optimization can be derived as follows:

$$\frac{\partial s(\mathbf{a}, \mathbf{b})}{\partial \mathbf{a}} = -\frac{S_{a,b} \cdot \mathbf{a}}{|\mathbf{a}|^2} + \frac{\mathbf{b}}{|\mathbf{a}| \cdot |\mathbf{b}|}, \tag{6}$$

Algorithm 1 Task-oriented Word Embedding Method.

Input: Corpus C, the labeled training set $\mathcal{D}$ with g categories, dimensionality d, sampling times n, and word vocabulary $\mathcal{V}$

Output: Embeddings $\mathbf{w} \in \mathcal{R}^d$ of all words in the vocabulary $\mathcal{V}$.

Initialization: randomly set $\mathbf{w} \in \mathcal{R}^d$ for all words in $\mathcal{V}$; generate the salient words set S; constructing T prediction tasks using a sliding window.

      optimize $\mathcal{L}_{function}$ using Eq.(5) to update $\mathbf{w}$, $\mathbf{u}$, $\mathbf{v}$.
    end for
  end if
end for
return $\mathbf{w}$ for all words in $\mathcal{V}$.

where $S_{a,b} = \frac{\mathbf{a}\cdot\mathbf{b}}{|\mathbf{a}|\cdot|\mathbf{b}|}$. The pseudo code for our word embedding method is shown in Algorithm 1, and the source code is available on the Github[1].

4 Experiments

4.1 Datasets

To undertake an extensive evaluation, we investigate the empirical performances of our proposed method on five text classification datasets. The detailed statistics of all the datasets are listed in Table 1. Each dataset is briefly described as follows:

Datasets	Type	Train Size	Test Size	#Classes	Avg.L	Vocab Size	#Tokens
20NewsGroup	Doc.	11,314	7,532	20	315	179,092	6,555,230
5AbstractsGroup	Doc.	2,500	3,756	5	223	38,103	1,203,022
IMDB	Doc.	25,000	25,000	2	126	170,543	6,141,136
MR	Sen.	32,361	32,359	2	21	47,568	974,626
SST	Sen.	5,928	5,927	2	12	19,362	152,474

Table 1: Statistics of the five mainstream datasets for text classification.

(1) The **20NewsGroup**[2] is a popular text classification dataset which contains 18,846 documents from 20 different newsgroups. Each document contains several sentences. The dataset is separated into a training set of 11,314 documents and a test set of 7,532 documents. (2) The **5AbstractsGroup** dataset is academic papers from five different domains collected from the Web of Science namely, business, artificial intelligence, sociology, transport and law. We extracted the abstract and title fields of each paper as a document. The dataset contains 6,256 documents, and we randomly selected 500 papers in each category as the training set, and the others as the test set. The dataset is published on the Github[3]. (3) The **IMDB**[4] contains movie reviews with binary classes (i.e., positive and negative). It consists of 50,000 movie reviews (Maas et al., 2011), and each movie review has several sentences. (4) The **MR**[5] dataset consists of movie reviews from Rotten Tomato website with two classes labeled by (Pang and Lee, 2005). Each review contains only one sentence. (5) The **SST**[6] dataset contains the movie reviews

in the Stanford Sentiment Treebank labeled by (Socher et al., 2013) comprising one sentence for each review. 50% of the MR and SST datasets are partitioned randomly into the training set and 50% into the test set.

4.2 Baseline Methods

To evaluate our method, we consider the following baselines: (1) the **BOW** method is employed as a basic baseline. It represents each document as a bag of words and the weighting scheme is TFIDF. We select the top 2,000 words according to the TFIDF scores as features; (2) the Word2Vec method is a neural network language method which learns word embeddings by maximizing the conditional probability leveraging contextual information. It comprises two models, i.e., **CBOW** which predicts the target word using context information, and the Skip-gram (denoted as **SG**) which predicts each context word using the target word; (3) the **GloVe** (Pennington et al., 2014) method is a state-of-the-art matrix factorization method. It leverages global count information aggregated from the entire corpus as word-word occurrence matrix to learn word embeddings; (4) the Topical Word Embedding method (denoted as **TWE**) (Liu et al., 2015c) learns a topic model from the training set, then generates word embeddings by jointly considering words and topics in a neural network; (5) the **Retrofit** method (Faruqui et al., 2015) is a popular method that refines pre-trained word embeddings using relational information from the knowledge base (e.g., WordNet used in our experiments).

4.3 Experimental Settings

In this paper, we use the text classification task to evaluate the performance of word embeddings. Word embeddings are used to construct the document embeddings $\mathbf{d}$ by simply averaging all word embeddings in the given document, i.e., $\mathbf{d} = \frac{1}{|d|}\sum_{w \in d} \mathbf{w}$, where w is a word in document d. We regard document embedding as a document feature and trained a linear classifier using Liblinear[7] (Fan et al., 2008), since the feature size is large, and Liblinear can quickly train a linear classifier with high dimension features. The classifier is then used to predict the class labels of documents in the test set. The multi-group

Table 2: Performance of our methods on five datasets against the baselines. Bold scores are the best overall.

classification performance was evaluated in terms of four measures: accuracy (Acc.), precision (Prec.), recall (Rec.) and F-measure (F1), and the binary classification performance was evaluated by accuracy (Acc.). All the measures are computed by averaging the metrics of each class and are weighted by the number of true instances for each class.

For each dataset, all documents are joined together as a corpus for embedding training. We tokenized the corpus with the Stanford Tokenizer[8] and converted it to lower case, then removed the stop words. For a fair comparison, all word embeddings adhere to the following settings: the dimensionality of vectors is 300, the size of the context window is 5, the number of negative samples is 25.

In our method, an offline process is used to extract salient word set S from labeled training set $\mathcal{D}$. To obtain an intuitive understanding of these salient words, we list the top ten words for each category in the 5AbstractsGroup dataset. The result is displayed in Table 2. We vary parameter N (detailed in section 3.2) in the range between 30 and 200, and show the performance in Figure 3. Our method achieves the best performance when N is set to 150 for the 5AbstractsGroup dataset. If the value of N is too large, this may hinder the performance because too much noise will be involved. The recommended N is 150 with the constraint that the total size of S is under 1200 based on practical experience.

There are two hyper-parameters in our method, i.e., the combination parameter λ in Eq.(4) and the size n of sample set $P(w)$ in Eq.(3). We carefully tune these parameters by fixing one and varying the other. The parameters corresponding to the best accuracy in 20NewsGroup are used to report the final settings. As shown in Figure 4, the optimal values for λ were tuned from 0 to 1, with a step size of 0.1. The proposed method based on Skip-gram and CBOW reaches optimal performance when $\lambda = 0.4$ and $\lambda = 0.3$, respectively. We tuned the value for n from 50 to 300, and the methods achieve the best performance when $n = 150$. We follow the optimal settings in this work, with recommended settings of $\lambda \in (0.3, 0.4)$ and $n \in (100, 150)$.

4.4 Overall Performance

We compared our proposed method with the baseline methods. Table 2 shows the evaluation results. Based on the experiment results, we make several observations:

(1) Our method performs better than the other methods, and are proved to be highly reliable for the text classification task. In particular, the ToWE-SG method significantly outperforms the other baselines on the 20NewsGroup, 5AbstractsGroup, and MR. This is mainly attributed to the task-specific modeling mechanism, which enables our models to capture functional features among words, therefore, it can more accurately distinguish classes.

(2) The word embedding methods outperform the basic bag-of-words methods in most cases, indicating the superiority of distributed word representation over the one-hot representation. Moreover, the

(a) Business (b) AI (c) Law (d) Sociology (e) Transport

Figure 5: Performance of SG and ToWE-SG methods for each category in the 5AbstractsGroup dataset.

methods which integrate the abundant information discovered from the datasets (i.e., TWE and ToWE) achieve better performance compared to those that only consider contextual information, such as GloVe, CBOW, and SG. This demonstrates the effectiveness of refining context-aware word embeddings with task information.

(3) The Retrofit method is the knowledge-base enhanced word embedding method. Our method achieves better performance over Retrofit method, indicating that the task-specific features could be more effective compared with general semantic relations constructed by humans in the knowledge bases.

(4) In sentence classification, such as the MR and SST datasets, it is obvious that TWE achieves a relatively lower performance. This observation shows that topical information enhanced word embedding does not accurately represent a short text. Our method outperforms the TWE method on both the document-level and sentence-level tasks, which shows the stability and reliability of modeling task-specific features in real-world applications.

4.5 Case Study

A case study was conducted to qualitatively analyze in-depth why task-oriented word embedding methods surpass typical context-aware word embedding methods. We selected several salient words from different categories in the 5AbstractsGroup dataset, and then compared the top ten similar words obtained by ToWE-SG and SG, respectively. The results are displayed in Table 3. We observe that the similar words selected by the ToWE-SG method belong to the same category, while the SG method may select words from different categories. Taking the word *manager* as an example, the most similar words selected by ToWE-SG all belong to the *Business* category, whereas the SG method selects *helps*, *create* which can hardly be regarded as being in the *Business* category. This demonstrates that our method is capable of capturing a clear boundary in the embedding space. For further investigation, we compared the classification performance of these two word embeddings in each category. As shown in Figure 5, ToWE-SG outperforms SG in all these categories. This indicates that by forcing words in the same category to have similar representations, the classifier achieves better performance.

5 Conclusion

In this paper, we proposed a novel approach for learning task-oriented word embedding, especially for the text classification task. Instead of learning embedding vectors merely based on context information, we incorporate task-specific features into the training process in order to reveal the words functional

attributes in the embedding space. The results of the experiments with different datasets show that the proposed method outperforms the existing state-of-the-art word embedding learning methods on text classification tasks. In the future, we will study how to effectively construct the task-oriented word embeddings with the help of transferable task-features across domains.

Abstract

Representation learning is a key issue for most Natural Language Processing (NLP) tasks. Most existing representation models either learn little structure information or just rely on pre-defined structures, leading to degradation of performance and generalization capability. This paper focuses on learning both local semantic and global structure representations for text classification. In detail, we propose a novel Sandwich Neural Network (SNN) to learn semantic and structure representations automatically without relying on parsers. More importantly, semantic and structure information contribute unequally to the text representation at corpus and instance level. To solve the fusion problem, we propose two strategies: Adaptive Learning Sandwich Neural Network (AL-SNN) and Self-Attention Sandwich Neural Network (SA-SNN). The former learns the weights at corpus level, and the latter further combines attention mechanism to assign the weights at instance level. Experimental results demonstrate that our approach achieves competitive performance on several text classification tasks, including sentiment analysis, question type classification and subjectivity classification. Specifically, the accuracies are MR (82.1%), SST-5 (50.4%), TREC (96%) and SUBJ (93.9%).

1 Introduction

Representation learning plays an important role in various NLP tasks, especially in text classification (Bengio et al., 2013; Le and Mikolov, 2014). Existing representation models for text classification can be categorized into four types: *bag-of-words representation models*, *sequence representation models*, *structure representation models* and *attention-based models*. *Bag-of-words representation models* (Salton et al., 1975) are able to represent the sentence accounting for the different words, but fail to encode word order and syntactic structures. *Sequence representation models* (Kim, 2014; Kalchbrenner et al., 2014) consider word order without using structure information. *Structure representation models*, such as Tree-LSTM (Tai et al., 2015) and DSCNN (Zhang et al., 2016), take the structure information into account. *Attention-based models* (Yang et al., 2017; Lin et al., 2017) use attention mechanism to build representations by scoring input words respectively.

However, most structure representation methods either learn little structure information or rely heavily on parsers, leading to relatively low performance or gradient vanishing problem. Moreover, to our best knowledge, no one has considered effective fusion of semantic and structure information. These hinder the performance of sentence representation for text classification.

To address these issues, we propose a novel model named Sandwich Neural Network, which consists of a Convolutional Neural Network (CNN) layer in the middle of two Long Short-Term Memory (LSTM) layers like a sandwich. We define local semantic representation as n-grams feature and global structure representation as the dependency relationship between words or phrases in the sentence. SNN can generate both local semantic representation and global structure representation without relying on parsers. Then two dynamic fusion methods are developed to make full use of these information.

*They contribute equally to this paper.

Proceedings of the 27th International Conference on Computational Linguistics, pages 2033–2043
Santa Fe, New Mexico, USA, August 20-26, 2018.

The contributions of this paper can be summarized into two parts:

1) We propose a novel SNN to extract semantic and structure representations, which enriches information of sentence representation. Thus SNN improves the performance of text classification.

2) In order to make full use of these two representations, we design and implement two fusion methods to learn the weights of semantic and structure representations at corpus and instance level respectively. The former employs adaptive learning strategy to automatically learn a pair of weights for the whole corpus. The latter integrates attention mechanism to adjust the weights subtly for each single instance.

The rest of our paper is organized as follows: Section 2 elaborates the related work about structure representation and attention mechanism. Section 3 details the proposed SNN and two fusion methods. Section 4 conducts experiments on four datasets to verify the effectiveness of our model. Section 5 draws a conclusion and discusses the future work.

2 Related Work

Text classification develops from rule-based method, statistical machine learning method to deep learning method (Aggarwal and Zhai, 2012). Many researches on text classification focus on the sentence representation (Liu et al., 2018). Structure representation and attention mechanism are important for sentence representation.

2.1 Sentence Structure Representation

Current researches about sentence representation pay much attention to structure representation. Structure representation models can be divided into three types: *hierarchical models*, *tree-based models* and *reinforcement learning (RL) models*. *Hierarchical models* combine CNN and RNN to learn structure representation, such as C-LSTM (Zhou et al., 2015) and DSCNN (Zhang et al., 2016). C-LSTM utilizes CNN to extract a sequence of higher-level phrase representations. Then the representations are fed into an LSTM to obtain sentence representation with long dependency structure. DSCNN utilizes CNN to extract features from hidden states of an LSTM layer, which is able to catch long dependency structure at a certain level. *Tree-based models*, such as Tree-LSTM (Tai et al., 2015) and TBCNN (Mou et al., 2015), rely on existing parsers. Tree-LSTM utilizes LSTM along the tree structure and treats root as sentence representation. TBCNN combines CNN with tree structure and uses pooling results as sentence representation. More recently, *RL models* are attempted in structure representation, such as ID-LSTM (Zhang et al., 2018) and HS-LSTM (Zhang et al., 2018), which are integrated seamlessly with a policy network and a classification network. These works contribute significantly to sentence structure representation.

However, *hierarchical models* are not able to learn adequate structure information and lack effective fusion of semantic and structure representations; *tree-based models* are time-consuming and rely on parsers which are unable to guarantee an accurate syntactic structure; *RL models* require much experience to initialize and design reward function, which yields moderate performance.

2.2 Attention Mechanism

Attention mechanism for NLP is first proposed by Bahdanau et al. (2014) to improve machine translation task. The neural machine translation model consists of two RNNs: an encoder and a decoder. When decoding the hidden state s_i, the decoder calculates attention distribution $\boldsymbol{\alpha}$ on the whole source sentence. The attention mechanism is defined as follows:

$$\begin{aligned} \boldsymbol{\alpha}_{ij} &= exp(\boldsymbol{e}_{ij}) / \sum_{k=1}^{T_x} exp(\boldsymbol{e}_{ik}) \\ \boldsymbol{e}_{ij} &= \sigma(\boldsymbol{s}_{i-1}, \boldsymbol{h}_j) \end{aligned} \tag{1}$$

where x is the source sentence, T_x is the length of source sentence, σ is an activation function, $\boldsymbol{s}_{i-1}$ is the hidden state of the decoder RNN at time step $i-1$, $\boldsymbol{h}_j$ is the hidden state of the encoder RNN at time step j.

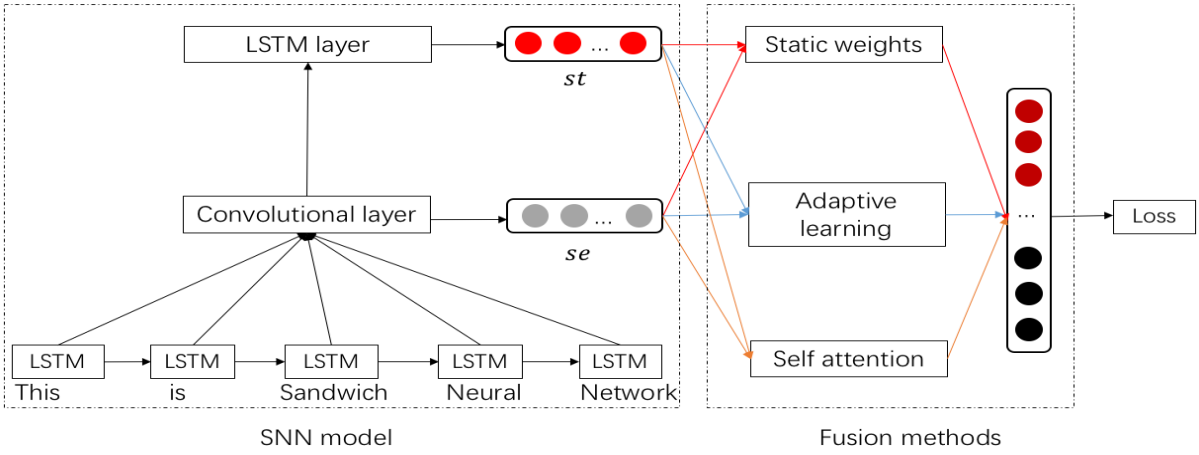

Figure 1: SNN and fusion methods.

Because of its promising performance, attention mechanism attracts lots of attention. For example, Rush et al. (2015) apply it to solve sentence summarization. Xu et al. (2015) utilize it to generate caption of images. Tan et al. (2017) employ it to handle reading comprehension task.

3 Proposed Model

In order to address problems as discussed in Section 2.1, we are inspired by Section 2.2 to propose our novel methods. As shown in Figure 1, there exists three major parts: (1) SNN model: build the semantic and structure representations through SNN; (2) Fusion methods: fuse the semantic and structure representations with different methods; (3) Loss function: train the model with cross-entropy objective function. The core of our methods can be formulated as $\boldsymbol{M} = \phi(\boldsymbol{se}, \boldsymbol{st})$, where ϕ is a fusion function which combines the semantic representation $\boldsymbol{se}$ with the structure representation $\boldsymbol{st}$.

3.1 Obtaining the semantic and structure representations

As shown in Figure 1, SNN consists of three parts: First LSTM layer, CNN layer and Second LSTM layer. The first LSTM layer utilizes the hidden states of LSTM as tuned word representations to take the context into account and the tuned representations are the input of CNN layer. The CNN layer is designed to learn local n-gram high-level semantic representations like standard CNN (Kim, 2014) through convolution and max pooling. The second LSTM layer feeds results from the convolution into LSTM and use the last hidden state of LSTM to obtain global structure representations.

First LSTM layer

Let the input of our model be a sentence of length $s : [w_1, w_2, ..., w_s]$, c be the total number of word embedding versions and $\boldsymbol{x}_i^{(j)}$ is the i^{th} word's embedding of the j^{th} version. The common word embedding versions are Word2vec (Mikolov et al., 2013) and Glove (Pennington et al., 2014).

The first layer of our model consists of LSTM networks processing multiple versions of word embeddings. For each version of word embedding, we construct an LSTM network where the input $\boldsymbol{x}_t \in \mathbb{R}^d$ is the d-dimensional word embedding for w_t. The LSTM layer will produce a hidden state $\boldsymbol{h}_t \in \mathbb{R}^d$ at each time step. We collect hidden states as the output of LSTM layers:

$$\boldsymbol{h}^{(i)} = [\boldsymbol{h}_1^{(i)}, \boldsymbol{h}_2^{(i)}, ..., \boldsymbol{h}_t^{(i)}, ..., \boldsymbol{h}_s^{(i)}] \tag{2}$$

for $i = 1, 2, ..., c$.

Then these hidden states are fed into CNN layer as input.

CNN layer

To utilize multiple kinds of word embeddings, we apply a filter $\boldsymbol{F} \in \mathbb{R}^{c \times d \times l}$, where l is the window size. Hidden state sequence $\boldsymbol{h}^{(i)}$ produced by the i^{th} version of word embedding forms one channel of the feature maps. Then these feature maps are stacked c-channel feature maps $\boldsymbol{X} \in \mathbb{R}^{c \times d \times s}$. Afterwards,

Sentence	Ground truth	Reason
What is the conversion rate between dollars and pounds ?	numeric	key word "rate"
What does target heart rate mean ?	describe	key structure "what does ... mean" and word "rate" is a disturbance

Table 1: Examples of TREC classification

filter F convolves with the window vectors (l-gram) at each position to generate a feature map $\boldsymbol{c} \in \mathbb{R}^{s-l+1}$; c_k is the element of the feature map $\boldsymbol{c}$ for window vector $\boldsymbol{X}_{k:k+l-1}$ at position k and it is produced as follows:

$$c_k = f(\sum_{i,j,r}(\boldsymbol{F} \odot \boldsymbol{X}_{k:k+l-1})_{i,j,r}) \tag{3}$$

where $\odot$ denotes element-wise multiplication.

The n feature maps generated from n filters can be rearranged through column vector concatenation method to form a new representation,

$$\boldsymbol{W} = [\boldsymbol{c}_1; \boldsymbol{c}_2; ...; \boldsymbol{c}_n] \tag{4}$$

Each row $\boldsymbol{W}_j$ of $\boldsymbol{W} \in \mathbb{R}^{(s-l+1)\times n}$ is the feature map generated from n filters for the window vector at position j. The new successive higher-level representations are then fed into the second LSTM layer.

Here, a max-over-time pooling layer is added after the convolution neural network. The pooling result of the feature map $\boldsymbol{c}$ is :

$$p = max(c_1, c_2, ..., c_{s-l+1}) \tag{5}$$

These pooling results are used as our local semantic representation $\boldsymbol{se} \in \mathbb{R}^n$:

$$\boldsymbol{se} = [p_1, p_2, ..., p_n] \tag{6}$$

Second LSTM layer

This layer feeds the high-level phrase representation $\boldsymbol{W}$ generated from CNN into LSTM. We use the same number of filters n to denote the dimension in this LSTM layer for simple and fair fusion and use the last hidden state of LSTM as global structure representation $\boldsymbol{st} \in \mathbb{R}^n$.

Thus, we get the local semantic representation $\boldsymbol{se}$ and the global structure representation $\boldsymbol{st}$. Then we combine $\boldsymbol{se}$ and $\boldsymbol{st}$ to get the concatenated weighted sentence representation.

3.2 Fusion methods

To make better use of semantic and structure representations and address the fusion problems discussed in Section 1, we explore three different fusion ways to learn the weights of semantic and structure representations.

Static weights

Combine semantic and structure representations to get the sentence representation. That is to say, this method gives equal weights to these two kinds of representations.

Adaptive learning at corpus level

Different properties (i.e. semantic and structure property) of a sentence contribute unequally according to the specific corpus. Table 1 shows examples of this phenomenon. To take the above observation into account, we design an adaptive learning method to learn the semantic weight g_{se} and the structure weight g_{st} at corpus level. To reflect the difference of these two properties, we use a simple but elegant and effective method: set g_{se} to be α and g_{st} to be $1 - \alpha$. They are parameters that can be learned automatically during the training process. Each element in the semantic representation $\boldsymbol{se}$ will multiply α to get the weighted semantic representation. It is the same with structure representation $\boldsymbol{st}$ and $1 - \alpha$. Figure 2 shows the adaptive learning method.

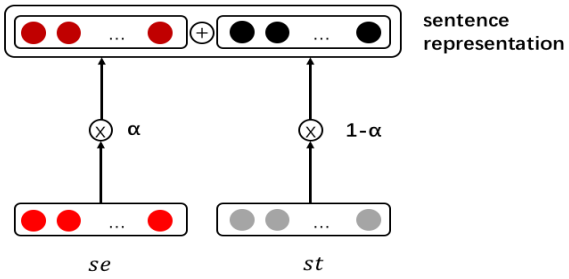

Figure 2: Adaptive learning at corpus level.

Self-attention at instance level

With the adaptive learning strategy, the weights are learned based on the whole corpus. However, the weights of semantic and structure information vary according to the sentence itself. For instance, "*The dog the stick the fire burned beat bit the cat*" is rich in structure information, and we should pay more attention to its structure. Motivated by the attention mechanism, we propose the self-attention strategy to learn weights at instance level. First, we average the word embeddings of the sentence to get a simple but useful sentence representation $\boldsymbol{S}$. Second, linear transformations are used to transform the representations into semantic space representation $\boldsymbol{S}_{se}$ and structure space representation $\boldsymbol{S}_{st}$. The transformed dimension is d. Third, we compute the similarity of representations through inner product. Last, softmax is used to normalize weights. Figure 3 shows the whole process. The computational procedure is as follows:

$$
\begin{aligned}
(att_{se}, att_{st}) &= softmax(p_{se}, p_{st}) \\
p_{se} &= \rho(\boldsymbol{S}_{se}, \boldsymbol{se}) \\
p_{st} &= \rho(\boldsymbol{S}_{st}, \boldsymbol{st}) \\
\boldsymbol{S}_{se} &= \boldsymbol{W}_{se} \times \boldsymbol{S} + \boldsymbol{b}_{se} \\
\boldsymbol{S}_{st} &= \boldsymbol{W}_{st} \times \boldsymbol{S} + \boldsymbol{b}_{st} \\
\boldsymbol{S} &= (\boldsymbol{x}_1 + \boldsymbol{x}_2 + ... + \boldsymbol{x}_s)/s
\end{aligned}
\tag{7}
$$

where $\boldsymbol{x}_i$ is the word embedding, size of d; $\boldsymbol{S}$ is a representation of the sentence, calculated by averaging the word embeddings, size of d; $\boldsymbol{S}_{se}$ and $\boldsymbol{S}_{st}$ are the transformed semantic and structure representations, size of n; $\boldsymbol{W}_{se}$ and $\boldsymbol{W}_{st}$ are the projection matrixes, size of $n \times d$; $\boldsymbol{b}_{se}$ and $\boldsymbol{b}_{st}$ are the projection biases, size of d; ρ is an average inner product operator; att_{se} and att_{st} are the attention weights.

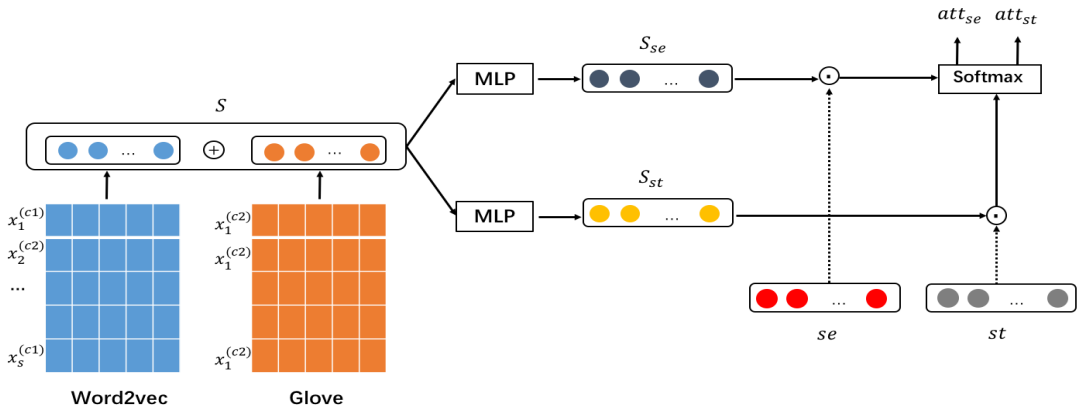

Figure 3: Self-attention at instance level.

In the above fusion methods, the adaptive learning strategy and self-attention strategy can learn weights on the two representations. Then, we concatenate weighted semantic and structure represen-

Data	Class	Len	Max Len	Size	Test
MR	2	20	56	10662	CV
SST-5	5	18	53	11855	2210
TREC	6	10	37	9592	500
SUBJ	2	23	120	10000	CV

Table 2: Statistics for experiment datasets. Class: number of classes. Len: average length of sentence. Max: max length of sentence. Size: Dataset size. Test: test set size (CV means no standard train/test split and thus 10-fold CV is used).

tations to get the final sentence representation.

$$\boldsymbol{M} = \begin{cases} [\boldsymbol{se}; \boldsymbol{st}], \text{for fixed weights} \\ [g_{se} * \boldsymbol{se}; g_{st} * \boldsymbol{st}], \text{for adaptive weights} \\ [att_{se} * \boldsymbol{se}; att_{st} * \boldsymbol{st}], \text{for self-attention} \end{cases} \tag{8}$$

where $\boldsymbol{M}$ is the sentence representation, and operator $[\boldsymbol{v1}; \boldsymbol{v2}]$ denotes concatenation of vector $\boldsymbol{v1}$ and $\boldsymbol{v2}$.

3.3 Training Models

After getting both semantic and structure representations, a fully-connected layer follows. To learn the model parameters, we minimize a cross-entropy objective function as follows:

$$Loss = -\frac{1}{m}\sum_{i=1}^{m} y^i \times log(\hat{y}_i) \tag{9}$$

where y^i is the one-hot vector representation of real label of the i-th sentence, $\hat{y}_i$ is the predicted probability representation in the neural network, and m is the number of samples.

4 Experiments

4.1 Datasets

We test our model on several datasets. The detailed information is listed in Table 2.

• **Movie Review (MR)** proposed by Pang and Lee (2005) is a dataset for sentiment analysis of movie reviews. It contains two classes: positive and negative.

• **Stanford Sentiment Treebank with Five Labels (SST-5)** is another popular sentiment classification dataset proposed by Socher et al. (2013). The sentences are labeled in a fine-grained way: very negative, negative, neutral, positive, very positive.

• **Text REtrieval Conference (TREC)** dataset proposed by Li and Roth (2002) contains sentences that are questions in the following 6 classes: abbreviation, entity, description, location, numeric, human.

• **SUBJectivity (SUBJ)** classification dataset released by Pang and Lee (2004) contains two classes: subjective and objective.

4.2 Experimental Configuration

Literature usually adopts 100-300 as the dimension of word embedding. Here, we use two versions of word embeddings, Word2vec and Glove, with dimension 300. We use 100 convolution filters each for window sizes of 3,4,5. Rectified Linear Units (RELU) is chosen as the nonlinear function in the convolutional layer. For the second LSTM, we set the dimension to be 100. For regularization, both word-embedding and the penultimate layer use dropout (Hinton et al., 2012) with rate 0.5. We don't impose L2 regularization at each layer. We use the gradient-based optimizer Adam (Kingma and Ba, 2014) to minimize the loss between the predicted and true distributions, and the training is early stopped when the accuracy on validation set starts to drop. Additionally, we use the same configuration for all datasets.

Method	MR	SST-5	TREC	SUBJ

Table 3: Experiment results of our methods compared with other models. Performance is measured in accuracy(%). The results with * is from Zhang et al. (2018). Models are categorized into 7 classes. The first block is RNN and its variants. The second is CNN and its variants. The third is tree-based model. The forth is the hierarchical model. The fifth is RL model. The sixth is attention-based model. And the last is our models. **Standard-RNN**: Standard Recursive Neural Network (Socher et al., 2013). **Standard-LSTM**: Standard Long Short-Term Memory Network (Tai et al., 2015). **bi-LSTM**: Bidirectional LSTM (Tai et al., 2015). **CNN**: Convolutional Neural Network (Kim, 2014) . **DCNN**: Dynamic Convolutional Neural Network with k-max pooling (Kalchbrenner et al., 2014). **MVCNN**: Multichannel Variable-Size Convolution Neural Network (Yin and Schütze, 2016). **Tree-LSTM**: Tree-Structured LSTM (Tai et al., 2015). **TBCNN**: Tree-Based Convolutional Neural Network (Mou et al., 2015). **Dep-CNN**: Dependency-based Convolutional Neural Network (Ma et al., 2015). **DSCNN**: Dependency Sensitive Convolutional Neural Network (Zhang et al., 2016). **C-LSTM** :Convolutional LSTM (Zhou et al., 2015). **ID-LSTM**: Information Distilled LSTM (Zhang et al., 2018). **HS-LSTM**: Hierarchical Structured LSTM (Zhang et al., 2018). **Self-Attentive**: Structured Self-Attentive model (Lin et al., 2017).

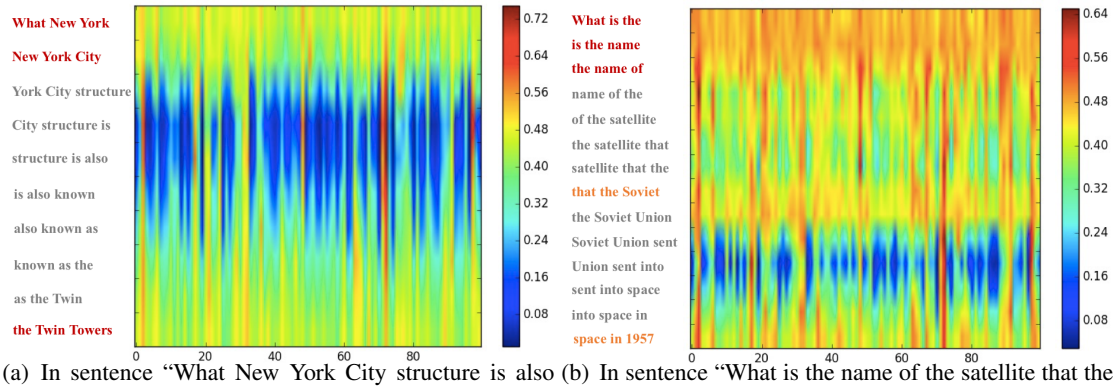
4.3 Results and Discussion

As shown in Table 3, the results demonstrate effectiveness of our model in comparison with other state-of-the-art methods. Among the models without relying on parsers, the other models get the highest accuracy in one certain task (e.g. HS-LSTM in MR and MVCNN in SUBJ), but our models get the highest accuracy on all datasets: MR, SST-5, TREC and SUBJ. It shows strong generalization capability. Additionally, compared with TBCNN, which relies heavily on parsers, our models get the same highest accuracy on TREC and are on a par with TBCNN's performance on SST-5.

The benefit of SNN is attributed to its ability to capture both semantic and structure representations. The benefit of adaptive learning is attributed to its ability to learn the weights of both representations according to the specific corpus. The benefit of self-attention is attributed to its ability to adjust the weights of both representations at instance level. In the following, we first give visualization of our models to show the learned structure. Then, we give some examples to show how our models make progress from SNN, adaptive learning to self-attention. At last, we make quantitative analysis to show the correlation between structure attention value and structure complexity.

4.3.1 Visualization of learned structure

The input gate value of LSTM is able to show how much a word representation contributes to the final sentence representation (Palangi et al., 2016). We draw a heat map of input gates of the second LSTM layer to show the learned structure. Figure 4 gives two examples from TREC. The color represents the values (from 0 to 1) of input gate. The higher means the n-gram part contributes more to the final sentence representation.



(a) In sentence "What New York City structure is also known as the Twin Towers", structure "What New York City" – "the Twin Towers" is learned. It is very related to sentence class "location".

(b) In sentence "What is the name of the satellite that the Soviet Union sent into space in 1957", structure "What is the name of" is important and related to sentence class "entity". More amazing, attributive clause structure "that" is learned. The content before "that" contributes more than the content after "that", which makes the representation focus more on what is related to the classification.

Figure 4: Visualization of learned structure.

Sentence	Dataset	Ground truth	DSCNN	SNN
What does your spleen do ?	TREC	describe	abbreviation	describe
Some actors have so much charisma that you'd be happy to listen to them reading the phone book.	SST-5	positive	negative	positive

Table 4: Examples that SNN makes right while DSCNN fails.

4.3.2 SNN analysis

SNN can learn both semantic and structure representations. As shown in Table 4: in the first sentence, word "spleen" does not appear in the train data, but its topically related words in medical domain like "AIDS", "HIV", "BPH", "SIDS" appear in abbreviation class frequently. Traditional models (e.g. DSCNN) ignore the structure "what does ... do" and misclassifies it into abbreviation class. In contrast, our model captures the structure and correctly classifies it into entity class.

4.3.3 AL-SNN analysis

AL-SNN can learn the weights of semantic and structure representations at corpus level. As shown in Table 5: g_{se} denotes semantic weight and g_{st} denotes structure weight as mentioned in Section 3. In the first sentence, the structure "what is ... the name of" appears with almost the same frequency (67 and 66 times) in human and entity class and appears very little in the other classes. Thus, more weights should be added on semantic representation. Through adaptive learning at corpus level, AL-SNN achieves it.

Sentence	Dataset	Ground truth	SNN	AL-SNN	g_{se}	g_{st}
What was the name of the plane Lindbergh flew solo across the Atlantic?	TREC	entity	human	entity	0.94	0.06
The acting is stiff, the story lacks all trace of wit, the sets look like they were borrowed from gilligan's inland, and – the cgi scooby might well be the worst special-effects creation of the year.	SST-5	very negative	negative	very negative	0.56	0.44

Table 5: Examples that AL-SNN makes right while SNN fails.

Sentence	Dataset	Ground truth	AL-SNN	SA-SNN	g_{st}	att_{st}
What is Hawaii 's state flower ?	TREC	entity	location	entity	0.06	0.33
The director byler may yet have a great movie in him, but charlotte sometimes is only half of one .	SST-5	negative	positive	negative	0.44	0.57

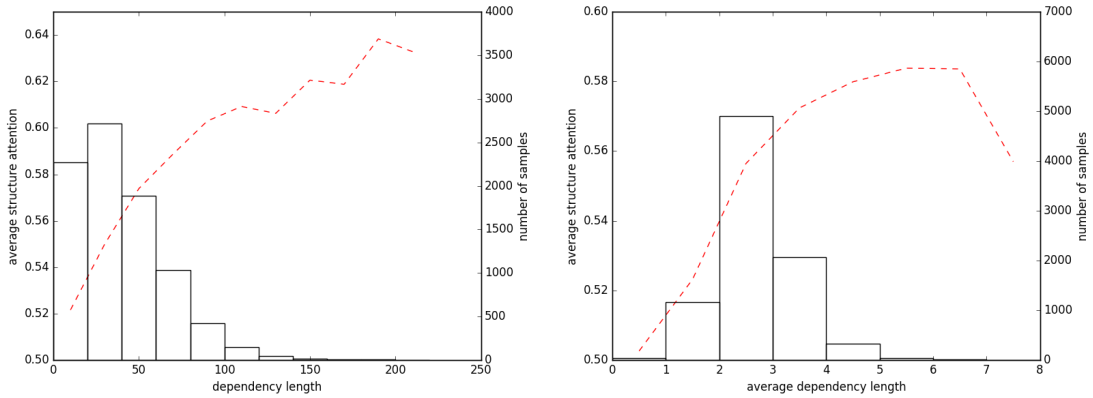
Table 6: Examples that SA-SNN makes right while AL-SNN fails.

4.3.4 SA-SNN analysis

SA-SNN can adjust weights at instance level. As shown in Table 6: g_{st} denotes structure weight and att_{st} denotes structure attention as mentioned in Section 3. In the first sentence, AL-SNN gives more weight to semantic representation at corpus level, focuses on word "Hawaii" and misclassifies the sentence into location class. Through self attention, SA-SNN gives more weight to structure, focuses on structure "what is ... ?" and correctly classifies the sentence into entity class.

4.3.5 Quantitative analysis

It is obvious that more complicated structure means higher structure weight. We use four statistics to represent structure complexity: dependency length (dl), average dependency length (adl), max dependency length (mdl) and sentence length (sl). Among them, average dependency length is dependency length divided by the number of dependency relationships of the sentence. Figure 5 depicts the correlation between the average structure attention (asa) of SA-SNN and the four statistics on SST-5. It shows a strongly positive correlation apart from a few small random variations caused by a limited sample size. Thus, it proves that our attention mechanism is very reasonable.



(a) the correlation between asa and dl

(b) the correlation between asa and adl

(c) the correlation between asa and mdl

(d) the correlation between asa and sl

Figure 5: The correlation between structure attention of SA-SNN and structure complexity on SST-5.

5 Conclusion

In this paper, we propose a novel SNN model and two effective fusion methods, i.e. AL-SNN and SA-SNN. By capturing and fusing both local semantic information and global structure information effectively, our model achieves state-of-the-art in several text classification tasks among the methods without relying on parsers, which verifies its great performance and strong generalization capability. Additionally, we give examples, visualization and quantitative analysis to make explanations in detail. In the future, we will pay more attention to knowledge-embedded methods to speed up training and improve performance.

Abstract

Lyrics contain repeated patterns that are correlated with the repetitions found in the music they accompany. Repetitions in song texts have been shown to enable lyrics segmentation – a fundamental prerequisite of automatically detecting the building blocks (e.g. chorus, verse) of a song text. In this article we improve on the state-of-the-art in lyrics segmentation by applying a convolutional neural network to the task, and experiment with novel features as a step towards deeper macrostructure detection of lyrics.

Title and Abstract in French

Segmenter les paroles de chansons:
détection par réseau de neurones convolutif d'une macrostructure textuelle

Les paroles de chansons contiennent des passages qui se répètent et sont corrélés aux répétitions trouvé dans la musique qui les accompagne. Ces répétitions dans les textes de chansons ont montré leur utilité pour la segmentation des paroles qui est une étape préalable fondamentale dans la détection automatique des blocs de construction d'une chanson (ex. le refrain, les couplets). Dans cet article, nous améliorons l'état de l'art de la segmentation des paroles en concevant un réseau de neurones convolutif pour cette tâche et expérimentons de nouvelles caractéristiques pour aller vers une détection plus profonde de la macrostructure des paroles.

1 Introduction

Among the seas of textual resources available online are the lyrics of songs that are very popular resources for professional, cultural and social applications. To support intelligent interactions with these resources (e.g. browsing, visualizing, synchronizing) one of the first needs is to access the structure of the lyrics (e.g. intro, verse, chorus). However, lyrics are essentially provided as flat text files without structural markup. In this article, we address the problem of textual macrostructure detection in lyrics.

Lyrics encode an important part of the semantics of a song and a motivating scenario for this work is to improve structural clues that can be used by search engines handling large collections of lyrics. Ideally we would like to be able to detect these structures reliably in different music genres to support new search criteria such as "find all the songs where the chorus talks about freedom".

As a first step, structure segmentation could serve as a front end processor for music content analysis, since it enables a local description of each section rather than a coarse, global representation of the whole song (Cheng et al., 2009; Casey et al., 2008). Music structure discovery is a research field in Music Information Retrieval where the goal is to automatically estimate the temporal structure of a music track by analyzing the characteristics of its audio signal over time. However only a few works have addressed such task lyrics-wise (P. G. Mahedero et al., 2005; Watanabe et al., 2016; Baratè et al., 2013). Given that lyrics contain rich information about the semantic structure of a song, relying on textual features could

Proceedings of the 27th International Conference on Computational Linguistics, pages 2044–2054
Santa Fe, New Mexico, USA, August 20-26, 2018.

help in overcoming the existing difficulties associated with large acoustic variation in music. Moreover, a complete music search engine should support search criteria exploiting both the audio and the textual dimensions of a song.

In this direction, this paper focuses on the following research question: *given the text of the lyrics, can we learn to detect the lines delimiting segments in the song?* This question is broken down into two sub questions: *which features are the most relevant to detect that a line delimits a segment?* and *which classification method is the most efficient to detect that a line delimits a segment?*

In order to infer such lyrics structure, we introduce a neural network-based model that *i)* efficiently exploits the Self-Similarity Matrix representations (SSM) used in the state-of-the-art (Watanabe et al., 2016), *ii)* can utilize traditional features alongside the SSMs, and *iii)* jointly infers the structure of the entire text. An evaluation on two standard datasets of English lyrics (Music Lyrics Database V.1.2.7[1], and the WASABI corpus (Meseguer-Brocal et al., 2017)), shows that our proposed method can effectively detect the boundaries of music segments outperforming the state of the art, and is portable across collections of song lyrics of heterogeneous musical genre.

Generally speaking, structure segmentation consists of two stages: a text segmentation stage that divides lyrics into segments, and a semantic labeling stage that labels each segment with a structure type (e.g. intro, verse, chorus). Although a few works have addressed the task of finding chorus or repeated parts in music (P. G. Mahedero et al., 2005; Baratè et al., 2013), full song text segmentation remains challenging unless some complexity reduction strategies are applied (as selecting a subset of songs belonging to musical genres characterized by repeating patterns, e.g. Country or Pop songs). As the accuracy of lyrics segmentation in state of the art is not fully satisfying yet (Watanabe et al., 2016), and given the variability in the set of structure types provided in the literature according to different genres (Tagg, 1982; Brackett, 1995), rare attempts have been made to achieve semantic labeling. Therefore, in our work, we focus on improving the state of the art in lyrics segmentation, leaving the task of semantic labeling for future work.

Earlier in this section, we presented our research questions and motivation. In the remainder of the paper, in Section 2 we define the task of classifying lines as segment borders, and in Section 3 we detail the features used to represent the lines and the classification methods we selected for the task. Section 4 presents the experiment we conducted and compares the results obtained by the different models and configurations to perform the segment border classification. In Section 5 we position our work in the current state of the art, and in Section 6 we conclude with future research directions to provide ever more metadata to music information retrieval systems.

2 Segmentation task definition

Figure 1 shows a song text and its segmentation into the segments A, B, C, D, E, as given by the annotation of the text. As a Pop song, this example lyrics has a fairly common structure which can be described as: *Verse 1-Chorus-Verse 2-Chorus-Outro*. The reasoning behind this structure analysis is that perfectly repeating parts usually correspond to the chorus. Hence, B and D should both be a chorus. A and C are verses, as they lead to the chorus and there is no visible bridge. The last segment, E, repeats the end of the chorus and is very short, so it can be classified as an outro. While the previous analysis appears plausible, it relies on world knowledge, such that the chorus is the most repeated part, a verse usually leads into a chorus (optionally via a bridge), and an outro ends a song text, but is optional.[2]

Labelling the segments of a song text is a non-trivial task that requires diverse knowledge. As explained in the introduction, in this work we focus on the first task of segmenting the text. This first step is fundamental to segment labelling when segment borders are not known. Even when segment borders are "indicated" by line breaks in lyrics available online, those line breaks have usually been annotated by users and neither are they necessarily identical to those intended by the songwriter, nor do users in general agree on where to put them. Thus, a method to automatically segment unsegmented song texts is needed to automate that first step. Many heuristics can be imagined to find the segment borders. For

[1] `http://www.odditysoftware.com/page-datasales1.htm` (retrieved 11/24/17)

[2] For more details on the set of structure types, we refer the reader to (Tagg, 1982; Brackett, 1995).

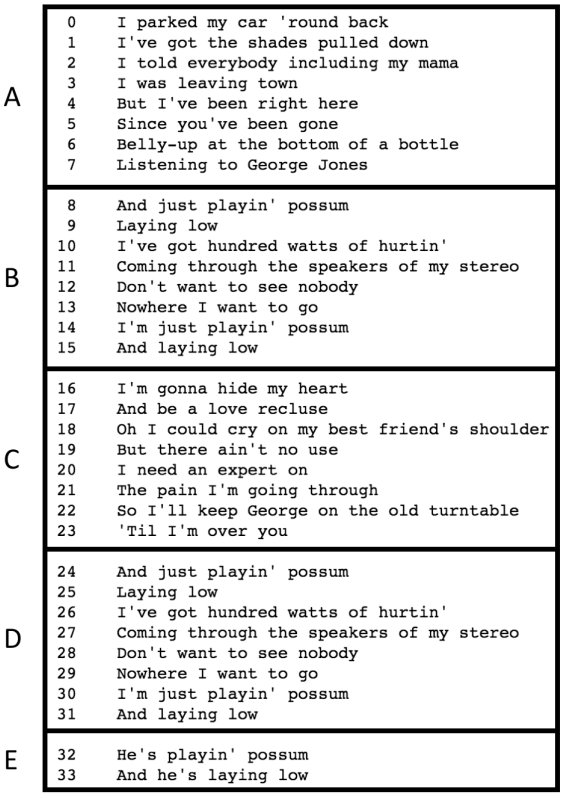

Figure 1: Segment structure of a Pop song ("Don't Rock The Jukebox" by A. Jackson, MLDB-ID: 2954)

example, separating the lines into segments of consistent lengths, which in our example gives 8-8-8-8-2 lines. Another heuristic could be to never start a segment with a conjunction. But as we can see, this rule does not hold for our example, as the chorus starts with the conjunction "And". This is to say that enumerating heuristic rules can be an open-ended task. Among previous works in the literature on lyrics structure analysis, (Watanabe et al., 2016) heavily exploited repeated patterns present in the lyrics to address this task, and it shows that this general class of pattern is very helpful with segment border detection.

For this reason in this paper we follow (Watanabe et al., 2016) by casting the segmentation task as binary classification task. Each line of a song text is defined as either ending a segment or not. Let L_s be the lyrics of a song s composed of n lines of text: $L_s = \{l_1, l_2, ..., l_n\}$. Let $seg \subseteq (L_s, \mathbb{B})$ be a function that returns for each line $l_i \in L_s$ if it is the end of a segment. We define the segmentation task as learning a classifier that approximates seg. At the learning stage, the segment borders are observed from segmented text as double line breaks. At the testing stage the classifier has to predict the now hidden segment borders.

3 Modelling segments in song texts

In order to infer the lyrics structure, we propose a neural network-based model that *i)* efficiently relies on repeated patterns in a song text that are conveyed by the self-similarity matrix representations (SSM) used in the state-of-the-art (Watanabe et al., 2016), *ii)* can utilize traditional features alongside the SSMs (e.g., n-grams and characters count) and *iii)* jointly infers the structure of the entire text.

In the following, Section 3.1 describes the similarity measures that we have tested to produce the SSM representations, and Section 3.2 explains how such SSMs are produced. Section 3.3 lists the set of features used by the neural network-based model, and Sections 3.4 and 3.5 describe the model itself.

3.1 Similarity measures

The choice of the similarity measure is particularly important. Different measures and their combinations have been explored, for example, in musicology (Cohen-Hadria and Peeters, 2017). For our model, we produce SSMs based on three line-based similarity measures:

1. *String similarity* ($\text{sim}_{\text{string}}$): a normalized Levenshtein string edit distance between the characters of two lines (Levenshtein, 1966).

2. *Phonetic similarity* (sim_{phon}): a simplified phonetic representation of the lines computed using the "Double Metaphone Search Algorithm" (Philips, 2000). When applied to "i love you very much" and "i'l off you vary match" it returns the same result: "ALFFRMX". This algorithm was developed to capture the similarity of similar sounding words even with possibly very dissimilar orthography. After translating the words into this "phonetic language", we compute the character-wise edit distance like with string similarity.

3. *Lexico-structural similarity* ($\text{sim}_{\text{lex-struct}}$): this measure, initially proposed in (Fell, 2014), combines lexical with syntactical similarity. $\text{sim}_{\text{lex-struct}}$ captures the similarity between text lines such as "Look into my eyes" and "I look into your eyes": these are partially similar on a lexical level and partially similar on a syntactical level. Given two lines x, y lexico-structural similarity is defined as: $sim_{lex-struct}(x, y) = sim^2_{lex}(x, y) + (1 - sim_{lex}) \cdot sim_{struct}(\hat{x}, \hat{y})$, where sim_{lex} is the overlap of the bigrams of words in x and y, and sim_{struct} is the overlap of the bigrams of pos tags in $\hat{x}, \hat{y}$, the remaining tokens that did not overlap on a word level.

3.2 Self-similarity Matrices

We start by constructing features for each target lyrics. First, the line-based self-similarity matrices are produced to capture repeated patterns in a text. Such representations have been previously used in the literature to estimate the structure of music (Foote, 2000; Cohen-Hadria and Peeters, 2017) and lyrics (Watanabe et al., 2016). Given a text with n lines, a self-similarity matrix $SSM_M \in \mathbb{R}^{n \times n}$ is constructed, where each element is set by computing a similarity measure between the two corresponding lines $(SSM_M)_{ij} = sim_M(l_i, l_j)$, where sim_M is one of the similarity methods we defined. As a result, SSMs highlight distinct blocks of the target text revealing the underlying structure.

Figure 2 shows an example of lyrics consisting of five segments (left) along with its $\text{SSM}_{\text{string}}$ encoding (right). The segment borders are indicated by green lines. The repeated patterns in the song text are revealed by its SSM. This is illustrated as the song text (left) is nicely aligned to the SSM (right).

There are two common patterns that were investigated in the literature: *diagonals* and *rectangles*. Diagonals parallel to the main diagonal indicate text sequences that repeat and are typically found in a chorus. Rectangles, on the other hand, indicate text sequences in which all the lines are highly similar to one another. Both of these patterns were found to be indicators of segment borders.

3.3 Final features

After the SSMs were produced, each possible segment border was represented by the surrounding lines in a context window. Formally, given a fixed window size w_{size}, for each line l_i the submatrix (or patch) of the SSM was selected: $P_i = SSM_M[i - w_{\text{size}} + 1, ..., i + w_{\text{size}}; *] \in \mathbb{R}^{2w_{\text{size}} \times d}$. The resulting submatrices are the SSM features used for classification ($\text{SSM}_{\text{string}}$, SSM_{phon}, and $\text{SSM}_{\text{lex-struct}}$).

In addition to similarity matrices, we extracted the character count from each line, a simple proxy of the orthographic shape of the song text. Intuitively, segments that belong together tend to have similar shapes. Finally, we extracted n-grams (similar to (Watanabe et al., 2016)'s term features) from each line that were most indicative for segment borders, using the tf-idf weighting. We extracted n-grams that are typically found left or right from the border, varied n-gram lengths and also included indicative PoS tag n-grams. This resulted in 240 term features in total. The most indicative words at the start of a segment were: {ok, lately, okay, yo, excuse, dear, well, hey}. As segment-initial phrases we found: {Been a long, I've been, There's a, Won't you, Na na na, Hey, hey}. Typical words ending a segment were: {..., ..,

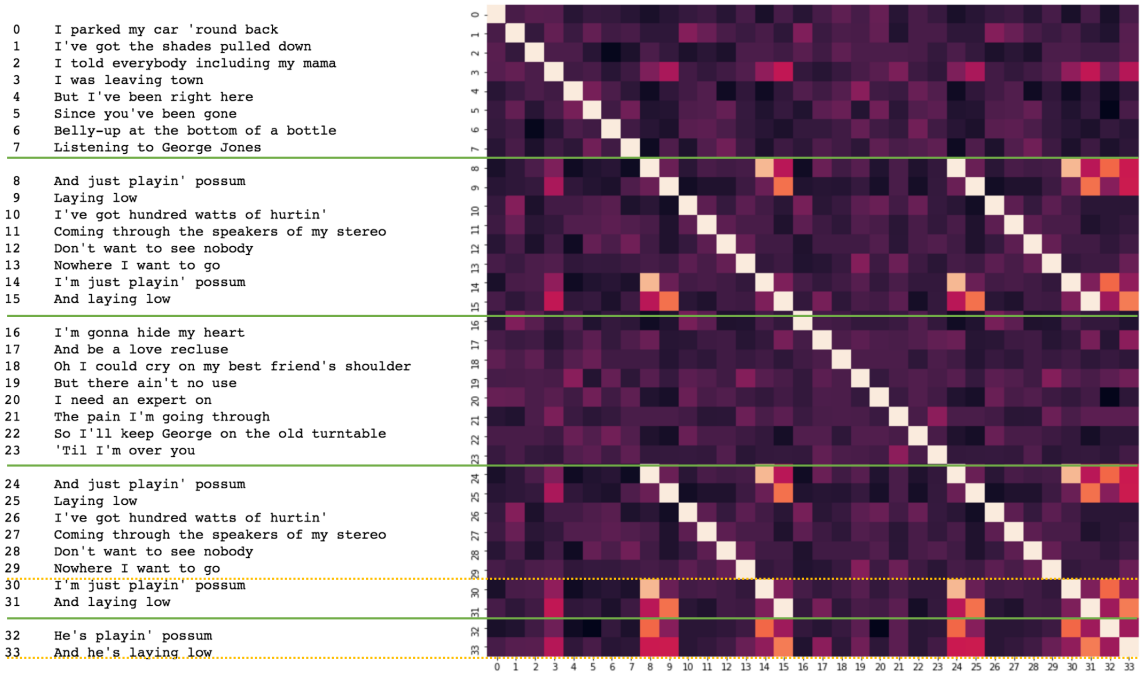

Figure 2: Green lines indicate the true segment borders. Diagonal stripe patterns from (8,24) to (15,31) co-occur well with the borders of the true segment from line 8 to line 15. Note, there is also a large square pattern from (30,30) to (33,33) indicated by the yellow lines - this is a highly repetitive musical state, but not a true segment. This is a typical false positive segment. ("Don't Rock The Jukebox" by Alan Jackson, MLDB-ID: 2954)

!, ., yeah, ohh, woah. c'mon, wonderland}. And as segment-final phrases we found as most indicative: {yeah!, come on!, love you., !!!, to you., with you., check it out, at all., let's go, ...}

3.4 Convolutional Neural Network-based Model

Figure 3 outlines our approach. The goal of the model is to predict if the segment border should be placed after the given line in a text. So, for each line, the model receives patches extracted from the precomputed SSMs: $\text{input}_i = \{P_i^1, P_i^2, ..., P_i^c\} \in \mathbb{R}^{2w_{\text{size}} \times d \times c}$, where c is the number of SSMs or number of channels.

Then, the input goes through a series of convolutions. Convolutional layers (Goodfellow et al., 2016) have been extensively used in image processing to allow the neural network to extract translation, scaling, and rotation invariant features anywhere on the input image. We employ the same motivation here: segment borders manifest themselves in the form of distinct patterns in the SSM. Thus convolutions allow the network to capture those patterns efficiently regardless of their location and relative size.

The first convolution uses a filter of size $(w_{\text{size}}+1) \times (w_{\text{size}}+1)$ so that each feature extracted captures a prospective segment border. The following max pooling layer downsamples the resulting tensor by w_{size} on both dimensions. The second convolution has a filter of size $1 \times w_{\text{size}}$ and the second max pooling layer further downsamples each feature to a scalar. Convolutions employ the ReLU function for activation. After the convolutions, the resulting feature vector is concatenated with the line-based features described above and goes through a series of densely connected layers with $tanh$ as the activation function. Then the $softmax$ is applied to produce probabilities for each class (border/not border). The model is trained using Adam (Kingma and Ba, 2014) with the cross-entropy as an objective function.

Finally, after repeating the procedure for each line in the text and picking the most probable class, we acquire the inferred structure for the entire text. Note that the usage of the self-similarity matrix as input allows us to make predictions based on the entire text: each input patch contains similarity scores between the lines surrounding the provisional segment border and all others. As shown in Section 4, CNN-based models significantly outperform the state-of-the-art.

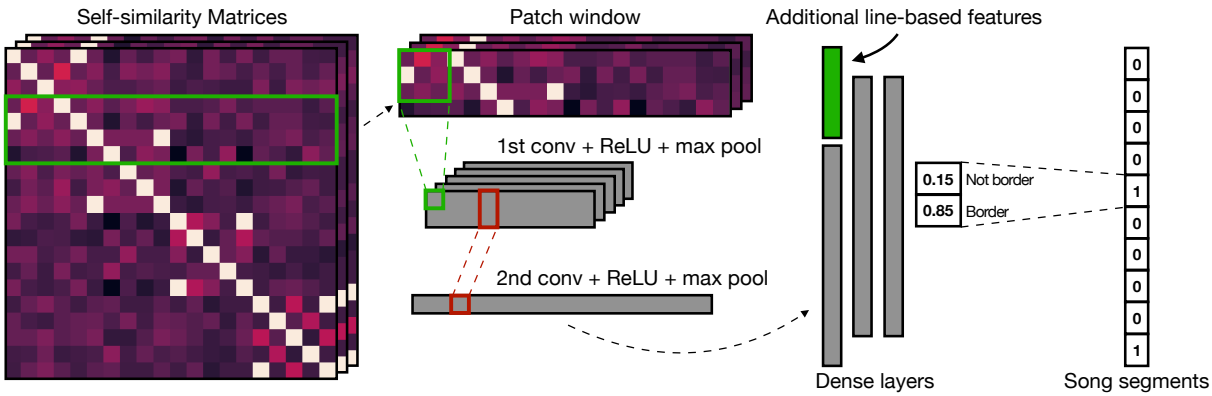

Figure 3: Convolutional Neural Network-based model inferring text structure.

3.5 Joint Predictions via a Recurrent Layer

Following the CNN-based model, we investigate the possibility of making segment border predictions jointly for the entire input text instead of producing labels for a single line at the time. The idea is to refine predictions for the target line using previous predictions. With this in mind, instead of producing the label directly, dense layers are wired through an additional recurrent layer.

Recurrent layers (Goodfellow et al., 2016) consist of cells containing a state that is able to carry information from the previous predictions for the same song and combine it with the current input to produce a refined output. We use LSTM cells and $tanh$ as an activation function. Each line is fed consecutively through the convolutional layers into the RNN cell, which outputs class probabilities.

4 Experimental setting

This section describes the experiments carried out to perform the segment border classification. First, we describe the different models and configurations that we have investigated (Section 4.1), the datasets on which we have run our method evaluation (Section 4.2), and then we discuss the obtained results (Section 4.3).

4.1 Models and configurations

We compare to the state-of-the-art (Watanabe et al., 2016) and successfully reproduce their best features to validate their approach. Two groups of features are used in the replication: repeated pattern features (RPF) extracted from SSMs and n-grams extracted from text lines.

Then, our own models are neural networks (CNNs and RNNs) that use as features SSMs, n-grams (as described in Section 3.3), and character count. We index the SSM features according to the similarity they embed (see Section 3.1): $\text{SSM}_{\text{string}}$ embeds the string similarity, SSM_{phon} the phonetic similarity and $\text{SSM}_{\text{lex-struct}}$ the lexico-structural similarity. The feature set SSM_{all} means that all SSMs are used in parallel. For convolutional layers we empirically set $w_{\text{size}} = 2$ and the amount of features extracted after each convolution to 128. Dense layers have 512 hidden units, the size of the LSTM hidden state is 25. We have also tuned the learning rate (negative degrees of 10), the dropout probability with increments of 0.1. The batch size was selected from the beginning to be 256 to better saturate our GPU. Both the CNN and RNN models were implemented using Tensorflow.

For comparison, we implement two baselines, i.e. the random baseline (as defined in (Watanabe et al., 2016)), and a logistic regression that uses the character count of each line as feature. For the simple character count baseline we used sklearn.LogisticRegression with the option class_weight='balanced' to account for highly imbalanced data.

4.2 Datasets

Song texts are available widely across the Web in the form of user-generated content. Unfortunately for research purposes, there is no comprehensive publicly available online resource that would allow a more standardized evaluation of research results. This is mostly attributable to copyright limitations and has been criticized before in (Mayer and Rauber, 2011). Research therefore is usually undertaken on corpora that were created using standard web-crawling techniques by the respective researchers. Due to the user-generated nature of song texts on the Web, such crawled data is potentially noisy and heterogeneous, e.g. the way in which line repetitions are annotated can range from verbatim duplication to something like *Chorus (4x)* to indicate a triple repetition of a chorus.

To compare our approach with the state of the art, as a first corpus we selected the English part of the Music Lyrics Database V.1.2.7, a proprietary lyrics corpus previously used in (Watanabe et al., 2016). We call this corpus henceforth MLDB. Like (Watanabe et al., 2016) we only consider those song texts that have five or more segments. We use the same training, development and test indices, which is a 60%-20%-20% split. In total we have 102802 song texts with at least 5 segments. 92% of the remaining song texts count between 6 and 12 segments. Evaluation metrics are precision, recall, and f-score.

To test the system portability to bigger and more heterogeneous data sources, we selected the WASABI corpus[3] (Meseguer-Brocal et al., 2017), which is a larger corpus of song texts (henceforth called WASABI). This dataset contains 743939 English song texts with at least 5 segments, and for each song it provides the following information: its lyrics[4], the synchronized lyrics when available[5], DBpedia abstracts and categories the song belongs to, genre, label, writer, release date, awards, producers, artist and/or band members, the stereo audio track from Deezer, when available, the unmixed audio tracks of the song, its ISRC, bpm, and duration. Moreover, we aligned MLDB to WASABI as the latter provides genre information. Song texts that had the exact same title and artist names (ignoring case) in both data sets were aligned. This rather strict filter resulted in an amount of 58567 (57%) song texts with genre information in MLDB. Table 2 shows the distribution of the genres in MLDB song texts. Thanks to the alignment with WASABI, we were able to group MLDB lyrics according to their genre. We then tested our method on each subset separately, to verify our intuition that classification is harder for some genres in which almost no repeated patterns can be detected (as Rap songs). To the best of our knowledge, previous work did not report on genre-specific results.

In this work we did not normalize the lyrics in order to rigorously compare our results to (Watanabe et al., 2016). We estimate the proportion of lyrics containing tags such as *Chorus* to be marginal (0.1-0.5%) in the MLDB corpus. When applying our methods for lyrics segmentation to lyrics found online, an appropriate normalization method should be applied as a pre-processing step. For details on such a normalization procedure we refer the reader to (Fell, 2014), Section 2.1.

4.3 Results and discussion

Table 1 shows the results of our experiments on the MLDB dataset. We start by measuring the performance of our replication of (Watanabe et al., 2016)'s approach. This reimplementation exhibits 56.3% F_1, similar to the results reported in the original paper. The divergence could be attributed to a different choice of hyperparameters and feature extraction code. Much weaker baselines were explored as well. The random baseline resulted in 13.3% F_1, while the usage of simple line-based features, such as character count, improves this to 25.4%.

The best CNN-based model, SSM_{all}+n-grams, outperforms all our baselines reaching 67.4% F_1, 8.2% better than the results reported in (Watanabe et al., 2016). We perform an approximate randomization test of this model against all other models reported below. In every case, the performance difference is statistically significant ($p < .05$). Subsequent feature analysis revealed that the $\text{SSM}_{\text{string}}$ is by far the best individual SSM. The $\text{SSM}_{\text{lex-struct}}$ feature exhibits much lower performance, despite being a

	SSM_{all} + n-grams	71.7	61.8	66.4

Table 1: Performances obtained by the different models and configurations on MLDB test set.

much more complex feature. We believe the lexico-structural similarity is much noisier as it relies on n-grams and PoS tags, and thus propagates error from the tokenizers and PoS taggers. The SSM_{phon} exhibits a small but measurable performance decrease from SSM_{string}, possibly due to phonetic features capturing similar regularities, while also depending on the quality of preprocessing tools and the rule-based phonetic algorithm being relevant for our song-based dataset. However, despite lower individual performance, SSMs are still able to complement each other with the SSM_{all} model yielding the best performance.

In addition, we test the performance of several line-based features on our dataset. Most notably, the n-grams feature provides a significant performance improvement producing the best model. The CC feature shows marginal improvement.

Finally, the best RNN-based model exhibits 66.4% F_1. As mentioned above, the motivation to use this model was to improve predictions on the subsequent lines in the text by leveraging previous predictions. We did not observe an improvement over the CNN-based model most likely due to SSMs already accommodating enough global information so that convolutional layers are able to utilize it for prediction efficiently. As a result, the introduction of an additional recurrent layer increased the complexity of the model without providing much of a benefit. However, we believe that the addition of a more substantial amount of local features could make this additional complexity relevant.

Results differ significantly based on genre. In Table 2 we report the performances of the SSM_{string} on subsets of songs divided by their musical genre. The model is trained on the whole MLDB dataset and separately tested on each subset. Songs belonging to genres such as Country, Rock or Pop, contain recurrent structures with repeating patterns, which are more easily detectable by the CNN-based algorithm. Therefore, they show significantly better performance. On the other hand, the performance on genres such as Hip Hop or Rap, is much worse. An SSM for a Rap song is depicted in Figure 4. As texts in this genre are less repetitive, the SSM-based features are becoming much less reliable to determine a song's structure.

To show the portability of our method to bigger and more heterogeneous datasets, we ran the CNN model on the WASABI dataset, obtaining the following results (very close to the ones obtained on MLDB dataset): precision: 67.4%, recall: 67.3%, f-score: 67.4% using the SSM_{string} features.

5 Related Work

Besides the work of (Watanabe et al., 2016) that we have discussed in detail in Section 3, only a few papers in the literature have focused on the automated detection of the structure of lyrics. (Mahedero et al., 2005) report experiments on the use of standard NLP tools for the analysis of music lyrics. Among the tasks they address, for structure extraction they focus on lyrics having a clearly recognizable structure (which is not always the case) divided into segments. Such segments are weighted following the results given by descriptors used (as full length text, relative position of a segment in the song, segment simi-

Table 2: SSM_{string} model performances across musical genres in the MLDB dataset. Underlined are the performances on genres with less repetitive text. Genres with highly repetitive structure are in bold.

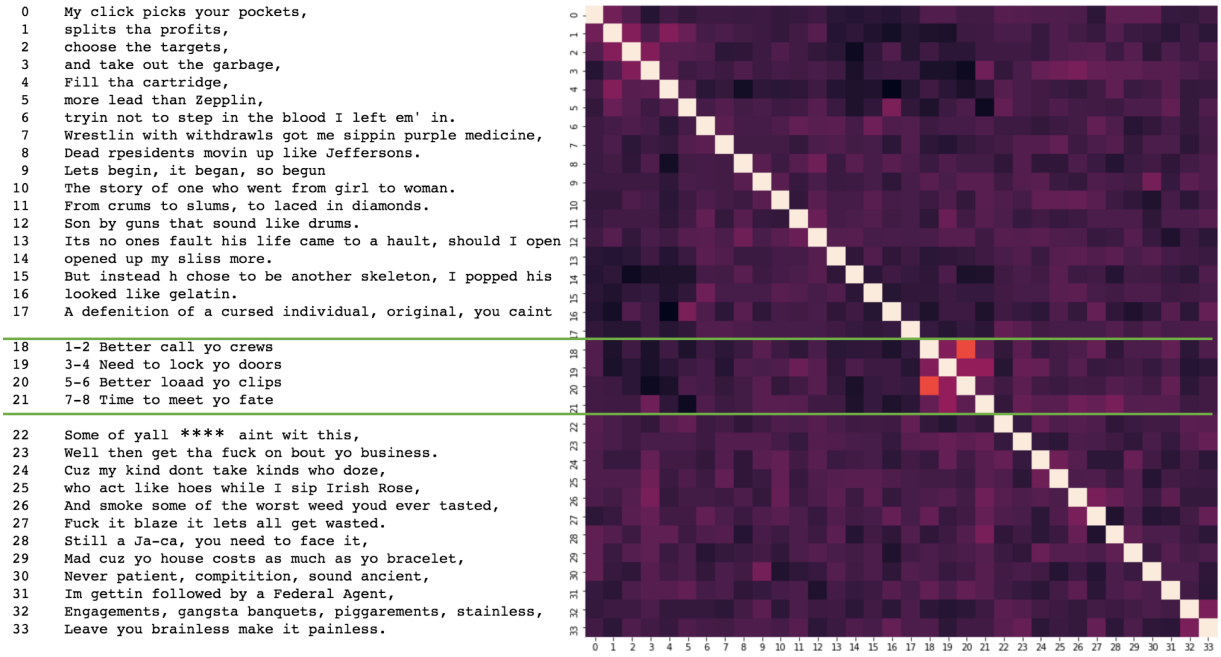

Figure 4: As common for Rap song texts, this example does not have a chorus (diagonal stripes). However, there is a highly repetitive musical state from line 18 to 21 which can be recognized by inspecting the SSM the from line 1 to line 4 is indicated by the corresponding rectangle in the SSM spanning from (18,18) to (21,21). ("Meet Your Fate" by Southpark Mexican, MLDB-ID: 125521)

larity), and then tagged with a label describing them (e.g. chorus, verses). They test the segmentation algorithm on a small dataset of 30 lyrics, 6 for each language (English, French, German, Spanish and Italian), which had previously been manually segmented.

More recently, (Baratè et al., 2013) describe a semantics-driven approach to the automatic segmentation of song lyrics, and mainly focus on pop/rock music. Their goal is not to label a set of lines in a given way (e.g. verse, chorus), but rather identifying recurrent as well as non-recurrent groups of lines. They propose a rule-based method to estimate such structure labels of segmented lyrics, while in our approach we apply ML methods to unsegmented lyrics.

To enhance the accuracy of audio segmentation, (Cheng et al., 2009) propose a new framework utiliz-

ing both audio and lyrics information for structure segmentation. For audio segmentation, the proposed constrained clustering algorithm improves the accuracy of boundary detection by introducing constraints on neighboring and global information. For semantic labeling, they derive the semantic structure of songs by lyrics processing to improve structure labeling.

With the goal of identifying repeated musical parts in music audio signals to estimate music structure boundaries (lyrics are not considered), (Cohen-Hadria and Peeters, 2017) propose to feed Convolutional Neural Network with the square-sub-matrices centered on the main diagonals of several self-similarity-matrices (SSM), each one representing a different audio descriptors, building their work on (Foote, 2000).

Lastly, the discourse segmentation literature heavily relies on segments to reflect topics and on segment borders to indicate topic changes. However, the segments in lyrics tend to be short and lyrics tend not to change topic a lot compared to longer prose texts. We experimented with word embeddings to measure topical similarity, but did not find it useful in our experiments. Still, integrating a domain-independent segmentation algorithm into our approach - such as the divisive clustering found in (Choi, 2000) - might be beneficial.

6 Conclusion and Future Work

Lyrics encode an important part of the semantics of a song and relying on their textual features could help us in overcoming the difficulties in audio processing for music management systems. Moreover the support for search criteria exploiting both the audio and the textual dimensions of a song would improve the usefulness of music search engine and retrieval systems by providing more and combinable selection and filtering dimensions.

In this paper, we focused on improving the state of the art in lyrics segmentation which is a prerequisite before considering the semantic labeling of these segments. We defined the task of classifying lyrics lines as segment borders or not, and we detailed the features we considered to feed to the classification methods. Having identified several feature configurations and state of the art classification methods we conducted an experiment and compared performance on the task of segment border classification. The best result (67.4 % f-score) was obtained using the Convolutional Neural Network with a self-similarity-matrix with layers combining all the similarity metrics and, in addition, the n-gram features. Moreover, at this stage, the CNN models outperformed the state of the art models using hand-crafted features[6].

For future work, we plan to complement this analysis with acoustic and cultural metadata (coupling our work for instance with (Cohen-Hadria and Peeters, 2017)), in the direction of developing a comprehensive music information retrieval systems over a real-world song collection.

Abstract

Neural network based multi-task learning has achieved great success on many NLP problems, which focuses on sharing knowledge among tasks by linking some layers to enhance the performance. However, most existing approaches suffer from the interference between tasks because they lack of selection mechanism for feature sharing. In this way, the feature spaces of tasks may be easily contaminated by useless features borrowed from others, which will confuse the models for making correct prediction. In this paper, we propose a multi-task convolutional neural network with the Leaky Unit, which has memory and forgetting mechanism to filter the feature flows between tasks. Experiments on five different datasets for text classification validate the benefits of our approach.

1 Introduction

Convolutional neural network (CNN) models have achieved impressive results on many natural language processing (NLP) tasks, which use convolving filters to extract local features and have been successfully applied in computer vision field. In recent years, increasing works transfer CNNs to natural language processing tasks, such as representation learning (Liu et al., 2015), information retrieval (Shen et al., 2014), text classification (Kalchbrenner et al., 2014), etc. In particular, feed-forward CNNs with word embedding have been proven to be a relatively simple yet powerful kind of models for text classification (Kim, 2014).

However, the reliance on large-scale corpus has been a formidable constraint for deep neural networks (DNNs) based methods due to their numerous parameters. It costs a lot for a large-scale dataset to train the huge volume of parameters, because constructing a large-scale labeled dataset is extremely labor-intensive. To solve this problem, these models usually employ a pre-trained phase to map words into vectors with semantic implication (Collobert et al., 2011), which just introduces extra knowledge and does not directly optimize the target task. The problem of insufficiency for annotated resources is not intrinsically solved either.

Multi-task learning (MTL) can implicitly increase the corpus size and create a synergy effect among datasets (Caruana, 1997). By learning related tasks in parallel, MTL has the ability to exploit the relations between similar tasks to benefit each other, and eventually improves the performance for classification. In addition, models handling multiple tasks also benefit from a regularization effect to decrease the overfitting. It can help the models to learn a more universal representation for text sequences.

Inspired by this, more DNN-based models (Collobert and Weston, 2008; Liu et al., 2015; Liu et al., 2016) utilize multi-task learning to improve their performance. Traditionally, multi-task learning only shares a few shallow layers among tasks, so only low-level knowledge is exchanged to benefit each other (Collobert and Weston, 2008). But recently more works prefer to share deeper layers to share more high-level knowledge, which has been proven effective to enhance the performance (Liu et al., 2015; Liu et al., 2016).

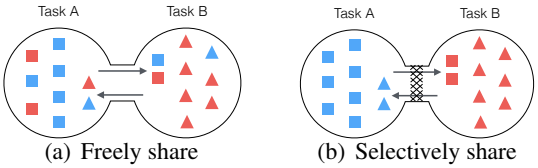
Santa Fe, New Mexico, USA, August 20-26, 2018.



(a) Freely share (b) Selectively share

Figure 1: Two schemes for sharing knowledge among tasks. Boxes and triangles denote the features for Task A and B respectively. The red boxes and blue triangles represent the features can be shared to benefit the other task.

The scheme for information sharing is the linchpin for designing a practical multi-task network. Most existing work attempts to find an appropriate proportion to sharing the layers between tasks, despite they entirely reuse some layers among tasks (Liu et al., 2015; Caruana, 1997) or add the tasks' layers up at a proportion (Fang et al., 2017). And recently, the latter architecture shows its advantages for controlling the relation intensity among tasks and becomes prevailing. More models adopt this thought to enhance the performance (Liu et al., 2015; Liu et al., 2016).

However, under the scheme of proportional addition (Ruder et al., 2017; Misra et al., 2016), all the features, between every pair of tasks, are shared in the same weight without selection. Helpless or harmful features if freely transported between tasks with the same importance as helpful ones, namely, the interference is generated just like Figure 1(a) shows. This would burden the network for distinguishing the helpful features and even mislead the predictions.

To resolve above problems, we propose a new CNN-based model *LK-MTL* for multi-task learning, which shares the features with a selective mechanism (Figure.1(b)). Our model employs a "split structure" that every task owns a private subnet and shares their features through a well-designed module—*Leaky Unit*, which has memory and forgetting mechanisms to control the feature flows, deciding what features should be shared or discarded. By that the feature flows are purified and the interference would be restrained.

We conduct extensive experiments on five benchmark datasets for text classification. And the result shows that our multi-task model gains great improvement over the single-task CNNs and other multi-task competitors.

The contributions of this paper can be briefly summarized as follows:

- Proposed Leaky Unit has the ability to remember and forget, which is effective for filtering the feature flows and can help multi-task learning dispel the interference among tasks.
- The architecture of our multi-task model combines the advantages of GRU and CNN. The performance is enhanced by both memory mechanism from gated recurrent unit (GRU) and the feature extraction ability from convolutional neural network.
- Our model achieves strong results on several benchmark classification datasets and outperforms the state-of-the-art baselines on four datasets.

2 CNN Models for Text Classification

The main capability of DNNs for text classification is to represent word sequences into fix-length vectors. There are many frameworks can be used for sentence modeling, involving Neural Bag-of-Words (NBOW) model, recursive neural network (RecNN) (Socher et al., 2012; Socher et al., 2013), recurrent neural network (RNN) (Chung et al., 2014) and convolutional neural network (CNN) (Collobert et al., 2011).

In recent years, CNN has shown its advantages in the NLP field. CNN models can not only handle input sentences of varying length but also capture short and long range relations through the feature graph over the sentence (Kalchbrenner et al., 2014). Most of the CNN models for text sequences are

constructed by alternating the convolution layers and pooling layers. In this paper, this kind of CNN architectures is defined as the subnet in our multi-task network, which can be detailed as follows.

2.1 CNN for Text Representation

Given a text sequence $x_{1:l} = x_1 x_2 \cdots x_l$, we first use a lookup table to get the embedding results (word vector) $\mathbf{x}_i$ for each word x_i. Then the input matrix can be represented as $\mathbf{x} = \mathbf{x}_1 \oplus \mathbf{x}_2 \oplus \cdots \oplus \mathbf{x}_l$ by concatenating each word vector, where $\oplus$ denotes the operation of concatenation. CNNs produce the representation of the input sequence through stacking the layer of convolution, pooling in order, which can be briefly formalized as:

$$\boldsymbol{F} = \mathbf{H} * \mathbf{x} \tag{1}$$

$$\hat{\boldsymbol{F}} = pooling(\boldsymbol{F}) \tag{2}$$

$$\mathbf{y} = \boldsymbol{w}\hat{\boldsymbol{F}} + \boldsymbol{b}, \tag{3}$$

where $\boldsymbol{H}$ is the filter for convolutional operation $*$; $pooling$ denotes the pooling operation; $\boldsymbol{F}$ and $\hat{\boldsymbol{F}}$ represent the feature maps; $\boldsymbol{w}$ and $\boldsymbol{b}$ denote the weight and bias respectively in fully connected layer. Usually, drop out mechanism is used as a kind of regularization for output layer and the Eq.3 can be rewrote as

$$\mathbf{y} = \boldsymbol{w}\hat{\boldsymbol{F}} \circ \boldsymbol{r} + \boldsymbol{b}. \tag{4}$$

Here $\circ$ refers to the element-wise multiplication operator, and $\mathbf{r} \in \mathbb{R}^d$ is a "masking" vector comprising Bernoulli random variables with probability p to be 1.

2.2 Output Layer for Text Classification

Following the pooling layer, a fully connected layer with dropout and the softmax layer was used, which transforms the vector representation into the probability distribution over classes.

During backpropagation, the parameters in the network are updated by gradient of the loss between the predicted and true distributions. Such as cross-entropy function

$$L(\hat{\mathbf{y}}, \mathbf{y}) = -\sum_{i=1}^{N}\sum_{j=1}^{C} \mathbf{y}_i^j log(\hat{\mathbf{y}}_i^j), \tag{5}$$

where $\hat{\mathbf{y}}$ is the predicted probability distribution; $\mathbf{y}$ is the ground-truth label; N and C are the batch size and the number of classes respectively.

3 Multi-Task CNN for Text Classification

The goal of multi-task learning is to utilize the connection among these related tasks to improve classification when learning tasks in parallel. Recently, "split architecture" that provides each task a private subnet is widely accepted by researchers, since it has ability to make a balance between task specific features and shared features. Hence, the key factor of multi-task learning is the fusion mechanism for the information flow between tasks. In CNN models, the information lies in the feature maps. Therefore, the biggest difference of the multi-task architecture is the method for fusing the feature maps. Here we introduce a typical architecture for CNN based multi-task models: PA-MTL.

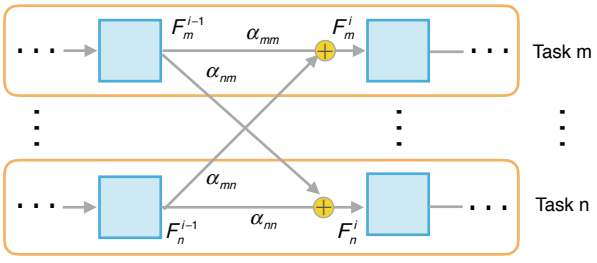


Figure 2: Illustration of proportional addition model.

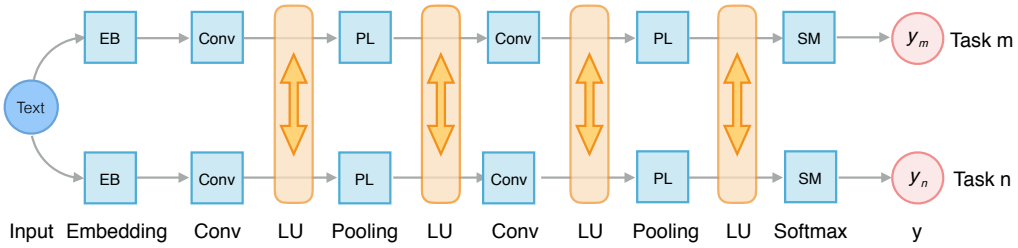

Figure 3: Illustration of the architecture of Leaky Multi-Task Network. LU denotes the Leaky Unit.

Proportional Addition Model (PA-MTL) Generally, most existing multi-task CNN models share the information between tasks by proportional addition (Misra et al., 2016; Fang et al., 2017). As Figure 2 shows, they share the information by adding the feature maps between tasks m, n with scalar weights α^{i-1}. α^{i-1} is updated by back-propagation, which reflects the strength of association between tasks but has no selection for the features. Between the $i-1$-th and i-th layers, the whole process for fusing the feature maps F^{i-1} from M tasks can be formulated as:

$$\begin{bmatrix} \mathbf{F}_1^i \\ \vdots \\ \mathbf{F}_M^i \end{bmatrix} = \begin{bmatrix} \alpha_{11} & \cdots & \alpha_{1M} \\ \vdots & \ddots & \vdots \\ \alpha_{M1} & \cdots & \alpha_{MM} \end{bmatrix} \begin{bmatrix} \mathbf{F}_1^{i-1} \\ \vdots \\ \mathbf{F}_M^{i-1} \end{bmatrix}, \tag{6}$$

4 Leaky Multi-Task CNN

The key factor for multi-task learning is the scheme for sharing the features. So an elaborate architecture that can well control the feature sharing among tasks is very crucial for multi-task learning. A good architecture is supposed to not only fully exchange the features to help extend tasks' feature space, but also select the helpful features to avoid the contamination. So, in this section, we propose a selective architecture to optimize the sharing scheme.

4.1 Model Architecture Choice

Multi-task model with deeper layers shared can fuse high-level knowledge and greatly increase the feature space. But undesirable interference is inevitable and simultaneously comes with the benefits, especially between the less-related tasks. This would burden the models with the overhead on distinguishing helpful features. To overcome above problem, we explore another structure— *Leaky Multi-Task CNN (LK-MTL)*, in which the tasks have ability to selectively borrow helpful knowledge from others.

As shown in Figure 3, in order to reduce the interference, we assign each task a private subnet, under which circumstance the information is shared indirectly and easy to control. These relatively separated tasks can only borrow information from others through the bridge: *Leaky Unit*. Memory mechanism is employed in this unit to control the feature sharing. The parameters are updated through backpropagation to optimize the selection without needing for extra supervision. This is an end-to-end and easy-training method and its thought is easy to be employed by other works. The convolutional neural network can be easily replaced by multi-layer perceptrons or recurrent neural networks for other applications.

4.2 Leaky Unit

In this separate architecture, we design a module named *Leaky Unit* to selectively share the information between tasks, which is inspirited by the hidden unit of Gated Recurrent Unit (GRU) (Cho et al., 2014), a variant of Leaky Integration Unit proposed by (Bengio et al., 2013). The hidden state of GRU fuses the cell and hidden state of standard LSTM to make the structure easier to compute and implement, which has a sophisticated mechanism for remembering and forgetting features. Thus we make some revision and use it as a tool to filter the feature flows between tasks. Leaky Unit addresses two problems in the process of sharing: what features could be helpfully borrowed from other tasks and How many features should be preserved for current task?

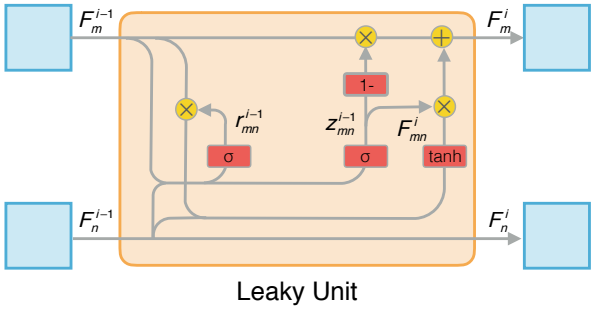

Figure 4: Illustration of the details for Leaky Unit

As shown in Figure 4, a *Leaky Gate* r_{mn} is first generated from the feature maps in $(i-1)$-th layers

$$\mathbf{r}_{mn}^{i-1} = \sigma(\mathbf{W}_r^{i-1} \cdot [\mathbf{F}_m^{i-1}, \mathbf{F}_n^{i-1}]), \tag{7}$$

where mn means the direction of feature flow is from task n to task m; σ denotes the logistic sigmoid function, which limits the values into $[0, 1]$; $\mathbf{F}_m^{i-1}$, $\mathbf{F}_n^{i-1}$ is the feature maps from task m, n respectively. Leaky gate decides what features will be leaked in from other tasks. Hence, a new feature map is calculated by

$$\tilde{\mathbf{F}}_{mn}^i = tanh(\mathbf{U}^{i-1} \cdot \mathbf{F}_m^{i-1} + \mathbf{W}^{i-1} \cdot (\mathbf{r}_{mn}^{i-1} \odot \mathbf{F}_n^{i-1})). \tag{8}$$

When the j-th element in vector $\mathbf{r}_{mn}^{i-1}$ is close to 0, the corresponding feature $[\mathbf{F}_n^{i-1}]_j$ in task n will be discarded. On the contrary, feature $[\mathbf{F}_n^{i-1}]_j$ will be kept and passed to task m.

In addition, we employ another *Update Gate* z_{mn}^{i-1} to determine how much information should be maintained from current task m into the next layer, which is emitted by

$$\mathbf{z}_{mn}^{i-1} = \sigma(\mathbf{W}_z^{i-1} \cdot [\mathbf{F}_m^{i-1}, \mathbf{F}_n^{i-1}]). \tag{9}$$

And final output for current task m is calculated by

$$\mathbf{F}_m^i = \mathbf{z}_{mn}^{i-1} \cdot \mathbf{F}_m^{i-1} + (1 - \mathbf{z}_{mn}^{i-1}) \cdot \tilde{\mathbf{F}}_{mn}^i. \tag{10}$$

If we consider all the directions of information flows and extend above formulations into all M tasks, the output of Leaky Unit is the sum of each row in

$$\begin{bmatrix} \sum_{k=1}^M \mathbf{z}_{1k}^{i-1} & (1-\mathbf{z}_{12}^{i-1}) & \cdots & (1-\mathbf{z}_{1M}^{i-1}) \\ (1-\mathbf{z}_{21}^{i-1}) & \sum_{k=1}^M \mathbf{z}_{2k}^{i-1} & \cdot & 1-\mathbf{z}_{2M}^{i-1}) \\ \vdots & \vdots & \ddots & \vdots \\ (1-\mathbf{z}_{M1}^{i-1}) & (1-\mathbf{z}_{M2}^{i-1}) & \cdots & \sum_{k=1}^M \mathbf{z}_{Mk}^{i-1} \end{bmatrix} \cdot \begin{bmatrix} \mathbf{F}_1^{i-1} & \mathbf{F}_{12}^{i-1} & \cdots & \mathbf{F}_{1M}^{i-1} \\ \tilde{\mathbf{F}}_{21}^i & \mathbf{F}_2^{i-1} & \cdots & \tilde{\mathbf{F}}_{2M}^i \\ \vdots & \vdots & \ddots & \vdots \\ \tilde{\mathbf{F}}_{M1}^i & \tilde{\mathbf{F}}_{M2}^i & \cdots & \tilde{\mathbf{F}}_M^i \end{bmatrix} /M. \tag{11}$$

Leaky units adjust the states of two gates according to the helpfulness of other tasks' features. The units tend to borrow more features from other tasks will more frequently activate the leaky gate. On the contrary, the update gate will be more active to preserve more information in current task.

4.3 Training

In the last layer of model, the vector representations $\hat{\mathbf{F}}_m$ of input sequences are fed into different output layers to fit the number of class, which emits the prediction of probability distribution for task m

$$\hat{y}_m = softmax(\mathbf{W}_m \hat{\mathbf{F}}_m + b_m), \tag{12}$$

where $\hat{y}_m$ is predictive result, $\mathbf{W}_m$ is the weight of the full-connected layer, and $\mathbf{b}_m$ is the bias term.

Given the prediction of all tasks, a global loss function forces models to take every task into account.

$$\Phi = \sum_{m=1}^{M} \lambda_m L(\hat{y}_m, y_m), \tag{13}$$

Dataset	Target	Type	Train Size	Dev. Size	Test Size	Class	Avg. Length
SST-1	Sentiment	Sentence	8544	1101	2210	5	19
SST-2		Sentence	6920	872	1821	2	19
IMDB		Document	25000	-	25000	2	279
SUBJ	Subjectivity	Sentence	9000	-	1000	2	21
QC	Question Types	Sentence	5153	-	489	6	10

Table 1: Statistics of the five text classification datasets. Dev. and Avg. are the abbreviations of development and average respectively.

where λ_m is the weight for the task m. In this paper, we simply set λ_m to $1/M$ for all M tasks to make a balance.

In order to train the parameters with different datasets, following (Collobert and Weston, 2008), each task is trained by turn in a stochastic manner. The steps can be described as follows:

1. Pick up a task m randomly;
2. Select an arbitrary sample s from the task m;
3. Feed the sample s into the model and update the parameters;
4. Go back to 1.

Following the training phase, we employ fine tuning strategy (Liu et al., 2016) to further optimize the parameters for each task alone.

5 Experiments

In this section, we investigate the empirical performances of our models on five related benchmark tasks for text classification. And the results are compared with the state-of-the-art models. Furthermore, we also intuitively show the operation mechanism of leaky unit via visualization.

5.1 Datasets

As Table 1 shows, we collect five benchmark datasets for text classification that are related to each other to different degree. These datasets contain sentiment, subjectiveness and question type classification, which belong to different class of target and can be briefly introduced as follows:

- **SST-1** Stanford Sentiment Treebank[1] (Socher et al., 2013), a movie review dataset with five classes of labels (very positive, positive, neutral, negative, very negative), and split into train/dev/test three parts.

- **SST-2** Also from the Stanford Sentiment Treebank, but with neutral reviews removed and binary labels.

- **SUBJ** Subjectivity dataset[2] that the task is to classify a sentence level text as being subjective or objective (Pang et al., 2004).

- **IMDB** Binary class dataset[3] (Maas et al., 2011) consisting of 100,000 document-level movie reviews that are classified to be positive/negative.

- **QC** Question dataset classifying a given question into six types (whether the question subjects to person, location, numeric information, etc.) (Li and Roth, 2002).

5.2 Hyperparameters and Training

Initializing word vectors with the dataset trained by an unsupervised neural network model is an efficient method to enhance the performance without a large-scale supervised training data (Collobert et al., 2011; Socher et al., 2011; Iyyer et al., 2014). In all of our experiments, our models contain a lookup table by employing Word2Vec (Mikolov et al., 2013) trained on Google News, which comprises more than 100B words with a vocabulary size of around 3M. Word2Vec derives from a continuous bag-of-words architecture and each vector has 300 dimensions.

Word vectors are further fine-tuned during training to get a more optimized embedding result that fits the datasets. The whole network is trained through stochastic gradient decent using Adadelta update rule (Zeiler, 2012). For datasets without development set, we randomly select 10% of the training data as the dev set. The key hyperparameters are chosen via a small grid search, and final setting is illustrated in Table 2.

5.3 Performance of Multi-task CNN

We simultaneously train our model LK-MTL on five datasets and compare it with single-task scenario in Table 3. We can see that our model improves the performance with a large margin over the single task models, which demonstrates the positive synergy of our multi-task architecture. This also testified our assumption that separate structure for MTL is conducive to the information sharing between tasks, helping making better representations for text sequences.

We also test several variants of LK-MTL. The first one replaces Leaky Unit by the Hidden Unit [5] of standard LSTM, and the second one further adds the peephole connections. The results reported in Table

[4]We use reported data for MT-GRNN and MT-RNN and implement MT-CNN, MT-DNN and PA-MTL since the authors do not release the code.

[5]To suit the multi-task learning architecture, hidden state h_t is removed from the formulations of hidden unit.

3 shows that our LK-MTL with Leaky Unit outperforms its variants, which proves the mechanism of Leaky Unit is more suitable for multi-task CNNs.

Comparisons with the State-of-the-art Models
We compare our proposed model against the following models:

- **RNTN** Recursive Neural Tensor Network with tensor-based feature function and parse trees (Socher et al., 2013).
- **DCNN** Convolutional Neural Network with a novel dynamic k-max pooling (Kalchbrenner et al., 2014)
- **MGNC-CNN** Multi-group norm constraint CNN. We use the result of MGNC-CNN(w2v+Syn+Glv) (Zhang et al., 2016).
- **PV** Paragraph vectors based logistic regression (Le and Mikolov, 2014).
- **MT-GRNN** A general multi-task learning architecture with Recurrent Neural Network (Zhang et al., 2017).
- **MT-RNN** Multi-task learning with Recurrent Neural Networks by a shared-layer architecture (Liu et al., 2016)
- **MT-DNN** Multi-Task learning with Deep Neural Networks that uses bag-of-word representations and a hidden shared layer (Liu et al., 2015).
- **MT-CNN** Multi-Task learning with Convolutional Neural Network that partially shares a lookup table (Collobert and Weston, 2008).

As shown in Table 3, LK-MTL also outperforms the state-of-the-art multi-task learning works in four datasets and show competitive results in the other one. Competitors slightly outperform our models in IMDB, since its unique character that the sequences are much longer than other datasets. Specifically, LK-MTL surpasses the PA-MTL, which result demonstrates that the memory and forgetting mechanisms in leaky unit indeed have advantages over other sharing approaches, which help distinguish the helpfulness of the features and making a balance between features in current task and borrowed features. In another word, task-specific feature and shared feature is organically fused by leaky unit in a better way.

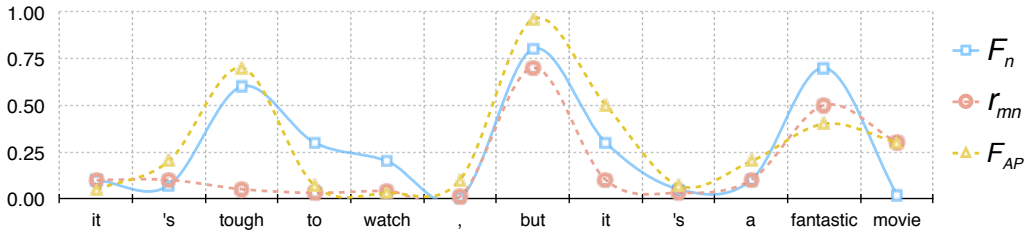

Figure 5: Lines illustrate the feature weights of $\mathbf{F}^1_{SUBJ}$ in SUBJ subnet. And red line shows the value of $\mathbf{r}^1_{SST-1 \leftarrow SUBJ}$ that filters the features from SUBJ subnet to SST-1 subnet. F_{AP} line visualizes the feature weights in the first layer of PA-MTL.

5.4 Visualization

To intuitively show the selection process in leaky unit, we design an experiment to show the values of gate and how they block the useless features. For the first convolutional layer and leaky unit, we visualize the activations $\mathbf{F}^1_m$ of the filters with normalized values and show their corresponding leaky gate $\mathbf{r}^1_{mn}$ in the gate units. By that we can easily find what kind of features are discarded as interference.

Figure 5 illustrates the behavior of leaky unit on a random selected sentence from test set of SST-2 task. We visualize the results of the first feature map for SUBJ subnet and the leak gate $\mathbf{r}^1_{mn}$ that filters the features from SUBJ to SST-2 task. For the positive sentence "it's tough to watch, but it's a fantastic movie", we can see that subnet for SUBJ task focuses on two critical positions "tough" and "fantastic". The word "tough" is subjective for SUBJ task, so the subnet focuses on that world, but actually it is useless and may mislead the prediction of SST-2 task. Successfully, our leaky gate lowers the intensity of that interference "tough", making a correct prediction. However, PA-MTL wrongly makes a negative prediction for lacking resistance to interference. This indicates the effectiveness of our memory and forgetting mechanism in the leaky unit.

6 Related Work

In the NLP field, NN-based multi-task learning has been proven to be effective (Collobert and Weston, 2008; Liu et al., 2015; Liu et al., 2016). The synergy between multi-task learning and neural network is obvious. The earliest idea can be traced back to (Caruana, 1997).

(Collobert and Weston, 2008) develops a multi-task learning model based on CNN. It shares only the partial lookup table to train a better word embedding. And (Liu et al., 2015) proposes a DNN based model for multi-task learning, which shares some low layers to represent the text. These works allow the tasks to reuse low-level layers but separate the high-level layers.

Some models are proposed to sharing deeper layer of networks, which can exchange high level knowledge among tasks and gain better performance. (Liu et al., 2016) and (Zhang et al., 2017) introduce some RNN architectures and design different schemes for knowledge sharing among tasks. These trials promote the performance of models, but they give no consideration to the interference in multi-task learning.

Thus, more approaches are proposed to reduce the interference among tasks. One is to strengthen connection between the strong-related tasks and weaken the less-related ones. (Misra et al., 2016; Fang et al., 2017) proposes a model for images, trying to reduce the interference through weighting the connections between tasks and finding an appropriate proportion. Though this kind of methods weakens the noise from less-related tasks, the processing is coarse-grained and cannot distinguish the useful information in smaller feature level.

Different from these models, our model control the information flows between tasks in feature level, which uses the mechanism of remembering and forgetting, passing only the useful features for the current task. It solves the problems of what should be maintained in current task and what should be borrowed from other tasks. By that our model is capable of reducing the interference without extra supervision.

7 Conclusion and Future Work

In this paper, we propose a CNN based framework for multi-task learning, which has the structure to control the passing of information in feature level. By remembering the helpful features and forgetting the useless ones, LK-MTL can reduce the interference between the tasks. And we also visualize the property of our models and intuitively show the selection mechanism of Leaky Unit. Experiment result on five datasets for text classification demonstrates the effectiveness of our model for text representation.

In the feature, we would like to investigate deeper into the interference problem, testing more kinds of gate mechanisms and find better one to purify the feature flows. We also want to equip our unit on other neural networks for other applications, such as multi-layer perceptrons and RNNs.

Towards an argumentative content search engine using weak supervision

Abstract

Searching for sentences containing claims in a large text corpus is a key component in developing an argumentative content search engine. Previous works focused on detecting claims in a small set of documents or within documents enriched with argumentative content. However, pinpointing relevant claims in massive unstructured corpora, received little attention. A step in this direction was taken in (Levy et al., 2017), where the authors suggested using a weak signal to develop a relatively strict query for claim–sentence detection. Here, we leverage this work to define weak signals for training DNNs to obtain significantly greater performance. This approach allows to relax the query and increase the potential coverage. Our results clearly indicate that the system is able to successfully generalize from the weak signal, outperforming previously reported results in terms of both precision and coverage. Finally, we adapt our system to solve a recent argument mining task of identifying argumentative sentences in Web texts retrieved from heterogeneous sources, and obtain F_1 scores comparable to the supervised baseline.

1 Introduction

The arguments raised during a decision making process, will often determine its outcome. A common component in all argument models (e.g., (Toulmin, 2003)) is the *claim*, i.e. the assertion the argument aims to prove. The problem of automatically detecting claims supporting or contesting a given controversial topic [1] (Levy et al., 2014) is considered a fundamental task in the emerging field of computational argumentation (Lippi and Torroni, 2016; Palau and Moens, 2009). We refer to their definition of a Topic and a Claim; **Topic** - a short phrase that frames the discussion and **Context Dependent Claim** - a general, concise statement that directly supports or contests the given Topic (we henceforth use the term claim instead of Context Dependent Claim).

Previous works have focused on detecting claims within a small set of documents related to the topic (Levy et al., 2014), or within documents enriched with argumentative content (Stab and Gurevych, 2014). However, pinpointing relevant claims within massive unstructured corpora, received relatively little attention. While this problem is obviously more challenging, its potential value is also much higher. For a widely discussed topic, one should expect many relevant claims to be mentioned across a widespread set of articles in the given corpus. The remaining issue is to develop a technology to swiftly detect these claims and present the results to potential users, similarly to search engines that retrieve information in response to a query.

A step in this direction was taken in (Levy et al., 2017). They suggested a relatively strict sentence–level query (strict in the sense that it considerably limits the set of potential answers hence reduces the coverage). Their query combines three query parts that must appear in order, with possible gaps between them. The first part requires the sentence to contain the token *'that'* as it is often a precursor for a claim (e.g. <someone> argued that <claim>). The second query part requires some restriction on the scope of topics the system can handle, and assumes that each topic deals with exactly one concept (denoted

*First three authors contributed equally.

[1] We will henceforth refer to claims supporting or contesting a given controversial topic as *relevant claims*.

Proceedings of the 27th International Conference on Computational Linguistics, pages 2066–2081
Santa Fe, New Mexico, USA, August 20-26, 2018.

MC – for main concept) and that this concept has a Wikipedia title (e.g. Affirmative Action). The second part of the query thus restricts the returned sentences to those in which the MC follows the word *'that'* (possibly with a gap). The third and final query part requires a token from a pre–specified *claim lexicon* (CL) to appear after the MC (possibly with a gap). The CL lexicon aims to characterize *claim sentences* (CS) and the process of its creation did not involve any labeled data. Table 1 shows the fifty most indicative tokens from the lexicon. Relying on this formulation led to promising precision results in the challenging task of corpus wide claim detection, albeit with low recall . Specifically, while each of the sentences in Table 2 contains a valid and relevant claim, only $S1$ satisfies their query; In contrast, $S2$ satisfies only the first part of the query ('that' preceding the MC); $S3$ satisfies the second part of the query (CL token following the MC); and $S4$ only mentions the MC. By construction, these latter three sentences, are out of the radar of Levy et al. (2017).

Claim Lexicon - partial
should, tuned, could, unconstitutional, violate, might, violated, violates, wrong, rather, valid, invalid, irrelevant, inherently, necessarily, cannot, prevail, justify, flawed, merely, corpus, ought, inevitably, cause, justifiable, unacceptable, untrue, abhorrent, unless, harmful, punished, liable, incompatible, beneficial, justifying, undecided, skimmed, indefensible, impossible, undermine, necessary, flourish, meaningless, outweigh, substantiated, refute, jeopardized, incapable, irrational, heterosexual

Table 1: Fifty most indicative words in the Claim Lexicon (starting from the most indicative)

Example Id	Sentence
S1	*He believed* **that nuclear power** *would become* **obsolete**, *to be replaced by clean energy sources.*
S2	*The author concludes* **that wind energy** *has the greatest potential for near-term expansion.*
S3	*As Buckley writes, "If* **atheism** *was* **unacceptable**, *superstition and fanaticism were even more so".*
S4	*Any form of* **corporal punishment** *is barbaric and has no place in a civilized polity.*

Table 2: CS examples for the topics 'We should further exploit nuclear power', 'We should further exploit wind power', 'Atheism is the only way' and 'We should prohibit corporal punishment'. The query items 'that', MC and CL are highlighted in boldface.

The main contribution of the current work is to propose a more flexible approach for corpus wide claim detection, that significantly outperforms previous work, in terms of both precision and of coverage. We also release two data sets, one of $\approx 1.5M$ sentences matching the topics in this study, and one of $2,500$ sentences predicted by our method, annotated for whether they contain a relevant claim or not [2].

We use Deep Neural Networks (DNN) trained with weak supervision that stems from different parts of the aforementioned query. Considering the list of 100 MC used by Levy et al. (2017), we first construct two weakly supervised labeled data sets, each composed of two classes. In the first, the weakly–positive class includes all sentences that mention the MC preceded by 'that'; while the weakly–negative class contains a similar number of sentences that mention the MC *without* a preceding 'that'. Our underlying assumption is that the former set will be more enriched with CS (this we first noted in (Levy et al., 2014)). However, since these two classes are trivially distinguished via the (non) presence of 'that', we train the DNN on the *suffixes* of the sentences in these data, where the suffix of a sentence is defined as the sentence part immediately following the MC.

Similarly, we construct another data set, in which the weakly–positive class includes all sentences that mention the MC followed by a token from CL; while the weakly–negative class contains a similar number of sentences that mention the MC *without* a following token from CL. Here as well, to avoid the trivial signal, we train the DNN on the *prefixes* of the sentences in these data, where the prefix of each sentence is defined as the part preceding the MC.

[2]The data sets can be downloaded from `http://www.research.ibm.com/haifa/dept/vst/debating_data.shtml`

The priors for the two positive classes as well as the strict query were estimated in (Levy et al., 2017) by performing a small labeling experiment. We present their results in table 3 in order to demonstrate that the assumptions indeed hold.

Query Name	Query	Estimated Prior
q_{MC}	MC	2.4%
q_{that}	*that* $\rightarrow$ MC	4.8%
q_{CL}	MC $\rightarrow$ CL	Not Estimated
q_{strict}	that $\rightarrow$ MC $\rightarrow$ CL	9.8%

Table 3: Estimated priors for different queries from (Levy et al., 2017).

Finally, we restrict both datasets to sentences in which the number of suffix (prefix) words is greater than 3. We assume this restriction mostly removes negative examples, and in any case will not convey a lot of information to the DNN in the learning process.

We test the performance of these DNNs over a distinct test set of 50 topics, also from (Levy et al., 2017). However, in contrast to this previous work, we consider a much more relaxed query that only requires the MC to be mentioned in the sentence. Our results clearly indicate that both DNNs were able to generalize and obtain promising precision results, that are further improved when their scores are averaged. That is, combining the predictions of a DNN trained over prefixes of sentences enriched with claims, with those by a DNN trained over suffixes of such sentences, results in a pincer–movement like approach, that successfully pinpoints a wide range of CS in a massive unstructured corpus, while using only weak supervision for training.

2 Related Work

Recently, Wachsmuth et al. (2017) suggested an argument search framework and a corresponding search engine prototype. However, the proposed system relies on arguments crawled from dedicated resources that suggest pre–written arguments for various topics, and hence, is only relevant for topics covered in these resources, and cannot be used directly over unstructured textual data. Stab et al. (2018) tackled the argument mining task in heterogeneous texts retrieved by Google search when queried with a controversial topic. They show that it is feasible to annotate the retrieved documents via crowd-sourcing and to use these labels in order to build a supervised learning system that finds arguments in the given documents. Similar to our work, sentences are treated in isolation (ignoring the document context). The only work we are aware of that tackles corpus wide claim detection, is the work by (Levy et al., 2017). Here, we demonstrate how this work can be leveraged to define weak signals for training DNNs to obtain significantly greater performance.

Several works used DNN to tackle a variety of computational argumentation tasks, such as argument mining (Eger et al., 2017), predicting argument convincingness (Habernal and Gurevych, 2016), detecting context dependent claims and evidence (Laha and Raykar, 2016) and attack and support relations between arguments (Cocarascu and Toni, 2017). However, these works used the fully–supervised learning paradigm, which is inherently demanding, especially in the context of argument mining where obtaining labeled data is notoriously difficult (Aharoni et al., 2014). In addition, Al-Khatib et al. (2016) used a distant supervision approach trained over debate portals' data, to develop a classifier for argumentative texts stored in these portals. To the best of our knowledge, the present work is the first to demonstrate the value of DNN trained solely with weak supervision (Hearst, 1992) in this challenging field.

For a good exposition on the field of argument mining refer to (Lippi and Torroni, 2016). Some notable works include (Palau and Moens, 2009) who first suggested the argument mining task, (Levy et al., 2014; Rinott et al., 2015) who focused on mining claims/evidence in the context of a user given controversial topic and several works related to specific text genres such as student essays (Stab and Gurevych, 2014), legal documents (Wyner et al., 2010; Moens et al., 2007; Grabmair et al., 2015), user comments on proposed regulations (Park and Cardie, 2014) and newspaper articles (Feng and Hirst, 2011).

3 Method

3.1 Setup and pre-processing

We follow the setup and pre-processing described in (Levy et al., 2017) – see appendix for details. We consider the same train [3] and test sets, consisting of 100 and 50 topics respectively. Next, we prepared a sentence–level index from the Wikipedia May 2017 dump, and used a simple Wikification tool (to be described in a separate publication)[4] to focus our attention on sentences that mention the MC. Filtering out sentences that mention a location/person named entity using Stanford NER (Finkel et al., 2005), after the MC, results in an average of $\approx 10K$ sentences per MC.

3.2 Claim sentence queries and weak labels

The basic query we start with, denoted q_{MC}, only requires that the MC will appear in the sentence. For the 150 topics of this study, we retrieve a total of $\approx 1.5M$ sentences matching q_{MC} (Table 4), which we release as a data set to enhance future research. Next, we consider the query q_{that}, which retrieves all sentences in which the token 'that' precedes the MC (cf. $S1$ and $S2$ in table 2). There are $\approx 1,100$ such sentences per topic (Table 4). Aiming to increase the prior of CS in the weak–positive set, for training the network, we focus on the subset of these sentences in which the token 'that' immediately precedes the MC. As a weak–negative set we consider a similar number of sentences, with similar length distribution, selected at random from the q_{MC} sentences with the additional requirement of *not* having 'that' before the MC. As explained in section 1, the corresponding DNN, termed DNN_{suff}, is trained only on the sentence suffixes.

Query Name	Query	# Sentences Per Topic
q_{MC}	MC	9,947
q_{that}	*that* → MC	1,073
q_{CL}	MC → CL	793
q_{strict}	that → MC → CL	164

Table 4: Queries used to construct weak labels. # Sentences Per Topic is averaged over the 150 topics used in this study. q_{strict} is added for reference and was not used in training the networks.

Similarly, we consider the query q_{CL}, which retrieves all sentences in which the MC is followed by a token from CL, e.g., sentences $S1$ and $S3$ in table 2. Again, these sentences as well are expected to be relatively enriched with claims. In Table 4 we see that on average we have ≈ 790 such sentences per topic. As a weak–negative set we consider a similar number of sentences, with similar length distribution, selected at random from the q_{MC} sentences with the additional requirement of *not* having a CL token after the MC. Again, the corresponding DNN, denoted by DNN_{pref} is trained only on the sentence prefixes.

Table 5 lists examples of sentences in the weak–positive and weak–negative sets used to train the networks. The part "seen" by the relevant network appears in bold, where by an anecdotal examination it is indeed possible to identify a signal in the positive sets. Table 6 summarizes the characteristics of the two datasets used to train the networks.

3.3 DNN System

For both DNN_{suff} and DNN_{pref}, we use a Bi-LSTM architecture with self-attention (Yang et al., 2016). The networks were trained on sentences retrieved for 70 of the 100 train–set topics, where sentences retrieved from the other 30 train–set topics (heldout set) were used to optimize hyper-parameters. We used Adam optimizer (Kingma and Ba, 2014) over the cross-entropy loss. The best model was

[3] The set of 100 topics was termed *dev set* in their work because there was no training involved.

[4] A Wikification tool allows retrieving sentences that mention the topic explicitly, as well as sentences which use a different surface form, as in S2 in Table 2 (wind energy surface-form linked to the wind power concept).

Network	Positive/Negative	Sentence
DNN_{suff}	Positive	*There is no good evidence that organic food* **tastes better than its non-organic counterparts**.
DNN_{suff}	Negative	*Today it is known for its remoteness, its somewhat "alternative" atmosphere, organic food* **production, and its pioneering use of wind power**.
DNN_{pref}	Positive	**Fermi did not believe that** *atomic bombs would deter nations from starting wars, nor did he think that the time was ripe for world government.*
DNN_{pref}	Negative	**In particular, fission products do not themselves undergo fission, and therefore cannot be used for** *nuclear weapons.*

Table 5: Examples from the positive and negative sets of DNN_{suff} and DNN_{pref} for the topics "Organic Food" and "Nuclear weapon". The respective prefix/suffix appears in bold.

Network	Positive sentences	Negative sentences	Part of sentence used by the network	Size of data
DNN_{suff}	*that* $\rightarrow$ MC	MC without preceding 'that'	following the MC	11,624
DNN_{pref}	MC $\rightarrow$ CL	MC without a following CL token	preceding the MC	132,856

Table 6: Characteristics of the two datasets used to train the networks. Note that the data for the suffix network is much smaller because of the restriction to sentences in which the token 'that' immediately precedes the MC.

trained with a dropout of 0.15, using a single dropout mask across all time-steps as proposed by (Gal and Ghahramani, 2016), one LSTM layer with a cell size of 128, and an attention layer of size 100. Words are represented using the 300 dimensional GloVe embeddings (Pennington et al., 2014). Inference is performed for any q_{MC} sentence by averaging the DNN_{suff} score of its suffix with the DNN_{pref} score of its prefix.

We used the heldout set to determine early stopping and to optimize the following hyper–parameters (each parameter was optimized independently): Number of layers $(1/2)$, LSTM cell size $(64/128/256/512)$, attention FF size $(50/100/200)$ and dropout rate $(0/0.05/0.1/0.15/0.2/0.25/0.3/0.35)$.

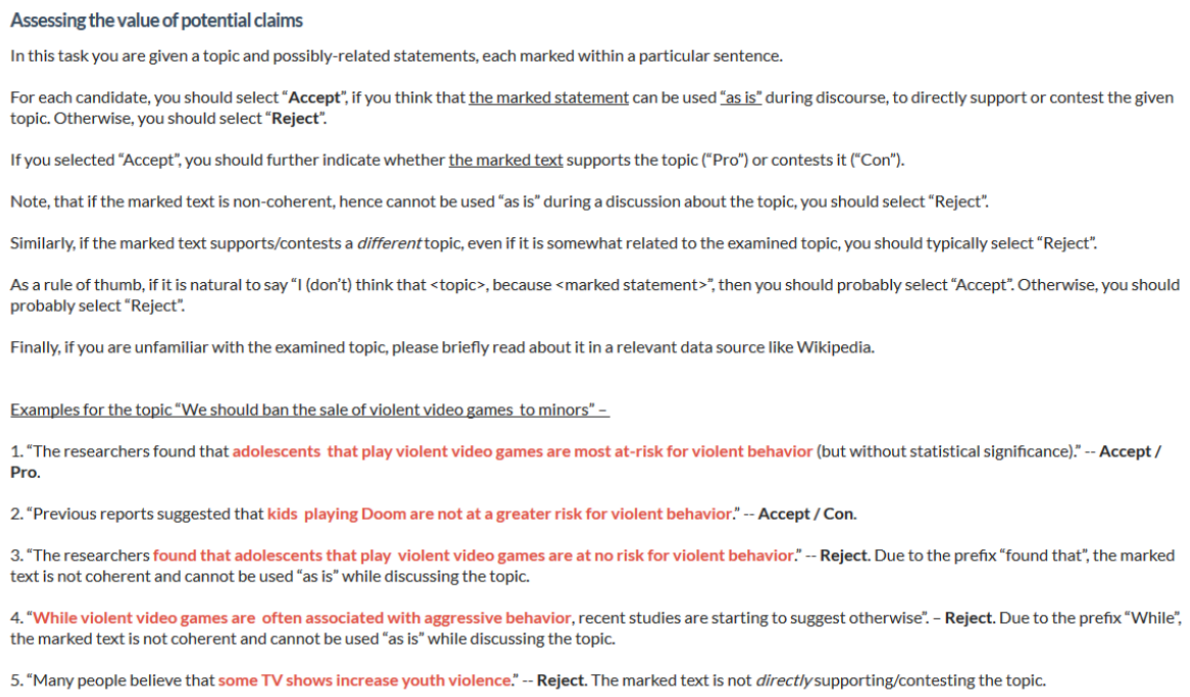
4 Data for evaluation

We labeled via crowd the top 50 predicted sentences for each of the 50 test-set topics, taking the majority vote of at least 10 workers. The guidelines are presented in figure 1. The inference is applied to all sentences containing the MC (matching q_{MC}), and hence there are always 50 predictions, that are all released along with their manual evaluation. We also label in the same manner the predictions of the system described in (Levy et al., 2017) [5]. There, since all predictions must match q_{strict}, for some topics there are less than 50 predictions. In those cases, we label all predictions.

This paper focuses on retrieving claim sentences, however, we have found that it is easier for the crowd workers to label a sentence if the phrase suggested to be the claim is highlighted. For this reason, we used an internal boundary detection component and applied it to all system versions (including the re-implementation baseline of (Levy et al., 2017)). The rest of the labeling process was done similarly to (Levy et al., 2017). Each sentence was labeled by 10-15 crowd workers per row via the Figure–Eight platform [6]. We used the MACE de–noising tool (Hovy et al., 2013) to filter labels before computing Cohen's Kappa coefficient. We averaged the Kappa coefficient across all worker pairs with at least 50 joint labeled instances. Using a threshold of 0.9 (i.e. keeping 90% of the labels) the Kappa was 0.58.

[5] We re-implemented their system since since we used a more recent Wikipedia dump and a different Wikification tool. The results we obtained are very close to the reported results.

[6] https://www.figure-eight.com/ (previously known as CrowdFlower)



Assessing the value of potential claims

In this task you are given a topic and possibly-related statements, each marked within a particular sentence.

For each candidate, you should select "**Accept**", if you think that the marked statement can be used "as is" during discourse, to directly support or contest the given topic. Otherwise, you should select "**Reject**".

If you selected "Accept", you should further indicate whether the marked text supports the topic ("Pro") or contests it ("Con").

Note, that if the marked text is non-coherent, hence cannot be used "as is" during a discussion about the topic, you should select "Reject".

Similarly, if the marked text supports/contests a *different* topic, even if it is somewhat related to the examined topic, you should typically select "Reject".

As a rule of thumb, if it is natural to say "I (don't) think that <topic>, because <marked statement>", then you should probably select "Accept". Otherwise, you should probably select "Reject".

Finally, if you are unfamiliar with the examined topic, please briefly read about it in a relevant data source like Wikipedia.

Examples for the topic "We should ban the sale of violent video games to minors" –

1. "The researchers found that adolescents that play violent video games are most at-risk for violent behavior (but without statistical significance)." -- **Accept / Pro.**

2. "Previous reports suggested that kids playing Doom are not at a greater risk for violent behavior." -- **Accept / Con.**

3. "The researchers found that adolescents that play violent video games are at no risk for violent behavior." -- **Reject.** Due to the prefix "found that", the marked text is not coherent and cannot be used "as is" while discussing the topic.

4. "While violent video games are often associated with aggressive behavior, recent studies are starting to suggest otherwise". – **Reject.** Due to the prefix "While", the marked text is not coherent and cannot be used "as is" while discussing the topic.

5. "Many people believe that some TV shows increase youth violence." -- **Reject.** The marked text is not *directly* supporting/contesting the topic.

Figure 1: Labeling guidelines exactly as they appeared in the Figure–Eight platform. Note that for the sake of this work we ignore the stance labeling (pro/con answers).

5 Results

To evaluate the performance of the network, we employ two sets of experiments. In the first we use the test-set topics in a manner similar to (Levy et al., 2017). In the second, we test our network on the UKP Sentential Argument Mining Corpus released in (Stab et al., 2018). Note that the UKP data is more inline with our goal than other argument mining tasks as it separates between sentences that support/contest a given topic from sentences that don't. A major difference between the UKP data and our test set is the source from which the sentences were taken – while we used Wikipedia, the UKP data comes from various sources, and hence it would test how well our approach generalizes to other text genres. Another important difference is in the definition of positive examples - we consider sentences containing relevant claims as positive, whereas they require that a sentence contain some supporting evidence or reasoning. The results on our test set are presented in subsection 5.1 and the results on the UKP data are presented in subsection 5.2.

5.1 Results on the Test Set

Figure 2 depicts the average number of CS (i.e., true positives) retrieved per the top $K = 10, 20, 50$ predictions. Both DNN_{pref} and DNN_{suff} seem to generalize well from the weak signal and provide comparable results to (Levy et al., 2017). More importantly, using the average score (DNN) yields the best performance, consistently outperforming (Levy et al., 2017) (with p-value < 0.005 for $K = 20, 50$ based on a two-tailed Wilcoxon test). The gap is most prominent for $K = 50$, where the DNN yields $\approx 30\%$ more CS compared to the the non–learning system that used a strict query with limited recall.

A major question is whether the learned system is able to generalize from the weak labels and identify CS that do not match the weak queries we started with. By construction, all sentences retrieved by the (Levy et al., 2017) system, match q_{strict}. From Table 7, we see that although the DNN system trained on sentences matching q_{that} or q_{CL} or both, 28% of the 2500 sentences predicted by the system, *do not match either*. Sentence $S4$ in Table 2 is an example of such a predicted sentence. The precision on those sentences, that are only known to contain the MC, is still considerably high – 0.22, and in fact comparable

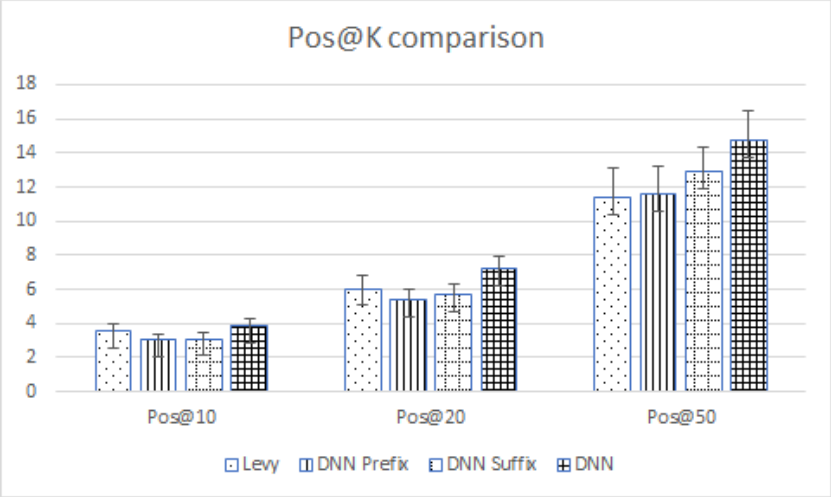


Figure 2: Results for the 50 test-set topics. $Pos@K$: The number of claim sentences (CS) out of the top K predicted sentences per topic, averaged over all test topics. Bars denote the standard error. Levy – Results reproduced on current index using the system described in (Levy et al., 2017); DNN – using the average score of DNN_{pref} and DNN_{suff}.

to the precision achieved in the restricted, low–recall system of (Levy et al., 2017). These results suggest that the DNN captures some general characteristics of CS, that are not limited to sentences that satisfy the two weak–signal queries we started with, q_{that} and q_{CL}. In addition, the precision on sentences containing one or both of the weak signals is even higher. Specifically, the precision on the subset of sentences matching q_{strict} is 0.42, a factor of two compared to the precision of (Levy et al., 2017) on this set of sentences. Thus, overall we were able to increase the potential recall from the restricted set of sentences matching q_{strict} to the full set of q_{MC} sentences, while also increasing the precision of the predictions from 0.23 to 0.3 (see the column q_{MC}).

Measure	System	q_{strict}	q^*_{that}	q^*_{CL}	q^*_{MC}	q_{MC}
Percent	Levy	100	0	0	0	100
	DNN	30	26	16	28	100
Precision	Levy	0.23	NA	NA	NA	0.23
	DNN	0.42	0.32	0.22	0.22	0.30

Table 7: Distribution and precision of predictions. q^*_{that}: matches q_{that} but not q_{CL}; q^*_{CL}: matches q_{CL} but not q_{that}; q^*_{MC}: matches q_{MC}, but not any of the other queries. Percent: out of the top 50 (or all if less available) predicted sentences matching the query. Precision: Precision of the corresponding candidates, calculated per topic, and averaged over test topics.

5.2 Results on the UKP Sentential Argument Mining Corpus

The UKP Sentential Argument Mining Corpus (Stab et al., 2018) contains a total of 25,492 labeled sentences (11,139 argumentative, 14,353 non-argumentative), divided to train (70%), validation (10%), and test sets (20%). The sentences are associated with one of 8 controversial topics – *abortion*, *cloning*, *death penalty*, *gun control*, *marijuana legalization*, *minimum wage*, *nuclear energy* and *school uniforms* – and were derived from the top 50 results of a Google query for the topic name, thus representing various genres and text types.

Adapting to the UKP dataset

In order to evaluate our method on the UKP dataset we had to adapt it to sentences that do not necessarily contain the MC. In our formulation, the MC was used as a natural point to divide the sentence into its prefix and suffix, which were then used by the appropriate networks. To overcome this difference, we applied DNN_{suff} (DNN_{pref}) to all possible suffixes (prefixes) and used the maximal score.

For a sentence S comprised of n words, $w_1, w_2, ..., w_n$, we define,

$$DNN'_{suff}(S) = max_{\{i:1..n\}} DNN_{suff}(w_i, ..., w_n)$$
$$DNN'_{pref}(S) = max_{\{i:0..n-1\}} DNN_{pref}(w_1, ..., w_{n-i})$$

The adapted scores may still be at a disadvantage because without the MC we don't have a way to select sentences that are more related to the topic. For this reason we add a similarity score $Score_{w2v}$ which is computed by taking the maximal word2vec (Mikolov et al., 2013) similarity of a word in the topic against all words in the sentence and then averaging across the words of the topic. More formally, for a topic T comprised of k words, $t_1, ..., t_k$,

$$Score_{w2v}(S) = avg_{\{i:1..k\}} max_{\{j:1..n\}} word2vec(t_i, w_j)$$

Finally, we define,

$$DNN'_{suff,w2v} = avg(DNN'_{suff}, Score_{w2v})$$
$$DNN'_{pref,w2v} = avg(DNN'_{pref}, Score_{w2v})$$

We employ the same setup that was used by (Stab et al., 2018) for the cross topic evaluation, in which the train set is comprised of the train part of all topics except for the tested topic. We use the training set only to tune the threshold from which we predict the positive class. To do so, we run the different DNN methods on the train set, compute the F_1 over all sentences, and choose the score that maximizes the F_1. This score is then used in the test set as the threshold that determines whether the network predicts a positive or not. Overall, this tuning was done 8 times, one for each train set induced by the left-out test topic.

Evaluation

The results are shown in table 8. Interestingly, our system achieves comparable results to the state of the art in the Accuracy and F_1 measures but without using human labels for training and without training on multiple text genres. These results also demonstrate the ability of the proposed method to generalize to topics that are not characterized by a single MC or that such a concept was not provided by the user. Note, the results reflect that our system and the baseline operate at different points on the precision/recall curve, choosing a different compromise between precision and recall. This is not surprising, given the choice of tuning the F_1 measure on the train set, however, it makes the comparison less obvious.

Method	Accuracy	F_1	Precision	Recall
UKP	0.69	0.66	0.75	0.52
DNN'_{suff}	0.57	0.65	0.51	0.90
$DNN'_{suff,w2v}$	0.67	0.69	0.59	0.83

Table 8: Results of the cross topic evaluation on the UKP dataset (averaged across the 8 topics). UKP method stands for the best supervised results reported in (Stab et al., 2018). From the networks combined with $w2v$ the $DNN'_{suff,w2v}$ performed best and is the one presented here.

It should be noted that the lower precision of our method may be explained by the different assumption on what an argumentative sentence is. Whereas Stab et al. (2018) reject sentences that contain claims but provide no evidence or reasoning, our network was designed to identify claims regardless of the

existence of a surrounding argument. Indeed, as mentioned in section 6.2, by sampling 50 false-positives we found that in 25% of the cases they contained relevant claims but with no evidence or reasoning.

6 Error Analysis

6.1 Test Set - 50 Topics

We analyzed the top 50 labeled predictions over three test topics for which the performance was above/near/below average (table 9).

Topic Text	Main Concept	Pos@50
We should further exploit wind power	Wind power	29
Private education brings more good than harm	Private school	13
We should protect whistleblowers	Whistleblower	9

Table 9: Test topics chosen for error analysis.

Each sentence rejected by the labelers was assigned one of the following types: **Factual** – a sentence with no argumentative content, that merely states a fact; **Different Topic** – a sentence that contains a claim for a different topic; **Other** – an assortment of problems such as bad sentence split, missing context, etc; and finally **Accept** – a sentence that should have been accepted by the labelers. The two main types of errors were Factual and Different topic, each accounting for 35% of the analyzed errors. The Accept type accounted for 18% of the rejected sentences, though this high number was mostly due to the Whistleblowers topic. We suspect that many such sentences were rejected because of bad claim boundary choices by the system [7]. Table 10 shows examples from the topic *"Private education brings more good than harm"*.

Error Type	Sentence
Different Topic	*Changes in private school enrollment is not a likely contributor to any changes in schools segregation patterns during that time.*
	In 2014 Hunt proposed that private schools should be required to form "partnerships" with local state schools if they wanted to keep their charitable status.
Factual	*Before enrolling the children, however, Mr. Brar ensured that the total cost of private school tuition would not exceed* $\$10,000$.
	The IRS announced in 1970 that private schools with racially discriminatory admissions policies would no longer receive tax exemptions
Accept	*Coaches were concerned that the private schools were winning a disproportionate amount of conference titles and had several unfair advantages.*
Other*	*It is clear that affording private education is a mere fantasy for these families.*

Table 10: Examples of sentences from the topic 'Private education brings more good than harm'. The sentences are split according to their assigned error type. * The example for the Other type was rejected because of a missing context – it is hard to judge this example without resolving the reference to "these families"

6.2 Test Set - UKP Dataset

We analyzed 50 random sentences from the UKP test set labeled as non-argumentative, on which the score of the $DNN'_{suff,w2v}$ network was higher than 0.9 (the average threshold obtained by tuning F_1 was 0.65). We add the following error type to the list above: **No Reasoning** – a sentence containing a claim with no supporting evidence or reasoning. The most frequent type of error was Factual, accounting

[7] We used a claim boundary component (Levy et al., 2014) on top of all systems in order to simplify the labeling task. This came at a cost of some CS being rejected due to errors in the boundary component.

for about 33% of the errors. The No Reasoning type accounted for about 25% of the errors, similar to the Different Topic type. Table 11 shows examples of No Reasoning sentences. These sentences contain text boundaries that are relevant claims, e.g., the boundary *the life in the womb is not human* in the first sentence, and thus are typical to sentences that our network was trained to find.

Topic	Sentence
abortion	*A question for those who believe in abortion, and that* **the life in the womb is not human**.
death penalty	**We need stricter laws and swift death penalty**.
minimum wage	*Myth:* **Raising the minimum wage will only benefit teens**.
marijuana legalization	*A small share of opponents (7%) say that while* **the recreational use of marijuana should be illegal**, *they do not object to legalizing medical marijuana.*

Table 11: Examples of sentences marked as No Reasoning from the UKP test set. The phrases marked in boldface are the suggested claim boundaries according to our analysis.

7 Discussion and Future Work

This work aims at making the first steps towards a search engine for argumentative content, by focusing on the problem of corpus wide claim detection. A variety of argument theories have been proposed throughout the years, which all agree on the importance of one argument component – the claim. Thus, properly addressing the problem of corpus wide claim detection seems like a key component in developing a full fledged argument search engine. Such an engine could add massive amounts of data to argument networks such as the world wide argument web (Rahwan et al., 2007), and further enhance decision processes in various ways. Using a similar methodology for evidence detection would be a natural way to push the boundary of existing work, e.g., (Rinott et al., 2015) from considering a pre-selected list of articles to searching full corpora. To the best of our knowledge this is the first work using weak supervision to train DNNs for argument mining, demonstrating the potential of this coupling in the field. Two directions for future work could increase the precision and coverage of our system. For increasing precision, we intend to employ a supervised approach, using labels on top of predictions from the weak–supervision approach, as it may help reach a reasonable prior of positive examples before starting the labeling effort. For the coverage, we intend to explore the same approach on top of sentences which do not necessarily contain the MC. This direction is challenging since it requires integrating a method for identifying whether a sentence is related to the topic, and would need to score sentences in which the prior for a claim is even lower.

During the error analysis on the 'Wind power' topic, we encountered the following high-scoring sentence – *"When Scratchy suggests that wind power is cheap and safe, Itchy chops Scratchy's head off with the blades of a wind turbine."*. On the one hand, Scratchy raises a legitimate claim, and on the other hand, Scratchy is a fictional character from the TV show The Simpsons. The example demonstrates a phenomenon that may be exasperated when moving from argument mining on pre-selected high-quality documents to mining large (possibly heterogeneous) text corpora – the phenomenon of claims made by unreliable sources. In extreme cases the claims made by such parties may be ridiculous or offensive and a practical search engine would need to detect and remove such claims.

Appendix A Index and Preprocessing

We processed the Wikipedia dump from May 1st, 2017. We applied text cleaning and sentence splitting using OpenNlp Sentence Detector [8] and an internal Wikification tool to wikify each sentence [9]. Starting from 5.4M articles, the sentence level index contains approximately 102M sentences. The inverted index along with the support for queries that mix surface form tokens with Wiki concepts was implemented as in (Levy et al., 2017).

We annotated the sentences retrieved by all queries using Stanford NER (Finkel et al., 2005), and removed sentences with a person/location entity after the MC (e.g., the sentence *"Yan warned Li that the Nationalist cause was doomed unless Li went to Guangdong"* for the topic *"Nationalism does more harm than good"* would be removed). This filter is motivated by our goal of retrieving general claim sentences for the topic, assuming that claims about specific entities are less interesting for potential users.

Appendix B Topics and Folds

The list of 150 topics is taken from (Levy et al., 2017) and split to dev/test in the same manner. Since here we use a learning system, we further split the dev set into a train set of 70 topics and a heldout set of 30 topics which was used to decide when to stop the learning. Tables 12 and 13 show the train topics and tables 14 and 15 show the topics of the heldout and test sets respectively.

Appendix C Released Data

We release two datasets, one containing $\approx 1.5M$ sentences matching the topics in this study based on the q_{MC} query, and one containing $2,500$ sentences predicted by our network and annotated for whether they contain a relevant claim or not (top 50 predictions across the 50 topics in the test set)[10]. The q_{MC} dataset can be found in the attached `q_mc_train.csv`, `q_mc_heldout.csv` and `q_mc_test.csv` files, according to the topics split used in the learning/evaluation process. A detailed description of this dataset appears in the `readme_mc_queries.txt` file. The system prediction dataset is in the `test_set.csv` file with a corresponding description in the `readme_test_set.txt` file.

#	Id	Topic Text	Main Concept
1	1	We should ban the sale of violent video games to minors	Video game controversies
2	2	We should legalize doping in sport	Doping in sport
3	3	We should ban boxing	Boxing
4	4	We should abolish intellectual property rights	Intellectual property
5	5	We should protect endangered species	Endangered species
6	6	Operation Cast Lead was justified	Gaza War (2008-09)
7	7	Tower blocks are advantageous	Tower block
8	8	Private universities bring more good than harm	Private university
9	9	We should disband ASEAN	Association of Southeast Asian Nations
10	10	The free market brings more good than harm	Free market
11	11	We should ban child actors	Child actor
12	12	Religion does more harm than good	Religion
13	13	We should ban cosmetic surgery	Plastic surgery
14	14	Same sex marriage brings more good than harm	Same-sex marriage
15	15	Reality television does more harm than good	Reality television
16	16	Internet censorship brings more good than harm	Internet censorship
17	17	Socialism brings more harm than good	Socialism
18	18	We should ban beauty contests	Beauty pageant
19	19	We should adopt vegetarianism	Vegetarianism
20	20	We should adopt libertarianism	Libertarianism
21	21	The internet brings more harm than good	Internet
22	22	Science is a major threat	Science
23	23	Suicide should be a criminal offence	Suicide
24	24	Nationalism does more harm than good	Nationalism
25	25	The atomic bombings of Hiroshima and Nagasaki were justified	Atomic bombings of Hiroshima and Nagasaki
26	26	Casinos bring more harm than good	Casino
27	27	We should lower the age of consent	Age of consent
28	28	We should abolish standardized tests	Standardized test
29	29	We should ban extreme sports	Extreme sport
30	30	The alternative vote is advantageous	Instant-runoff voting
31	31	Illegal immigration brings more harm than good	Illegal immigration
32	32	We should subsidize renewable energy	Renewable energy
33	33	We should end daylight saving times	Daylight saving time
34	34	We should further exploit geothermal energy	Geothermal energy
35	35	Assisted suicide should be legalized	Assisted suicide
36	36	Security hackers do more harm than good	Hacker (computer security)
37	37	We should disband the United Nations	United Nations
38	38	We should ban hate sites	Hate speech
39	39	We should privatize future energy production	Energy development
40	40	Child labor should be legalized	Child labour
41	41	The paralympic games bring more good than harm	Paralympic Games
42	42	Chain stores bring more harm than good	Chain store
43	43	We should subsidize Habitat for Humanity International	Habitat for Humanity
44	44	We should subsidize public art	Public art
45	45	IKEA brings more harm than good	IKEA
46	46	We should ban online advertising	Online advertising
47	47	Mixed-use development is beneficial	Mixed-use development
48	48	We should ban Greyhound racing	Greyhound racing
49	49	The Israeli disengagement from Gaza brought more harm than good	Israeli disengagement from Gaza
50	50	We should not subsidize single parents	Single parent

Table 12: Train topics 1-50

#	Id	Topic Text	Main Concept
51	51	We should ban private military companies	Private military company
52	52	Coaching brings more harm than good	Coaching
53	53	We should abandon disposable diapers	Diaper
54	54	PayPal brings more good than harm	PayPal
55	55	The Internet archive brings more harm than good	Internet Archive
56	56	The 2003 invasion of Iraq was justified	2003 invasion of Iraq
57	57	Virtual reality brings more harm than good	Virtual reality
58	58	Internet cookies bring more harm than good	HTTP cookie
59	59	Magnet schools bring more harm than good	Magnet school
60	60	The right to strike brings more harm than good	Strike action
61	61	We should subsidize student loans	Student loan
62	62	We should abandon Youtube	YouTube
63	63	Ecotourism brings more harm than good	Ecotourism
64	64	Academic freedom is not absolute	Academic freedom
65	65	Homeschooling should be banned	Homeschooling
66	66	We should abolish the US Electoral College	Electoral College (United States)
67	67	Generic drugs should be banned	Generic drug
68	68	We should fight global warming	Global warming
69	69	We should fight for Quebecan Independence	Quebec sovereignty movement
70	70	We should subsidize newspapers	Newspaper

Table 13: Train topics 51-70

#	Id	Topic Text	Main Concept
1	71	The freedom of speech is not absolute	Freedom of speech
2	72	We should criminalize blasphemy	Blasphemy
3	73	Holocaust denial should be a criminal offence	Holocaust denial
4	74	Television does more harm than good	Television
5	75	We should subsidize higher education	Higher education
6	76	We should ban organic food	Organic food
7	77	Urbanization does more harm than good	Urbanization
8	78	We should adopt direct democracy	Direct democracy
9	79	We should ban lotteries	Lottery
10	80	We should close the Guantanamo Bay detention camp	Guantanamo Bay detention camp
11	81	We should abandon the insanity plea	Insanity defense
12	82	We should protect coral reefs	Coral reef
13	83	We should disband NASA	NASA
14	84	We should abolish nuclear weapons	Nuclear weapon
15	85	We should cancel the speed limit	Speed limit
16	86	Randomized controlled trials bring more harm than good	Randomized controlled trial
17	87	Anarchism brings more good than harm	Anarchism
18	88	We should subsidize public service broadcasters	Public broadcasting
19	89	We should ban labor organizations	Trade union
20	90	Pride parades bring more harm than good	Pride parade
21	91	Paternity leave brings more harm than good	Parental leave
22	92	Tabloid journalism brings more harm than good	Tabloid journalism
23	93	We should disband UNESCO	UNESCO
24	94	We should disband the National Rifle Association	National Rifle Association
25	95	Second Life brought more harm than good	Second Life
26	96	Economic sanctions bring more harm than good	Economic sanctions
27	97	Vietnam War was justified	Vietnam War
28	98	Animal slaughter is not justified	Animal slaughter
29	99	We should raise the corporate tax	Corporate tax
30	100	Division of labor is a major threat	Division of labour

Table 14: Heldout topics

#	Id	Topic Text	Main Concept
1	101	Affirmative action brings more good than harm	Affirmative action
2	102	We should ban gambling	Gambling
3	103	We should abolish the monarchy	Monarchy
4	104	Atheism is the only way	Atheism
5	105	We should further exploit wind power	Wind power
6	106	We should legalize polygamy	Polygamy
7	107	We should further exploit hydroelectric dams	Hydroelectricity
8	108	We should privatize water supply	Water supply
9	109	We should legalize prostitution	Prostitution
10	110	Zoos bring more harm than good	Zoo
11	111	Private education brings more good than harm	Private school
12	112	Recall elections are beneficial	Recall election
13	113	We should further exploit nuclear power	Nuclear power
14	114	We should abolish temporary employment	Temporary work
15	115	Surrogacy should be banned	Surrogacy
16	116	Progressive tax is beneficial	Progressive tax
17	117	We should ban alcoholic beverages	Alcoholic drink
18	118	We should ban abortions	Abortion
19	119	Astrology brings more harm than good	Astrology
20	120	Embryonic stem cell research brings more good than harm	Embryonic stem cell
21	121	We should abolish the Olympic Games	Olympic Games
22	122	We should end athletic scholarships	Athletic scholarship
23	123	Social media does more harm than good	Social media
24	124	We should disband the United Nations Security Council	United Nations Security Council
25	125	We should legalize insider trading	Insider trading
26	126	We should prohibit hydraulic fracturing	Hydraulic fracturing
27	127	We should prohibit corporal punishment	Corporal punishment
28	128	We should disband NATO	NATO
29	129	We should abolish the two-party system	Two-party system
30	130	Capital punishment brings more harm than good	Capital punishment
31	131	We should abolish term limits	Term limit
32	132	We should protect whistleblowers	Whistleblower
33	133	Twitter brings more harm than good	Twitter
34	134	ISO brings more harm than good	International Organization for Standardization
35	135	Conscientious objectors are justified	Conscientious objector
36	136	The American Bar Association brings more harm than good	American Bar Association
37	137	Digital rights management brings more harm than good	Digital rights management
38	138	We should ban the Church of Scientology	Church of Scientology
39	139	eBay brings more good than harm	EBay
40	140	We should abolish the caste system in India	Caste system in India
41	141	We should abolish infant baptism	Infant baptism
42	142	EHRs bring more harm than good	Electronic health record
43	143	Wildlife management brings more good than harm	Wildlife management
44	144	We should tax plastic bags	Plastic bag
45	145	The energy industry should be nationalized	Energy industry
46	146	We should fight protectionism	Protectionism
47	147	We should limit genetic testing	Genetic testing
48	148	We should end manned spaceflights	Human spaceflight
49	149	Extra-curricular activity should be mandatory	Extracurricular activity
50	150	We should abolish homework	Homework

Abstract

Previous studies have shown that linguistic features of a word such as possession, genitive or other grammatical cases can be employed in word representations of a named entity recognition (NER) tagger to improve the performance for morphologically rich languages. However, these taggers require external morphological disambiguation (MD) tools to function which are hard to obtain or non-existent for many languages. In this work, we propose a model which alleviates the need for such disambiguators by jointly learning NER and MD taggers in languages for which one can provide a list of candidate morphological analyses. We show that this can be done independent of the morphological annotation schemes, which differ among languages. Our experiments employing three different model architectures that join these two tasks show that joint learning improves NER performance. Furthermore, the morphological disambiguator's performance is shown to be competitive.

Title and Abstract in Turkish

Biçimbilimsel Etiketleri Ayrıştırmayı Birlikte Öğrenerek Varlık İsmi Tanıma Başarısını Artırmak

Daha önceki çalışmalar, biçimbilimsel olarak zengin dillerdeki varlık ismi tanıma (VAT) başarısını artırmak için sözcüklerin iyelik, genitif ve benzeri hâllerinin kullanılabileceğini göstermiştir. Ancak, bu türden varlık ismi tanıma işaretleyicilerinin çalışabilmesi için elde edilmesi zor veya bazı diller için imkansız olan dışsal biçimbilimsel ayrıştırıcılara (BA) ihtiyaç vardır. Bu çalışmada, bu tür ayrıştırıcılara olan ihtiyacı ortadan kaldırmak için VAT ve BA görevlerini aynı anda çözen ve aday biçimbilimsel çözümlemelerin sunulabildiği dillere uygulanabilen bir model önerilmektedir. Bunun dillere göre değişen biçimbilimsel işaretleme şemalarından bağımsız olarak yapılabildiği gösterilmiştir. Bu iki görevi aynı anda gerçekleştiren üç farklı model mimarisi kullanarak yaptığımız deneyler birlikte öğrenmenin VAT başarısını artırdığını göstermiştir. Buna ek olarak, biçimbilimsel ayrıştırıcının başarısının önceki çalışmalarla karşılaştırılabilir olduğu görülmüştür.

1 Introduction

Named entity recognition (NER) is the task of selecting the portions of text which refer to an entity that designate a person, location or organization. This makes it a basic natural language processing (NLP) task closely related to relation extraction, knowledge base population, and entity linking.

Works that represent the current state of the art in NER generally start by representing words with pretrained word embeddings, embeddings which rely on surface form characters (Lample et al., 2016; Ma and Hovy, 2016). These architectures feed the word representations to a bidirectional long short-term memory layer (Bi-LSTM) to represent the context where the disambiguation between the possible entities is undertaken by decoding on trellis provided by a conditional random field (CRF) model.

Proceedings of the 27th International Conference on Computational Linguistics, pages 2082–2092
Santa Fe, New Mexico, USA, August 20-26, 2018.

When these models are trained and evaluated for morphologically rich languages (MRLs), it has been shown that using embeddings based on characters or linguistic properties of the word such as morphological features indicating a grammatical case improves the performance compared to using only pretrained word embeddings (Gungor et al., 2017). Even though they provide a better approach for MRLs, they require an external morphological disambiguator for every language of interest, a requirement which can be hard or even impossible for some languages to satisfy. This is especially true for agglutinative languages where there can be many roots and morphological tag sequences for a single word. Although there is an effort to provide a tool for POS tagging and lemmatization for many languages in a single format (Straka and Straková, 2017), it has been shown that there is a better approach for morphological tagging in terms of performance which can utilize the information in the context of the target word (Shen et al., 2016).

In this paper, we propose a model to jointly learn the NER and morphological disambiguation (MD) tasks to offer a solution to this problem. We design our model so that any language with a mechanism which can provide a number of candidate morphological analyses for a word can utilize our joint model. This is easier compared to providing disambiguated morphological analyses because systems that disambiguate morphological analyses are harder to build. Furthermore, we do not require the labels of each task to be present in the same dataset. One can easily train the part of the model which is responsible for the MD task in another -preferably larger- dataset and start with the pretrained model. Our main contribution is to show that jointly disambiguating morphological tags and predicting the NER tags results in an equivalent level of performance compared to using externally provided morphological tags.

We give a survey of related work on the subject in Section 2. We explain our basic models and the proposed joint models in Section 3. In Section 4, we describe our dataset which is derived from a frequently used database in the literature. After running the experiments described in Section 5, we observe that jointly training our model for NER and MD results in an increase in the NER performance.

2 Related Work

Early approaches to NER typically use several hand-crafted features such as capitalization, word length, gazetteer based features, and syntactic features (part-of-speech tags, chunk tags, etc.) (McCallum and Li, 2003; Finkel et al., 2005; Humphreys et al., 1998; Appelt et al., 1995). Some of them are data-driven approaches such as conditional random fields (CRF) (McCallum and Li, 2003; Finkel et al., 2005), maximum entropy (Borthwick, 1999), bootstrapping (Jiang and Zhai, 2007; Wu et al., 2009), latent semantic association (Guo et al., 2009), and decision trees (Szarvas et al., 2006).

Recently, RNN based sequence taggers have dominated the state of the art in NER (Lample et al., 2016; Ma and Hovy, 2016; Huang et al., 2015; Yang et al., 2016). These approaches model the words as fixed length vectors and employ Bi-LSTM or GRU layers to obtain a characterization of the relevant context of the word to be labeled. These context vectors are then transferred to a CRF module after transforming into score vectors. However, in these studies, the morphological information present in the surface form of the word is handled only through the use of character based embeddings. Although this is not a limiting factor for languages which are not morphologically rich, it has been shown that employing morphologically disambiguated tags when representing words in a neural architecture improves the NER performance (Gungor et al., 2017; Straková et al., 2016).

There has been other approaches to the NER task for morphologically rich languages (Demir and Özgür, 2014; Seker and Eryiğit, 2012; Yeniterzi, 2011; Tür et al., 2003; Hasan et al., 2009). A study which can be considered as one of the first attempts in tackling NER for morphologically rich languages uses a hidden Markov model and takes the morphological tag sequence as input along with others like the surface form, capitalization features and similar features (Tür et al., 2003). In a study which basically depends on handcrafted features given to a CRF-based sequence tagger system, the word morphology was captured using the first and last three characters of the word as a feature resulting in an improvement in the NER tagging performance for Bengali (Hasan et al., 2009). In another study (Yeniterzi, 2011), a similar approach is taken with features generated using the output of an external morphological disambiguator and also shown to improve the performance. Another study (Seker and Eryiğit, 2012) uses the

same method but with a different approach for extracting morphological information, where they show an improvement over the previous state of the art results of Yeniterzi (2011). The first study focusing on morphologically rich languages to employ neural networks (Demir and Özgür, 2014) contains a regularized averaged perceptron (Freund and Schapire, 1999) and relies on handcrafted rules along with pretrained word embeddings. However, they refrain from using output from external morphological disambiguators and only rely on the first and last few characters of a word as features. Our work in this paper differs from these studies as it does not rely on handcrafted features. We represent words as fixed length vectors, employ morphological information to disambiguate the correct morphological analysis, and then combine them in such a way to obtain a context vector to label with NER tags.

In a recent study on morphological disambiguation (Yildiz et al., 2016), the authors propose a two-layer network for prediction. In the first layer, they process the candidate morphological analyses along with the correctly predicted analyses of previous words and obtain a vector to be processed in the second layer. The second layer takes all vectors propagated from the previous words and computes a `softmax` function over positive and negative classes. They predict the correct morphological analysis starting from the first word and use this prediction in the next word positions. The model is evaluated on a dataset manually labeled by the authors and considered as the state of the art for Turkish and competitive for French and German. Our proposed model for morphological disambiguation relies on scoring the candidate morphological analyses to predict the correct one for a word in a sentence. We borrow this idea from Shen et al. (2016). In their study, they feed the word representations to a Bi-LSTM and obtain context embeddings for each position. Using these embeddings, they score each morphological analysis by calculating a similarity function reaching the state of the art or competitive results for Turkish, Russian and Arabic.

Most of the work in morphological disambiguation or tagging strictly depend on their chosen specific output format for morphological analysis. This is due to the fragmented nature of computational approaches to morphological analysis for every language in the literature. However, we argue that our approach is immune to this problem as all of these output formats can be treated as a sequence. An example from Finnish is '`raha+[POS=NOUN]+[NUM=SG]+[CASE=ADE]`' (Silfverberg et al., 2016), another from Turkish is '`Ankara+Noun+Prop+A3sg+Pnon+Loc`' (Oflazer, 1994), and one for Hungarian is '`hír+NOUN+Case=Nom+Number=Plur`' (Trón et al., 2005). All of these can be split by the '+' symbol and transformed into a root and tag sequence. Moreover, there is an attempt in the area to unify the morphological annotation along with syntax annotation across many languages which will contribute more towards a solution (Nivre et al., 2016).

Many models targeting NLP tasks are designed to work independently although they usually employ linguistic information related with other tasks. Given that there are state of the art models which are similar in the sense that they all employ a sentence level Bi-LSTM, it is reasonable to hypothesize that jointly learning several tasks will improve the performance as shown in the literature (Hashimoto et al., 2017; Luong et al., 2015). In a recent study, it has been suggested that using separate layers for separate tasks is better rather than using the same (or usually top) layer for all the tasks (Søgaard and Goldberg, 2016).

3 Models

We test our hypothesis by training a number of models where we choose to enable or disable the selected components and features[1]. We start by explaining two basic models for each task: (i) a Bi-LSTM based sequence tagger where we predict the correct NER tags with a CRF (Section 3.1), (ii) a Bi-LSTM tagger which is used to represent the context for selecting the correct morphological analysis at the given position (Section 3.2). The joint models are combinations of these two basic models in various ways (Section 3.3).

[1]The code to replicate the experiment environment and the actual source code is published at `https://github.com/onurgu/joint-ner-and-md-tagger`

3.1 NER Model

We formally define an input sentence as $X = (x_1, x_2, \ldots, x_n)$ where each x_i is a vector of size l and the corresponding NER labels as $y_{\text{NER}} = (y_{\text{NER},1}, y_{\text{NER},2}, \ldots, y_{\text{NER},n})$. x_i are then fed to a Bi-LSTM which is composed of two LSTMs (Hochreiter and Schmidhuber, 1997) treating the input forwards and backwards. The output of this Bi-LSTM at position i, h_i, is a vector of size $2p$ where p is the size of the LSTM cell. Further, we transform h_i through a fully connected layer $\texttt{FC}_{last}$ with $\texttt{tanh}$ activations at the output to combine the left and right contexts into a vector of size p. This is followed by another fully connected layer to obtain a vector s_i of size K, where K is the number of the NER tags.

We follow a conditional random field (CRF) based approach to model the dependencies between the consequent tokens (Lafferty et al., 2001). To do this, we take the vector s_i at each position i as the score vector of the corresponding word and aim to minimize the following loss function $\texttt{loss}_{\text{NER}}(X, y_{\text{NER}})$ for a single sample sentence X:

$$-\sum_{i=0}^{n} A_{y_i, y_{i+1}} - \sum_{i=1}^{n} s_{i,y_i} + logZ(X)$$

where $A_{i,j}$ represents the score of a transition from tag i to j, $Z(X) = \sum_{y' \in \mathbb{Y}} \texttt{exp}\left(\sum_{i=0}^{n} A_{y_i, y'_{i+1}} + \sum_{i=1}^{n} s_{i,y'_i}\right)$ where $\mathbb{Y}$ is the set of all possible label sequences. Using this model, we decode the most probable tagging sequence y^*_{NER} as $\text{argmax}_{\tilde{y}_{\text{NER}}} \texttt{loss}_{\text{NER}}(X, \tilde{y}_{\text{NER}})$. We call this basic model the NER model (Lample et al., 2016) (see Figure 2).

In the remaining part of the section, we explain the details of the word representations used in this study.

Representing words. As the default setting, we obtain word and character based embeddings as described below and combine them by concatenation. For the first component, we allocate a word embedding vector of size w_d for every word in our dataset. This can be loaded from a pretrained word embeddings database as is done frequently in the literature, but we chose to learn the word embeddings during training. The second component is generated from the surface forms. We feed the character sequence of the word into a Bi-LSTM as described at the beginning of this section. However, instead of using the outputs of LSTM cells at each position, we just take the last and the first cell outputs of the forward and backward LSTMs and concatenate them (Figure 1). The resulting representation is two times the length of one character embedding length, $2\texttt{ch}_d$. This second component is in turn concatenated with the first component to obtain a word representation vector x_i of size $w_d + 2\texttt{ch}_d$.

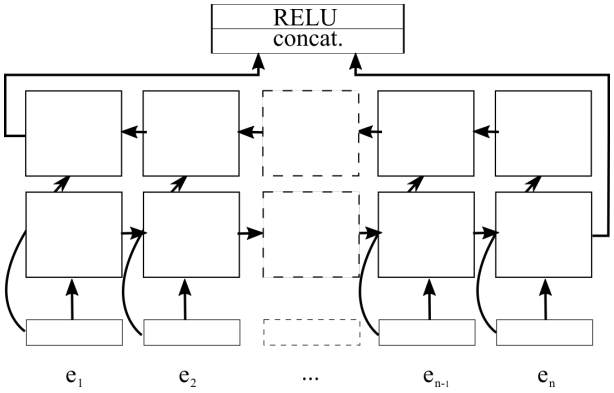

Figure 1: The basic model to generate representations for surface forms, roots, and morphological tag sequences. The input sequence $(e_1, e_2, \cdots, e_{n-1}, e_n)$ can either be the characters of the surface form, the characters of the root of the word, or the tags in the morphological tag sequence. RELU unit is active only for root and morphological tag sequences.

External morphological features. In order to compare our models with a previous method (Gungor et al., 2017), we utilize the golden morphological analysis provided with the dataset in addi-

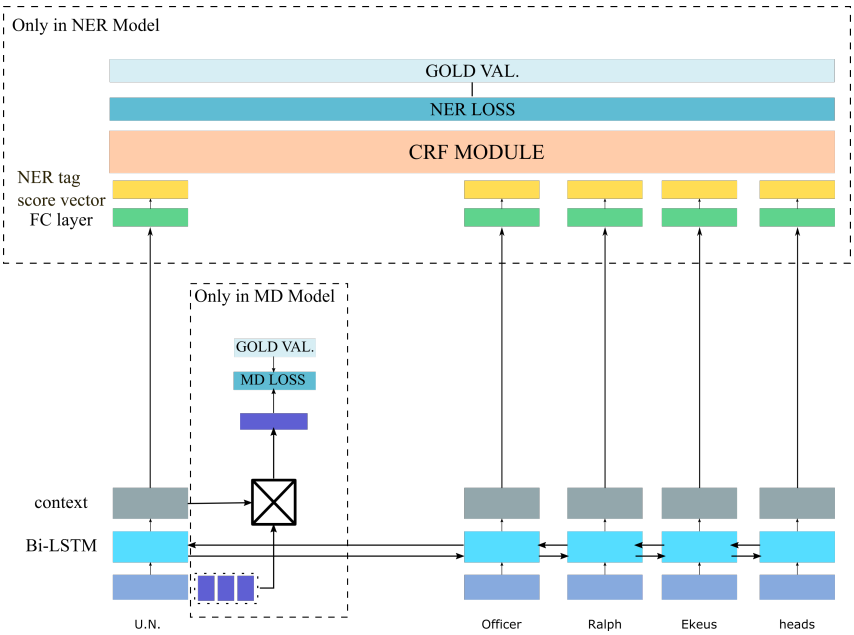

Figure 2: Our basic models: NER and MD. The portions of the model which are only active either for NER or MD models are indicated with dashed lines. The symbol ⊠ represents the selection of $\texttt{ma}_{ij^*}$.

tion to the word and character based embeddings and call this model EXT_M_FEAT. The best approach reported by Gungor et al. (2017) treats the string form of a morphological analysis as a sequence of characters and apply the process depicted in Figure 1. For example, a morphological analysis in Hungarian is '`Magyar+PROPN+Case=Nom+Number=Sing`' in string form and can be split into a list of characters as `(M,a,g,y,a,r,+,P,R,O,P,N,+,C,a,s,e,=,N,o,m,+,N,u,m,b,e,r,=,S,i,n,g)`. Using the sequence of characters of the morphological analysis instead of the sequence of morphemes might seem counterintuitive at first glance. However it has been argued that a benefit of treating morphological analyses as sequences of characters is the information conveyed by the characters within the tags. For example, in Turkish, the tags '`A3sg`' and '`A3pl`' indicate third person singular and third person plural where the leading two characters '`A3`' indicate third person agreement. This allows the model to represent the fragments of the tags which may improve the training performance. In this case, '`A3`' would represent the third person agreement independent of the singular or plural case. The resulting vector representation is thus of length $2\texttt{mt}_d$ which is added to word and character based embeddings to obtain a word representation of $w_d + 2\texttt{ch}_d + 2\texttt{mt}_d$.

3.2 MD Model

In this section, we describe our model for morphological disambiguation which is based on (Shen et al., 2016). In this model, we are given a sentence X in the same form as in the NER task, however we optimize the model to predict y_{MD} where $y_{\text{MD},i}$ represents the correct morphological analysis out of the candidate morphological analyses for word i. Like in the NER model, the MD model also employs a Bi-LSTM layer to obtain context representations when fed with the word representations x_i (Figure 2). We define the candidate morphological analyses for word i as $\texttt{ma}_i = \{\texttt{ma}_{i,1}, \texttt{ma}_{i,2}, \cdots, \texttt{ma}_{i,j}, \cdots, \texttt{ma}_{i,K}\}$. To determine the correct morphological analysis, we examine each morphological analysis output form to extract the root surface form and the morpheme sequence and generate the representation $\texttt{ma}_{ij}$ which we explain below.

We design this approach to be generalizable to many morphological analysis output forms described in Section 2. We give an example from Turkish here: the unique analysis of the Turkish word "Moda'da" is "`Moda+Noun+Prop+A3sg+Pnon+Loc`". The word literally means 'in Moda' (which is a district in Istanbul) and a common morpheme naming convention is used (Oflazer, 1994). So, we determine the root as 'Moda' and the morpheme sequence as '`(Noun, Prop, A3sg, Pnon, Loc)`'. The root

and the morpheme sequence are used to generate a representation as depicted in Figure 1. Except in this case the RELU activation function (Nair and Hinton, 2010) is also applied to the concatenation of the root and morpheme sequence representations. We choose the resulting representations r_{ij} and $\texttt{ms}_{ij}$ to be of two times the length of a morpheme embedding $\texttt{mt}_d$. Furthermore, we add the root representation vector r_{ij} and the morpheme sequence representation vector $\texttt{ms}_{ij}$ and apply hyperbolic tangent function ($\texttt{tanh}$), thus the morphological analysis representation $\texttt{ma}_{ij}$ is defined as follows $\texttt{tanh}(r_{ij} + \texttt{ms}_{ij})$.

We then select the morphological analysis ma_{ij^*} by performing a dot product with the context vector h_i: $\texttt{ma}_{ij^*} = \text{argmax}_j\, h_i \cdot \texttt{ma}_{ij}$ when decoding. During training, the loss $\texttt{loss}_{\text{MD}}(X, y_{\text{MD}})$ is calculated as

$$-\sum_{i=1}^{n} \texttt{log softmax}(\texttt{mscore}_i)$$

over a score vector $\texttt{mscore}_i$ such that $\texttt{mscore}_{ij} = \{h_i \cdot \texttt{ma}_{ij}\}$.

3.3 Joint model for NER and MD

We have experimented with three approaches for jointly learning NER and MD tasks. In this section, we explain the details of each approach.

Integration mode 1 - In this scheme, we employ a Bi-LSTM layer which is fed with word representations as in the basic models, NER and MD. We then use the same context h_i to calculate the losses separately for NER and MD as explained in Sections 3.1 and 3.2. We call this joint model JOINT1 and show in Figure 3a. We then learn the model parameters to optimize $\texttt{loss}_{\text{JOINT1}}$

$$\texttt{loss}_{\text{NER}}(X, y_{\text{NER}}) + \texttt{loss}_{\text{MD}}(X, y_{\text{MD}}).$$

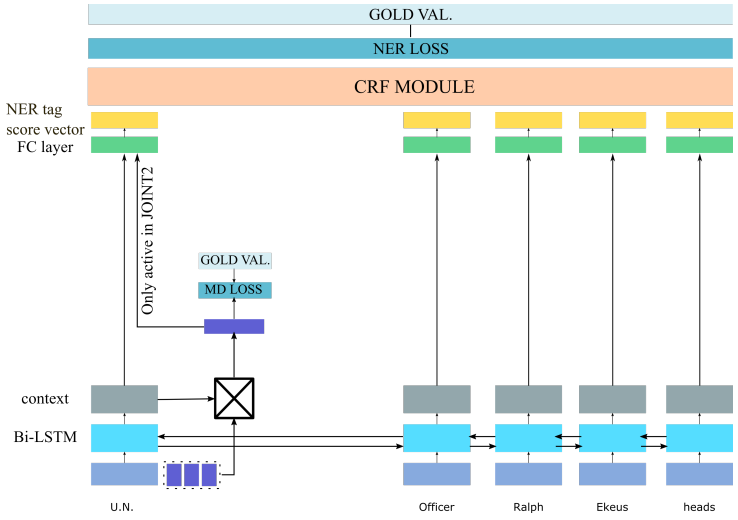
Integration mode 2 - As in the JOINT1 model, this model also calculates separate losses for each task and sums them to obtain a single loss to optimize. However, we additionally concatenate the selected morphological analysis representation $\texttt{ma}_{ij^*}$ to h_i before feeding it into the fully connected network with $\texttt{tanh}$ outputs as described in Section 3.1. The model is shown in Figure 3a. The rationale of this concatenation is to facilitate information flow from the disambiguated morphological analysis. We call this model JOINT2. The loss function $\texttt{loss}_{\text{JOINT2}}$ of this model is then calculated similar to $\texttt{loss}_{\text{JOINT1}}$.

Multilayer and Shortcut Connections. Our most complicated model is employing three Bi-LSTM layers instead of only one. We basically feed the output of the first layer h_i^1 to layer 2, the output of the second layer h_i^2 to layer 3. In addition to this, we transfer the word representation x_i to all layer inputs and concatenate with h_i^{level} to obtain $\overline{h}_i^{level}$. When processing to obtain the third layer's output $\overline{h}_i^3$, we also concatenate the selected morphological analysis representation $\texttt{ma}_{ij^*}$ to h_i^3 in addition to x_i. This is done to propagate the information gained from the disambiguated morphological analysis to the last layer of the network. We use the first layer's output h_i^1 when calculating $\texttt{mscore}_i$ as shown to be better for a variety of tasks (Hashimoto et al., 2017). We call this model J_MULTI and depict in Figure 3b.

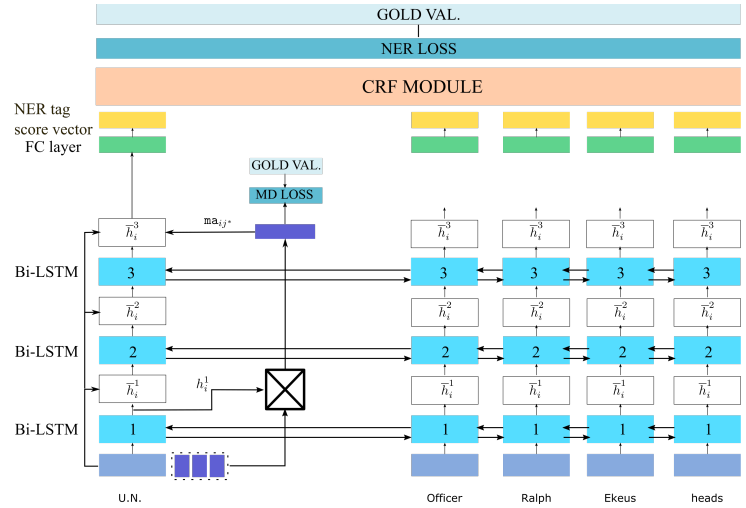
4 Data

To test our proposed model, we derived a new dataset based on a dataset commonly used in the literature for the NER task for Turkish (Tür et al., 2003). This dataset contains sentences from the online edition of a Turkish national newspaper with NER labels. The creators of the dataset also provide a golden morphological analysis along with each word. However, golden morphological analyses in this dataset are sometimes erroneous. For example, words which are inflections of foreign words are usually problematic. An example is "Hillary'nin" which is the genitive case for the word "Hillary". It has been incorrectly labeled as if it is in nominal case. Also, when the surface form is a number in some noun case, like "98'e" which is the dative case for the number ninety eight, the morphological analysis is almost always nominal. We believe the reason for this is the incorrect handling of the quote character when preparing the original version.

In our study, we have first divided the training portion of the original dataset into training and development sets. We then augmented these portions using candidate morphological analyses for each word



(a) (i) Model JOINT1: two losses for two tasks sharing a Bi-LSTM. (ii) Model JOINT2: We concatenate the selected morphological analysis' vector representation to the last layer's context vector.



(b) Model J_MULTI: We employ shortcut connections and two more Bi-LSTM layers.

Figure 3: Our joint models: (a) JOINT1 and JOINT2 models (b) J_MULTI model. The symbol ⊠ represents the selection of $\mathtt{ma}_{ij^*}$.

with a commonly used morphological analyzer (Oflazer, 1994). Unfortunately, the golden morphological analyses in about 5% of the word tokens were not found in these candidate analyses. To mitigate this issue, we listed the most frequent contexts where a specific mismatch happens, selected the most suitable morphological analysis out of the candidates for each context, thus providing a solution to the mismatch. We then automatically corrected all contexts with a mismatch which has a solution in our solution database. Although we tried to give the utmost attention to selecting the best solution, some of our solutions might be problematic. Thus, we share the data, the scripts and the tool which helps the user to select a solution as described for academic use and examination[2]. Unfortunately, there were still left a few hundred mismatches. As providing a solution for them required a lot of manual work and would only save 1-2 sentences for each, we just removed any sentence that contains any of these mismatches. This way, we have retained 25511 out of 28835 sentences in the original dataset for training, 2953 of 3336 for development and 2913 of 3328 for test. By this process, despite losing some of the sentences,

[2]The data can be found at `https://github.com/onurgu/joint-ner-and-md-tagger`

we have built a new dataset with both the NER labels and the candidate morphological analyses which have correct golden labels.

4.1 Training

We implemented the model using the DyNet Neural Network Toolkit in Python. The model parameters are basically the word embeddings, the parameters of Bi-LSTMs, the weights of the fully connected layer $\texttt{FC}_{last}$, and the CRF transition matrix A. We trained by calculating the gradients of the loss for a batch of five sentences consisting of surface forms and its associated NER and/or MD labels and updated the parameters with Adam (Kingma and Ba, 2014) for 50 epochs and reported the performance on test set of the model with the highest development set performance. We applied dropout (Srivastava et al., 2014) with probability 0.5 to the word representations x_i. To facilitate the reproducibility of our work, we also provide our system as a virtual environment[3] that provides the same environment on which we evaluated our system in an open manner.

5 Results

To test our approach, we train and evaluate every model for 10 times and report the mean F1-measure value for named entity recognition and accuracy for morphological disambiguation. This is done to decrease the potential negative effects of random initialization of model parameters as shown in the literature (Reimers and Gurevych, 2017). To accomplish this given our limited computing resources, we set the parameter dimension sizes to 10 and do not employ pretrained word embeddings.

The results are shown in Table 1. We see that the mean NER performance increases in joint models. We see that the JOINT2 model is performing better than just calculating two losses at the last layer as we did in the JOINT1 model. However, applying the Welch's t-test between the JOINT1 and JOINT2 runs does not strongly imply this difference ($p = .24$). Adding multiple Bi-LSTM layers to JOINT2 and obtaining J_MULTI also helped and achieved the best score among our joint models[4]. Employing Welch's t-test confirms the significance of this difference with other joint models, $p < .05$ for each pair.

Table 1: Evaluation of our models for NER performance with our dataset. We report F1-measure results over the test portion of our dataset averaged over 10 replications of the training with the same hyper parameters.

To make a comparison with a previous method (Gungor et al., 2017), we also evaluated a model where the golden morphological analysis in the corpus is represented as a vector and included in the word representation x_i, namely EXT_M_FEAT (see Section 3.1). As one can see from the table, it achieved the best results compared to our joint models. However, we cannot confirm the difference between EXT_M_FEAT and J_MULTI models as the calculated p is well above .05. Thus our best performing model J_MULTI is performing at a competitive level with an additional advantage of disambiguating the morphological tags while predicting the NER tags. This also serves as another confirmation to the

[3] You can obtain our implementation and find more information about how to use our virtual environment at `https://github.com/onurgu/joint-ner-and-md-tagger`.

[4] One can wonder whether this performance improvement could be due to an increase in the total number of parameters of the model. We saw that the increase is negligible as it only accounted for a 2% increase.

hypothesis that employing linguistic information such as morphological features leads to an increase in the NER performance.

Table 2: Evaluation of our models for MD performance. As in the NER evaluation, we report accuracies over the test dataset averaged over 10 replications of the training.

To evaluate the performance of morphological disambiguation, we have tested the MD performance of our models, which are trained with the training portion of our dataset, on the test portion of a frequently used dataset (Yuret and Türe, 2006). As can be seen from Table 2, we are very close to the state of the art MD performance even if we only trained with a low number of parameters as stated in the beginning of this section. We have to also note that in contrast with the NER task, the MD task did not enjoy a performance increase from joint learning. The mean morphological disambiguation accuracies for the test portion of our dataset also suggests the same, all hovering around 77% without much change. This might be due to the fact that NER can utilize the disambiguated morphological analysis of a word to predict the correct label, however a correctly predicted NER label does not contribute to the disambiguation of the word's morphology.

6 Conclusions

In this work, we propose a joint model of NER and MD tasks that removes the need for external morphological disambiguators. The method is applicable to every language given that one can provide the candidate morphological analyses for a word, making this approach portable to many languages. We have also shown that joint learning leads to an increase in the NER tagging performance. However, there is more work to do as we are still bound to language specific tools in obtaining the list of candidate morphological analyses. Generating the list of candidate analyses within the model, testing our hypothesis on other morphologically rich languages, and testing with models which have higher number of parameters are left for future work.

Abstract

Question answering over knowledge graphs is an important problem of interest both commercially and academically. There is substantial interest in the class of natural language questions that can be answered via the lookup of a single fact, driven by the availability of the popular SIMPLEQUESTIONS dataset. The problem with this dataset, however, is that answer triples are provided from Freebase, which has been defunct for several years. As a result, it is difficult to build "real-world" question answering systems that are operationally deployable. Furthermore, a defunct knowledge graph means that much of the infrastructure for querying, browsing, and manipulating triples no longer exists. To address this problem, we present SIMPLEDBPEDIAQA, a new benchmark dataset for simple question answering over knowledge graphs that was created by mapping SIMPLEQUESTIONS entities and predicates from Freebase to DBpedia. Although this mapping is conceptually straightforward, there are a number of nuances that make the task non-trivial, owing to the different conceptual organizations of the two knowledge graphs. To lay the foundation for future research using this dataset, we leverage recent work to provide simple yet strong baselines with and without neural networks.

1 Introduction

Question answering over knowledge graphs is an important problem at the intersection of multiple research communities, with many commercial deployments. To ensure continued progress, it is important that open and relevant benchmarks are available to support the comparison of various techniques. In this paper, we focus on the class of questions that can be answered by a single triple (i.e., fact) from a knowledge graph. For example, the question "What type of music is on the album Phenomenon?" can be answered via the lookup of a simple fact—in this case, the "genre" property of the entity "Phenomenon". Analysis of an existing benchmark dataset (Yao, 2015) and real-world user questions (Dai et al., 2016; Ture and Jojic, 2017) show that such questions cover a broad range of users' needs.

The SIMPLEQUESTIONS dataset (Bordes et al., 2015) has emerged as the de facto benchmark for evaluating these simple questions over knowledge graphs. However, there is one major deficiency with this resource: the answers draw from Freebase. Unfortunately, Freebase is defunct and no longer maintained. This creates a number of insurmountable challenges: First, because the knowledge graph is stale, it is no longer possible to build a "real-world" operational QA system using models trained on SIMPLEQUESTIONS. Second, a defunct knowledge graph means that researchers must develop custom infrastructure for querying, browsing, and manipulating the graph. Thus, we are not able to leverage multiple cooperative and interchangeable service APIs that are deployed and maintained by different parties—which is the strength of the broader "open linked data" ecosystem. While it may be the case that one can apply transfer learning so that models trained on SIMPLEQUESTIONS can be re-targeted to another "live" knowledge graph, we are not aware of research along these lines.

*These authors contributed equally.

Dataset	Training	Validation	Test	Total
SIMPLEQUESTIONS	75,910	10,845	21,687	**108,442**
SIMPLEDBPEDIAQA	30,186	4,305	8,595	**43,086**

Table 1: Statistics of SIMPLEQUESTIONS and SIMPLEDBPEDIAQA.

To address these issues, we present SIMPLEDBPEDIAQA, a new dataset that we have created by mapping entities and predicates that comprise the answers to SIMPLEQUESTIONS from Freebase to DBpedia. Unlike Freebase, DBpedia is actively maintained by a dedicated community. We describe how this dataset migration is accomplished via high-quality alignments between entities in the two different knowledge graphs, and explain many of the nuances that make the creation of this dataset non-trivial. Our new dataset includes a total of 43,086 questions and corresponding answers that cover 40% of the original dataset. Summary statistics of SIMPLEDBPEDIAQA and SIMPLEQUESTIONS are shown in Table 1. The complete dataset is available at https://github.com/castorini/SimpleDBpediaQA.

In addition to the contribution of providing the community with a new evaluation resource, we provide a series of simple yet strong baselines to lay the foundation for future work. These baselines include neural network models and other techniques that do not take advantage of neural networks, building on recently-published work (Mohammed et al., 2018). An additional contribution of this paper is that having two parallel datasets allows us to examine the effects of different conceptual organizations and knowledge graph structures: For example, we notice that many single-fact triples in Freebase require two-hop traversals in the DBpedia knowledge graph, which makes them no longer "simple" questions. Finally, evaluation resources targeting different conceptual organizations of knowledge help "keep researchers honest" in guarding against model overfitting on a single dataset.

2 Background and Related Work

The development and continual advance of question answering techniques over knowledge graphs require benchmark datasets that cover different aspects of the task. Quite obviously, each dataset has to target one (or more) knowledge graphs, which means that the structure of the answers are dictated by the conceptual organization of the particular knowledge graph.

Over the years, researchers have built a number of datasets based on Freebase (Bollacker et al., 2008). For instance, FREE917 (Cai and Yates, 2013) contains 917 questions involving 635 distinct Freebase predicates. WEBQUESTIONS (Berant et al., 2013) contains 5,810 question-answer pairs collected using the Google Suggest API and manually answered using Amazon Mechanical Turk (AMT). Both contain answers that require complex, multi-hop traversals of the knowledge graph. In contrast, the SIMPLEQUESTIONS dataset focuses on questions that can be answered via the lookup of a single fact (i.e., triple). Due to its much larger size and thus support for data-hungry machine learning techniques, this dataset has gained great popularity with researchers. Unfortunately, Google shut down Freebase in 2015; a final snapshot of the knowledge graph is still available online for download, but the associated APIs are no longer available.

Like Freebase, DBpedia (Bizer et al., 2009) has also been used as the target knowledge graph for multiple question answering datasets. For example, QALD[1] (Question Answering over Linked Data) is a series of evaluation campaigns focused on question answering over linked data. LC-QUAD (Trivedi et al., 2017) is another recent dataset that comprises 5,000 questions with answers in the form of SPARQL queries over DBpedia. These questions are relatively complex and require the integration of evidence from multiple triples. However, a more recent analysis by Singh et al. (2018) found that only 3,252 of the questions returned answers using the provided queries.

We are not the first to attempt to migrate SIMPLEQUESTIONS to another knowledge graph. Diefenbach et al. (2017) mapped the dataset from Freebase to Wikidata.[2] However, our migrated SIMPLE-

[1] https://qald.sebastianwalter.org/

[2] https://www.wikidata.org/wiki/Wikidata:Main_Page

DBPEDIAQA dataset has roughly twice the number of mapped questions. DBpedia is generally considered to be more mature than Wikidata due to its longer history, and thus we believe targeting DBpedia will ultimately yield higher-impact applications.

3 Problem Definition

We begin with a formal definition of our problem. Some preliminaries: Let $E = \{e_1, e_2, \cdots, e_r\}$ be a set of entities, where e_i is a Uniform Resource Identifier (URI) uniquely identifying each entity. Let $P = \{p_1, p_2, \cdots, p_s\}$ be a set of predicates. Let $S \subseteq E$ be a set of subjects and $O \subseteq (L \cup E)$ be a set of objects, where L is a set of literals. In this context, $t = (s, p, o)$ denotes a Resource Description Framework (RDF) triple, comprised of a subject $s \in S$, a predicate $p \in P$, and an object $o \in O$.

Given this formalism, Freebase (Bollacker et al., 2008) represents a specific knowledge graph T^b, where $T^b = \{t_1^b, \cdots, t_m^b\}$ (i.e., a set of Freebase triples). Each Freebase entity is uniquely identified by a MID (Machine ID). Similarly, DBpedia (Bizer et al., 2009) represents another knowledge graph T^d, where $T^d = \{t_1^d, \cdots, t_n^d\}$.

The SIMPLEQUESTIONS dataset is a collection of natural language questions and answers based on Freebase. Formally, $Q^b = \{q_1^b, \cdots, q_l^b\}$, where $q_i^b = (\mathcal{Q}_i, t_j^b)$; $\mathcal{Q}_i$ is a natural language question and $t_j^b \in T^b$ is a Freebase triple that supplies the answer to that question.

For example, the question "Who wrote The New Canada?" has the following answer triple:

(fb:m/02qtvzv, fb:book/written_work/author, fb:m/01hxz2)

where fb stands for the prefix http://www.freebase.com/. The subject of the above answer triple is referred to as the topic entity, and the object of the triple is referred to as the answer entity. To answer the natural language question, a system must correctly identify the topic entity and the predicate, and then consult the knowledge graph to look up the answer entity.

Given Freebase T^b, DBpedia T^d, and SIMPLEQUESTIONS Q^b, our problem can be formally defined as follows: for each $q_i^b = (\mathcal{Q}_i, t_j^b) \in Q^b$, find $q_i^d = (\mathcal{Q}_i, t_k^d)$, where $t_k^d \in T^d$ is a DBpedia triple, such that t_j^b is semantically equivalent to t_k^d. The result $Q^d = \{q_1^d, \cdots, q_l^d\}$ is our SIMPLEDBPEDIAQA dataset. Although this characterizes the basic structure of the problem, there are a number of nuances that deviate from this formalism, which we describe in the following sections.

4 Dataset Migration

Our overall strategy for dataset migration breaks down into the following steps: entity mapping, predicate mapping, and candidate refinement. At a high level, we begin by first mapping the topic and answer entities from Freebase to DBpedia; these then serve as anchors from which we can project the Freebase predicates to DBpedia. To assist in the process, we ingest the knowledge graphs into an RDF store to facilitate querying via SPARQL. For this effort, we use the latest version of DBpedia released in 2017.[3]

4.1 Entity Mapping

The first step is to map Freebase entities from SIMPLEQUESTIONS to entities in DBpedia. Freebase MIDs and DBpedia URIs are linked through the predicate http://www.w3.org/2002/07/owl#sameAs; these official mappings are released as part of DBpedia.[4] For each Freebase entity MID (topic entity or answer entity), we issue a SPARQL query to retrieve the corresponding DBpedia URI. For example, Justin Trudeau, the current Prime Minister of Canada, is mapped via the triple:

(dbr:Justin_Trudeau, http://www.w3.org/2002/07/owl#sameAs, fb:m/02b5jh).

Here and throughout the paper we use dbr as the DBpedia prefix for http://dbpedia.org/resource/. For approximately 56% of questions in SIMPLEQUESTIONS, we can map both the topic entity and the answer entity from Freebase to DBpedia. For the remaining questions, we are only able to map the topic entity, the answer entity, or neither. The detailed breakdowns are shown in Table 2.

[3] https://wiki.dbpedia.org/develop/datasets/dbpedia-version-2016-10

[4] http://downloads.dbpedia.org/2016-10/core-i18n/en/freebase_links_en.ttl.bz2

Note that the URI for Justin Trudeau can be used to uniquely identify this entity within the broader open linked data ecosystem. For example, a human-readable version of facts associated with this individual is located at http://dbpedia.org/page/Justin_Trudeau. This, as well as a variety of other libraries, toolkits, APIs, etc. provide infrastructure that simplifies the development of operational question answering systems. The existence of these resources illustrates one of the major benefits of migrating SIMPLEQUESTIONS over to a knowledge graph that is actively maintained by a dedicated community.

4.2 Predicate Mapping: One-Hop Predicates

Let us consider the case where we are able to map both the topic entity and the answer entity from Freebase to DBpedia. We can then issue a SPARQL query over DBpedia to enumerate the paths (sequence of one or more predicates) connecting those entities. In the simplest case, there is a single predicate connecting the topic entity to the answer entity, which yields a straightforward mapping of the triple from Freebase to DBpedia. This occurs for approximately half of the questions with successfully mapped topic and answer entities; see detailed statistics in Table 2.

Consider the question "Which city is McCormick Field in?" The Freebase topic entity fb:m/05_xgn is mapped to DBpedia as dbr:McCormick_Field and the answer entity is mapped from fb:m/0ydpd to dbr:Asheville,_North_Carolina. The DBpedia predicate dbo:location connects those two entities, which provides a valid and correct mapping for the Freebase predicate fb:location/location/containedby. Here and throughout the paper we use dbo as the DBpedia prefix for http://dbpedia.org/ontology/.

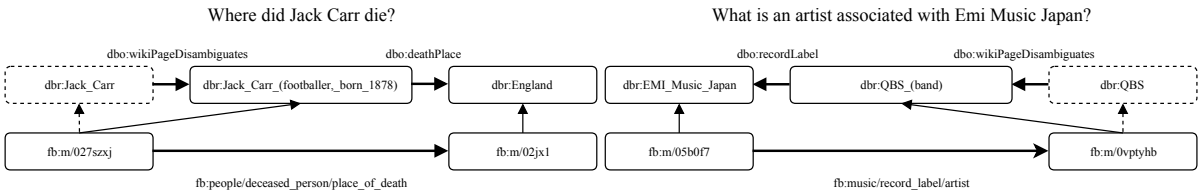
Due to differences in the conceptual organization of the two knowledge graphs, the directionality of equivalent predicates in Freebase and DBpedia may differ. For example, the DBpedia predicate dbo:birthPlace takes a person as the subject and a location as the object, whereas the equivalent predicate in Freebase fb:location/location/people_born_here inverts the subject and object. Therefore, for a question such as "Who was born in Aguascalientes?", the subject in the Freebase triple becomes the object in the DBpedia triple.

During the migration from Freebase to DBpedia, if the directionality of the mapped predicate is the same, we refer to the result as a forward predicate; if the directionality is reversed, we refer to the result as a backward predicate. We explicitly keep track of this metadata, which is necessary for the actual question answering task.

4.3 Predicate Mapping: Two-Hop Predicates

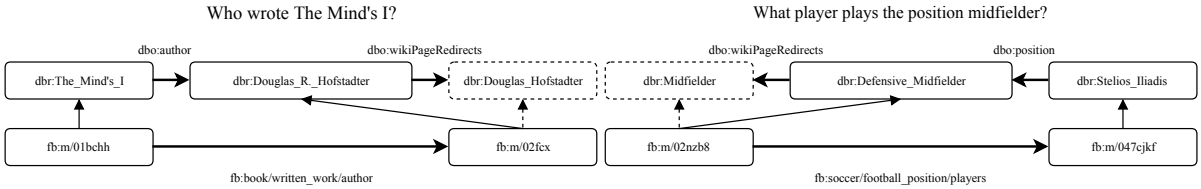
Next, we consider the more complex case where the topic entity and the answer entity are *not* directly connected by a single predicate in DBpedia. That is, the results of our SPARQL query over DBpedia to enumerate the paths connecting the mapped entities contain multiple hops. In this work, we only consider two-hop traversals, as even longer paths are generally rare and spurious. These two-hop predicates can be categorized into *disambiguation predicates*, *redirection predicates*, *complex predicates*, and *missing predicates*, detailed as follows:

- *Disambiguation Predicates*: DBpedia uses wikiPageDisambiguates predicates to disambiguate different entities with the same name. The DBpedia sameAs links, however, might map a Freebase MID to an ambiguous URI, thus yielding a two-hop traversal from the topic entity to the answer entity. In these cases, we can "compress" the path back into a single predicate by changing the original topic entity to the disambiguated entity. Note that this disambiguation process can occur with forward predicates, as in Figure 1a, where dbr:Jack_Carr is disambiguated to dbr:Jack_Carr_(footballer,_born_1878), as well as backward predicates, as in Figure 1b, where dbr:QBS is disambiguated to dbr:QBS_(band).
- *Redirections Predicates*: Similar to disambiguation links, DBpedia uses wikiPageRedirects predicates to redirect an entity to another entity (typically, the canonical variant of that entity). As with disambiguation predicates above, these two-hop redirection predicates can also be compressed into a single triple. For example, dbr:Douglas_Hofstadter is redirected back to dbr:Douglas_R._Hofstadter and dbr:Midfielder is redirected back to dbr:Defensive_Midfielder, as shown in Figure 2a and Figure 2b, respectively. Once again, this can occur with both forward and backward predicates.



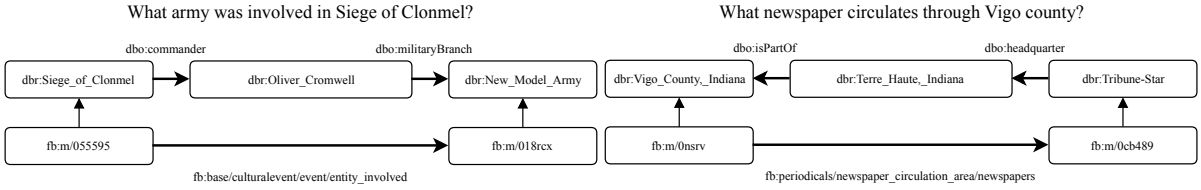
(a) Forward Predicate (b) Backward Predicate

Figure 1: Examples of mapping disambiguation predicates from Freebase to DBpedia.



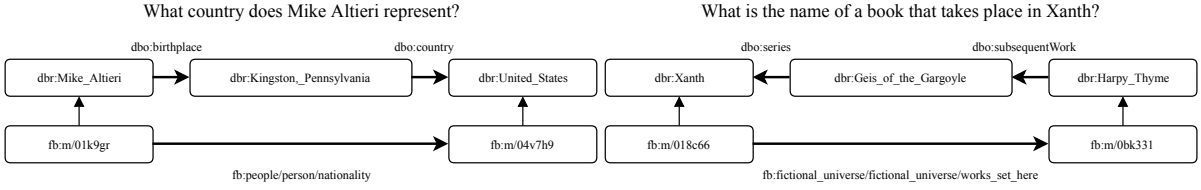
(a) Forward Predicate (b) Backward Predicate

Figure 2: Examples of mapping redirection predicates from Freebase to DBpedia.



(a) Forward Predicate (b) Backward Predicate

Figure 3: Examples of mapping complex predicates from Freebase to DBpedia.



(a) Forward Predicate (b) Backward Predicate

Figure 4: Examples of missing predicates in DBpedia.

- *Complex Predicates*: Due to differences in the conceptual organization of Freebase and DBpedia, there is no direct equivalent in DBpedia for some Freebase predicates. Instead, a chain of two predicates is necessary to capture the relationship between the topic and answer entities. An example is shown in Figure 3a: the question "What army was involved in Siege of Clonmel?" can be answered using the Freebase predicate fb:base/culturalevent/event/entity_involved, but in DBpedia the same fact requires a chain of two predicates, dbo:commander and dbo:militaryBranch. Note that this can also occur with backward predicates, as shown in Figure 3b.
- *Missing Predicates*: Some questions in DBpedia are answered using two-hop predicates even though there exists a one-hop predicate in the knowledge graph that represents a better mapping; this situation arises due to the incompleteness of DBpedia. Note that missing predicates actually represent a special case of complex predicates, which we only discovered by manual examination of the predicate mapping results. Nevertheless, it seems appropriate to separately categorize this particular type of predicate mismatch between Freebase and DBpedia. An example is shown in Figure 4a: The entity dbr:Mike_Altieri should have a predicate dbo:nationality that directly links to dbr:United_States, as is typical of person entities. However, since this predicate is missing, our SPARQL query discovered a roundabout path via dbo:birthplace then dbo:country. Figure 4b shows a similar case involving a backward predicate, where the entity dbr:Harpy_Thyme should have a predicate dbo:series that directly links to dbr:Xanth; instead, the answer entity is discovered via the extra hop dbo:subsequentWork. We believe that DBpedia can be enhanced by inserting these missing links, but augmenting DBpedia is beyond the scope of this work.

Detailed statistics of these two-hop predicate matches are shown in Table 2. As described above, there is no automatic way to differentiate between complex and missing predicates, and thus we provide the sum of the two categories. For questions that have both topic and answer entity mappings, we are not able to find any predicate mappings for approximately 34% of them.

4.4 Candidates Refinement

The output of the initial entity and predicate mapping process (as described above) is then refined to produce the final SIMPLEDBPEDIAQA dataset; detailed statistics are shown in Table 3. In this section, we detail the candidate refinement process.

The need for post-processing candidate results from the output of the processes described above is apparent from manual examination. While the entity mappings are generally of high quality, some of the mapped predicates are invalid, primarily due to two reasons:

- *Semantic drift:* Some candidate predicates are not semantically correct even though the answer may be factually correct. For example, consider the question "From where does Anjali Devi claim nationality?" The predicate mapping produces dbo:deathPlace instead of the correct predicate, dbo:nationality. This is because the correct predicate is missing for this entity, and by coincidence, this person's nationality is the same as her death place.
- *Predicate constraints:* In some cases, we observe mismatches between the domains of the subjects or objects of a Freebase predicate and its corresponding DBpedia predicate. For example, the DBpedia predicate dbo:author can take as subject books, movies, etc. However, the Freebase predicate fb:book/author/works_written can only be mapped to the DBpedia predicate dbo:author (in the backward direction) if the DBpedia subject has the type dbo:WrittenWork. More generally, a predicate mapping is valid only under certain type constraints.

To tackle these challenges with minimal manual effort, we construct manual rules that map high-frequency Freebase predicates in the initial mappings to all potentially correct (at the semantic level) DBpedia predicates. Each rule includes a Freebase predicate and a list of corresponding DBpedia predicates, an associated directionality (forward or backward), and an optional type constraint. A few examples are shown in Table 4. The interannotator agreement of these rules based on three human annotators

Sub-Total				**3,979**	**602**	**1,107**	**5,688**
SIMPLEDBPEDIAQA **Total**				**30,186**	**4,305**	**8,595**	**43,086**

Table 3: Final statistics of SIMPLEDBPEDIAQA following candidates refinement.

is 97%, where agreement is computed as the number of predicates that were identically labeled by all the annotators, divided by the count of all predicates.

Using these mapping rules, we can filter and discard spurious one-hop mappings (including the disambiguation and redirection cases) where both the topic and answer entities are correctly mapped. Furthermore, we can expand the dataset by applying these rules to a few additional cases. Consider the case of complex and missing predicate: since these questions have two-hop predicates, making them no longer "simple questions", they would have been discarded from our dataset. However, we can issue a SPARQL query using the topic entity and the mapped DBpedia predicates from our mapping rules to search for valid answers (ignoring the answer entity). If the query returns a result, we can add the question to our dataset. Heuristically, this means that the question *does* have an answer in DBpedia, just not the same as the one provided in Freebase.

The same process can be applied to cases where we have successfully mapped the entities but not the predicates, and even to cases where we have only successfully mapped the topic entity. As a concrete example, for the question "What is a song by John Rutter?", only the topic entity is mapped. Based on our rules, the Freebase predicate fb:music/artist/track is mapped to the DBpedia predicate dbo:artist with a constraint of dbo:MusicalWork in the backward direction. Using the topic entity as an anchor, a SPARQL query returns a valid result.

Detailed statistics from the refinement process are shown in Table 3. The final output of entity mapping, predicate mapping, and candidate refinement is our SIMPLEDBPEDIAQA dataset, which successfully migrates SIMPLEQUESTIONS from Freebase over to DBpedia.

Freebase Predicate	DBpedia Predicate	Directionality	Type Constraint
fb:architecture/structure/architect	dbo:architect	forward	-
fb:location/location/contains	dbo:country	backward	-
fb:baseball/baseball_position/players	dbo:position	backward	dbo:BaseballPlayer
fb:music/album_release_type/albums	dbo:type	backward	dbo:Album
fb:book/author/works_written	dbo:author	backward	dbo:WrittenWork

Table 4: Examples of predicate mapping rules.

5 Question Answering Baseline

To lay the foundation for future work on our new dataset, we provide simple yet strong baselines using recent work by Mohammed et al. (2018), who applied techniques with and without neural networks to SIMPLEQUESTIONS. In this paper, we used their open-source code[5] to generate the experimental results reported here. We briefly describe their approach, which decomposes into four tasks:

- **Entity Detection**: Given a question, the task is to identify the topic entity of the question. For this task, we examined bidirectional LSTMs and Conditional Random Fields (CRFs).
- **Entity Linking**: Detected entities (text strings) need to be linked to entities in the knowledge graph (e.g., URI from DBpedia in our case). This is formulated as a string matching problem: Levenshtein Distance is used along with a few heuristics for ranking candidate entities.
- **Predicate Prediction:** Given a question, the task is to identify the predicate being queried. We examined three models: bidirectional GRU, convolutional neural network (CNN), and logistic regression (LR). The first two are standard neural network models; for logistic regression we used as input the average of the word embeddings of each word. BiGRU was selected over BiLSTM based on the experiments of Mohammed et al. (2018), where it was found to be slightly more accurate.
- **Evidence Integration:** With *m* candidate entities and *r* candidate predicates from the previous components, the evidence integration model selects the best (entity, predicate) pair based on the product of each component score as well as a number of heuristics.

One additional detail is necessary to understand our experimental methodology for entity detection. In SIMPLEQUESTIONS, the topic entity is not explicitly tagged in the natural language question at the token level; as a result, SIMPLEDBPEDIAQA does not have token-level annotations either. This presents a problem, as our formulation of entity detection as sequence labeling requires per-token labels. The solution adopted by Mohammed et al. (2018) with SIMPLEQUESTIONS was to "back-project" the entities onto the natural language questions to automatically derive token labels, either ENTITY or NOTENTITY. We performed exactly the same back-projection in this work. If the entity text can be matched exactly in the question, the corresponding tokens are tagged appropriately. If there is no exact match, n-grams are generated from the question (from length one up to the length of the question) and the Levenshtein Distances between these n-grams and the entity text are computed. The n-gram with the highest score is selected and the corresponding tokens are tagged appropriately. We find that 94.1% of questions have exact matches with entity strings.

6 Experiment Results and Error Analysis

We evaluated the quality of our models in the same way as Mohammed et al. (2018): For entity detection, we compute F1 in terms of the entity labels. For both entity linking and predicate prediction, we evaluate recall at N (R@N). For the final end-to-end evaluation, we use accuracy (or equivalently, R@1). For evidence integration, our model considers 20 entity candidates and 5 predicate candidates. All hyperparameters and other settings follow the original paper; we have not specifically fine-tuned parameters for this dataset.

[5] http://buboqa.io/

Entity Linking	R@1	R@5
BiLSTM	78.0	88.2
CRF	75.1	85.4
Predicate Prediction	**R@1**	**R@5**
CNN	89.2	99.1
BiGRU	88.1	99.0
LR	84.2	97.6

(a) Component accuracy on validation set.

Entity Detection	Relation Prediction	Accuracy
BiLSTM	CNN	78.5
BiLSTM	BiGRU	78.2
BiLSTM	LR	75.8
CRF	CNN	76.1
CRF	BiGRU	76.0
CRF	LR	73.5

(b) End-to-end accuracy on test set.

Figure 5: Experiment results applying the models of Mohammed et al. (2018) to SIMPLEDBPEDIAQA.

Error Type	# Errors	Prevalence
Hard ambiguity	42	21.0%
Soft ambiguity	21	10.5%
Entity detection error	19	9.5%
Predicate prediction error	28	14.0%
Error in both	90	45.0%
Total	200	100.0%

Figure 6: Results of error analysis.

For entity detection, on the validation set, the BiLSTM achieves 90.3 F1, compared to the CRF at 88.1. The top of Table 5a shows the entity linking results for the BiLSTM and the CRF. These results are consistent with the findings of Mohammed et al. (2018): the BiLSTM achieves a higher F1 score than the CRF, which translates into higher recall in entity linking (both R@1 and R@5). Predicate prediction results are shown on the bottom of Table 5a: the CNN slightly outperforms the BiGRU on R@1, but in terms of R@5 the accuracy of both are quite similar. The neural network models appear to be more effective than logistic regression.

Finally, Table 5b shows end-to-end accuracy on the test set. The best model combination uses the BiLSTM for entity detection and the CNN for predicate prediction, achieving 78.5% accuracy. By swapping the BiLSTM with the CRF for entity detection, we observe a 2.4% absolute decrease in end-to-end accuracy. Results from other combinations are also shown in Table 5b. Note that using the CRF for entity detection and logistic regression (LR) for predicate prediction, which is a baseline that does not use neural networks (with the exception of word embeddings), is also reasonably accurate. This finding is also consistent with Mohammed et al. (2018), who advocate that NLP researchers examine baselines that do not involve neural networks as a sort of "sanity check".

Following Lukovnikov et al. (2017), we sampled 200 examples of errors on the test set from the Bi-LSTM + CNN model to analyze their causes. We manually classified them into the following categories, summarized in Table 6 and described below:

- *Hard ambiguity:* The context provided by the question is insufficient, even for a human, to disambiguate between two or more entities with the same name. In these cases, our model correctly identified the entity string, but linked it to an incorrect entity in the knowledge graph. For example, in the question "What is the place of birth of Sam Edwards?", it is unclear if Sam Edwards refers to the actor dbr:Sam_Edwards or the physicist dbr:Sam_Edwards_(physicist).
- *Soft ambiguity:* The context provided by the question is sufficient to disambiguate the entity, but our model fails to identify the correct entity in the knowledge graph. In these cases, our model correctly identified the entity string, so the error is isolated to the entity linking component. For example, in the question "What kind of show is All In?", the model predicted dbr:All_In_(song) instead of dbr:All_In_(TV_series) (the correct entity). Note that in this case, it is clear to a human based on context that the question refers to a show and not a song.

- *Entity detection error:* The extracted entity string is incorrect.
- *Predicate prediction error:* The predicted predicate is incorrect.
- *Error in both:* Both the extracted entity and the predicted predicate are incorrect.

From the above analysis, we find that there is still substantial room to improve on the effectiveness of our baselines. However, these results also suggest that there is an upper bound on accuracy that lies substantially below 100%, as the cases of hard ambiguity are difficult to resolve, even for humans. In those cases, correct entity linking is more a matter of luck and other idiosyncratic characteristics of the dataset rather than signals that can be reliably extracted to understand the true question intent.

7 Conclusion

This paper presents SIMPLEDBPEDIAQA, a new benchmark dataset for simple question answering over knowledge graphs created by migrating the SIMPLEQUESTIONS dataset from Freebase to DBpedia. Although this mapping process is conceptually straightforward, there are a number of nuances and complexities we had to overcome with a combination of special-case handling and heuristics. The result is a dataset targeting a knowledge graph that is actively maintained by a dedicated community. We hope that our efforts better connect existing research communities, in particular, NLP researchers with the open linked data community, and spur additional work in question answering over knowledge graphs.

An Analysis of Annotated Corpora for Emotion Classification in Text

Laura-Ana-Maria Bostan and **Roman Klinger**

University of Stuttgart, Pfaffenwaldring 5b, 70569 Stuttgart, Germany
laura.bostan@ims.uni-stuttgart.de
roman.klinger@ims.uni-stuttgart.de

Abstract

Several datasets have been annotated and published for classification of emotions. They differ in several ways: (1) the use of different annotation schemata (*e. g.*, discrete label sets, including *joy*, *anger*, *fear*, or *sadness* or continuous values including *valence*, or *arousal*), (2) the domain, and, (3) the file formats. This leads to several research gaps: supervised models often only use a limited set of available resources. Additionally, no previous work has compared emotion corpora in a systematic manner. We aim at contributing to this situation with a survey of the datasets, and aggregate them in a common file format with a common annotation schema. Based on this aggregation, we perform the first cross-corpus classification experiments in the spirit of future research enabled by this paper, in order to gain insight and a better understanding of differences of models inferred from the data. This work also simplifies the choice of the most appropriate resources for developing a model for a novel domain. One result from our analysis is that a subset of corpora is better classified with models trained on a different corpus. For none of the corpora, training on all data altogether is better than using a subselection of the resources. Our unified corpus is available at http://www.ims.uni-stuttgart.de/data/unifyemotion.

Title and Abstract in German

Eine Analyse von annotierten Korpora zur Emotionsklassifizierung in Text

Es existieren bereits verschiedene Textkorpora, welche zur Erstellung von Modellen für die automatische Emotionsklassifikation erstellt wurden. Sie unterscheiden sich (1) in den unterschiedlichen Annotationsschemata (z.B. diskrete Klassen wie *Freude*, *Wut*, *Angst*, *Trauer* oder kontinuierliche Werte wie *Valenz* und *Aktivierung*), (2) in der Domäne, und, auf einer technischen Ebene, (3) in den Dateiformaten. Dies führt dazu, dass überwacht erstellte Modelle typischerweise nur einen Teil der verfügbaren Ressourcen nutzen sowie kein systematischer Vergleich der Korpora existiert. Hier setzt unsere Arbeit mit einem Überblick der verfügbaren Datensätze an, welche wir in ein gemeinsames Format mit einem einheitlichen Annotationsschema konvertieren. Darauf aufbauend führen wir erste Experimente durch, in dem wir auf Teilmengen der Korpora trainieren und auf anderen testen. Dies steht im Sinne zukünftiger, durch unsere Arbeit ermöglichten Analysen, die Unterschiede zwischen den Annotationen besser zu verstehen. Des Weiteren vereinfacht dies die Wahl einer angemessenen Ressource für die Erstellung von Modellen für eine neue Domäne. Wir zeigen unter anderem, dass die Vorhersagen für einige Korpora besser funktioniert, wenn ein Modell auf einer anderen Ressource trainiert wird. Weiterhin ist für kein Korpus die Vorhersage am besten, wenn alle Daten vereint werden. Unser aggregiertes Korpus ist verfügbar unter http://www.ims.uni-stuttgart.de/data/unifyemotion.

1 Introduction

Emotion detection and classification in text focuses on mapping words, sentences, and documents to a set of emotions following a psychological model such as those proposed by Ekman (1992), Plutchik (1980) or Russell (1980), *inter alia*. The task has emerged from a purely research oriented topic to playing a role in a variety of applications, which include dialog systems (chatbots, tutoring systems), intelligent agents, clinical diagnoses of mental disorders (Calvo et al., 2017), or social media mining.

As the variety of applications is large, the set of domains and differences in text is large. An early work, motivated by the goal to develop an empathic storyteller for children stories, is the corpus creation and modelling of emotions in tales by Alm et al. (2005). Afterwards, the idea has been transferred to the Web, namely blogs (Aman and Szpakowicz, 2007), and microblogs (Schuff et al., 2017; Mohammad, 2012; Wang et al., 2012). A different domain under consideration are news articles: Strapparava and Mihalcea (2007) focus on emotions in headlines. It can be doubted that emotions are expressed in a comparable way in these different domains: Journalists ideally tend to be objective when writing articles, authors of microblog posts need to focus on brevity, and one might assume that emotion expressions in tales are more subtle and implicit than, for instance, in blogs. Therefore, the transfer across emotion recognition models is, presumably, challenging. The most straight-forward alternative is, however, to build resources from scratch, a costly process. Given this situation, it remains unclear, given a novel domain for which an emotion recognition system should be developed, how to start. Next to the methodological issues we just discussed, another challenge is to acquire and compare available corpora.

With this paper, we aim at contributing to all these challenges. We support future research by comparing existing datasets, exploring how they complement each other, and mapping them to a common format such that future emotion detection can benefit from being developed on different domains and annotation schemata. In addition, we perform cross-corpus experiments by training classifiers on each dataset and evaluating them on others. One challenge here is that corpora are from different domains and are annotated following different guidelines and schemata. We aim at helping to make decisions which support the best model development for a future domain by selecting appropriate corpora. Parameters to be taken into account are the source of the text (*e. g.*, blogs, news, social media), the annotation schema (*e. g.*, Plutchik, Ekman, subsets of them), and the annotation procedure (*e. g.* crowdsourcing, self-reporting, expert-based, distant labeling). Our main contributions are therefore (1) to describe existing resources, (2) to evaluate which state-of-the-art classifiers perform well when trained on one dataset and applied on another, (3) to evaluate which datasets generalize best to other domains, and (4) to compare the datasets qualitatively and quantitatively. To achieve our goals and as additional support for future research, we unify all available datasets in a common file format. We provide a script that downloads and converts the datasets, and instructs on how to obtain datasets where the license requires no redistributions. Our resources are available via `http://www.ims.uni-stuttgart.de/data/unifyemotion`. We aim at keeping the unified corpus up to date in the future.

2 Background & Related work

In the following, we discuss differences in psychological models and annotation schemata (Section 2.1), annotation procedures (Section 2.2), different domains and topics (Section 2.3), and different prediction methods (Section 2.4). An overview on the resources and previous work is shown in Table 1. In addition to this, we recommend the surveys by Munezero et al. (2014) and Santos and Maia (2018).

2.1 Emotion Models in Psychology & Annotation Schemata

Emotion models are still debated in psychology (Barrett et al., 2018; Cowen and Keltner, 2018). We do not contribute to these debates but focus on the main theories in psychology and natural language processing (NLP): discrete and finite sets of emotions (categorical models) and combinations of different continuous dimensions (dimensional models).

Early work on emotion detection (Alm et al., 2005; Strapparava and Mihalcea, 2007) focused on conceptualizing emotions by following Ekman's model which assumes the following six basic emotions: *anger, disgust, fear, joy, sadness* and *surprise* (Ekman, 1992). Suttles and Ide (2013), Meo and Sulis

(2017), and Abdul-Mageed and Ungar (2017) follow the *Wheel of Emotion* (Plutchik, 1980; Plutchik, 2001) which also considers emotions as a discrete set of eight basic emotions in four opposing pairs: *joy–sadness*, *anger–fear*, *trust–disgust*, and *anticipation–surprise*, together with emotion mixtures.

Dimensional models were more recently adopted in NLP (Preoţiuc-Pietro et al., 2016; Buechel and Hahn, 2017a; Buechel and Hahn, 2017b): The circumplex model (Russell and Mehrabian, 1977) puts affective states into a vector space of valence (corresponding to sentiment/polarity), arousal (corresponding to a degree of calmness or excitement), and dominance (perceived degree of control over a given situation). Any emotion is a linear combination of these.

2.2 Annotation Procedures

A standard way to create annotated datasets is via *expert annotation* (Aman and Szpakowicz, 2007; Strapparava and Mihalcea, 2007; Ghazi et al., 2015; Li et al., 2017; Schuff et al., 2017; Li et al., 2017). However, having an expert annotate a statement means that they must estimate the private state of the author. Therefore, the creators of the ISEAR dataset follow a different, but similar, route making use of *self reporting*: subjects are asked to describe situations associated with a specific emotion (Scherer and Wallbott, 1994). This approach can be considered an annotation by experts in their own right.

Crowdsourcing, for instance using the platforms Amazon's Mechanical Turk[1] or CrowdFlower[2], is another way to acquire human judgments. Crowdsourcing often lacks sufficient quality control but some popular datasets have been successfully acquired with this approach, *e. g.*, the dataset released by Crowdflower for Cortana[3] or the datasets constructed by Milnea et al. (2015) and Lapitan et al. (2016). Another example is the dataset by Mohammad (2012), who design two detailed online questionnaires and annotate tweets by crowdsourcing.

Lastly, social networks play a central role in data acquisition with *distant supervision* (also called *self-labeling* in this context), because they provide a quick and cheap way to get large amounts of noisy data annotated by writers or readers (Mohammad and Kiritchenko, 2015; Abdul-Mageed and Ungar, 2017; De Choudhury et al., 2012; Liu et al., 2017). For example, on Twitter one could add a "#joy" hashtag to a happy tweet or on Facebook one could tag personal posts with a "feeling" and people can show an emotional "surprised reaction". In this last example, two levels of annotation are provided that are relevant to emotion analysis, namely both the reader's and the writer's emotional state. Accessing this information is comparably straight-forward in these social network platforms. More challenging is to acquire such data for other domains. Buechel and Hahn (2017a) and Buechel and Hahn (2017b) look specifically into distinguishing between writers' and readers' emotion expressions.

It should be noted that some of these approaches exist in parallel to previous research in assessing emotion states of people, despite the fact that standardized psychological instruments exist (Bradley and Lang, 1994).

2.3 Domains and Topics

Previous work on emotion detection focuses on different domains and topics, *e. g.*, descriptions of *self reported emotional events* (Scherer and Wallbott, 1994), *news* (Lei et al., 2014; Buechel et al., 2016), *news headlines* (Strapparava and Mihalcea, 2007), *blogs* (Aman and Szpakowicz, 2007), *tales* (Alm et al., 2005), *micro-blog posts* (*i. e.*, tweets) (Wang et al., 2012) to different domains, such as *health*, *politics* (Mohammad, 2012), and *stock markets* (Bollen et al., 2011).

An early example and one of the first initiatives of emotion classification is the work by Aman and Szpakowicz (2007), who use *blog posts*, sampled without taking a specific topic into account. They identify the emotion, category, intensity and cue words and phrases. Mishne and de Rijke (2005), Balog et al. (2006) and Nguyen et al. (2014) works on LiveJournal[4] data to develop predictive models for moods.

Similarly, *user-generated data in social media* has been a subject of research. Mohammad et al. (2015) and Mohammad and Bravo-Marquez (2017b) annotate electoral *tweets* for sentiment, intensity, semantic

[1] https://www.mturk.com/

[2] https://www.crowdflower.com/

[3] https://www.crowdflower.com/data/sentiment-analysis-emotion-text/

[4] https://www.livejournal.com

roles, style, purpose and emotions. De Choudhury et al. (2012) identify more than 200 moods frequent on Twitter. Mohammad (2012), Mohammad et al. (2015), Wang et al. (2012), Volkova and Bachrach (2016) make use of Twitter distantly labeled data. Recently, Liu et al. (2017) analyzed the role of context that grounds sentiment in *tweets*, and looked into whether the effect of weather and news events relate to the emotion expressed in a given tweet. EmoNet is claimed to be the largest dataset constructed of *tweets* (Abdul-Mageed and Ungar, 2017) .

Twitter is often the preferred subject of research as it is easy to use and has a well-documented API. However, Facebook is also used, *e. g.*, Preoţiuc-Pietro et al. (2016) create a dataset of *Facebook posts* and train prediction models for valence and arousal. Pool and Nissim (2016) and Krebs et al. (2017) make use of the reaction feature in Facebook to collect labeled data for distant supervision of a classifier. A different approach within the same domain was used by Polignano et al. (2017) who labeled posts with emoticons mapped to Ekman's model.

Data in social media can be in the form of *dialogues*. Li et al. (2017) manually label a dataset of conversations. Wang et al. (2016) introduce EmotionPush, a system that automatically conveys the emotion of received text on mobile devices, deployed on Facebook's messenger app. From the same domain, but on a different topic is the study of patients' emotional states dynamics expressed by their Facebook posts (Lombardo et al., 2017).

Motivated by the work of literary scholars is the creation of datasets to study emotion in *literature*. One of the first datasets is the tales corpus by Alm et al. (2005). Kim et al. (2017) investigate the relationship between literary genres and emotions.

2.4 Methods used in Emotion Identification

Emotion classification is commonly phrased as text classification. As text classification in general, the array of methods seen for emotion classification can be divided into rule-based methods and machine learning, which we discuss in the following.

2.4.1 Rule-based Algorithms

Rule-based text classification typically builds on top of lexical resources of emotionally charged words. These dictionaries can originate from crowdsourcing or expert curation. Examples include WordNet-Affect (Strapparava et al., 2004) and SentiWordNet (Esuli and Sebastiani, 2007), both of which stem from expert annotation. Partly built on top of them is the NRC Word-Emotion Association Lexicon (Mohammad et al., 2013), which uses the eight basic emotions (Plutchik, 1980). Warriner et al. (2013) use crowdsourcing to assign values of valence, arousal, and dominance (Russell, 1980).

Another related category of lexical resources which has been used for emotion analysis is *concreteness* and *abstractness* (Köper et al., 2017). Brysbaert et al. (2014) publish a lexicon based on crowdsourcing, where the task was to assign a rating from 1 to 5 of the concreteness of 40,000 words. Similarly, Köper and Schulte im Walde (2016) automatically generate affective norms of abstractness, arousal, imageability, and valence for 350,000 lemmas in German. Lastly, the Linguistic Inquiry and Word Count (LIWC) is a set of 73 lexicons (Pennebaker et al., 2001), built to gather aspects of lexical meaning regarding psychological tasks. Dictionary and rule-based approaches are particularly common in the field of digital humanities due to their transparency and straightforward use.

2.4.2 Machine Learning

A performance improvement over dictionary lookup has been observed with supervised feature-based learning. Common features include word n-grams, character n-grams, word embeddings, affect lexicons, negation, punctuation, emoticons, or hashtags (Mohammad, 2012) . This feature representation is then usually used as input to feed classifiers such as naive Bayes, SVM (Mohammad, 2012), MaxEnt and others to predict the relevant emotion category (Aman and Szpakowicz, 2007; Alm et al., 2005). Similarly to the paradigm shift in sentiment analysis, from feature-based modelling to deep learning, state-of-the-art models for emotion classification are often based on neural networks (Barnes et al., 2017). Schuff et al. (2017) applied models from the classes of CNN, BiLSTM (Schuster and Paliwal, 1997), and LSTM (Hochreiter and Schmidhuber, 1997) and compare them to linear classifiers (SVM and MaxEnt), where the

Table 1: Selection of resources for emotions analysis. Ann. refers to the following annotation schemata: [E] *Ekman: anger, disgust, fear, joy, sadness, surprise*, [P] *Plutchik: anger, disgust, fear, joy, sadness, surprise, trust, anticipation*, [CF] *enthusiasm, fun, hate, neutral, love, boredom, relief, empty*, [DS] *disgust, surprise*, [JS] happy, sad, [V] *valence*, [A] *arousal*, [D] *dominance*, [SG] *shame, guilt*, [±S] *positive surprise, negative surprise*, [ne] *no emotion* [me] *mixed emotion* and Availability refers to the following [D-RO] *Available to download, research only*, [D-U] *Available to download, unknown licensing*, [R] *Available upon request*, [GPLv3] *GNU Public License version 3*, [CC-by 4] *Creative Commons Attribution version 4.0*

BiLSTM show best results with the most balanced precision and recall. Abdul-Mageed and Ungar (2017) claim the highest F_1 following Plutchik's emotion model with gated recurrent unit networks (Chung et al., 2015).

One approach to tackle sparsity of datasets is transfer learning; to make use of similar resources and then transfer the model to the actual task. A recent successful example for this procedure is Felbo et al. (2017) who present a neural network model trained on emoticons which is then transfered to different downstream tasks, namely the prediction of sentiment, sarcasm, and emotions.

3 Unified Dataset of Emotion Annotations

In this section, we describe each dataset we aggregate in our unified corpus. We provide a brief description and then show how the different schemata are merged. Please note that our interpretation might differ from the author's original description (though we aimed at avoiding that).

3.1 Datasets Overview

AffectiveText The dataset AffectiveText published by Strapparava and Mihalcea (2007) is built on news headlines and consists of 1,250 instances. The main goal of this resource is the classification of emotions and valence in news headlines. The annotation schema follows Ekman's basic emotions, complemented by valence. It is multi-label annotated via expert annotation and can be freely downloaded, the license is not specified. The emotion categories are assigned a score from 0 to 100. Training/developing data amounts to 250 annotated headlines, while systems are evaluated on another 1,000 instances.

Blogs This dataset, published by Aman and Szpakowicz (2007) consists of 5,205 sentences from 173 blogs. Instances are annotated with one emotion label each, emotion intensity and emotion indicators. The annotation schema for the emotion category corresponds to the six fundamental Ekman emotions to which *no emotion* is added. This resource can be obtained through contacting the authors.

CrowdFlower The dataset "The Emotion in Text, published by CrowdFlower" consists of 39,740 tweets. Part of this data has been used in Microsoft's Cortana Intelligence Gallery. The set of labels is non-standard (see Table 4). It is annotated via crowdsourcing with one label per tweet and can be freely downloaded, the license is not specified. The data is comparably noisy.

DailyDialogs The dataset, published by Li et al. (2017), is built on conversations and consists of 13,118 sentences. The annotation schema follows Ekman, complemented by "no emotion". It is single label annotated via expert annotation and can be freely downloaded for research purposes. This dataset has additional annotations for communication intention and topic.

Electoral-Tweets The dataset, published by Mohammad et al. (2015), targets the domain of elections. It consists of over 100,000 responses to two detailed online questionnaires (the questions targeted emotions, purpose, and style in electoral tweets). The tweets are annotated via crowdsourcing. The set of labels for emotion is non-standard (see Table 1). In addition to document-level annotations, tweets are annotated with emotion words. It can be freely downloaded for research purposes.

EmoBank The dataset published by Buechel and Hahn (2017a) builds on multiple genres and domains. It consists of 10,548 sentences where each sentence was manually annotated according to both the emotion which is expressed by the writer, and the emotion which is perceived by the readers. The annotations are according to the valence-arousal-dominance model. A subset of the corpus is AffectiveText, which makes this dataset a good resource to design models that map between both discrete or dimensional representations.

EmoInt The EmoInt published by Mohammad and Bravo-Marquez (2017a) builds on social media content that amounts to 7,097 tweets altogether. The main goal of this resource is to associate text with various intensities of emotion. The tweets are annotated via crowdsourcing with intensities of *anger*, *joy*, *sadness*, and *fear*, while most tweets are only annotated with one emotion. It can be freely downloaded for research purposes.

Emotion-Stimulus The Emotion-Stimulus dataset published by Ghazi et al. (2015) consists of 820 sentences which are annotated both with emotions and their causes, and 1,549 sentences which are marked only with their emotion. The set of labels used for annotation consists of Ekman's basic emotions to which *shame* is added. The main goal of this resource is to predict the cause of an emotion in the text. It is annotated using FrameNet's emotions-directed frame with one emotion label per sentence. It is available for download for research purposes.

fb-valence-arousal The fb-valence-arousal dataset published by Preoţiuc-Pietro et al. (2016) is built on Facebook posts. It consists of 2,895 posts stratified by age and gender. The main goal of this resource is to train prediction models for *valence* and *arousal*. Each message is written by a distinct user and all messages are from the same time interval. The posts are annotated with valence and arousal on a nine point scale via expert annotation. It is available for download.

Grounded-Emotions The dataset published by Liu et al. (2017) is built on social media and consists of 2,557 single labeled instances published by 1,369 unique users. The main goal of this resource is to put emotions into context of other factors including weather, news events, social network, user predisposition, and timing. The set of labels is *happy* and *sad*. The tweets are annotated by the authors. The information is used in experiments aiming at showing the role played by external context in predicting emotions.

ISEAR The "International Survey on Emotion Antecedents and Reactions" dataset published by Scherer and Wallbott (1994) is built by collecting questionnaires answered by people with different cultural backgrounds. These people report on their own emotional events. The final dataset contains reports by approximately 3,000 respondents, for a total of 7,665 sentences labeled with single emotions. The labels are *joy, fear, anger, sadness, disgust, shame*, and *guilt*. It is available for download.

SSEC The Stance Sentiment Emotion Corpus published by Schuff et al. (2017) is an annotation of the SemEval 2016 Twitter stance and sentiment dataset (Mohammad et al., 2017). It consists of 4,868 tweets. The main goal of this resource is to enable further research on the relations between emotions and other factors. It is annotated via expert annotation with multiple emotion labels per tweet following Plutchik's fundamental emotions. An additional feature of this resource is that they not only provide a majority annotation but publish the individual information for all annotators.

Tales The Tales corpus published by Alm et al. (2005) is built on literature and consists of 15,302 sentences from 185 fairytales by B. Potter, H.C. Andersen and the brothers Grimm. Out of these 15,302 sentence, all annotators agree only on 1,280. The main goal of this resource is to build

Table 2: The distribution of categories across the datasets, limited to *anger*, *disgust*, *fear*, *joy*, *sadness* and *surprise*. Non-availability of a class in a set is marked with —. [o]: original distributions, without taking high agreement annotations; [m]: counts after mapping to our labels (see Table 4).

emotion classifiers for literature. The annotation schema consists of Ekman's six basic emotions. In the final data the labels *angry* and *disgust* are merged. It can be freely downloaded for research purposes.

TEC The Twitter Emotion Corpus published by Mohammad (2012) is built on social media. It consists of 21,051 tweets. The main goal of this resource is answering the question if emotion-word hashtags can successfully be used as emotion labels. The annotation schema corresponds to Ekman's model of basic emotions. They collected tweets with hashtags corresponding to the six Ekman emotions: *#anger*, *#disgust*, *#fear*, *#happy*, *#sadness*, and *#surprise*, therefore it is distantly single-label annotated. It can be freely downloaded for research purposes.

3.2 Analysis

The majority of resources consists of user generated data. The biggest dataset is CrowdFlower with 39,740 annotated tweets, followed by TEC with 21,051 tweets, and Blogs with 15,000 annotated sentences from blog posts. Out of all 14 resources, 9 are annotated with the six fundamental emotions defined by Ekman, with small variations. SSEC and Electoral-Tweets follow Plutchik's model. Electoral-Tweets is annotated with 19 emotions and the authors provide a mapping to Plutchik's set (which we follow in the aggregation). Non-fundamental emotions are annotated in CrowdFlower (*fun, worry, enthusiasm, and love*).

Not only the size, also the distribution of labels is different in the corpora. Table 2 shows the distribution for Ekman's emotions before and after having applied the mapping to a unique set of emotion labels (see Table 4 in the Appendix A). In many corpora, *joy* is the dominating emotion, followed by *sadness*, *surprise*, and *anger*. Exceptions are SSEC, Electoral-Tweets, and EmoInt, in which negative emotions are more frequent. In SSEC, this is because of its origin as a stance dataset. Similarly, Electoral-Tweets shows a polarizing nature of political debates with *disgust* and *anger* being more common.

Figure 1 shows a quantitative similarity comparison of the data. We represent each dataset by its term distribution, taking the top 5,000 most common words from each dataset and calculating the cosine similarity across corpora (inspired by Ruder and Plank (2017) and Plank and Van Noord (2011)). Twitter corpora are more similar to each other (EmoInt and CrowdFlower are the most similar to TEC) than to other domains with the exception of SSEC, which is the most dissimilar to the other tweet datasets. DailyDialogs is more similar to the tweets than to ISEAR and Blogs.

The column *All* stands for the union of all datasets except the one that is being compared to. In this context, the most dissimilar towards the respective aggregated set is AffectiveText. The reason is that this is a small dataset compared to the tweet-based corpora and that it covers a specific topic, *headlines*. Grounded-Emotions is also notably dissimilar. Most similar to *All* is EmoInt, followed closely by TEC and Blogs, which covers blog posts and not tweets.

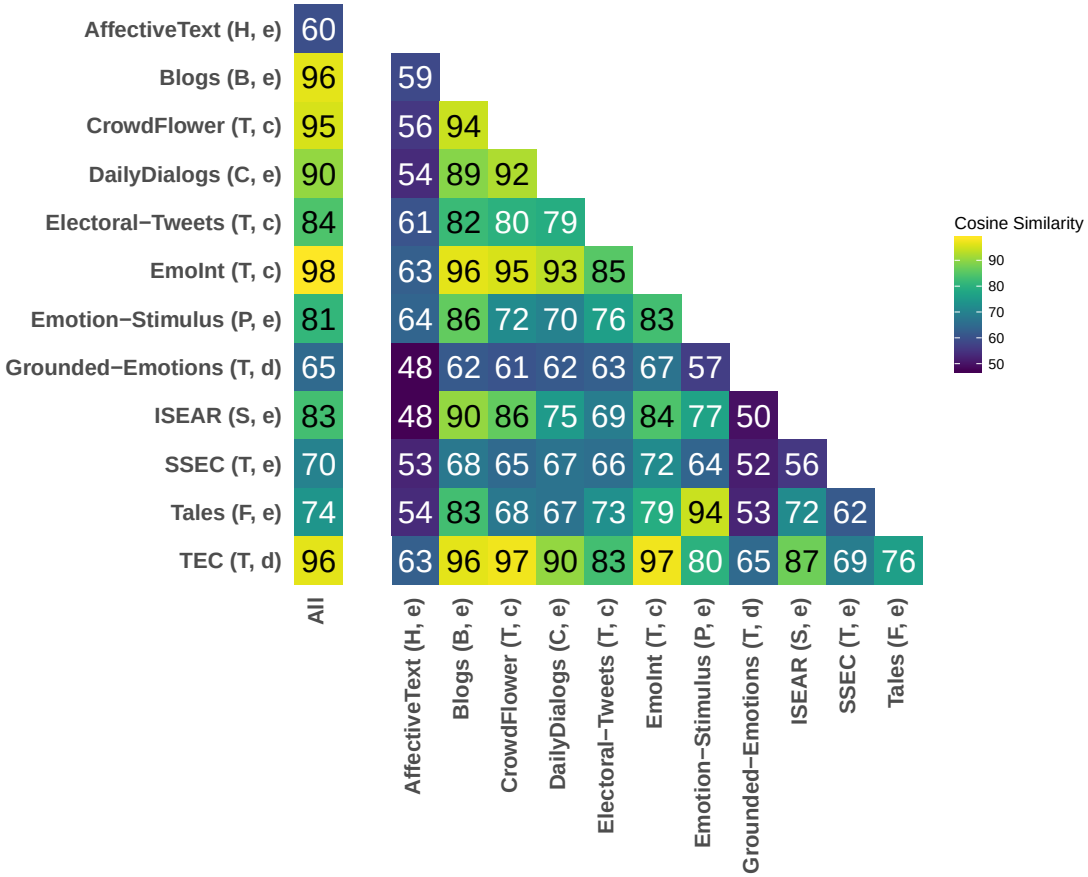

Figure 1: Similarity of corpora with cosine measure. T: tweets, F: tales, P: paragraphs, S: descriptions, H: headlines, B: blogpost, C: conversations; e: expert annotation, d: distant supervision, c: crowdsourcing.

3.3 Aggregation

To provide a standardized access to the datasets, we define *joy, anger, sadness, disgust, fear, trust, surprise, love, confusion, anticipation* and *noemo* as our common label set. The original resources additionally include other 44 labels that come from Electoral-Tweets and CrowdFlower. Where availble from the original publication, we follow proposed mappings (*e. g.*, Electoral-Tweets with 19 emotions and a mapping to Plutchik's model). Table 4 in Appendix A summarizes the mapping. We include *valence, arousal*, and *dominance* where annotated, however, we currently do not map the categorical emotion models onto the dimensional ones.

Each instance in the unified dataset contains, in addition, a unique id, the source corpus name, the text, and an assignment of a real number to each of the 11 emotion variables. In most datasets, each instance is only annotated discretely with single labels (exceptions are SSEC and AffectiveText). Therefore, most instances have exactly one label marked with a 1.0. For the multi-labeled datasets, several emotions can be marked. For datasets with annotated emotion intensity, values can range between 0 and 1. For datasets with multiple annotator information, we follow the recommendations by the original authors. For SSEC, that means, accepting a label if at least one annotator assigned it. For Tales, the authors provide a gold annotation, in which *angry* and *disgust* are merged. We handle them separately, and accept a label if and only if all annotators agree. For Blogs, we take the examples of the dataset with the high agreement annotations.

Next to these fundamental attributes, we provide the domain and annotation style information, as well as additional, dataset specific attributes (*e. g.*, the story from which an instance originates, in the Tales corpus). Our unified data includes all datasets for which the licenses are available; as some datasets are not redistributable, but free to download, we provide a script that interactively downloads and converts the existing resources into our unified format. An excerpt of the data is depicted in Appendix B.

4 Experiments

We perform experiments in the following settings: Firstly, we perform a within-corpus emotion classification (training on one corpus and testing on the same, using cross-validation[5]). Secondly, we do pairwise-corpus evaluation: training on the entire data of one corpus and evaluating on all the data of a different one, for all corpus pairs. This includes the use of the aggregated corpus, but for this experiment excluding the test corpus – this corresponds to a cross validation setting in which the subsets correspond to corpora.

4.1 Experimental settings

Previous methods have shown that linear classifiers are nearly *en par* with neural methods (Schuff et al., 2017). We therefore use maximum entropy classifiers as implemented in scikit-learn (Pedregosa et al., 2011) with bag-of-words (BOW) features for these experiments for simplicity and easy reproducibility. We use L2 regularization and balance the classes in the training data with instance weights. Training/test splits are 80%/20%. Cross-validation is 10-folds stratified.

For datasets in which the labels do not align following our mapping, we use the intersection of labels in the train and test data. We do not discard any instances. For datasets that are designed for other tasks than emotion classification such as EmoInt and Emotion-Stimulus, we do not change the setting of our classification task.

For experiments in which we move from a *multi-label setting* (more than one emotion can hold per instance) to a *single-label setting* (only one emotion holds), we train multiple binary classifiers from which we only accept, in the prediction phase, the highest scoring emotion. For experiments in which we move from a *single-label setting* to a *multi-label setting*, we as well train separate binary classifiers and accept all emotions for which the binary classifiers output one. The case *multi-label* to *multi-label* works analogously. For *single-label* to *single-label*, we use one multi-class MaxEnt model.

4.2 Results

Within-corpus emotion classification. The results for our first experiment are shown per emotion in Table 3 (where we restrict the results to the six fundamental emotions defined by Ekman) and in the diagonal of Figure 2. These should be interpreted in context to the similarity analysis in Figure 1. We see that some datasets and domains are more difficult to be modeled than others. The "easiest" dataset seems to be Emotion-Stimulus, followed by EmoInt. The reason for the high scores lies in the fact that both datasets are constructed for different tasks (stimulus and intensity prediction). As such, our task does not suit these two very well.

Next datasets with comparably high performance measures are Blogs and DailyDialogs. In contrast, CrowdFlower and Electoral-Tweets seem to be the most challenging in the within-corpus setting. For CrowdFlower, the results are due to the larger label set, which makes the task more difficult. Mostly, the emotions that occur less frequently (like surprise) show lower results than the ones occurring frequently (like *joy* and *sadness*). In addition, manual inspection shows that this data is comparably noisy. This is also backed by the general observation that our model performs in general worse on Twitter data than on most other domains.

In terms of annotation procedures, these experiments allow almost for no judgement, since most of the datasets use expert annotation and we only have few examples for the other two ways of annotation (crowdsourcing and distant supervision) being used. However, we could observe that the crowdsourced datasets are more difficult which might be due to a more noisy annotation.

Cross-corpus emotion classification The in-corpus results (the diagonal in Figure 2) shows higher F_1-scores than the cross-corpus results. The exception is Electoral-Tweets, where the same performance is observed by training on a different corpus, Blogs. Models trained on Twitter data perform slightly

[5]Some datasets came with designated train and test parts, but in order to treat all datasets equal, we chose to ignore that. However, in the aggregated dataset, the information about which part of the corpus an example is from is preserved in a special field.

	Joy			Sadness			Fear			Anger			Disgust			Surprise		
Dataset	P	R	F	P	R	F	P	R	F	P	R	F	P	R	F	P	R	F
AffectiveText	68	64	66	72	64	68	85	55	67	37	76	50	44	55	49	69	74	71

EmoInt	94	92	93	83	81	82	85	90	88	90	86	88	0	0	0	0	0	0
Emotion-Stimulus	98	99	98	95	100	97	99	98	98	99	98	98	100	90	95	97	97	97
Grounded-Emotions	61	53	57	41	48	44	0	0	0	0	0	0	0	0	0	0	0	0
ISEAR	61	74	67	73	66	69	69	69	69	45	48	47	58	61	59	0	0	0
SSEC	67	67	67	59	89	71	45	72	55	79	74	76	64	62	63	44	55	49
Tales	34	35	34	24	30	26	27	28	27	28	34	31	16	21	18	19	28	23
TEC	67	69	68	46	44	45	58	56	57	41	40	40	27	26	26	54	50	52

Table 3: Results obtained via 10-fold crossvalidation in precision, recall, and F_1 micro-averaged of the MaxEnt classifier with BOW as features, reported per Ekman's fundamental emotion. Zeros denote that the respective class is not annotated in the respective data set. Note that a subset of datasets has more classes annotated than the provided Ekman's emotions.

better on other Twitter sets, with an exception of Electoral-Tweets, for which the distribution of labels is different, with *disgust* dominating the set.

It is notable that EmoInt, Emotion-Stimulus, Grounded-Emotions ISEAR, and SSEC are easier to classify (high performance when used for testing) while DailyDialogs, Blogs, CrowdFlower, and Tales are more informative: training on them and classifying other datasets leads to better results. Models trained on ISEAR and SSEC perform comparably well. DailyDialogs is classified best not by a classifier trained on itself, but by a classifier trained on Blogs.

We cannot recommend to train on Emotion-Stimulus and Grounded-Emotions as long as the specific properties of these datasets are not required. The models estimated on these data do not perform well on other sets. Note that this is not a quality judgement, Grounded-Emotions has different labels and Emotion-Stimulus was designed for a different purpose.

Note that the similarity measure is an approximation of mediocre quality for model performance, with a Pearson correlation of $r = 0.32$.

All vs. one cross-corpus emotion classification. The results for this setting can be seen in the *All* column of Figure 2. These results show which datasets are easier to classify, namely DailyDialogs, Blogs, and EmoInt. It might seem intuitive that adding more and diverse training data could be helpful in classifying almost all datasets. However, we can see in the results that this is not the case. Especially the multi-labeled datasets AffectiveText and SSEC together with the datasets that were the most transformed (*i. e.*, many labels unified) during the aggregation process, such as Electoral-Tweets and CrowdFlower are more difficult to classify while training on all the other datasets.

5 Conclusion & Future Work

Datasets annotated for emotion classification are important in emotion analysis research as they are used in many downstream tasks as well; having these datasets all in place reduces drastically the amount of work needed in preprocessing and transferring the needed data. Yet, it is a diverse collection of datasets driven by different psychological emotion models, on different domains, and approaches used in annotation. With this paper, we present the first survey on emotion datasets on text.

In addition to this literature review, we provide a unified, aggregated corpus to support future research on standardized data. The existence of such a benchmark opens up the possibility of other experiments, such as transfer learning and domain adaptation work, with focus on different domains and on different label sets. From the collected unified datasets one could learn how to select the most suitable dataset for a given new domain and evaluate it across different classification models, domains, and annotation procedures, easier than it was possible until now. Also having this open will help the emotion detection

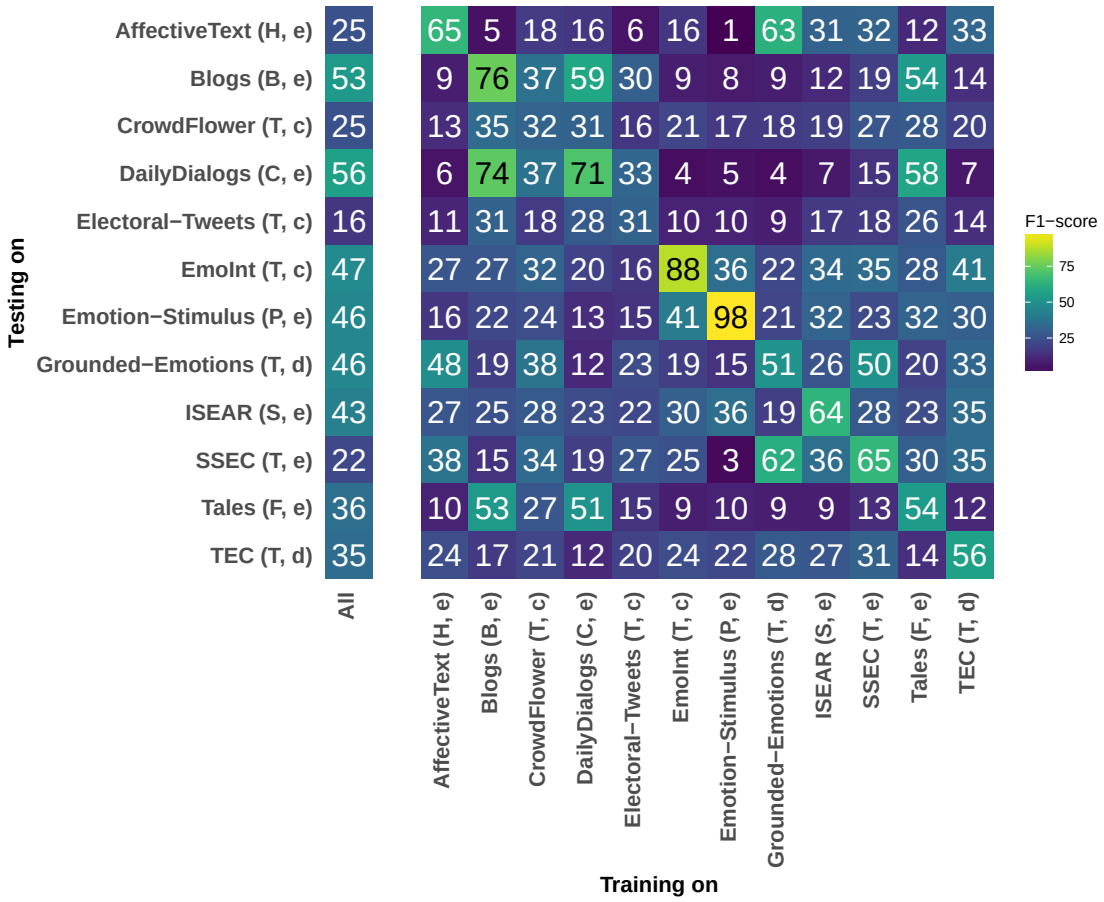

Figure 2: Results of MaxEnt in F_1 measure (micro-averaged) for all cross-corpus experiments. T: tweets, C: conversations, F: tales, P: paragraphs, S: descriptions, H: headlines, B: blogsposts; e: expert annotation, d: distant supervision, c: crowdsourcing.

task to become a standard task on which state-of-the-art methods used in general classification are tested upon, similarly to other tasks like sentiment classification, which plays this role already.

In addition, this work can be used by anyone who wants to explore the current state of the emotion analysis field. As future work we plan to release another version of the dataset in which the conversion between the different emotion models are added and to perform transfer learning experiments between datasets, domains, and annotation procedures. Furthermore, we propose to use the resource to qualitatively analyze the different realizations of emotions across annotation schemata and domains.

Abstract

Text classification is one of the most widely studied tasks in natural language processing. Motivated by the principle of compositionality, large multilayer neural network models have been employed for this task in an attempt to effectively utilize the constituent expressions. Almost all of the reported work train large networks using discriminative approaches, which come with a caveat of no proper capacity control, as they tend to latch on to any signal that may not generalize. Using various recent state-of-the-art approaches for text classification, we explore whether these models actually learn to compose the meaning of the sentences or still just focus on some keywords or lexicons for classifying the document. To test our hypothesis, we carefully construct datasets where the training and test splits have no direct overlap of such lexicons, but overall language structure would be similar. We study various text classifiers and observe that there is a big performance drop on these datasets. Finally, we show that even simple models with our proposed regularization techniques, which disincentivize focusing on key lexicons, can substantially improve classification accuracy.

1 Introduction

Text classification is one of the fundamental tasks in natural language processing (NLP) in which the objective is to categorize text documents into one of the predefined classes. This task has a lot of applications such as topic classification of news articles, sentiment analysis of reviews, email filtering, etc. Text classification still remains a significant challenge in language understanding as we need to encode the intrinsic grammatical relations between sentences in the semantic meaning of a document. This is especially crucial for sentiment classification because relations like "contrast" and "cause" can have great influence on determining the meaning and the overall polarity of a document.

Traditionally, for text classification, bag-of-words model (Harris, 1954) was used to represent a document. This simple approach uses the term frequency as features followed by a classifier such as Naïve Bayes (McCallum and Nigam, 1998) or Support Vector Machine (SVM) (Joachims, 1998). One drawback of this approach is that it ignores the word order and grammatical structure. It also suffers from data sparsity problem when the training set's size is small but has shown to give good results when size is not an issue (Wang and Manning, 2012). Before applying these methods, feature selection is typically carried out to reduce the effective vocabulary size by removing the noisy features (Manning et al., 2008). A key property of these linear classifiers is that they assign high weights to some class label specific keywords, which are also known as lexicons.

The next generation of approaches includes neural networks that have shown to outperform bag-of-words models in text classification tasks (Kim, 2014; Johnson and Zhang, 2016). These methods typically use multiple layers of Convolutional Neural Network (CNN) (Lecun et al., 1998) and/or Long Short Term Memory (LSTM) networks (Hochreiter and Schmidhuber, 1997). The motivation of using these complex neural network approaches for classification tasks comes from the principle of compositionality (Frege, 1948), which states that the meaning of a longer expression (e.g. a sentence or a document) depends on

Proceedings of the 27th International Conference on Computational Linguistics, pages 2120–2131
Santa Fe, New Mexico, USA, August 20-26, 2018.

the meaning of its constituents. It is believed that lower layers of the network learn representations of words or phrases, and as we move up the layers more complex expressions are represented (Peters et al., 2018).

However, we believe that these state-of-the-art text classification techniques do not actually follow this mechanism, despite the motivations. Like any discriminative approach which can pick up any signal, it appears that these techniques most likely still learn and rely heavily on key lexical items or phrases and just use these lexicons to classify the document, which might not generalize to new documents.

To test our hypothesis, we first construct datasets (Section 3) where the training and test splits have no direct overlap of such key lexicons while taking care of class imbalance, although remaining language structure remains the same. Such dataset split also occurs in many real-world classification problems. For example, in the case of scientific documents, with the discovery of a new phenomenon/law/theorem, a new keyword is born. The document containing the new word would still belong to one of the existing classes, such as optics/biochemistry/discrete math, and a text classifier should be able to correctly classify the given document as the language structure would remain the same.

We study the performance of various text classifiers on this new training-test split and compare performance results with the commonly used random training-test split of such a dataset (Section 5). We observe that there is a big performance gap in current approaches between the two splits. We further show that even simple regularization techniques of replacing key lexicons with random embeddings can improve performance on the training-test split where there is no overlap of such keywords. We also present a novel approach based on the gradient of word embeddings that leads to further improvement on such dataset split (Section 4). We also provide two large-scale text classification datasets which contain both the random split and lexicon based split.

We report additional experimental results by modeling the above problem as that of unsupervised domain adaptation where the data distribution of training domain and test domain are different (Ganin et al., 2016; Zhang et al., 2017). Even such domain adaptation approaches do not yield better results than our proposed regularization techniques (Section 5).

2 Background and Related Work

In this section, we first discuss work related to neural network approaches for text classification followed by a discussion on recent domain adaptation techniques which can be thought of as an alternative solution for our problem.

2.1 Neural Network Approaches

Recent research on text classification tasks makes use of neural networks which has shown to outperform methods based on the bag-of-words model. These approaches take distributed representation of words as input which is also known as word vectors (Mikolov et al., 2013). These word vectors can be learned either using skip-gram (Mikolov et al., 2013) or Glove (Pennington et al., 2014) methods. One remarkable property of these vectors is that they learn the semantic relationships between words such that in the embedding space, semantically similar words are closer together. To learn document embeddings from these word vectors, Le and Mikolov (2014) use distributed bag-of-words (DBOW) approach also known as paragraph vectors while Joulin et al. (2017) computes the average of the word and subword vectors of a document to train a linear classifier.

To extract sentence level features for text classification task, Kim (2014) uses shallow CNN with max-pooling on top of pre-trained word vectors. They also observe that learning task-specific vectors through fine-tuning leads to better classification accuracy. Similarly, LSTM network pre-trained using language model parameters or sequence autoencoder parameters is used by Dai and Le (2015) for various text classification tasks. Recently, it was shown by Johnson and Zhang (2015a) that a CNN with dynamic max pooling layer can effectively use the word order structure when trained using one-hot encoding representation of input words. They also learn multi-view region embeddings through semi-supervised learning and incorporate them as additional features to further improve the model's performance (Johnson and Zhang, 2015b). Similarly, they also perform semi-supervised experiments using a simplified LSTM

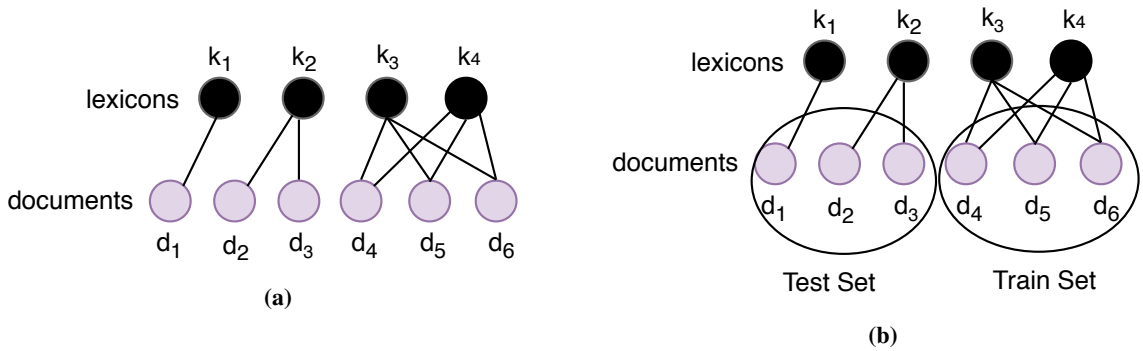

Figure 1: Schematic diagram illustrating the methodology of lexicon dataset construction. In (a), we construct a bipartite, undirected graph between the identified keywords ($k_1, \ldots, k_4$) and all the documents ($d_1, \ldots, d_6$). We identify all the connected components in this graph. In (b), all the documents belonging to the largest connected component (d_4, d_5, d_6) are selected as the training set while those documents belonging to all the other connected components (d_1, d_2, d_3) are selected as the test set.

model which also takes one-hot encoding of words as input (Johnson and Zhang, 2016).

2.2 Domain Adaptation

Next, we discuss the recent works applicable to domain adaptation of text classifiers. In unsupervised domain adaptation, the labeled instances from training data are considered as the source domain while unlabeled instances from test data are considered as the target domain. In this paper, it is assumed that there exists covariate shift between the two domains such that the conditional distribution of class label remains the same in both the domains while the marginal distribution of instances may differ (Shimodaira, 2000; Bickel et al., 2007). To address the problem of covariate shift, attempts have been made by adversarially training the encoder so as to make document representation domain invariant (Ganin et al., 2016).

Another approach to domain adaptation is multi-task learning as it can help improve the performance of text classifiers on lexicon dataset (Caruana, 1997). It is assumed that by learning related tasks in parallel while using a shared representation of document encoder can improve generalization by inducing proper inductive biases.

3 Lexicon Dataset Construction

As mentioned previously, to test our hypothesis whether the text classifiers just focus on key lexicons, we consider three text corpora: IMDB reviews, its standard subset (Maas et al., 2011), and Arxiv abstracts. For each dataset, we construct two versions: random split version and lexicon split version. In the random split version, selection of training and test examples is done by random sampling. The ratio of test to training examples is kept approximately the same for both the random and lexicon version of each dataset. In the lexicon split version, we make sure that key lexicons in training and test examples do not overlap while taking care of class imbalance. Below, we provide stepwise details of the approach used for the construction of lexicon version of the datasets.

1. **Identification of important label specific lexicons:** We begin by extracting *tf-idf* weighted, unigram to five-gram word features for all the documents. Using thus obtained feature vectors as input, we train a multinomial Naïve Bayes classifier for predicting the class on the entire dataset (both training and test examples). From the trained Naïve Bayes classifier, we extract the feature weights. Next, we rescale the feature weights by dividing all the feature values by the corresponding minimum value for that feature across all the classes. Lastly, to identify lexicons, we select the top-*k* features with the maximum weight for every class. We set the value of *k* to be 1500 for IMDB datasets and 150 for Arxiv abstracts dataset. We also experiment with Logistic Regression and SVM classifiers but observe that multinomial Naïve Bayes selects the most diverse set of features.

(a) Arxiv abstracts

	most-positive	positive	neutral	negative	most-negative
Train	absolutely amazing awesome experience fantastic movie	completely satisfied good experience great movie	average movie is just ok moderate movie	disappointed scope for improvement movie sucks	a huge let down movie was awful very frustrating
Test	outstanding performance very impressive	nice experience movie is good	satisfactory movie avg performance	not a good no plot in movie	worst experience pretty bad

(b) IMDB reviews

Table 1: Example lexicons for training and test set of Arxiv abstracts and IMDB reviews datasets. The column headers in both the tables indicate the names of various classes in these datasets. For Arxiv abstracts dataset, the details of all the class names can be found in the URL: `https://arxiv.org`

2. **Creation of lexicons-documents graph:** Since each label specific lexicon term can occur in multiple documents, and one document can contain many such lexicons, in order to create a disjoint partition of lexicons and documents into training/test sets, it is natural to represent documents and lexicons using a graph-based structure. Therefore, for each class, we create an undirected graph whose nodes are lexicons and documents respectively. If a lexicon occurs in a document, we create an edge in the graph between the two corresponding nodes. The resulting graph is bipartite, as edges only exist between the lexicon nodes and the document nodes but not among each other (Figure 1a).

3. **Graph partitioning to generate training/test splits:** We compute all the connected components of the lexicons-documents graph. We then identify the largest connected component, i.e. one which contains the maximum number of nodes and select all the documents in it as the training set.[1] The remaining documents from all the other connected components are selected as the test set (Figure 1b). If the ratio of the number of test to training documents is below a cutoff threshold, we repeat the above steps by gradually selecting fewer top-*k* features (i.e. smaller set of lexicons). Some example lexicons for training/test splits of Arxiv abstracts and IMDB reviews datasets is shown in Table 1.

We want to emphasize that after the creation of training and test sets, the majority of the words appear in both the sets for the lexicon version.

4 Methods

In this section, we will first briefly describe a simple neural network for text classification on which our proposed regularization methods are based.

Let the vocabulary size be V and embedding dimension be D. Our network consists of an embedding layer ($E \in \mathbb{R}^{V \times D}$), single layer bidirectional LSTM (BiLSTM) (Schuster and Paliwal, 1997), a pooling layer, and finally a linear layer with softmax function for classification. The sequence of word ids ($w_t, t \in [1, T]$) are given as input to the embedding layer which maps them to dense vectors. The forward LSTM and backward LSTM of a BiLSTM processes these input sequence of word vectors in forward and reverse directions respectively. The hidden state of forward LSTM and backward LSTM is concatenated at every time-step and are passed to the pooling layer which computes the maximum value over time

[1] We also tried spectral partitioning of lexicons-documents graph but it didn't generate balanced graph partitions.

dimension to obtain the representation of the input sequence (Conneau et al., 2017). We train the model by minimizing the cross-entropy loss.

While training various neural network models on both random and lexicon splits of ACL IMDB dataset (Maas et al., 2011), we observed that on the lexicon split, the network is easily able to learn the training data distribution in 1-2 epochs. These models also overfit on the lexicon split as the accuracy gap between the training and test set widens up. We hypothesize that this happens because, during training step, the model is able to memorize common label-specific keywords occurring in the training set. During evaluation, when the model is not able to spot such keywords in the test set, as it contains non-overlapping partition of keywords from the training set, the performance degrades quite rapidly as compared to the random split version. Therefore, motivated by these observations, we propose two methods which attempt to prevent neural networks from memorizing the word order structure in keywords by introducing more randomness in them.

4.1 Keyword Anonymization

In order to prevent the model from memorizing keyword specific rules and thus learning degenerate representations, we introduce more randomness in our training data split (Hermann et al., 2015). In the first step, we identify some keywords with high scores using a supervised classifier trained using bag-of-words as features. The first step is similar to the first step of data construction, with the important distinction that now we only operate on training set as test set is assumed to be unknown during the training phase. In the second step, we anonymize the corpus by replacing a single word selected at random from the occurrences of such keyword phrases with a placeholder word '`ANON`'. In the third step, we assign a random word embedding during model training for every occurrence of the placeholder word '`ANON`'. These modified word embeddings are given as input to the neural network encoder.

In this way, we corrupt the information present in keywords by introducing some form of random noise in the data. This is one of the ways to regularize model training. We later show that this regularization forces the network to learn context-aware text representations which gives a significant gain in classification accuracy. Motivated by the effectiveness of this method, we now propose an end-to-end version as the next approach.

4.2 Adaptive Word Dropout

This approach is based on embedding layer's gradient which is computed at every optimization step. The motivation of this approach is based on the observation that key lexicon terms have a higher norm of the embedding gradient. In this method, we first compute the word embedding gradient ($\nabla E \in \mathbb{R}^{V \times D}$) during the backward step. In the second step, for every word we maintain the running average ($A(w)$) of the L2-norm of this gradient. This average is computed with respect to the number of completed optimization steps.

$$\tilde{A}(w) = \tilde{A}(w) + \sqrt{\sum_{j=1}^{D} \nabla E_{ij}^2}$$

$$A(w) = \frac{1}{\text{optim\_steps}} \tilde{A}(w)$$

In the third step, we compute the dropout probability of every word as:

$$P_d(w) = 1 - \sqrt{\frac{t}{A(w)}}$$

In the above equation, t is a hyperparameter (typical values of t are 10^{-3}, 10^{-4}). We apply dropout on the words before the word embedding layer with probability $P_d(w)$ (Srivastava et al., 2014). We also apply variational dropout (Gal and Ghahramani, 2016) on the output of word embedding layer.

5 Experiments

We now present empirical studies in order to establish that (i) many text classifiers resort to just identifying key lexicons and thus poorly performing on specially crafted dataset splits (Section 5.3), and (ii) simple regularization techniques which disincentivize focusing on key lexicons can significantly boost performance (Section 5.4).

5.1 Dataset Description

To illustrate aforementioned claims, we evaluate on an existing dataset for binary sentiment classification and also collected two more large-scale text classification datasets. The details of these three datasets are described below:

- **ACL IMDB**: This is a popular benchmark dataset (Maas et al., 2011) of IMDB movie reviews for coarse-grained sentiment analysis in which the task is to determine if a review belongs to the positive class or to the negative class. The original random split version of this dataset contains an equal number of highly positive and highly negative reviews. To construct its lexicon based version, we apply our approach to the combined training and test splits of this dataset.

- **IMDB reviews**: This is a much bigger version of the IMDB movie reviews dataset in which the task is to do fine-grained sentiment analysis. We collect more than 2.5 million reviews from IMDB website and partition them into five classes based on their ratings out of 10. These classes are *most-negative*, *negative*, *neutral*, *positive*, and *most-positive*.

- **Arxiv abstracts**: In this, the task is to do multiclass topic classification. We construct this dataset by collecting more than 1 million abstracts of scientific papers from "*arxiv.org*". Each paper has one primary category such as cs.AI, stat.ML, etc. which we use as its class label. We selected those primary categories which have at least 500 papers. In order to extract text data, we use the title and abstract of each paper. In both the Arxiv abstracts and IMDB reviews dataset, we keep the ratio of the number of instances in the test set to that of training set as 0.6.

We pre-process the data by converting all the text to lowercase followed by Penn Treebank style tokenization. An overall summary of the training/test sets of lexicon and randomized splits is provided in Table 2.

5.2 Experimental Setup

In this section, we will discuss our experimental setup. For simple baseline comparisons, we conduct experiments with methods which take bag-of-words as input feature representations. Specifically, we compute *tf-idf* weighted *n-gram* features for each document to train multinomial Naïve Bayes and Logistic Regression classifiers. For neural network models, we have a common experimental setup based on Pytorch framework (Paszke et al., 2017) for all the datasets unless specified otherwise. Due

to computational constraints, we did not perform extensive hyperparameter tuning for the methods considered.

We select most common 80K words for model training. We initialize the embedding layer parameters for all the models using 300-dimensional pre-trained embeddings. These embeddings are trained using skip-gram approach (Mikolov et al., 2013) on the combined training and test set.[2] The embeddings of words which are not present in these vectors are uniformly initialized. The hidden state of LSTM and BiLSTM has 1024 and 512 dimensions respectively. For training of CNN models, we follow the settings mentioned in Kim (2014). We perform model training using mini-batch stochastic gradient descent with a batch size of 150. Optimization is performed using Adam Optimizer (Kingma and Ba, 2014) with default parameter settings. To train LSTM models, we perform backpropagation for 250 timesteps on IMDB datasets and 150 timesteps on Arxiv abstracts dataset. For model regularization, we apply dropout (Srivastava et al., 2014) with probability 0.5 to the input and output of LSTM. In order to prevent gradient explosion problem, we perform gradient clipping (Pascanu et al., 2013) by constraining the norm of the gradient to be less than 5.

5.3 Results

In order to estimate the difficulty level on both the lexicon and random splits version of a dataset, we do experiments with a wide range of popular approaches and show their results in Table 3. It can be observed from the results that for each dataset, there is a big performance gap between the random split and lexicon split for all the models. In this section, we will analyze these performance results. During our analysis, we will mostly focus on classifier's performance on the lexicon version of a dataset. For a detailed analysis of the performance of a method on the random version, we encourage the reader to read the associated paper.

5.3.1 Bag-of-Words Model

Here, we analyze the performance of methods which takes bag-of-words representation as input. We observe that the simple generative classifier of Naïve Bayes performs poorly as compared to other approaches on both Arxiv abstracts and IMDB reviews dataset, while its results are competitive on ACL IMDB dataset. Because of its relatively low scores, we don't experiment with more complex generative models. In contrast, a simple discriminative classifier such as Logisitic Regression performs significantly better than Naïve Bayes on the random version for all the datasets. However, on lexicon version, it's performance is quite low when compared to neural network methods. Due to this, the accuracy gap for this method is largest between both the dataset versions. These low scores of above classifiers on lexicon version can be explained owing to the conditional independence assumption among the input features. During training step, bag-of-words based models assign high weights to class-specific keywords. When this trained model is not able to spot such discriminative keywords in the test set due to strict no overlap condition, the performance of these methods degrades.

5.3.2 Simple Word Embedding based Methods

Next, we analyze the results of classifiers which are based on simple linear or nonlinear transformation of word embeddings. We train 300-dimensional document vectors (Le and Mikolov, 2014) using standard training settings for DBOW model.[3] Similarly, we use the recommended training setting for FastText method (Joulin et al., 2017). These methods further improve the lexicon results in both the IMDB datasets. Although DBOW and FastText methods don't strictly make use of word order in a sentence, improved performance suggests that they leverage the semantic properties of the embedding space as the document vectors are also learned in the same geometrical space as the word vectors.

5.3.3 Convolutional and Recurrent Networks

As discussed previously (Section 2), it has been shown that both CNN and LSTM models can learn effective text representations. We observe that these networks show much better performance on both the random and lexicon version as compared to the above-discussed methods. We also note that the use of a

[2]We use *word2vec* tool from `https://code.google.com/p/word2vec`

[3]We use the existing implementation from the open-source gensim toolkit.

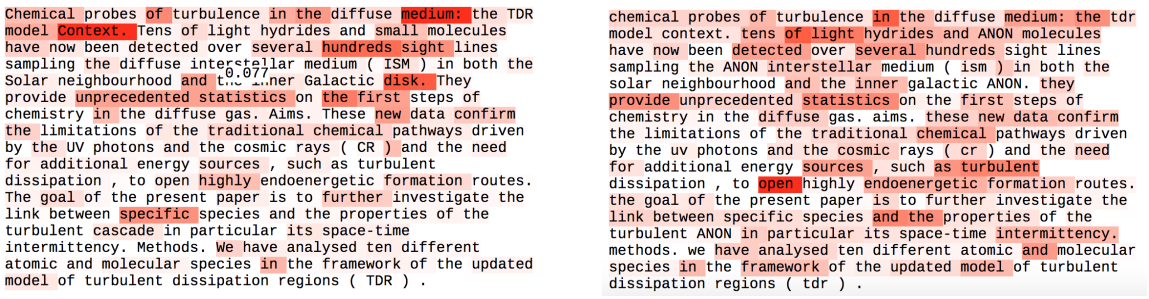
Table 3: Classification accuracy of various models on random and lexicon based version of each dataset. We also show the accuracy difference (Δ) between these two results. **Naïve Bayes**: *n-gram* feature extraction using *tf-idf* weighting followed by Naïve Bayes classifier. **Logistic Regression**: *n-gram* feature extraction using *tf-idf* weighting followed by Logistic Regression classifier. **DocVec**: Document vectors trained using DBOW model (Le and Mikolov, 2014). **FastText**: Average of the word and subword embeddings (Joulin et al., 2017). **Deep Sets** (Zaheer et al., 2017): two layer MLP on top of word embeddings with max pooling layer. **LSTM**: Word level LSTM as a document encoder in which hidden state of the last time-step is used for classification. **BiLSTM**: Word level bidirectional LSTM as a document encoder in which forward LSTM and backward LSTM hidden states are concatenated followed by max pooling layer (Conneau et al., 2017). **CNN-MaxPool**: CNN with max pooling layer (Kim, 2014). **CNN-DynMaxPool**: CNN with dynamic max pooling layer. For details on dynamic max pooling, we request the reader to refer to Johnson and Zhang (2015a). **Adv-Training**: Adversarial training of encoder is done to fool the discriminator and make the representation of training and test instances domain invariant. **Multi-task Learning**: A shared BiLSTM encoder is used to perform joint training of text classifier, denoising autoencoder, and adversarial training. **LSTM-Anon**: LSTM encoder applied to the anonymized training data. **BiLSTM-Anon**: BiLSTM encoder applied to the anonymized training data. **Adaptive Dropout**: BiLSTM encoder applied after embedding gradient-based adaptive word dropout.

more complex model such as BiLSTM gives performance improvement in both random and lexicon splits for all the datasets.

Although there is an improvement in classification accuracy, still there is a large drop in performance from random to lexicon split. For the best performing approach of BiLSTM model, accuracy difference between random and lexicon split of ACL IMDB, IMDB reviews, and Arxiv abstracts dataset is 8.3%, 18.9%, and 21.3% respectively. In order to narrow down this performance gap, there is a need for approaches which can learn more robust context-based representations so that the performance on documents containing new unseen key phrases can be improved.

5.3.4 Domain Adaptation Methods

For the lexicon split, one can consider that the training and test data distributions are different, and thus model this as an instance of unsupervised domain adaptation. We evaluate two different approaches for such domain adaptation: adversarial training and multi-task learning.



(a) without word anonymization

(b) with word anonymization

Figure 2: This attention heat map shows the change in hidden state activations of BiLSTM encoder when some label specific keywords are anonymized for an example instance from Arxiv abstracts dataset whose label is *astro-ph.GA*. In Figure 2a, the trained classifier makes an incorrect prediction as it can be seen that the model is performing a keyword-based classification. In Figure 2b with word anonymization, the attention span also involves other context words and the prediction is correct.

To address lexical/covariance shift in lexicon dataset split, we adversarially train BiLSTM model with the objective that the resulting document representation will be discriminative for the text classification task while indiscriminative to the training/test domain classification. To perform such domain-invariant adversarial training, we include a discriminator module which consists of three feed-forward layers. To learn the model parameters, we follow the training method of Ganin et al. (2016), but instead of gradient reversal, we feed the interchanged labels of the domains to fool the discriminator. From the results, we observe that adversarial training of encoder hurts the performance on lexicon datasets.

In multi-task learning, the various tasks which were trained jointly are text classification, denoising autoencoder (Hill et al., 2016), and adversarial training. In all these tasks, we share the embedding layer and BiLSTM encoder layer. Denoising autoencoder was trained on the entire dataset using the strategy described in Lample et al. (2017). From the results, we observe that multi-task learning doesn't help and it further hurts the overall classification accuracy.

We didn't experiment with these domain adaptation approaches on the random split of the dataset, as it is assumed that it contains the same distribution of lexicons in the training and test set. Also, as the initial results were not promising on lexicon dataset, we didn't try more complex approaches.

5.4 Our Methods

BiLSTM encoder applied to anonymized training data with random embedding substitution performs around 2% better on Arxiv abstracts dataset, 2.5% better on IMDB reviews dataset and gives around 1% improvement on ACL IMDB lexicon dataset. This shows that keyword anonymization with random embedding substitution can be a good strategy for model regularization in case of lexicon-based split. From a qualitative perspective, we show in Figure 2 the change of hidden state activations for the BiLSTM encoder after the data is anonymized.

Our approach of adaptive word dropout performs 2.6% better on Arxiv abstracts, 3.6% better on IMDB reviews and gives around 2.8% improvement on ACL IMDB lexicon datasets. We also note that this approach leads to an only marginal drop in accuracy for the random split version of the datasets. One of the reasons why this method is more effective is that word dropout partially masks some lexical terms in the training set thereby lowering the variance of the fitted model.

6 Conclusion

Recently, multilayer neural network models have gained wide popularity for text classification tasks due to their much better performance than traditional bag-of-words based approaches. It is widely believed that this happens as neural networks can effectively utilize the word order structure present in documents. But, a potential drawback is that since all neural network approaches are discriminative, they tend to identify key signals in the training data which may not generalize to test data. In this work, we investigate

whether these neural network models actually learn to compose the meaning of sentences or just use discriminative keywords.

To test the generalization ability of different state-of-the-art text classifiers, we construct hard datasets where the training and test splits have no direct overlap of lexicons. Our experiments with popular text classifiers show that there is a large drop in test classification accuracy between random and lexicon splits of these datasets. We show that simple regularization techniques such as keyword anonymization can substantially improve the performance of text classifiers. We also observe that adaptive word dropout method which is based on embedding layer's gradient can further improve accuracy and thus reduce the gap between the two dataset splits.

Acknowledgments

This work was supported by a generous research funding from CMU, MCDS students grant. We would also like to thank the anonymous reviewers for giving us their valuable feedback which helped to improve the paper.

A Review on Deep Learning Techniques Applied to Answer Selection

sheli@adobe.com

Abstract

Given a question and a set of candidate answers, answer selection is the task of identifying which of the candidates answers the question correctly. It is an important problem in natural language processing, with applications in many areas. Recently, many deep learning based methods have been proposed for the task. They produce impressive performance without relying on any feature engineering or expensive external resources. In this paper, we aim to provide a comprehensive review on deep learning methods applied to answer selection.

1 Introduction

Answer selection is an active research field and has drawn a lot of attention from the natural language processing community. Given a question and a set of candidate answers, the task is to identify which of the candidates contains the correct answer to the question. For example, given the question "Who established the Nobel Prize?" and the following candidate answers:

1. The Nobel Prize was established more than 100 years ago.
2. The Fields Medal, established in 1936, is often described as the Nobel Prize of mathematics.
3. The Nobel Prize was established in the will of Alfred Nobel.

The third answer should be selected. This example shows that simple word matching is not enough. Even though, all of the sentences contain the keywords "established" and "Nobel Prize", only the third sentence answers the question. From this point, we assume that each candidate answer is a sentence although the discussion is also applicable to more general case such as each candidate answer is a passage.

Answer selection is an important problem in its own right as well as in the context of open domain question answering. Although details vary from system to system, a typical open domain question answering system can be considered as consisting of: (a) question analysis (b) retrieval of potentially relevant documents (c) ranking and selecting of the most promising sentences (or more generally, passages) within the retrieved documents; and optionally d) extracting the exact natural language phrase that answers the question (Prager, 2006; Ferrucci, 2012; Sequiera et al., 2017). Figure 1 depicts a typical question answering pipeline. In this setup, answer selection can be applied to identify the sentences that are most relevant to the question within the retrieved documents. Besides its application in open domain question answering, the techniques developed for answer selection can be potentially used to predict answer quality in community question answering (cQA) sites (Nakov et al., 2015).

Previous work on answer selection typically relies on feature engineering, linguistic tools, or external resources (Wang et al., 2007; Wang and Manning, 2010; Heilman and Smith, 2010; Yih et al., 2013; Yao et al., 2013). Recently, many deep learning based methods have been proposed for the task (Bian et al., 2017; Shen et al., 2017; Tran et al., 2018). They outperform traditional techniques. In addition, they do not need any feature-engineering effort or hand-coded resources beyond some large unlabeled corpus on which to learn the initial word embeddings, such as word2vec (Mikolov et al., 2013) or GloVe (Pennington et al., 2014).

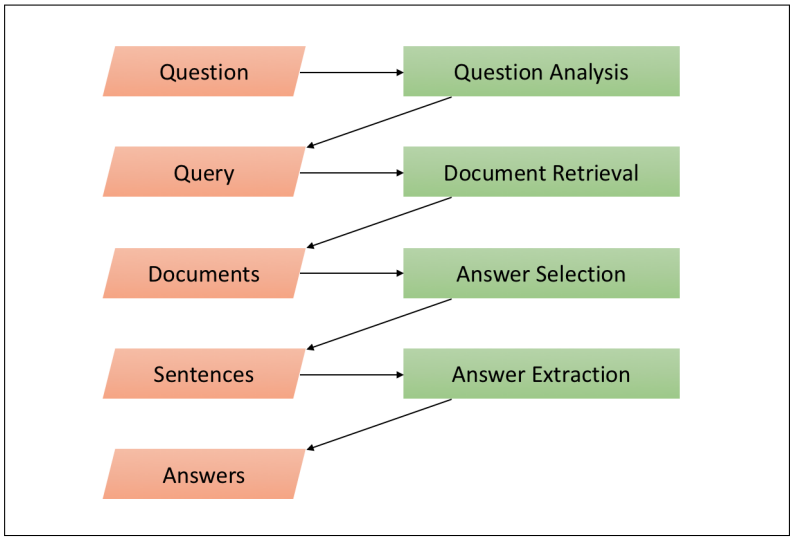

Figure 1: A typical question answering pipeline architecture, adapted from (Sequiera et al., 2017)

While previous work has recognized the increasing use of deep learning techniques in natural language processing (Young et al., 2017), no systematic survey of deep learning methods for answer selection to date has been published. Therefore, in this paper, we aim to give a comprehensive review of various deep learning methods that have been used to tackle the answer selection task.

In Section 2, we present a review of deep learning methods for answer selection. In Section 3, we examine the most popular datasets and the evaluation metrics for answer selection. We conclude this paper in Section 4 by discussing the potential future research directions.

2 Methods

Existing deep learning methods for answer selection can be examined along two dimensions: (i) learning approaches (ii) neural network architectures (Table 1).

2.1 Learning Approaches

Given a question and a set of candidate sentences, the task is to identify candidate sentences that contain the correct answer to the question. From the definition, the problem can be formulated as a ranking problem, where the goal is to give better rank to the candidate sentences that are relevant to the question. There are three most common approaches to learn the ranking function h_θ, namely, *pointwise*, *pairwise* and *listwise* (Liu, 2011).

In the *pointwise* approach, the ranking problem is transformed to a binary classification problem. More specifically, the training instances are triples (q_i, c_{ij}, y_{ij}), where q_i is a question in the dataset, c_{ij} is a candidate answer sentence for q_i, and y_{ij} is a binary value indicating whether c_{ij} contains the correct answer to q_i. It is enough to train a binary classifier: $h_\theta(q_i, c_{ij}) \rightarrow \hat{y_{ij}}$, where $0 \leq \hat{y_{ij}} \leq 1$. For example, in (Yu et al., 2014), the training objective is to minimize the cross entropy of all labelled question-candidate pairs in the training set. During inference, given a question, the trained classifier h_θ is used to rank every candidate sentence, and the top-ranked candidate is selected (i.e., $\text{argmax}_{c_{ij}} h_\theta(q_i, c_{ij})$ should be selected as the answer to q_i). Many work adopted this approach (Yu et al., 2014; Severyn and Moschitti, 2015; Wang et al., 2016b; Shen et al., 2017).

The second approach to ranking is the *pairwise* approach, where the ranking function h_θ is explicitly trained to score correct candidate sentences higher than incorrect sentences. Given a question, the approach takes a pair of candidate answer sentences and explicitly learns to predict which sentence is more relevant to the question. For example, in (Feng et al., 2015), the training instances are triples (q_i, c_i^+, c_i^-), where q_i is a question, c_i^+ is a correct sentence for q_i, and c_i^- is an incorrect sentence sampled from the

Method	Learning Approach	Model Architecture	MAP (Raw TrecQA)	MAP (Clean TrecQA)
TRAIN-ALL unigram+count (Yu et al., 2014)	Pointwise	Siamese	0.693	-
TRAIN-ALL bigram+count (Yu et al., 2014)	Pointwise	Siamese	0.711	-
QA-LSTM (Tan et al., 2015)	Pairwise	Siamese	-	0.682
QA-LSTM with attention (Tan et al., 2015)	Pairwise	Attentive	-	0.690
QA-LSTM/CNN (Tan et al., 2015)	Pairwise	Siamese	-	0.706
Attentive Pooling CNN (dos Santos et al., 2016)	Pairwise	Attentive	-	0.753
(Severyn and Moschitti, 2015)	Pointwise	Siamese	0.746	-
L.D.C Model (Wang et al., 2016b)	Pointwise	Compare-Aggregate	-	0.771
Pairwise Word Interaction Modelling (He and Lin, 2016)	Pointwise	Compare-Aggregate	0.758	-
Multi-Perspective CNN (He et al., 2015)	Pointwise	Siamese	0.762	0.777
HyperQA (Hyperbolic Embeddings) (Tay et al., 2018a)	Pairwise	Siamese	0.770	0.784
PairwiseRank+Multi-Perspective CNN (Rao et al., 2016)	Pairwise	Siamese	0.780	0.801

Dynamic-Clip Attention (Bian et al., 2017)	Listwise	Compare-Aggregate	-	0.821
IWAN (Shen et al., 2017)	Pointwise	Compare-Aggregate	-	0.822
IWAN+CARNN (Tran et al., 2018)	Pointwise	Compare-Aggregate	-	0.829
MCAN (Tay et al., 2018b)	Pointwise	Compare-Aggregate	-	0.838

Table 1: Overview of existing deep learning methods to answer selection

whole candidate sentence space. And the hinge loss function is defined as follows:

$$L = max\{0, m - h_\theta(q_i, c_i^+) + h_\theta(q_i, c_i^-)\} \quad (1)$$

where m is the margin. If $h_\theta(q_i, c_i^+) - h_\theta(q_i, c_i^-) < m$ then L is positive. When this condition is satisfied, the implication is that the system ranks the positive sentence below the negative sentence, or does not sufficiently rank the positive answer above the negative answer. On the other hand, if the correct sentence has a score higher than the incorrect sentence by at least a margin m (i.e., $h_\theta(q_i, c_i^+) - h_\theta(q_i, c_i^-) \geq m$), and then the above expression has zero loss. In summary, the loss function is designed to encourage the correct answer to have a higher score than the incorrect answer by a certain margin. Similar to the *pointwise* approach, during testing, the candidate answer with the largest score is selected. (Tan et al., 2015; Yang et al., 2016; dos Santos et al., 2016; Tay et al., 2018a) also used the pairwise hinge loss function above.

The third method is the *listwise* approach (Cao et al., 2007). The *pointwise* approach and the *pairwise* approach ignore the fact that answer selection is a prediction task on list of candidate sentences. In

the *listwise* approach, a single instance consists of a question and its list of candidates. For example, (Bian et al., 2017) adopted the approach. Concretely, during training, given a question q_i and its list of candidate sentences $\mathbf{C}$ $\{c_{i1}, c_{i2}, ..., c_{im}\}$ and the ground truth labels $\mathbf{Y}$ $\{y_{i1}, y_{i2}, ..., y_{im}\}$, the normalized score vector $\mathbf{S}$ is calculated as follows:

$$\begin{aligned} Score_j &= h_\theta(q_i, c_{ij}) \\ \mathbf{S} &= softmax([Score_1, Score_2, ..., Score_m]) \end{aligned} \tag{2}$$

Target labels also need to be normalized:

$$\mathbf{Y} = \frac{\mathbf{Y}}{\sum_{j=1}^{m} y_{ij}} \tag{3}$$

And the objective is to minimize the KL-divergence of $\mathbf{S}$ and $\mathbf{Y}$.

Even though many work (Yu et al., 2014; Severyn and Moschitti, 2015; Wang et al., 2016b; Shen et al., 2017) adopted the *pointwise* approach, this approach is not close to the nature of ranking. The *pairwise* approach and the *listwise* approach exploit more information about the ground truth ordering of candidate sentences. (Rao et al., 2016) proposed a *pairwise* ranking approach that can directly exploit existing *pointwise* neural network models as base components. The approach outperforms many competitive *pointwise* baselines. (Bian et al., 2017) showed that the *listwise* approach performs better than the *pointwise* approach on public datasets such as TrecQA (Wang et al., 2007) and WikiQA (Yang et al., 2015). In the next section, we describe various neural network architectures for modeling the ranking function h_θ, which takes a question-candidate pair and returns a score indicating whether the candidate is relevant to the question.

2.2 Neural Network Architectures

There are three main types of general architectures for measuring the relevance of a candidate sentence to a question.

- **Siamese Architecture.** In a Siamese architecture (Bromley et al., 1993), the same encoder (e.g., a CNN or a RNN) is used to build the vector representations for the input sentences (i.e., the candidate answer and the question) individually. After that, the relevance score is determined solely based on the encoded vectors. There is no explicit interaction between the input sentences during the encoding process.
- **Attentive Architecture.** Instead of generating representations for the candidate answer and the question independently, attention mechanisms (Bahdanau et al., 2014; Hermann et al., 2015; Luong et al., 2015) can be used to allow the information from an input sentence to influence the computation of the other's representation (Tan et al., 2015; dos Santos et al., 2016). Even though the weakness of the Siamese models is alleviated, the interaction between the input sentences during the encoding process is still minimal in most Attentive architectures.
- **Compare-Aggregate Architecture.** The Compare-Aggregate architectures can capture more interactive features between input sentences than the Siamese architectures and the Attentive architectures, therefore typically have better performance when evaluated on public datasets such as TrecQA (Wang et al., 2007) and WikiQA (Yang et al., 2015). In a Compare-Aggregate architecture, vector representations of small units such as words of the sentences are first compared. After that, these comparison results are aggregated to calculate the final relevance score.

It is worth mentioning that the boundaries between the architecture types are not always crystal clear. For example, while many Siamese architectures typically capture less interactive features between the input sentences than the Attentive architectures, few recently proposed Siamese architectures have sophisticated comparison layer after the encoding layer (He et al., 2015; Rao et al., 2016). As a result, they even outperform some Attentive architectures. Even though the boundaries are not crystal clear, separating the existing different neural architectures into the three categories can provide the big picture more easily.

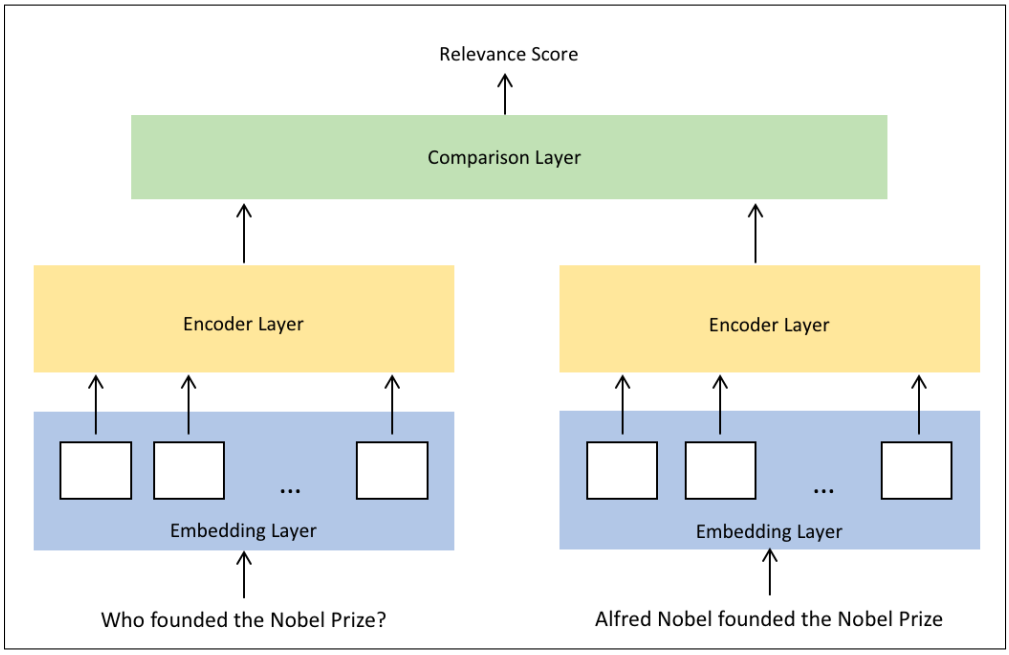

Figure 2: The general architecture of a Siamese model. The same encoder is used to generate the vector representations for the input sentences.

2.2.1 Siamese Architecture

Siamese neural networks have been proposed for a number of sentence pair modeling tasks, including semantic similarity (Mueller and Thyagarajan, 2016), paraphrase identification (Hu et al., 2014), and natural language inference (Conneau et al., 2017). Figure 2 shows the general architecture of a Siamese model. The vector representations of the input sentences are built separately by the encoder. Two input sentences have no influence on the computation of each other's representation. After that, the encoded vectors are compared using measures such as cosine similarity (Feng et al., 2015; Yang et al., 2015), element-wise operations (Tai et al., 2015), or neural network-based combination (Bowman et al., 2015). An advantage of this architecture is that applying the same encoder to each input sentence makes the model smaller. In addition, the sentence vectors can be used for visualization, sentence clustering and many other purposes (Wang et al., 2016a).

One of the first attempts at applying deep learning to answer selection was the bag-of-words model proposed by (Yu et al., 2014). The model generates the vector representation of a sentence by simply taking the average of all the word vectors in the sentence - having previously removed all the stop words. Integrating additional overlapping word count features with the model achieves performance better than many traditional techniques that require large numbers of hand-crafted features or external resources. Tan et al. (2015) proposed the QA-LSTM model that employs a bidirectional long short-term memory (biLSTM) network (Hochreiter and Schmidhuber, 1997) and a pooling layer to construct distributed vector representations of the input sentences independently. Then the model utilizes cosine similarity to measure the distance of the sentence representations. Severyn and Moschitti (2015) proposed a model that employs a convolutional neural network (CNN) to generate the representations of the input sentences. The CNN is based on an architecture that has previously been applied to many sentence classification tasks (Kalchbrenner et al., 2014; Kim, 2014). In (He et al., 2015), each input sentence is modeled using a CNN that extracts features at multiple levels of granularity and uses multiple types of pooling. The representations of the input sentences are then compared at several granularities using multiple similarity metrics. Finally, the comparison results are fed into a fully connected layer to obtain the final relevance score. The proposed model outperforms many other Siamese models. Tay et al. (2018a) proposed a simple but novel deep learning architecture that models the relationship between a question and a candidate sentence in Hyperbolic space instead of Euclidean space. It achieves highly competitive performance

without employing any sophisticated neural encoder such as LSTM or CNN. Vector representations of the input sentences are generated independently in a bag-of-words manner.

2.2.2 Attentive Architecture

In a Siamese architecture, the input sentences are first encoded into fixed-length vector representations separately, and these representations are then compared. Despite its conceptual simplicity, a disadvantage is the absence of explicit interaction between the input sentences during the encoding process. A question is always mapped to the same vector regardless of the candidate answer in consideration, and vice versa. Attention mechanisms have been applied to alleviate the weakness. Tan et al. (2015) extended the basic QA-LSTM model with attention (Figure 3). The model employs a biLSTM network and a pooling layer to generate the question representation $\mathbf{o}_q$. The candidate representation $\mathbf{o}_c$ is calculated similarly, except that prior to the pooling layer, each biLSTM output vector will be multiplied by a weight, which is determined by the question representation $\mathbf{o}_q$. Conceptually, the attention mechanism gives more weights on certain words in the candidate answer, and the weights are computed according to the question information. In this case, the attention mechanism is performed only in a single direction. dos Santos et al. (2016) proposed a two-way attention mechanism called Attentive Pooling (AP). AP allows the information from the two input sentences to influence the computation of each other's representation.

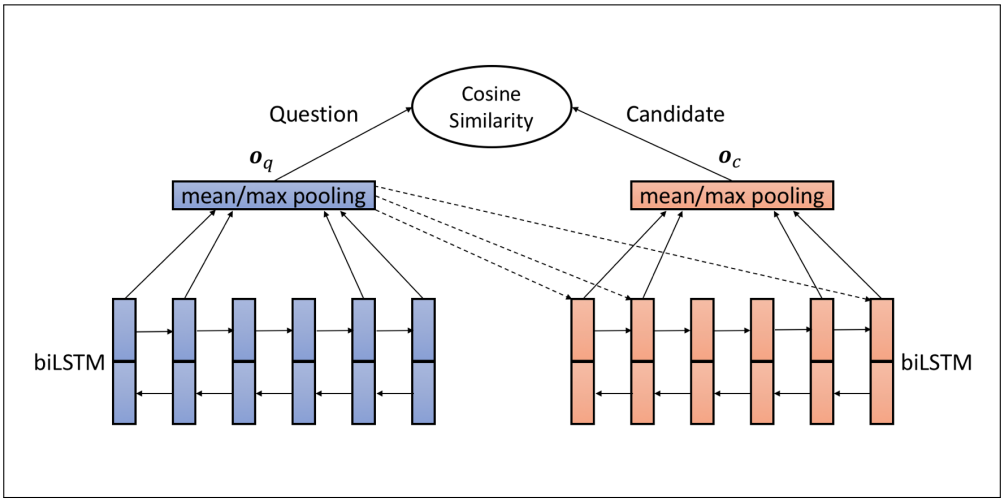

Figure 3: QA-LSTM with attention (figure adapted from (Tan et al., 2015))

2.2.3 Compare-Aggregate Architecture

A common trait of a number of recent state-of-the-art methods for answer selection is the use of the Compare-Aggregate architecture (Wang and Jiang, 2016; Wang et al., 2017; Bian et al., 2017; Shen et al., 2017; Tran et al., 2018). Under this architecture, smaller units (such as words) of the input sentences are compared. And then the comparison results are aggregated (e.g., by a CNN or a RNN) to make the final decision. Figure 4 shows the architecture of BiMPM, a Compare-Aggregate model proposed in (Wang et al., 2017). The model consists of five layers as follows.

Word Representation Layer. The goal of this layer is to represent each word in the input sentences with a d-dimensional vector. BiMPM constructs the d-dimensional vector with two components: a character-composed embedding and a word embedding pre-trained with GloVe (Pennington et al., 2014) or word2vec (Mikolov et al., 2013).

Context Representation Layer. The goal of this layer is to obtain a new representation for each position in the input sentences that captures some contextual information in addition to the word at the position. BiMPM employs a biLSTM to generate the contextual representations.

Matching Layer. The goal of this layer is to compare each contextual representation of one sentence against all contextual representations of the other sentence. The output of this layer are two sequences of

matching vectors, where each matching vector corresponds to the comparison result of one position of a sentence against all the positions of the other sentence.

Aggregation Layer. The goal of this layer is to aggregate the comparison results from the previous layer. BiMPM employs another BiLSTM to aggregate the two sequences of matching vectors into fixed-length vectors.

Prediction Layer. The goal of this layer is to make the final prediction. BiMPM uses a two layer feed-forward neural network to consume the fixed-length vectors from the previous layer, and apply the softmax function to get the final score.

Even though specific details vary from model to model, other Compare-Aggregate models for answer selection (Bian et al., 2017; Shen et al., 2017; Tran et al., 2018) have a similar structure to the BiMPM model. The Compare-Aggregate architectures can capture more interactive features between input sentences than the Siamese architectures and the Attentive architectures, therefore typically have better performance when evaluated on public datasets such as TrecQA (Table 1)

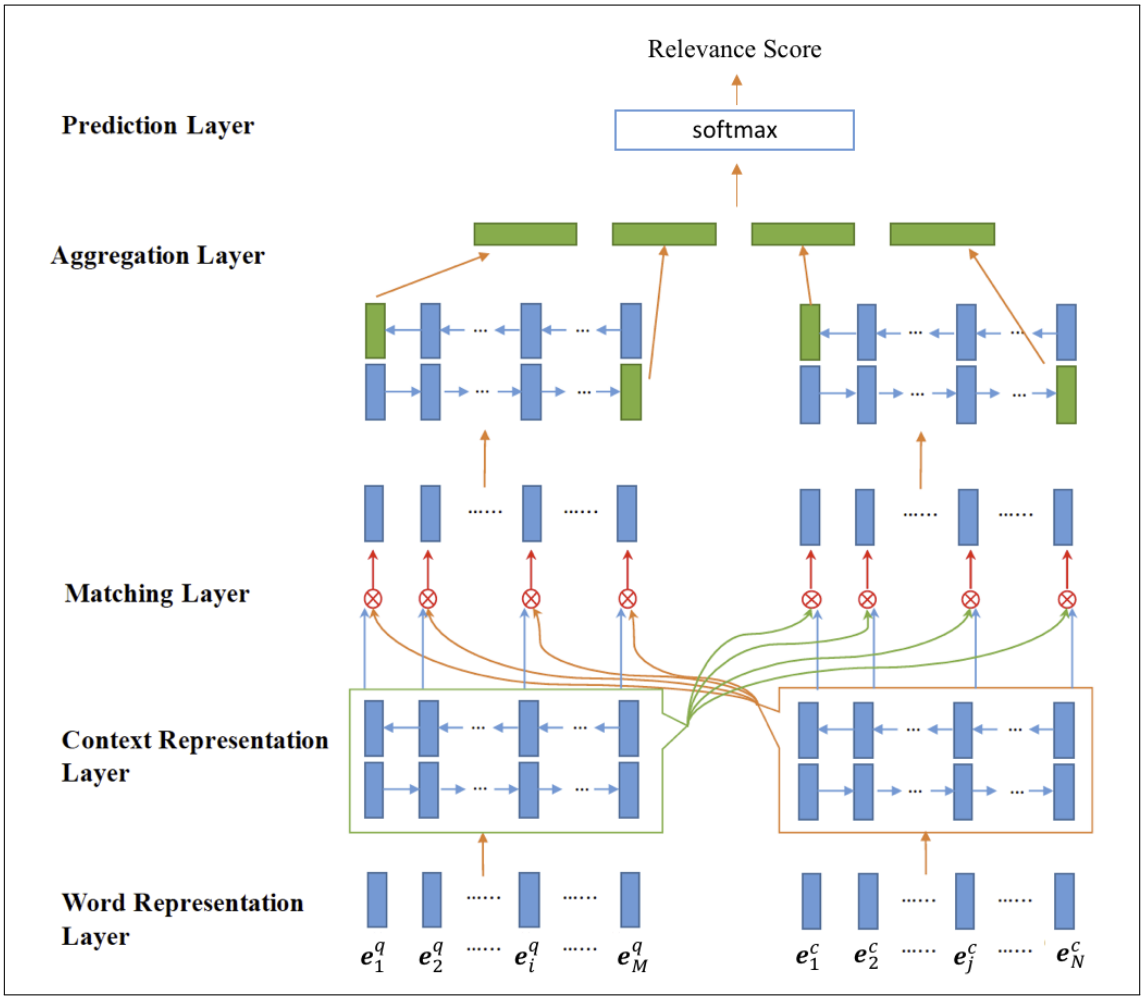

Figure 4: The architecture of the BiMPM model (figure adapted from (Wang et al., 2017))

3 Datasets and Evaluation Metrics

TrecQA, WikiQA, and InsuranceQA datasets have been widely used for benchmarking answer selection systems.

- The TrecQA dataset (Wang et al., 2007) was created from the TREC Question Answering tracks. In the literature (Yih et al., 2013; Yu et al., 2014; Severyn and Moschitti, 2015; Wang et al., 2016b;

dos Santos et al., 2016), we observe two versions of TrecQA: both have the same training set but their development and test sets differ. The Raw version has 82 development questions and 100 test questions. The Clean version removed questions in development and test sets with no answers or only positive/negative answers, reducing the development and test set's sizes to 65 and 68 questions, respectively. Relevant statistics are shown in Table 2. The data provided for training come as two sets: a small set of 94 questions (TRAIN) that were manually judged and a more noisy set of 1229 questions (TRAIN-ALL) that comes with automatic judgements.

Split	# Questions	# QA pairs	% Correct
TRAIN	94	4718	7.4%
TRAIN-ALL	1229	53417	12.0%
Raw DEV	82	1148	19.3%
Raw TEST	100	1517	18.7%
Clean DEV	65	1117	18.4%
Clean TEST	68	1442	17.2%

Table 2: Statistics of the TrecQA dataset

- The WikiQA dataset (Yang et al., 2015) is an open-domain question answering dataset that was constructed from real queries of Bing and Wikipedia. Relevant statistics are shown in Table 3. There are 3047 questions and 29258 candidate answer sentences in the dataset, and 1473 sentences were labeled as correct answer sentences to their corresponding questions. In the WikiQA dataset, there are questions with only incorrect answers. All questions with no correct answers are usually removed when the dataset is used to train and evaluate answer selection systems (Yang et al., 2015; Bian et al., 2017; Shen et al., 2017). The excluded WikiQA has 873/126/243 questions and 8627/1130/2351 question-answer pairs for train/dev/test split.

	Train	Dev	Test	Total
# Questions	2118	296	633	3047
# Candidate Answers	20360	2733	6165	29258
# Correct Answers	1040	140	293	1473
# Questions w/o Correct Answers	1245	170	390	1805

Table 3: Statistics of the WikiQA dataset

- The InsuranceQA dataset (Feng et al., 2015) is a large-scale domain specific answer selection dataset in which all question and candidate pairs are in the insurance domain. The original dataset consists of four parts: train, development, test1 and test2. Relevant statistics are shown in Table 4. There could be multiple correct answers for some questions so that the number of correct answers is larger than the number of questions. The released dataset contains 24981 unique answers in total. For each question, the candidate answer pool size is set to be 500. These candidate pools were constructed by including the correct answer(s) and randomly selecting candidates from the complete set of unique answers.

Split	# Questions	# Correct Answers
TRAIN	12887	18540
DEV	1000	1454
TEST1	1800	2616
TEST2	1800	2593

Table 4: Statistics of the original InsuranceQA dataset

Community Question Answering (cQA) platforms such as Stack Overflow [1] and Yahoo Answers [2] have become an important resource of information for many Web users. A person posts a question on

[1] http://stackoverflow.com
[2] https://answers.yahoo.com

a specific topic and other users post their answers. The techniques developed for answer selection can be potentially used to improve various aspects of a cQA platform. For example, in a cQA platform, it is not unusual for a question to have hundreds of answers, the vast majority of which would not satisfy a user's information needs. Therefore, using answer selection techniques to find relevant answers can be very beneficial. In the literature, the SemEval-2016 cQA dataset (Nakov et al., 2016) has been widely used to test different answer selection systems.

- In the SemEval-2016 cQA challenge (Nakov et al., 2016), there are three subtasks for English. Subtask A (*Question-Comment Similarity*): Given a question and its first ten comments in the question thread, the goal is to rank these ten comments according to their relevance with respect to the question. Subtask B (*Question-Question Similarity*): Given a new question and the set of the first ten related questions from the forum retrieved by a search engine, the goal is to rank the related questions according to their similarity with respect to the new question. Subtask C (*Question-External Comment Similarity*): Given a new question and the set of the first ten related questions from the forum retrieved by a search engine, each associated with its first ten comments appearing in its thread, the goal is to rank the 100 comments according to their relevance with respect to the new question. The data of the three subtasks was extracted from the community-created Qatar Living Forums [3]. Answer selection techniques can be directly applied to each of the subtask. All the information related to the dataset can be found on the SemEval-2016 Task 3 website[4].

Table 5 shows examples from the datasets. Each example consists of a question with a positive answer and a negative answer. A major difference between the SemEval-2016 cQA dataset and the other answer selection datasets is the average length of a question. In WikiQA (Yang et al., 2015) and TrecQA (Wang et al., 2007), a question is typically a short sentence, while in the cQA dataset, the question body typically contains quite a few sentences.

Dataset	Example
TrecQA	**Question**: Who established the Nobel prize awards? **Positive Answer**: The Nobel Prize was established in the will of Alfred Nobel, a Swede who invented dynamite and died in 1896. **Negative Answer**: The awards aren't given in specific categories.
WikiQA	**Question**: How many albums has Eminem sold in his career? **Positive Answer**: He has sold more than 100 million records worldwide, including 42 million tracks and 49.1 million albums in the United States. **Negative Answer**: Eminem is one of the best-selling artists in the world and is the best-selling artist of the 2000s.
InsuranceQA	**Question**: Does Medicare cover my spouse? **Positive Answer**: If your spouse has worked and paid Medicare taxes for the entire required 40 quarters, or is eligible for Medicare by virtue of being disabled or some other reason, your spouse can receive his/her own medicare benefits. If your spouse has not met those qualifications, if you have met them, and if your spouse is age 65, he/she can receive Medicare based on your eligibility. **Negative Answer**: If you were married to a Medicare eligible spouse for at least 10 years, you may qualify for Medicare. If you are widowed, and have not remarried, and you were married to your spouse at least 9 months before your spouses death, you may be eligible for Medicare benefits under a spouse provision.
SemEval-2016 cQA	**Question**:Hi;Can any one tell me a place where i can have a good massage drom philipinies????? yesterday i had a massage in Bio-Bil they charged me 300qr for 01 hour bt it is totally waste... pls advice me if theres any philipinos.... **Positive Answer**: Try Magic Touch in Abu Hamour (beside Abu Hamour Petrol Stn)it will just cost you 60QR per hour and I've seen a lot of Qataris as their customers. **Negative Answer**: I dont know the name; you can call them. Do it fast; they have sooooo many reservations ;)

Table 5: Examples from different datasets

Typically, the performance of an answer selection system is measured in Mean Reciprocal Rank (MRR) and Mean Average Precision (MAP), which are standard metrics in Information Retrieval and

[3] http://www.qatarliving.com/forum

[4] http://alt.qcri.org/semeval2016/task3

Question Answering. Given a set of questions Q, MRR is calculated as follows:

$$\text{MRR} = \frac{1}{|Q|}\sum_{i=1}^{|Q|}\frac{1}{\text{rank}_i} \tag{4}$$

where rank_i refers to the rank position of the first correct candidate answer for the i^{th} question. In other words, MRR is the average of the reciprocal ranks of results for the questions in Q. On the other hand, if the set of correct candidate answers for a question $q_j \in Q$ is $\{d_1, d_2, ..., d_{m_j}\}$ and R_{jk} is the set of ranked retrieval results from the top result until you get to the answer d_k, then MAP is calculated as follows:

$$\text{MAP} = \frac{1}{|Q|}\sum_{j=1}^{|Q|}\frac{1}{m_j}\sum_{k=1}^{|m_j|}\text{Precision}(R_{jk}) \tag{5}$$

When a relevant answer is not retrieved at all for a question, the precision value for that question in the above equation is taken to be 0.

Whereas MRR measures the rank of any correct answer, MAP examines the ranks of all the correct answers. In general, MRR is higher than MAP on the same list of ranked outputs, except that they are the same in the case where each question has exactly one correct answer. Table 1 shows the performance of several deep learning methods when trained and evaluated on the Raw TrecQA dataset or the Clean TrecQA dataset.

4 Discussion and Future Directions

Answer selection is an important problem in natural language processing, and many deep learning methods have been proposed for the task. In this paper, we give a comprehensive and systematic review of various deep learning methods for answer selection along two dimensions: (i) learning approaches (*pointwise*, *pairwise*, and *listwise*) (ii) neural network architectures (*Siamese architecture*, *Attentive architecture*, and *Compare-Aggregate architecture*). In addition, we examine the most popular datasets and the evaluation metrics for answer selection. Below we discuss several promising future research directions.

Transfer learning (Pan and Yang, 2010) has achieved success in domains such as speech recognition (Huang et al., 2013), computer vision (Razavian et al., 2014), and natural language processing (Zhang et al., 2017). Its applicability to question answering and answer selection has recently been studied (Min et al., 2017; Chung et al., 2017). Min et al. (2017) created SQuAD-T, a modification of the original large-scale SQuAD dataset (Rajpurkar et al., 2016) to allow for directly training and evaluating answer selection systems. Through a basic transfer learning technique from SQuAD-T, the state-of-the-art result in the WikiQA dataset can be improved. This demonstrates the potential of developing novel transfer learning techniques for the answer selection task.

Many deep learning methods for answer selection are applicable to other sentence pair modeling tasks such as natural language inference (He and Lin, 2016; Wang et al., 2017), paraphrase identification (He and Lin, 2016; Wang et al., 2017), or measuring semantic relatedness (Shen et al., 2017). Extending existing methods for answer selection to achieve state-of-the-art results on other sentence pair modeling tasks can be an interesting research direction, and vice versa.

In addition to its applications in open domain question answering and community question answering, answer selection has many other applications. Lai et al. (2018) formulated the task of answering questions related to product facts and specifications as an answer selection problem. Given a question and a set of candidate product specifications, an answer selection technique was used to identify the specification that is most relevant to the question. Applying answer selection techniques to real-world problems can be an interesting research direction. For example, answer selection techniques can be potentially used to enhance truth discovery methods (Li et al., 2017; Zhang et al., 2018).
